Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

ELSEVIER Book Aid International Working together to grow libraries in developing countries
www.elsevier.com • www.bookaid.org

I dedicate this contribution to the memory of my parents, *Nicholas* and *Yvonne Sidawy*, who endeavored to instill in me at a very young age the values of hard work and persistence, along with the importance of pursuing a professional education. Their sacrifices enabled me to pursue my goal of becoming a surgeon and their selfless love, guidance, and unwavering support have always been my inspiration.

I dedicate my contribution to this book to the memory of my father and mother, *J. Leonard* and *Marcia Perler*. Although they never saw the inside of a college classroom, I learned more important life's lessons from them than from any school I ever attended; most important, the values of hard work, honesty, respect for others, and loyalty, which have always been the principles that have guided me in my career and in my life. Without their love, support, and lessons I would never have been this book's Editor.

We both dedicate this book to the patients with vascular disease, for the confidence they have expressed in all of us, allowing us the absolute privilege of caring for their vascular surgical needs. And to the trainees and to all those who care for the vascular patient by all means available—prevention, medical therapy, and surgical and endovascular techniques—and for whom the lessons of this book are intended.

ASSOCIATE EDITORS

Ali F. AbuRahma, MD, RVT, RPVI
Professor of Surgery
Chief, Vascular and Endovascular Surgery
Director, Vascular Fellowship and Residency Programs
West Virginia University
Medical Director, Vascular Laboratory
Charleston Area Medical Center
Charleston, West Virginia

Jan D. Blankensteijn, MD, PhD
Professor of Vascular Surgery
VU Medical Center
Amsterdam, The Netherlands

John F. Eidt, MD
Vice Chair, Vascular Surgical Services
Baylor Jack and Jane Hamilton Heart and Vascular Hospital
Professor of Surgery
Texas A&M Health Science–Dallas Campus
Dallas, Texas

Thomas L. Forbes, MD, FRCSC, FACS
Professor and Chair
Division of Vascular Surgery
University of Toronto
Division of Vascular Surgery
Peter Munk Cardiac Centre and University Health Network
Toronto, Ontario, Canada

Medical Director of Research and Sponsored Trials
Vascular Surgeon
Henry Ford Allegiance Health
Jackson, Michigan

Lisa M. Kodadek, MD
Fellow
Department of Surgery
The Johns Hopkins University School of Medicine
Baltimore, Maryland

Ted R. Kohler, MD
Professor
Department of Surgery
University of Washington
Veterans Affairs Puget Sound Health Care System
Seattle, Washington

Larry W. Kraiss, MD
Professor and Chief
Department of Vascular Surgery
University of Utah
Salt Lake City, Utah

Christopher J. Kwolek, MD, FACS
Chairman, Department of Surgery
Newton-Wellesley Hospital
Newton, Massachusetts
Visiting Surgeon
Division of Vascular and Endovascular Surgery
Massachusetts General Hospital
Associate Professor of Surgery
Harvard Medical School
Boston, Massachusetts

Jonathan M. Kwong, MD
Staff Surgeon
Division of Vascular Surgery
Louis Stokes Cleveland Veterans Affairs Medical Center
Cleveland, Ohio

Lidie Lajoie, MD, MSc
Assistant Professor of Surgery
Georgetown University School of Medicine
Attending Surgeon
Division of Vascular Surgery
Veterans Affairs Medical Center
Washington, District of Columbia

Brajesh K. Lal, MD
Professor of Vascular Surgery
University of Maryland School of Medicine
Professor of Biomedical Engineering
University of Maryland
Chief of Vascular Surgery
Baltimore Veterans Affairs Medical Center
Director, Center for Vascular Diagnostics
University of Maryland Medical Center
Baltimore, Maryland

Glenn M. LaMuraglia, MD
Division of Vascular and Endovascular Surgery
Massachusetts General Hospital
Professor of Surgery
Harvard Medical School
Boston, Massachusetts

Giora Landesberg, MD, DSc, MBA
Professor
Anesthesiology and Critical Care Medicine
Hadassah-Hebrew University Medical Center
Jerusalem, Israel

Gregory J. Landry, MD
Professor of Surgery
Division of Vascular Surgery
Knight Cardiovascular Institute
Oregon Health and Science University
Portland, Oregon

Russell C. Langan, MD
Gastrointestinal and Hepatobiliary Oncology
Rutgers Cancer Institute of New Jersey
RWJBarnabas Health
Livingston, New Jersey

Lawrence A. Lavery, DPM, MPH
Professor of Plastic Surgery
University of Texas Southwestern Medical Center
Dallas, Texas

Peter F. Lawrence, MD
Wiley Barker Professor of Surgery
Chief, Division of Vascular and Endovascular Surgery
University of California, Los Angeles
Los Angeles, California

Jeffrey H. Lawson, MD, PhD
Professor of Surgery
Professor of Pathology
Duke University School of Medicine
Director of Vascular Surgery Research Laboratory and Clinical Trials for Vascular Surgery
Duke University Medical Center
Durham, North Carolina

Andy M. Lee, MD
Vascular Surgery
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Byung-Boong Lee, MD, PhD
Professor of Vascular Surgery
George Washington University Hospital
Washington, District of Columbia

Beatriz V. Leong, MD

PREFACE

It is with a sense of deep professional pride and responsibility that we accepted our appointment as editors of *Rutherford's Vascular Surgery and Endovascular Therapy,* and by which we dedicated the past three years to build upon the unparalleled excellence of this textbook. This is *the definitive* reference text that has carried the name of one of the giants of our specialty, the late Dr. Robert Rutherford, who was a dear friend whose impact on the education of students, trainees, and practicing clinicians has been immeasurable. We are indebted to Dr. Rutherford, and to our colleagues, Drs. Jack Cronenwett and Wayne Johnston, who edited the seventh and eighth editions, for handing over to us a superb text to build on; a book that is without question the *bible* of vascular surgery.

Technology is advancing at a faster rate than at any time in our history, in terms of both the diagnosis and treatment of vascular disease, especially with respect to the endovascular treatment of aneurysmal and occlusive disease. Therefore, we decided to revise the title of this ninth edition to more accurately reflect the evolution of our specialty from purely open surgery to incorporating endovascular therapy in our armamentarium. Indeed, the content of these two volumes reflects the totality of care delivered by vascular surgeons in contemporary practice; namely, open surgery, endovascular therapy, and medical management of patients with the entire spectrum of circulatory disease, as well as presenting the most valuable diagnostic modalities.

This ninth edition contains 200 chapters organized in 31 sections. A concerted effort has been made to create shorter and more focused chapters to allow easier access to the desired information; having that in mind, we also included at the beginning of every chapter a listing of the topics discussed in that chapter. The roster of authors in this text includes the innovative leaders from all over the world who have been engaged in the advancement of the scientific basis and management of vascular disease to provide an unparalleled insight into the most appropriate contemporary and future treatment of these conditions. No other text can match the level of expertise assembled in this one book. Optimal patient outcomes increasingly are achieved through multidisciplinary care; therefore, we have recruited a unique roster of the most respected experts from the entire spectrum of medical specialties as well as vascular surgery and basic science, to provide the most comprehensive presentation of up-to-date knowledge and future directions in the care of circulatory disease. Likewise, in an increasingly global health care system, the authorship is decidedly international in scope to an unprecedented degree.

In many countries reimbursement for clinical services is being linked to quality outcomes rather than volume. The editors have tailored the presentation of information in each chapter so that the reader can practically apply the information provided to achieve the optimal outcomes at the least risk for the patient. This includes basing the content of each chapter on an evidence-based approach to the presentation of information.

Overall, we increased the number of the chapters in the book while we worked with our associate editors and contributors to make the chapters shorter and more focused so the overall number of pages did not significantly increase. We felt that the expansion in the number of chapters was necessary to incorporate new topics, reflect the rapid generation of new information, reorganize information on topics that gained more relevance over the years, or add topics that have not been included in past editions. For example, since many of today's vascular surgeons and interventionalists are being called upon to consult on vascular issues of the pediatric population, we added a section dedicated exclusively to pediatric vascular disease and its management. Recognizing the increasing regulatory and financial pressures faced by contemporary clinicians, this text includes an entire section on the business of vascular practice with a focus on the development and successful operation of outpatient vascular centers, multidisciplinary cardiovascular centers, importance of maintaining a vascular registry for the practice, and effective marketing strategies. Also, some sections have been strengthened by adding chapters that cover conditions being encountered more frequently in the daily practice of our practitioners, such as medial arcuate ligament syndrome and its contemporary management, vascular reconstructions in oncologic surgery, management of complex regional pain syndrome, and management of chronic compartment syndrome, among others. With the increasing performance of endovascular interventions, exposure to open surgery is decreasing while the contemporary vascular surgeon must continue to possess open vascular surgical skills. This text directly addresses that need by adding new chapters devoted to open surgical exposure and operative techniques with extensive illustrations and videos. In total, the ninth edition includes over 35 new chapters.

We are indebted to our twelve excellent associate editors who were each responsible for editing specific sections of the book; these are Drs. AbuRahma, Blankensteijn, Eidt, Forbes, Henke, Hoballah, Killewich, LaMuraglia, Mills, Rockman, Upchurch, and Weaver. Their diligence in working with the contributors to control the size and direct the focus of each chapter was instrumental in allowing us to execute our vision of increasing the number of chapters in the book while meeting our page allotment. We would like to thank our contributors who managed to produce the most up-to-date information available; they are the ones who did the majority of the work while following our, sometimes, burdensome instructions to make the book look and feel as one entity despite the participation of over 350 authors. We also greatly appreciate the hard work and attention to details by the production team at Elsevier, in particular, Joanie Milnes, Senior Content Development

Specialist; Cindy Thoms, Senior Project Manager, Books; and Russell Gabbedy, Publisher.

Finally, we would like to thank the Society for Vascular Surgery and its Publications Committee for putting their trust in us; we hope we were able to deliver what the readership will find educationally valuable, but most important, beneficial in improving the care of the vascular patient.

COMMON ABBREVIATIONS

2,3-DPG, 2,3-diphosphoglycerate
2D, two-dimensional
3D, three-dimensional
5-HT, serotonin
AAA, abdominal aortic aneurysm
ABFB, aortobifemoral bypass
ABI, ankle-brachial index
ACA, anterior cerebral artery
ACE, angiotensin-converting enzyme
ACT, activated clotting time
ADA, American Diabetes Association
ADP, adenosine diphosphate
AEF, aortoenteric fistula
AF, atrial fibrillation
AFB, aortofemoral bypass
AGE, advanced glycosylation end product
AHA, American Heart Association
AHRQ, Agency for Healthcare Research and Quality
AI, aortoiliac
AIDS, acquired immunodeficiency syndrome
AKA, above-knee amputation
AMP, adenosine monophosphate
APC, activated protein C
APG, air plethysmography/ic
aPTT, activated partial thromboplastin time
ARB, angiotensin receptor blocker
ARDS, acute respiratory distress syndrome
ARF, acute renal failure
ASA, acetylsalicylic acid
ATN, acute tubular necrosis
ATP, adenosine triphosphate
AV, arteriovenous
AVF, arteriovenous fistula
AVG, arteriovenous graft
AVM, arteriovenous malformation
AVP, ambulatory venous pressure
bFGF, basic fibroblast growth factor
BKA, below-knee amputation
BSA, body surface area
BUN, blood urea nitrogen
CABG, coronary artery bypass grafting
CAD, coronary artery disease
cAMP, cyclic adenosine monophosphate
CAS, carotid artery stenting
CAVH, continuous arteriovenous hemofiltration
CAVHDF, continuous arteriovenous hemodiafiltration
CCA, common carotid artery
CCB, calcium channel blocker
CDC, Centers for Disease Control and Prevention
CEA, carotid endarterectomy
CEAP, clinical, etiologic, anatomic, pathologic [staging system]
CFA, common femoral artery
CFV, common femoral vein
cGMP, cyclic guanosine monophosphate
CI, confidence interval
CIA, common iliac artery
CK-MB, MB isozyme of creatine kinase
CKD, chronic kidney disease
CLI, critical limb ischemia
CMS, Centers for Medicare and Medicaid Services
CNS, central nervous system
CO, carbon monoxide
CO_2, carbon dioxide
COPD, chronic obstructive pulmonary disease
COX, cyclooxygenase
CRI, chronic renal insufficiency
CRP, C-reactive protein
CRPS, complex regional pain syndrome
CSF, cerebrospinal fluid
CT, computed tomography
CTA, computed tomographic angiography/ic
CTD, connective tissue disease
CTO, chronic total occlusion
CTV, computed tomographic venography/ic
CVD, cerebrovascular disease
CVI, chronic venous insufficiency
CVP, central venous pressure
CVVH, continuous venovenous hemofiltration
CVVHDF, continuous venovenous hemodiafiltration
DBI, digital-brachial index
DBP, diastolic blood pressure
DDAVP, desmopressin
DES, drug-eluting stent
DFU, diabetic foot ulcer
DIC, disseminated intravascular coagulation
DM, diabetes mellitus
DNA, deoxyribonucleic acid
DRIL, distal revascularization–interval ligation
DSA, digital subtraction angiography/ic
DSE, dobutamine stress echocardiography/ic
DTAA, descending thoracic aortic aneurysm
DUS, duplex ultrasound
DVT, deep venous thrombosis
EC, endothelial cell
ECA, external carotid artery
ECG, electrocardiogram
EC-IC, extracranial-intracranial [bypass]
ECM, extracellular matrix
ED, erectile dysfunction
EDS, Ehlers-Danlos syndrome
EDV, end-diastolic velocity
EEG, electroencephalography/ic
EF, ejection fraction
EIA, external iliac artery
ELAM-1, endothelial leukocyte adhesion molecule-1
ELISA, enzyme-linked immunosorbent assay
ELT, euglobulin lysis time
EMG, electromyography/ic
eNOS, endothelial nitric oxide synthase
ePTFE, expanded polytetrafluoroethylene
ESR, erythrocyte sedimentation rate
ESRD, end-stage renal disease
EVAR, endovascular aneurysm repair
FDA, U.S. Food and Drug Administration
FDP, fibrin/fibrinogen degradation product
FEV_1, forced expiratory volume in 1 second
FFP, fresh frozen plasma
FGF, fibroblast growth factor
FMD, fibromuscular dysplasia
FRC, functional residual capacity
FVC, forced vital capacity
G6PD, glucose-6-phosphate dehydrogenase
GA, general anesthesia
GFR, glomerular filtration rate
GI, gastrointestinal
GMP, guanosine monophosphate
GP-IIb/IIIa, glycoprotein IIb/IIIa
GSM, gray-scale median
GSV, great saphenous vein
GSW, gunshot wound
GTP, guanosine triphosphate
GUI, graphic-user interface

GW, guide wire
HD, hemodialysis
HDL, high-density lipoprotein
HIPAA, Health Insurance Portability and Accountability Act
HIT, heparin-induced thrombocytopenia
HIV, human immunodeficiency virus
HLA, human leukocyte antigen
HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A
HR, hazard ratio
HRQoL, health-related quality of life
hsCRP, high-sensitivity C-reactive protein
HTN, hypertension
I/R, ischemia-reperfusion
ICA, internal carotid artery
ICAM-1, intercellular adhesion molecule-1
ICAVL, Intersocietal Commission for the Accreditation of Vascular Laboratories
ICD, implantable cardioverter-defibrillator
ICH, intracerebral hemorrhage
ICU, intensive care unit
IDL, intermediate-density lipoprotein
IEL, internal elastic lamina
IFN, interferon
IFU, instructions for use
IGF, insulin-like growth factor
IH, intimal hyperplasia
IL, interleukin
IL-6, interleukin-6
IMA, inferior mesenteric artery
iNOS, inducible nitric oxide synthase
IOM, Institute of Medicine
IPC, intermittent pneumatic compression
IPG, impedance plethysmography
IPPB, intermittent positive pressure breathing
ISI, international sensitivity index
IVC, inferior vena cava
IVUS, intravascular ultrasound
JAK-2, Janus kinase-2
JNK, jun *N*-terminal kinase
KDOQI, Kidney Disease Outcomes Quality Initiative
KM, Kaplan-Meier
LAO, left anterior oblique
LDL, low-density lipoprotein
LMWH, low-molecular-weight heparin
LOS, length of stay
Lp(a), lipoprotein (a)
LS, lumbosacral
LV, left ventricular
LVEDP, left ventricular end diastolic pressure
LVEDV, left ventricular end diastolic volume
LVH, left ventricular hypertrophy
MAP, mean arterial pressure
MCA, middle cerebral artery
MI, myocardial infarction
MIP, maximum intensity projection
MMP, matrix metalloproteinase
MOF, multiple organ failure
MR, magnetic resonance
MRA, magnetic resonance angiography
MRI, magnetic resonance imaging
MRSA, methicillin-resistant *Staphylococcus aureus*
MRV, magnetic resonance venography
MTHFR, 5,10-methylenetetrahydrofolate reductase
NAC, *N*-acetylcysteine
NAD^+, oxidized nicotinamide dinucleotide
NADH, reduced nicotinamide adenine dinucleotide
NADPH, reduced nicotinamide adenine dinucleotide phosphate
NAIS, neo-aortoiliac system
Nd:YAG, neodymium:yttrium-aluminum-garnet
NF-κB, nuclear factor κB
NIH, National Institutes of Health
NIS, National Inpatient Sample
NOS, nitric oxide synthase
NPV, negative predictive value
NSAID, nonsteroidal anti-inflammatory drug
NSQIP, National Surgical Quality Improvement Program
OR, odds ratio
OTW, over-the-wire
PA, pulmonary artery
PAD, peripheral arterial disease
PAI, proximalization of arterial inflow
PAI-1, plasminogen activator inhibitor-1
PAOD, peripheral arterial occlusive disease
PAU, penetrating aortic ulcer
PBI, penile-brachial index
PBRCs, packed red blood cells
PCA, posterior cerebral artery
PCI, percutaneous coronary intervention
PCNA, proliferating cell nuclear antigen
PCWP, pulmonary artery wedge pressure
PD, peritoneal dialysis
PDE, phosphodiesterase
PDGF, platelet-derived growth factor
PE, pulmonary embolism
PECAM-1, platelet–endothelial cell adhesion molecule-1
PEEP, positive end-expiratory pressure
PEG, polyethylene glycol
PET, positron emission tomography/ic
PF4, platelet factor 4
PFA, profunda femoris artery
PFT, pulmonary function test/testing
PGE_2, prostaglandin E_2
PGI_2, prostaglandin I_2
PICCs, percutaneously inserted central catheters
PKC, protein kinase C
PMN, polymorphonuclear neutrophil
PPG, photoplethysmography
PPV, positive predictive value
PRBCs, packed red blood cells
PSA, pseudoaneurysm psi, pounds per square inch
PSV, peak systolic velocity
PT, prothrombin time
PTA, percutaneous transluminal angioplasty
PTFE, polytetrafluoroethylene
PTT, partial thromboplastin time
PVI, peripheral vascular intervention
PVR, pulse volume recording
QALY, quality-adjusted life year
QoL, quality of life
RAAA, ruptured abdominal aortic aneurysm
RAGE, receptor for advanced glycosylation end products
RAO, right anterior oblique
RAS, renal artery stenosis
RBC, red blood cell
RCT, randomized controlled trial
Re, Reynolds number
RFA, radiofrequency ablation
RGD, Arg-Gly-Asp
RI, resistive index
RIND, reversible ischemic neurologic deficit
RP, retroperitoneal
RR, relative risk
RS, Raynaud syndrome
rt-PA, recombinant tissue plasminogen activator
RUDI, revision using distal inflow
SBP, systolic blood pressure
SD, standard deviation
SE, standard error
SEPS, subfascial endoscopic perforator surgery
SF-36, Short Form (36) Health Survey
SFA, superficial femoral artery
SFJ, saphenofemoral junction
SK, streptokinase
SLE, systemic lupus erythematosus
SMA, superior mesenteric artery

SMC, smooth muscle cell
SOD, superoxide dismutase
SPECT, single-proton emission computed tomography
SPJ, saphenopopliteal junction
SSV, small saphenous vein
STEMI, ST-segment elevation myocardial infarction
SVC, superior vena cava
SVS, Society for Vascular Surgery
TAA, thoracic aortic aneurysm
TAAA, thoracoabdominal aortic aneurysm
TAAD, thoracic aortic aneurysm and dissection
TAO, thromboangiitis obliterans
TASC, Trans-Atlantic Inter-Society Consensus for the Management of Peripheral Arterial Disease
TCD, transcranial Doppler
TEE, transesophageal echocardiography/ic
TEVAR, thoracic endovascular aortic repair
TF, tissue factor
TGF-β, transforming growth factor-β
TIMP-1, tissue inhibitor of matrix metalloproteinase-1
TIPS, transjugular intrahepatic portosystemic shunting
TLR, target lesion revascularization
TLR, Toll-like receptor
TMA, transmetatarsal amputation
TNF-α, tumor necrosis factor-α
TOS, thoracic outlet syndrome
t-PA, tissue plasminogen activator
TT, thrombin time
TTE, transthoracic echocardiography
TXA_2, thromboxane A_2
UFH, unfractionated heparin
UK, urokinase
u-PA, urinary (urokinase) plasminogen activator
USPSTF, U.S. Preventive Services Task Force
VATS, video-assisted thoracoscopic surgery
VCAM-1, vascular cell adhesion molecule-1
VEGF, vascular endothelial growth factor
VFI, venous filling index
VLDL, very-low-density lipoprotein
VSMC, vascular smooth muscle cell
VSS, Venous Severity Score
VTE, venous thromboembolism
vWF, von Willebrand factor
WBC, white blood cell
WIQ, Walking Impairment Questionnaire

OUTCOMES TRANSLATIONAL RESEARCH 11

The goal of this chapter is to introduce the vascular surgeon to the principles that underlie the design, conduct, and interpretation of epidemiology and clinical research. Disease-specific outcomes otherwise detailed in subsequent chapters are not covered here. Rather, this chapter discusses the historical context, current methodology, and future developments in epidemiology, clinical research, and outcomes analysis. This chapter serves as a foundation for clinicians to better interpret clinical results and as a guide for researchers to further expand clinical analysis.

EPIDEMIOLOGY

The word *epidemiology* is derived from Greek terms meaning "upon" *(epi)*, "the people" *(demos)*, and "study" *(logos)* or "the study of what is upon the people." It exists to answer the four major questions of medicine: diagnosis, etiology, treatment, and prognosis.

Brief History

Hippocrates and his disciples not only marked the beginning of western medicine but were also among the first to begin to contemplate the role of external factors in disease. Sparking the beginnings of epidemiology, a great deal of time was spent investigating the progression of illness in their patients and their prognoses.[1] John Snow is often cited as the first modern epidemiologist. In the middle of a cholera epidemic in the summer of 1854, Snow, a physician, by mapping the geographic distribution of incident cases, successfully identified the source of the outbreak as contaminated water from the Broad Street pump.

Abstract

Evidence-based medicine seeks to guide the practice of medicine by using evidence from research studies. Basic understanding of epidemiology and clinical research methodology, therefore, is critical in interpreting research results and identifying its limitations. The application of research findings to practice and policy also is a key step in translating science into the care of patients.

Keywords

Epidemiology
Clinical Research
Statistics
Methodology

He then convinced local officials to remove the pump handle, thus shutting down the pump and stopping the outbreak.[2]

Modern Developments

The study of epidemiology continues the work of Hippocrates and Snow, working to investigate the cause and impact of disease. To achieve this goal and to be able to speak to causality, the ideal experiment often involves introducing an at-risk population to an exposure of interest and observing the results. In order to determine causality, one must then compare these results to what would have happened had that population not received the exposure. The first, or the observed outcome, is often referred to as the *factual outcome* and the alternative is the *counterfactual outcome.* Ideally one would be able to observe the outcome of the same individual in both the presence and absence of the exposure. However, lacking the ability to create multiple parallel universes, it must fall to clinical research and statistical methods to approximate this ideal.

CLINICAL RESEARCH METHODS

The choice of study design and statistical analysis technique depends on the available data, the hypothesis being tested, and patient safety and/or ethical concerns. Multiple options exist, each with their strengths and weaknesses.

Study Design

Clinical research can be broadly divided into observational studies and experimental studies. Observational studies are characterized by the absence of a study-directed intervention. Experimental studies involve testing a treatment, be it a drug, device, or clinical pathway. Observational studies can follow ongoing treatments but cannot influence choices made in the treatment of a patient. Observational studies can be executed in a prospective or retrospective fashion, whereas experimental studies can be performed only prospectively.

Deciding between these approaches is influenced by a number of factors. A key first step is to determine how common the disease or exposure of interest is. The *prevalence* of disease is the ratio of persons affected for the population at risk and reflects the frequency of the disease at a single time point, regardless of the time of disease development. In contrast, the *incidence* is the ratio of persons in whom the disease develops within a specified period for the population at risk. For diseases with short duration or high mortality, prevalence may not accurately reflect the impact of disease because the single time point of measurement does not capture resolved disease or patients who died of the disease. Prevalence is a more useful parameter in discussing diseases of longer duration, whereas incidence is more useful for diseases of shorter duration.

Observational Studies

There are two main types of observational studies: cohort and case-control. A cohort is a group that has something in common; in epidemiology this is frequently risk of a developing a disease of interest. Cohort studies enroll a population at risk and follow them for a period of time. Individuals who develop the disease in that time are then compared with individuals who remain disease-free. Many prominent studies of the modern epidemiology era have been cohort studies, including the Framingham Heart Study (FHS), which enrolled 5209 residents of Framingham, Massachusetts, in 1948 and has been monitoring that group and their descendants prospectively since that time; this endeavor has contributed greatly to our understanding of heart disease.[3] Since cohort studies tell us about the risk of a disease in two populations, exposed and nonexposed, one can determine a *relative risk* of a disease from a cohort study. If one were interested in evaluating the impact of smoking on developing peripheral artery disease (PAD), one could not simply look at the rate of PAD in smokers, since a baseline rate of PAD exists in the population that is not related to smoking. Instead, one could look at the rate of PAD in smokers and the rate of PAD in nonsmokers and compare the two to determine a relative risk.

For rare diseases with low frequency, it is not cost-effective to use a cohort study design. Instead, a *case series* seeks to prospectively follow or to retrospectively report findings of patients known to have a disease. When linked to a group free of the disease in question, a case series becomes a *case-control study.* Case-control studies are often less costly and are an important tool in studying a rare disease or a disease with a long latency time, since the disease is present at the time of enrollment.

Risk factors correlated with disease can be deduced by comparisons between the case and control groups. In this retrospective design, an *odds ratio* (OR) is calculated from the ratio of patients exposed to patients not exposed to the risk factor. This differs from relative risk (RR), in that the starting cohort is estimated only in case-control studies. The use of ORs reflects *Bayesian inference*, in which observations are used to infer the likelihood of a hypothesis. Bayesians describe probabilities conditional on observations and with degrees of uncertainty. In contrast, the alternative *probability theory* of Frequentists relies only on actual observations gained from experimentation.

The main challenge in case-control studies is to identify an appropriate control group with characteristics similar to those of the general population at risk for the disease. Inappropriate selection of the control group may lead to the introduction of additional confounding and bias. For example, matched case-control studies aim to identify a control group "matched" for factors found in the exposure group. Unfortunately, by matching even basic demographic factors, such as gender and the prevalence of comorbid conditions, unknown coassociated factors can also be included in the control group and may affect the relationship of the primary factor to the outcome. Appropriate selection of the control group can be achieved by using broad criteria, such as time, treatment at the same institution, age boundaries, and gender when the exposure group consists of only one gender.

Experimental Studies

The other large class among study designs is the *experimental study*. Unlike observational studies, experimental trials involve

introducing participants to an exposure of interest. One benefit of experimental studies is the ability to randomize participants, commonly via the *randomized controlled trial* (RCT). Although randomization ensures that known factors are evenly distributed between the exposure and control groups, the importance of RCTs lies in the even distribution of *unknown* factors. Thus, in a well-designed RCT, complex statistical models are not necessary to control for confounding factors.

There are several ways of structuring a randomization to address potential issues including complete randomization of the entire study population, block randomization, and adaptive randomization. For *complete randomization*, each new patient is randomized without prior influence on previously enrolled patients. The expected outcome at the completion of the trial is an equal distribution of patients within each treatment group, although unequal distribution may occur by chance, especially in small trials. *Block randomization* creates repeated blocks of patients in which equal distribution between treatment groups is enforced within each block. Block randomization ensures better end randomization and periodic randomization during the trial. End randomization is important in studies with long enrollment times or in multi-institutional studies that may have different local populations. Because the assignment of early patients within each block influences the assignment of later patients, block randomization should occur in a blinded fashion to avoid bias. Intrablock correlation must also be tested in the final analysis of the data. *Adaptive randomization* seeks to achieve balance of assignment of randomization for a prespecified factor (e.g., gender or previous treatment) suspected of affecting the treatment outcome. In theory, randomization controls for these factors, but unique situations may require stricter balance.

Experimental studies face stricter ethical and patient safety requirements than their observational counterparts. One basic assumption of experimental trials is *clinical equipoise*, or the existence of more than one generally accepted treatment.[4] This must exist both to create the situation where the research that is being undertaken will lead to clinical relevant information and that the treatment options to which a participant is randomized will not be assuming risk of care that is known to be inferior. Whereas you could not randomize people to observation only for a ruptured aortic aneurysm, for certain populations you could make an argument for endovascular versus open repair. This type of situation often arises when clinical experts professionally disagree on the preferred treatment method.[4] It is worth noting that although the field may have equipoise, individual healthcare providers or patients may have bias for one treatment. In such a case, enrollment in an RCT may be difficult because the patients or their providers are not willing to be subject to randomization.

Although RCTs represent the pinnacle in clinical design, there are many situations in which RCTs are impractical or impossible. Clinical equipoise may not exist, or common sense could prevent randomization of well-established practices, such as the use of parachutes during free fall.[5] RCTs can also be costly to conduct and must generate a new control group with each trial. For this reason, some studies are single-arm trials that use historical controls similar to the case-control design. In addition, patient enrollment may also be difficult, particularly if patients or clinicians are uneasy with the randomization of treatment. RCTs can also have methodologic and interpretative limitations. For example, if study patients are analyzed by their assigned randomization grouping (*intent to treat*) studies with asymmetric or high overall dropout and/or crossover rates may not reflect actual treatment effects. Given the cost and time required, RCTs are often conducted in high-volume specialty centers; as a result, enrollment and treatment of study patients may not reflect the general population with the disease or providers in the community. Finally, as with any analysis, inaccurate assumptions made in the initial power calculations may lead to failure to capture a true effect.

Special Techniques: Meta-Analysis

Meta-analysis is a statistical technique that combines the results of several related studies to address a common hypothesis. The first use of meta-analysis in medicine is attributed to Smith and Glass in their review of the efficacy of psychotherapy in 1977.[6] By combining results from several smaller studies, researchers may decrease sampling error and increase statistical power, thus helping to clarify disparate results among different studies.

The related studies must share a common dependent variable. *Effect size* specific to each study is then weighted to account for the variance in each study. Because studies may differ in patient selection and their associated independent variables, a test for heterogeneity should also be performed. Where no heterogeneity exists ($P > .5$), a fixed-effects meta-analysis model is used to incorporate the within-study variance for the studies included. A random-effects model is used when concern for between-study variance exists ($.5 > P > .05$). When heterogeneity among studies is found, the OR should not be pooled and further investigation for the source of heterogeneity may then exclude outlying studies.

The weighted composite dependent variable is visually displayed in a forest plot along with the results from each study included. Each result is displayed as a point estimate, with a horizontal bar representing the 95% confidence interval for the effect. The symbol used to mark the point estimate is usually sized proportional to other studies to reflect the relative weight of the estimate as it contributes to the composite result (Fig. 1.1). Classically, meta-analyses have included only RCTs, but observational studies can also be used.[7,8] Inclusion of observational studies can result in greater heterogeneity through uncontrolled studies or controlled studies with selection bias.

The strength of a meta-analysis comes from the strength of the studies that make up the composite variable. Furthermore, if available, the results of unpublished studies can also potentially influence the composite variable, because presumably many studies with nonsignificant results are not published. Therefore an assessment of *publication bias* should be included with every meta-analysis. Publication bias can be assessed graphically by creating a *funnel plot* in which the effect size is compared with the sample size or another measure of variance. If no bias is present, the effect sizes should be balanced around the population

mean effect size and decrease in variance with increasing sample size. If publication bias exists, part of the funnel plot will be sparse or empty of studies. *Begg's test* for publication bias is a statistical test that represents the funnel plot's graphic test.[9] The variance of the effect estimate is divided by its standard error to give adjusted effect estimates with similar variance. Correlation is then tested between the adjusted effect size and the meta-analysis weight. An alternative method is *Egger's test*, in which the study's effect size divided by its standard error is regressed on 1/standard error.[10] The intercept of this regression should equal zero, and testing for the statistical significance of nonzero intercepts should indicate publication bias.

OUTCOMES ANALYSIS

As physicians, we can usually see the natural progression of disease or the clinical outcome of treatment. Although these observations can be made for individual patients, general inferences about causation and broad application to all patients cannot be made without further analysis. Clinical analysis attempts to answer these questions by either observing or testing patients and their treatments. Because clinical analysis can be performed only on a subset or sample of the relevant entire population, a level of uncertainty will always exist in clinical analysis. Statistical methods are an integral aspect of clinical analysis because they

help the researcher understand and accommodate the inherent uncertainty in a sample in comparison to the ideal population. In the following sections, common clinical analytic methods are reviewed so that the reader can better interpret clinical analysis and also have foundations to initiate an analysis. Reference to biostatistical and econometric texts is recommended for detailed derivation of the methods discussed.

Bias in Study Design

In discussing statistical methods, it is important to remember that clinical analysis can estimate only the "true" effects of a disease or its potential treatments. Because the true effects cannot be known with certainty, analytic results carry potential for error. All studies can be affected by two broadly defined types of error: random error and systematic error. *Random error* in clinical analysis comes from natural variation and can be handled with the statistical techniques covered later in this chapter. *Systematic error*, also known as *bias*, affects the results in one unintended direction and can threaten the validity of the study. Bias can be further categorized into three main groupings: selection bias, information bias, and confounding.

Selection bias occurs when the effect being tested differs among patients who participate in the study as opposed to those who do not. Because actual study participation involves a researcher's determination of which patients are eligible for a study and then the patient's agreement to participate in the study, the decision points can be affected by bias. One common form of selection bias is self-selection, in which patients who are healthier or sicker are more likely to participate in the study because of perceived self-benefit. Selection bias can also occur at the level of the researchers when they perceive potential study patients as being too sick and preferentially recruit healthy patients.

Information bias exists when the information collected in the study is erroneous. One example is the categorization of variables into discrete bins, as in the case of cigarette smoking. If smoking is categorized as only a yes or no variable, former smokers and current smokers with varying amounts of consumption will not be accurately categorized. *Recall bias* is another form of information bias that can occur, particularly in case-control studies. For example, patients with abdominal aortic aneurysms may seemingly recall possible environmental factors that put them at risk for the disease. However, patients without aneurysms may not have a comparable imperative to stimulate memory of the same exposure.

Confounding is a significant factor in epidemiology and clinical analysis. Confounding exists when a second spurious variable (e.g., race/ethnicity) correlates with a primary independent variable (e.g., type 2 diabetes) and its associated dependent variable (e.g., critical limb ischemia). Researchers can conclude that patients in certain race/ethnicity groups are at greater risk for critical limb ischemia when diabetes is the stronger predictor. *Confounding by indication* is especially relevant in observational studies. This can occur when, without randomization, patients being treated with a drug can show worse clinical results than untreated counterparts because treated patients were presumably sicker at baseline and required the drug a priori. Confounding can be addressed by several methods: assigning confounders equally to the treatment and control groups (for case-control studies), matching confounders equally (for cohort studies), stratifying the results according to confounding groups, and multivariate analysis.

Statistical Methods

At the beginning of most clinical analyses, *descriptive statistics* are used to quantify the study sample and its relevant clinical variables. *Continuous variables,* or variables that can take on any value in a range between a minimum and a maximum, such as weight or age, are expressed as means or medians; *categorical variables*, or variables that have only a discrete value, such as institution of treatment or TASC Classification, are expressed as numbers or percentages of the total. A subset of categorical variables are *ordinal variables,* in which categories have some structure or relative value, such as good, better, best. Study sample characteristics and their relative distribution of comorbid conditions help determine whether the sample is consistent with known population characteristics and hence addresses the issue of generalizability of the clinical results to the overall population.

The next step in clinical analysis is *hypothesis testing*, in which the factor or treatment of interest is tested against a control group. The statistical methods used in hypothesis testing depend on the research question and characteristics of the data under comparison (Box 1.1). At its core, hypothesis testing asks whether the observable differences between groups represent true differences or if they just appear different because of random change. A wide variety of tests exist and each attempts to answer this question in a way that is appropriate to the data in question.

One major distinguishing characteristic of data is whether they fit a *normal*, or *Gaussian*, *distribution*, where the distribution of continuous values is symmetric and has a mean of 0 and a variance of 1. Gaussian distributions are one example of *parametric data* in which the form of the distribution is known. In contrast, *nonparametric data* are not symmetric around a mean, and the distribution of the data is more random. Nonparametric statistical methods make fewer assumptions about the shape of the distribution and trade power for accuracy. In general, nonparametric methods can be used for parametric data to increase robustness, but at the cost of statistical power. However, the use of parametric methods for nonparametric data or data containing small samples can lead to misleading results.

Regression Analysis

Among the statistical tests available, a few deserve special mention because of their common application to the clinical analysis of studies of vascular patients. *Regression analysis* is a mathematical technique in which the relationship between a dependent (or response) variable is modeled as a function of one or more independent variables, an intercept, and an error term. Models often describe a linear relationship between dependent and independent variables; however, they can also take on polynomial relationships, including quadratic and cubic functions. Regression analysis produces regression coefficients for each variable of

BOX 1.1 Choosing Statistical Tests Based on Research Question and Data Characteristics

Is There a Difference Between Means, Medians, and Proportions?

One Group

- Parametric data: one sample *t*-test
- Nonparametric data: sign test, Wilcoxon signed rank test, transform data for *t*-test
- Proportions: exact binomial test, z approximation to exact test

Two Independent Groups

- Parametric data: *t*-test
- Nonparametric data: Wilcoxon rank-sum test
- Proportions: chi-squared or Fisher's exact test

Two Related Groups

- Parametric data: paired *t*-test
- Nonparametric data: sign test, Wilcoxon signed-rank test
- Proportions: McNemar's test or kappa statistic

Three or More Independent Groups

- Parametric data: ANOVA
- Nonparametric data: Kruskal–Wallis test
- Proportions: chi-squared or Fisher's exact test

Three or More Related Groups

- Parametric data: repeated-measures ANOVA
- Nonparametric: ANOVA by ranks

Is There an Association?

Two Comparable Variables

- Nominal data: relative risk
- Ordinal data: Spearman's rank correlation test
- Continuous data: linear regression

One Dependent Variable and Two or More Independent Variables

- Binary dependent variable: logistic regression
- Categorical dependent variable: ANCOVA
- Continuous dependent variable: multiple linear regression
- Censored observations: CPH model
- Clustered or hierarchic parametric data: linear mixed models
- Clustered or hierarchic semiparametric data: GEE

ANCOVA, analysis of covariance; *ANOVA*, analysis of variance; *CPH*, Cox proportional hazards; *GEE*, generalized estimating equations.

interest. Regression coefficients, or *betas* (β), describe the magnitude of the effect that each independent variable *(x)* has on the dependent variable *(y)*. For binary dependent variables, a *logistic* (logit) *regression* is used, whereas for continuous dependent variables, a *linear regression* is used (see Box 1.1). The *goodness of fit* for the model is tested by using the R^2 value (R squared) and the analysis of residuals. R^2 is the proportion of variability that is accounted for by the model and has a range of 0 to 1. Although larger R^2 values imply better fit, there is no defined threshold for goodness of fit and R^2 can be artificially inflated by adding more variables to the model. Thus an adjusted R^2, which also accounts for the number of variables in the model, should be used.

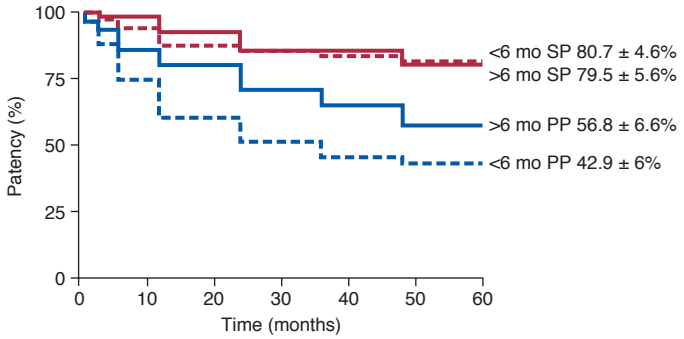

Figure 1.2 Example of life-table analysis of primary patency *(PP)* and secondary patency *(SP)* of bypass grafts after being revised before or after 6 months from the index operation. (Redrawn from Nguyen LL, Conte MS, Menard MT, et al. Infrainguinal vein bypass graft revision: factors affecting long-term outcome. *J Vasc Surg*. 2004;40:916–923.)

Survival Analysis

Survival analysis was developed to assess patient survival, and while death is often the primary event of interest, survival analysis can also be used to assess treatment failure, such as time to loss of graft patency or amputation. Rather than simply addressing frequency, survival analysis also captures an element of time to an event. It also incorporates *censorship*, in which data about the event of interest are unknown because of withdrawal of the patient from the study. Traditionally in clinical analysis, *death* is the event variable, and *loss to follow-up* is the censorship variable. In vascular surgery, where graft patency is more often the endpoint of interest, *graft patency* is treated as the event variable and *death* and/or *study withdrawal* is treated as the combined censoring variable. This assumes that censorship (death) is not due to the event (loss of graft patency); however, this assumption cannot be held true in other fields, such as oncology (death attributable to failure of cancer treatment) or cardiac surgery (death caused by loss of coronary artery bypass graft patency).

In essence, survival analysis accounts for event status between fixed periods of measurement. For example, in traditional methods, if graft patency is measured only after 1 year, a graft that fails at 30 days is statistically treated the same as a graft that fails on day 364. Similarly, a graft that was patent at 360 days but was lost to follow-up is treated the same as a graft that was patent but lost to follow-up at 60 days. In contrast, *life-tables* measure events at fixed intervals (e.g., every 30 days), so occurrences before 365 days are accounted for (Fig. 1.2).[11] Such analysis allows greater precision of events, but resolution is still limited to fixed time points. These limitations are addressed by using the *Kaplan–Meier* (KM) *method*. KM captures each event at the time of occurrence without the need for fixed time frames (Fig. 1.3).[12] Although the KM method allows more precise analysis of events and censorship, life tables are still appropriate when only predetermined periodic measurement of events is available or when arbitrary important milestones are of interest, such as 1-year graft patency or patient survival.

The strength of survival analysis lies in the ability to statistically account for censored data. The *KM estimator* (also known as the *product-limit estimator*) is the nonparametric maximum

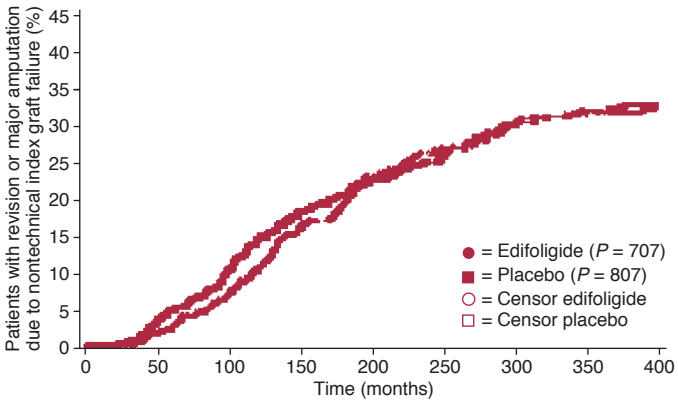

Figure 1.3 Example of Kaplan-Meier analysis of the effect of edifoligide on nontechnical graft failure. Each mark represents an event (graft failure) or censor (death or dropout). (Redrawn from Conte MS, Bandyk DF, Clowes AW, et al. Results of PREVENT III: A multicenter, randomized trial of edifoligide for the prevention of vein graft failure in lower extremity bypass surgery. *J Vasc Surg*. 2006; 43:742–751, discussion 751.)

likelihood estimator of the survival function, which is based on the probability of an event conditional on reaching the time point of the previous event. The *life-table method* (or *actuarial method*) treats censored events as though they had occurred at the midpoint of the time period. Most commonly, the Greenwood formula is used to calculate the standard error of the KM and life-table estimator for independent events.

Several tests are commonly used to test for differences between survival functions. The *log-rank test* adds observed and expected events within each group and sums them across all time points containing events. The log-rank statistic serves as the basis for the proportional hazards model (further on). In contrast, the *Wilcoxon test* is the log-rank test weighted by the number of patients at risk for each time point. Mathematically, the Wilcoxon test gives more weight to early time points and is thus less sensitive than the log-rank test to differences between groups that occur at later time points. Unlike the parametric log-rank and Wilcoxon tests, *Cox proportional hazards models* assume that the underlying hazard (risk) function is proportional over time, so that parameters can be estimated without complete knowledge of the hazard function. Other hazard models—such as the exponential, Weibull, or Gompertz distributions—instead assume knowledge of the hazards function. The Cox proportional hazards assumption allows the application of survival analysis techniques to multivariable models because individual hazards do not have to be specified for each independent variable in the model.

Longitudinal Analysis

Longitudinal data, or repeated measures from the same patient or patients over time, can be of interest in many situations, such as improvements in walking scores over time following exercise interventions for PAD. There are two aspects of longitudinal data that complicate statistical analysis. One is that repeated measures in the same patient are often positively correlated. For example, a patient who is obese at baseline is more likely to be overweight at the next measure no matter the intervention. The other issue is that that the degree of variability in repeated measures tends to vary over time. For example, the variability in individuals' response to a medication or treatment will become more apparent over time. This violates the assumption of homoscadicity, that variance around a regression line is the same for all values of a predictor. Several models exist to address these issues and to capture the covariance of repeated measures. *Mixed effects models* capture a more typical regression but also include terms for variability for individuals. Covariance structures, or assuming patterns to covariance rather than allowing them to be completely random, can capture covariance but preserve power.

Propensity Scoring

In comparing two groups that were not randomized, *propensity scoring* is a technique that can be employed to control for confounding and is often used when treatment groups are related to indication; for example, in comparing endarterectomy with stenting for carotid artery stenosis, as patients who underwent stenting may have more comorbidities or a different disease pattern than patients selected for carotid endarterectomy. Each individual included in the trial is assigned a propensity score that reflects the conditional probability of being in a treatment group based on selected variables. This balances the treatment groups for the variables on which the score is based.

There are two common methods of propensity scoring: trimming and reweighting. In trimming, patients at the extremes of the propensity score are eliminated from the analysis so that the remaining cohorts are more comparable matches. In reweighting, all patients are kept in the analysis, but their characteristics are reweighed to provide equivalency between groups.

As with other methods, propensity scoring can control only for known confounders, again falling short of the randomized controlled trial in its ability to balance unknown factors. Further, to appropriately balance but not confound the outcome, the variables used to create the propensity score should be related to treatment assignment but not to the outcome of interest.

Despite these drawbacks, when an RCT is not possible or practical, propensity scoring methods are useful for providing some insight in comparing treatment groups. Propensity score methods have also been used for other purposes, including nesting covariates for multivariable regression models and generating reweighted estimating equations to rebalance weights from missing data. RCTs further have the advantage of limiting the number of variables in a model and thus preserving power.

Errors in Hypothesis Testing

Important to an understanding of statistical methods is an appreciation of the potential pitfalls and shortcomings of the tools presented in the following paragraphs.

The default understanding of hypothesis testing, or the null hypothesis, is that there is no difference between the groups of patients in question. The alternative to this, called *the alternative hypothesis*, is that a difference does exist. Because you can only ever estimate the effect of various factors, you can never prove the alternative hypothesis. Instead, if the data suggest that a

difference does exist, you can reject the null hypothesis and conclude that there may be an effect. If the data suggest that there is no difference between groups, then you fail to reject the null hypothesis and conclude that there is likely no difference between them.

Two types of errors can be made in hypothesis testing. A *type I error* is rejection of the null hypothesis when the null hypothesis is in fact true. Alpha (α) is the probability of making a type I error. The *P* value is calculated from statistical testing and represents the probability of obtaining a result as extreme or more extreme than the results observed. Commonly, α is set at .05, and a *P* value less than α would reject the null hypothesis. Because 0.05 is a somewhat arbitrary setting, many will report actual *P* values to more precisely communicate statistical significance. Stricter α can be used when concern for a type I error is heightened, as in the testing of a large number of independent variables. For example, if 20 variables are tested, 1 variable (on average) is expected to be falsely positive with an α of .05. Accordingly, a stricter α of .01 or less may be required to reduce type I error. Conversely, a more relaxed α (typically .20) can be used in building stepwise regression models to be more inclusive of borderline variables.

A *type II error* is failure to reject the null hypothesis when the null hypothesis is false. Beta (β) is the probability of making a type II error. *Power* is defined as the probability of rejecting the null hypothesis when it is false (or concluding that the alternative hypothesis is true when it is true). In other words, power is the ability of a study to detect a true difference. Power is calculated as $1 - \beta$ and is closely related to sample size. Power analysis can be performed before or after data collection. *A priori power analysis* is used to determine the sample size needed to achieve adequate power for a study. *Post hoc power analysis* is used to determine the actual power of the study. Power analysis requires specification of several parameters, including α (usually 0.05), the level of power desired (usually 80%), expected effect size, and variance. Variance is simply estimated from previous measurements of related outcomes. However, the expected effect size is a parameter most susceptible to unintended influence. Setting the expected effect size too small decreases type I error but also decreases power and results in the necessity of enrolling larger numbers of patients. Setting the expected effect size too large allows lower enrollment numbers, but at the cost of type I error. The actual calculation for necessary sample size depends on the expected statistical test for the data and can be performed by using "power calculators" available at statistics websites or with statistical software packages.

Statistical and Database Software

Before the widespread use of computers, statistics were calculated by hand. Statistical software and computing power have greatly improved the ability and efficiency of statisticians and clinical researchers. Even rapid advancements in desktop computing allow for increasingly complex modeling. At its core, statistical software requires user coding of specific commands to perform data analysis and database manipulation. *SAS* (originally meaning Statistical Analysis System) was created by Anthony Barr from his work as a graduate student at North Carolina State University in the early 1960s. He and other collaborators later created the SAS Institute in 1976 to commercialize the statistical package. SAS statistical software is widely used in clinical analysis of large trials, epidemiology, the insurance industry, and other business applications of data mining. Frequently the development of new statistical techniques is included as new SAS commands or macros. *Stata* was created by Statacorp and is the other widely used statistical program, especially in the social sciences and economics.

Both SAS and Stata, in addition to their native coding interface, also have graphics user interfaces (GUIs) that automate or facilitate statistical analysis. Most other statistical packages, such as *SPSS* (originally Statistical Package for the Social Sciences), *JMP*, and *Minitab*, are promoted with GUIs and pulldown menus as the primary interface for performing statistical tests. Another statistical package that is rapidly gaining in popularity is *R*, particularly because it is both free and highly functional.

Economic Analysis

The concept of providing value in healthcare continues to gain traction in the current political and economic environment. Success following bypass graft or stent placement is not measured only in patency but also in improvements in a patient's ambulatory status and overall quality of life (QoL). This has driven an increasing interest in economic and cost-benefit analysis both in procedural fields and across medicine as a whole.

Utility Measures

In economic analysis and decision analysis, patients are considered to be in distinct "states" governed by specific diagnoses or symptoms; for example, asymptomatic versus symptomatic carotid artery stenosis or claudication versus critical limb ischemia. *Utility measures* capture the value a person places on a state of health. Such measures then can be used in decision trees and cost-effectiveness analysis. The Health Utilities Index and the EQ-5D are two widely used utility measures. The simplest method of determining utility is to ask patients to value their own health or a hypothetical state of health by using a rating scale. This information is then transformed into a utility measure by using data from a reference population. Transformations of health states from descriptive instruments (e.g., SF-36) have also been created, although low correlations between descriptive and preference measures have been demonstrated. For transformations to be meaningful, the reference population itself has to be subject to utility assessment.

Direct assessment of utility can be performed by using the *standard gamble*, in which, for a given health state, patients are asked whether they would choose to remain in that state or take a gamble between death and perfect health. The question is then repeated with varying gamble probabilities. The utility of the health state is then derived from the probability of achieving perfect health when the patient is at equilibrium (or indifferent between the choices) between taking the gamble or remaining in the known state of intermediate health. Another common

direct utility assessment method is the *time tradeoff*, in which the patient is asked to choose between a length of life in a given compromised state and a shorter length of life in a perfect state. The utility of the health state is then derived from the ratio of the shorter to the longer life expectancy at the point of equilibrium.

Because these utility assessment methods are artificial and do not actually expose subjects to decisions with true implications, variations in utility values exist between the methods. Generally, standard gamble methods generate the highest utility values because most patients are unwilling to accept a significant risk of sudden death, even if the alternative health state is poor. Utility values from time tradeoff methods are lower, which is consistent with the theory that decreased life expectancy is an easier price to pay for a chance to improve health. Rating scales usually generate the lowest utility values because there is no perceived penalty for underrating, as there is with the other methods.

Decision Analysis

Decision analysis is the formal methodology of addressing decisions by defining a problem, considering alternative choices, and then modeling the consequences of these alternatives based on an estimated risk of each alternative. This process has the potential to capture varying outcomes for individual types of patients and can also demonstrate critical factors that may alter their decisions.

One of the primary tools used in decision analysis is the decision tree, where the relevant factors are represented in chronologic relationship flowing left to right. The alternative choices (diagnostic tests, natural history states, treatments, etc.) are visually represented as branches of the tree, and each branch point is a decision node (usually represented as a square) in which a choice is possible, or a chance node (usually represented as a circle) in which the probability of a consequence is conditional on the events that preceded it. The end of each branch has an outcome that is based on the one that preceded it and their probabilities. Each outcome (life expectancy, quality-adjusted life years [QALYs], etc.) is given a value and the expected value for each alternative is then calculated on the basis of cumulative probabilities and outcome values. Decisions can then be made to optimize an outcome value, such as the lowest cost or highest QALYs.

The results from decision analysis are strongly influenced by the event probabilities and outcome values used. Ideally, these figures are derived from strong clinical studies in the field, although a consensus on precise figures and values can be difficult. *Sensitivity and threshold analysis* can then be performed to test the results of decision analysis under different probability and outcome assumptions. Sensitivity analysis is performed mathematically by setting the key probability as an unknown variable to be solved algebraically. This results in a probability value threshold around which the analysis can change to favor different decisions. If the threshold value (or probability) is within accepted estimated clinical probabilities for that event, researchers can have greater confidence in the applicability of the decision analysis results.

Markov Models and Monte Carlo Simulation

The decision trees discussed in the previous section work well for clinical situations in which one or a small number of decisions are made over a defined time frame. In reality, decision points may occur repeatedly, and the relevant factors influencing the outcome may also change over time. *Markov models* (named after the Russian mathematician Andrey Markov) assume that patients begin in one of a discrete number of possible mutually exclusive "states." For every cycle, each patient has a probability of remaining in the state or transitioning between one state and the next. Markov models also assume the Markov property, whereby future states are independent of past states. The model can then be analyzed by using matrixes, cohort simulation, or Monte Carlo simulation. *Matrix solutions* require matrix algebra techniques and can be used only when transition probabilities do not vary over time and costs are not discounted. *Cohort simulation* begins with a hypothetical large cohort of patients and subjects them to the Markov transition probabilities. A table is then generated with the new cohort distribution among the states. The process is repeated for the next and subsequent cycles until there is equilibrium or all patients are in a state without an exit, called *the absorbing state*. *Monte Carlo simulation* is similar to cohort simulation except that one patient at a time is simulated rather than the entire cohort. The simulation continues until the patient arrives at the absorbing state or the predetermined cycle is reached in models without absorbing states. Simulation of individual patients allows researchers to measure the variance of outcomes in addition to the mean.

Cost-Benefit and Cost-Effectiveness Analysis

At the heart of cost analysis is the assumption that resources are constrained. If unlimited resources are available, all testing and treatment would be offered as long as they were not harmful. However, in an environment of limited resources, cost analysis helps policymakers and clinicians decide on the greatest utility of the resources available. Cost analysis is certainly not the only or necessarily the best criterion for making health policy decisions. It is, however, an objective, quantitative tool that yields important information about the efficacy of clinical practice and does help to better clarify healthcare decisions.

From an economic standpoint, tests or treatments can be measured on two parameters: health improvement and cost savings. Treatments that both improve health and save costs are the goal and should be readily adopted. At the opposite end of the spectrum, treatments that worsen health and increase costs should be abandoned. Less clear cut are those interventions that fall within the spectrum—treatments that improve outcomes but also increase costs or those that save costs but fail to show improved outcomes. *Cost-effectiveness analysis* compares treatments based on a common measure of costs and effectiveness. The measure of effectiveness can be represented by the number of lives saved, cases cured, cases prevented, and preference-based utility measures such as QALYs. *Cost-benefit analysis* seeks to quantify costs and effectiveness in monetary

terms. Cost-benefit analysis is useful for comparing very different choices of treatments or interventions. Because many involved in healthcare are uncomfortable with the monetary valuation of life and life-years, cost-effectiveness is more commonly used in health-related analysis, whereas cost-benefit is more prevalent in economically oriented healthcare analysis.

The cost-effectiveness measure is the ratio of cost to effectiveness, typically dollars per QALY gained. Comparative choices (treatments, programs, tests) are subsequently ranked in order of lowest cost-effectiveness ratio to highest. These ratios can then be used to drive funding decisions. If funding is distributed to programs starting with the lowest cost per unit of efficacy, the cost-effectiveness ratio of the last funded program in this algorithm is defined as the *permissible cost-effectiveness threshold* for other programs to meet. In the United Kingdom, the National Institute for Health and Clinical Excellence has adopted a cost-effectiveness threshold range of £20,000 to £30,000 ($28,400-42,600 in US dollars) per QALY gained. In the United States, no official threshold has been adopted, although many in practice have used the threshold of $60,000 per QALY. This figure is based on the calculated average cost of hemodialysis per person per year and Medicare's special coverage of renal failure patients regardless of age.

The term *cost* is often misunderstood and misused. In economic analysis, cost is not limited to currency but can be applied to the use of other resources including time, personnel, and space. *Opportunity cost* is the loss or sacrifice incurred when one mutually exclusive option is chosen over another. Thus, if a plot of land is chosen to be developed into a hospital, the cost of that project includes the building cost as well as the lost opportunity to build a different facility at that site.

Specific to healthcare is the fact that cost must also be distinguished from "charges" by healthcare researchers because administrative accounting data often contain billing charges, which are based on the cost of materials and services but may also include indirect costs and a margin for profit. For most healthcare cost analyses, cost is stated from the perspective of the society. This utilitarian perspective differs from the perspective of the patient, provider, and institution. Although these other perspectives have validity, the societal perspective is more comprehensive and eliminates distortions, such as moral hazard and cost shifting.

Evidence in Practice

Evidence-based medicine is a relatively modern approach to the practice of medicine that aims to qualify and encourage the use of currently available clinical evidence to support a particular treatment paradigm. This practice encourages the integration of an individual practitioner's clinical expertise with the best currently available recommendations from clinical research studies.[2] Reliance on personal experience alone can lead to biased decisions, whereas reliance solely on results from clinical research studies can lead to inflexible policies. Evidence-based medicine stratifies the strength of the evidence from clinical research studies based on study design and statistical findings (Table 1.1). The criteria differ when the evidence is sufficient to support a specific therapeutic approach, prognosis, diagnosis, or other health services research. Criteria also differ among research institutions, including the US Preventive Services Task Force and the UK National Health Service. However, common themes can be seen among the different fields. Systematic reviews with homogeneity are preferred over single reports, whereas RCTs are preferred over cohort and case-control studies. Even within similar study design groupings, the statistical strength of each study is evaluated, with preference for studies with large numbers, complete and thorough follow-up, and results with small confidence intervals. Clinical recommendations are then based on the available evidence and are further graded according to their strengths (Table 1.2).

TABLE 1.1 Levels of Evidence for Therapeutics

Level	Evidence
1a	Systematic reviews of RCT studies with homogeneity
1b	Individual RCT with narrow confidence intervals
1c	"All or none" trials[a]
2a	Systematic reviews of cohort studies with homogeneity
2b	Individual cohort studies
2c	Clinical outcomes studies
3a	Systematic reviews of case-control studies with homogeneity
3b	Individual case-control studies
4	Case-series studies
5	Expert opinion without critical appraisal or based on bench research

[a]In which *all* patients died before the therapeutic became available, but some now survive with it, or in which some patients survived before the therapeutic became available, but now *none* die with it.
RCT, randomized controlled trial.
Modified from Oxford Centre for Evidence-Based Medicine (2001).

TABLE 1.2 Grades of Recommendation

Grade	Recommendation	Basis
A	Strong evidence to support practice	Consistent level 1 studies
B	Fair evidence to support practice	Consistent level 2 or 3 studies or extrapolations from level 1 studies
C	Evidence too close to make a general recommendation	Level 4 studies or extrapolation from level 2 or 3 studies
D	Evidence insufficient or conflicting to make a general recommendation	Level 5 evidence or inconsistent studies of any level

OUTCOMES TRANSLATIONAL RESEARCH

The practice of surgery has changed greatly since its early beginnings. Issues of anatomy, physiology, and anesthesia gave way to improving technology and the refinement of surgical technique. As surgeons gained technical skill and collective expertise, clinical outcomes and evidence-based medicine began to take on increasing importance. The proliferation of surgical care (and medicine as a whole) does come with a cost, however. In the United States, healthcare expenditures for the year 2014 reached $3 trillion, or approximately $9523 per person or 17.5% of the gross national product. Other developed countries spend less, but their expenditures are increasing.

Although the actual care of patients will continue to challenge us, the way we conduct and finance healthcare will also have a profound impact. Healthcare is a continuum from advancements in basic sciences, patient applications, clinical outcomes, efficacy analysis, and policy. The ultimate goal of the many tools described here is to improve patient care. Where *translational research* captures the connection between the basic sciences and patient care, *outcomes translational research* can be thought of as the connection between clinical outcomes and healthcare policy. Policy decisions based on expenditure caps can control healthcare costs. However, if these decisions are made arbitrarily, the resulting distribution of resources may be inefficient. Ideally, healthcare policy should be based on clinical evidence and efficacy should maximize limited resources.

Outcomes translational research begins with a careful analysis of clinical results. Such an analysis should ideally incorporate carefully designed studies to elucidate the natural history of a disease and compare treatment options. Even the outcome measure itself needs thoughtful selection. For example, in the surgical treatment of claudication, the classic measure of outcome was bypass graft patency. With the greater adoption of percutaneous treatment methods, vessel patency has been adopted. However, vessel patency does not accurately reflect all outcomes. From the patient's perspective, symptom relief and improvement in QoL is the benchmark. Although vessel patency clearly influences walking function, a patent vessel does not confer improved walking if other comorbid conditions, such as severe arthritis or neuropathy, are limiting. Conversely, assessment of functional and QoL endpoints alone does not allow analysis of the components leading to patient-perceived improvements. Greater understanding of technical success, vessel patency, and treatment durability will allow further improvements in the treatments themselves. Therefore measurement of clinical outcomes is a multimodal technique involving the use of integrated components that measure several aspects of success and failure.

Although there is no doubt that the results of clinical trials have had an impact on the care of surgical patients, these trials are costly and may not have comprehensive generalizability. The majority of vascular surgery occurs outside of clinical trials, in institutions of varying size, and by practitioners of varying expertise. The outcomes of these "real world" efforts are not well studied and may not mirror the experience of large academic institutions. To begin to address healthcare at a population level, many have used large national or statewide administrative databases in an attempt to analyze care broadly. Although such efforts can be informative when they are used appropriately, it is often difficult to draw clinical recommendations from these databases, which are primarily based on billing rather than clinical information. Often limiting in vascular surgery, most administrative databases do not distinguish the left from the right extremity. Thus, two vascular procedures performed on an extremity within 1 year can represent a revision of the first procedure, or they can signify sequential bilateral procedures. Comprehensive registries that allow broader inclusion of patients who receive care within specific diagnostic groups have begun to address these issues. Although countries with single-payer healthcare are more easily able to establish national registries, databases comprising regional vascular surgery patients exist and have helped to inform vascular care. The cost of such endeavors is certainly a factor in achieving a nationwide database, although arguably the cost of not knowing the outcomes and efficacy of healthcare may be greater.

The use of economic analysis is an important component of outcomes translational research because healthcare, like all human effort, requires resources. Economics has often been maligned as being "cold"; however, this quality is its strength, not its weakness. Few of us can hope to be without bias in making healthcare decisions for ourselves, our patients, or our relatives, and each specialty group strives to increase resources that can be applied to their disease or cause. The economic analysis of healthcare allows assessment of outcomes as measured by a common comparable unit (cost). However, economics as a whole can shed light only on the tradeoffs between different alternatives and their impact. It is up to policymakers to assign value to these tradeoffs and, in the end, make decisions about the allocation of healthcare resources. In some ethical and societal frameworks, additional value may be assigned to the treatment of specific disease groups (e.g., dialysis care) not captured by traditional analytic methods. Nevertheless, without clinical and economic analytic tools, such decisions are made without reference to their impact on alternative decisions. Clinician researchers in outcomes translational research are well suited to contribute to the policies that affect healthcare because they can generate data to help formulate policy and they also see the effect of policy on the individual patients they are treating.

The fundamental purposes of the vascular system are to supply the organism with oxygen and nutrients and to remove metabolic waste products. During the first 3 weeks of gestation, simple diffusion is sufficient to support the embryo; however, by the fourth week, a functional cardiovascular system must be in place to maintain the rapidly developing embryo. The cardiovascular system in the embryo is one of the first and earliest systems to appear and begin to function. Isolated blood vessels and blood components form in the yolk sac by day 17, while just a day later, isolated blood vessels begin to appear in the embryo proper. The heart begins to beat by day 22 and pumps blood by day 24. Failure of the vascular system to properly develop can result in the appearance of variations or abnormalities that can have clinical ramifications. By understanding the embryology of the vascular system, the vascular surgeon will be better able to recognize vascular anomalies and understand how they may have developed.

FORMATION OF EMBRYONIC BLOOD VESSELS

Molecular Signaling of Vasculogenesis and Angiogenesis

Historically the development of the vascular system has been thought to be no more than the growth of arteries, veins, and lymphatic vessels from a basic set of tubes. In reality, the development of the vascular system is a complex orchestration of signaling molecules, receptor molecules, and transcription factors. The initial step is the modification of splanchnic mesodermal cells into angioblasts that form vesicular aggregates in the splanchnic mesoderm of the embryo and extraembryonic regions, including the yolk sac, the connecting stalk, and the chorion.[1] Under the control of signaling molecules, these angioblasts develop into flattened endothelial cells that form

Abstract

The development of the vascular system is a complex but orderly process orchestrated by signaling and receptor molecules, transcription factors, and environmental factors. When normal development fails to occur, anatomic variations or anomalies ensue which in turn can have clinical implications. Normal development of the arterial, venous and lymphatic systems is outlined in the chapter. Common vascular anomalies that occur with failure of proper development of the vascular system are also highlighted.

small vessel cords, which will, in turn, coalesce with one another to form vessels. This process, termed *vasculogenesis*, begins first in the yolk sac at day 17. Hemangioblastic aggregates composed of an inner core of hematopoietic stem cells and an outer rim of endothelial cells form in the yolk sac.[2,3] The hematopoietic stem cells serve as the source of blood cells to the embryo until day 60, when the liver, spleen, thymus, and ultimately the bone marrow become the source of blood cells. Hemangioblastic aggregates also form in the connecting stalk and chorion at day 17, and coalesce to form the extraembryonic umbilical vessels that will act as the circulatory connection between the embryo and the maternal tissue.

Once endothelial cells are established as vascular elements, they begin to sprout and bud, forming simple capillary networks. These capillary networks remodel into arterial, capillary, and venous systems, as determined by the surrounding environment. In addition, some presumptive vessels will undergo vascular intussusception to remodel and generate additional vessels. Much of this growth is under the influence of vascular endothelial growth factor (VEGF), which activates a series of molecular and cellular events that ultimately lead to a stable vascular network.[4] Local hypoxia upregulates a number of genes and facilitates angiogenic sprouting from existing vessels. Signaling molecules also lead to endothelial specificity, such as vessels with a fenestrated endothelial layer found within the capillaries, as seen in endocrine glands and the kidneys, or tight junctions as seen in the capillaries of the brain (i.e., the blood-brain barrier).[4,5]

Veins and arteries have been used to describe vessels whose direction of blood flow is either toward (veins) or away from (arteries) the heart. Although there are morphologic differences in the walls of veins and arteries, it was not until recently that it has been demonstrated that arteries and veins are also different with regard to specific cell surface markers that trace back to the receptors found on angioblasts. The development of lymphatics is also under the control of specific genes that are expressed in a specific subpopulation of endothelial cells associated with the anterior cardinal veins. Cells from the cardinal veins bud, divide, and migrate to form lymph sacs and ultimately lymphatic vessels.[6,7]

Early Angiogenesis

As the major vascular structures including the heart, dorsal aortas, umbilical vessels, vitelline vessels, and cardinal veins are being formed by vasculogenesis, the embryo is already beginning to remodel this vascular system by the processes of angiogenesis and vascular intussusception. Other factors, especially related to the heart and dorsal aortas, have a profound effect on the definitive vascular system's configuration. By day 20, the growth of the neural tube forces the cardiogenic area ventrally and caudally to its final position in the thoracic region, whereas lateral folding of the embryo causes the two endocardial tubes to fuse along the midline, resulting in a single endocardial tube with a more cranially placed outflow and a more caudally located inflow region. As the developing heart lengthens, a series of swellings become visible. Beginning at the inflow end, these include the sinus venosus with its right and left horns, primitive atrium, primitive left ventricle, bulbus cordis (future right ventricle), and truncus arteriosus. The aortic sac, the rostral dilation of the truncus arteriosus, connects the developing heart to the dorsal aortas. Between days 22 and 24, the developing heart moves into its ventral position, and the attached dorsal aortas are forced into a dorsoventral bend that forms the first aortic arch. The first aortic arch is contained in the thickened mesoderm of the developing first pharyngeal arch surrounding the pharynx. Aortic arches 2 through 6 form from mesenchyme within their own pharyngeal arches in a rostral to caudal sequence between days 26 and 30. Lateral folding of the embryo also forces the paired dorsal aortas, beginning at the fourth thoracic somite, to fuse with one another as a common aorta; however, rostral to this level, the dorsal aortas remain as separate vessels. By the beginning of the fourth week, intersegmental vessels between each somite arise from the dorsal aortas. Each intersegmental vessel has a dorsal branch, a lateral branch, and a ventral branch that supply the individual somite regions.

Aortic Arch

Normal Arch Development

The vascular system in humans is symmetric, with the exception of the adult aortic arch. The right common carotid and right subclavian arteries arise from the brachiocephalic (innominate) artery, whereas the left common carotid and left subclavian arteries originate as separate vessels from the aortic arch. These differences are a consequence of the changes in the connections of the aortic arches, the dorsal aortas, and the aortic sac. Diagrammatic representation of these changes would suggest that the aortic arches are all present at the same time, but in reality, the first arches are already regressing while others are still developing.

The first two aortic arches appear and regress quickly and contribute very little to adult structures, whereas the fifth aortic arch never develops in humans (Fig. 2.1A). The third aortic arches become the common carotid arteries and proximal segments of the internal carotid arteries. The distal segments of the internal carotid arteries are derived from the dorsal aorta between the first and third arches. The external carotid arteries sprout from the common carotid arteries. The dorsal aorta on each side of the embryo between the third and fourth arches disappears, thus directing blood through the third aortic arch system to the head and neck regions (see Fig. 2.1B). The fourth aortic arches are asymmetrical with regard to their fate. The left aortic arch forms that part of the adult aortic arch between the left common carotid and left subclavian arteries, whereas the right aortic arch becomes the proximal segment of the right subclavian artery. The remainder of the right subclavian artery is derived from the right dorsal aorta and its right seventh intersegmental artery. The right dorsal aorta distal to the seventh intersegmental artery, but proximal to the fused common aorta, involutes (see Fig. 2.1C). The right horn of the aortic sac, connected to the right third and fourth aortic arches, elongates to become the brachiocephalic (innominate) artery, and the left horn becomes the initial portion of the aortic arch. The proximal portions of

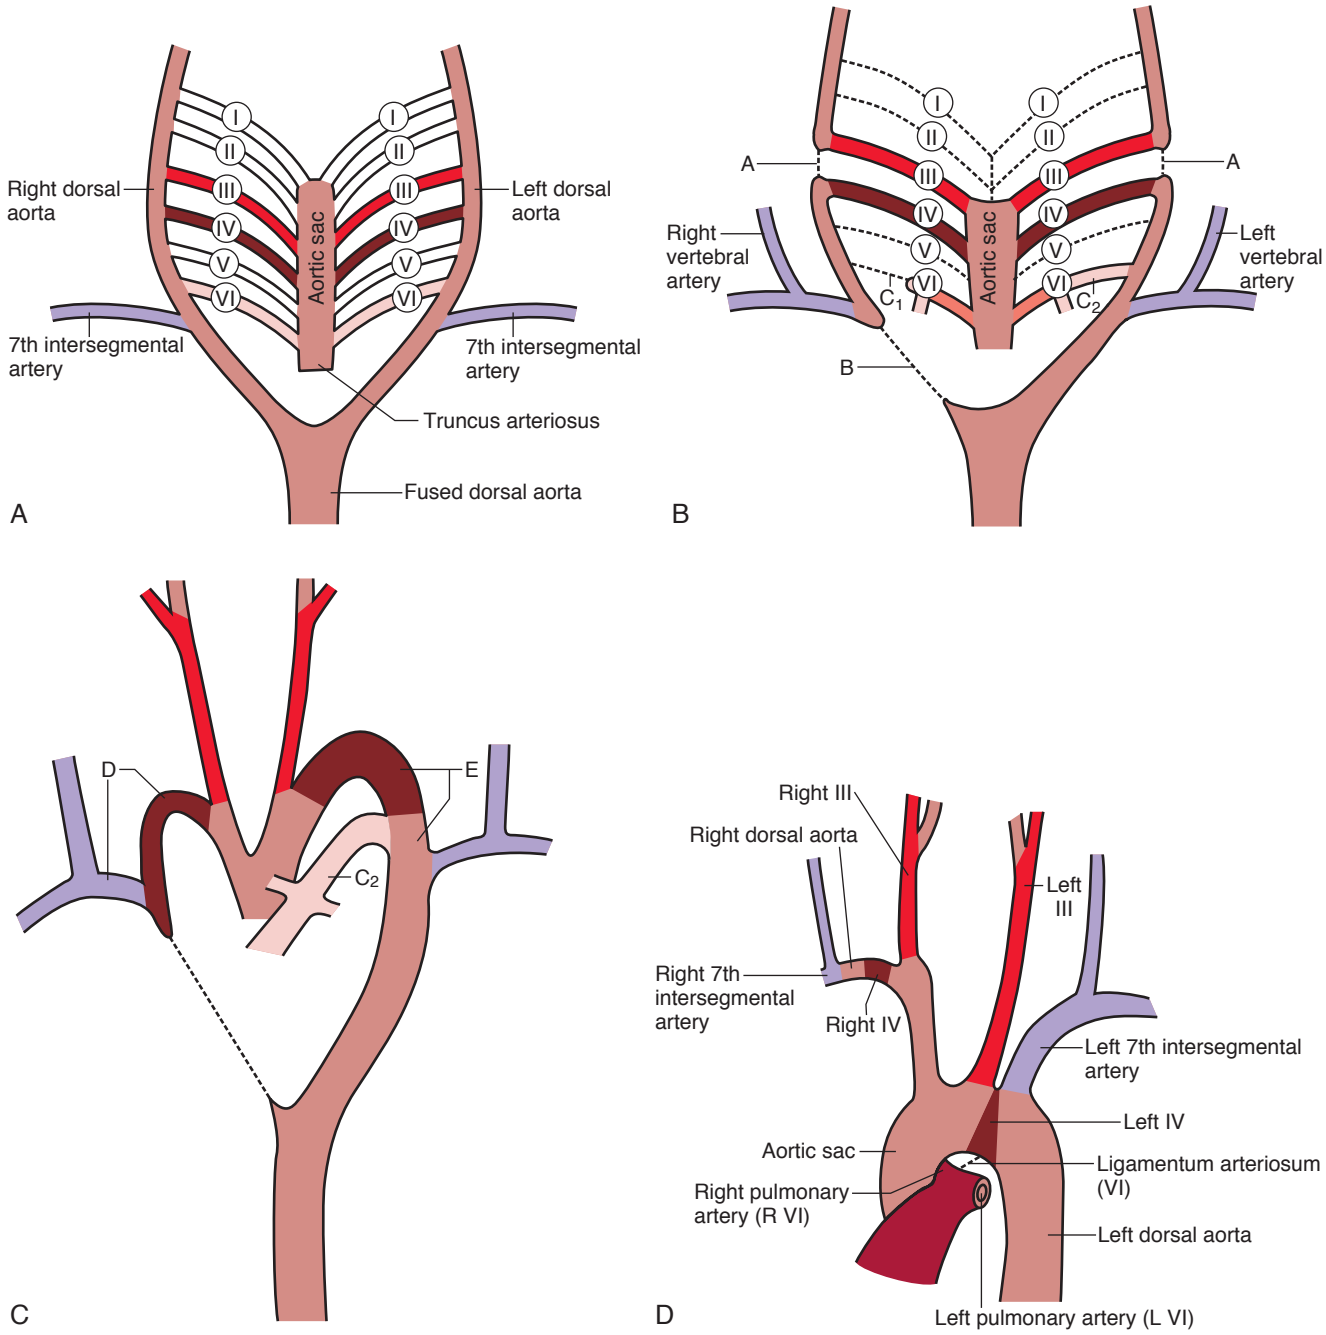

Figure 2.1 **(A)** The six primitive aortic arches. The first, second, and fifth arches disappear. The paired dorsal aortas fuse at the level of the seventh cervical vertebra to become the thoracic and abdominal aorta. **(B)** Differentiation of the aortic arches. The dorsal aorta between the third and fourth arches *(A)* involutes so that blood entering the third arch perfuses the head only. The third arch and its branches become the carotid system. The right dorsal aorta distal to the right seventh intersegmental artery *(B)* involutes so that blood entering the right fourth arch perfuses the right upper limb. This system becomes the right subclavian artery. The distal part of the right sixth arch *(C_1)* involutes, but the distal part of the left sixth arch *(C_2)* persists and becomes the ductus arteriosus. **(C)** Development of the aortic arches. The right fourth arch, the dorsal aorta distal to the right fourth arch, and the right seventh intersegmental artery become the right subclavian artery *(D)*. The left fourth arch and the left dorsal aorta distal to it become part of the aortic arch *(E)*. The left seventh intersegmental artery becomes the left subclavian artery. Pulmonary arteries form from the sixth arch with the ductus arteriosus *(C_2)* present. **(D)** Segments of the aortic arches that produce the adult aortic arch. The patent ductus arteriosus becomes the ligamentum arteriosum.

both sixth arches become the right and left pulmonary arteries. The distal segment of the right sixth arch disappears, but the distal segment of the left sixth arch becomes the ductus arteriosus during fetal life and atrophies after birth to become the ligamentum arteriosum (see Fig. 2.1D).

Aortic Arch Anomalies

In light of the complexity of events that must occur for normal development of the aortic arch and its branches, anomalies do occur.[8-14] Anomalies result when segments of the primitive aortic arch that should disappear persist or vice versa, when other parts that should persist disappear. Variations in the development of vessels as they arise from the aortic arch are relatively common. The most common developmental pattern considered to be "normal," as described in the preceding sections and illustrated in Fig. 2.1D, occurs in 65% of the population. In 22% of the population, the left common carotid artery originates from the brachiocephalic trunk rather than from the aortic arch, in what is termed a "bovine arch." In this case, the brachiocephalic trunk gives rise to the right subclavian, right common carotid, and left common carotid arteries, whereas the left subclavian artery originates from the aortic arch as normally expected. This variant accounts for 73% of all arch anomalies. Many other variations, each occurring in less than 3% of the population, have been described. Some of these anomalies include a very shortened brachiocephalic trunk that bifurcates immediately into the right subclavian and right common carotid arteries, with the left common carotid arising from the aortic arch at the base of the brachiocephalic trunk and a normal origin for the left subclavian artery from the aortic arch. The left vertebral artery can originate directly from the aortic arch between the left common carotid and left subclavian arteries. A left brachiocephalic trunk may be present, which bifurcates into left subclavian and left common carotid arteries.[8]

Patent Ductus Arteriosus

The ductus arteriosus develops from the distal portion of the left sixth aortic arch and is responsible for shunting blood from the immature, developing fetal lungs to the systemic circulation. A patent ductus arteriosus is the most common vascular anomaly. At birth, the ductus normally constricts in response to exposure of the now high oxygen content in the blood by oxygen-sensitive smooth muscle cells in its wall. By the age of 1 month, the ductus normally obliterates to become the ligamentum arteriosum. If the ductus arteriosus does not constrict and remains patent, blood is shunted from the high-pressure thoracic aorta to the low-pressure pulmonary system, eventually resulting in significant pulmonary hypertension (Fig. 2.2).

Coarctation of the Aorta

Aortic coarctation can be seen at any level of the aorta, but the most common location is postductal, just distal to the ligamentum arteriosum; the preductal type occurs immediately proximal to the ligamentum. The etiologic mechanism of coarctation remains unclear, but it is hypothesized that its development is similar to the process that results in normal, physiologic obliteration of the ductus arteriosus. It is thought that oxygen-sensitive

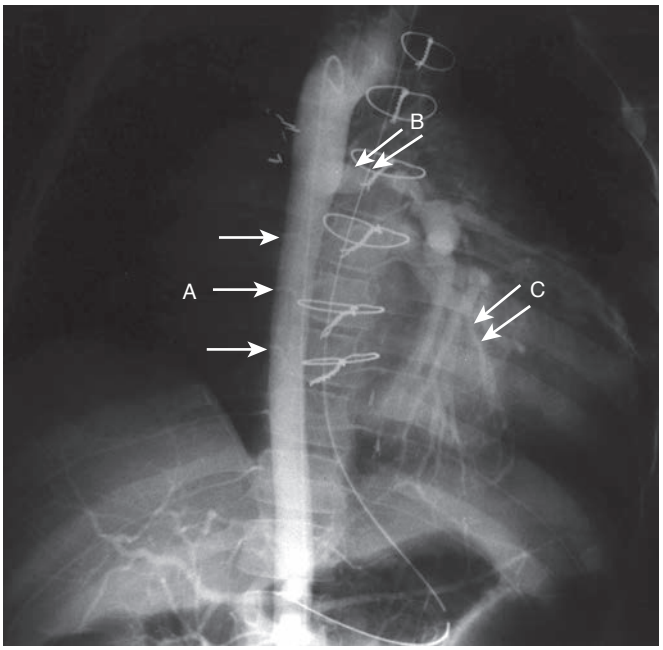

Figure 2.2 Right-sided aorta with a patent ductus arteriosus. *Arrows* point to the right-sided aorta *(A)*. A patent ductus arteriosus *(B)* is filling the pulmonary arteries *(C)*.

muscle tissue from the ductus arteriosus is incorporated into the wall of the aorta. This smooth muscle, which constricts when exposed to high oxygen tension, results in narrowing of the aorta at this level. Eventually chronic changes develop, and the constriction becomes permanent. Relative ischemia of the body below the constriction stimulates the development of collateral vessels. Radiographically, notching on the inferior aspect of the third to eighth ribs may be seen as a consequence of the increased collateral blood flow in the intercostal arteries (Figs. 2.3 and 2.4).[6,14,15]

Double Aortic Arch

The right dorsal aorta distal to the right seventh intersegmental artery may fail to involute, with the result being a double aortic arch. This segment passes posterior to the esophagus and joins the left aortic arch, which passes anterior to the trachea. As a result, a vascular ring forms around the esophagus and trachea. Symptoms may develop from compression of the esophagus and/or trachea (Fig. 2.5).

Right Aortic Arch

Involution of the left dorsal aorta distal to the left seventh segmental artery with persistence of the right dorsal aorta (opposite the normal sequence) creates a right aortic arch (Fig. 2.6). The ligamentum arteriosum arises from the distal right sixth arch instead of the distal left sixth arch, but still connects to the aorta. If the arch passes to the left side and posterior to the esophagus, a vascular ring is formed with the ligamentum arteriosum and is known as a right aortic arch, with an aberrant left subclavian artery or a retroesophageal component. If the right aortic arch passes anterior to the esophagus and trachea, a vascular ring is not formed, and it is considered to be a right

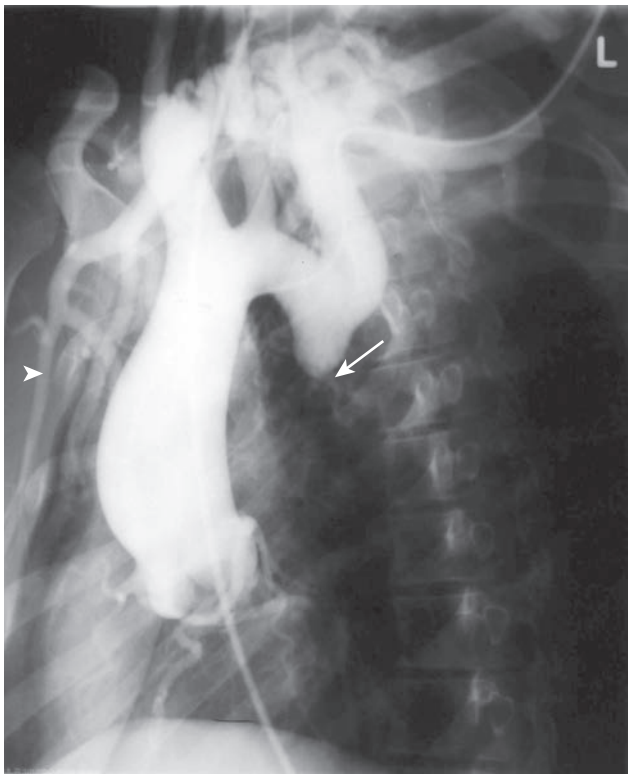

Figure 2.3 Coarctation of the aorta is identified by the *arrow*. Note the enlarged great vessels. The right internal mammary *(arrowhead)*, a major collateral vessel to the lower portion of the body, is very visible and enlarged.

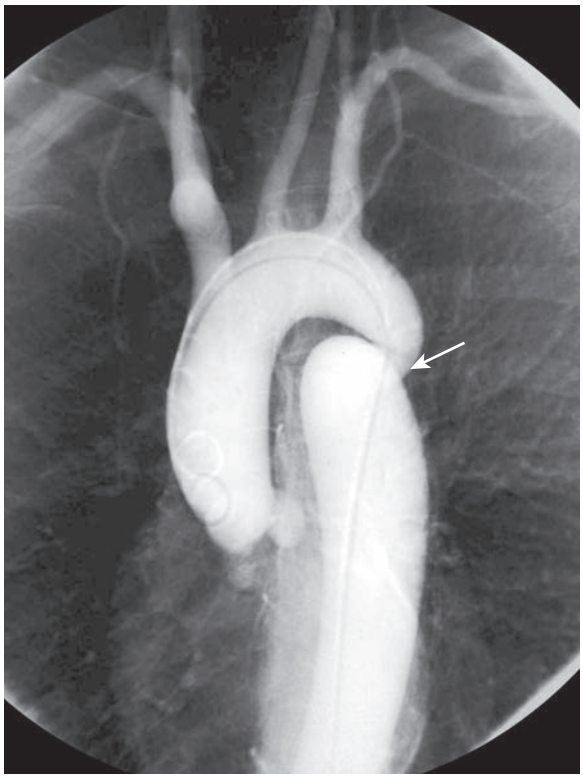

Figure 2.4 Coarctation of the aorta *(arrow)*, with poststenotic dilation of the aorta.

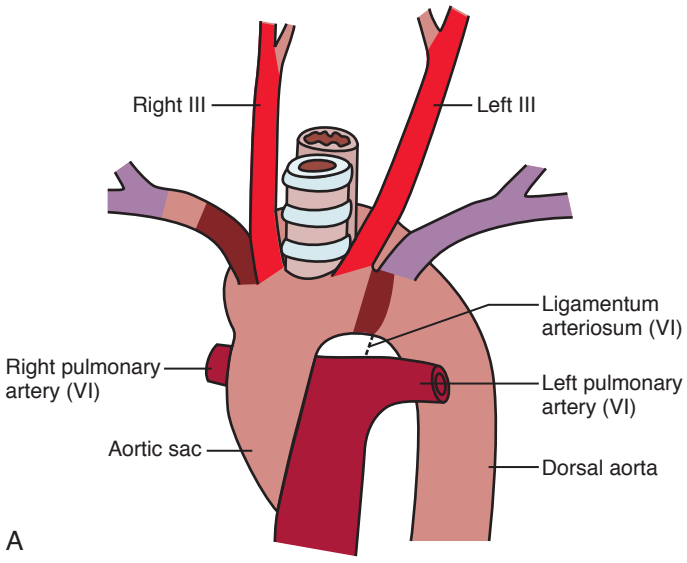

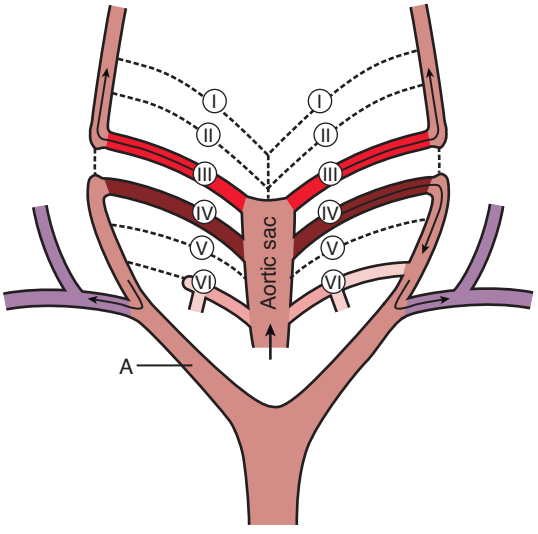

Figure 2.5 Double aortic arch. **(A)** The aortic arch passes anterior and posterior to the trachea and esophagus to form a vascular ring. **(B)** The right dorsal aorta distal to the right seventh intersegmental artery *(A)*, which normally involutes, persists to become part of the double aortic arch.

aortic arch with mirror image branching. The former anomaly may initially be a double aortic arch, in which the left dorsal aorta later regresses (see Fig. 2.2). The latter is a mirror image of normal anatomy and is associated with a higher incidence of heart malformations in which almost all infants are cyanotic. An example of a heart malformation associated with mirror image branching of the aortic arch is tetralogy of Fallot.[14]

Retroesophageal Right Subclavian Artery

The right subclavian artery normally forms from the right fourth aortic arch and the seventh intersegmental artery, connected by the intervening segment of the right dorsal aorta. A retroesophageal right subclavian artery forms as a result of abnormal involution of the right fourth aortic arch and the connected right dorsal aorta (Fig. 2.7). The right dorsal aorta distal to the

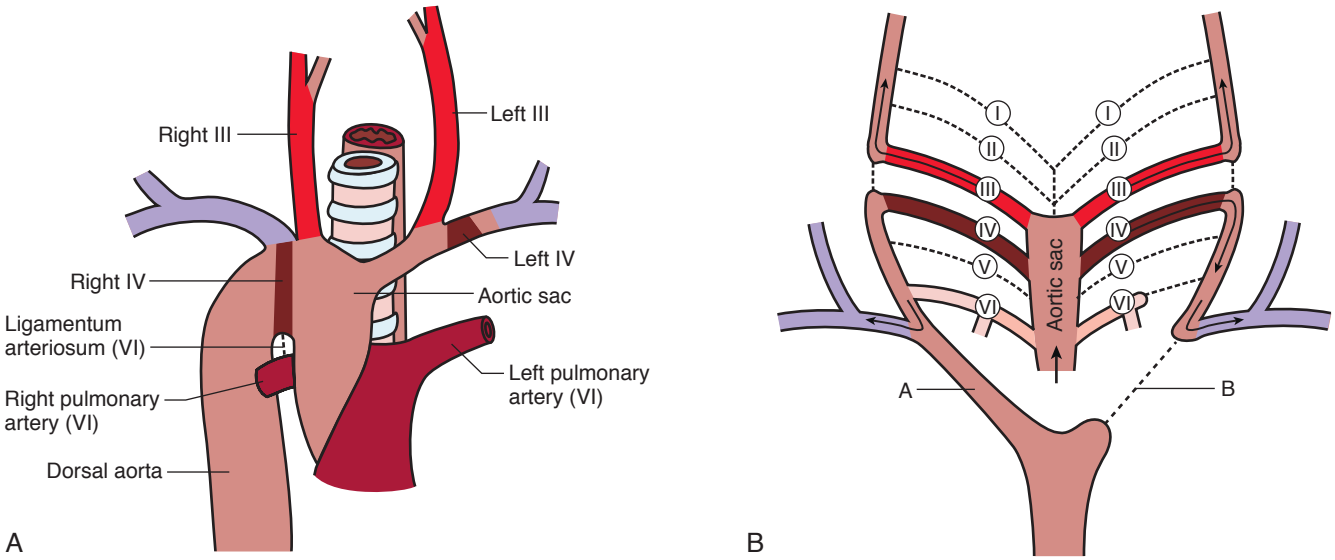

Figure 2.6 Right aortic arch. **(A)** One of two types in which the right arch passes anterior to the trachea and esophagus so that no vascular ring is formed. If the right arch passes posterior to the trachea and esophagus, the ligamentum arteriosum and the right arch form a vascular ring. **(B)** The right dorsal aorta distal to the right seventh intersegmental artery persists *(A)*, but the left dorsal aorta distal to the left seventh intersegmental artery involutes *(B)*, the opposite of the normal occurrence.

right intersegmental artery persists instead of involuting and joins the right seventh intersegmental artery to form the right subclavian artery. As the proximal portion of the aortic arch develops from the aortic sac, the right subclavian artery is forced to the left side and has an origin distal to the left subclavian artery. The right subclavian artery travels from the left side of the aorta behind the esophagus to supply the right upper limb. Most patients with this entity are asymptomatic, but about 5% have compression of the esophagus, resulting in difficulty with swallowing, a condition known as *dysphagia lusoria*.[10] In addition, this anomaly is prone to developing an aneurysm, a condition termed *Kommerell diverticulum*. These aneurysms can lead to compressive symptoms (dysphagia, cough, dyspnea), thromboembolism, or rupture (Fig. 2.8).

DEVELOPMENT OF THE DESCENDING (THORACIC AND ABDOMINAL) AORTA

During the fourth week, the paired dorsal aortas caudal to the level of the seventh cervical somite fuse to become the descending (thoracic and abdominal) aorta. At about the same time, the first of 36 to 38 segments or somites begin to form throughout the length of the embryo. At each somite level, segmental arteries continue to form dorsal, ventral, and lateral branches. The dorsal branches supply the developing neural tube and epimere (which becomes the epaxial muscle of the back), whereas the ventral branches supply the hypomere that become the intercostal muscles, external, and internal obliques, and transversus abdominus and overlying skin. In cervical regions, the dorsal intersegmental branches anastomose with one another to form the vertebral arteries, as well as the deep cervical and ascending cervical arteries. In thoracic regions, the dorsal branches form the intercostal arteries. Ventral branches anastomose with one another and contribute to the formation of the superior thoracic artery, internal thoracic artery, and the superior epigastric arteries. At the lumbar level, the dorsal intersegmental branches become lumbar arteries, with the fifth lumbar pair remaining as the common iliac arteries. The lumbar ventral branches form allantoic and vitelline vessels. The segmental arteries forming the allantoic vessels become the umbilical arteries, whereas the other paired ventral segmental vessels connect to the yolk sac and develop into the vitelline arteries. As the gastrointestinal tract develops, the vitelline arteries become its blood supply and fuse to become the three unpaired gut vessels: the celiac artery supplying the foregut, the superior mesenteric artery supplying the midgut, and the inferior mesenteric artery supplying the hindgut. The embryonic-derived components of the umbilical arteries are originally the ventral branches of the dorsal aorta. The bases of these segmental vessels later connect with the fifth intersegmental branches. The proximal portions involute, ultimately leading to the formation of the internal iliac arteries in the adult.

The lateral segmental arteries supply the primitive urogenital ridge, which is the source of the gonads and kidney. The most rostral part of the urogenital ridge develops two sets of primitive kidneys, the pronephros and mesonephros, which over time disappear. The most caudal part of the urogenital ridge becomes the metanephros, which develops into the adult kidney. At the seventh week of gestation, the "rostrally migrating" metanephros establishes and loses connection with a series of arteries, each of which will eventually regress. The metanephric kidneys establish connections with several rostral lateral segmental arteries that persist and fuse with one another to form definitive renal arteries. Not surprisingly, considerable variations exist in the

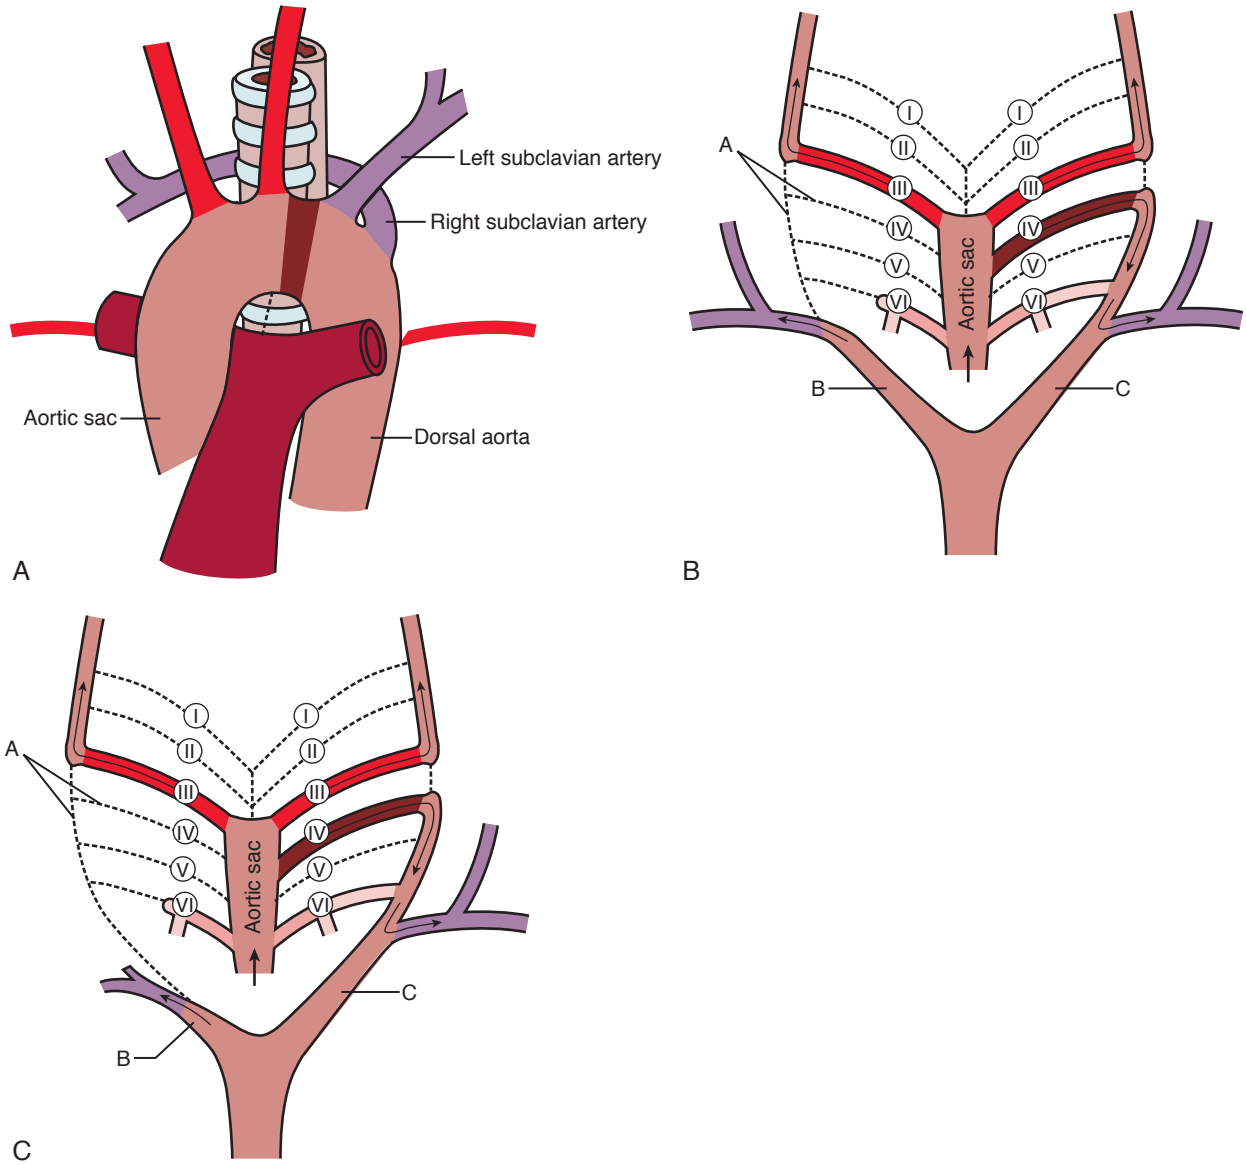

Figure 2.7 Retroesophageal right subclavian artery. **(A)** The right subclavian artery originates distal to the left subclavian artery and reaches the right upper limb by passing posterior to the trachea and esophagus. **(B)** The right fourth arch and the dorsal aorta distal to the right fourth arch *(A)* abnormally involute, and therefore cannot contribute to formation of the right subclavian artery. The right subclavian artery is then formed by the right dorsal aorta distal to the right seventh intersegmental artery *(B)*, which normally involutes *(C)*. This becomes part of the thoracic aorta. **(C)** The left dorsal aorta *(C)* elongates, enlarges, and moves craniad to become the thoracic aorta. The right dorsal aorta *(B)* shortens considerably to become a branch of the thoracic aorta leading to the subclavian artery *(A)*. This section abnormally involutes (see **B**).

arterial supply to the kidney.[16,17] Most individuals (71%) have a single artery to each kidney, whereas remaining individuals have a variety of combinations of hilar and accessory branches to the poles of the kidneys. Horseshoe kidneys develop with fusion of the caudal kidney poles. Such fusion arrests rostral migration of the kidney, and multiple segmental arteries persist to provide blood supply to the fused kidney. Similarly, ectopic kidneys frequently have several segmental arteries instead of a single renal artery. Therefore, when a patient is found to have either a horseshoe or an ectopic kidney, the clinician should suspect that the patient is likely to have an anomalous arterial blood supply.[18] Other lateral segmental branches become the adrenal and gonadal arteries.

DEVELOPMENT OF THE LIMBS

The limbs begin as an outgrowth of tissue originating from the embryonic trunk, called a *limb bud*. Within each limb bud, an apical ectodermal ridge is formed along the anteroposterior plane that differentiates ventral structures (e.g., palm of the hand) from dorsal structures (e.g., back of the hand). The first structure to differentiate in the limb bud is the skeletal tissue

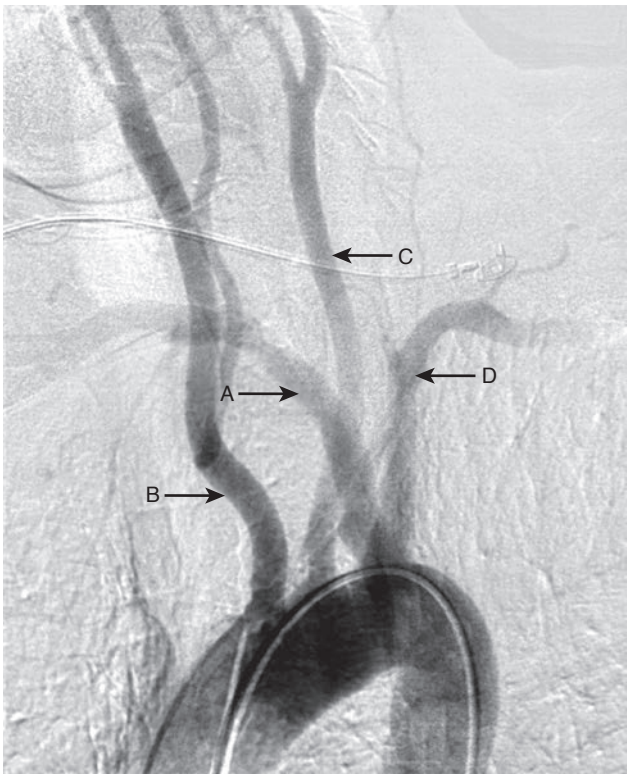

Figure 2.8 Aberrant origin of the right subclavian artery. The right common carotid artery *(B)* is the first branch of the arch, followed by the left common carotid *(C)*, left subclavian *(D)*, and then the right subclavian artery *(A)*.

from a cluster of mesenchymal cells. Shortly thereafter, muscle tissue develops from myogenic cells located in the ventral portion of the dermomyotome of the somite. Motor neurons appear in the limb muscles around the fifth week, followed by sensory neurons. The blood vessels that arise from endothelial cells in the segmental branches of the aorta, cardinal veins, and angioblasts within the limb bud mesoderm are the last tissue to be differentiated within the limb bud. Initially, a fine capillary network provides blood supply to the limb, but preferential enlargement of vessels gives rise to a single large central artery. Blood from this central artery feeds into a peripheral capillary bed and then collects in a marginal sinus located beneath the apical ectodermal ridge.[19]

Upper Limb

Normal Development

Development of the arterial supply to the upper limb is relatively simple (Fig. 2.9). The arterial supply to the upper limb is derived from the seventh cervical intersegmental artery, which supplies the upper limb by joining with the axial artery that develops within the limb bud. The developing axial artery becomes the brachial artery, whereas the portion of the axial artery in the forearm becomes the anterior interosseus artery. In the hand, a portion of the axial artery persists as the deep palmar arch. The ulnar, radial, and median arteries sprout from the axial artery to take over the supply of the forearm as the interosseous artery begins to regress. By the eighth week, the definitive vascular morphology of the arm is in place and consists of the subclavian artery, arising directly (left subclavian) or indirectly (right subclavian as a branch of the brachiocephalic) from the aortic arch. The subclavian artery continues into the arm as the axillary artery and next as the brachial artery. The deep brachial artery forms as a bud from the brachial artery and supplies blood to the posterior aspect of the arm. The brachial artery gives rise to the radial and ulnar arteries, a common interosseous artery that further bifurcates into anterior and posterior interosseous arteries, and a median artery.[19,20] Over time, the radial and ulnar arteries replace the anterior interosseous artery as the dominant arteries in the hand, whereas the median artery regresses.

Upper Limb Vascular Anomalies

There are some variations in vascular anatomy but very few anomalies of the arm vasculature. The main variations are a high origin of the radial artery proximal to the level of the elbow at the cubital fossa, which occurs in 14.2% of the population, and persistence of the median artery into the palm, which is present in up to 12% of the population.[20]

Lower Limb

Normal Development

Development of the arterial supply to the lower limbs is more complex than that in the upper limb (Fig. 2.10).[21] The axial artery of the lower limb initially is a distal continuation of the internal iliac artery, a ventral branch of the fifth lumbar intersegmental artery. During the fourth week, the right and left umbilical arteries connect with the paired dorsal aortas in the sacral region. The umbilical arteries join with the proximal portion of the fifth lumbar dorsal intersegmental arteries, giving rise to the common iliac arteries. The external iliac artery forms as a second branch of the fifth lumbar intersegmental artery, developing into the iliofemoral artery. The axial (sciatic) artery arising from the internal iliac artery regresses by the beginning of the eighth week, although parts of it persist as the sciatic (ischiadic) artery, part of the popliteal artery, and a portion of the peroneal artery. The remainder of the lower limb arteries develops as sprouts of the external iliac artery.

In the lower part of the thigh, the sciatic artery joins the iliofemoral system at the level of the popliteal fossa. The popliteal artery develops from the union of two arteries: (1) the deep popliteal artery, which is part of the sciatic system and lies anterior to the popliteus muscle, and (2) the later-developing superficial popliteal artery from the iliofemoral system (Fig. 2.11). The distal section of the deep popliteal artery regresses, whereas the superficial popliteal artery unites with the proximal portion of the deep popliteal artery to form the definitive popliteal artery and lies posterior to the popliteus muscle.

Lower Limb Vascular Anomalies

Persistent Sciatic Artery

If the iliofemoral artery fails to develop, the sciatic artery may persist as the dominant vessel supplying blood to the thigh.

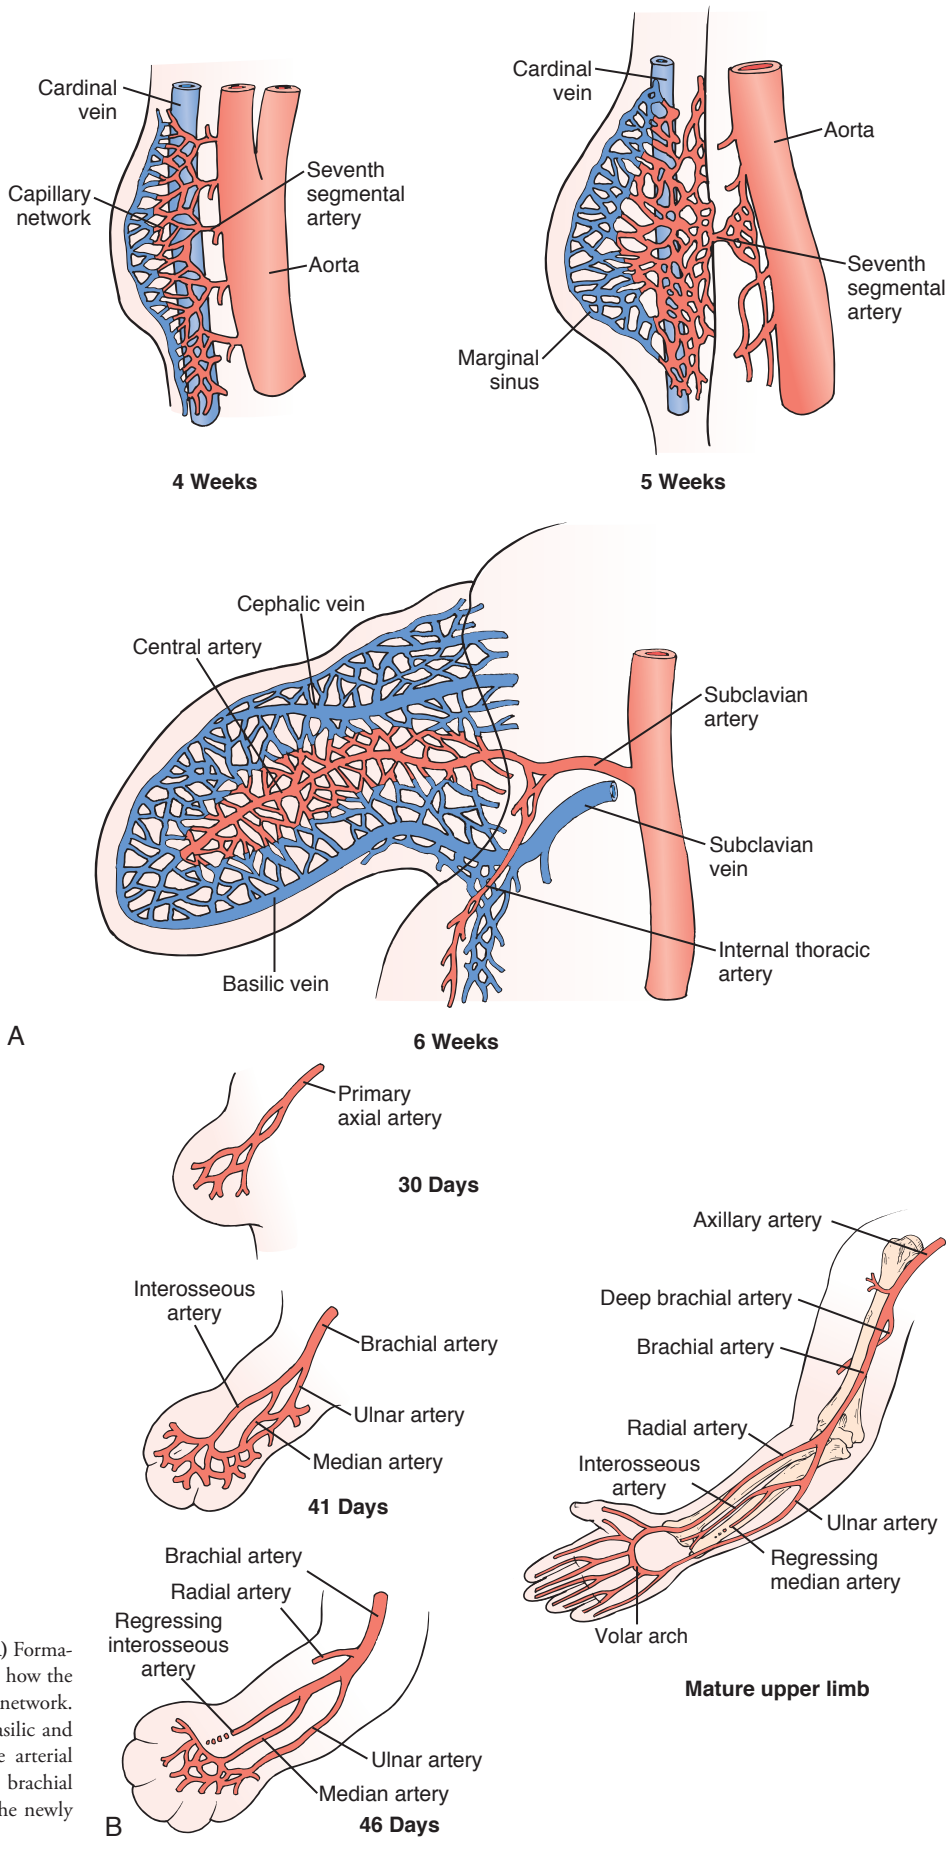

Figure 2.9 Arterial supply to the right upper limb. **(A)** Formation of the vascular system within the limb bud. Note how the capillary bed separates into an arterial and a venous network. At about 6 weeks, the marginal sinus becomes the basilic and cephalic veins, and a central artery forms from the arterial network. **(B)** The primary axial artery becomes the brachial artery, which gives rise to a number of branches in the newly developing forearm.

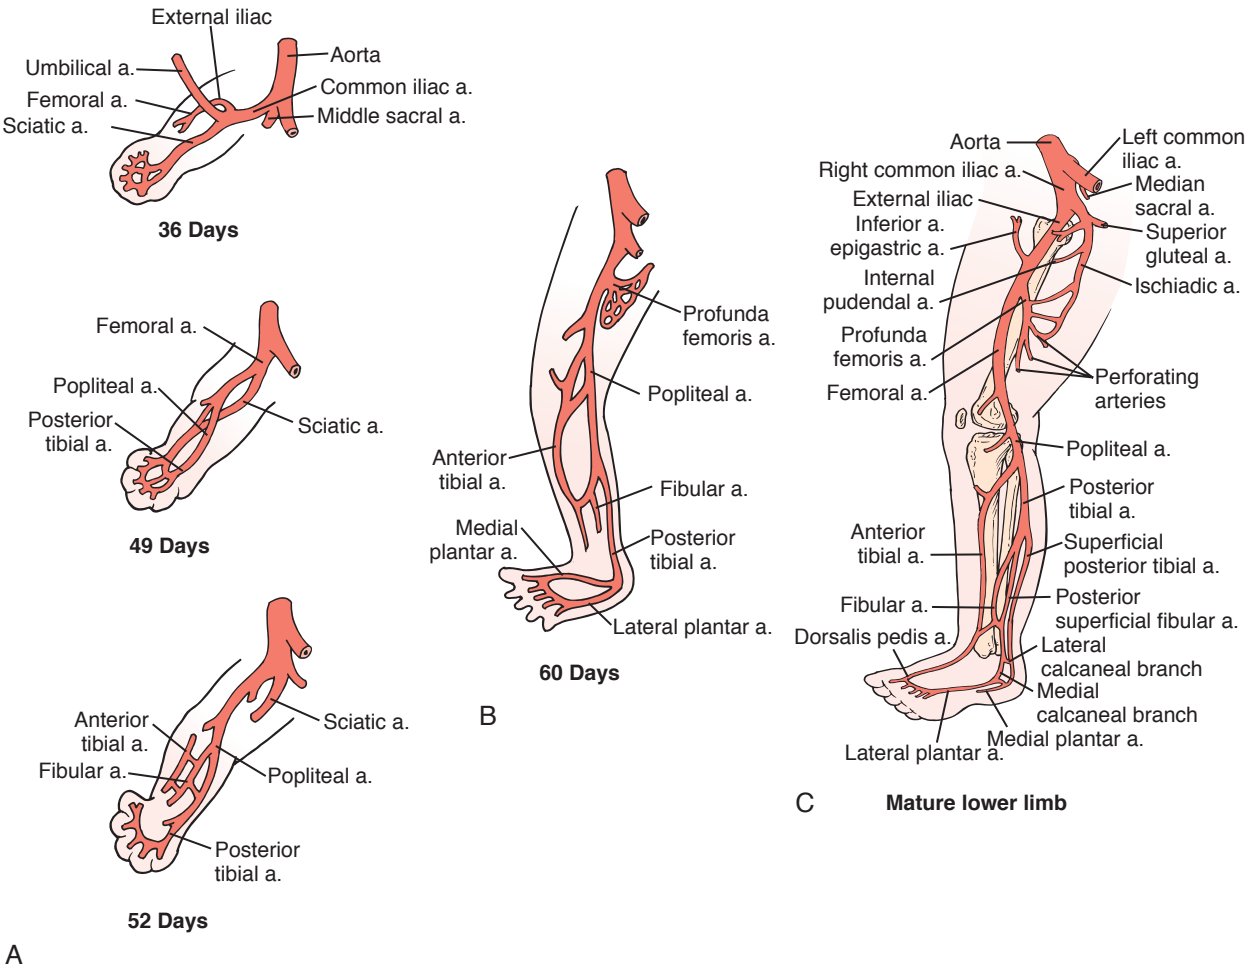

Figure 2.10 Arterial supply to the left lower limb. **(A)** The sciatic artery forms as a branch of the umbilical artery and initially supplies the entire leg. **(B)** The sciatic artery regresses, and the external iliac artery develops into the common femoral artery to supply the thigh. Note that the sciatic artery communicates with the popliteal artery just above the knee. **(C)** The sciatic artery disappears, although small portions remain to form the popliteal and peroneal arteries.

This is a rare anomaly, with an incidence of 0.05%[22] with variable morphologically, ranging from a persistent sciatic artery that is complete from its origin at the internal iliac artery to its union with the popliteal artery, to an incomplete sciatic artery that connects with the internal iliac or popliteal artery through small collaterals. A persistent sciatic artery is anatomically located next to the sciatic nerve and thus passes into the thigh through the sciatic notch and remains posterior to the adductor magnus until the insertion of that muscle, where it enters the popliteal fossa to join the popliteal artery. On physical examination, patients with a complete persistent sciatic artery may have an absent femoral pulse but a normal popliteal pulse. A persistent sciatic artery is superficial in the buttocks and can be traumatized by normal activity such as sitting. This causes early atherosclerotic changes and, possibly, aneurysm formation of the artery in the buttocks.[23-25] An aneurysm in a sciatic artery can compress the sciatic nerve and result in neurologic symptoms (Fig. 2.12).

Popliteal Entrapment Syndrome

Popliteal entrapment syndrome is caused by displacement of the popliteal artery medial to the medial head of the gastrocnemius. It results from migration of the medial head of the gastrocnemius that forces the vessels across the popliteal fossa and entraps them against the medial condyle of the femur.[21,26] Normally, at the time of attachment of the medial head of the gastrocnemius, the deep popliteal artery has involuted, and the mature popliteal artery has already formed in its normal location. No case of compression of the popliteal artery on the lateral epicondyle has been observed, most likely because the lateral head attaches well before the popliteal artery forms. Clinically, compression of the artery against the femur by the medial head of the gastrocnemius can cause claudication and formation of a popliteal artery aneurysm. Popliteal entrapment syndrome tends to be diagnosed in patients at an early age.

DEVELOPMENT OF THE VENOUS SYSTEM

Within 4 weeks of gestation, a cluster of capillary networks begins to enlarge and develop into the definitive veins of the embryo.[1] Greater anatomic variation is possible within the venous system because there are many multichanneled beginnings and a myriad of options for the venous channels to develop and

flow. At 4 weeks, three paired venous systems form. The vitelline veins drain the yolk sac, the umbilical veins return oxygenated blood from the placenta, and the cardinal veins return blood to the embryonic heart (Fig. 2.13).

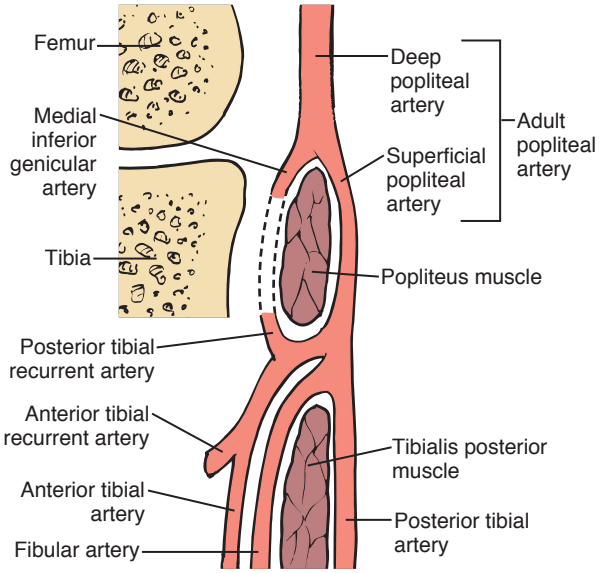

Figure 2.11 Embryologic development of the popliteal artery. The deep popliteal artery anterior to the popliteus muscle regresses, and the superficial popliteal artery posterior to the popliteus muscle becomes the mature popliteal artery. (From Gibson MHL, Mills JG, Johnson GE, et al. Popliteal entrapment syndrome. *Ann Surg*. 1977;185:341; modified from Senior HD. The development of the arteries of the human lower extremity. *Am J Anat*. 1919;25:55.)

The right and left vitelline veins drain blood from the yolk sac and the developing gastrointestinal tract. Before the vitelline vein enters the sinus venosus (the venous end of the heart), it forms a venous plexus in the developing liver, resulting in the formation of the liver's hepatic sinusoids (Fig. 2.14).[1] The left vitelline vein regresses, resulting in blood being shunted to the enlarged right vitelline vein as it passes through the developing liver. The enlarged right vitelline vein in the liver becomes the

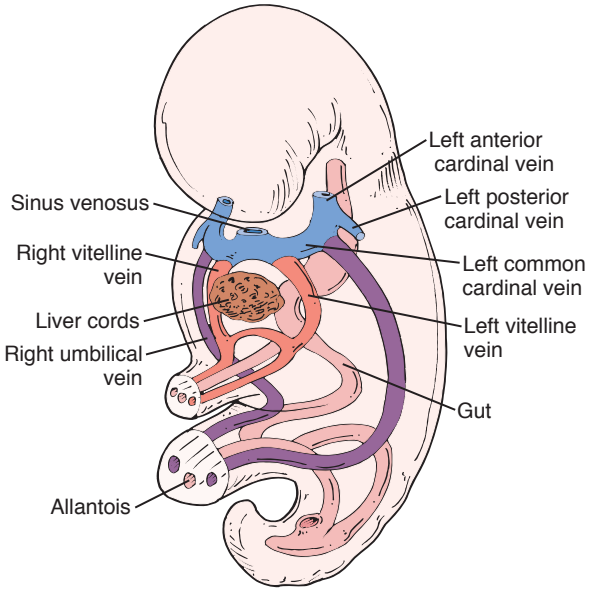

Figure 2.13 Venous system of a 4-week-old embryo.

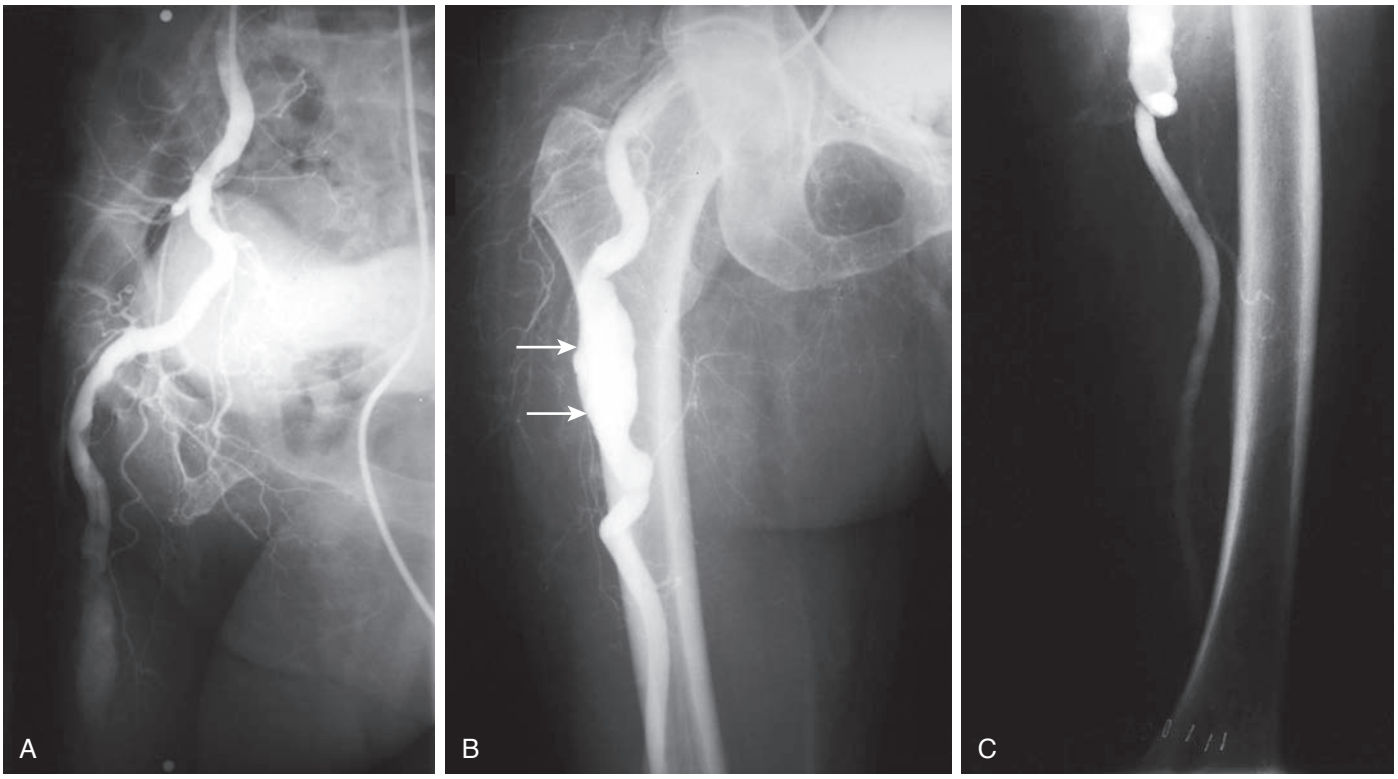

Figure 2.12 Persistent sciatic artery. **(A)** The sciatic artery in the pelvis is coursing posteriorly. **(B)** In the thigh, the sciatic artery has developed aneurysmal changes *(arrows)* and courses lateral to the normal location of the femoral artery. **(C)** More distally in the thigh, the sciatic artery is located laterally and ultimately joins the popliteal artery in the popliteal fossa (not seen on the radiograph).

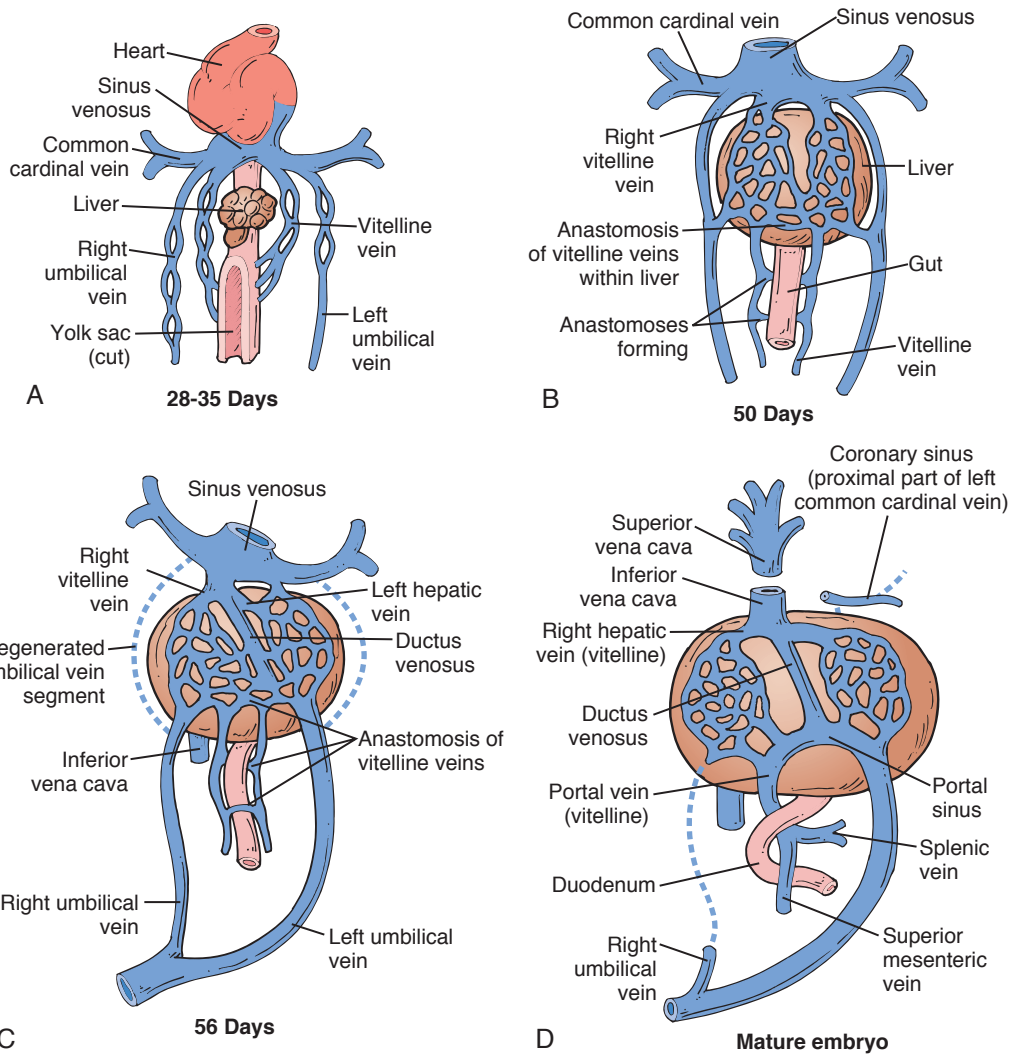

Figure 2.14 **(A-D)** Development of the umbilical and hepatic portal veins and the intrahepatic circulation.

ductus venosus, and the cranial portion develops into the inferior vena cava between the liver and heart. The portion of the right vitelline vein caudad to the liver becomes the portal vein and superior mesenteric vein. Left-to-right vitelline anastomoses remodel to form the splenic and inferior mesenteric veins, bringing blood from the foregut and hindgut, respectively, to the distal end of the portal vein.

The umbilical veins bring oxygenated blood from the placenta to the heart. Initially the umbilical veins are paired, but as the fetus develops, the right umbilical vein regresses, while the left persists. The left umbilical vein forms a direct anastomosis with the ductus venosus, which bypasses oxygenated blood from the placenta around the liver's sinusoids to directly enter the inferior vena cava. After birth, the ductus venosus atrophies and becomes the ligamentum venosum, whereas the left umbilical vein also atrophies to become the ligamentum teres (hepatis) contained within the falciform ligament.

The paired cardinal veins provide the blueprint for development of the intraembryonic venous system. The anterior cardinal veins, located cranial to the heart, join the posterior cardinal veins, located caudal to the heart, to form the paired short common cardinal veins, which drain blood into the right and left horns of the heart's sinus venosus. The paired anterior cardinal veins will eventually become the superior vena cava and its major tributaries; the posterior cardinal veins, subcardinal veins, and supracardinal veins contribute to formation of the inferior vena cava, its tributaries, and the azygos system.[1]

Superior Vena Cava

The cranial portions of the paired anterior cardinal veins become the internal jugular veins and connect with the external jugular veins, which develop from venous plexuses of the face.[1] The subclavian veins are formed from venous plexuses of the upper limb bud and empty into the proximal anterior cardinal veins. At the seventh week of gestation, an anastomosis develops obliquely between the left and right anterior cardinal veins. This anastomosis becomes the left brachiocephalic vein in the adult. The portion of the left anterior cardinal vein caudal to the developing left brachiocephalic vein and the left posterior

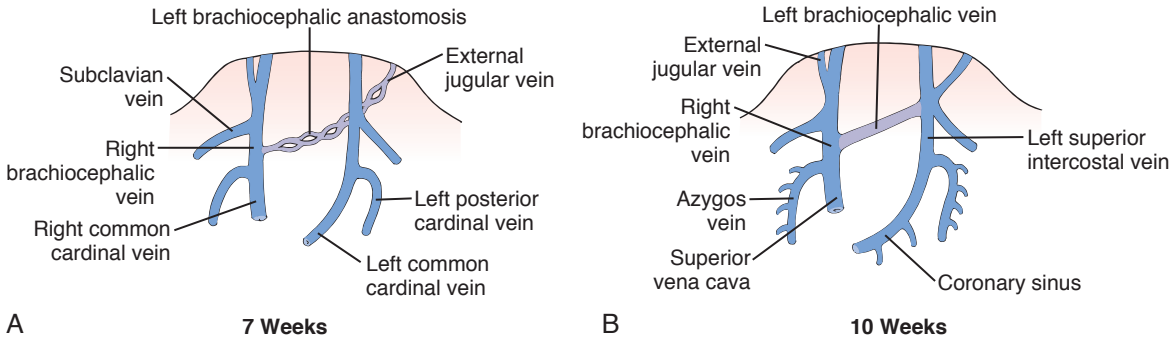

Figure 2.15 **(A)** Development of the superior vena cava and its major branches. **(B)** Completed development of the superior vena cava and its major branches.

cardinal vein regresses, directing blood from the left side of the head and neck to enter the heart through the left brachiocephalic vein to the superior vena cava. The superior vena cava, which develops from the junction of the left and right brachiocephalic veins and then enters the right atrium, is an enlargement of the right anterior cardinal and right common cardinal veins. The left common cardinal vein becomes the coronary sinus (Fig. 2.15).

Inferior Vena Cava and Associated Vessels

The inferior vena cava, common iliac veins, renal veins, and gonadal veins develop from a series of veins that have multiple anastomoses with one another and eventually coalesce to shunt the blood from the left to the right side of the embryo.[1] The inferior vena cava develops from four different embryonic vessels. The most rostral part (first part) of the inferior vena cava is formed from the enlargement of the right vitelline vein in the liver. The remainder of the inferior vena cava arises from parts of three parallel, but different, sets of veins that appear sequentially between the sixth and tenth weeks of gestation (Fig. 2.16A and B). The veins go through various changes, but eventually parts of each set coalesce to form the inferior vena cava and other veins of this region. The paired posterior cardinal veins appear first and are located on the posterior aspect of the fetus but eventually regress, with the exception of (1) the most distal portion of each, which fuse with one another to become the future most caudal portion (fourth part) of the inferior vena cava and the common iliac veins; and (2) the most proximal part that connects directly to the two horns of the sinus venosus and persists as the root of the azygos vein. The next pair of veins, the subcardinal veins, arise from the posterior cardinal veins before the latter regresses. They are located anterior and medial to the posterior cardinal veins and drain the mesonephric kidneys. The subcardinal veins anastomose with one another at the level of the metanephric kidneys. The right subcardinal vein enlarges and becomes the renal portion of the inferior vena cava (second part), whereas the left subcardinal vein forms an anastomosis with the right subcardinal vein at the level of the kidneys to form the left renal vein. This anastomosis has both anterior and posterior components that surround the aorta. The posterior vein regresses, whereas the anterior vein persists to become the left renal vein (see Fig. 2.16C and D). The left subcardinal vein rostral to the subcardinal anastomosis regresses, whereas the caudal portion remains as the left gonadal vein. The right renal vein and right gonadal vein sprout from the renal segment of the right subcardinal vein. The last pair of veins to appear, the supracardinal veins, also sprout from the posterior cardinal veins. They become the primary veins that drain the body wall. The thoracic and abdominal portions of the supracardinal veins have different fates. In the abdomen, the right supracardinal vein anastomoses with the right subcardinal portion of the inferior vena cava, thus becoming the infrarenal portion of the inferior vena cava (third part). At its caudal end, it will anastomose with the fused left and right posterior cardinal veins (fourth part of the inferior vena cava). The left abdominal supracardinal vein regresses. The thoracic portion of the supracardinal veins drains the posterior wall by a series of intercostal veins. They drain into the left and right horns of the sinus venosus by way of the rostral remnants of the posterior cardinal veins. Eventually the left supracardinal vein loses its communication with the left horn of the sinus venosus and instead anastomoses with the right supracardinal vein before its entrance into the right horn of the sinus venosus. The right supracardinal vein becomes the azygos vein, whereas the left supracardinal vein becomes the hemiazygos vein.

Anomalies

Superior Vena Cava

Two anomalies that can occur from development of the superior vena cava are described: double superior vena cava and left-sided superior vena cava. Neither anomaly is clinically important, except that they produce unusual shadows on chest radiographs. A double superior vena cava develops when the caudal section of the left anterior cardinal vein fails to regress.[27] This anomaly may occur with or without development of the brachiocephalic vein. A left-sided superior vena cava occurs if the caudal section of the right anterior cardinal vein regresses, but the caudal section of the left anterior cardinal vein remains open—the opposite of normal development.[28] A brachiocephalic vein forms, but in this anomaly, it connects the right anterior cardinal vein to the left anterior cardinal vein, becoming a left-sided superior vena cava (Fig. 2.17).

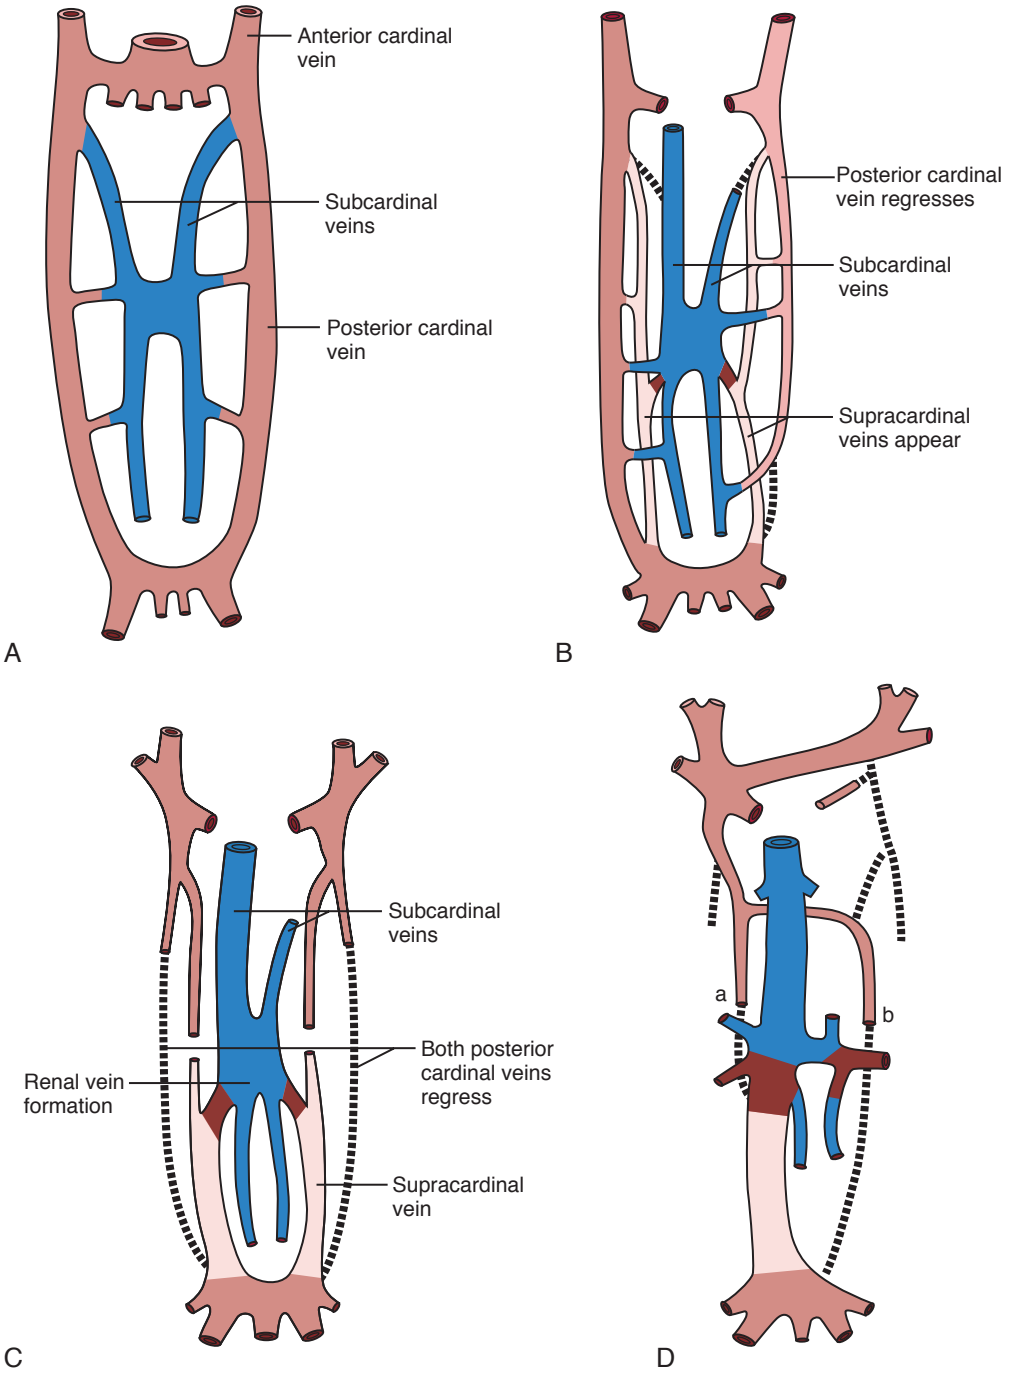

Figure 2.16 Development of the inferior vena cava. **(A)** At 6 weeks of gestation, the posterior cardinal veins are dominant and the subcardinal system is beginning to appear. **(B)** At 7 weeks of gestation, the subcardinal veins are dominant and the supracardinal system begins to appear. The posterior cardinal veins are beginning to regress. **(C)** At 8 weeks of gestation, the subcardinal veins form the suprarenal inferior vena cava. The supracardinal veins form the infrarenal inferior vena cava. The posterior cardinal veins regress. **(D)** The adult inferior vena cava. Portions of the posterior cardinal veins persist to form the azygos system *(a)* and the hemiazygos system *(b)*. (From Giordano JM, Trout HH, III. Anomalies of the inferior vena cava. *J Vasc Surg*. 1986;3:924–928.)

Inferior Vena Cava Duplication/Left-Sided Inferior Vena Cava

Duplication occurs if the left supracardinal vein fails to regress. If both supracardinal veins persist and join at the level of the renal arteries, a double inferior vena cava is observed. If the left supracardinal vein persists and the right supracardinal vein regresses (the opposite of normal), a left-sided inferior vena cava is seen. In this anomaly, the vein crosses to the right side at the level of the renal arteries and is a mirror image of normal anatomy. In the case of a left-sided inferior vena cava, the right adrenal and gonadal veins, instead of emptying into the inferior

Figure 2.17 Duplicated superior vena cava. Note the right-sided central venous catheter *(arrow)* entering the right atrium, indicative of the presence of a right-sided vena cava in addition to a left-sided vena cava.

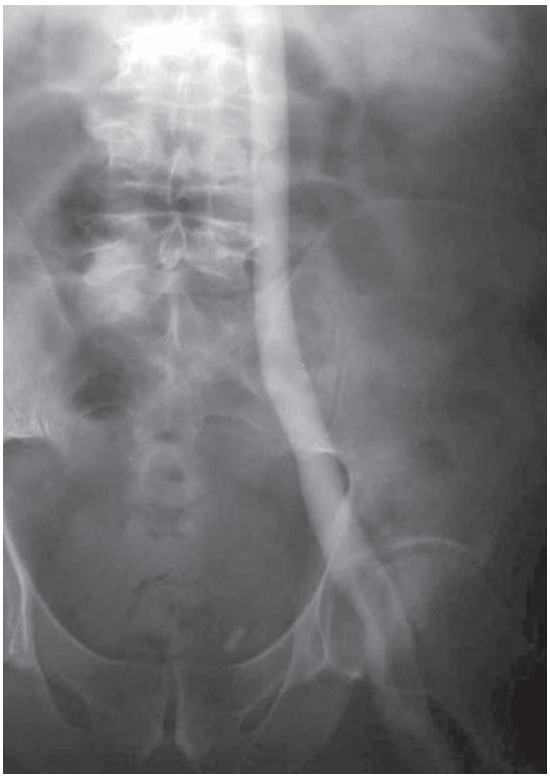

Figure 2.18 Left-sided inferior vena cava. The left-sided vena cava crosses over the midline at the level of the renal vein.

vena cava as normal, empty into the right renal vein; likewise, the left adrenal and gonadal veins empty into the inferior vena cava instead of the left renal vein. Recognition of a duplicated inferior vena cava or a left-sided vena cava is important when placing an inferior vena caval filter (Fig. 2.18).[29-35]

Renal Vein Anomalies

The most common venous anomaly is persistence of the posterior component of the left renal vein. This results in either a retro-aortic left renal vein if the anterior component regresses (the opposite of normal) or a left circum-aortic renal vein if both anterior and posterior renal veins persist. In cases of circum-aortic renal veins, both veins join before entering the inferior vena cava, resulting in a venous collar around the aorta. Awareness of a retro-aortic renal vein is important during dissection of the aorta at the level of the renal arteries to avoid injuring the vein (Fig. 2.19).[29-35]

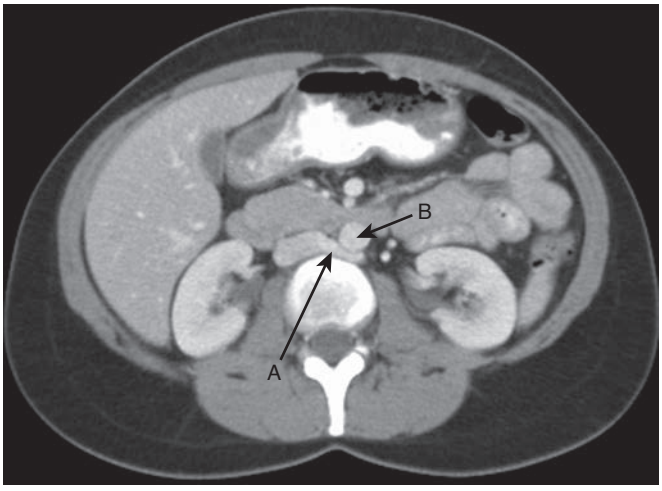

Figure 2.19 Retroaortic left renal vein. The left renal vein *(A)* can clearly be seen coursing posterior to the aorta *(B)*.

Development of the Lymphatic System

The Italian anatomist, Gasparo Asellius, first described the lymphatic system as a network of milky veins surrounding the intestines of a recently fed dog. The lymphatic system is important not only for the absorption of lipids from the intestines but also for the removal of interstitial fluids, and serves as a pathway for lymphatic cells involved in the immune response. Until recently, the mechanism responsible for the development of the lymphatic system was unclear. During the early twentieth century two hypotheses were proposed for its development: first, the "centrifugal theory," which proposed that in very specific regions, the lymphatic system budded from the developing venous system to form discrete lymph sacs; and second, the "local origin theory," which proposed that the lymphatic system developed de novo from embryonic mesoderm adjacent to the developing venous system.[35,36] Recent evidence supports the hypothesis that the lymphatic system buds from the developing venous system, as opposed to the concept that it develops from a mesodermal origin.

Development of the lymphatic system (Fig. 2.20) begins as six lymph sacs, two paired and two unpaired, that begin

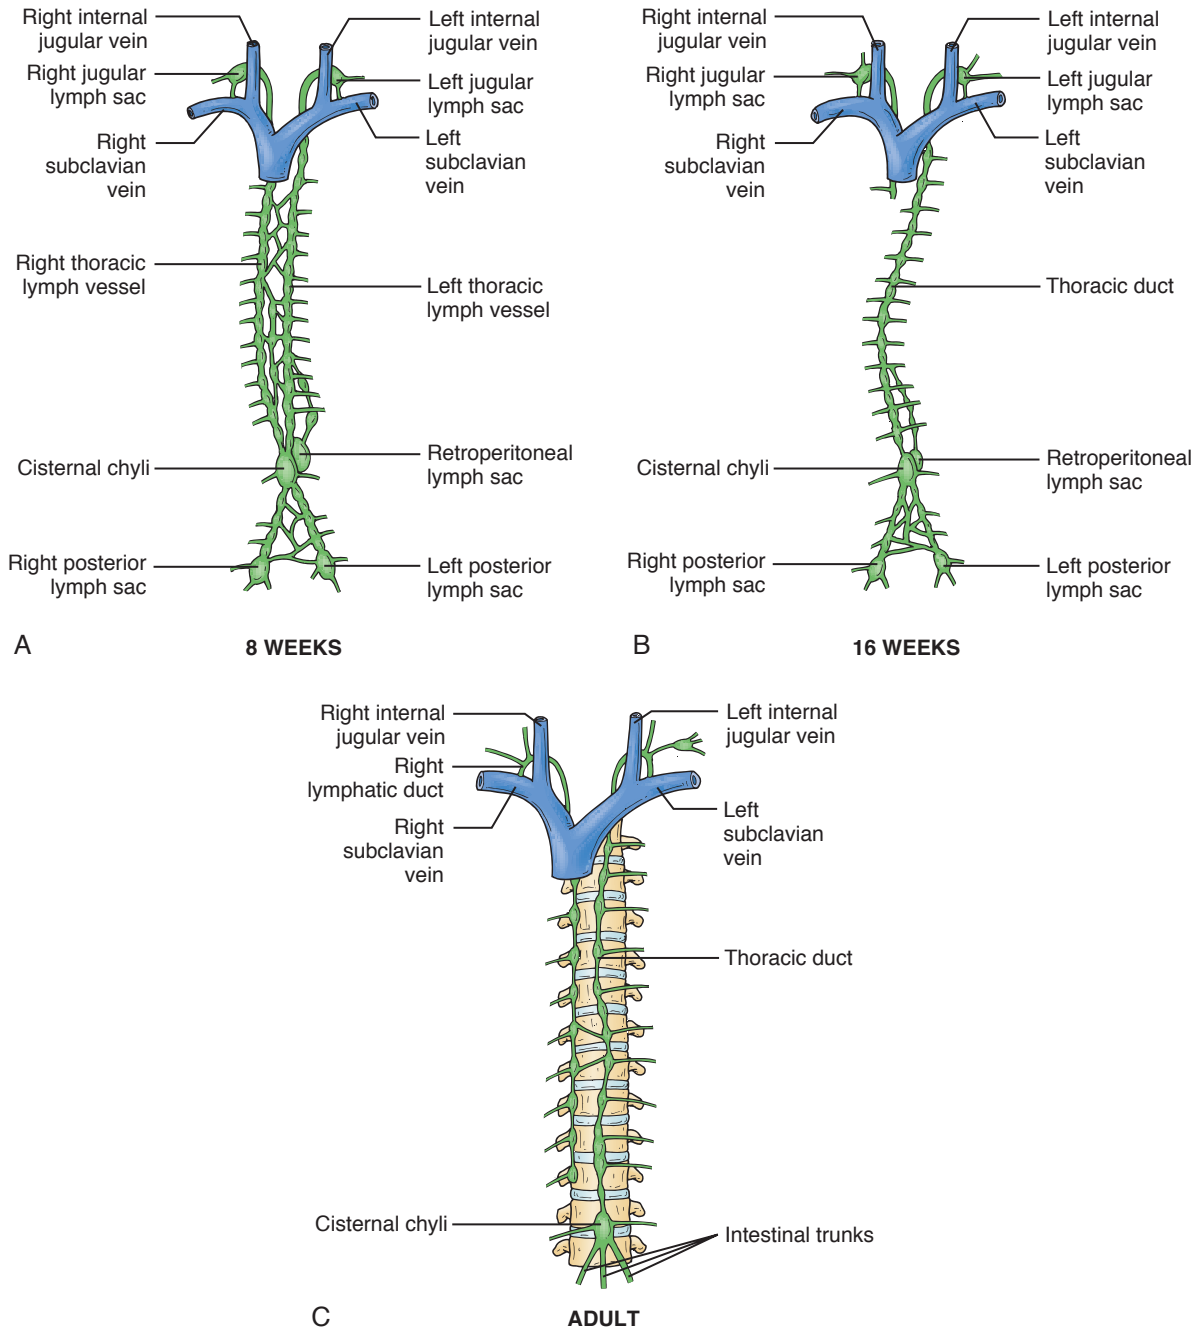

Figure 2.20 Development of the lymphatic system. **(A)** By 8 weeks, lymphatic vessels are established as outgrowths of the six lymph sacs that budded off of the vascular system. At this point in time the embryo has a pair of thoracic lymph vessels that connect the cisterna chyli to the venous system superiorly. **(B)** By 16 weeks, portions of the right and left thoracic lymph vessels have been remodeled to form a single thoracic duct. **(C)** By the adult stage, all the embryonic lymphatic sacs have regressed with the exception of the cisterna chyli. The definitive thoracic duct and right lymphatic duct are present.

to develop in a cranial to caudal sequence. These lymph sacs begin to appear in the fifth week and are complete by the end of the sixth week in the human embryo.[37] First to appear are a pair of jugular lymph sacs that bud off from the anterior cardinal veins (at the junction of the presumptive subclavian veins and internal jugular veins), whereas a second pair, the posterior lymph sacs, bud from the caudal segment of the posterior cardinal veins (at the junction of the internal and external iliac veins). The posterior lymph sacs appear late in the sixth week of development. The remaining lymph sacs, the retroperitoneal lymph sac and cisterna chyli, are unpaired and appear between the end of the fifth week and beginning of the sixth week. The retroperitoneal lymph sac develops from the part of the mesonephric venous system near the developing suprarenal gland, whereas the cisterna chyli buds from veins at lumbar levels 3 to 4.

Additional lymphatic vessels sprout from these six initial lymph sacs and follow the course of the developing veins.

Extensions of the two jugular sacs extend caudally to meet with rostral extensions of the cisterna chyli, forming a pair of thoracic lymph vessels that empty into the venous system at the internal jugular and subclavian junction on both the left and right sides. Later in development, these two thoracic vessels fuse at midthoracic levels, whereas the caudal portion of the left thoracic vessel and thoracic portion of the right are lost, leaving a right to left directed definitive thoracic duct, formed from the caudal part of the right thoracic duct and rostral part of the left thoracic duct. The right jugular sac remains connected to the venous system and will eventually form the right lymphatic duct. Additional lymphatic vessels bud from existing lymphatic vessels to form deep lymphatic vessels. Superficial lymphatic vessels develop as sprouts from these deep lymph vessels. Lymphatic vessels and nodes do not invade the central nervous system, meninges, eye, internal ear, cartilage, epidermis, or spleen. All the lymph sacs except the rostral part of the cisterna chyli develop connective tissue bridges and are seeded with lymphatic cells, which, in turn, form lymph nodes. The lymphatic connections to the venous system are lost, with the exceptions of the final connections of the right lymphatic duct and thoracic duct.

The previous sections have addressed the development of the arterial, venous, and lymphatic systems in isolation. However, it should be apparent that these systems develop simultaneously and likely interact with each other. As the initial fine capillary network forms (the retiform plexus stage), errors in morphogenesis can result in various vascular malformations. For example, persistence of capillary networks could explain the development of port-wine stains. Alternatively, failure of regression of arteriovenous communications could result in the development of arteriovenous malformations. Such malformations would have a greater venous component with persistence of the venous morphology, whereas the opposite would be true with persistence of the arterial morphology. Failure of the main vascular trunks to develop in the later phases of development can give rise to conditions in which there may be hypoplasia or aplasia of these vessels, as can be seen in Klippel-Trenaunay syndrome. Likewise, abnormal lymphatic system development can be manifested concurrently or separately as the venous and arterial systems develop. Failure of normal lymphatic development can lead to aplasia and hypoplasia that appears clinically as lymphedema.

Complex organisms rely on the fluid, nutrient, and waste transport capabilities of the cardiovascular system whose subdivisions each have unique structure and biology to perform crucial metabolic and mechanical functions. The arterial network reacts to hemodynamic forces through constriction or dilation and also via activation of signaling pathways. Its venous counterpart is an adaptable system with unique mechanisms for accommodating the hemodynamic stresses of the body. The lymphatic system is a distinct but closely related network that augments fluid transport and immunologic functions (Table 3.1).

ARTERIAL WALL ANATOMY

The arterial wall exhibits a common organizational structure throughout the body, although proportions of components fluctuate through different regions. It consists of cells and matrix fibers arranged in three tunicae: intima, media, and adventitia (Fig. 3.1).

Intima

The intima, the innermost luminal layer, extends from the lumen to the internal elastic lamina (IEL). The intimal luminal surface is lined by the endothelium. The actual intimal layer is very narrow, consisting primarily of a few scattered leukocytes, smooth muscle cells (SMCs), and connective tissue fibers. The matrix fibers consist mainly of elastic and collagen fibers and proteoglycans.

Endothelium

The vascular endothelium is a continuous layer of flat polygonal endothelial cells (ECs) in direct contact with blood flow. The

Abstract

The circulatory system of the human body is composed of three main subdivisions: arterial, venous, and lymphatic. The vessel wall in and throughout each of these subdivisions has varying compositions directly related to and responding to their hemodynamic environment. This chapter describes the biologic structure of the vessel wall in these subdivisions and how this biology relates to each subdivision's function.

TABLE 3.1 Vessel Wall Characteristics of Circulatory Systems

	Arterial Wall	Venous Wall	Lymphatic Wall
Collagen content	Moderate	High	Mixed
Elastic fiber content	High	Moderate	Mixed
Central pressure	High	Very low	Low
Shear stress	High	Low	Low
Stretch force	High	Low	Low
Pulsatility	High	Low	Low
Compliance	Moderate	High	High
Oxygen tension	High	Low	Low
Intrinsic propulsion	None	None	Predominant
Valves	None	Some	Many

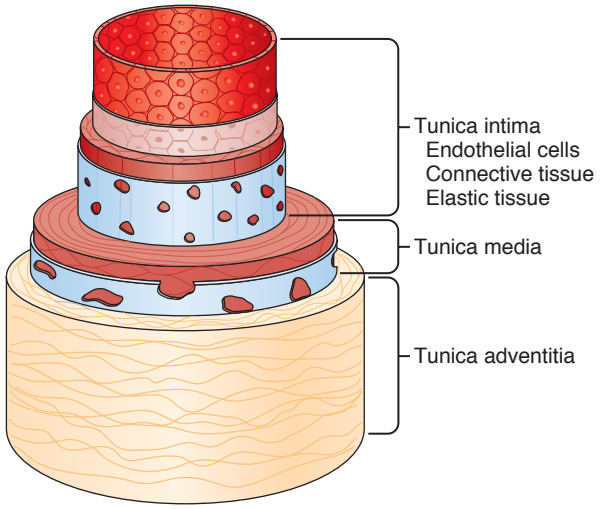

Figure 3.1 Anatomy of the Vessel Wall. Arteries and veins maintain the same basic structure, which consists of the tunica adventitia, tunica media, and tunica intima, although capillaries consist of no more than endothelium, connective tissue, and support cells called pericytes. (Redrawn from Hast J. *Self-mixing interferometry and its applications in noninvasive pulse detection* [dissertation]. Finland, University of Oulu; 2003.)

endothelium participates in both physiologic and pathologic processes and reacts to physical forces, chemical signaling, and immunologic mediators.[1] The endothelium interacts with its cellular and acellular environments and is an important regulator of vasomotor tone, hemostatic balance, permeability, cell proliferation, survival, and immunity.[2]

The endothelium provides a continuous lining throughout the arteries, capillaries, veins, heart valves, and endocardial surfaces. Cell thickness varies from less than 0.1 µm in the capillaries and veins to 1 µm in the aorta.[2] The luminal surface of ECs is smooth and regular.[3] The cells are covered by a glycocalix responsible for the antithrombogenic properties of the endothelial surface.[4] The glycocalix reduces friction from blood flow and serves as a barrier for fluid loss through the vessel wall. Its thickness varies across the vascular tree.[5] During inflammation, the glycocalix is sheared off, permitting the attachment of leukocytes and the transport of water from microvessels, and possibly initiating the development of atherosclerotic lesions.[6]

ECs, which are typically aligned in the direction of blood flow, tend to overlap immediately adjacent cells. The nature of the cell bonding is relevant to both the mechanical strength and the permeability of the endothelial layer. Membranes of adjacent cells are mainly parallel and separated by an intercellular space of 15 to 20 nm in size.[4] Sites of firmer attachment include tight junctions (zona occludens) and adherens junctions (zona adherens). Tight junctions form a barrier to transport between ECs and help maintain polarity between the luminal and abluminal sides of the cells. At these sites, opposing cell membranes form a continuous band around the side of the cells, forming a zona occludens. This tight seal prevents the passage of molecules between the lumen and cell base. Large artery ECs have a well-developed system of tight junctions due to high rates of pulsatile blood flow, whereas junctions become progressively looser as the system transitions to arterioles, capillaries, and venules. Postcapillary venules possess a less dense system of tight junctions to mediate the inflammation-induced extravasation of leukocytes and plasma constituents. In contrast, the blood-brain barrier, protecting neural tissue from fluctuations in blood composition, has rigid tight junctions.[2] Adherens junctions are less common and exist primarily in large arteries. Their primary role is to permit inter–EC communication via movement of ions, metabolites, and regulatory factors.[4]

The ECs contain pinocytic vesicles, which regulate the permeability of the endothelial layer. The pinocytic vesicles are responsible for the movement of material from the lumen of the vessel into its wall. The vesicles exist primarily in muscular small blood vessels and are found in large numbers in the heart and lung and to a lesser extent in the retina and the brain.[7]

The endothelium may be nonfenestrated continuous, fenestrated continuous, or discontinuous (Fig. 3.2).

Nonfenestrated Continuous

Nonfenestrated continuous endothelium functions as a selective filter, and exists in the arteries, veins, and capillaries of the brain, skin, heart, and lung. Highly selective microcirculations, such as the brain, with its tight blood-brain barrier, and luminal and abluminal plasma membranes fused only at the tight junctions, dictate the vascular permeability.[8]

Fenestrated Continuous

Fenestrated endothelium occurs in locations of increased filtration or transendothelial transport, including the capillaries of exocrine and endocrine glands, gastric and intestinal mucosa, choroid plexus, glomeruli, and renal tubules. Fenestrae are transcellular pores approximately 50 to 70 nm in diameter that extend through the entire endothelial layer.[2] The majority of fenestrae have a 5- to 6-nm nonmembranous diaphragm across their openings, although fenestral density varies in differing vascular beds and increases with greater need to absorb or secrete.[9-11] Cultivation of ECs on an extracellular matrix (ECM) derived

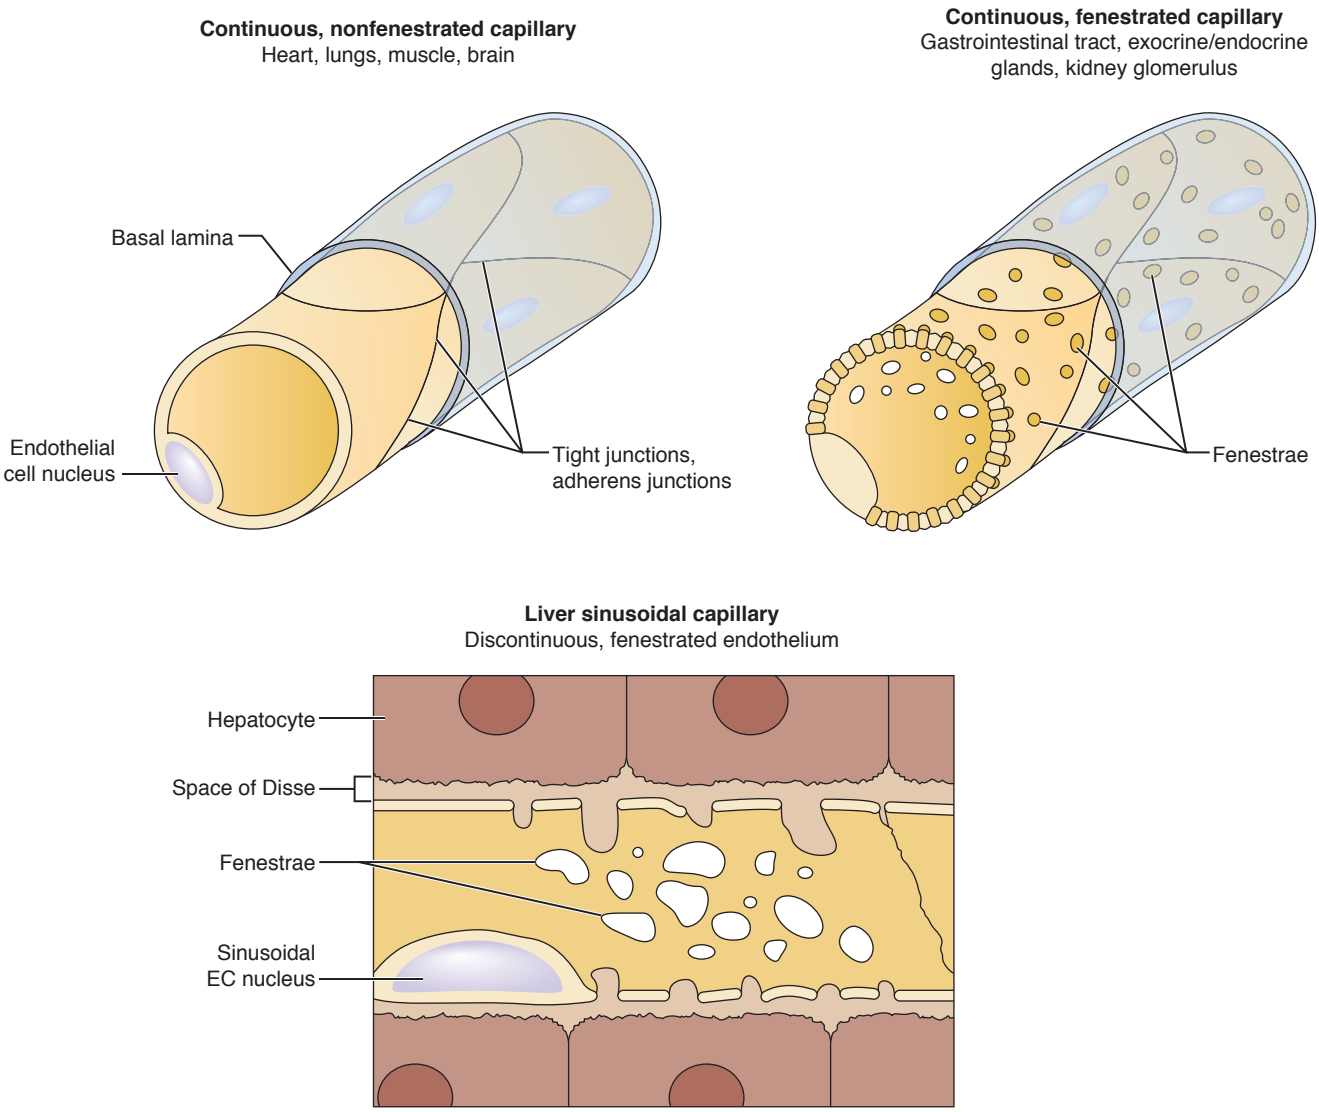

Figure 3.2 Nonfenestrated continuous, fenestrated continuous, and discontinuous capillary endothelium. These configurations affect the vascular permeability of the capillary bed with highly selective circulations such as the blood-brain barrier having continuous nonfenestrated capillary endothelium, and high fluid and macromolecule exchange circulations such as the liver having discontinuous capillary endothelium. (Redrawn from Kanasty RL, Whitehead KA, Vegas AJ, Anderson DG. Action and reaction: the biological response to siRNA and its delivery vehicles. *Mol Ther.* 2012;20(3):513-524.)

from renal epithelium results in diaphragmed fenestrations,[12] which allow the filtered reabsorption of ultrafiltrate from the tubular system.

Discontinuous

Discontinuous endothelium possesses larger fenestrations, ranging from 100 to 200 nm in diameter. These fenestrations lack a diaphragm and contain gaps or pores within individual cells.[13] Large intercellular and intracellular gaps with an incomplete basal lamina may be up to 0.1 to 1 μm in diameter and may also undergo dynamic changes.[8] Such capillaries form large irregularly shaped vessels, such as the sinusoids of sinusoid capillaries. In hepatic sinusoids, endothelial gaps are clustered in sieve plates to control the exchange of fluids, solutes, and macromolecules between the sinusoid and space of Disse.

Basal Lamina

The basal lamina, which borders the ECs on their abluminal surfaces, forms a generally continuous boundary between the endothelium and the immediately underlying intimal structure. It is involved in the regeneration and attachment of the endothelial layer, blood vessel permeability, initiation of blood clotting, and provides a barrier to cellular migration.[14] It connects the EC compartment to subjacent cell layers and SMCs.[15]

The basal lamina consists of two zones: a clear inner zone (lamina rara) and a dense fibrillar zone (lamina densa) adjacent to the interstitial connective tissue.[1] The clearer inner layer contains the glycoprotein laminin, whereas the dense layer is composed of type IV collagen. The basal lamina provides a pliable extensive bond, which permits ECs to comply with

changes in configuration related to cardiac pulsation and to vessel torsion and flexion.[4,16] Furthermore, discrete adhesion points of increased electron density have been observed between basal peripheral cytoplasmic dense bodies of ECs and the IEL, which prevent slippage of the lining cells when shear stress increases.[16]

The basal lamina is formed by glycoproteins; adhesion molecules, such as laminin, fibronectins, entactin, and thrombospondin; various proteoglycans, such as heparan sulfate, that can influence viscoelasticity, permeability, hemostasis, and thrombosis; and microfibrils of collagen types IV and V secreted by the endothelium.[14,17]

Mechanically, the basal lamina strengthens the vascular wall. Collagen type IV chains form a covalently stabilized framework and provide mechanical resistance. Laminin forms a second polymer network and connects ECs as well as heparan sulfate to the collagen.[15,18] Entactin binds laminin and collagen. Fibronectin transmits mechanical forces between integrin receptors on SMCs and the ECM to redistribute the mechanical load within the arterial wall.[19]

The monolayer of endothelium is normally quiescent with cell-cell contact inhibiting proliferation, resulting in a low mitotic index contributing to the stability and integrity of the vessel wall.[1] In this state, the ECs form cell-to-cell junctions, synthesize, and secrete ECM and basement membrane components, including fibronectins, laminin, proteoglycans, and collagen.

The underlying reticular layer of the endothelium is composed of collagen types I and III, which are produced by both ECs and SMCs and are the most abundant of all interstitial collagen. Evidence suggests that the ECM components influence cell phenotype in ECs and SMCs. In culture, EC phenotype is influenced by growth media, surface, and the age of the cultures. Further, cultures of these cells on various surfaces, including collagens, fibronectins, and reconstructed basement membranes, demonstrate different rates of production of gap junctions, actin, messenger RNA (mRNA), protein, cell proliferation, and membrane specialization.[20-22]

Internal Elastic Lamina

The IEL is a layer of elastic fibers 70 to 100 nm in thickness. Experimental evidence suggests that both abluminal SMCs and luminal ECs are collaboratively responsible for elastin formation and IEL synthesis.[23,24] The IEL separates the subendothelial intimal layer from the medial layer. Collagen- and proteoglycan-based fenestrations permit flow, driven by a pressure gradient, across the arterial wall tissues into the intimal layer.[4,25,26]

Elastin is organized into fenestrated cylindrical lamellae that are separated from neighboring lamellae by single layers of SMCs.[27] Lamellar units are determined prenatally, and postnatal changes in thickness or circumference of the media accompany parallel changes of the thickness and circumference of the elastic lamellae.[28,29]

The IEL and elastic lamellae in large arteries may function as barriers to macromolecular accumulation in the vascular wall. Structural defects within the IEL are directly implicated in the onset of intimal thickening in human arteries.[25] Fragmentation of the IEL and disruption of medial layers is common in advanced plaques in apolipoprotein E knockout mice.[30] Defective IEL may result in abnormal attachment with ECs, causing gaps in the endothelial surface facilitating the entry of macromolecules, lipids, and leukocytes into the intima.[25,31,32]

Although macromolecules are believed to cross the normal arterial EC layer through vesicular transport, macromolecules are believed to cross the IEL via diffusion through the fenestrations. The diffusion rate is inversely dependent on its size. Therefore, as the size of the macromolecule increases, the resistance of the endothelium does not change, but IEL resistance strengthens.[33] Owing to this difference in transfer rate, the IEL most likely plays a significant role in regulating macromolecular accumulation in the intima, restricting plasma-borne macromolecules from entering the media, and regulating discrete microenvironments between the intima and the media.[33]

Media

The tunica media extends from the IEL to the adventitia. The medial layer is a porous heterogeneous medium consisting of an ECM phase with embedded SMCs. Under normal conditions, SMCs in the tissue matrix beneath the IEL are shielded from the direct shear forces of flowing blood. At low and physiologic pressures, the media is the chief determinant of arterial wall properties. Its composition and microarchitecture ensure arterial stability. Arterial media elasticity dictates arterial distensibility and the capacitive effects of larger arteries.[34] Its elasticity also affects the mechanical load-bearing of the arterial wall. The metabolic state of the media also plays an important role in the pathogenesis of atherosclerotic lesions.

The media consists of vascular SMCs, elastin, and collagen fibers arranged in a highly organized fashion.[35] Closely packed layers of SMCs associated with elastin and collagen fibers distinguish the outer layer of the media in all intact arteries. The SMCs are surrounded by a basement membrane composed mainly of laminin, collagen IV, heparan sulfate proteoglycan, entactin/nidogen, and fibronectins, which prevent the proliferation and migration of the SMCs. This arrangement maintains the SMCs in a contractile state as opposed to the synthetic state.[36] In the contractile state in normal arterial vessels, SMCs are differentiated and contain abundant contractile and intermediate filament proteins. In certain physiologic and pathologic conditions, the SMCs abandon the contractile phenotype for an immature synthetic phenotype. This change permits migration into the intima, proliferation, and secretion of ECM components.[37]

The SMC layers consist of groups of similarly oriented cells, each surrounded by a common basal lamina in a closely associated interlacing basketwork of type III collagen fibrils. The fibrils are arranged to tighten around the cell groups as the media is brought under tension. This configuration holds the groups of cells together and prevents excessive stretching or slippage. At low and physiologic pressures, collagen fibers are slack and not substantially load-bearing.[35] The thickness and abundance of collagen bundles depends largely on vessel diameter with the

average tangential tension per medial layer approximately 2000 dynes/cm, regardless of species.[38]

Arteries are classified as either elastic or muscular according to the proportion of cellular and fibrous components.[39] In elastic arteries, well-defined elastic lamellae and collagen bundles are prominent in the media, whereas connective tissue fibers are less frequent. The prominent elastic arteries are those with large diameters and in close proximity to the heart—the aorta, the brachiocephalic trunk, and the iliac arteries. Elastic arteries consist of lamellar units, which are close associations of elastin, collagen, and SMCs. Between the lamellae, SMCs, collagen fibers, elastin microfibrils, and glycosaminoglycans are organized into functional units. Although the number of lamellar units depends on the arterial diameter, humans have from 40 to 60 units in the aorta, which are located approximately 12 to 17 μm in distance from the lumen of the artery. The number of lamellar units decreases from the heart to the peripheral arteries.[4]

Muscular arteries predominate in the second- or third-order branch arteries. The media consists primarily of SMCs with fewer connective tissue fibers. Nonparallel branching elastin strands increase the capacity to change diameter under neurohumoral stimulation.

Electron microscopy has illuminated a further structural breakdown of arterial microarchitecture in elastic and muscular arteries. The media is composed of groups of fascicles, which are jointly oriented, elongated SMCs within an encompassing network of branching elastic fibers.[35] Bundles of slack collagen fibers are interposed between the adjacent elastic fibers. Each fascicle is invested by a sheath of basal lamina and collagen fibrils oriented in the same direction as the fascicle cells.[4] Each fascicle is oriented in the direction of imposed tensile stress.[34] In straight segments of aortas and arteries, fascicles are uniform in size and oriented primarily circumferentially. At bends and branching points, fascicles are smaller and less uniform in size and orientation.[38]

Adventitia

The adventitia extends from the external elastic lamina to an ill-defined boundary usually contiguous with the perivascular connective tissue. The adventitia varies in thickness and organization. Whereas the aorta has minimal adventitial fibrous connective tissue, large muscular arteries contain prominent adventitial elastic and collagen fibers. Here, adventitia may be more prominent than media. Generally, adventitial cells are sparse and consist mainly of fibroblasts.

The adventitia contains vasa vasorum and nerves, which provide nutrition to the adventitia and media and contribute to the regulation of the medial smooth muscle function. The vasomotor nerve fibers induce vasoconstriction or vasodilation via adrenergic receptors. Nervous stimuli are transmitted to the outer SMCs through neuromuscular junctions. The signal is transmitted to the inner cells by electrical coupling between adjacent SMCs.

Vasa vasorum are present in arteries with diameters larger than 200 μm. Also, when the medial layer has more than 29 lamellar units, the outer part of the media is irrigated by the vasa vasorum. Nutrients may also be provided from the luminal blood flow for the inner part of the media. The vasa vasorum are composed of small arteries, arterioles, capillaries, and venous channels, as well as nerves that mediate smooth muscle tone. Vasa vasorum arise from the parent artery at branch junctions and arborize in the adventitia. In thick-walled arteries, mural stresses and deformations may affect the vasa vasorum. Hypertension may impair vasa flow. A lymphatic network in the adventitia collects the proteins, ions, and water from the blood and transports these substances through the vessel wall.

ARTERIAL WALL SYSTEM

Large Arteries

The arterial system commences with the aorta and its branches whose primary function is to provide a conduit for blood flow to the peripheral tissues and to smooth out the pulsations of intermittent ventricular ejection. The large arteries cushion the pulsations during ventricular ejection. This cushioning function is characterized by the relationships between oscillatory pressure, flow, and frequency, which in turn depend on arterial diameter and elasticity.[4]

The aorta is the main trunk of the vascular system, originating at the upper section of the left ventricle. It arches backward over the root of the left lung and descends within the thorax on the left side of the spine. It then flows into the abdominal cavity through the aortic hiatus in the diaphragm and ends opposite the lower border of the fourth lumbar vertebra. At this point, it is decreased to 1.75-cm in size and divides into the right and left common iliac arteries.

Medial cells in the aorta are organized into groups of overlapping elongated cells, bracketed by elastic fibers. Successive layers of cells and surrounding elastic fibers are separated from one another by a narrower, intervening acellular zone containing thick, crimped bundles of collagen.

Because of their significant size, the aorta and the large arteries offer little resistance to blood flow. Large arteries store a large portion of the blood volume during systole and drain it during diastole. They are able to accommodate the stroke volume ejected with each contraction of the heart. This ability allows for propagation of the pulse and also offers dynamic resistance to the oscillatory components of pulsatile flow.

Blood pressure is the highest at the origin of systemic circulation, although decreases in blood pressure are not linear with vessel diameter or distance down the vascular tree.[4] Blood pressure decreases to 30% to 40% of aortic pressure in vessels 250 to 50 μm in diameter. Significant pressure drop occurs in the terminal arterioles, which branch into small capillaries with diameters less than 100 μm (Fig. 3.3). In vessels smaller than 60 μm, no correlation has been found between central arterial pressure and microvascular pressure, suggesting that perfusion pressure is controlled directly in these blood vessels and those with smaller diameters.[40]

The larger arteries are predominantly under control of downstream resistance vessels, and there is little evidence that vasomotor changes in large arteries occur independently of

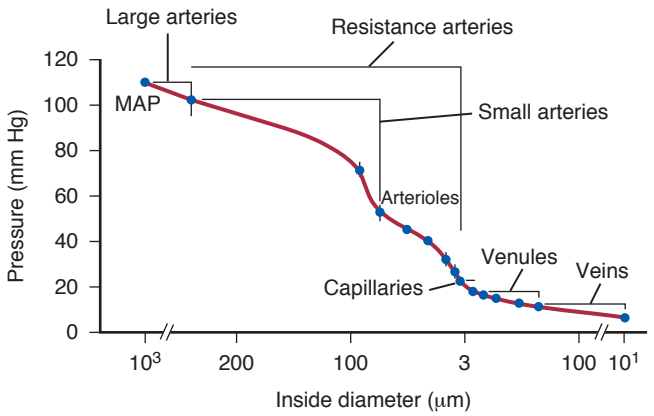

Figure 3.3 Pressure Drop Through Hamster Cheek Pouch Circulation. *MAP*, Mean arterial pressure, measured in the femoral artery. Bars indicate standard error. (Redrawn from Mulvany M, et al. Structure and function of small arteries. *Physiol Rev.* 1990;70:922-949.)

those in small resistive arteries.[41] Changes in caliber of large arteries occur passively through changes in transmural pressure and actively through changes in vascular SMC contraction. Arteriolar vasomotion may induce systemic or local blood pressure changes that alter the diameter of the artery and its viscoelastic properties. Arteriolar constriction or dilation may also modify arterial SMC tone through the endothelium-dependent mechanism of high-flow dilation.

Chemical stimulation may exert significant influence on arterial tone. Studies in isolated vessels, animals, and humans suggest that large arteries respond directly to both autonomic reflex and neurohumoral stimulation.[42] There are significant differences in the response to adrenoreceptor stimulation between large and small arteries. The aorta is poorly innervated in comparison with peripheral arteries. However, in conjunction with highly sensitive vascular SMCs and an excess of α_1-adrenoreceptors, larger arteries are sensitive to adrenergic stimulation.[43] Sympathetic control of vascular tone in large arteries is more sensitive to α-adrenergic blockade than that of smaller vessels.[44]

Small Arteries

Small arteries are the principal regulators of peripheral resistance with the ability to change diameter markedly in response to stimuli. The diameter of individual arteries in peripheral regions decreases, while the percentage of total blood volume increases, leading to a fall in blood pressure. The amount of elastic fibers in the tunica media decreases owing to these physiologic changes, in addition to having the lowest proportion of medial fibrous connective tissue. Initially, it was believed that resistance arteries consisted solely of arterioles with only one layer of SMCs and diameters of less than 30 to 50 μm. However, it has been shown that approximately 50% of precapillary resistance lies proximal to the arterioles and to vessels with diameters of 100 μm.[45]

Small arteries are considered muscular arteries. The tunica intima is thinner than in elastic arteries. ECs form a normal continuous layer; however, the subendothelial connective tissue, aside from a fenestrated IEL, is difficult to discern. The ECs of small arteries often project through fenestrations in the IEL and may come into contact with vascular SMCs in the tunica media.[46] The tunica media demonstrates numerous concentric layers of SMCs and few elastic fibers and collagen fibers. The external elastic lamina is clearly marked, though incomplete in various areas. The thickness of the adventitia in the arterial wall is variable, being small in cerebral small arteries and taking up approximately half of the wall in other regions. Nerves remain within the adventitia and do not penetrate the media.[47] The nerves, which are primarily adrenergic, consist of unmyelinated axons along which are interspersed varicosities. Axons remote from the adventitia-media border exist in bundles of up to 50. Closer to SMCs, axon bundles contain 1 to 11 axons. Although there are multiple junctions between axons and SMCs, the neuromuscular junctions in small arteries are less developed than in skeletal muscle.[45]

The number of SMC layers within the media of small arteries decreases relative to vessel diameter from approximately six layers in 300-μm vessels to a monolayer in 30- to 50-μm arterioles. The volume fraction of SMCs in the media of small arteries as seen by electron micrographs is from 70% to 85%, a fraction that is greater than in larger vessels.[45]

The resistance provided by a small artery is a function of the diameter-pressure relation. This compliance depends on the amount, arrangement, and characteristics of the connective tissues and SMCs and on the activation level of SMCs.[45]

Coronary Arteries

A special mention should be made of the coronary artery wall, given the prevalence and importance of coronary artery disease with regard to diagnosis and treatment in patients undergoing vascular surgery. The adventitia is thicker in proportion to other muscular arteries and includes a mix of collagen and elastic fibers, as well as adipose tissue. Collagen predominates in the adventitia compared with elastic fibers, in order to provide greater tensile strength and low stretch. Richly innervated SMCs in the media and adventitia are bundled longitudinally and circumferentially to respond to the repeated deforming forces caused by the contraction of the heart. Branching sites in the arteries also show normal, periodic thickenings of intima, termed musculoelastic cushions, that may contribute to atherosclerosis in these areas.[48]

Arterioles

Arterioles are the chief source of vascular resistance and control the distribution of flow. Abnormal constriction and dilation cause systemic hypertension and hypotension, respectively. The smooth muscle of arterioles, and small arteries to lesser extent, regulate tissue blood flow.

Small arteries and arterioles are controlled by both sympathetic and parasympathetic innervation. The response of small arteries and arterioles to neurohumoral activation under normal conditions largely depends on the type of stimulus and the arterial bed. Vasomotor responses depend on arteriolar territory, as in the case of emotional stress. Emotional stress dilates arterioles of skeletal muscles through activation of cholinergic vasodilator

fibers and release of epinephrine, while it constricts the splanchnic and renal arterioles.[4] In large arteries, emotional stress increases pressure and flow velocity, but does not change arterial diameter.[4,49]

Capillaries

Capillaries are responsible for the transfer of nutrient materials and waste products between blood and tissues. The low rate of blood flow and large surface area facilitate the provision of nutrients and oxygen to surrounding tissue; the absorption of nutrients, waste products, and carbon dioxide; and the excretion of waste products from the body.

The blood volume of all capillaries is significantly larger than that of the aorta, causing a decrease in blood pressure and flow rate. The capillaries have a very large surface-area-to-volume ratio, allowing for nutrients to cross the capillary wall. Diameter ranges from 4 to 15 μm. Only the tunica intima is present in capillaries and typically only consists of endothelium, its basal lamina, and an incomplete layer of cells surrounding the capillary called pericytes. Pericytes have contractile properties and are able to regulate blood flow in the capillaries. During vascular remodeling and repair, pericytes differentiate into ECs and SMCs.

Capillaries have a wide variety of configurations dependent on the structure of the endothelium, which is in turn related to the function of their specific vascular bed. They may be nonfenestrated continuous, fenestrated continuous, or discontinuous, as previously mentioned.

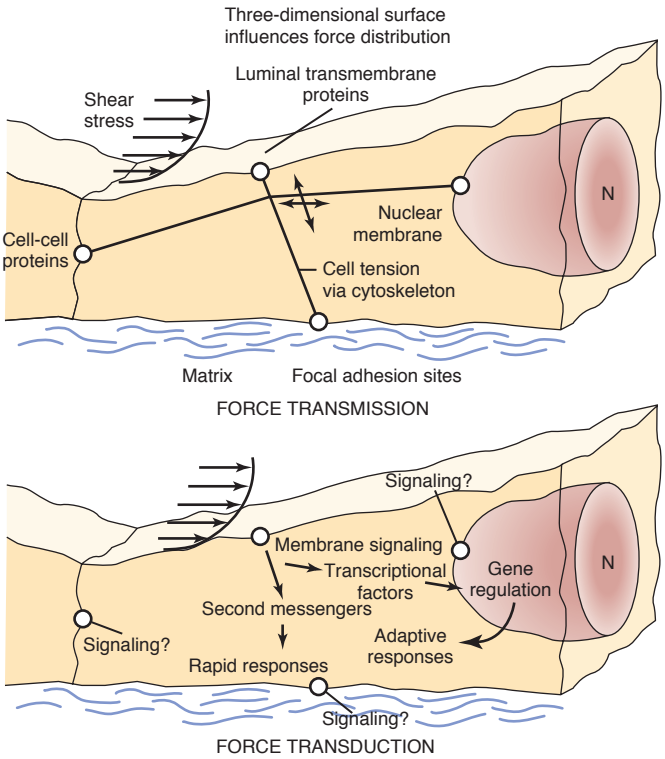

Figure 3.4 Transmission of Mechanical Force to Arterial Wall Surfaces. Extracellular fluid mechanical forces acting on the luminal surface are transmitted by the cytoskeleton to remote intracellular locations, such as cell-cell junctions, focal adhesion sites, and the nucleus *(N)*. (Redrawn from Helmke B, Davie P. Cytoskeleton under external fluid mechanical forces: hemodynamic forces acting on the endothelium. *Ann Biomed Eng.* 2002;30:284-296.)

HEMODYNAMICS AND VASCULAR WALL BIOLOGY

Blood vessels constantly experience the mechanical forces of cyclic strain and shear stress. Blood pressure is the primary determinant of cyclic strain as radial and tangential forces in the vessel wall work to counteract the intraluminal pressure. Hemodynamic forces have long been viewed as important modulators of protein synthesis, cell morphology, migration, differentiation, and proliferation. The tension per unit of thickness of the wall, which represents the stress exerted on the wall in the circumferential direction, is given as $\sigma = Pr/h$, where P is blood pressure, r is vessel radius, and h is wall thickness. Shear stress results from the flow of blood against the vessel wall and the stress acts parallel to the vessel surface. Shear stress is expressed as $\tau = 4\mu Q/\pi r^3$, where μ is viscosity, Q is flow rate, and *r* is the vessel radius. Cyclic strain affects all cell types in the vessel wall, whereas shear stress principally exerts its frictional forces on ECs at the interface of the blood and vessel wall (Fig. 3.4).

Shear Stress

Normal stress involves pulsatile pressure and flow, which includes changes in pressure and blood velocity throughout the duration of the cardiac cycle. Pulsatile flow induces both long- and short-term reactions, which vary among different regions of the vasculature. During changes in stress, the vessel wall compensates to restore the vessel to basal levels of tensile and shear stress. Acute changes in stretch and shear stress induce transient changes, including the release of vasoactive agents and alterations in vessel diameter. Chronic changes in mechanical forces demand vascular remodeling—and significant adaptive alterations in vessel wall shape and composition.

Shear stress is a determinant in the release of relaxing factors. Long-term increases in shear stress enhance the L-arginine/nitric oxide (NO) pathway in ECs. Marked increases in NO synthase mRNA and cyclic guanosine monophosphate occur with chronic increases in shear stress and, joined with matrix metalloproteinases (MMPs), can lead to apoptosis, enlargement, and vascular remodeling. An increase in flow rate through an isolated artery induces the release of endothelium-derived hyperpolarizing factor, prostaglandin I_2 (PGI_2), and NO. This finding suggests that flow-induced dilation depends on the release of endothelium-derived factors.[4,50-52] Further, long-term exposure to increased shear stress upregulates the expression of type III NO synthase in cultured ECs. NO and superoxide anions help activate MMPs. It is believed that MMPs are induced in the vessel wall in response to increased blood flow and are involved significantly in arterial wall remodeling. Increased shear stress stimulates the production of MMP-2 and MMP-9 in the arterial wall, inducing matrix degradation, tears in the IEL, and increases in arterial

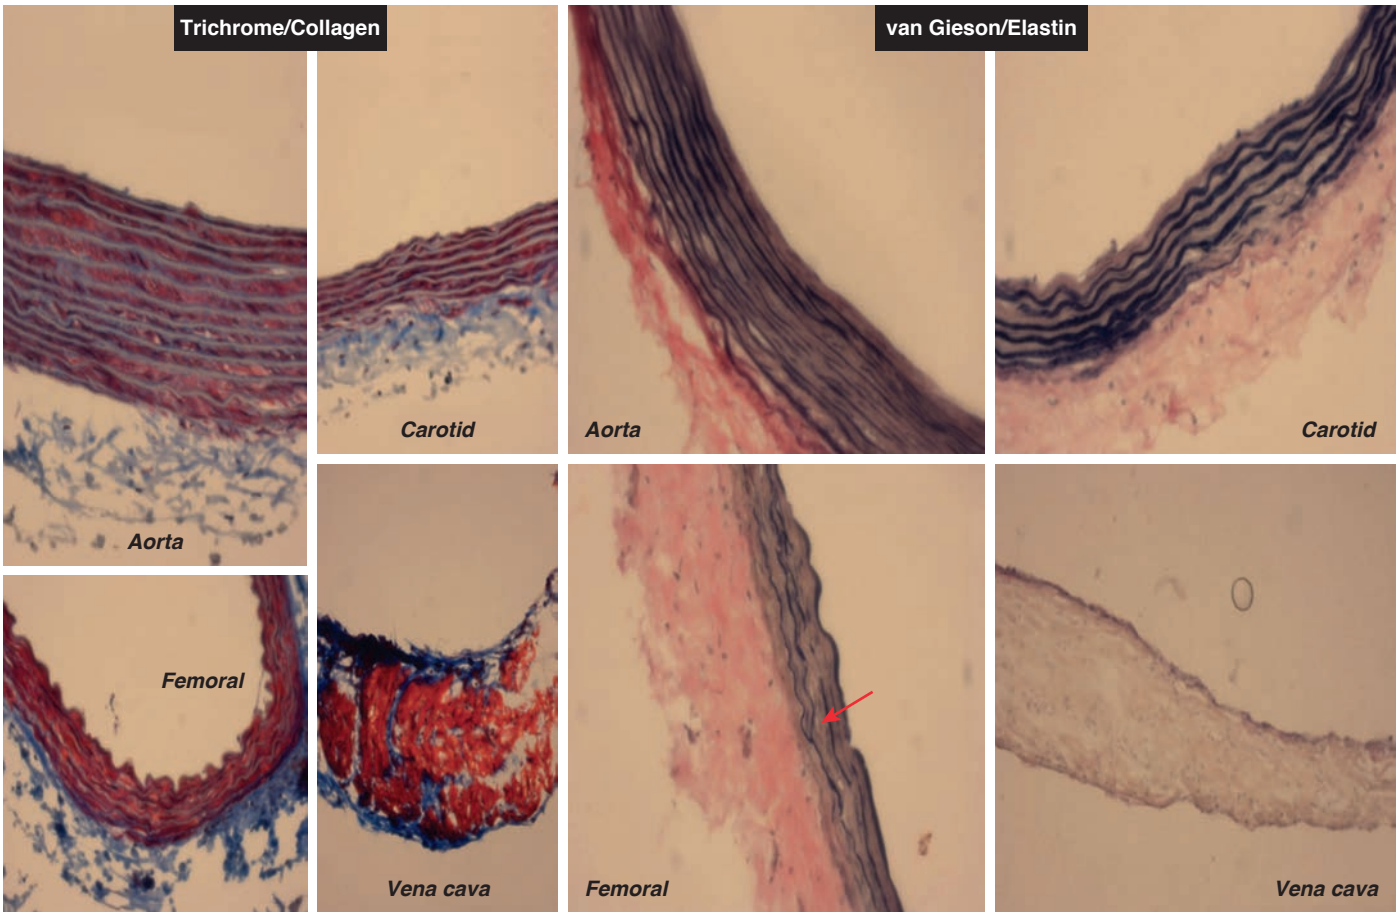

Figure 3.5 Masson trichrome blue staining of collagen, and van Gieson staining of elastin in different vessels. Blue represents collagen on the trichrome staining. There is a relative abundance of collagen in large veins such as the vena cava, as well as certain arteries such as the femoral artery, while there is minimal collagen expression in the aorta and carotid. Blackish-brown represents elastin on the van Gieson staining. The aorta and carotid have higher levels of elastin compared to the femoral artery and vena cava. The *red arrow* also indicates the broken structure of the elastin in the femoral artery specimen, which in this case could be associated with the higher level of expression of MMP-9 in the femoral artery compared to other vessels. (Redrawn from Basu P, Sen U, Tyagi N, Tyagi SC. Blood flow interplays with elastin: collagen and MMP: TIMP ratios to maintain healthy vascular structure and function. *Vasc Health Risk Manag*. 2010;6:215-228.)

diameter and distensibility (Fig. 3.5). MMP-induced remodeling will continue until arterial caliber has increased to such a point that wall shear stress is normalized. In contrast, restriction of blood flow, and thus a decrease in shear stress, causes a significant delay in the growth of the carotid artery, a 25% reduction in diameter in the carotid artery, and a decrease in elastin content in young rats.[53] Mean physiologic shear stress on the vascular endoluminal surface ranges from 10 to 15 dynes/cm^2 throughout the arterial, venous, and capillary networks.

Studies have shown that arterial circumference increases with age, but under normal physiologic conditions maintains consistent tensile stress. Medial thickness remains unchanged and intimal thickness demonstrates a pronounced increase. A study found that although wall thickness increases with age, lumen diameter also increases, thus maintaining stress levels. In a study comparing rats aged 6 to 30 months, there were significant increases in aortic wall elastin and collagen concomitant with aortic enlargement. There were also ruptures and lack of continuity in the elastic lamellae, resulting in significant decreases in wall distensibility. Thus, the walls of large arteries are stiffer in older animals. This decrease in distensibility is counterbalanced by a subsequent increase in lumen and overall vascular volume.

When there is limited vascular stretch, arteries experience an increase in intraluminal pressure, resulting in pressure-induced arterial wall crush. For instance, in percutaneous balloon angioplasty, the arterial wall is subjected to high intraluminal pressure, leading to pressure-induced crush. Sustained pressure leads to increased DNA synthesis and cell proliferation via autocrine or paracrine fibroblast growth factor-2 (FGF-2) in human vascular smooth muscle.[50] It has also been associated with an increase in *c-fos* expression in the rat model, which is associated with a proportional increase in SMC proliferation. Thus, pressure-induced crush may be involved significantly in vascular remodeling regarding the proliferation of smooth muscle.

Endothelium

Shear stress primarily affects ECs, although long-term changes in shear stress encourage vascular remodeling throughout the

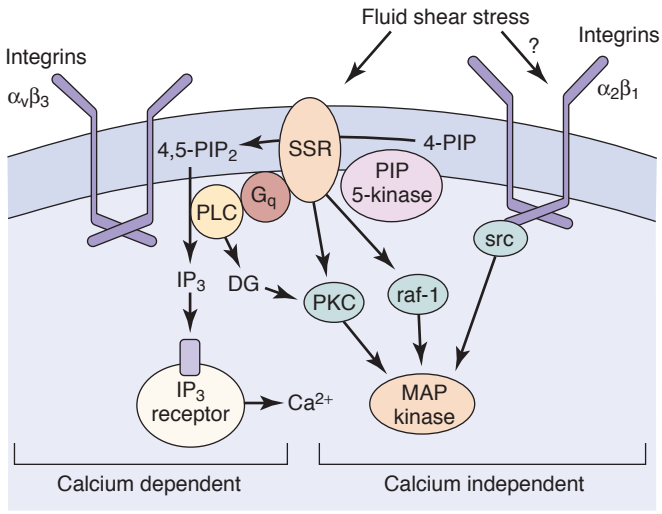

Figure 3.6 Signal Transduction Activated by Fluid Shear Stress in Endothelial Cells. Calcium-dependent and calcium-independent pathways are shown. *DG*, Diacylglycerol; G_q, G-protein; *IP$_3$*, inositol 1,4,5-triphosphate; *MAP*, mitogen-activated protein; *PIP*, phosphatidylinositol 4-phosphate; *PKC*, protein kinase C; *PLC*, phospholipase C; *SSR*, shear stress receptor.

arterial wall. ECs align in the direction of stress, and the greater the shear stress, the more elongated the cells.[54,55] Such changes are correlated with a redistribution of intracellular stress fibers and fiber quantity. In areas of high shear stress, ECs express higher amounts of stress fibers, including actin, myosin, and other contractile proteins. Although arterial levels of shear stress induce significant changes in stress fiber expression, venous levels of shear stress induce no change. Further, bovine aortic ECs retain their polygonal shape and do not develop actin stress fibers, either under oscillatory shear stress or in static culture (Fig. 3.6).

It is believed that transient changes in laminar shear stress do not permanently alter protein levels, although they may lead to the reorganization of cytoskeletal proteins and changes in cell shape. Shear stress dictates genes encoding for many growth factors, vasodilators, vasoconstrictors, and adhesion molecules. Cyclic strain interacts with shear stress, in that the strain reduces EC sensitivity to shear stress. In vivo, however, it is difficult to distinguish between shear stress and cyclic strain–induced changes in endothelium function.

Mechanotransduction begins on the luminal side of the ECs, causing deformation at the level of individual cells. This deformation is transduced through the cytoskeleton to other points on the cell, including basal adhesion points where the cells are attached to the ECM, cell junctions, and the nuclear membrane. The redistribution of forces stimulates immediate and delayed processes. The cell membrane responds by activation of stretch-induced ion channels, phospholipids, and integrins.[56,57] The nuclei upregulate the production of platelet-derived growth factors α and β, tissue plasminogen activator (tPA), transforming growth factor-β, endothelin-1, nitric oxide synthase III, and intercellular adhesion molecule-1 (ICAM-1).[58,59] Increased shear stress upregulates ICAM-1, steady shear stress upregulates vascular cellular adhesion molecule-1 (VCAM-1), and oscillatory stress decreases levels of both molecules.

It has been suggested that potassium channels, as opposed to calcium channels, are the mechanoreceptors by which ECs respond to shear stress and pressure.[60] A decrease in fluorescent dye used to measure potassium ion concentrations in bovine ECs was observed after exposure of the ECs to increases in shear stress. This decrease was due to an influx of potassium ions from the cells. An increase in inositol 1,4,5-triphosphate (IP_3) was also observed in conjunction with the onset of shear stress. This finding implies that phospholipase C (PLC) is activated by flow and that protein kinase C (PKC) activation occurs in flow-stimulated ECs.

Shear stress functions as an important modulator of arterial diameter through the release of vasoactive substances by the endothelium. Though ECs do not synthesize arachidonic acid, it is a crucial precursor to PGI_2, a vasodilator and platelet inhibitor released by ECs. It has been found that the percentage of arachidonic acid incorporated into diacylglycerol and phosphatidylinositol is significantly increased in ECs exposed to arterial levels of shear stress. Further, studies have shown that shear stress–induced PGI_2 release is significantly dependent on the PLC/diacylglycerol lipase pathway for arachidonic acid supply.[61-63]

Media

In the arterial media, vascular SMCs remain in a contractile phenotype, underscored by its spindle-shaped morphology, helical organization, contractile protein expression, low rate of proliferation, and ability to contract.[64]

Medial thickening occurs in response to hypertension and general increases in pressure and wall tensile stress. In resistance arteries, pressure increases induce medial thickening due primarily to SMC hyperplasia and changes in the proportion of contractile and matrix proteins. Such hypertrophy causes a decrease in lumen diameter and results in increased hemodynamic resistance. The increase in media-to-lumen ratio ensures that the media stress, or force exerted by the vascular smooth muscle per unit area, does not increase.

Circumferential Stretch

Cyclic or circumferential stress represents the constant, rhythmic deformation of the vascular wall caused by pulsatile, hydrostatic pressures linked to the oscillations of systole and diastole. Both ECs and underlying vascular SMCs are subjected to such forces and are susceptible to altered phenotype and changes in morphology.

In ECs, cyclic stretch has been shown to induce cell proliferation, with maximum proliferation occurring during day 1 of exposure. ECs also demonstrated an increase in total protein content. Endothelin release and gene expression in vascular ECs are stimulated by both shear stress and cyclic strain. Prostacyclin production in stretched cells has been shown to be double that in unstretched cells after incubation with arachidonic acid, although this difference also depends on the tissue source of ECs. Chronic cyclic strain for 3 to 5 days causes doubling in tPA secretion.[65]

SMCs, like ECs, when subjected to cyclic strain, change their orientation. They uniformly align perpendicular to the

direction of the strain vector—in an annular fashion. When exposed to cyclic strain, SMCs increase in proliferation rate but also fail to align. SMC hypertrophy in major arterial trunks tends to develop only when the distending pressure reaches a threshold level.[4] Cyclic stretch at low intraluminal pressure demonstrated decreased levels of smooth muscle marker proteins h-caldesmon and filamin. Physiologic intraluminal pressure, 80 mm Hg, maintained these levels. Further cyclic stretching of cultured SMCs increased expression of smooth muscle myosin heavy chains and myosin light chain kinase,[66] augmented smooth muscle myosin heavy chain SM-1 and SM-2 protein content, and decreased nonmuscle myosin NM-A. It is believed that certain levels of stretch are needed to maintain SMCs in a quiescent state and that excessive stretching triggers an increase in protein synthesis and hypertrophy.

In regard to ECM production, cyclic stretch induces an increase in collagen production in the cells and media of porcine aortic SMCs. Cyclic strain will also increase smooth muscle production of types I and III collagen, while in fibroblasts, it will increase the ratio of type II to type I collagen production. Elastin levels are markedly elevated in stretched SMCs. ECs subjected to the identical regimen demonstrated inhibition of collagen production.

In summary, increases in circumferential stress induce increases in SMC hypertrophy and in collagen and elastin production. Inversely, a decrease causes the wall to atrophy.[67] As the diameter of a blood vessel increases, the number of lamellar units and the overall wall thickness increase in order to maintain circumferential stress. In elastic large arteries, the adaptive response works to normalize tensile stress. Sustained hypertension is associated with an ongoing response in large arteries and arterioles, including increased medial wall thickness, changes in wall composition, altered arterial function, and increased SMC size and number.[68]

VEIN WALL ANATOMY

The venous system is an adaptable and variable system from person to person. In spite of the common basic function of arteries and veins in transporting blood, significant distinctions continue to be found in the organic backgrounds of the two types of vessels.

The basic cellular structure of the venous system in general conforms to the same three-layer (tunica) morphology present throughout the arterial system.[69] The IEL further separates the intima and media, and the external elastic layer separates the media and adventitia.

Intima

The intima consists of one layer of ECs sitting on an incomplete elastic basement membrane.[48] Under normal healthy conditions, the ECs have essential roles in venous wall integrity and function. These cells produce vasorelaxants and platelet inhibitors, such as PGI_2 and NO. NO also negatively affects the expression of chemical mediator secretion and inflammatory cell adhesion molecules including ICAM-1 and VCAM-1.[70-72] These functions of the venous intima and ECs in their normal state play important roles in pathologic processes such as neointimal hyperplasia when under arterial pressure.

Media

The media is composed of circularly arranged SMCs, and varies greatly according to location; however, in general it is less developed than that of the arterial system. This may contribute to the development of varicosities in lower extremity veins. The SMCs of this layer are held in a quiescent state in the normal venous environment by various factors.[73] Transforming growth factor-β downregulates their mitogenesis and stabilizes the ECM against SMC migration. In addition, heparin and heparin-like molecules neutralize FGF to downregulate cell proliferation. This process is important because these factors keep the normal vessel wall in a state of low cell turnover with low rates of proliferation and apoptosis. Injury or changes to the environment, as when veins are exposed to arterial flow, can increase rates of proliferation or apoptosis.[73]

Adventitia

The adventitia is generally the thickest layer in large veins, sometimes blending with the media. Bundles of longitudinally oriented SMCs are interspersed with collagen and elastic fibers. Collagen fibers may be particularly abundant in large veins as well and can have either a longitudinal or helical orientation. Compared with the vasa vasorum of arteries, vasa vasorum are much more extensive in venous adventitia and penetrate into deeper regions as well.[48] Lower oxygen tension in venous blood is a possible explanation for this phenomenon.

Developmental Concepts in Distinct Vein Wall Anatomy

Until 2005, vein was thought to be the default vascular state for undifferentiated vascular tissue development. The discovery of COUP transcription factor-2 (COUP-TFII) provided a direct molecular pathway to illustrate that the morphology of the vein wall is not due solely to environmental factors.[74] In the specification stage of embryonic vascular development, it was already known that the Sonic Hedgehog/vascular endothelial growth factor (VEGF) cascade in ECs activated the Delta-Notch signaling cascade, ultimately inducing expression of ephrin-B2, an arterial marker, and limiting expression of EphB4, a venous marker. COUP-TFII actively inhibits the VEGF receptor in venous development, thus suppressing Notch signaling and ephrin-B2 expression while increasing expression of EphB4.[74,75]

The decreased ephrin-B2 and increased EphB4 both contribute to the thinner, less cellular wall of veins in comparison with arteries. Ephrin-B2, a cell surface–anchored ligand for Eph receptor tyrosine kinases, regulates mural-cell migration, spreading, and adhesion during wall assembly; therefore, its deficiency in the venous development cascade may limit mural cell recruitment.[76] EphB4 expression is associated with decreased

intimal and medial thickening, largely composed of mature SMCs that otherwise localize to areas of decreased EphB4.[77] EphB4 also limits cell proliferation by extracellular-signal-regulated kinase (ERK) dephosphorylation.[73]

Physiologic Implications of Vein Wall Composition

In general, veins have thinner walls than arteries because their cellular and fibrous components are more limited in quantity. The composition of vein walls is also different, with a relative abundance of collagen fibers, particularly in large veins, and a relative paucity of elastic fibers—as might be assumed from the diminished elastic laminae (see Fig. 3.5).

This wall composition leads to the properties of veins as "capacitance vessels" and arteries as "resistance vessels." Compliance is extremely high for veins in comparison with arteries. A relaxed vein can increase in volume by up to 200% for a small increase in transmural pressure from 0 to 10 mm Hg. This increase reflects a change in geometry, with a low-pressure vein having an ellipsoidal cross-section that becomes circular with a small pressure increase—greatly enlarging the cross-sectional area.[78] The abundance of adventitial collagen and lack of medial elastin allow the vein wall to accommodate 60% to 80% of the body's blood volume.

VEIN WALL SYSTEM

The venous system begins from the capillary beds and drains blood from the extremities and body to transport it back to the heart. The vein wall changes in structure throughout its course.

Venules

Postcapillary venules are the smallest of venous vessels and form from the confluence of several capillaries. Their dimensions have ranges of 50 to 650 µm in length and 10 to 50 µm in diameter. Similar in structure to large capillaries, they have an endothelium and pericytes but no SMC layer. The attenuated endothelium is 0.2 to 0.4 µm wide. The endothelium is loosely organized and leaky with only a few intercellular junctions linking cells. A thin basal lamina is present. Given these characteristics and their slow flow, they are the main sites for white blood cell diapedesis and tissue exudate from circulation to interstitial tissue during inflammation.[48,69]

Postcapillary venules drain into collecting venules, which are larger but structurally similar with more pericytes. These continue to drain into muscular venules, which have a clearly defined intimal layer with no elastic fibers and a tunica media with one or two layers of SMCs.[69]

Veins

Veins form from the confluence of multiple venules. Typical small and medium-sized veins are 1 to 9 mm in diameter. Although these veins have three tunicae, the boundaries are less distinct than those in arteries. They may have a poorly developed IEL enclosed by a thicker media made of up to three layers of circumferentially oriented SMCs. This thicker media is still thinner than that of arteries. The adventitia, usually the thickest layer, consists primarily of longitudinally oriented collagen fibers. It may be continuous with the surrounding collagen of the supporting tissue. Large muscular veins, such as the femoral veins, exhibit a narrow intima but a substantial media with several layers of SMCs separated by collagenous tissue and scant elastic fibers.

Venae Cavae

The superior and inferior venae cavae are the largest veins and deliver deoxygenated blood into the right atrium of the heart. Other large systemic veins, such as the portal, pulmonary, azygos, splenic, and mesenteric veins, have similar features. A distinct intima of fibroelastic tissue is present. The media is narrow and composed of predominantly circumferentially oriented SMCs. A thick adventitia is most notable for the numerous bundles of longitudinally oriented collagen and smooth muscle fibers. Elastic fibers may be scattered throughout all the layers.

At the entrance to the heart, venae cavae and pulmonary veins can have a small amount of cardiac tissue in the adventitia. An extensive vasa vasorum is also present in the adventitia.[48]

Venous Valves

An important structural distinction found in veins and not present in arteries is valves. They are characteristic of small and medium-sized veins more than 2 mm in diameter.[69] Composed of local semilunar infoldings of wall intima, the valves project into the lumen in the direction of blood flow and prevent backflow as the blood returns to the heart against gravity. A reverse velocity of 30 cm/s appears required for valve closure.[79] Structurally, valves are composed of a mixed collagen-elastic fiber core of connective tissue covered by thin endothelium, making them stronger and more elastic than the vein wall.[48] They are typically found distal to the confluence of venous branches forming larger veins. The valve sinus is wider than the lumen above and below the cusps. Generally, valves assist in the caudal-to-cephalad flow of blood, but also ensure the flow from the superficial veins to the deep system. A notable exception to this is in the feet, where flow is from the deep muscles in the sole to the superficial veins in the dorsum of the foot.[80] Valves disappear more proximally in the venous system and are absent in the common iliac veins and inferior vena cava, as well as the veins of the head and neck.

It is the normal physiology of valves to disrupt the laminar flow of blood through the vein. This is important considering that this disruption occurs to a greater extent in high-flow states, such as when healthy vein is used in an arterial bypass. Turbulence caused by valves is known to induce endothelial injury in this setting and may contribute to intimal hyperplasia.[73]

The exact starting point for the development of venous diseases such as chronic venous insufficiency and varicose veins is not completely clear; however, there is little doubt that venous

valve incompetence plays a role. A reduction in the number of valves per unit length has been seen in chronic venous insufficiency.[81] The normal architecture of valve leaflets is also changed in chronic venous insufficiency, with significant infiltration by monocytes and macrophages.[82] Also, valves exposed to abnormally high pressures experience increased MMP-2 and MMP-9 levels, favoring the accumulation of ECM. Remodeling with reductions in leaflet height, width, and total disappearance also occurs.[81]

LYMPHATIC WALL ANATOMY

Although lymphatic vessels have been long known, the absence of large, consistent vessels has delayed more active research into the realm of lymphatics. However, advances in imaging and tissue engineering have revealed distinct structural and functional differences of lymphatics.

The lymphatic wall morphology has distinct anatomy at different levels. These differences play important roles in the drainage and propulsion of lymph through vessels. Briefly, at the level of the capillaries and initial lymphatics, a single layer of ECs is present, with large gaps between cells and an incomplete basal lamina.[48] These smaller lymph vessels coalesce into large vessels with thin walls that resemble veins. Like veins and arteries, large lymph vessels have three concentric tunicae. These layers, however, are not as readily delineated as they are in the cardiovascular system.[48] As in veins, valves are present within the lymph vessel lumen but are also much greater in number.

LYMPHATIC WALL SYSTEM

The lymphatic system is a unidirectional flow network originating in the interstitial space throughout the body, draining fluid from the ECM into initial lymphatics, which in turn contribute to gradually larger precollecting lymphatics, collecting lymphatics, trunks, and ducts (Fig. 3.7).[83] Lymph is pumped by the contraction of larger vessel walls containing smooth muscle.

Initial Lymphatics

The lymphatic system starts in connective tissue spaces at blind-ended vessels called initial lymphatics. These are most abundant in the connective tissue of the skin; beneath the mucous membranes of the respiratory, gastrointestinal, and genitourinary tracts; and in the connective tissue of the liver.[48] Skin on the lower extremities has a denser network of lymphatics than other areas. The capacity for transport is also higher in the lower extremities to compensate for increased interstitial fluid filtration due to gravity.[84]

Initial lymphatics are 10 to 60 μm in diameter with a wall thickness of 50 to 100 nm. The wall is composed of a monolayer of nonfenestrated ECs.[85] On electron microscopy, these blind-ended vessels are usually collapsed and have a discontinuous or completely absent basal lamina.[83] The ECs of the initial lymphatics are rich in actin filaments, which are contractile. These filaments may contribute to forward propulsion, although there is no proof yet of this ability.

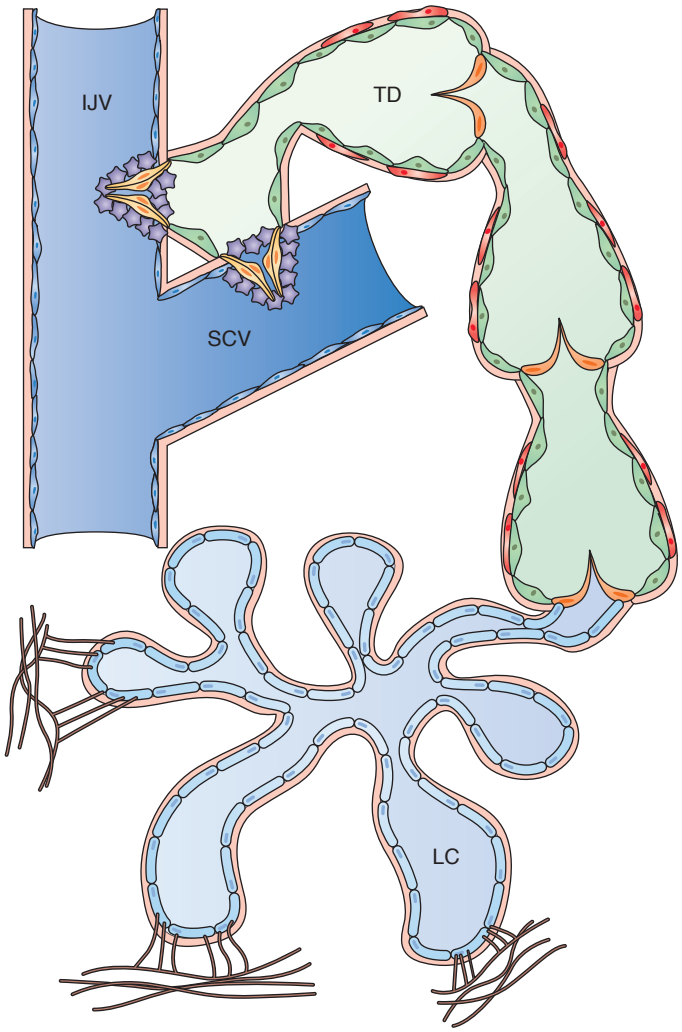

Figure 3.7 Schematic Diagram of the Lymphatic System. Lymphatic capillaries *(LC)*, also known as initial lymphatics, have endothelial cells with anchoring filaments connected to the surrounding connective tissue to form endothelial microvalves. These LCs drain into precollecting lymphatics and collecting lymphatic vessels, which have perivascular cell coverage to propel lymph and valves to prevent regurgitation. The thoracic duct *(TD)* is the longest collecting lymphatic vessel and returns lymph to the blood circulation by draining into the junction of the left subclavian *(SCV)* and left internal jugular veins *(IJV)*. (Redrawn from Chen H, Griffin C, Xia L, Srinivasan RS. Molecular and cellular mechanisms of lymphatic vascular maturation. *Microvasc Res*. 2014;96:16-22.)

Endothelial Microvalves

Because initial lymphatics have no complete basal lamina, gaps between ECs up to 10 μm wide provide an entry for lymph. When the vessels are collapsed, the ECs have overlapping extensions of cell membrane interconnected by discontinuous buttonlike junctions containing few intercellular tight junctions or adherens junctions.[86] Gaps are made possible by anchoring filaments, 6 to 10 nm in diameter, that anchor the ECs externally to the surrounding connective tissue.[87,88] When the interstitial fluid pressure increases and the surrounding matrix expands, the ECs anchored to this matrix are prevented from collapsing and allow fluid to flow through the resultant gaps between them.[83] As the interstitial fluid decreases and internal pressure

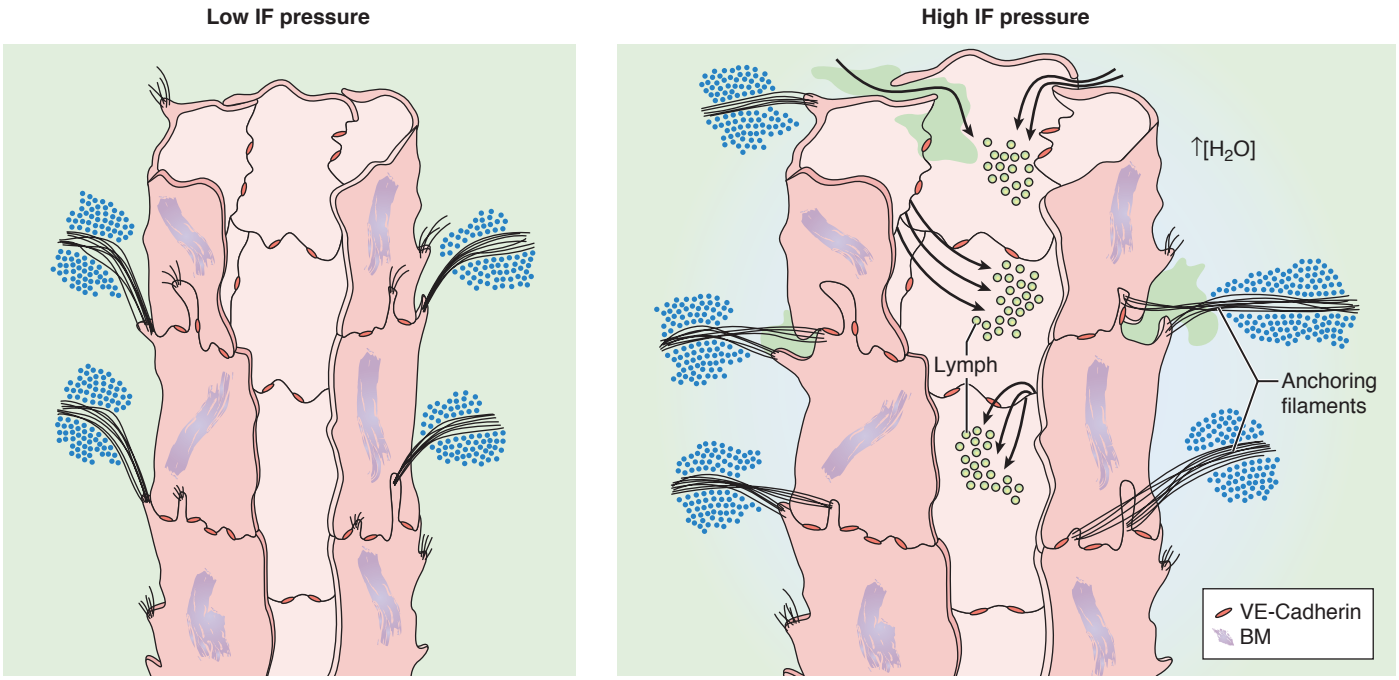

Figure 3.8 Endothelial Microvalve Drainage Response to Fluid Pressure Changes. When interstitial fluid *(IF)* pressure is low, junctions between endothelial cells are closed, not allowing flow into the lumen. When IF pressure is high, anchoring filaments pull the overlapping junctions apart and allow fluid entry into the lumen. (Redrawn from Bazigou E, Wilson JT, Moore JE Jr. Primary and secondary lymphatic valve development: molecular, functional and mechanical insights. *Microvasc Res*. 2014;96:38-45.)

rises, the ECs come together, overlap, and the gaps close (Fig. 3.8). In this way, the unidirectional flow of lymph into the lymphatics is ensured.[89] This complex is an endothelial microvalve or primary valve.

Secondary Valves

As in venous system, secondary valves are a prominent feature of the lymphatic system. They are generally bicuspid and present at regular intervals along the collecting lymphatics.[83] At the valve location, the vessel wall bulges to accommodate the opening and closing of the lymphatic valves, allowing them to form a tight seal. When viewed in vivo, lymphatic vessels often resemble a string of pearls because of these abrupt diameter changes.[90] Structurally, they are composed of a monolayer of ECs on a collagen matrix.[91] A buttress structure formed by the fusion of opposing leaflets has been observed in rat spinotrapezius lymph vessels, which has been theorized to allow the valve to close without inversion. Additional studies in other species have not demonstrated a buttress structure, and for now the valves appear to be passive structures closing in response to pressure gradients alone.[83]

Precollecting Lymphatics

Precollecting lymphatics are segments of vessels connecting the initial lymphatics to collecting vessels. Like vein walls, lymphatic walls project bicuspid, one-way valves (termed secondary valves) into the vessel lumen. Unlike in larger collecting lymphatics, these valves are irregularly spaced and sometimes constitute only a single leaflet. At this level, SMCs also start to appear around the vessels in one or more layers. These smooth muscle layers may contract and begin the forward propulsion of lymph through the system. However, many areas still are without any muscular layer or basal lamina and can act as a primary valve. Therefore, precollecting lymphatics fulfill a dual function in absorbing more lymph and also propelling it forward.[83,92]

Collecting Lymphatics

At the level of the collecting lymphatics, the basal lamina surrounding the endothelium of the lymph vessel becomes complete. Here the three typical layers of vessel wall also become more evident. The luminal side is bordered by an intimal monolayer of ECs. The media contains one to three layers of SMCs intermixed with collagen and elastic fibers. The muscle bundles are arranged in a helicoidal manner. This is all surrounded by an adventitia composed of fibroblasts, connective tissue, and nerve terminals.[93] Secondary valves also become more regularly spaced.

Lymphangions each represent the vessel space between two of these secondary valves. In humans, lymphangions of collecting lymphatics in the head and neck average 0.2 mm in diameter with a length of 2 mm. Those of the lower extremities may have a diameter of 1 to 2 mm with a similar 2-mm length. Lymphangions are innervated by sympathetic and parasympathetic nerves and rhythmically contract to propel lymph forward.[83]

Vascular surgeons care for a diverse set of clinical manifestations related to atherosclerosis—from symptomatic transient cerebral ischemic attacks to aortoiliac occlusions to aortic aneurysms repairs to mesenteric ischemia and to lower extremity arterial occlusive disease. However, despite the wide range of manifestations, culprit lesions are more alike than different. Accumulation of large amounts of cholesterol ester in the arterial wall and formation of complex advanced plaque are common to all these lesions. Although the formation of atherosclerotic lesions is insidious and spans decades, the lesions can reach a clinical dénouement within minutes and manifest as catastrophic myocardial infarction (MI), stroke, or limb ischemia. Atherosclerotic-related cardiovascular disease (CVD) is the leading cause of death in every region of the world except sub-Saharan Africa.[1] However, during the last two decades, CVD age-specific death rates fell by more than 40% in high-income countries.[2] The improved survival has translated into growing disease prevalence and a staggering financial burden. It is estimated that 81,000,000 Americans have CVD with an estimated annual cost of treatment of $449 billion.[3] Globally, 202 million people have peripheral arterial disease (PAD), which disproportionately affects blacks and individuals living in low- to middle-income countries.[1,3] Particularly troubling is the high prevalence of CVD risk factors in children and young adults.[4,5] A sedentary lifestyle, abdominal obesity, and poor diets contribute to dyslipidemia and high blood pressure. Autopsy studies in children and young adults demonstrate a link between these risk factors and early lesions.[4]

This chapter outlines the existing theories of the pathophysiology of atherosclerosis and the relationship to traditional and emerging risk factors. It also describes our current conceptual understanding of the fundamental biology of atherosclerotic plaque.

ATHEROSCLEROTIC LESIONS

Lesions of the arterial wall have been divided into six types based on their histopathologic features.[6,7] However, although the classification system is useful for comparing pathologic specimens, it has limited clinical practicality.

Autopsy studies from the Bogalusa Heart Study and the Pathobiological Determinants of Atherosclerosis in Youth study demonstrate that atherosclerotic lesions form in early childhood and increase with age.[4,8-10] In an intravascular ultrasound (IVUS) study of heart donors, 17% of individuals younger than 20 years had evidence of atherosclerosis.[11] Notably, both the Bogalusa Heart Study and the Pathobiological Determinants of Atherosclerosis in Youth study emphasize that the number and severity of early lesions are directly related to known cardiovascular risk factors, thus suggesting that a paradigm shift is needed to address

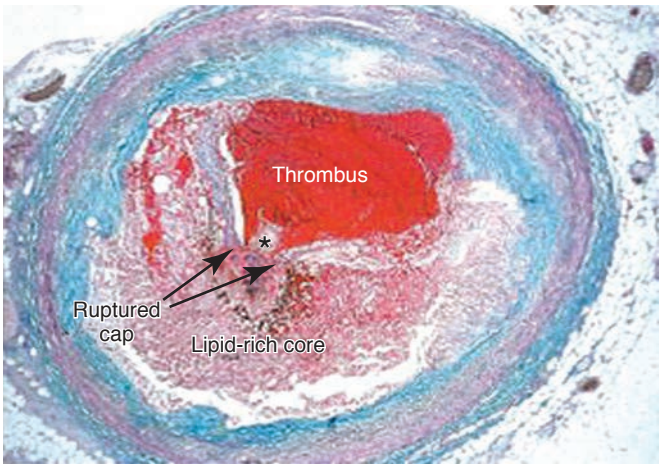

Figure 4.1 Thrombotic complication of a fibroatheroma seen on a trichrome-stained (thrombus and intraplaque hemorrhage stain *red*; collagen stains *blue*) cross-section of a human coronary artery. The fibrous cap has ruptured (area between the *arrows*), and the highly thrombotic lipid core is exposed to circulating blood with the subsequent production of acute occlusive thrombosis.

risk factors in childhood rather than pharmacologic therapy later in the disease process.

Diffuse intimal thickening has been identified in the atherosclerotic-prone areas of coronary arteries as early as 36 weeks of gestation.[12] Although the fatty streak—dominated by lipid-filled macrophages—is itself benign, it is the precursor of the more clinically relevant late lesion. The fatty streak is the first lesion visible to the naked eye. Its yellow color is attributed to lipid in the form of cholesterol and cholesterol esters within macrophages and smooth muscle cells (SMCs).

Advanced lesions, or fibrous plaque, are characterized histologically by the amount of extracellular lipid and fibrous connective tissue. They are whitish in gross appearance and are elevated so that they protrude into the lumen. These fibroatheromas are prone to provoking clinical sequelae by erosion of the surface endothelial cells, rupture of the fibrous cap, erosion of a calcium nodule, or intraplaque hemorrhage (Fig. 4.1).[6,13] Plaques differ in consistency and may be relatively soft and friable or densely sclerotic and calcific. Likewise, some have well-formed fibrous caps, whereas others are covered by a narrow zone of loose connective tissue or by endothelium alone.

The necrotic core usually occupies the deeper central regions of the plaque and contains amorphous lipid and cholesterol crystals. The term *atheroma* is derived from the Greek word *athere*, meaning "porridge-like gruel." SMCs and inflammatory cells are located adjacent to the necrotic core and at the shoulders of the plaque, where it is most susceptible to rupture.

The fibrous caps contain varied levels of SMCs adjacent to the collagen and basement membrane. These cells have reduced proliferative ability and may be regarded as senescent. However, the fibrous cap of ruptured plaque is often infiltrated with foam cells, which are largely of macrophage origin[14] and thus indicative of active inflammation and vulnerability to rupture. A priori identification of these so-called thin-cap fibroatheromas is an active area of cardiovascular imaging research.[15]

THEORIES OF PATHOGENESIS

Each of the well-regarded theories of atherosclerosis discussed in this section attempts to explain the underlying pathogenesis of atherosclerotic plaque. Each theory has undergone a steady evolution since the time that it was initially proposed, a consequence of advancements in our scientific inquiry from histologic descriptions to discernment of powerful molecular mechanisms. Each theory, held accountable over time, must incorporate new scientific data within a clinical context of risk factors and biomarkers to result in a model of atherosclerotic lesion formation.

Lipid Hypothesis

Cholesterol has been one of the most studied molecules in biomedical research. The modern era of cholesterol research began in St. Petersburg, Russia, at the turn of the 20th century, when Nikolai Anitschkow produced vascular lesions in rabbits by feeding them purified cholesterol dissolved in sunflower oil.[16,17] These lesions closely resembled those seen in human atherosclerosis. He hypothesized that they were caused by elevated serum cholesterol and also noted a distinctive pattern consisting of the location of the lesions near arterial branch points and concluded that this was probably determined by hemodynamic factors. Nevertheless, this work was criticized because the levels of cholesterol produced were too high and could not be experimentally reproduced in more conventional animal models such as rats and dogs.[16,17]

Cholesterol is insoluble in water, and the early work done in Russia provided no clues as to how it was transported to the arterial wall and formed plaques. The discovery that cholesterol was associated with proteins that allowed it to be transported in the aqueous environment led to investigations into lipoproteins. The first investigation in which the lipoprotein content in whole serum was accurately quantified involved analytic ultracentrifugation and was led by John Gofman of the Donner Laboratory at University of California at Berkeley.[18] Lipoprotein fractions were isolated and characterized by their densities and floatation characteristics.[18] Of note, this group noted that it was not simply the total cholesterol that was important but the species of lipoprotein contained within the cholesterol.[19]

Cholesterol is transported in the aqueous environment by esterification of the sterol of long-chain fatty acids and packaging of these esters with the hydrophobic cores of plasma lipoproteins. With its polar hydroxyl group esterified, cholesterol remains sequestered within this core, which is essentially an oil droplet composed of cholesteryl esters and triglycerides, solubilized by a surface monolayer of phospholipid and unesterified cholesterol and stabilized by protein. In persons who are fasting, lipids circulate in plasma as lipoprotein particles that are defined on the basis of their density as very-low-density lipoprotein (VLDL), intermediate-density lipoprotein (IDL), LDL, and high-density lipoprotein (HDL). The protein of the VLDL, IDL, and LDL molecule is apoB-100, which has β-electrophoretic mobility.

The major milestone in the lipoprotein field was the discovery of the defective gene associated with familial hypercholesterolemia

by Goldstein and Brown. In fibroblasts cultured from normal human subjects, the activity of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, the rate-controlling enzyme in cholesterol biosynthesis, is regulated by the content of LDL (but not HDL) in the culture medium. Goldstein and Brown found that HMG-CoA was not sensitive to normal feedback regulation by LDL in cultured skin fibroblasts from homozygous familial hypercholesterolemia patients.[20,21] They then determined that the defect was related to deficient binding of LDL to the cells of patients with familial hypercholesterolemia and that suppression of HMG-CoA activity was related to the amount of bound LDL.[22] Therefore, these patients had overproduction of cholesterol because they lacked the appropriate receptor. They demonstrated that cellular uptake of LDL absolutely requires the LDL receptor, without which the LDL cholesterol concentration builds up to 800 to 1000 mg/dL (20.7-25.9 mmol/L). This important work culminated in a Nobel Prize in Physiology and Medicine for Goldstein and Brown in 1985.

Epidemiologic evidence from numerous studies, including the Japanese migration studies[23,24] and the Framingham Heart Study,[25] demonstrated the association between cholesterol and incident CVD. Other studies showed that diets rich in unsaturated fats resulted in lowered cholesterol and reduced cardiovascular events.[26]

Widespread acceptance of the causative role of cholesterol began with publication of the Coronary Primary Prevention Trial, sponsored by the National Institutes of Health.[27,28] This trial demonstrated that lowering cholesterol with the bile acid punding resin cholestyramine reduced cardiovascular events. A decade later, this trial was reinforced with powerful data that emerged from the statin era.[29] Although the primacy of the "cholesterol hypothesis" has been called into question, there is no doubt that lipids play a critical role in the pathogenesis of atherosclerosis.

Response-to-Injury Hypothesis

The basis of this hypothesis lies in the similarities between atherosclerosis and the response of arteries to experimental injury. Although the origins of the hypothesis date back to Virchow, the modern version of the hypothesis builds on earlier work by Duguid,[30] Poole and Florey,[31] and French[32] and was formally advanced in 1973 by Ross and Glomset,[33] who emphasized the importance of injury to the endothelium as a seminal event in the development of atherosclerosis lesions. Even though the definition of the term *injury* has been modified over the last three decades,[34] all response-to-injury hypotheses have emphasized the primacy of the endothelium in stimulating the cascade of events leading to lesion formation.[33-38]

Endothelial injury may result from mechanical disruption, exposure to toxic or infectious agents, or endogenous inflammatory signals. Injury to the endothelium allows adhesion of platelets and an influx of LDL and other serum factors into the subendothelial space. Platelets release their alpha granules and stimulate migration of SMCs into the intima, where they proliferate and form a thickened neointima responsible for narrowing of the arterial lumen. Restoration of a healthy endothelial cell layer abates the process. During work on this hypothesis, Ross et al. performed experiments leading to the discovery of platelet-derived growth factor (PDGF).[39,40]

Other investigators have countered that it is not injury to the endothelium that is the initiating event but rather retention of inflammatory lipids in the subendothelial space that renders a particular area susceptible to atherosclerosis. The observation that LDL accumulates in the intima within two hours after a bolus infusion[41] and that the accumulation occurs before the formation of fatty streaks[42,43] led to the conclusion that retention of LDL is the initiating event of atherosclerosis. The so-called "response-to-retention" theory purports that retained apoB–containing lipoproteins stimulate a macrophage- and T cell–dominated inflammatory response in the arterial wall.[44,45]

Monoclonal Hypothesis

This hypothesis suggests that each lesion of atherosclerosis is derived from a single SMC that serves as a precursor for the clonal expansion of proliferating SMCs.[46] The hypothesis put forth by Benditt and Benditt used the concept that in every female cell there is only one active X chromosome and the progeny of that cell will express the same X chromosome as the parent cell. Glucose-6-phosphate dehydrogenase (G6PD) has two isoforms that can be separated by electrophoresis. Its gene is located on the X chromosome and can therefore be used to identify the progeny of a parent cell. This approach was used to determine that uterine leiomyomas are composed of cells with the same active X chromosome, whereas adjacent normal myometrium is composed of a mixture of cells containing both G6PD isoforms, implying that both X chromosomes are active.[47]

The Benditts examined a series of atherosclerotic plaques from four black females and compared them with adjacent normal areas of arterial wall. They determined that SMCs from the plaque contained only one G6PD isoform, whereas adjacent control areas contained a mixture of isoforms. This allowed them to conclude that each lesion is a clonal outgrowth derived from a single precursor SMC located in the intima. It is noteworthy that SMCs within individual neonatal intimal thickenings are monoclonal in origin, whereas cells from the subjacent media are polyclonal.

Others challenged the hypothesis by noting that identification of a single enzyme phenotype does not necessarily imply clonal origin.[48,49] Regardless, the work was importantly heuristic, and hinted toward the role that modern molecular biology would play in unraveling the genetic basis of atherosclerosis.

ATHEROSCLEROSIS AS A CHRONIC INFLAMMATORY DISEASE

The original version of the response-to-injury hypothesis of atherosclerosis proposed that endothelial denudation was the first step in atherosclerosis.[33] Subsequent versions of the hypothesis proposed that an endothelium chronically bathed in serum with high concentrations of LDL or exposed to other

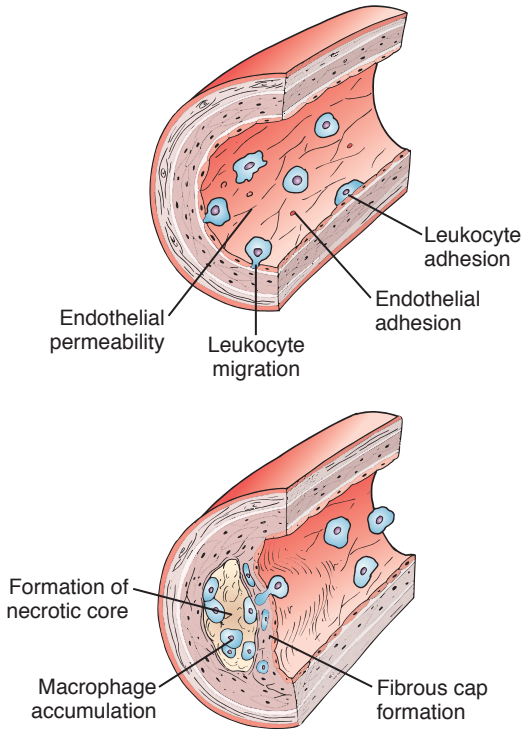

Figure 4.2 Initiation and progression of atherosclerotic plaque. Cardiovascular risk factors, hemodynamic forces, toxins, and infectious agents interact with the vessel at the level of the endothelium to produce injury, resulting in decreased nitric oxide production and increased permeability. Once injured, the endothelium increases the expression of leukocyte adhesion molecules such as vascular cell adhesion molecule-1, intracellular adhesion molecule-1, and P- and E-selectin, which increases the adherence of macrophages and other leukocytes. Permeability of the endothelium also increases and permits entry of leukocytes and lipoproteins into the subendothelial space. Chemokines and cytokines such as monocyte chemotactic protein-1 and interleukin-8 further enhance the recruitment of leukocytes and smooth muscle cells (SMCs) into the subendothelial space. Lipoproteins retained in the subendothelial space are biochemically modified such that they can be taken up by macrophages and SMCs to form foam cells. Foam cells at the central-most position of the developing atheroma become necrotic and form the central lipid core, whereas the shoulder regions contain SMCs, macrophages, and other leukocytes. Platelet-derived growth factor and transforming growth factor-β stimulate SMC migration and collagen formation in the subendothelial space, as well as formation of the fibrous cap.

cardiovascular risk factors would render susceptible areas of the endothelium dysfunctional or activated.[37] Indeed, an intact endothelium may be a necessary factor for lesion progression, and it is now clear that developing atheromas are covered by an intact endothelium throughout most stages of lesion progression.[7,34,50-52] In humans, only the most advanced ulcerated lesions are focally devoid of endothelium. The injury results in increased adhesiveness and an increase in permeability of the endothelium to inflammatory cells (Fig. 4.2).

Atherosclerosis is now recognized as an inflammatory disease, and components of the innate and adaptive immune system are involved in every step of the atherosclerotic process. Much of our modern understanding comes from examination of human pathology specimens and transgenic animals. Genetic deletion of apolipoprotein E *(ApoE$^{-/-}$)* or the LDL receptor *(Ldlr$^{-/-}$)*, which produce mice with severe hypercholesterolemia and atherosclerotic lesions with features of mature human atheroma, have become cornerstones in atherosclerosis research laboratories.[53-55] The importance of the LDL receptor in cholesterol regulation was noted by Goldstein and Brown when studying patients with familial hypercholesterolemia. Apolipoprotein E suppresses atherosclerosis, and *ApoE$^{-/-}$* mice have very low levels of pre-β HDL and their plasma is poor at promoting the efflux of cholesterol from lipid-laden macrophages.[56] Crossbreeding these mice with other strains carrying null mutations in immunologically relevant genes produces a robust research tool to dissect out the contribution of individual components of immune pathways in atherosclerosis. For example, some of the earliest approaches using compound mutant mice involved the global loss of the entire adaptive immune system. *Rag1$^{-/-}$* and *Rag2$^{-/-}$* mice lack the V(D)J recombinase required to form lymphocyte antigen receptor genes and hence have a complete loss of B and T cells. *ApoE$^{-/-}$* mice fed a regular chow diet developed plasma cholesterol levels between 390 and 470 mg/dL. Double knockout *ApoE$^{-/-}$/Rag1$^{-/-}$* mice had a 40% reduction in aortic atherosclerotic lesion reduction compared with immunocompetent animals, thus demonstrating the role cellular immunity plays in the pathogenesis of atherosclerosis.[57]

Low-Density Lipoprotein Retention

Trafficking of circulating LDL into and out of the subendothelial space is probably a function of concentration gradients and endothelial permeability.[58,59] Normal intima does not retain LDL particles, thus suggesting that most particles return to plasma or are degraded in situ. However, subendothelial retention of apoB-100–containing lipoproteins is an early event in atherosclerosis.[59] Factors favoring net retention include a balance of uptake and degradation of LDL by macrophages, egress of LDL-containing macrophages into the circulation, and complex interaction with proteoglycans such that the LDL particles are sufficiently modified to maintain the gradient. Once bound to the matrix, the lipoprotein is modified so that it becomes oxidized.[58,60] Oxidized LDL, unlike native LDL, is chemotactic to monocytes and rapidly taken up by macrophages to form foam cells by scavenger receptors.

Monocytes

As early as 1958, Poole and Florey noted that macrophages adhere to the surface of endothelial cells overlying atheroma.[31] In studies of hypercholesterolemic monkeys, monocytes are seen attached to the endothelium within 12 days of initiation of an atherogenic diet.[61] It is now apparent that monocytes play a very early role in atheroma formation.[62,63] Endothelium, which is rendered activated, expresses adhesion molecules that interact with circulating leukocytes, principally monocytes and lymphocytes. E- and P-selectins slow monocytes, mediate rolling, and loosely tether them to the endothelium.[64] More permanent fixation is due to members of the immunoglobulin superfamily—vascular cell adhesion molecule-1 (VCAM-1)[65] and intercellular adhesion molecule-1 (ICAM-1)—which are soon upregulated and firmly fix the leukocytes to the wall. The importance of the selectins, VCAM-1, and ICAM-1, in the pathogenesis of

atherosclerosis is evident in either ICAM-1 or VCAM-1 mutant mice exhibiting, which exhibit far less atherosclerosis than wild type control mice.[66-68] The adherent leukocytes are stimulated to migrate into the subendothelial space by a number of chemokines, including monocyte chemoattractant protein-1 and oxidized LDL.[69-71]

Macrophages

Once within the subendothelial space, monocytes undergo a series of phenotypic modulations and become resident tissue macrophages that take up oxidized LDL via the scavenger receptor A (SR-A), as well as CD36.[72] One of the key signals for macrophage activation, macrophage colony-stimulating factor, can enhance scavenger receptor expression and promote replication of macrophages and their production of proinflammatory cytokines. Experiments in mutant mice deficient in macrophage colony-stimulating factor have shown the importance of this factor in atheroma formation.[73,74] Although most foam cells are macrophage in origin, SMCs also take up lipids via scavenger receptors and CD36.

In mice, proinflammatory subsets of macrophages called M1-macrophages, induced by hyperlipidemia, produce the inflammatory cytokines IL-1β and TNF-α. The IL-1 gene family encodes three major proteins. The first two, IL-1α and IL-1β, exert proinflammatory effects by binding to the IL-1 receptor type 1. The third is IL-1 receptor antagonist (IL-1Ra), an endogenous inhibitor that competitively blocks the binding of IL-1α and IL-1β to the IL-1 receptor. Direct evidence for the proatherogenic role of IL-1 was obtained in experiments in which *ApoE*$^{-/-}$ mice received subcutaneous injection of recombinant IL-1 receptor antagonist. Mice injected with IL-1 receptor antagonist displayed a marked reduction in atherosclerotic lesion size. Similarly IL-18, previously called interferon-γ (IFN-γ)–inducing factor, is a Th1-promoting cytokine and therefore has the capacity to promote inflammation through the innate and the adaptive immune pathways.[75,76] Knockout of IL-18 in atherosclerosis-prone animals reduces aortic atherosclerotic lesion size.

Macrophages also contribute to thrombosis in several pivotal ways. As discussed later, atherosclerotic lesions that have ruptured characteristically contain abundant macrophages underlying a thin and collagen-poor fibrous cap. Specific collagenases matrix metalloproteinase (MMP)-1, MMP-8, and MMP-13, co-localize with macrophages in human atheroma. Rupture of the fibrous cap may be a balance between collagen synthesis by SMCs and collagen breakdown by interstitial (matrix metalloproteinases) collagenases generated by activated macrophages. Studies in collagenase-resistant mutant "knock-in" mice crossbred with *ApoE*$^{-/-}$ mice demonstrated increased intimal collagen and SMC content.[77] Similarly, compound mutant *ApoE*$^{-/-}$ mice crossed with MMP-13/collagenase-3$^{-/-}$ mice have increased fibrillar collagen that is thicker and more aligned in aortic atherosclerosis.[78] Hence, interstitial collagenases produced by activated macrophages greatly influence the structure and integrity of the fibrous cap overlying atherosclerotic plaques. Macrophages and SMCs within atherosclerotic plaques also overexpress the potent procoagulant tissue factor in response to C-reactive protein or CD40 ligand. Hence, inflammation links atherosclerosis and thrombosis, leading some to refer to it as "atherothrombosis."

Lymphocytes and Adaptive Immunity

The finding in the early 1980s that macrophages expressed the major histocompatibility class II antigens needed for antigen presentation to CD4$^+$ T cells suggested that adaptive immunity was involved in the atherosclerotic process.[79] T lymphocytes, which account for as much as 10% to 20% of the leukocyte population, are found most abundantly in the shoulder and fibrous cap region of the atheroma. In advanced lesions, these T cells display markers of chronic activation and produce the prototypical Th1 cytokine, (IFN-γ), which further stimulates expression of class II major histocompatibility antigens in SMCs and macrophages. The crossbreeding of severe combined immunodeficiency (SCID) mice that lack T and B cells with *ApoE*$^{-/-}$ mice produces offspring that are both hypercholesterolemic and immunodeficient. When lesions in these mice were compared with those in the immunocompetent *ApoE*$^{-/-}$ animals, a dramatic 70% reduction of lesion size was observed. However, transfer of oxidized LDL-reactive T cells to *ApoE*$^{-/-}$/SCID mice is more efficient at lesion acceleration than the transfer of T cells with no specificity to a plaque-derived antigen, demonstrating the importance of antigen presentation in the pathogenesis of atherosclerosis.[80]

Because of the participation of all components of the innate and adaptive immune system, atherosclerosis resembles other inflammatory and autoimmune diseases such as rheumatoid arthritis and type 1 diabetes mellitus. Potential endogenous autoantigens that activate T cells include LDL or heat shock protein 60.[80,81] Cellular and humeral immune responses are mounted toward these antigens in humans and mice, and protective immunization strategies in mice have provided encouraging results.

In mice, functionally distinct T cell subsets appear to exist in atheroma. Natural killer T cells appear to accelerate atherosclerosis when recognizing lipid antigens presented through CD1 molecules.[82] Conversely, regulatory T cells may suppress Th1 effector cells through production of antiinflammatory cytokines such as IL-10 and transforming growth factor-β (TGF-β).[83] T cells, although far fewer in number than macrophages, likely serve as key regulators of the concerted immune response.

Mast cells are located at the shoulder and more central area of the cap, where they may participate in rupture or erosion of the cap.[84] Once recruited to the subendothelial space in the intima, they can perpetuate and amplify the ongoing inflammatory response that led to their recruitment.[85] The CD40 receptor and CD40 ligand are expressed by several inflammatory cells, including macrophages and B and T lymphocytes.[86] It is thought that this system contributes to leukocyte adhesion, matrix degradation, and cytokine-induced inflammation. Interruption of the CD40 signaling pathway reduces progression of atherosclerosis in experimental models.

Smooth Muscle Cells

Proinflammatory mediators can stimulate the migration of SMCs from the tunica media into the intima. Growth factors produced locally provide a paracrine stimulus for SMC proliferation and activation. Activated SMCs appear capable of producing growth factors (e.g., PDGF, fibroblast growth factors) that can stimulate their own proliferation and that of their neighbors in an autocrine and paracrine fashion.[87] TGF-β stimulates the production of matrix and collagen in the subendothelial space. As the plaque matures, necrotic foam cells contribute to the central lipid core, whereas collagen contributes to the overlying fibrous cap of a mature fibroatheroma.

Calcification

Bone morphogenetic protein-2 (BMP-2), a member of the TGF-β family, and inorganic phosphate induce the osteochondrogenic phenotype in SMCs.[88] BMP-2, in turn, is produced by endothelial cells exposed to hypoxia, reactive oxygen species, turbulent flow, high pressure, or inflammation.[88] Atherosclerotic calcification proceeds through a process similar to chondrogenesis, whereby cartilaginous metaplasia precedes osteoblast induction. This is distinct from medial artery calcification, which proceeds through a process similar to intramembranous bone formation. The latter is common in patients with diabetes or chronic kidney disease. The reason that some plaques undergo calcific changes whereas others do not is not clear.

Thus, the inflammatory reaction stimulated by modified LDL and white blood cells in the subendothelial space provides a nidus for the subsequent events leading to the formation of mature fibrocalcific atherosclerotic plaque. Notably, this process, which probably begins in childhood, is silent until sufficient arterial stenosis exists or until a catastrophic plaque-destabilizing event occurs and produces a clinical symptom.

Putting It All Together: The Inflammasome

Clinically, cholesterol is an established causative risk factor for atherosclerosis. Recent evidence has shown that crystalline cholesterol is present early in the formation of atherosclerotic lesions and coincides with the presence of immune cells.[89,90] Cells of innate immunity are equipped with receptors that detect pathogen-associated molecular patterns and endogenous danger signals. Once these receptors are activated, monocytes and macrophages secrete inflammatory cytokines such as IL-1β into the arterial wall. In the last 10 years, considerable efforts in several laboratories have established a role for the interleukin 1 family in complex diseases, including atherosclerosis, diabetes mellitus, rheumatoid arthritis, and gout. As discussed earlier, IL-1β has several layers of regulation and is synthesized as pro-IL-1β and requires activated caspase-1 to cleave pro-IL-1β and IL-18 into their active and secreted form. Caspase-1 activation requires a second signal mediated through a complex of intracellular proteins known as inflammasomes. The nucleotide-binding domain leucine-rich (NLR) family pyrin domain–containing 3 (NLRP3) inflammasome has been most extensively studied. When NLRP3 receptors are activated, they oligomerize and recruit caspase-1 through the adapter protein ASC (apoptosis-associated speck-like protein containing a caspase recruitment domain) and autocatalytically activate caspase-1, which cleaves pro-IL-1β into its mature forms.[91] NLRP3 inflammasome activation historically included pore-forming toxins, extracellular adenosine triphosphate, viral DNA, and gout-associated uric acid crystals. However, recent evidence demonstrates that cholesterol crystals can also activate the inflammasome and therefore increase secretion of the potent proinflammatory cytokines IL-1β and IL-18. These data argue that cholesterol crystals are not solely an inert byproduct within the wall of the artery but an active contributor to atherosclerosis.[89,90]

Moreover, hypercholesterolemic *Ldlr*$^{-/-}$ mice reconstituted with bone marrow from mice deficient in NLRP3, ASC, or IL-1β have significantly reduced aortic lesion sizes compared with those reconstituted with wild-type bone marrow.[89] These mice showed significantly lowered levels of IL-1β and IL-18. The implication of caspase-1 was evaluated recently in atherosclerosis as a pathogenic enzyme because this deficiency decreases atherosclerosis in apoE-deficient mice.[92] Hence, within the vascular wall, lipids and inflammation appear to be inextricably linked.

C-Reactive Protein

The clinical detection of inflammation within the vascular wall is limited to the measurement of spillover circulating biomarkers of the inflammatory process. Many prospective studies have established an association between biomarkers of inflammation and first and recurrent cardiovascular events. For example, studies have noted that the circulating soluble ICAM-1 and VCAM-1 are elevated in the plasma of patients before the development of peripheral arterial disease.[93] Similarly, the inflammatory cytokines IL-6 and IL-1β, as well as acute-phase reactants C-reactive protein, fibrinogen, and serum amyloid A, have all been associated with peripheral arterial disease and its progression.[94,95] Among the many inflammatory biomarkers evaluated, high-sensitivity C-reactive protein (hsCRP) has emerged as the leading biomarker for clinical application. This is because CRP is a very stable analyte over time, has a relatively long half-life, has no diurnal variation, and requires no special processing for sampling.[96] In addition, very low (<0.5 mg/L) and very high (>10 mg/L) values of hsCRP both provide important prognostic information on cardiovascular risk.[97,98]

Currently, more than 20 large prospective studies across North America and Europe demonstrate the relationship between the baseline inflammatory state, as measured by hsCRP, and the risk for future cardiovascular events. Furthermore, in 28,000 apparently healthy women, hsCRP was a stronger predictor of cardiovascular events (including coronary events, stroke events, and cardiovascular death) than LDL cholesterol, total cholesterol, or other markers of inflammation and thrombosis.[99,100] Prediction models for future cardiovascular risk demonstrate that hsCRP enters the model just behind high blood pressure but ahead of smoking and total and LDL cholesterol.[101] The predictive value of hsCRP for cardiovascular

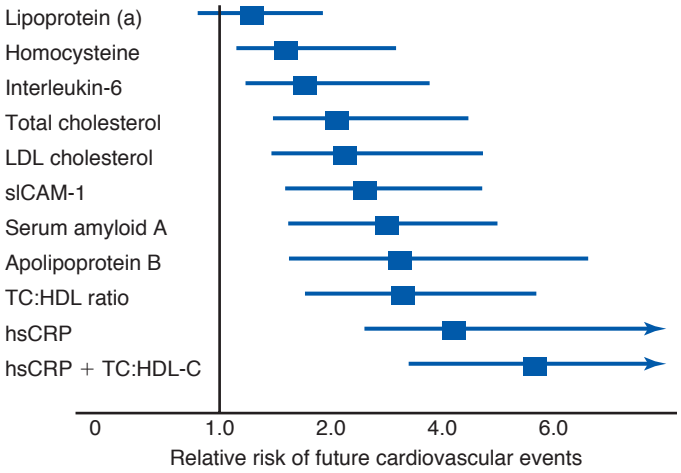

Figure 4.3 Comparison of lipid and nonlipid risk factors for cardiovascular disease (CVD) in 28,000 women enrolled in a nested case-control study from the Women's Health Study cohort of postmenopausal, apparently healthy women. hsCRP adds to the total predictive value of cholesterol. Note that lipoprotein (a) and homocysteine are relatively weak predictors of CVD. *HDL,* High-density lipoprotein; *hsCRP,* high-sensitivity C-reactive protein; *LDL,* low-density lipoprotein; *sICAM-1,* soluble intercellular adhesion molecule-1; *TC,* total cholesterol.

risk is similar in the United States and Europe, thus demonstrating consistency in different populations.[102] hsCRP is predictive in both primary and secondary prevention. In the Pravastatin or Atorvastatin Evaluation and Infection Therapy—Thrombolysis in Myocardial Infarction 22 (PROVE IT-TIMI 22) study, patients with acute coronary syndromes and the fewest subsequent events were those who reached LDL cholesterol levels of less than 70 mg/dL (1.81 mmol/L) and those who reduced their CRP levels to less than 2 mg/L (19.1 mmol/L).[103,104] Accordingly, hsCRP is at least as robust a biomarker for predicting future cardiovascular events as are traditional cholesterol-based biomarkers (Fig. 4.3).

The recently completed Justification for the Use of Statins in Primary Prevention: An Intervention Trial Evaluating Rosuvastatin (JUPITER) adds further circumstantial evidence of the role inflammation plays in atherosclerosis. The primary objective of JUPITER was to determine whether treatment with rosuvastatin would reduce the rate of first major cardiovascular event in patients with normal cholesterol levels but high levels of inflammation.[105] The inclusion criteria of the trial stipulated that patients have a median hsCRP greater than 2.0 mg/L (median 4.2 mg/L) and LDL levels less than 130 mg/dL (median, 108 mg/L). The trial was terminated early because rosuvastatin resulted in a 44% reduction in the composite primary endpoint of MI, stroke, hospitalization for unstable angina, arterial revascularization, and cardiovascular death. Of particular interest to the surgical community was the 46% reduction in arterial revascularization and 48% reduction in stroke in patients allocated to rosuvastatin. The latter is particularly intriguing given the favorable data for statins in patients with carotid stenosis.[106-108] Thus, the JUPITER trial determined that individuals with elevated levels of inflammatory biomarkers are at high vascular risk even when other risk factors are acceptable. Further, individuals at increased risk due to inflammation benefit from therapy they otherwise would not have received.[109] Whether or not reducing inflammation with a drug that does not also modify lipids is an intriguing hypothesis that is currently being tested.[110]

LOCALIZATION OF ATHEROSCLEROSIS

The propensity of atherosclerosis to occur at specific sites in the arterial tree has been observed since the time of Anitschkow's cholesterol-fed rabbits.[108] Other investigators noted increased incorporation of 3H-thymidine into endothelial cells at branch sites in animals not exposed to injury; this was thought to be due to hemodynamic consequences.[111-113] Insull and colleagues found that atherosclerosis was predominantly located at intercostal branch points of the human thoracic aorta.[114]

Only recently have the molecular mechanisms underlying this phenomenon become elucidated. Areas of well-developed laminar shear stress are relatively resistant to atheroma formation, whereas areas of turbulent or low shear stress (such as the carotid bifurcation) are more susceptible to atherosclerosis. Shear stress response elements occur in the promoter regions of a number of atheroprotective genes. Endothelial nitric oxide synthase (eNOS) is the product of one such gene. Laminar shear increases eNOS activity and thus nitric oxide (NO) production, which renders endothelial cells more thromboresistant and results in less adhesion molecule expression and decreased SMC migration. NO reduces VCAM-1 gene expression through a novel pathway involving the inhibition of nuclear factor κB (NF-κB). Superoxide dismutase is expressed at higher shear stress and may reduce oxidative stress by catabolizing the highly reactive superoxide anion O_2^-. Thus, areas of high laminar shear stress have antiinflammatory and antioxidant properties and exhibit less adhesion to circulating leukocytes.

Branch points, bifurcations, and major curvatures disrupt laminar flow and cause boundary layer separation, flow reversal, and shifting stagnation points. Such areas are characterized by increased particle contact time with the luminal surface, which may favor lipid deposition. Hemodynamic forces may predispose specific areas of the arterial tree to atherosclerosis when the appropriate risk factors are present. Areas of arterial branch points demonstrate elevated NF-κB activity.[115] CAM-1, an NF-κB–dependent protein, is expressed on the endothelium at arterial branch points even in normocholesterolemic animals. Disrupted laminar flow may promote a phenotypic transition in arterial cells that favors a proliferative state. NF-κB binds to several areas in the cyclin D1 promoter and stimulates the G1-to-S transition in the cell cycle.[116] Alternatively, laminar shear stress induces the cyclin-dependent kinase inhibitor p21 and suppresses the G0/G1-to-S phase transition.[117]

Hence, fluid mechanical forces influence endothelial gene expression through certain response elements sensitive to shear stress. Endothelial dysfunction, characterized by decreased NO production, promotes vessel wall entry and modification of circulating LDL. Therefore, it is possible that the differential regulation of endothelial genes by distinct flow profiles allows

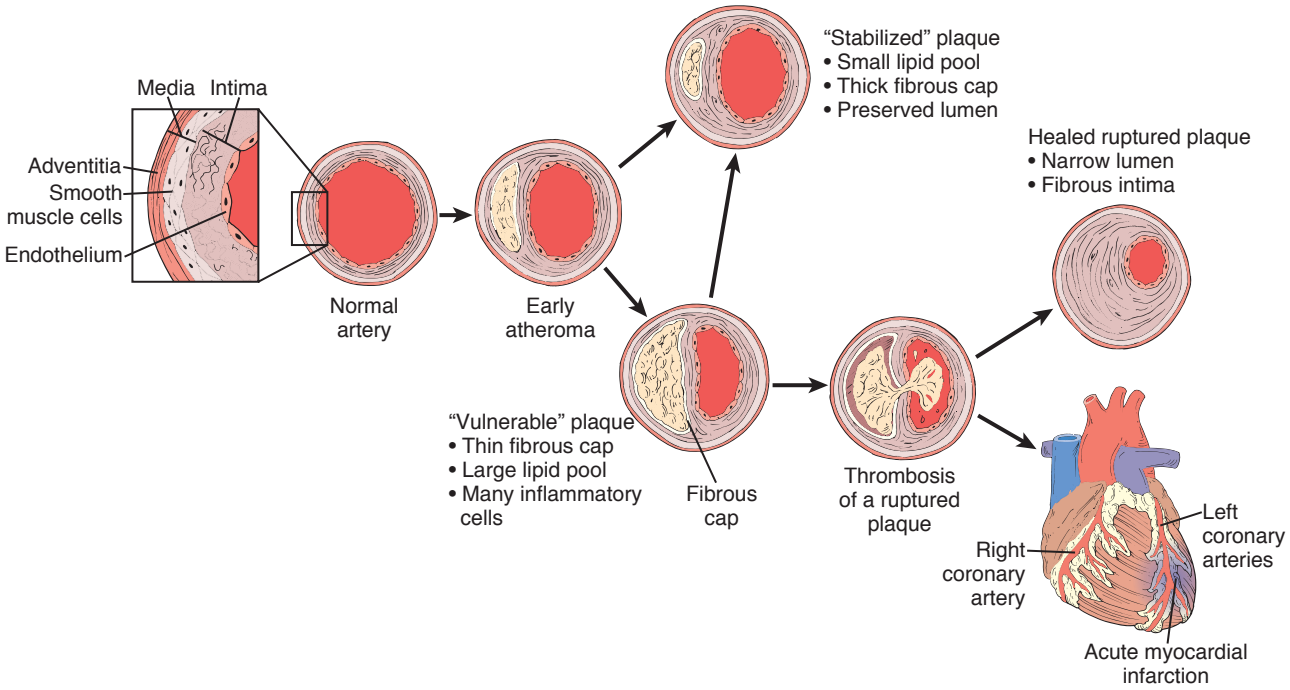

Figure 4.4 Life cycle of human atherosclerotic plaque. Rather than relentless progressive enlargement, human atherosclerotic plaque may undergo periods of progression, regression, and growth spurts. As the plaque extrudes into the lumen, the vessel undergoes compensatory enlargement, which preserves the lumen. The so-called vulnerable plaque consists of a relatively large lipid core and a thin (<100 mm) fibrous cap. Thrombotic complications can occur as a result of cap rupture, superficial endothelial erosion, intraplaque hemorrhage, or erosion of a calcified nodule in which circulating blood elements come in contact with the thrombogenic lipid core. The fate of such an event may be manifested as a myocardial infarction, transient ischemic attack, or in situ thrombosis of a lower extremity artery. Far more commonly, however, they result in a nonocclusive thrombus inciting a healing response. These healed ruptures result in a fibrous plaque with a narrowed lumen. (From Fowkes FG, Rudan D, Rudan I, et al. Comparison of global estimates of prevalence and risk factors for peripheral artery disease in 2000 and 2010: a systematic review and analysis. *Lancet*. 2013;382:1329–1340.)

certain areas of the vasculature to more effectively resist the influence of risk factors such as hyperlipidemia and diabetes.

PROGRESSION/REGRESSION OF PLAQUES

DePalma and others, in an important series of experiments, noted progression and regression of atherosclerosis in canines and subhuman primates by serial laparotomy and autopsy examinations.[118-121] The observation that plaque reduction correlated with a reduction in serum cholesterol paved the way for cholesterol-lowering trials in laboratory animals with bile acid sequestrants to test the hypothesis that reduced serum cholesterol would reduce plaque burden.[120,121] The success of these early animal trials engendered considerable optimism that atherosclerosis was not universally progressive and eventually leads to lumen occlusion. Hence our current understanding of atherosclerotic plaque emphasizes a dynamic evolution.

Serial angiographic studies of human coronary arteries demonstrate periods of intermittent growth spurts followed by relative quiescence.[122,123] What may account for the nonuniform progression of these atherosclerotic lesions? One prevailing theory suggests that most plaque disruptions with in situ thrombus formation do not always proceed to total occlusion and clinical sequelae, but instead are clinically silent (Fig. 4.4). Though unnoticed by the patient or clinician, they are far from benign. The local nonocclusive platelet thrombus induces a healing response with local inflammatory cytokine and growth factor production. TGF-β and PDGF stimulate SMC collagen production and migration. Thrombin production accelerates SMC migration and proliferation, and fibrin stimulates wound contraction and progressive luminal narrowing.[124,125] Healed fibrous cap ruptures can be detected microscopically by the identification of breaks in the fibrous cap with a surrounding repair reaction consisting of a proteoglycan-rich mass or collagen-rich scar.[126] Thus, in contrast to slow steady plaque growth in which compensatory enlargement of the vessel may protect from luminal encroachment, acute plaque rupture with nonocclusive thrombosis may signal a cascade of events leading to a fibrous atheroma and constrictive remodeling. Whether this mechanism is operative in peripheral vessels (e.g., femoropopliteal arteries) remains to be determined.

The use of cross-sectional images by IVUS reveals that segments of arteries that appear normal by angiography may nonetheless harbor substantial atherosclerotic disease.[127] Through morphometric studies of nonhuman primates and detailed autopsy studies of human coronary arteries, we understand that

vessels undergo compensatory enlargement (remodeling) and recognize that lumen encroachment is a relatively late occurrence in the evolution of atherosclerotic plaque.[128,129]

More recently, IVUS has been used to document plaque progression/regression in human coronary arteries with intensive statin treatment.[130,131] The Reversal of Atherosclerosis with Aggressive Lipid Lowering (REVERSAL) trial measured the rate of disease progression in patients treated with either 40 mg of pravastatin or 80 mg of atorvastatin. LDL was reduced to 79 mg/dL (2.05 mmol/L) in the atorvastatin arm versus 110 mg/dL (2.85 mmol/L) in the pravastatin arm, and CRP was reduced 36.4% versus 5.2%. This resulted in a significant change in the primary endpoint of total atheroma progression of −0.4% in the atorvastatin arm versus 2.7% in the pravastatin arm.[131] In an open-label trial known as A Study to Evaluate the Effect of Rosuvastatin on Intravascular Ultrasoundr Ultrasound to EvAtheroma Burden (ASTEROID), 80 mg of rosuvastatin resulted in a change in atheroma volume of −0.98% over a 24-month treatment period. Collectively, these trials suggest that atherosclerotic plaque, far from being fixed, is a dynamic and mutable lesion that may regress in response to intensive hypolipidemic therapy. These trials also reflect the clinical benefit seen in the intensive treatment arms in trials such as PROVE IT-TIMI 22 and provide further rationale for recommendations of reducing LDL cholesterol below 100 mg/dL (2.59 mmol/L).[132] Further effort is needed to determine whether intensive statin therapy can reduce the progression of atherosclerotic disease in other vascular territories, such as the femoral arteries.

THROMBOTIC COMPLICATIONS OF ATHEROSCLEROSIS

A significant amount of resources in vascular surgery are expended in caring for the acute thrombotic events complicating atherosclerosis and in situ thrombosis of the peripheral circulation. These catastrophic clinical syndromes often occur suddenly and without warning.

In the coronary circulation, various lines of evidence reveal that generally the culprit lesions are not necessarily those associated with the tightest stenosis.[133-135] This is not to say that high-grade stenosis does not undergo thrombotic complications; on a per-lesion basis, the individual probability of a complication from a high-grade lesion is higher than the probability from a less severe lesion.[136] However, because noncritical stenoses outnumber lesions producing critical stenosis, the total probability of a thrombotic complication attributable to the noncritical stenosis is higher. It must also be remembered that these assessments are based on standard planar angiography and do not take into account compensatory enlargement. Thus, low-grade stenosis does not necessarily equate with smaller lesions. Other variables such as inflammation also contribute to plaque rupture.

Physical disruption of the atherosclerotic plaque rather than critical stenosis can commonly precipitate arterial thrombosis. Four mechanisms of plaque disruption may cause thrombosis or rapid plaque expansion.[13] Each may be operative in different vascular territories or with a different constellation of risk factors. For example, complete fracture of the plaque's fibrous cap causes most cases of fatal coronary thrombosis.[137] Plaque rupture is probably caused by both mechanical and biologic factors.[138,14] Physical forces acting on the shoulder region of the plaque, where circumferential wall stress and cap fatigue are the greatest, render this area particularly vulnerable, especially when the central lipid core accounts for greater than 40% of the total lesion area and the cap is relatively thin, (less than 100 μm).[139] Inflammation within the plaque may destabilize the cap and potentiate injury by hemodynamic factors. Macrophages and mast cells degrade the extracellular matrix by phagocytosis and secretion of proteolytic enzymes.[140] SMCs and macrophages, when stimulated by inflammatory cytokines, produce MMPs including collagenases, elastases, gelatinases, and stromelysins, which degrade the matrix of the fibrous cap and result in thinning and weakening.[141-146] It is now apparent that endothelial cells, SMCs, and macrophages all increase the expression of the CD40 ligand and its receptor under the direction of the inflammatory cytokines. Ligation of CD40 in turn upregulates the production of MMPs, inflammatory cytokines, and tissue factor, thus emphasizing the autocrine and paracrine nature of the local inflammatory response of the fibrous cap.[143-146]

Once the plaque is fractured, blood is exposed to the underlying thrombogenic substrate and thrombosis ensues. Tissue factor initiates the extrinsic clotting cascade and is a major regulator of coagulation and thrombosis. Thrombus formation and platelet adhesion create further stenosis and thrombotic occlusion. As previously mentioned, most thrombotic complications of plaque lead to progression of stenosis rather than occlusion of the artery. Cigarette smoking, hyperglycemia, and elevated LDL cholesterol all increase blood thrombogenicity.[147] These same risk factors are characterized by endothelial abnormalities such as increased generation of superoxide anion and decreased endothelium-derived NO.[148,149-151] Thus risk factors are linked to progression of atherosclerosis and to its thrombotic complications at susceptible areas in the vascular tree through abnormalities in blood coagulation, as well as endothelial function.

Although complete fracture of the fibrous cap may be the most common cause underlying coronary thrombosis, other mechanisms may be more important in the periphery. Intraplaque hemorrhage can transform an asymptomatic carotid plaque into a symptomatic lesion and produce transient ischemic attacks or stroke. Neovascularization and proliferation of the vasa vasorum, as in diabetic retinopathy, may produce a local microvascular network that is fragile and friable. Intraplaque hemorrhage can cause rapid plaque expansion and thinning or disruption of the cap. Superficial plaque erosion producing in situ thrombus without plaque rupture is prevalent in patients with diabetes and in women.[13,152] Apoptosis of endothelial cells may promote superficial erosion, and various inflammatory stimuli may promote apoptosis.[153] In particular, macrophage-derived myeloperoxidase may be operative in that it promotes both tissue factor generation and endothelial cell apoptosis, thus linking superficial erosion and in situ thrombosis.[154] Finally, erosion through the intima of a calcified nodule represents another

less common form of atherosclerotic thrombosis that may be relevant in both the coronary and peripheral circulations.

Distinct artery-dependent patterns of atherosclerosis probably account for differences in the pathogenesis of thrombotic-related complications.[155] Both coronary and carotid atherosclerotic plaques appear to be laden with foam cells and to have large lipid cores; plaque rupture or intraplaque hemorrhage is common. In the femoral artery, plaque is more commonly fibrous without extensive foam cells. Here, it is likely that superficial plaque erosion and erosion of a calcific nodule more commonly lead to thrombosis.

IDENTIFICATION OF VULNERABLE LESIONS

How does one predict a priori which patients may be more likely to progress from an asymptomatic carotid lesion to one with symptoms? Who will develop an MI following noncardiac vascular surgery or the progression of a stenosis in the superficial femoral artery at Hunter's canal? After all, many patients do perfectly fine with stable 60% carotid bifurcation disease or stable claudication. Understanding of the in vivo structural, functional, and biologic aspects of an atherosclerotic lesion may identify plaques that are "vulnerable" to either progression or symptomatic transformation.

Identification of such vulnerable lesions has been an area of intense recent work. As discussed previously, IVUS evaluation determines the true extent of the size of the atherosclerotic plaque as opposed to what is visible on angiography, the latter of which dramatically underestimates the true dimensions of the lesion. IVUS can detect the degree to which an artery has remodeled in response to a plaque. For instance, it has been determined that excessive expansive remodeling may result in a thin vulnerable plaque.[156]

Impaired endothelial vasodilator function is seen in patients with cardiovascular risk factors, and cardiovascular risk factors predict coronary events and stroke. Brachial artery flow-mediated vasodilation has been used as a surrogate for the more relevant coronary circulation.[157,158] Impaired flow-mediated vasodilation is seen in patients with inflammation and in those with classic risk factors,[159,160] and it is often present before symptoms of peripheral or coronary arterial disease are evident.[161] Impaired flow-mediated vasodilation has also been demonstrated to predict adverse events in patients undergoing vascular surgery.[162-164] Hence, the classic Framingham risk factors, as well as inflammation, appear to impair endothelial function and promote atherosclerosis.

Finally, molecular imaging is on the immediate horizon to help identify vulnerable plaque. For example, plaque with active inflammation may be identified by extensive accumulation of macrophages. Successful detection of plaque inflammation with magnetic resonance imaging was possible with gadolinium-loaded micelles coupled with antibodies to the scavenger receptor.[165] Alternatively, computed tomography may be used with a novel iodinated nanoparticulate contrast agent to detect inflammation in atherosclerotic plaque.[166] Contrast-enhanced ultrasound may also be used by attaching VCAM-1 to microbubbles and identifying areas of active adhesion molecule expression.[167]

CONCLUSION 63

Intimal hyperplasia is the universal response of vessels and grafts to injury and describes a chronic structural change occurring in denuded arteries and arterialized vein and prosthetic bypass grafts. Intimal hyperplasia has been more narrowly defined as the abnormal migration and proliferation of vascular smooth muscle cells with the associated deposition of extracellular connective tissue matrix that is then followed by remodeling of this new tissue (Table 5.1). Its development can be chronologically subdivided into hyperacute, acute, and chronic stages reflecting the timelines of classical wound healing. Macroscopically the chronic lesion appears firm, pale, and homogeneous. The involved area in the vessel is smooth and uniformly located between the endothelium and the internal elastic lamina of an artery or between the endothelium and the medial smooth muscle cell layer of a vein graft. The distribution pattern of intimal hyperplastic lesions may be diffuse throughout a vessel, focal at an anastomosis, or focal within the body of the vessel. The biology of a vessel's response to injury is complex and has many biologic targets that testify to the therapeutic dilemma it poses to control. Arterial injury, venous injury, and prosthetic graft incorporation share many common mechanisms (coagulation, inflammation, cell proliferation, cell migration, proteases and extracellular matrix [ECM], and remodeling) but should be considered distinct biologies.

RESPONSE OF THE ARTERY TO INJURY

Angioplasty may be considered a controlled injury to the vessel wall (Figs. 5.1 and 5.2). The immediate response of the vessel to injury is the hemostatic response. Endothelial denudation exposes the subendothelial matrix and leads to platelet adherence and aggregation. Platelet accumulation occurs in a rapid but time-dependent manner which appears to last approximately 8 to 10 hours after injury.[1] The rationale for the use of aspirin across the cardiovascular specialties and the short-term use of dextran infusions after carotid endarterectomy stem from this important observation. Platelet levels on the surface have been noted to decrease from days 3 to 7. Platelet adhesion requires the interaction of subendothelial collagen with three platelet membrane glycoprotein receptors (GPIb, GPIc/GPIIa, and GPIa/GPIIa), plasma von Willebrand factor, and fibronectin. These observations have been used as the biologic rationale for the use of glycoprotein IIb/IIIa inhibitor class of drugs after percutaneous coronary interventions.[2,3] Elements of the coagulation cascade (tissue factor, factor V, factor VIIa, factor Xa, or α-thrombin) will modulate intimal hyperplasia development following angioplasty. Controlling the coagulation cascade early is the key to preventing the phenomenon of early stent thrombosis within 30 days. Coupled to the hemostatic response on the surface, apoptosis (programmed cell death) can be identified at 1 to 2 hours within the wall and appears to abate by 4 hours.[4] No apoptosis can be identified in the wall after injury at 3 days, but by day 7, 50% of the cells again show signs of apoptosis and by day 14, the number of apoptotic cells is again markedly decreased. Enhancing immediate apoptosis is one of the biologic benefits attributed to cryoangioplasty.[5]

Following vessel wall injury, there is a robust inflammatory response with polymorphonucleocytes (PMNs) and monocytes adhering to the subendothelial surface. There is a predictable

sequential expression of inducible cell surface molecules in both endothelial cells and smooth muscle cells after experimental angioplasty.[6,7] Compared with the uninjured endothelium, regenerating endothelial cells show high levels of VCAM and ICAM expression; this pattern of expression appears to follow the leading edge of the regenerating endothelium. Within 10 days, smooth muscle cells show expression for both ICAM and class II MHC antigens. However, by 30 days the expression of adhesion cell molecules in endothelial cells and smooth muscle cells returns to the pattern observed in uninjured vessels. Chemokines and their family of receptors have been shown to participate at every step of the remodeling process.[8] The monocyte chemotactic protein (MCP)-1/CC motif receptor 2 (CCR2) axis induces monocyte infiltration of the injured vessel wall and can stimulate smooth muscle cell proliferation. The RANTES (Regulated upon activation, normally T-cell expressed, and presumably secreted) receptors CC motif receptor 1 (CCR1) and CC motif receptor 5 (CCR5) help to regulate this monocyte infiltration into the injured vessel and expansion of the intimal hyperplasia. Reconstitution of the endothelium over the injured area appears to depend on CXC motif ligand 1 (CXCL1), which is augmented by stromal cell–derived factor (SDF)-1 alpha and its receptor CXC motif receptor 4 (CXCR4) recruiting VSMC progenitor cells to the injured vessel wall during the early phases of the injury response.

Cytokines including tumor necrosis factors, interleukins, lymphokines, monokines, interferons, colony-stimulating factors, and transforming growth factors (TGFs) are produced by both the inflammatory infiltrate and the cells of the vessel wall after injury.[9] The various cytokines interact with specific receptors on various cell types and activate JAK-STAT, NF-κB, and Smad signaling pathways leading to an inflammatory response, cell adhesion, proliferation migration, and apoptosis. Cytokines are also linked to increase production of mitochondrial reactive oxygen species, activation of Ca^{2+}, and multiple intracellular protein kinase pathways. Cytokines also interact with integrins and matrix metalloproteinases (MMPs) and modify ECM composition, a key component of the developing neointima.[10] In humans, targeted therapy against interleukin-1α has shown a trend toward lower incidence of restenosis following SFA interventions in humans.[11] Exogenous G-CSF will increase the

TABLE 5.1 Stages of Intimal Hyperplasia Development

	Vessel Lumen	Vessel Wall
Stage 1		
Hyperacute (minutes–hours)	Endothelial cell denudation	SMC injury
	Platelet aggregation	Activation of SMC
	Release of growth promoters	Proto-oncogene expression
		Release of growth promoters
Stage 2		
Acute (hours–weeks)	Organization of thrombosis	Medial SMC replication
	Endothelial cell ingrowth	Medial SMC migration
	Release of growth inhibitors	Infiltration of leukocytes
	Progenitor cell deposition	Infiltration of adventitial cells
		Infiltration of progenitor cells
		Synthesis of growth promoters
		Synthesis of growth inhibitors
Stage 3		
Chronic (weeks–months)	Re-endothelialization change of luminal dimensions	Intimal SMC replication
		Intimal SMC synthesis of ECM
		Remodeling of ECM
		Synthesis of growth inhibitors
		Vessel remodeling

ECM, Extracellular matrix; *SMC*, smooth muscle cell.

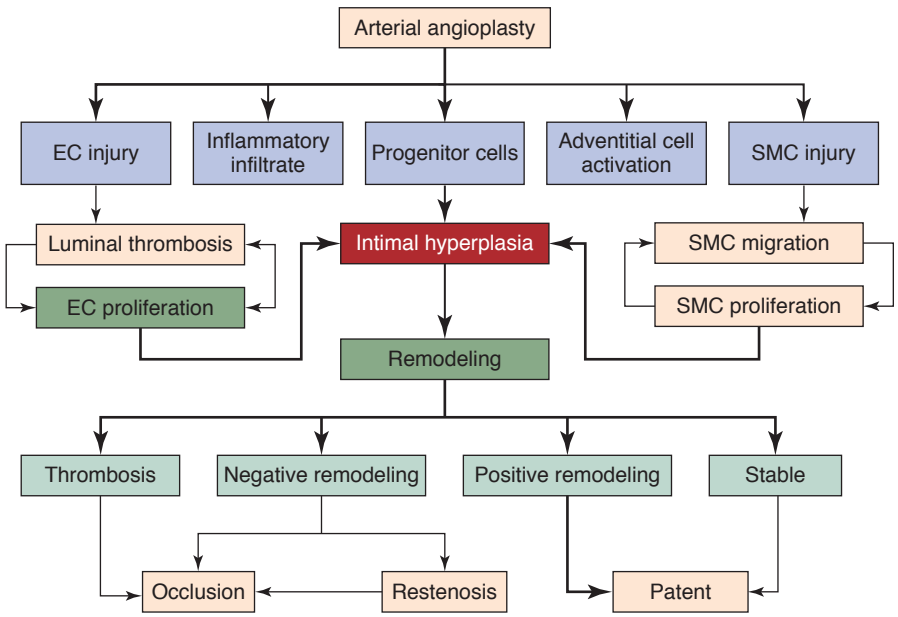

Figure 5.1 Pathobiology of the Injury Response After Angioplasty. Flow diagram demonstrating the key elements in the vessel's response to arterial injury. Endothelial cell (EC) injury leads to luminal thrombosis, inflammatory cell infiltration, cellular proliferation, and clearance of the thrombotic material on the surface with development of a neoendothelium. Injury to smooth muscle cells (SMCs) and adventitial cells leads to cell proliferation and migration. Progenitor cells are recruited to the vessel wall. With the migration of proliferation of SMC and adventitial cells, the appearance of progenitor cells and the deposition of extracellular matrix, intimal hyperplasia develops. Over time this lesion remodels and may either remain stable or demonstrate positive remodeling with an in luminal diameter or negative remodeling with a decrease in luminal diameter. These chronic changes in the intimal lesion can lead to continued patency, restenosis, or occlusion.

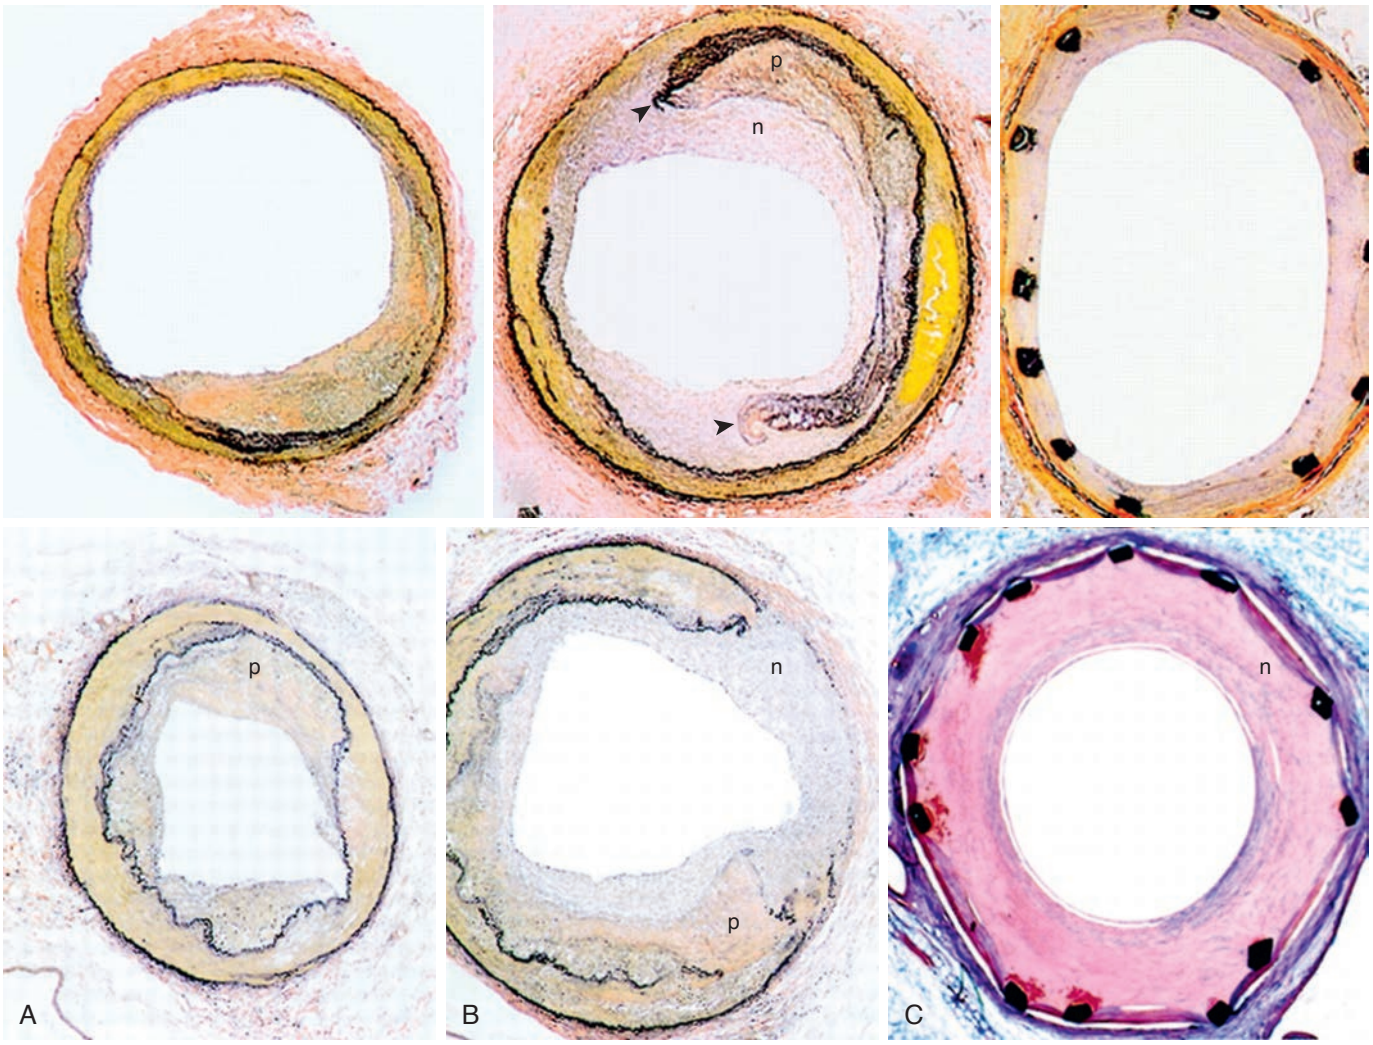

Figure 5.2 **Photomicrographs of Stented Vessel. Upper Panel:** Atherogenic diet induced complex intimal lesions shown in uninjured iliac artery **(A)**. Contralateral iliac artery was removed 35 days after experimental angioplasty **(B)**. Angioplasty has fractured the preexisting plaque (p; *arrowheads*) and injured the overlying media, with neointimal ingrowth (n). Palmaz stents were deployed in the proximal left subclavian artery, and after 35 days, neointimal ingrowth has covered the underlying plaque and stent struts **(C)**. Original magnification: **A** and **B,** ×40; **C,** ×100. All panels, Verhoeff-van Gieson stain. **Lower Panel:** Composite photomicrograph demonstrates a typical response 4 weeks after angioplasty and stenting. **A** and **B** show the uninjured and injured common iliac arteries, respectively, and panel **C** shows the stented external iliac artery. Animals consumed an atherogenic diet for 2.5 years, thus creating complicated plaques (p). **B** shows fractured plaque (p) and overlying media that have healed with neointimal ingrowth (n). **C** shows a stented external iliac artery with a typical neointimal lesion (n). Vessels were from a single treated animal. **A** and **B,** Verhoeff-van Gieson stain; **C,** trichrome stain; original magnification all panels, ×40. (**Upper Panel:** Reproduced with permission from: Deitch JS, Williams JK, Adams MR, et al. Effects of beta3-integrin blockade (c7E3) on the response to angioplasty and intra-arterial stenting in atherosclerotic nonhuman primates. *Arterioscler Thromb Vasc Biol*. 18(11);1998:1730–1737. **Lower Panel:** Reproduced with permission from: Cherr GS, Motew SJ, Travis JA, et al. Metalloproteinase inhibition and the response to angioplasty and stenting in atherosclerotic primates. *Arterioscler Thromb Vasc Biol*. 2002;22(1):161–166.)

number of circulating EPCs and result in rapid and nearly complete (>90%) reendothelialization of the angioplastied artery. This is paralleled by a decrease in inflammation in the vessel wall and a reduction in neointimal thickness.[12]

Smooth muscle cell proliferation within the media, which is normally less than 1%, increases to more than 20% within 48 hours after angioplasty.[13-17] The exact mechanisms, whereby smooth muscle cell proliferation is initiated, controlled, reduced, and eventually suppressed, are still not fully understood. Growth factors can regulate the proliferation of endothelial cells, the proliferation and migration of smooth muscle cells and adventitial cells, and the secretion of ECM throughout the vasculature. The first phase of smooth muscle cell proliferation appears to be driven by bFGF released from dead and damaged cells in the vessel wall following injury. The plasminogen activator, urokinase, also plays a role in bFGF activation and release.

Four weeks after injury the medial proliferative response returns to baseline levels. Intracoronary radiation after angioplasty inhibits this first wave of cell proliferation and prevents adventitial proliferation but also prevents reendothelization.[18]

By day 8 after the injury, smooth muscle cells are observed on the luminal side of the internal elastic lamina and appear to have migrated to the luminal surface through fenestrations in the internal elastic lamina. The mass of cells in the wall is augmented by circulating mesenchymal cells *(vide infra)* that subsequently differentiate into smooth muscle cells. The number of smooth muscle cells in the intima increases to a maximum at 2 weeks after injury, and approximately 30% of medial smooth muscle cells may migrate from the media to the intima. This migration of cells requires the degradation of the cage of matrix surrounding each cell by proteases and the synthesis of new matrix molecules. Migration of the smooth muscle cells from the media to the intima across the internal elastic lamina is mediated in part by both the receptor tyrosine kinase–linked agonists (PDGF, basic fibroblast growth factor, and hepatocyte growth factor) and the G-protein coupled receptor agonists (vascular endothelial cell growth factor, chemokines, LPA, thrombin, and uPA). Inhibition of the PDGR receptor PDGFR-β/β with parenteral chimeric antibodies that have been shown to be effective in animal models has failed to limit restenosis in human trials.[19-21] Smooth muscle cell migration is unaffected by irradiation and antimitotic drugs.

Once within the intima, approximately 50% of the smooth muscle cells proliferate, and this second phase of smooth muscle cell proliferation is first noted at day 7 and reaches a maximum at 14 days before returning to baseline by 28 days.[17] However, it may continue for up to 12 weeks in those areas where reendothelialization takes longer to complete. Thus a potential weakness of drug-elution techniques is inhibition of reendothelialization and a reinforcement of the proliferative responses. The second phase of smooth muscle cell replication in the intima appears to be mediated by autocrine and paracrine factors and remains poorly understood. It also appears that the thickness of the intimal hyperplasia peaks within 1 month, and its rapid development is due to both cellular elements and the production of the ECM (i.e., proteoglycans). Although the total number and volume of smooth muscle cells in the intima remains unchanged after 12 weeks, there is a decrease in the cellular fraction of the intima composed of smooth muscle cells as the ECM volume rises. This continued slow increase in intimal hyperplasia is the result of the synthesis and the accumulation of connective tissue components such as collagen and proteoglycans. In human restenotic lesions, staining for hyaluron was inversely related to collagen I and III staining. Little proteoglycan accumulation occurs over the first 1 to 2 months but dramatically increases from 3 to 6 months after balloon injury and then decreases gradually thereafter in restenotic human coronary atherosclerotic plaques.[22] In atherectomy specimens, zones of collagen and proteoglycan can be identified. The collagen-rich zone contains elongated smooth muscle cells closely packed together, and in these zones, collagen I, elastin, and biglycan predominate. In contrast, proteoglycan-rich zones contain both elongated and stellate smooth muscle cells, which are widely spaced. Versican and biglycan predominate in these areas, whereas elastin is sparsely identified.[23]

Changes in the ECM do not occur independent of changes in the smooth muscle cells. The cells sense these changes through integrins. Integrins are essential cell surface proteins that allow cells to interact with their environment and more particularly with the individual components of the ECM. There is an inverse correlation between the expression of the higher affinity form of β1 integrin and the migration and proliferation of smooth muscle cells and endothelial cells after arterial injury.[24] One of the principal cytokines involved in controlling ECM responses is TGF-β.[25] As collagen products increase in the ECM, "contractile" intimal smooth muscle supported by increased fibroblasts in the adventitia can lead to contraction and "negative" remodeling. This final event in the development of intimal hyperplasia has been used as a rationale for stent placement because it can prevent the luminal loss due to contraction of the vessel.

Bone marrow cells do contribute to the pathogenesis of lesion formation after mechanical vascular injury.[26-28] Associated with the changes in the intima and media, there are substantial changes in the adventitia, as evidenced by an increased cell proliferation and growth factor synthesis after angioplasty. Within the adventitia a marked infiltrate of cells termed "myofibroblasts" is observed by day 2, which by day 14 can represent up to 50% of cells within the intima.[29,30] The presence of myofibroblasts is common in wound healing and leads to contraction of the wound. A similar phenomenon may occur in the healing vessel. Injured vessels may undergo chronic elastic recoil or negative remodeling, which results in loss of luminal dimensions without a further increase in neointimal area. Retrieved atherectomy material from primary and restenotic lesions has shown that the proportion of cells that can be demonstrated to be proliferating in the restenotic lesion is low[31] but that the migratory activity and collagen synthesis of the human smooth muscle cells from the restenotic lesions are greatly elevated, strongly supporting that remodeling is important in the final determination of luminal diameter.[32,33]

The degree of intimal hyperplasia that develops in a vessel is dependent on the length and depth of the injury.[34] Minimal intimal proliferation occurs when the media is uninjured, but intimal hyperplasia increases in proportion to the depth of the medial injury, indicating that the proliferative response reflects the direct injury to the smooth muscle cells.[35,36] In addition, distension of smooth muscle cells without significant endothelial cell injury has been shown to result in smooth muscle cell proliferation. The length of the injury influences the duration of the reendothelialization process. Reendothelialization occurs from the margins of the denuded area and possibly from the endothelial cells of the vasa vasorum. The longer there is an incomplete endothelial cell covering, the greater time the smooth muscle cells are without the modulating influence of the endothelial cells and the longer the replication phases of the smooth muscle cells will be.[37,38] After deep vessel wall injury, luminal narrowing may be less dependent on intimal hyperplasia formation and more dependent on vessel wall remodeling.[39] Medial damage is accompanied by a massive adventitial cell

proliferation,[40] which in time provides cells capable of contraction and negative remodeling.

Hemodynamics

Acute distension of a vessel without substantial endothelial cell damage results in a low level of smooth muscle cell proliferation.[41] Deformation of smooth muscle cells leads to activation of protein tyrosine kinases, which may be an additional mechanism, whereby smooth muscle cell proliferation occurs.[42] Furthermore, limited vessel wall injury without associated subintimal dissection or direct media exposure increases transmural fluid flux, thus allowing soluble proliferogenic mediators to gain access to the media of a vessel.[43] Changes in hemodynamic parameters have been shown to affect the arterial structure of both normal and diseased vessels.[44] Clinical studies have suggested that after femoral angioplasty in patients with extensive distal disease, the rate of restenosis is increased. In an experimental study, Hehrlein confirmed that reduced vascular runoff after angioplasty results in the increased development of intimal hyperplasia.[45] Blood flow (closely associated with shear stress) is best associated with the formation of intimal hyperplasia, whereas deformation of the vessel wall in a circumferential direction is best associated with medial thickening.[46] Kohler[47,48] has shown a correlation between a reduction of intimal thickness, which forms early after angioplasty and an increase in flow, and between an increase in intimal hyperplasia and a decrease in flow, suggesting a direct effect of flow on smooth muscle cell function. However, they did not observe a similar change in mature intimal hyperplastic lesions, which had developed under conditions of normal flow, and were then subjected to either increased or decreased blood flow conditions.

Systemic Vascular Diseases

The development of intimal hyperplasia in a vessel with an already established atheromatous or hyperplastic lesion has considerable implications on the use of angioplasty as a primary endovascular procedure due to the fact that it mirrors the clinical situation. There is a limited understanding on the effects of preexisting vascular diseases on the subsequent development of intimal hyperplasia in the postoperative period. Clinically, hyperlipidemia and diabetes are associated with higher rates of post PTCA restenosis.[49-52] Exposure to cigarette smoke increases the development of experimental intimal hyperplasia by two fold.[53] Cholesterol reduction therapies with statins have been shown in some studies to reduce the development of restenosis,[54,55] whereas others have suggested that such therapy carries no long-term effect on restenosis because of the complex biology leading to a more acute restenotic response.[56]

Diabetes is a predictor for restenosis. Tissue from restenotic plaques in diabetic patients is composed primarily of atherosclerotic plaque rather than hypercellular tissue. This might suggest that recoil/remodeling may be predominant.[57] The medial response is more pronounced in the diabetic balloon-injured rat carotid.[58] Advanced glycosylation end products (AGEs) accumulate in vascular tissues with aging and at an accelerated rate in diabetes. AGEs are particularly abundant at sites of atherosclerotic lesions.[59] AGEs interact with specific receptors (RAGEs) present on all cells relevant to the restenosis process, including inflammatory cells and smooth muscle cells. AGE-RAGE interaction in the vessel wall may lead to inflammation, smooth muscle cell proliferation, and ECM production, culminating in exaggerated intimal hyperplasia and restenosis. Following arterial injury, the interaction of AGEs with monocytes expressing RAGEs can promote migration of inflammatory cells into the lesion and subsequent release of growth factors and cytokines. Binding of AGEs-RAGEs on smooth muscle cells increases chemotactic migration and cellular proliferation and can augment ECM production by upregulating TGF-β. Thus accumulation of AGEs in the vessel wall provides a common mechanism for the high restenosis rates of patients with diabetes.

Intravascular Bare Metal Stents

The biology of in-stent restenosis is different from that seen after balloon angioplasty.[60] A stent is generally used if the result of balloon angioplasty is technically unsatisfactory or if there is arterial occlusion, immediate elastic recoil, dissection, or restenosis (Fig. 5.3; see also Fig. 5.2). The response of a vessel to a stent is dependent on the stent design, length, composition, delivery system, and deployment technique.[61] In-stent restenosis is classified on the basis of length of restenosis in relation to stented length. Four categories of in-stent restenosis have been defined: (1) focal (≤10-mm length), (2) diffuse (>10-mm length), (3) proliferative (>10-mm length and extending outside the stent), and (4) occlusion.[62] After balloon angioplasty, there is thrombus formation, intimal hyperplasia development, elastic recoil, and negative remodeling. In contrast, after stent placement, elastic recoil and negative remodeling are eliminated[63] and thrombus formation followed by intimal hyperplasia development are the main contributors to in-stent restenosis.[64,65] Patients with diabetes and prior restenosis have a higher rate of in-stent restenosis,[66] and there is a correlation with in-stent thrombus and prolonged hyperglycemia.[67] Stent placement in a vessel results in both a generalized injury to the length of the vessel exposed and more focal injures at the areas of strut apposition to the wall.

Intravascular ultrasound has demonstrated that stents do not always completely appose the vessel wall along their entire length, thus resulting in uneven injury along the length of the stent.[63] After stent placement, the surface of the metal implanted into the vessel is covered by a strongly adherent monolayer of protein within 5 seconds. After 1 minute the surface is covered by fine layers of proteins, predominantly fibrinogen.[68] The holes between the stent struts are filled with thrombus, and the adherence of platelets and leukocytes is enhanced by disturbance of electrostatic equilibrium.[69,70] The basic mechanisms of smooth muscle cell proliferation and migration after stent placement are the same as those after balloon injury.[71] The intimal hyperplastic process in a stent is more prolonged and robust than in a balloon-injured artery and is proportional to the depth of injury the recipient vessel sustains[72] and the inflammatory response induced[73]; it can often be much more significant at the ends than in the body of the stent (see Fig. 5.2). In addition, the adventitial

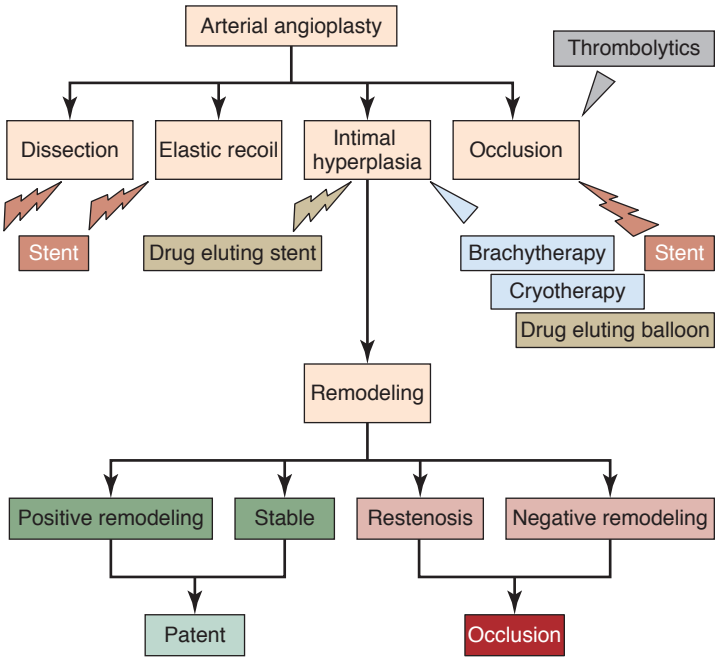

Figure 5.3 Consequences and Cures of Angioplasty. Flow diagram demonstrating the outcomes of a vessel's response to balloon angioplasty and the therapeutic maneuvers to correct the adverse outcomes. If a technical failure occurs after angioplasty due to elastic recoil or dissection, a stent is placed. If there is concern for the development of intimal hyperplasia, brachytherapy or cryotherapy may be applied. Sudden occlusion is corrected with thrombolysis or primary stenting. Remodeling will be influenced by placement of stents, drug-eluting stents, brachytherapy, or cryotherapy.

response is prolonged, with adventitial giant cell body formation being noted. Stents prevent chronic elastic recoil and cause progressive atrophy of the media.[74] Risk factors for late stent thrombosis include penetration of necrotic core, malapposition, overlapping stent placement, excessive stent length, and bifurcation lesions. Early after stenting in humans (≤11 days), fibrin, platelets, and acute inflammatory cells are always present in association with stent struts.[75] The degree of stent–arterial wall interface influences the severity of associated inflammation; increased numbers of inflammatory cells were seen when the stent strut is adjacent to injured media or lipid core rather than fibrous plaque. Chronic inflammation occurs adjacent to stent struts at all time points, especially greater than 12 days after stenting. Plaque compressed by stent struts is seen in 91% of vessel sections with penetration of the stent struts into the lipid core a common event.[75] A neointima containing smooth muscle cells develops within 2 weeks, and histologic success or failure of the stent is determined by neointimal growth within the stent and not influenced by artery or stent size. Neointimal thickness is increased when medial damage is present compared with struts in contact with atherosclerotic plaque or an intact media. Furthermore, increased intrastent neointimal growth is found in histologic failures, and increased neointimal area correlates with increased stent size relative to the proximal reference artery lumen. Therefore stent oversizing relative to the reference lumen appears to be an undesirable goal in deployment. Despite these histologic changes, neointimal cell density and the composition of the proteoglycan deposition in coronary stents were similar to those in matched PTCA coronary vessels.[75,76]

Intravascular Drug-Eluting Stents

Current successful drug-eluting stents (DESs) require a polymer coating for drug delivery.[77] Sirolimus-, paclitaxel-, and more recently, ABT-578–eluting stents are commercially available; each has demonstrated marked reduction in restenosis through decreases in smooth muscle cell proliferation. However, endothelial cell migration and proliferation are also decreased, and induction of tissue factor expression through specific interaction with signal transduction mediators occurs. These effects lead to an increased thrombogenic potential of DES.[78] The presence of a DES also decreases proliferation, differentiation, and homing of endothelial progenitor cells, which are believed to contribute to reendothelialization after stent implantation.[79] Furthermore, both rapamycin and paclitaxel have been demonstrated to induce endothelial dysfunction in the coronary vasculature distal to the stent.[80] Finally, the polymer used for DES can be associated with hypersensitivity reactions, which may, at least in some cases, favor stent thrombosis.[81]

Intravascular Drug-Eluting Balloons

The use of drug-eluting balloons (DEBs) is driven by the findings that short exposure of an artery to a drug (e.g., paclitaxel) delivered by a coated angioplasty balloon is sufficient for the attainment of an adequate tissue concentration of paclitaxel.[82] The chief benefit cited for DEBs is the avoidance of additional metal and polymer barriers, the presence of which may disrupt or hinder vascular healing, as discussed. However, DEB-treated vessels show delayed vascular healing characterized by dose-dependent increases in fibrin deposition, delayed re-endothelialization, lower number of neointimal cells, and increased medial VSMC loss.[83-85] The differences in reendothelialization may explain the observations that DEB-treated arteries behave generally similarly to plain balloon–treated vessels, regarding the endothelium-dependent vasodilation, but similarly to DES-treated arteries, and lead to proneness to vasoconstriction at 7 days and slow normalization of endothelium-independent vasodilation.[84]

RESPONSE OF VEIN TO INJURY

Saphenous veins demonstrate a spectrum of preexisting pathologic conditions ranging from significantly thickened walls to postphlebitic changes and varicosities at the time of harvest. Histologically, 91% of saphenous veins have moderate to severe fibrosis in the vein wall. In one study, 2% to 5% of veins were unusable and up to 12% can be considered "diseased."[86] These "diseased" veins have a patency rate one-half that of "nondiseased" controls. The etiology of the venous diseases observed are multifactorial in origin, and without gross morphologic evidence of disease there is currently no clear prognostic indicator to discriminate those veins that should be rejected as grafts.[86,87]

Intimal hyperplasia is the universal response of a vein graft to insertion into the arterial circulation and results from both the migration of smooth muscle cells out of the media into the intima and proliferation of these smooth muscle cells (Fig. 5.4). Whether the same series of events occurs in a vein graft as an injured artery remains to be determined. Progenitor cells may play a larger role in the vein graft than in the artery. It appears that in experimental models, many endothelial cells of vein grafts are derived from circulating progenitor cells and up to one-third appear to be derived from bone marrow progenitor cells.[88] In general, intimal hyperplasia is a self-limiting process that does not produce luminal compromise and usually becomes quiescent within 2 years of graft insertion. However, in focal areas the intimal hyperplastic process can proceed to significant stenosis.[89-92] Studies of peripheral vein grafts have documented that the majority of stenotic lesions that develop in a graft are composed of intimal hyperplastic tissue.[91,92] Graft stenoses develop at sites of unrepaired defects or early appearing conduit abnormalities[93] but not at the sites of valves or tributary ligation.[94]

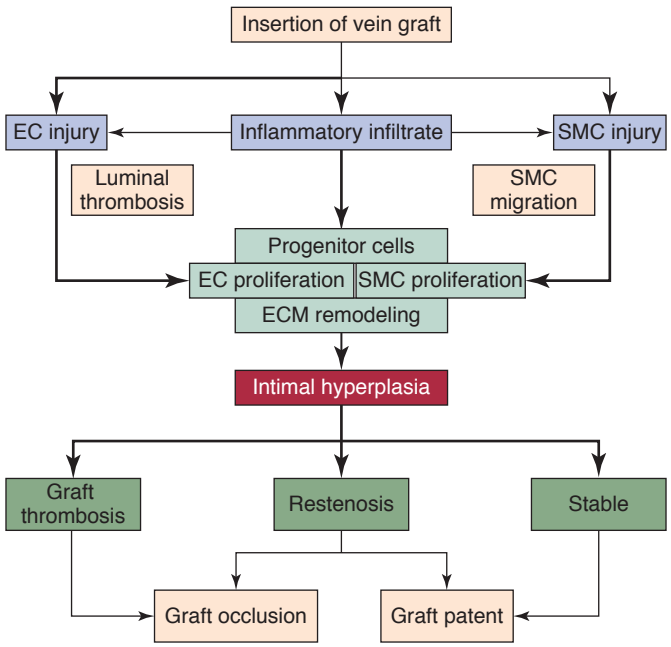

Figure 5.4 Pathobiology of the Vein Graft Response to Implantation. Flow diagram demonstrating the key elements in the vein's response to insertion into the arterial circulation. Denudation of the endothelium is dependent on the degree of implantation injury. Endothelial cell (EC) injury leads to luminal thrombosis, inflammatory cell infiltration, cellular proliferation, and clearance of the thrombotic material on the surface with restoration of the endothelium. If this fails to progress adequately, graft thrombosis may occur. Injury to smooth muscle cells (SMCs) leads to cell proliferation and migration. Progenitor cells are recruited to the vessel wall. With the migration of proliferation of SMC, the appearance of progenitor cells and the deposition of extracellular matrix (ECM), intimal hyperplasia develops to reestablish the tangential stress across the wall. Over time this lesion remodels and may produce a stenotic lesion due to the bulk of neointima or due to negative remodeling restenosis. This may result in graft occlusion.

Perioperative manipulations of veins prior to their insertion have been shown to produce significant tissue damage. Such implantation injury leads to endothelial dysfunction, endothelial cell injury, endothelial denudation, and smooth muscle cell injury, all of which are important factors in the initiation of intimal hyperplasia. It is now recognized that every effort should be made to reduce the degree of implantation injury that a vein graft suffers.[95-98] There appears to be a direct relationship between the morphologic integrity of the vein graft prior to grafting and its later histopathologic appearance and function.[96,98] Poorly prepared vein grafts develop significantly greater intimal hyperplasia and increased smooth muscle cell contractility compared with carefully prepared vein grafts.[96,98] Evidence suggests that deformation of smooth muscle cells by arterial hemodynamics can lead to activation of protein tyrosine kinases and thereby initiate smooth muscle cell proliferation.[42] Vein grafts with lower flows are associated with greater intimal thickening.[99] For example, a 50% reduction in arterial blood flow increased intimal hyperplasia by 60% and medial hypertrophy by 17% in arterial vein grafts after 4 weeks.[100] Other studies have suggested a role for increased wall tension in the development of intimal hyperplasia.[101,102]

With few exceptions, patients who undergo vein bypass grafting have a significant degree of arteriopathy and concomitantly have one or more atherogenic risk factors present. Hypertension in both human and experimental models does not affect the development of intimal hyperplasia in the short or long term.[103-106] Furthermore, it appears that hypertension is not associated with the later development of vein graft atherosclerosis.[103] In contrast, both experimental and clinical studies have shown an association of hyperlipidemia with the development of intimal hyperplasia/atherosclerosis and with higher vein graft failure rates.[103,107,108] Clinically, diabetes does not appear to impact significantly on vein graft patency, but experimentally it does increase short-term intimal hyperplasia development.[103,109] In cases of combined hypertension and hyperlipidemia, there appears to be no additive effect on intimal hyperplasia development in vein grafts compared with hyperlipidemia alone. However, in contrast, the combined presence of diabetes and hyperlipidemia has a significant additive effect on the formation of intimal hyperplasia in experimental vein grafts. The intimal hyperplastic lesions of vein grafts retrieved 1 month after aortocoronary bypass in humans have been shown to consist of proliferating smooth muscle cells with only scattered macrophages in the subendothelium.[110] With particular regard to peripheral vein graft stenoses, no association has been found with patient age, sex, presenting symptoms, hypertension, diabetes, or the condition of the outflow vessel. The incidence of stenosis appears higher the more distal the anastomosis is placed.[111]

Several peripheral factors may also play a role. Increased plasma fibrinogen concentrations have been identified as a potent risk factor for vein graft stenosis.[112] Increased homocysteine concentrations are also associated with increased incidence of vein graft stenosis.[113] Antibodies to cardiolipin are associated with infrainguinal vein bypasses failure.[114] Other studies have suggested that platelet dysfunction and lipoprotein (a) may be associated with an increased risk of stenosis development.[115,116] Smoking and plasma fibrinogen, lipoprotein (a), and serotonin concentrations are associated with the development of postoperative infrainguinal graft stenosis.[111,116,117] Others have suggested that there is no association between preoperative serum lipoprotein (a) and homocysteine levels and the frequency of 1-year graft occlusions.[118]

Lower serum cholesterol levels are associated with lower rates of vein graft occlusive disease for up to 7 years,[119] and high patency rates can be achieved in familial hypercholesterolemia in association with aggressive lipid-lowering therapy.[120] The Post CABG NHLBI study has shown that although saphenous vein graft atherosclerosis worsens with increasing age, lipid-lowering therapy can significantly reduce the probability of saphenous vein graft disease, regardless of the time of initiation of lipid-lowering therapy.[121] Glemfibozil retarded the progression of coronary atherosclerosis and the formation of bypass graft lesions after CABG in men with a low level of HDL cholesterol.[122]

Vein grafts retrieved from patients with angiographic evidence of occlusive disease demonstrate histologic features of atherosclerosis.[104,105,123-126] The earliest these lesions have been seen is 6 months after implantation. Thus, it appears that these late occlusions of vein bypass grafts are due to the development of a rapidly progressive and structurally distinct form of atherosclerosis which has been termed "accelerated atherosclerosis" to distinguish it from "spontaneous atherosclerosis."[90] Accelerated atherosclerosis is morphologically different from spontaneous atherosclerosis in that its lesions appear to be diffuse and more concentric and have a greater cellularity with varying degrees of lipid accumulation and mononuclear cell infiltration. The syndrome of accelerated atherosclerosis shares many of the pathophysiologic features of intimal hyperplasia; however, the prime mediators of this type of atherosclerosis are likely to be the macrophage. In addition, the endothelium overlying accelerated atherosclerotic lesions expresses the class II antigens, which are not observed in spontaneous atherosclerosis.

HEALING RESPONSE OF THE PROSTHETIC GRAFT

Studies of retrieved human polytetrafluorethylene (PTFE) grafts have shown that between 5 and 24 days after implantation, red blood cells and fibrin cover the anastomotic lines and some of the luminal surface. Macrophages can be found scattered throughout these thrombi. Between 11 and 48 months, one finds either a single layer of endothelial cells or a thin layer of fibrin covering the anastomotic segments of the graft. At this time, smooth muscle cells and collagen can be identified as a developing anastomotic intimal hyperplasia. From 94 to 149 months after implantation, this anastomotic intimal hyperplasia is relatively unchanged, with the same thickness and length as that seen in grafts retrieved between 11 and 36 months. Chronic inflammatory cells (macrophages, lymphocytes monocytes, and giant cells) can be identified in incorporated ePTFE grafts.[127] Perigraft tissue infiltration and tissue encapsulation occurs mainly in the external region of the prosthetic graft and increases with duration of implantation. Fibrous tissue penetrates the wall and partitions off the outer layer. The presence of external reinforcement does not effect this tissue infiltration.[128] Luminal surfaces of graft explanted between 94 and 149 months are covered by a connective tissue matrix with superposed scattered thrombi.[129] No current evidence exists that prosthetic grafts inserted into the human circulation are able to fully develop an endothelialized intima along the entire flow surface, which is in contrast to the majority of experimental models studied.[128] Rather, endothelial cells manage to populate the luminal surface in just the few centimeters near the anastomoses. The remainder of the graft is usually covered with a thin irregular layer of organized fibrin, containing platelets and leukocytes, interspersed with areas of exposed PTFE.[128,130] The incidence of lipid and cholesterol deposits is high,[131] and atheromatous changes have also been detected in retrieved PTFE grafts.[132] Staining for collagen type III is predominant, although collagen subtypes I, IV, and V can also be identified. No type II collagen is detectable. Elastin fibrils are seen within the anastomotic neointimal hyperplasia.[133]

Formation of the neo-endothelium in a PTFE graft can occur through two processes, transmural endothelialization by capillary ingrowth and endothelialization by migration from the anastomoses. Capillary ingrowth through the graft wall depends upon the porous characteristics of the graft. The porosity of the PTFE has a significant effect on these phenomena. In low-porosity grafts (10- and 30-μm internodal distance) placed in the aortoiliac position in the baboon, luminal endothelial coverage is limited to small areas near the anastomoses.[134] In higher-porosity grafts (60 and 90 μm), luminal endothelial coverage is complete.[135,136] A second process whereby endothelialization of PTFE grafts occurs is ingrowth from the anastomoses. Transmural fibrocapillary incorporation of PTFE vascular grafts provides a key supporting structure essential to the progression and attachment of endothelial cell ingrowth from the anastomoses. Porosity of the graft is important because nonporous grafts have a ragged and friable endothelial advancement zone.[137] New evidence in a canine model supports fallout endothelialization from the blood stream as a third possible mode of graft healing.[138] The process of neoendothelial healing can be divided into six stages: platelet aggregation phase (stage I), fibrin network phase (stage II), bridging phase (stage III), progression phase (stage IV-A), transmural migration phase (stage IV-B in thin wall long fibril length), intimal closure phase (stage V), and endothelial thromboresistance phase (stage VI).[139] In the ovine model, mural thrombosis is a prominent feature extending several centimeters from the venous anastomosis for up to 3 months after PTFE fistula placement. Over this 3-month period the thrombus is actively organized by invasion of macrophages and capillaries from adjacent areas of neointima and in places becomes covered by endothelial cells.[140] The process of healing

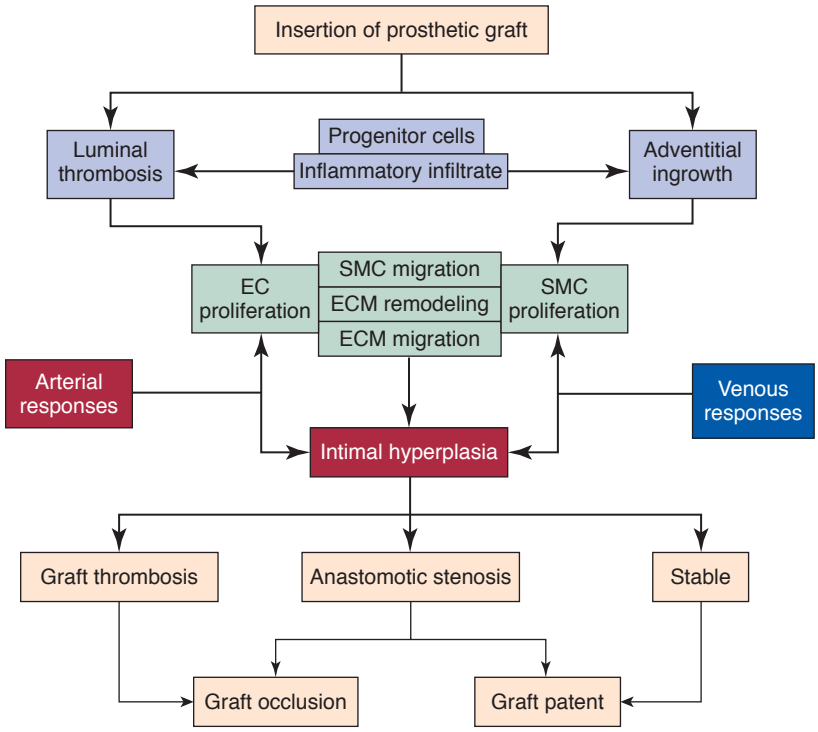

Figure 5.5 Pathobiology of the Prosthetic Graft Response After Implantation. Flow diagram demonstrating the key elements of the body's response to implantation of a prosthetic graft into the arterial or venous circulation. Luminal thrombosis and adventitial infiltration are associated with an inflammatory response and recruitment of progenitor cells. Injury to the endothelial cells (ECs) and smooth muscle cells (SMCs) at either the venous or arterial anastomosis leads to the development of intimal hyperplasia within the native vessel and ingrowth into the prosthetic conduit as a result of EC and SMC migration and proliferation occurs with the laying down of an extracellular matrix (ECM). Over time these lesions remodel and may produce a multifocal stenotic lesion at the anastomoses and in the floor of the recipient vessel.

in a prosthetic graft is shown in Fig. 5.5. Chronic administration of acetylsalicylic acid can prevent graft thrombosis between 2 and 4 weeks post implantation but does not appear to decrease distal anastomotic intimal hyperplasia development.[141]

INTIMAL HYPERPLASIA AND DIALYSIS ACCESS

Dialysis access grafts reflect an amalgamation of arterial, prosthetic, and venous intimal hyperplasia. Needle puncture sites are healed as a result of being filled in by surrounding connective tissue, and thus pseudoaneurysm formation is common at the puncture sites in the first 2 years.[142] Within the fistula, circumferential and valvular stenoses, and mural thrombi at needle sites can be identified angioscopically.[143] The anastomoses appear to be the areas of maximal intimal hyperplasia as a result of surgical trauma and the presence of flow disturbance. Two distinct regions of intimal thickening have been noted: one at the anastomotic site, which is greater in PTFE grafts than native vein, and the second in the floor of the artery, which is the same for both PTFE and native vessels.[144] The high failure rate of PTFE dialysis grafts is ascribed to problems in the venous distal outflow tract. The majority of stenoses occur at the venous anastomoses and within 1 cm of the anastomosis.[145] A greater initial mismatch in elastic properties between the vein and the graft and elevated local peak systolic velocity at the venous PTFE anastomoses correlates with the occurrence of anastomotic stenosis within the first 2 years.[146,147] Graft geometry can have a significant impact on internal hemodynamics and the development of venous intimal hyperplasia. The volume of the vibration signal set up by blood flowing through the relatively rigid PTFE graft has a better correlation with venous anastomotic intimal-medial thickness than either pressure or flow velocity.[148]

An end-to-end or end-to-side anastomosis has no impact on the intimal hyperplastic response in the recipient vein because flow stability, turbulence, and kinetic energy transfer are equivalent.[148] Venous anastomotic intimal hyperplasia develops in unbanded grafts, where flow is 100% greater than a banded equivalent and there is a direct correlation between the Reynold number and subsequent intimal hyperplasia development in the outflow vein.[149] Five anatomic stenotic lesions in arteriovenous fistula grafts have been categorized: stenosis in the draining vein proximal to the venous anastomosis (36%), stenosis in the central vein (24%), stenosis at the venous anastomosis (25%), stenosis at the arterial anastomosis (11%), and intragraft hyperplasia (4%).[150] The stenoses in these veins are intimal hyperplastic consisting of smooth muscle cells with extensive ECM. Proteoglycan was identifiable in the ECM close to the lumen, whereas collagen and elastin predominate deeper in the wall of the vein.[129] These venous intimal hyperplasia segments have significant neovascularization, and perivascular macrophages can be readily identified. There is intense staining for proliferating cell nuclear antigen (PCNA) in association with neovascularization. These PCNA-positive cells are both microvascular endothelial and smooth muscle cells and intimal hyperplasia smooth muscle cells.[151] In areas with a higher staining for PCNA within the intimal hyperplasia, there is intense perivascular staining for tenascin, prompting suggestions that there is an association of neovascularization with intimal hyperplasia formation.[152]

CONCLUSION

In summary, intimal hyperplasia remains a significant complication of vascular procedures, whether performed open or percutaneously. Substantial advances in our understanding of vessel wall physiology, biology, pharmacology, and pathology as it relates to the development of intimal hyperplasia have been made in the past two decades. However, we have not, as yet, managed to translate this knowledge into effective therapeutic regimens to allow us to control the progression of this disease. Therefore intimal hyperplasia remains the major short-term obstacle to patent angioplastied vessels and bypass grafts.

FUTURE DIRECTIONS IN ISCHEMIA-REPERFUSION INJURY 70

Recognition of ongoing lower extremity necrosis following successful revascularization in patients presenting with acute ischemia prompted the first reports of ischemia-reperfusion (I/R) injury in the 1950s.[1] Following these initial reports, canine models of cardiac I/R were used to correlate the ischemic time with subsequent risk of hemorrhagic necrosis.[2] These findings were further correlated with human adults undergoing aortic valve surgery, implicating I/R injury after cardiopulmonary bypass as a cause of death in these patients. Since these initial reports, I/R injury has been observed in multiple types of operations, including cardiac, vascular, transplant, and reconstructive, as well as following traumatic injury and heart failure. The clinical manifestations of I/R injury are a direct result of the biochemical aberrations that develop as a consequence of the two components of I/R injury—ischemic injury and reperfusion injury.

PATHOPHYSIOLOGY OF ISCHEMIA-REPERFUSION INJURY

The two phases of I/R injury—ischemic injury and reperfusion injury—are marked by unique cellular and systemic consequences. Understanding the complex interaction between the biologic responses during two phases informs the clinician to the expected clinical manifestations, as well as potential mechanisms to treat, and even prevent, these injuries.

Injury During Ischemia

The ischemic phase of I/R injury is marked by tissue hypoxia or anoxia and stasis of the microcirculation (Fig. 6.1). The temporal pattern of injury after ischemic injury depends largely on the baseline metabolic demands of the affected tissue. For instance, ischemic injury in the jejunum results after only 30 minutes, whereas human skeletal muscle can tolerate ischemic times beyond 2 hours.

Tissue ischemia results in shift from aerobic mechanisms of cellular respiration toward anaerobic because the mitochondria no longer have adequate O_2 levels to effectively produce adenosine triphosphate (ATP). ATP production no longer meets the metabolic needs of the cell, and, as a result, intracellular pH increases as lactic acid levels rise. The resultant change in intracellular pH inhibits further glycolysis and activates Na^+/H^+ antiporter in an attempt to return the intracellular pH to normal values. Due to ongoing ATP deficits, the Na^+,K^+-ATPase cannot adequately pump Na^+ out of the cell to deal with the influx. High intracellular Na^+ inhibits the Na^+/Ca^+ antiporter, resulting in high intracellular Ca^{2+} levels, activating degradative enzymes, such as phospholipase A2, and proteases, such as calpains. Prolonged ischemia results in cell membrane damage and necrotic cell death.

Mitochondrial injury during the ischemia phase not only results in decreased ATP production, but also contributes to the production and accumulation of reactive oxygen species

Abstract

Ischemia-reperfusion injury (I/R injury) represents a complex mechanism by which changes in both the intracellular composition and local tissue environment during periods of ischemia lead to ongoing cellular injury in the setting of reperfusion. Creation of reactive oxygen species and priming of the mitochondrial membrane permeability transition pore during ischemia are primary factors in determining cellular damage when perfusion is restored. These mechanisms, as well as the role of pro-inflammatory molecules, hypothermia and anticoagulants, are outlined here. Additionally, the clinical manifestations of I/R injury, especially within the lower extremity and renal vasculature, are discussed. Understanding of the factors contributing to I/R injury at the cellular level and familiarity with methods of treatment and prevention of I/R injury are essential to reduce the devastating impact on postoperative morbidity and mortality. Finally, the areas of ongoing research are explored, including the use of mesenchymal stem cells and storage advances within the transplant community.

Keywords

Ischemia-reperfusion injury
reactive oxygen species
compartment syndrome

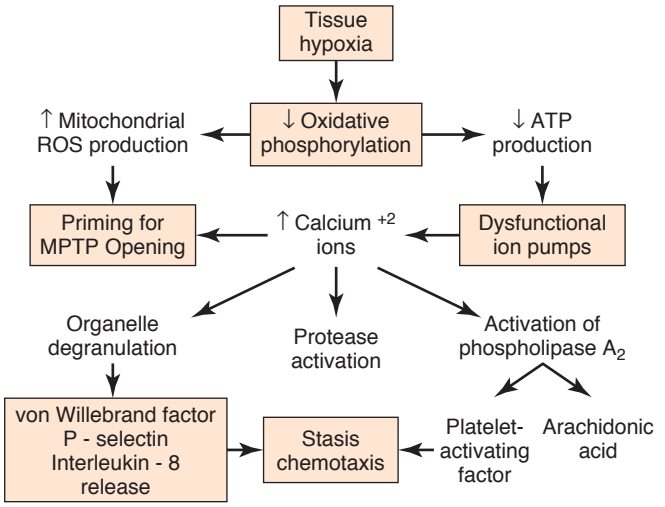

Figure 6.1 Injury During Ischemia. Decreased oxygen supply activates a complex cascade of metabolic, inflammatory, and prothrombotic pathways and sets the conditions for MPTP opening during reperfusion. *ATP*, Adenosine triphosphate; *MPTP*, mitochondrial membrane permeability transition pore; *ROS*, reactive oxygen species.

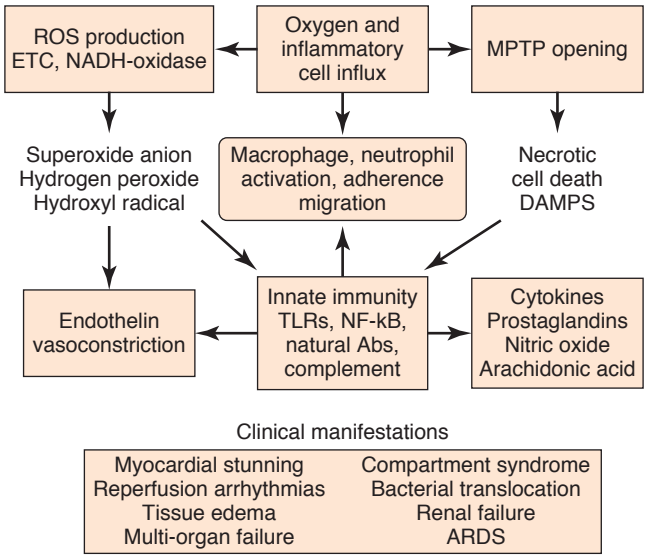

Figure 6.2 Injury During Reperfusion. The return of oxygen, influx of inflammatory cells, and washout of metabolites contribute to cell death and an inflammatory, prothrombotic milieu that exacerbates tissue injury. *Abs*, Antibodies; *ARDS*, acute respiratory distress syndrome; *DAMPS*, danger-associated molecular patterns; *METC*, mitochondrial electron transport chain; *MPTP*, mitochondrial membrane permeability transition pore; *NADH*, reduced nicotinamide adenine dinucleotide; *NF-κB*, nuclear factor kappa B; *ROS*, reactive oxygen species, *TLRs*, toll-like receptors.

(ROS).[3,4] Increases in the mitochondrial ROS concentration, in the setting of increased intracellular Ca^{2+} and elevation Pi levels, contribute to the priming of the mitochondrial membrane permeability transition pore (MPTP), an important component leading to necrotic cell death.[5,6] Indeed, data from Halestrap et al. indicate that the degree of ROS accumulation during ischemia is a key factor to determine the opening of the MPTP during reperfusion and the subsequent degree of tissue injury.[6a] During the ischemic phase, the low intracellular pH inhibits the MPTP opening. Pore opening upon return to normal intracellular pH during the reperfusion phase is a significant driver of necrotic cell death.

Tissue hypoxia results in movement of neutrophils and macrophages into the interstitium through the action of hypoxia-adaptive pathways.[7-9] Activated neutrophils subsequently release molecular mediators, including glutamate and adenine nucleotides, which contribute to the production of adenosine on the vascular endothelial surface, a protective factor that restores endothelial integrity.[10-12] Activated leukocytes also have significant proinflammatory consequences. Neutrophils release soluble factors that increase endothelial permeability and cytoskeletal rearrangement.[13] Data are emerging regarding the important role tumor necrosis factor-α (TNF-α), released from activated macrophages. TNF-α serves as an important proapoptotic agent through the induction of multiple cellular pathways, including NF-κB.[14] In addition, mechanisms that block TNF-α production have demonstrated protective effects against renal I/R injury in rat models.[15]

Injury During Reperfusion

Restoration of blood flow to an ischemic tissue bed results in a complex cellular and systemic response (Fig. 6.2). Paradoxically, this response often leads to further tissue injury than is seen during the ischemic phase alone. Insight into the mechanisms of reperfusion injury has led to the targeted studies for the prevention and mitigation of the deleterious effects of restoring blood flow to ischemic tissues.

Intracellular changes associated with reperfusion following ischemia include increased ROS production, increased sequestration of intracellular Ca^{2+} into mitochondria via the Na^{+}/Ca^{2+} antiporter and return toward normal intracellular pH.[5] As discussed with ischemic injury, mitochondrial damage is the primary determinant of tissue loss due to reperfusion.[16] Mitochondria are mediators of the multiple apoptotic and necrotic cell death pathways that result from ROS. ROS directly activate a family of proapoptotic proteins known as BH3-only proteins or trigger MPTP pore opening, resulting in increased permeability of the outer mitochondrial membrane and the release of proapoptotic proteins, such as cytochrome c.[17] Despite the MPTP typically being closed at normal pH, the combination of factors associated with the I/R injury, including ROS concentration, induces its opening and contribution to cellular injury.[18] Cytochrome c release may further be potentiated through the peroxidation of the mitochondrial protein cardiolipin, located on the inner mitochondrial membrane.[19] Loss of cytochrome c in the mitochondrial membrane results in decreased aerobic cellular respiration and increased ROS and ultimately stimulates increased apoptosis.[13,20-22]

Programmed cell death is further mediated by signaling from the TNF death receptor pathway.[23-25] Binding of circulating TNF to the TNF receptor 1 results in a conformational change in the receptor that promotes binding of cytosolic TNF receptor–associated death domain (TRADD) to the cytosolic domain of the receptor. The conformational change leads to the internalization of the receptor and production of secondary

cytosolic complexes, such as the necrosome. Two components of the necrosome, receptor-interacting protein 1 (RIP1) and receptor-interacting protein 3 (RIP3) undergo ROS-dependent phosphorylation and are thought to play a role in MPTP opening and subsequent cell death.[23,24] Evidence from cardiac models of I/R injury has outlined RIP3 activation of Ca^{2+}-calmodulin-dependent protein kinase II (CaMKII) as a trigger for MPTP opening and regulated cell death.[26] In these models, deficiencies in RIP3 and inhibition of CaMKII reduce myocardial necrosis resulting from I/R injury. In addition, TNF binding to the TNFR1 receptor may initiate the nuclear factor kappa B (NF-κB) proinflammatory pathway, described later.[24]

Activation of cell death pathways leads to the release of proteins and protein fragments that are typically sequestered within the cell, as well as cell surface accumulation of oxidatively modified proteins and lipids on the cell surface, triggering an immune response. Recognition of these surface moieties by the innate immune system as "danger-associated molecular patterns" (DAMPS) through activation of the toll-like receptors (TLRs) results in subsequent proinflammatory pathways.[27,28] Multiple reperfusion-associated DAMPS and their associated TLR targets have been identified, including heat shock protein 60 (HSP60), a ligand for TLR4; high-mobility group protein B1 (HMGB1), a ligand for TLR2, 4, and 9; low-molecular weight hyaluronic acid, a ligand for TLR2 and 4; and cardiac myosin, a ligand for TLR2 and 8.[29] Ligand binding to TLRs initiates TLR signaling pathways that result in cell necrosis through apoptosis or potentiation of the inflammatory response through signaling mediated by NF-κB.[29] NF-κB is a transcription factor in the cytosol in an inactive complex with inhibitor of NF-κB (I-κB). TLR signaling cleaves the I-κB component of the complex, allowing NF-κB to translocate to the nucleus and initiate the transcription of genes encoding multiple proinflammatory proteins, including TNF-α, interleukin-1β (IL-1β), IL-6, and intercellular adhesion molecule-1 (ICAM-1).[28,30,31] The presence of upregulated TLR-mediated apoptosis and cellular necrosis has been demonstrated in I/R injury in nearly all tissue types, including intestinal, cerebral, cardiac, hepatic, and renal.[32-36]

Activation of the complement cascade is also a significant mediator of tissue injury during ischemia and reperfusion. DAMPS also play an important role in antibody-mediated pathways of complement activation in I/R injury.[31] The dominant antibody class is immunoglobulin M (IgM).[27] The antibodies recognize epitopes formed by the oxidative modification of lipids and proteins that were translocated to the cell surface during reperfusion. In addition, cell damage sustained during I/R injury results in presentation of self-antigen that would have normally been sequestered from the immune system, such as myosin heavy chain II.[37] IgM binding to extracellular or cell surface epitopes induces the complement cascade, resulting in cell targeting via C3b binding and neutrophil chemotaxis via C5a binding.[31] Antibody-independent complement activation occurs with the binding of mannose-binding lectin (MBL) to cell surface carbohydrates.[38] MBL and C3 colocalization at the cell surface is significantly increased in the setting of ischemia and reperfusion and serves to further induce cell damage and necrosis.[39,40]

Reactive Oxygen Species Generation and Mitochondrial Injury

Mitochondrial injury due to derangements of the aerobic cellular respiration via the mitochondrial electron transport chain plays an important determinant role in tissue damage with I/R injury. During cellular respiration, ROS superoxide anions ($O^{\bullet -}$) are generated as a small percentage (2%-5%) of the O_2 consumed in the electron transport chain and may leak from the complex along the mitochondrial inner membrane.[40] The excess accumulation of ROS is mitigated by mitochondrial superoxide dismutase, which catalyzes the conversion to H_2O_2, which is subsequently converted to H_2O and O_2 by catalase.[40] In the setting of decreased O_2 tension, such as the ischemic phase of I/R injury, ROS generation paradoxically increases and overwhelms the compensatory mechanisms of the mitochondria. In addition, complexes along the electron transport chain, flavin mononucleotide (FMN) of complex I in particular, become saturated with electrons, due to the loss of O_2 as a final electron acceptor. With restoration of blood flow, the cell is saturated with O_2, which becomes a sink for electrons from FMN, leading to a burst of $O^{\bullet -}$. The increased concentration of mitochondrial ROS induces further damage of the mitochondrial cardiolipin and inner membrane complexes, driving further ROS formation.[41] High levels of ROS can lead to mitochondrial injury, protein misfolding, and cellular demise through the induction of apoptotic pathways, including triggered opening of the MPTP and release of cytochrome c.[42] Evidence suggests a beneficial role for intermediate levels of ROS to build tolerance to metabolic and oxidative stressors, although rampant dysregulation and accumulation in I/R injury can have devastating consequences.[40]

Nitric Oxide

Nitric oxide (NO) has contrasting impacts in I/R injury due to its potent antiinflammatory and antithrombotic properties, as well as potentially toxic, concentration-dependent effects.[15,43] NO results in stimulation of guanylate cyclase, causing increased intracellular concentrations of guanosine monophosphate and resultant smooth muscle relaxation, decreased cardiac contractility, and reduced platelet and inflammatory cell activation, due to increased intracellular calcium concentrations in these tissues. Increased NO levels may mitigate tissue damage in I/R injury through multiple mechanisms. NO activation, and more specifically the peroxynitrite ($ONOO^-$) molecule created by the interaction of NO and ROS, leads to increased membrane permeability through lipid peroxidation.[41] $ONOO^-$ contributes to activation of mitochondrial-dependent apoptosis and may increase NF-κB levels, discussed earlier as an inducer of apoptosis through the TNF pathway.[18,41] However, in vitro evidence suggests that $ONOO^-$ may inhibit NF-κB production, so the role of this pathway in the deleterious effects of NO remains unclear.[44,45] There are also beneficial properties of NO.

In vivo and ex vivo models of intestinal, neuronal, and hepatic injury when provided with NO donors show reduced injury.[46-48] NO induction of autophagy in ischemic-preconditioning additionally provides protection from tissue injury in hepatic

I/R.[49] Endogenous NO also inhibits vascular permeability and neutrophil adhesion to endothelium.[14,50] The complex interplay between the protective and deleterious effects of NO during I/R injury is likely impacted by duration of ischemia, magnitude of the injury, and the specific organ bed in which the I/R occurs.

Hypothermia

Hypothermia results in decreased rates of cellular metabolism and, specifically, reduces the rate of ATP breakdown more than the reduction in synthesis imposed by ischemia.[30] Accordingly, hypothermia is posited to have a protective effect against tissue damage in I/R injury. In animal models of skeletal muscle injury (canine) and spinal cord ischemia secondary to thoracoabdominal aortic occlusion (murine), hypothermia has been found to reduce damage secondary to I/R injury. The beneficial effect of hypothermia in spinal cord ischemia has also been demonstrated in humans in multiple studies. Animal models of renal I/R injury have shown beneficial effects of hypothermia, with temporary reduction in renal perfusion that does not result in permanent damage, as well as reduction of ROS production.[51,52] Lampe et al. have suggested two windows for the use of hypothermia in I/R injuries: at the time of ischemia to reduce mitochondria-free ROS production and upon reperfusion, when mitochondrial complexes formed during ischemia result in irreversible pathways toward apoptosis and necrosis.[53] The effect of cooling for reduction of infarct size in myocardial infarction was an area of recent interest, prompting the performance of multiple randomized clinical and feasibility trials, including the COOL MI, NICAMI, and LOWTEMP trials.[24,54,55] Although these trials have found only nonsignificant reductions in infarct size, they do support the safety and feasibility of both endovascular[24,37] and noninvasive[55] cooling strategies to lower core temperature to less than 35°C, which may have roles in mitigating I/R injuries in other tissue beds. The extent of benefits from hypothermia must be weighed with its contribution to potentially profound coagulopathy when deciding the utility of this strategy.

Anticoagulants

Anticoagulants are the mainstay of treatment during both phases of I/R injury, typically initiated on the suspicion of arterial occlusion and continued through restitution of flow. Unfractionated heparin and low-molecular-weight heparin are most commonly used. Unfractionated heparin has been shown to modulate endothelial cell permeability and pH. Despite reduced markers of local thrombosis, administration of enoxaparin does not appear to increase the rates of skeletal muscle salvage in a hind limb ischemia model. These results are in contrast to those seen in traumatic brain injury, in which administration of enoxaparin 30 hours after the onset of injury can reduce edema and infarct size in a rat model. A newer antithromboic agent, activated protein C (APC), has demonstrated a lower rate of inflammatory changes during I/R injury in models of renal I/R, through thrombomodulin activation resulting in a subsequent decrease in thrombin activity. Thrombin may represent a potential target to affect tissue damage in I/R injury. In a rodent model, pretreatment with antithrombin nanoparticles reduced creatinine increase, infarct size, and histologic evidence of microvascular thrombosis following 45 minutes of warm ischemia.[11] Evidence with neuronal damage in cerebral ischemia demonstrates increased thrombin expression in the affected neuronal bed and a decrease in neuronal loss after the administration of nafamostat mesilate, a serine protease inhibitor thought to act on the thrombin pathway.[56] Antithrombin, a serpin inhibitor that regulates proteolytic activity in the clotting cascade, has been shown to reduce infarct size following myocardial infarction in a murine model, although its effects appear independent of its anticoagulation properties and are due to an inhibition of the NF-κB pathway.[50]

CLINICAL MANIFESTATIONS OF ISCHEMIA-REPERFUSION INJURY

The clinical manifestations of I/R injury depend on the tissue bed affected, the duration of ischemia, and the ability to reperfuse. The time each tissue type can remain ischemic and maintain viability, known as the critical ischemia time, varies. The following discussion provides an overview to these clinical manifestations, highlighting the diagnosis and treatment by tissue type.

Lower Extremity Compartment Syndrome

Acute compartment syndrome of the lower limb can develop in multiple patient populations in which the arterial inflow or venous outflow are disrupted. In recent retrospective reviews, acute limb ischemia results most commonly from arterial embolism (39.5%) or thrombosis (50.23%), placing these patients at particular risk following reperfusion.[57] In patients who undergo arterial bypass, thrombosis of the graft is the most common cause of a repeated episode of acute limb ischemia.[57] Patients who undergo reperfusion following acute arterial injury or blunt/crush injury are at particular risk. Isolated injuries to either the artery or the vein can result in limb compartment syndrome. Aortic dissection, especially with extension into the iliac vessels, can result in limb compartment syndrome, as well as visceral compartment syndrome presentations.[58] Within the limb, muscle tissue is at the highest risk for I/R injury because it has the lowest critical ischemia time, at 4 hours, compared with ischemic time for bone (4 days).[31]

Compartment syndrome results from a reduction in the arteriovenous pressure gradient, a theory first posited in the 1970s.[59] Edema and increased intracompartmental pressure result in increased venous pressure, which results in a decrease in the flow gradient from lower extremity arteries to lower extremity veins. The increased interstitial pressure drives further increases in venous pressures and decreases venous drainage, contributing to worsening edema and thereby exacerbating the problem. Arteriolar compression may develop as interstitial pressure rises, resulting in nerve compression and the sensation of paresthesias and/or eventual numbness. These symptoms

may develop within 30 minutes of onset of ischemia. Irreversible damage results within 12 to 24 hours.[60]

In the conscious patient able to communicate, physical exam findings alone, including a swollen, tight limb with paresthesias, numbness, pain on passive flexion, and absent pulses, are enough to diagnose compartment syndrome. However, sedated patients, especially following large surgical procedures or trauma, may have equivocal findings that make it difficult to diagnosis compartment syndrome. In these patients the use of direct transduction of intracompartmental pressures can provide the diagnosis. Early research in the field defined 30 mm Hg as a critical compartmental pressure, above which treatment is necessary.[43] Despite nearly 40 years since these initial investigations, the 30-mm Hg threshold has persisted as a cutoff for surgical intervention in acute compartment syndrome.[61] Investigation into biomarkers for compartment syndrome has revealed elevated levels of inflammatory biomarkers, in particular matrix metalloproteinases (MMPs)-1, -2, -3 and -9, as well as neutrophil gelatinase-associated lipocalin (NGAL), in patients requiring fasciotomy for limb compartment syndrome.[19] The role of these biomarkers in directing therapy remains to be evaluated.

Left untreated, compartment syndrome of the lower extremity can result in multisystem organ failure through the action of inflammatory cytokines, myoglobinuria, and electrolyte abnormalities, especially following reperfusion and return of these molecules to systemic circulation. Accordingly, treatment is focused on decompressing the affected compartments to return blood flow and halt the ischemic insult. Initial nonsurgical management involving removal of any restrictive dressings (i.e., cast) may help; however, definitive management of compartment syndrome of the limb involves decompression with four-compartment fasciotomy.[61] Decompressive fasciotomy is performed through either one- or two-incision techniques. The single-incision technique involves a long incision along the anterolateral calf, terminating within 5 cm of the end of the fibula at either end, and can successfully decompress all four compartments while maintaining increased soft tissue stability for any underlying fracture.[16,29] The more traditional two-incision procedure decompresses through both a lateral and medial incision, with care taken to divide the intramuscular septum on the lateral incision to prevent incomplete decompression.[62] The use of vacuum-assisted closure (VAC) devices following either method may improve wound edema and facilitate easier closure.[63]

Beyond decompression for the treatment of I/R injury in the lower extremity, the initial ischemic insult may be addressed through catheter-based thrombolytic techniques or open revascularization. However, previous large, randomized trials have not focused on rates of I/R injury following reperfusion as a primary end point. However, the Thrombolysis or Peripheral Arterial Surgery (TOPAS) trial did enroll patients with 14 days or less of ischemic symptoms from either thrombosis or embolic occlusion of the lower extremity and found that distal embolization of thrombotic material occurred frequently during catheter-based thrombolysis techniques, although it could commonly be addressed through continued thrombolysis in most cases. This finding was further demonstrated in a recent Cochrane meta-analysis in which patients with lower extremity ischemia treated by thrombolytic techniques were more likely to have distal embolization within 30 days compared with patients who underwent open bypass.[65] However, DNA-based assays have demonstrated damage to DNA on the molecular level without phenotypic manifestations when using a tourniquet during surgical bypass.[64] Thus, regardless of reperfusion technique, a high degree of suspicious for I/R injury following treatment of lower extremity ischemia should be maintained.

Gastrointestinal Ischemia-Reperfusion Injury

Due to the high metabolic rate of the liver and small and large intestines, the gastrointestinal system is particularly susceptible to I/R injury. Ischemia to the mesenteric distribution may result from multiple sources, including low flow through decreased cardiac output or the administration of alpha-adrenergic agents, as well as embolic and thrombotic events.[47] In addition, mesenteric venous occlusion may result in ischemic insults similar to that seen in arterial etiologies. In the intestines the injury associated with reperfusion may be even greater than that of ischemia alone. In particular, in feline models a reduction in mucosal thickness and reduction of villi height has been observed following 3 hours of ischemia and 1 hour of reperfusion compared with 4 hours of ischemia alone.[65] The combination of ischemia and reperfusion in the intestinal tissue results in NO-induced damage to the mucosa and submucosa, contributing to loss of integrity of the intestinal wall, allowing for bacterial translocation.[17] Bacterial translocation into the portal and systemic circulation demonstrates a time-dependent increase even following reperfusion, highlighting the ongoing effects of I/R injury even after flow has been restored. Release of bacteria into the systemic circulation, as well as the accumulation and release of toxic metabolites, may have drastic systemic implications.

The liver has important roles in metabolism, detoxification, and the immune response, and, as such, there can be devastating consequences with hepatic I/R injury.[10] The bacterial burden and concentration of inflammatory molecules within the portal circulation is significantly increased after intestinal I/R. Within 2 hours of liver reperfusion, there is a significant increase in TNF-α and IL-1β concentrations within the liver, and neutrophils into the liver with resultant liver injury. Similarly, due to increased expression of ICAM-1 and the leukocyte adhesion protein CD11/CD18, there is a leukocyte-dependent increase in oxidative stress in the liver following intestinal ischemia.[66,67] Therefore the liver may demonstrate tissue damage following either as a result of ischemia to the liver itself or as collateral damage following intestinal ischemia and reperfusion.

The relatively high incidence of intestinal and hepatic I/R injury, as well as the detrimental systemic effects, have prompted investigation into factors that may mitigate the tissue damage of I/R injury in these tissue beds. Regional hypothermia may have benefits on limiting intestinal tissue damage, as well as systemic effects of intestinal ischemia. Within the gut, regional hypothermia has been shown to reduce the concentrations of NF-κB and rates of PMN priming within intestinal mucosa following I/R injury.[39] Systemically, therapeutic hypothermia has been shown to reduce distant organ damage following intestinal I/R injury in a rat model.[45]

Although PMN priming via ischemia preconditioning has been shown to increase superoxide production, it has also demonstrated augmented PMN bacterial killing and phagocytosis during intestinal I/R.[32] Decreases in the inflammatory response through modulation of the heme-oxygenase 1 (HO-1) pathway via ischemic preconditioning or regional hypothermia has improved outcomes in animal models, suggesting the possible future role for pharmaceuticals targeting the HO-1 pathway.[2,48] Administration of low-dose ethanol has been shown to decrease the liver damage associated with intestinal I/R injury via NO-dependent reduction in hepatic apoptosis.[68] Another alcohol analogue (dexpanthenol) has demonstrated protective effects against I/R injury in rat models and has shown preserved peristalsis in small intestines following I/R injury.[9] These experimental studies highlight the importance of novel mechanisms, in combination with surgical reperfusion, to mitigate the damage caused to the gastrointestinal system in I/R injury.

Renal Ischemia-Reperfusion Injury

Renal I/R injury significantly contributes to the morbidity and mortality of a large number of diseases.[69] The mechanism behind renal injury following renal I/R appears similar to other tissue beds discussed previously, namely, the activation of proinflammatory pathways, induction of ROS generation, mitochondria-mediated apoptosis signaling, and neutrophil accumulation in injured tissue beds.[25,46,69,70] The structure of the kidney leads to differential effects in the kidney. The outer medulla experiences a disproportionate reduction in blood flow during I/R, contributing to epithelial injury in the proximal tubule.[6] Renal I/R also induces damage and impaired healing in renal vasculature and microcirculation, through downregulation of vascular endothelial growth factor (VEGF) and upregulation of angiogenesis inhibitors, resulting in increased tubular fibrosis and higher risk of chronic kidney impairment after an episode of renal I/R.[3,71] Renal I/R injury also appears to alter the renin-angiotensin-aldosterone system (RAAS), toward an increased level of angiotensin II and aldosterone, promoting systemic hypertension, even following resolution of the acute renal I/R injury.[72]

Renal I/R can result in profound local and systemic disturbances (Fig. 6.3). In the kidney, medullary hypoxia due to ischemia results in salt wasting and vasoconstriction.[8] Reperfusion is marked by endothelial swelling, resulting in an initial "no reflow" phenomenon, followed by loss of endothelial integrity and resulting neutrophil invasion and tissue damage.[46] The distant organ effects may be the primary mediators of morbidity and mortality following renal ischemia and reperfusion. Renal ischemia induces apoptosis in the lung in murine models.[73] Systemic release of TNF-α, IL-1, and ICAM-1 are thought to play a role in cardiac injury due to neutrophil infiltration during renal I/R and increased rates of cardiac myocyte apoptosis have been observed in animal models of renal I/R.[74] In the central nervous system, increased concentrations of glial fibrillary acidic protein (GFAP) in the cerebral cortex may recruit neutrophils and result in neuronal damage, which may potentiate the effect of uremia to result in mental status changes in renal I/R.[75] Increased oxidative stress, apoptosis, and tissue damage have been experimentally demonstrated in hepatocytes following renal I/R injury, likely in part due to increased presence of systemic proinflammatory cytokines.[76] These manifestations help to explain the profound detrimental effect that even brief periods of renal I/R may have on patient morbidity and mortality in a wide variety of diseases.

Strategies to reduce the clinical manifestations of renal I/R injury have been studied in many populations, including the transplant population and patients undergoing juxtarenal aortic aneurysm repairs. In allografted organs, cold ischemic times are an important factor in determining the viability of a transplanted organ, with increased rates of delayed graft function associated with prolonged cold ischemic times.[77] Methods of machine preservation with pulsatile perfusion result in improved outcomes compared with static cold preservation, highlighting the importance of flow-responsive endothelial characteristics, including preservation of the endothelial barrier, for reducing the effect of renal I/R injury.[78] In vascular surgery, renal ischemia is of particular concern, especially with the high burden of preexisting renal disease among vascular patients. Renal dysfunction occurs in approximately 12% of patients undergoing thoracoabdominal aortic repair, although this represents a significant improvement from historical reports, likely due to the increased use of renal protective bypass methods (maintaining a perfusion pressure of at least 60 mm Hg) and cold perfusion strategies.[1] In addition, ischemic preconditioning has been shown to reduce tissue damage in a rat model of renal I/R, through a decreased inflammatory response following ischemic insult.[27,79]

Myocardial Ischemia-Reperfusion Injury

Following acute myocardial infarction, cardiac myocytes are susceptible to at least two different types of I/R injury. The first is known as myocardial "stunning" and refers to a reversible, transient dysfunction that persists following reperfusion despite the absence of irreversible damage. Myocardial stunning likely results from a complex interplay of multiple factors, including decreased ATP synthesis following reperfusion, microvascular spasm and plugging, and cytotoxic injury due to ROS and altered calcium metabolism. Stunning may result in malignant cardiac arrhythmias that result in sudden death following cardiac revascularization due to sudden changes in the intracellular ionic composition resulting in altered electrical coupling. In addition, following reperfusion of culprit lesions, a component of the cardiac microvasculature may remain nonperfused in up to 50% of patients, via a "no reflow" mechanism.[80] Ischemic time alone accounts for only a small component of morphologic changes following I/R injury, and tissue damage following cardiac ischemia depends on reperfusion time as well. In a rat model, ventricular wall thickness was significantly reduced in the group who experienced 30 minutes of ischemia followed by 60 minutes of reperfusion, compared with the groups experiencing either 30 minutes of ischemia or 90 minutes of ischemia without subsequent reperfusion.[80] Ventricular wall loss and altered electrical conduction have obvious implications on the clinical manifestations of myocardial I/R injury.

Multiple mechanisms have been explored to reduce the detrimental effect of I/R injury in cardiac myocytes. Rivaroxaban, the factor Xa inhibitor, delivered in high doses for 14 days

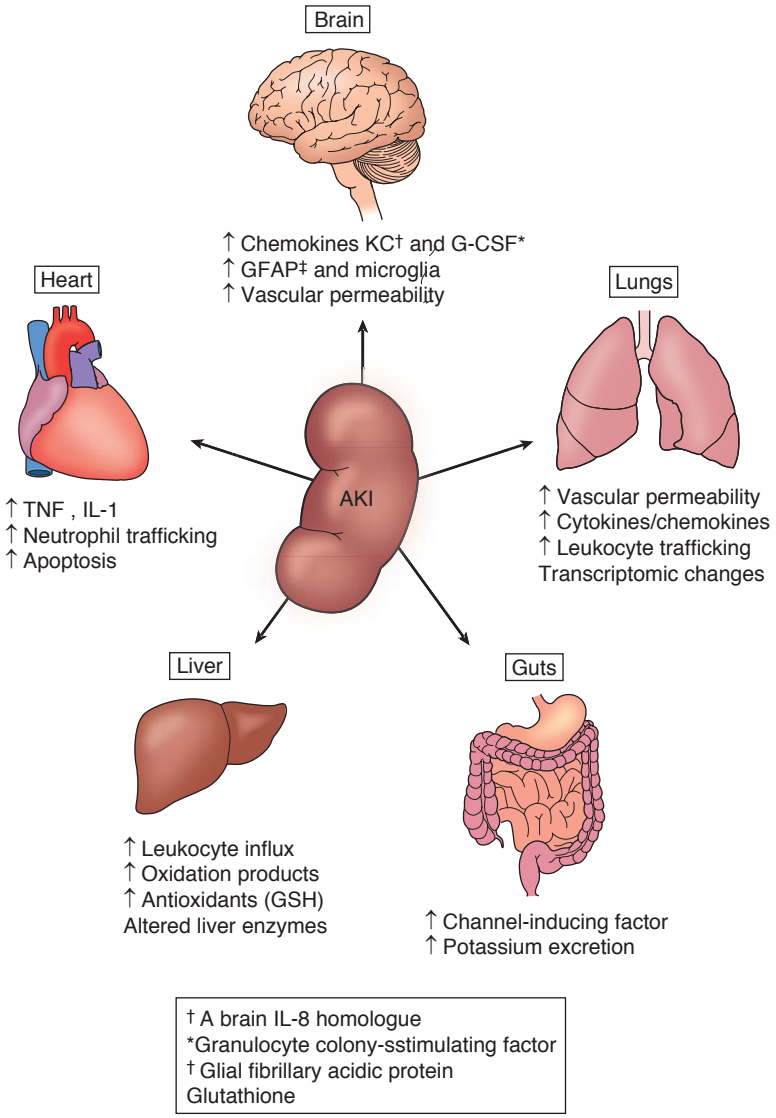

Figure 6.3 Systemic Effects of Acute Kidney Injury (AKI) Associated With Ischemia-Reperfusion (I/R) Injury. Systemic effects are responsible for the majority of morbidity and mortality associated with renal I/R injury. Universally, proinflammatory biomarkers are increased in distant organs, resulting in heart, brain, pulmonary, hepatic, and intestinal manifestations of renal I/R. Interesting, gut excretion of potassium may be responsible for the variable presence of hyperkalemia in AKI. *CSF*, Cerebrospinal fluid; *GFAP*, glial fibrillary acidic protein; *GSH*, growth stimulating hormone; *IL-1*, Interleukin-1; *KC*, CXCL1 chemokine; *TNF-α*, tumor necrosis factor alpha. (From White, LE, Hassoun, HT. Inflammatory mechanisms of organ crosstalk during ischemic acute kidney injury. *Int J Nephrol.* 2012;1–8.)

following myocardial I/R injury has been shown to increase survival compared with both no therapy and low-dose rivaroxaban therapy in a murine model.[38] These effects may be due in part to the pleomorphic effects of rivaroxaban, including antiinflammatory and antifibrotic effects. The incidence of malignant arrhythmias may be reduced through staged gradual reflow or transient acid reperfusion. New insights into the molecular pathway of myocardial I/R injury, including the role of the signal transducer and activator of transcription (STAT) pathway, may reveal individual molecular targets toward which pharmaceuticals may be directed, although such research is in preliminary stages only.[81]

Results from a multicenter randomized, prospective trial examining ischemic preconditioning for heart surgery have become available in the *New England Journal of Medicine*. In this trial, remote ischemic preconditioning was induced through four cycles of upper limb ischemia, each lasting 5 minutes. The concept is based on earlier reports in which infarct size within the heart is reduced through attenuation of endothelial dysfunction through exposure to previous ischemic periods.[82] However, Meybohm et al. report no significant difference in the rates of primary end points (death from any cause, nonfatal myocardial infarction, new stroke, or acute renal failure) in the groups with or without ischemic preconditioning prior to elective cardiac surgery.[83] These results echo the findings of myocardial protection for patients undergoing elective vascular surgery.[84] Thus it appears that despite the benefits seen in animal models, human use of ischemic preconditioning for the protection of myocardium during elective operations remains unproven.

FUTURE DIRECTIONS IN ISCHEMIA-REPERFUSION INJURY

Given the extensive clinical impact of I/R injury, reducing its effects remains an area of intense basic science and clinical research. Among patients with myocardial infarction, the use of mesenchymal stem cells has garnered increased attention. In murine models, delivery of adipose-derived stem cells following myocardial infarction results in decreased fibrosis and

improvements in left ventricular function.[85] In rat models, repeated transplantation of allogenic stem cells not only consistently reduces infarct size with each administration, but also does so without generating a rejection-like picture.[44] Mechanisms for transmyocardial delivery of stem cells with or without associated CABG in humans have been elucidated.[86] However, the ability to replicate beneficial findings from animal models in humans, and the role of stem cell delivery in other vascular beds, including the lower extremity, gastrointestinal system, and kidneys, remains to be seen.

Techniques for preservation of organs in transplantation may serve to improve outcomes in I/R injury. Cold storage solutions that incorporate the p38 MAPK inhibitor FR 167653 (with antiinflammatory) properties have been shown to reduce ATP depletion and intracellular calcium accumulation during I/R injury after transplantation. Furthermore, methods of organ procurement that involve pretreatment with low-dose dopamine have demonstrated reduced rates of dialysis in renal transplants, possibly due to membrane stabilization of the endothelial cell. Further investigation into this pathway may reveal potential pharmaceutical targets for reduction of tissue damage following I/R injury in other tissues, especially because alterations in endothelial barrier function are a hallmark to nearly all types of I/R injury. Finally, hypothermic machine perfusion with pulsatile flow in deceased donors may reduce the rates of delayed graft function following renal transplantation, highlighting the potential role for mechanical mechanisms to reduce tissue damage in I/R injury.[87,88]

Peripheral arterial disease (PAD) of the limbs can progress to critical limb ischemia (CLI), characterized by rest pain and tissue loss, including nonhealing ulceration and gangrene.[1,2] The body compensates via neovascularization, forming collateral circulation to bypass the obstructed vessel (arteriogenesis) or increasing capillary density (angiogenesis) to deliver oxygen and nutrients to ischemic tissue. Despite these responses, disease progression can lead to amputation, decreased quality of life, comorbidity, and death and is an economic burden to the healthcare system.

Traditional treatment of PAD includes risk factor modification (tobacco abuse, diabetes, hypertension, hyperlipidemia), exercise programs, and medical therapy (antiplatelet agents, phosphodiesterase inhibitors).[1-3] As atherosclerosis progresses, more invasive intervention may be necessary, including endovascular therapies and surgical bypass. Patients with CLI may not be candidates for surgical intervention because of severe medical comorbidity or nonreconstructable disease. This patient population may be candidates for biologic treatments, including gene-based, molecular, and cell-based therapies designed to promote healing and prevent amputation.

Advances in basic science research have developed these biologic therapies over the past two decades. Early clinical trials focusing on gene and molecular therapies, such as vascular endothelial growth factor (VEGF) and fibroblast growth factor (FGF), have demonstrated limited benefit. More promising results have been observed using cell-based therapies, including endothelial progenitor cells (EPCs) and bone marrow–derived mononuclear cells (BM-MNCs).

Herein, the basic science and processes involved in neovascularization (specifically arteriogenesis and angiogenesis), as well as recent human clinical trials designed to promote neovascularization for CLI, are discussed.

NEOVASCULARIZATION

Neovascularization refers to the formation of new blood vessels and includes vasculogenesis, arteriogenesis, and angiogenesis.[4]

Vasculogenesis is the de novo formation of embryonic blood vessels from vascular progenitor cells or hemangioblasts, which develop into hematopoietic precursors and endothelial cells.[5] These cells induce differentiation of discrete vascular layers as cells transform into endothelial cells, smooth muscle cells (SMCs), and adventitial pericytes. Although vasculogenesis primarily occurs during the embryonic stages of development, postembryonic adaptive vasculogenesis results from either arteriogenesis or angiogenesis.[6,7]

Arteriogenesis involves growth of collateral vessels and remodeling from preexisting arterial-arteriolar connections.[6,8] Arteriogenesis is induced by a change in hemodynamic forces (fluid shear stress [FSS]) resulting from pressure differences within an artery narrowed by atherosclerosis. FSS activates the endothelium, leading to increased transcription of the promoter regions of a variety of proteins contributing to vessel growth (Table 7.1).[4] With progressive arterial stenosis, blood follows the path of least resistance and is shunted into collateral vessels.[4] Collateral vessel formation maintains a degree of flow beyond the obstruction.

Angiogenesis, which refers to the sprouting of new capillaries from preexisting ones, is stimulated by decreases in oxygen tension secondary to reduced tissue perfusion. Local ischemia stimulates an increase in hypoxia-inducible factor-1 (HIF-1), which results in increased production of VEGF, a potent angiogenic factor. VEGF induces endothelial cell proliferation and increases endothelial permeability.[8] Matrix metalloproteinases (MMPs) locally degrade basement membrane and extracellular matrix (ECM), allowing vessel growth and increased tissue perfusion.[9-11] Although this increased flow provides greater delivery of oxygen and nutrients to ischemic tissues, it is often not sufficient to overcome major arterial obstruction.[8,11,12]

Postembryonic arteriogenesis and angiogenesis occur over a continuum of vascular adaptations (Fig. 7.1).[7]

ARTERIOGENESIS

Chronic, progressive arterial stenosis leads to generation of a collateral network by remodeling preexisting arterial-arteriolar connections (Fig. 7.2). Arteriogenesis is the formation of this collateral circulation, primarily in response to an increase in FSS with a contribution from increased circumferential wall stress. For example, femoral artery occlusion results in up to a 200-fold increase in shear stress in the arteriolar network.[5]

FSS is proportional to flow velocity and inversely proportional to the radius cubed, whereby small changes in radius can normalize shear stress.[11] Increased FSS activates the endothelium.[5,8,13] Nitric oxide (NO) is liberated by endothelial cells (via endothelial NO synthase [eNOS]) in addition to macrophages and SMCs in the adventitia (via inducible NOS). NO induces SMC relaxation and vasodilatation beyond the arterial occlusion, thereby improving blood flow.[12,14,15] NO also stimulates endothelial VEGF secretion, leading to the release of endothelial cell adhesion molecules (CAMs) and monocyte chemotactic protein-1 (MCP-1) by endothelial and SMCs.[5,6,15] Both molecules mobilize to the cell surface, generating a "sticky" endothelium that enhances leukocyte attraction, adhesion, and invasion of arteriolar collaterals and periadventitia.[6,8]

Monocytes either attach to CAMs to be incorporated into the lumen of the developing vessel, or accumulate in the adventitia.[15] Activated monocytes release tumor necrosis factor-α (TNF-α), further enhancing monocyte attraction. Platelet adherence and activation stimulates growth factor and interleukin-4 production, enhancing monocyte adhesion. Monocytes stimulate production of growth factors, chemokines, and cytokines, in addition to immune cells, leading to the proliferation of collateral arterioles (Fig. 7.3).[5] Macrophages contribute to remodeling of the collateral vessel by liberating proteases.[6,8,9] Endothelial cell proliferation and endothelial permeability increase, while

TABLE 7.1 Transcription and Growth Factors Influencing Arteriogenesis and Angiogenesis

Factor	Characteristics	Role in Arteriogenesis and Angiogenesis	Induced by
Transcription Factors			
HIF-1[118-126]	Helix:loop:helix structure Mainly involved in angiogenesis but possible role in VEGF stimulation in arteriogenesis	Induces gene transcription to promote angiogenesis in ischemic environment Is involved in hypoxic vasodilation, cell growth, proliferation, migration, sprouting, recruitment of pericytes/SMCs, vascular remodeling, mobilization of angiogenic cells and EPCs Also induces MMPs for ECM digestion	Hypoxia
EGR-1[142-147]	Increased expression in endothelial cells, SMC, fibroblasts, leukocytes	Required for expression of cyclin D1, a regulator of the cell cycle in vascular cells	Shear stress, mechanical injury, hypoxia, PDGF, FGF-1, FGF-2
Post-Transcriptional Regulators			
MicroRNAs[71,77,79,83,148,149,150,151]	~22 nucleotides in length, binds to 3′ UTR of target mRNA, single stranded RNA Post-transcriptional gene regulation	Promote and/or inhibit angiogenesis and arteriogenesis through interactions with various transcription factors, cytokines, and cell adhesion molecules	Varies with each miRNA

Continued

TABLE 7.1 Transcription and Growth Factors Influencing Arteriogenesis and Angiogenesis—cont'd

Factor	Characteristics	Role in Arteriogenesis and Angiogenesis	Induced by
Growth Factors/Cytokines			
VEGF[85-94]	Survival factor for endothelial cells Involved in angiogenesis and arteriogenesis	Promotes proliferation, migration, lumen formation Induces monocyte chemotaxis via binding to VEGFR1 on monocytes	Hypoxia and shear stress
FGF[85,87-92,100-102]	Perivascular macrophages are source of FGF-2 during collateral growth[7] Role in arteriogenesis and angiogenesis	Induces endothelial/SMC proliferation Stimulates endothelial cell migration/differentiation, and increases EGR-1 expression Potentiates VEGF and may be synergistic with VEGF-B	Shear stress, endothelial activation
TGF-β[11,16,123,152-154]	Expressed in areas of collateral formation	Expressed in developing collateral arteries Stimulates arteriogenesis by effects on endothelial cells, vascular SMCs, monocytes, macrophages	Shear stress, endothelial activation
TNFα[155-158]	Proximal mediator of inflammation	Angiogenic effects from TNFR2R Enhances activation and adhesion of monocytes by upregulating cell adhesion molecules Upregulates GM-CSF Necessary for migration/adhesion of BM-hematopoietic cells to endothelium via NO synthase-dependent mechanisms	Stimulated by endothelial activation by shear stress and LPS Lipopolysaccharide Ischemia stimulated TNFR2 expression
GM-CSF[6,11,159,160]	Enhances arteriogenesis through effects on circulating cells	Enhances release, proliferation, and differentiation of hematopoietic stem cells, mobilization of endothelial progenitor cells Amplifies effects of MCP-1,[11] promotes survival of monocytes and macrophages	Stimulated by endothelial activation by shear stress
HGF[106-109]	Augments arteriogenesis by enhancing endothelial cell function Role in angiogenesis and arteriogenesis	Activates Dll4-Notch-Hey2 pathway for inducing proliferation and migration of endothelial cells	Hypoxia, shear stress
ECM Proteins			
Del-1[109,115-117]	Involved with angiogenesis		Ischemia
Chemokines and Chemokine Receptors			
MCP-1 (or CCR2)[6,161-164]	CCR2 axis: MCP-1 binds CCR2 receptor on monocytes Potent stimulator of arteriogenesis and angiogenesis	Increases attraction/adherence of monocytes and tube formation. May attract endothelial progenitor cells to sites of vascular injury	Hypoxia and shear stress
ELR-containing CXC[161-163,165]	Binds receptors on CXCR1/2/3 Potent stimulator of angiogenesis, some forms inhibit angiogenesis via inhibition of VEGF/FGF	Binds chemokines MIG, IP-10, I-TAC, and PF-4 Decreases formation of collaterals and restoration of perfusion in knockout mice Perfusion improved with infusion of bone marrow mononuclear cells	Hypoxia
Cell Adhesion Molecules			
ICAM, VCAM-1, PECAM-[113,166-171]	Enhance attraction and adhesion of monocytes	Support diapedesis of monocytes, while enhancing cell signaling and activation of mechanosensory complexes that activate intracellular changes in response to shear stress	Shear stress

TABLE 7.1 Transcription and Growth Factors Influencing Arteriogenesis and Angiogenesis—cont'd

Factor	Characteristics	Role in Arteriogenesis and Angiogenesis	Induced by
Proteases			
MMPs[9,10,167,172-180]	Macrophages and monocytes are source of MMPs in ischemic/nonischemic tissue Involved in angiogenesis and arteriogenesis	Allow for ECM remodeling via proteolytic degradation of ECM/BM, enabling collateral vessel/capillary growth and endothelial cell migration Liberate growth factors and stimulate endothelial proliferation ECM/BM breakdown by MMPs promotes SMC proliferation and migration	Shear stress and hypoxia; MCP-1 activates macrophages to secrete MMPs MMPs activate release of more MMPs from macrophages
Immune Cells			
Monocytes/ Macrophages[6,9,48,155,167,168,177,178,181-188]	Induce vascular cell proliferation and wall remodeling via paracrine effects	Promote vascular growth and secrete growth factors (MMP, NO, VEGF, FGF-2, GM-CSF, TGF-β, TNFα) that stimulate arteriogenesis Monocytes accumulate in wall of growing collateral and differentiate into macrophages, liberating MMPs to digest ECM; encourages migration and proliferation of endothelial cells and SMCs	Shear stress-activated endothelium expresses MCP-1, leading to adhesion of monocytes
T cells/NK cells[4,170-200]	Immune Cells	CD4 and CD8 mononuclear cells migrate to collateral vessel, initiating arteriogenesis/ angiogenesis by cytokine activation Athymic mice have higher rates of autoamputation than heterozygotes NK cell deficient mice are unable to form collaterals	Shear stress
Mast Cells[10,11,200-202]	Present in adventitia of collateral arteries	Release TGF-β, VEGF, FGF-2, MMPs, histamine, serotonin	
Other Cells			
BM-EPCs[160,195-197,203-211]	BM-derived cells	Attracted to sites of neovascularization, differentiate into endothelial cells	Shear stress, ischemia Release stimulated by VEGF, SDF-1
Pericytes[211-213]	BM-derived cells	Release VEGF, FGF-2, MCP-1 and MMPs, promoting endothelial cell migration, proliferation, and survival	Shear stress
Vascular SMCs[11,213-216]	Derived from endothelial cells, mesenchymal cells, and BM-derived cells	Collateral vessel stabilization via ECM production	SMCs attracted by PDGF/VEGF Proliferation stimulated by ECM breakdown

Adapted from Huang P, Li S, Han M, et al. Autologous transplantation of granulocyte colony-stimulating factor-mobilized peripheral blood mononuclear cells improves critical limb ischemia in diabetes. *Diabetes Care.* 2005;28:2155–2160.

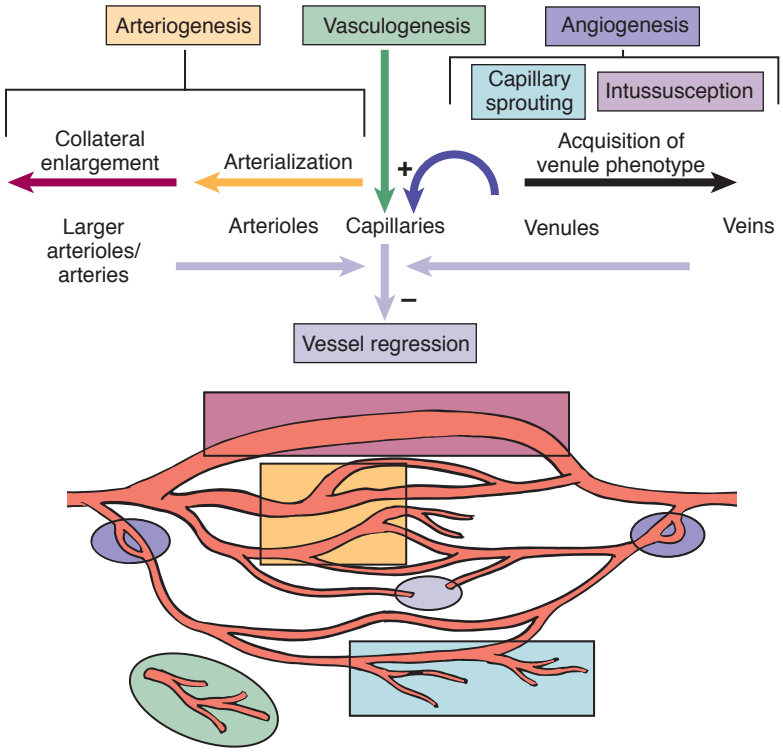

Figure 7.1 Vascular Development. Postembryonic vascular remodeling occurs in response to hypoxia and fluid shear stress and involves a complex continuum of vascular adaptations. (Redrawn from Peirce SM, Skalak TC. Microvascular remodeling: A complex continuum spanning angiogenesis to arteriogenesis. *Microcirculation.* 2003;10:99–111, with permission from Taylor & Francis Ltd. Available at http://www.tandf.co.uk/journals.)

vascular SMCs proliferate and change from a contractile to a proliferative phenotype.

Circumferential wall stress also plays a role in inducing arteriogenesis. As part of a second phase of arteriogenesis, vascular SMC growth is induced by circumferential wall stress. Increased intravascular pressure leads to SMC proliferation and increased vessel thickness. Increased vessel thickness enables normalization of circumferential wall stress at low blood pressure, which can lead to cessation of collateral vessel growth prior to the complete resolution of ischemia.[11]

The final phase of arteriogenesis involves "pruning" or regression of vessels. Poiseuille's law states that flow is proportional to radius and predicts that greater flow is observed within fewer larger arterioles rather than many smaller ones. As such, the process of "pruning" leads to regression of smaller collaterals, with persistence of a few larger collateral vessels. Vessel regression is the result of proliferation of the intima that leads to occlusion of the collateral.[11]

Cardiovascular Risk Factors Associated With Impaired Arteriogenesis

A variety of disease states perturb arteriogenesis, leading to impairment of endothelial or macrophage function. The recruitment of EPCs or growth factor production may also be impaired (Fig. 7.4). Aging itself affects arteriogenesis secondary to an overall decrease in endothelial production of NO[16] and by a higher rate of HIF degradation, along with decreased levels of VEGF, platelet-derived growth factor (PDGF), FGF-2, and chemokine signaling. Growth factor release is also impaired with aging.[16,17]

Diabetes mellitus retards vessel formation in relation to an attenuated response to the mobilization of mononuclear cells induced by granulocyte-macrophage colony-stimulating factor (GM-CSF)[18] and to impaired monocyte chemotaxis in response to VEGF.[16,17,19,20] This overall decrease in circulating EPCs leads to endothelial dysfunction and poor collateral artery formation.[16,20] In addition, eNOS is inhibited by an increase in free radicals related to diabetes.[17]

Hypertension can have a variety of effects on arteriogenesis. Elevated blood pressure can cause an increase in FSS, which stimulates arteriogenesis. Hypertension is also associated with activation of the renin-angiotensin system and subsequent activation of arteriogenesis. Angiotensin's role in regulating the inflammatory response can lead to initiation of arteriogenesis induced by inflammation. Angiotensin also stimulates increases in circulating VEGF, PDGF, and FGF, all of which stimulate arteriogenesis. Conversely, activation of angiotensin by hypertension is associated with endothelial cell dysfunction as a result of increased oxidative stress due to activation of NADPH (reduced nicotinamide adenine dinucleotide phosphate) oxidase activity. The increase in oxidative stress increases reactive oxygen and superoxide levels. These oxygen radicals uncouple eNOS, thereby reducing the availability of NO.[16,21,22]

Hyperlipidemia affects various steps in arteriogenesis and has direct toxic effect on both endothelial cells and vascular SMCs.[17] Oxidized low-density lipoprotein (LDL) cholesterol interferes with VEGF function, leading to disordered endothelial cell migration via eNOS inhibition.[17,22] In addition, endothelial cell FGF and T-lymphocyte migration are reduced, as is

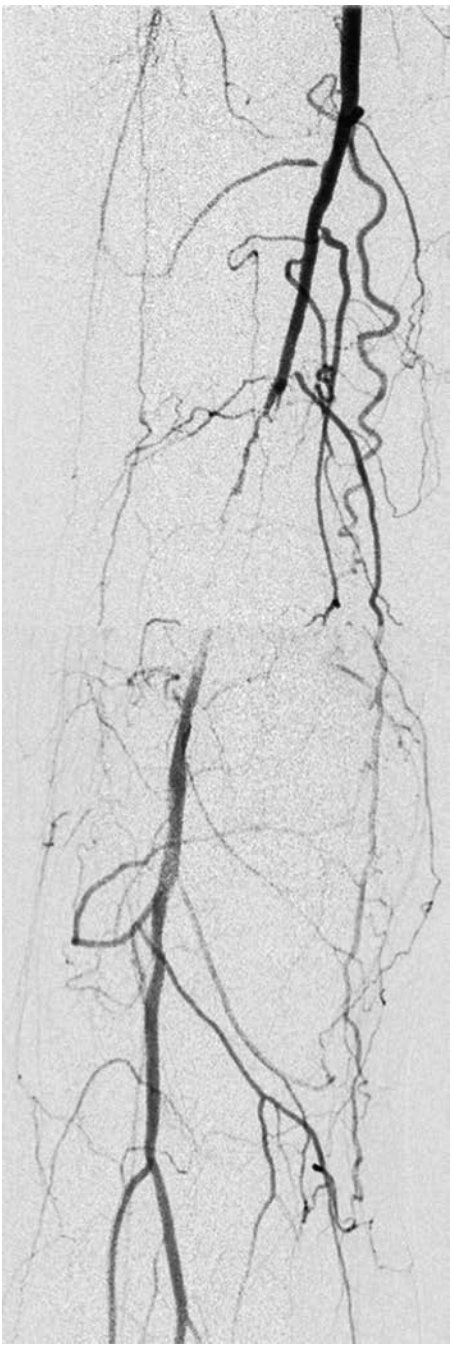

Figure 7.2 Clinical Example of Arteriogenesis. Digital subtraction arteriography of the right lower extremity in a patient with claudication. A distal superficial femoral artery (SFA) occlusion with reconstitution via collateral circulation is demonstrated. These collaterals formed via arteriogenesis in response to progressive SFA stenosis, allowing blood flow beyond the occlusion. The patient underwent successful angioplasty with stent placement, as these collaterals were insufficient to prevent symptomatic claudication (not shown). (Courtesy Paul DiMuzio, MD, Division of Vascular and Endovascular Surgery, Thomas Jefferson University Hospital, Philadelphia, Pennsylvania.)

endothelial cell replication. Expression of FGF receptors, HIF-1, and VCAM-1 is impaired, leading to impairment of monocyte chemotaxis.[23]

Lastly, tobacco abuse impairs EPC number, function, migration, and adherence. Monocyte migration in response to VEGF is disordered with smoking. Decreased levels of VEFG and HIF-1 further impair EPC function.[16,17,22]

ANGIOGENESIS

Arteriogenesis involves the formation of collateral arteries stimulated by FSS related to upstream arterial stenosis or occlusion; in distinction, angiogenesis involves new capillary formation induced by distal tissue ischemia. Angiogenesis occurs via sprouting and nonsprouting (intussusceptive microvascular growth [IMG]) mechanisms.[24-26]

Sprouting Angiogenesis

Sprouting angiogenesis involves endothelial cell projections into surrounding connective tissue. Breakdown of the basement membrane occurs along with interendothelial junction formation, enabling endothelial cell projection.[26-28] Endothelial cells migrate along the projection's front with further sprouting, ultimately developing a complex capillary meshwork.

Sprouting angiogenesis requires specialization of cells along the migrating projection into "tip," "stalk," and "phalanx" cell phenotypes on the basis of the interaction of factors promoting or inhibiting angiogenesis.[29-34] Tip cells are polarized migratory cells that are at the forefront of the endothelial sprout. These cells branch at the tip of the stalk as they extend filopodia toward the stimulus; this is accomplished with minimal proliferation. Stalk cells conversely exhibit a proliferative phenotype responsible for the lengthening of the endothelial sprout. These cells are also responsible for secretion of basement membrane along the stalk and formation of vascular lumina from the initial luminal slit.[32,34,35] Additional stability to the proliferating stalk is provided by pericytes, which surround the basement membrane and provide further vessel coverage and decrease leakage from the vessel.[35-37] Initially, the process of sprouting requires minimal endothelial cell proliferation, although this demand increases with continued sprouting.[29,30,35]

Phalanx cells are endothelial cells that become quiescent after completion of the vascular branch. These cells deposit basement membrane and form tight cellular junctions via increased expression of vascular endothelial cadherin (VE-cadherin). These cells are ultimately responsible for delivery of oxygen and nutrients to surrounding tissues.[35,38]

Regulation of Angiogenesis

Angiogenesis is initiated by ischemia, leading to increased VEGF expression. VEGF is a potent angiogenic factor, serving to encourage endothelial cell binding to VEGF receptor 2 (VEGFR-2), which promotes endothelial chemotaxis. VEGF expression induces extension of tip cells and proliferation of stalk cells with concomitant synthesis of basement membrane components.[39-41] In addition, pericytes are attracted and contribute to capillary network formation. Whereas VEGF induces sprouting, Notch signaling pathways function to limit tip migration. Notch signaling occurs by increasing expression of VEGFR-1, competitively binding VEGF and thereby limiting

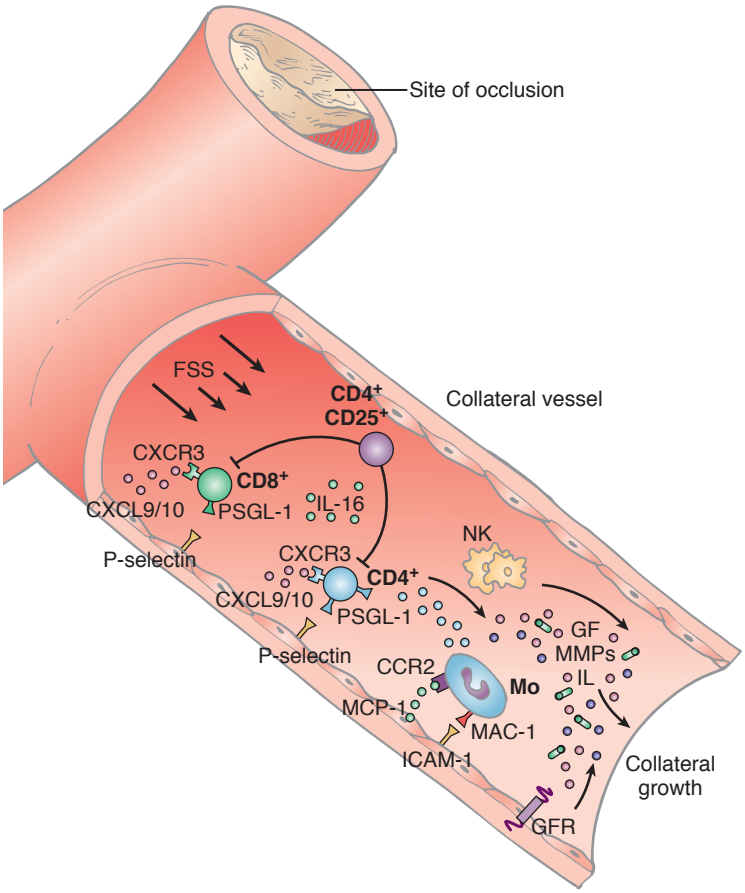

Figure 7.3 Role of Immune Cells in Arteriogenesis. With ischemia, CD8+ T cells are attracted to the growing collateral vessel and recruit CD4+ cells, which subsequently augment arteriogenesis in association with natural killer (NK) cells. Monocytes are recruited, initiating vessel growth by synthesis of angiogenic/arteriogenic cytokines. *CCR2*, CC chemokine receptor 2; *CXCL 9/10*, CXC chemokine ligand 9/10; *CXCR3*, CXC chemokine receptor 3; *FSS*, fluid shear stress; *GF*, growth factor; *GFR*, growth factor receptor; *ICAM-1*, intercellular adhesion molecule-1; *IL*, interleukin; *MAC-1*, membrane attack complex-1; *MCP-1*, monocyte chemotactic factor-1; *MMPs*, matrix metalloproteinases; *Mo*, monocytes; *PSGL-1*, P-selectin glycoprotein ligand 1. its availability.[25,31-33,42] The balance of VEGF and Notch signaling therefore regulates sprouting-related vessel development.

Transformation to a tip cell phenotype is induced by exposure of endothelial cells to VEGF. Delta-like ligand 4 (Dll4), a Notch binding ligand, is highly expressed by tip cells, increasing sensitivity to VEGF and binding to VEGFR-2.[31,32,39,43-46] Increased VEGF-VEGFR-2 binding upregulates Dll4, leading to downregulation of VEGFR-2 on adjacent endothelial cells. This process allows the tip cell to competitively maintain its position.[29,33,41,47] These adjacent cells transform into a stalk cell phenotype and express Notch, which is induced by Dll4.[31,46,48] Whereas tip cells have low Notch signaling, stalk cells express higher Notch signaling and higher expression of the jagged protein-1 (JAG-1), counteracting Notch-Dll4 activity and limiting tip cell migration (Fig. 7.5).[31,39,47-50]

Lumen Formation

Tubulogenesis, or lumen formation, is responsible for transforming endothelial stalks into vessels capable of carrying blood and nutrients to surrounding tissue. This process initially involves establishing endothelial cell apical-basal polarity, mediated by VE-cadherin. Apical borders face apposing cells, whereas the basal border faces the periphery. Beyond this first step, three proposed mechanisms may explain lumen development. The first process involves development of intracellular pinocytotic vesicles and vacuoles, which progressively fuse within the endothelial cell and then with adjacent cells, leading to lumen formation along the length of the stalk. The second mechanism is similar but involves exocytosis of these vacuoles between endothelial cells along the length of the growing stalk. These vacuoles then coalesce and form a lumen.

The third mechanism for lumen formation is by reorganization of intracellular junctions, mediated by VE-cadherin. Endothelial cells adhere to each other and become polar cells as VE-cadherin localizes CD34-sialomucins to the apical cell surface.[32,51-55] The negative charges of sialomucins lead to repulsion of adjacent surfaces of the endothelial cells, inducing lumen slit formation (Fig. 7.6).[32,51] As the lumen develops, the CD34-sialomucins are rearranged to the lateral surfaces of the cells and F-actin is attracted to the exposed lumen. VEGF attracts nonmuscle myosin II to the cell surface, with formation of an actinomyosin complex along the apical endothelial cell surface. This cytoskeletal interaction encourages cellular morphologic shape changes and further luminal expansion.[32,51-53] Beyond tubulogenesis, further increases in lumen diameter are primarily related to FSS.[29,51]

Intussusceptive Angiogenesis

Intussusceptive angiogenesis involves the formation of transcapillary tissue pillars that fuse to form new vessels. This leads to a rapid increase in the complexity of the capillary plexus and increased surface area for gas and nutrient exchange.[56-59] Initially cell contact is created between opposing capillary cells, followed by formation of a bilayer with reorganization of endothelial cell junctions. A pillar core then develops as the result of this activity. Pericytes, myofibrils, and interstitial cells are responsible for perforating the endothelial bilayer to define discrete vessels,[24,59,60] while collagen fibrils are deposited as a foundation for the developing meshwork.[60] After initial capillary formation by either vasculogenesis or sprouting angiogenesis, intussusception is initiated to allow for rapid capillary expansion and remodeling by three basic mechanisms: IMG, arborization, and intussusceptive branching remodeling (IBR).[24,59-61]

IMG initially involves formation of tissue pillars, which provides an increase in the surface area available for exchange of oxygen, carbon dioxide, and nutrients.[24,58-60]

The next phase, intussusceptive arborization, involves the development of "vertical pillars," which transform well-perfused capillary segments into arterioles and venules. This process

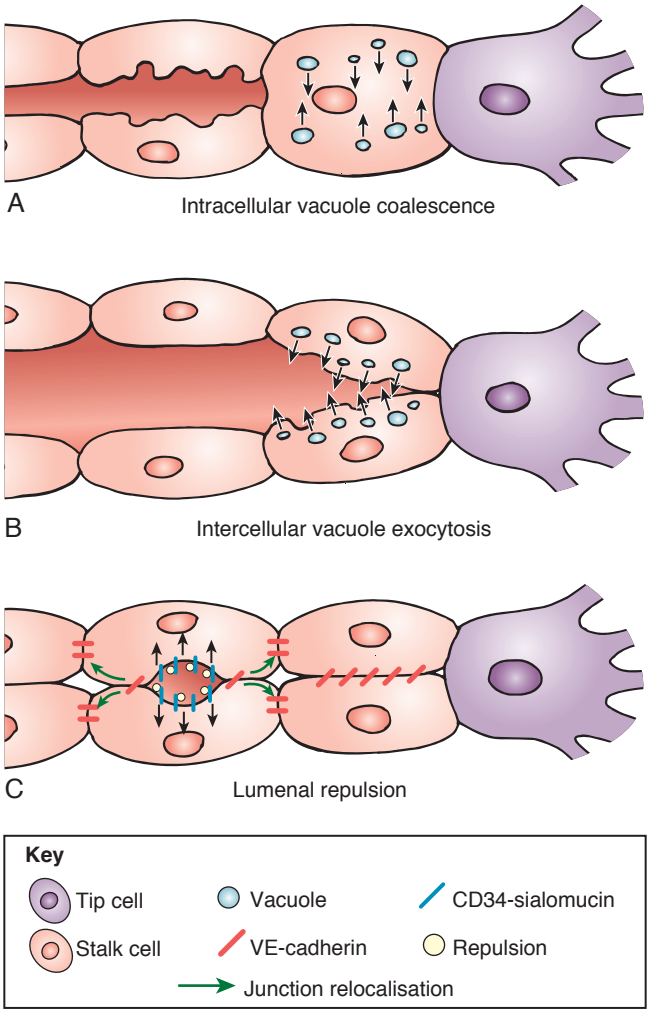

Figure 7.6 Paradigms of Lumen Formation in Angiogenesis. (A) Endothelial cells (ECs) form intracellular pinocytotic vesicles and vacuoles, which fuse within ECs and between adjacent cells, forming a lumen. (B) ECs exocytose vacuoles between cells along the growing stalk. (C) Polarization of ECs by vascular endothelial (VE)-cadherin–mediated localization of CD34-sialomucins to the EC apical surface, leading to apical-basal polarity and subsequent repulsion and lumen formation. (From Geudens I, Gerhardt H. Coordinating cell behavior during blood vessel formation. *Development.* 2011;138:4569–4583.)

decreases the distance between arteries and veins as the capillary plexus expands. Pillars form from endothelial cell reorganization and merging of developing tissue septa (Fig. 7.7). Horizontal folds develop and lead to pillar detachment from any remaining connections, ultimately separating the feeding vessel from the capillary plexus. Hemodynamic forces therefore have a role in further development of the arterial tree.[59,60,62]

IBR is the final process by which intussusception alters the vascular network. It involves adaptation of the angulation at branch points to optimize fluid hemodynamics in response to shear stress. Although this process has a role in branch remodeling, it is not involved in the formation of new capillary branches.[63] Vascular pruning also occurs with IBR because luminal obstruction leads to regression of the vessel in response to oxygen tension and growth factors, including VEGF, PDGF, and angiopoietin-1 (Ang-1).[30,59,64,65] Pruning encourages the predominance of more perfused capillaries with regression of less perfused ones (Fig. 7.8).[24,59,66]

There are multiple benefits of intussusceptive growth. One is that minimal endothelial proliferation is required given capillary expansion occurs primarily by rearrangement or remodeling of existing endothelial cells. Other advantages include low vascular permeability and minimal tissue disruption leading to less porous capillaries.[29,59,60]

Remodeling and Pruning

Remodeling of the capillary network occurs in response to the nutritional needs of local tissue. It involves growth of those vessels preferentially receiving flow, with regression of others. Vessels undergo alterations to increase in luminal diameter and mature their walls. Pruning is a dynamic process and involves vessel regression in response to luminal blood flow and possibly a reduction in VEGF. Areas with low wall shear stress undergo pruning to allow blood flow into larger bore vessels.[29,64,67]

After proliferation and remodeling are complete, blood vessels mature and stabilize largely on the basis of signaling from endothelial cells, pericytes, SMCs, and the ECM.[29,41] Pericytes invade and surround capillaries; subsequently, and likely in relation to interaction with the pericytes, the endothelial cells wrap around pericytes to stabilize the vessel.[68-70]

Postnatal angiogenesis is a dynamic process involving capillary growth related to sprouting and remodeling as directed by blood flow and the action of intussusceptive angiogenesis. Functional specialization of the endothelial cells during sprouting, regulation by VEGF and Notch signaling, and functional remodeling related to tissue metabolic needs are all hallmarks of angiogenesis.

ROLE OF MICRORNAS IN NEOVASCULARIZATION

MicroRNAs (miRNAs) are a class of short endogenous noncoding RNA molecules that regulate gene expression through inhibition of target gene translation.[71] These molecules are approximately 22 nucleotides in length and bind to the 3′-untranslated region (UTR) of target messenger RNA (mRNA).[72,73] The 3′-UTR is a specific section of mRNA following the stop codon of the coding region that contains regulatory regions which can influence post-transcriptional gene expression. The first miRNA identified was *lin-4* in 1993; they were subsequently recognized as a distinct class of regulatory RNAs in 2001.[72-74] A single miRNA can downregulate the expression of multiple target genes and thereby influence multifactorial physiologic processes.[75] In recent years, much has been discerned about miRNA and the important role it plays in post-transcriptional gene expression.

miRNAs influence both arteriogenesis and angiogenesis through interactions with various transcription factors, cytokines, and CAMs. The same miRNAs that are involved in adaptive vascular remodeling are also key regulators in maladaptive processes, such as atherosclerosis and aneurysm formation.[76] A few of the miRNAs involved include miR-126, miR-155, and

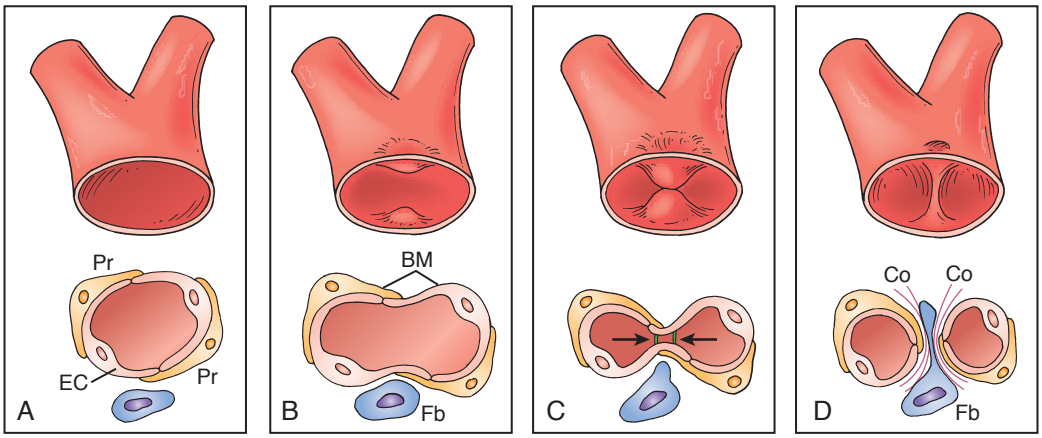

Figure 7.7 Intussusceptive Growth. (A and B) Impingement of endothelial cell wall into lumen, leading to creation of bilayer. (A through D from Kurz H, Burri PH, Djonov VG: Angiogenesis and vascular remodeling by intussusception: from form to function. *News Physiol Sci* 18:65-70, 2003; published by Int Union Physiol Sci/Am Physiol Soc. Entire figure is reproduced from Djonov V, Baum O, Burri PH. Vascular remodeling by intussusceptive angiogenesis. *Cell Tissue Res.* 2003;314:107–117. Published by Springer-Verlag.)

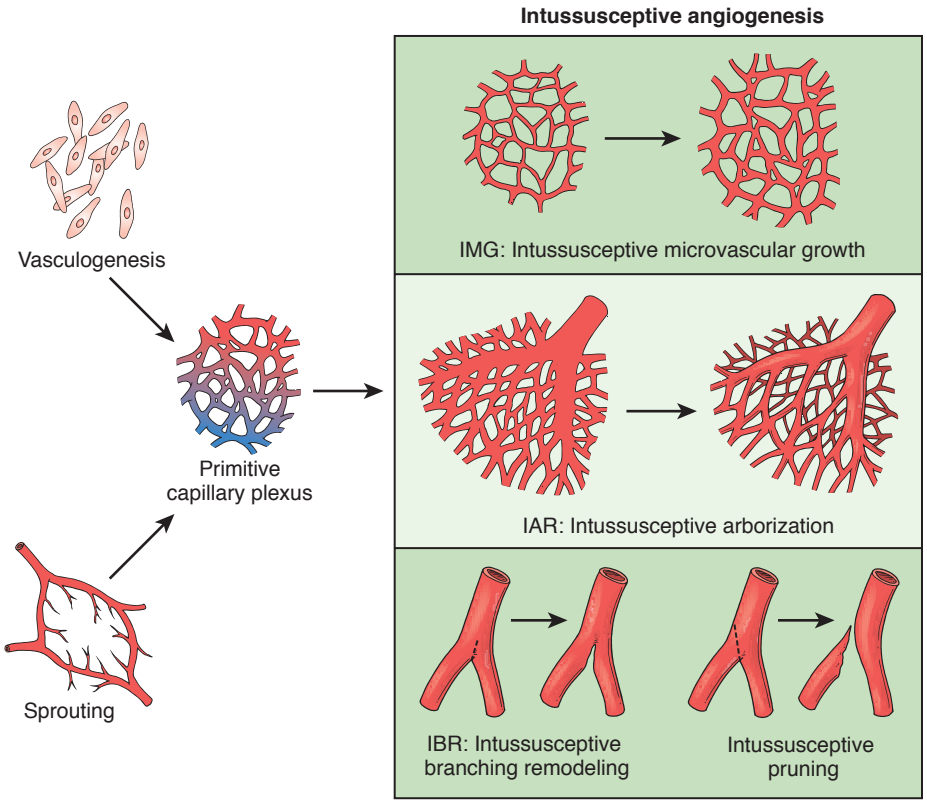

Figure 7.8 Intussusceptive Angiogenesis. The primitive capillary plexus undergoes organization and development into mature vessels via intussusceptive angiogenesis. Pillars develop by apposition of opposing capillary walls. "Vertical" pillars form and fuse, later definitively separating from the capillary plexus and forming new vessels. Local tissue demand promotes further modifications. Small diameter vessel pruning occurs due to low shear stress and possibly a decrease in vascular endothelial growth factor. (From Djonov V, Baum O, Burri PH. Vascular remodeling by intussusceptive angiogenesis. *Cell Tissue Res.* 2003;314:107–117, Springer-Verlag.)

the miRNA families miR-17/92 and miR-23/24/27.[77] The miR-126 gene is located on chromosome 9 and is one of the most abundantly expressed miRNAs in endothelial cells.[78] VCAM-1 expression has been shown to be inhibited by miR-126, which decreases leukocyte adherence to ECs and inhibits angiogenesis.[79] MiR-126 also promotes angiogenesis through inhibition of SPRED1 and PIK3R2, which are inhibitors of the VEGF signaling pathway.[80] The miR-155 gene is located on chromosome 21 and is highly expressed by activated B and T cells, as well as monocytes and macrophages.[81,82] MiR-155 has antiangiogenic as well as proarteriogenic functions through its interactions with AT1R and SOCS1, respectively.[83] It is coexpressed on SMCs with AT1R, where it inhibits the expression of AT1R and limits cell responsiveness to angiotensin II.[84] The

proarteriogenic effect of miR-155 is thought be mediated through SOCS1, which is upregulated in miR-155–deficient mice. These mice show significantly reduced levels of proarteriogenic cytokines.[83] These are only a few examples of the influence miRNAs have on neovascularization. As further progress is made in this area of study, the multifactorial role of miRNAs is certain to be expounded upon.

CLINICAL TRIALS

For a variety of reasons, patients with vascular disease may not be safe candidates for surgical intervention owing to comorbidities or extent of arterial disease. In this challenging patient population, stimulation of neovascularization via gene, protein or cell-based therapies has been proposed. Initial results of gene and protein therapies have been disappointing (Table 7.2); however, more encouraging results have been observed with cell-based therapies (Table 7.3).

Gene and Protein-Based Therapies

Vascular Endothelial Growth Factor

One of the first growth factors to be investigated was VEGF. This growth factor is responsible for promoting endothelial cell proliferation, migration, and lumen formation while inducing monocyte chemotaxis. It has been demonstrated to play an integral part in both arteriogenesis and angiogenesis.[85-94] VEGF was initially investigated in phase I clinical trials by Isner et al.[95] and Baumgarten et al.[96] With intraarterial administration of VEGF, these groups were able to demonstrate an increase in collateral vessels on arteriography, a significant improvement in ankle-brachial index (ABI), improvement in ischemic wounds, and limb salvage in three patients,[96] with the side effect of peripheral edema of the affected limb.[95] Since then several phase II clinical studies have further investigated the use of both intraarterial and intramuscular administration of VEGF.[97-99] Mäkinen et al.[97] in the VEGF peripheral vascular disease (VEGF-PVD) trial, found an increase in collateralization and an improvement in the ABI. Rajagopalan et al.[98] in the RAVE (Regional Angiogenesis with Vascular Endothelial Growth Factor) trial were unable to demonstrate any significant improvement in exercise tolerance or other quality of life indicators and found peripheral edema as a side effect. Kusumanto et al.[99] confirmed an improvement in both ABI and wound healing in a diabetic population, although no significant reduction in amputation rate was identified.

Fibroblast Growth Factor

FGF is a potent stimulator of angiogenesis and arteriogenesis. It induces proliferation, migration, and differentiation of endothelial cells and potentiates VEGF.[85,87-92,100-102] Several phase II and phase III clinical trials have studied the safety and efficacy of intraarterial and intramuscular injections of FGF. The Therapeutic Angiogenesis with Recombinant Fibroblast Growth Factor-2 for Intermittent Claudication (TRAFFIC) trial noted an improvement in exercise tolerance at 90 days, with more improvement observed in smokers, although this improvement did not persist to 180 days.[103] ABI improvements were also noted and did persist to 180 days.[103] The Therapeutic Angiogenesis Leg Ischemia Study for the Management of Arteriopathy and Non-Healing Ulcer(TALSIMAN) trial demonstrated a twofold risk reduction for all amputations and major amputations with FGF therapy, although the therapy achieved no improvement in ulcer healing when compared with placebo.[104] However, a nonsignificant trend toward a reduced mortality with intramuscular FGF was noted in the treatment population.[104] TAMARIS, the phase III trial to follow TALISMAN, was unable to replicate the reduction in amputations or mortality shown in TALISMAN.[105]

Hepatocyte Growth Factor

Hepatocyte growth factor is influential in angiogenesis because it enhances endothelial cell function by activation of the Dll4-Notch signaling pathway, inducing proliferation and migration of endothelial cells.[106-109] Investigation of intramuscular HGF injection in the HGF-STAT trial demonstrated increased transcutaneous oxygen tension ($tcPO_2$) when administered in high/moderate doses,[110] although there was no improvement in ABI, wound healing, or amputation rates. In a phase III trial by Shigematsu et al.,[111] there was 100% improvement in ulcer healing at 12 weeks and a significant improvement in quality of life, although no improvement in rest pain. Henry et al.[112] and Gu et al.[113] were both able to show an increase in median ABI and decrease in pain among patients with significant PAD using a novel form of intramuscular HGF. VM202 is a nonviral DNA plasmid that expresses two isoforms of HGF.[112,113] A more recent phase II trial involving VM202 showed significant reduction in ulcer size and an increase in $tcPO_2$ but failed to demonstrate an improvement in ABI.[114]

Developmentally Regulated Endothelial Locus-1

Developmentally regulated endothelial locus-1 (Del-1) is an angiomatrix protein capable of producing a highly angiogenic response by initiating $\alpha_v\beta_3$-dependent endothelial cell attachment and migration, upregulating an angiogenic phenotype.[108,115-117] In the DELTA (Del-1 for Therapeutic Angiogenesis) trial, intramuscular injection of Del-1 led to improvement in exercise tolerance, delayed the onset of claudication, and improved both quality of life and ABI, as demonstrated by Grossman et al.[117]

Hypoxia-Inducible Factor

HIF-1 is a transcriptional factor that regulates neovascularization in response to hypoxia. It induces gene transcription of VEGF and eNOS, promoting angiogenesis in ischemic environments. It induces vasodilatation, as well as cell proliferation and migration for sprouting angiogenesis. VEGF also recruits pericytes and SMCs and initiates ECM digestion via activation of MMP.[118-126] Creager et al.[127] have investigated HIF in the WALK (effect of HIF-1 gene therapy on walking performance in patients with intermittent claudication) trial to evaluate the effects in patients with claudication. These investigators were unable to demonstrate an improvement in exercise tolerance, claudication, quality of life, or ABI.

TABLE 7.2 Phase II/III Clinical Trials of Gene/Protein-Based Therapy

Trial (Phase)	Therapeutic Intervention	Study Group	Results
VEGF			
Mäkinen (2002)[97] VEGF in chronic limb ischemia (II)	IA VEGF-165 adenovirus/plasmid, after percutaneous transluminal angioplasty Control: LR	54 patients (18 VEGF-Ad, 17 VEGF-p, 19 LR)	Improved vascularity and ABI Rutherford class increased in both treatment and placebo groups
Rajagopalan (2003)[98] RAVE (Regional Angiogenesis with Vascular Endothelial growth factor trial) (II)	IM VEGF-121 adenovirus Control: placebo	105 patients (40 high dose, 32 low dose, 33 placebo)	No improvement in PWT Increased peripheral edema in treatment group
Kusumanto (2006)[99] VEGF in diabetes and chronic limb ischemia (II)	IM VEGF-165 adenovirus Control: NSS	54 patients with diabetes mellitus (27 VEGF-Ad, 27 NSS)	Significant improvements in ABI and ulcer healing, no reduction in amputation rates
FGF			
Lederman (2002)[103] TRAFFIC (Therapeutic Angiogenesis with Recombinant Fibroblast Growth Factor-2 for Intermittent Claudication) (II)	IA FGF-2 Control: placebo	174 patients (63 single dose, 54 double dose, days 1 and 30; 59 placebo)	Improvement in ABI at 90 and 180 days Improvement in PWT at 90 days (more improvement in smokers), not persisting to 180 days
Nikol (2008)[104] TALISMAN (Therapeutic Angiogenesis Leg Ischemia Study for the Management of Arteriography and Non-Healing Ulcer) (II)[a]	IM NV1FGF (FGF-1) Control: placebo	107 patients (51 NV1FGF, 56 placebo)	Reduction in risk of amputations, no significant improvement in ulcer healing Trend toward decrease mortality (NS)
Belch (2011)[105] TAMARIS (III)[a]	IM NV1FGF (FGF-1) Control: placebo	525 patients (259 NV1FGF, 266 placebo)	No improvement in death or major amputation
HGF			
Powell (2008)[110] HGF-STAT	IM plasmid HGF Control: placebo	106 patients (27 low dose, 26 middle dose, 27 high dose, 26 placebo)	$tcPO_2$ increased at 6 months in high/mid-dose group No improvement in ABI, TBI, pain relief, wound healing, major amputation
Shigematsu (2010)[111]	IM naked plasmid HGF Control: placebo	44 patients (30 HGFp, 14 placebo)	Improvements in ulcer healing and QOL Unable to demonstrate improvement in either ABI or rest pain
Henry (2011)[112] (I)	IM VM202(non-viral DNA plasmid) Control: none	12 patients (Dose escalation from 2-16 mg)	Improved ABI/TBI, wound healing and decreased pain
DEL-1			
Grossman (2007)[117] DELTA (Del-1 for Therapeutic Angiogenesis) (IIa)	IM VLTS-589/poloxamer 188 plasmid encoding Del-1 Control: poloxamer plasmid	105 patients (52 Del-1, 53 poloxamer 188 only)	Improvements in PWT, onset of claudication, ABI, QOL
HIF			
Creager (2011)[127] WALK (Effect of HIF-1 gene therapy on walking performance in patients with intermittent claudication) (II)	Induces gene transcription, vasodilation, and endothelial/SMC migration and proliferation to promote angiogenesis	289 patients (3 graded dosing or placebo)	No improvement in PWT, claudication, QOL, ABI

[a]TAMARIS is the phase III trial of the same group who performed TALISMAN, a phase II trial; although results in two studies were different.

ABI, Ankle-brachial index; *Ad,* adenovirus; *Del-1,* developmentally regulated endothelial locus-1; *eNOS,* endothelial nitric oxide synthase; *FGF,* fibroblast growth factor; *HGF,* hepatocyte growth factor; *HGFp,* plasmid HGF; *IA,* intraarterial; *IM,* intramuscular; *LR,* lactated Ringer solution; *NS,* nonsignificant; *NSS,* normal saline solution (0.9%); *NV1FGF,* nonviral 1 FGF; *p,* plasmid; *PVD,* peripheral vascular disease; *PWT,* peak walking time; *QOL,* quality of life; *TBI,* toe-brachial index; *$tcPO_2$,* transcutaneous oxygen tension; *VEGF,* vascular endothelial growth factor.

TABLE 7.3 Cell-Based Therapy, Human Trials[220]

Trial (Phase)	Therapeutic Intervention	Study Group	Results
EPCS			
van Royen (2005)[128] START (STimulation of ARTeriogenesis) trial (II)	SC rhGM-CSF Control: placebo	40 patients (20 rhGM-CSF, 20 Placebo)	Increased microcirculatory flow in treatment group No improvement in ABI or exercise tolerance
Kawamoto (2009)[129] EPOCH-CLI (I/IIa)	IM EPCs ($CD34^+$) Control: none	17 patients (6 low dose, 8 middle dose, 3 high dose)	Improvements in pain, TBI, pain-free walking distance, ulcer healing
Burt (2010)[130](I)	IM EPCs ($CD133^+$) Control: none	9 patients	Improvements in amputation rate, QOL
Zhang (2016) [131](II)	IV EPCs ($CD133^+$) Control: placebo	53 patients (27 treatment, 26 placebo)	Improvements in Rutherford Class, $tcPO_2$, ABI, ulcer healing, and amputation rate
BM-MNC/MSC			
Huang (2005)[217](I)	PB-MNCs Control: IV PGE_1	28 patients (14 PB-MNCs, 14 PGE_1)	Improvements in limb pain, ulcer healing, ABI, TBI, laser Doppler blood perfusion Angiogenic evidence of new vessel development
Powell (2011)[135] RESTORE-CLI (II)	IM BM-MNCs Control: placebo	46 patients (32 BM-MNCs, 14 Placebo)	Improvements in time to treatment failure, amputation free survival
Walter (2011)[134] PROVASA (II)	IA BM-MNCs Control: placebo	40 patients (19 BM-MNCs, 21 placebo), both groups received BM-MNCs at 3 months	Improvements in ulcer healing and rest pain, associated with repeat administration and BM-MNC number/function
Idei (2011)[218](I)	IM BM-MNCs Control: placebo	97 patients (25 w/atherosclerotic PAD, BM-MNCs; 26 w/ Buerger disease, BM-MNCs; 30 w/ atherosclerotic PAD, placebo; 16 w/ Buerger disease, placebo)	Buerger disease: improvements in ABI and $tcPO_2$ at 1 month and 3 years PAD: improvement in ABI at 1 month, gradual return to baseline
Iafrati (2011)[139,140] BMAC (Bone Marrow Aspirate Concentrate)(III)	IM BM-MNCs Control: placebo	48 patients (34 BM-MNCs, 14 placebo)	Improvement in amputation, pain, QOL, Rutherford classification, ABI
Lasala (2012)[136](II)	IM BM-MNCs/MSCs Control: placebo	26 patients (BM-MNCs/MSCs in more ischemic leg, placebo in contralateral)	Improvements in exercise tolerance, ABI; improved perfusion with Tc 99m tetrofosmin scintigraphy
Losordo (2012)[219](I)	IM $CD34^+$ cells—high/low dose, placebo	28 patients	Increased amputation free survival, further increase in high dose group
Fully Differentiated Cells			
Grossman (2016)[141](I) MultiGeneAngio(MGA)	IA MGA(fully differentiated venous ECs expressing Ang-1[angiopoetin-1] and SMCs expressing VEGF-165) Control: none	12 patients (Dose increases across 3 cohorts)	Improvement in mean PWT, COT ABI did not decrease over study period
Ongoing or Recruiting Phase III Clinical Trials (clinicaltrials.gov)[a]			
Maggi SCELTA (III) NCT02454231 Recruiting	Randomized, single center study evaluating IM BM-MNCs vs PB-MCs	(BM-MNCs vs. PB-MCs)	Primary outcome: Improvement in perfusion, evaluated by ultrasound Secondary outcomes: ABI, $tcPO_2$, QOL, rest pain, amputation
Dong (III) NCT02089828 Recruiting	Randomized, single blinded study evaluating purified $CD34^+$ cells vs. PB-MNCs	($CD34^+$ EPCs vs PB-MNCs)	Primary outcome: major amputation free survival Second outcomes: $tcPO_2$, peak pain-free walking time

[a]First researcher's name, trial acronym, and study number given. Information available online from clinicaltrials.gov.

ABI, Ankle-brachial index; *BM,* bone marrow; *BM-MNC,* bone marrow–derived mononuclear cell; *BM-MNCs/MSCs,* bone marrow–derived mononuclear and mesenchymal stem cells; *CLI,* critical limb ischemia; *COT,* claudication onset time; *EC,* endothelial cell; *EPCs,* endothelial progenitor cells; *IA,* intraarterial; *IM,* intramuscular; *MGA,* MultiGeneAngio; *NS,* nonsignificant; *PAD,* peripheral arterial disease; *PGE_1,* prostaglandin E_1; *PWT,* peak walking time; *QOL,* quality of life; *rhGM-CSF,* recombinant human granulocyte-macrophage colony-stimulating factor; *SC,* subcutaneous; *TBI,* toe-brachial index; *$tcPO_2$,* transcutaneous oxygen tension.

Cell-Based Therapies

Endothelial Progenitor Cells

EPCs are derived from bone marrow or peripheral blood and are responsible for initiating postnatal vasculogenesis, given their ability to proliferate and provide both cytokines and growth factors necessary for vessel development.[108,128] Investigation has focused on using recombinant human GM-CSF (rhGM-CSF) to stimulate release of these cells from bone marrow into the peripheral blood for use in initiating angiogenesis in the patients with PAD.

The START (STimulation of ARTeriogenesis using subcutaneous application of GM-CSF as a new treatment for peripheral vascular disease) trial, a phase II clinical trial conducted by van Royen et al.[128] described efficacy of the use of rhGM-CSF in 40 patients with moderate to severe claudication. There was a tendency toward higher peak flow and peak-minus rest flow in the group treated with rhGM-CSF, thought to be related to enhanced endothelial function at the level of the microcirculation. These researchers were able to demonstrate only a temporary increase in monocyte and CD34 stem cell counts over the study period. In addition, a large placebo effect was experienced because both the treatment and placebo groups experienced an increase in walking distance over a 2-week period.[128]

Another phase I/IIa clinical trial, conducted by Kawamoto et al.,[129] concentrated on the use of GM-CSF–mobilized CD34 EPCs in patients with CLI and no options for vascularization or with Buerger disease and CLI. GM-CSF apheresis was used to mobilize the EPCs for use as intramuscular injections in a population of 17 patients. The findings indicated that use of CD34 EPCs was safe and effective because patients experienced improvements in pain, in pain-free walking distance, and wound healing. In addition, toe-brachial index and $tcPO_2$ were improved.[129]

EPCs were also studied by Burt et al.[130] in a phase I trial using GM-CSF–mobilized CD133+ cells from patients with CLI and no other options for revascularization. Intramuscular injection of CD133+ EPCs was found to be safe and was able to prevent amputation in seven of nine patients. In addition, quality of life improved at 3 and 6 months, but effects did not persist at 1 year. A trend toward improvement in symptom-free ambulation and increased exercise capacity was noted at 1 year, although there was no improvement in ABI.[130] Zhang et al.[131] used intraarterial CD133+ cells to improve microvascular circulation and promote angiogenesis in patients with CLI. They first improved flow on a macroscopic level by performing angioplasty on infraaortic and infrapopliteal lesions. In patients with restored flow through either the anterior/posterior tibial or peroneal arteries, significant improvements in ABI, $tcPO_2$, and Rutherford classification were seen at 18 months.[131] Overall, the therapeutic use of EPCs has been shown to achieve modest enhancement of angiogenesis and microcirculatory flow.

Bone Marrow–Derived Cells

BMCs include endothelial stem and progenitor cells, hemangioblasts, angioblasts, and mesenchymal and hematopoietic stem cells. Some of these cell lines are able to differentiate into endothelial cells for angiogenesis,[108,132,133] whereas others, including mesenchymal and hematopoietic stem cells, are not. Most BMCs, regardless of ability to transform into endothelial cells, are proangiogenic and participate in angiogenesis via paracrine signaling and/or the ability to take on endothelial cell–like characteristics.[132]

Phase II clinical trials have been conducted focusing on the safety and efficacy of intraarterial or intramuscular injection of BM-MNCs with or without bone marrow–derived mesenchymal stem cells (BM-MSCs). Initial results have been promising in the treatment of patients with CLI. In the PROVASA trial, a multicenter, double-blinded, randomized phase II trial, Walter et al.[134] examined 40 patients with severe CLI who received intraarterial BM-MNCs or placebo. At 3 months, all patients (treatment and placebo groups) received intraarterial BM-MNCs. In the treatment group a significant improvement was seen in ulcer healing and rest pain within 3 months. Both increased number and functionality of the BM-MNCs and repeated administration were associated with greater improvements in wound healing, which then correlated with limb salvage. There was no difference in amputation-free survival or improvement in ABI between the groups.[134]

Two trials have been conducted using a combination product of BMCs. In the RESTORE-CLI trial (a randomized, double-blind multicenter phase II trial comparing expanded autologous bone marrow-derived tissue repair cells[TRCs] and placebo), Powell et al.[135] evaluated patients with CLI and no options for revascularization. Bone marrow aspiration was performed in 46 patients, and the aspirate was processed to obtain a population of TRCs. This cell population represents a collection of nucleated cells, including endothelial, mesenchymal, and hematopoietic stem and progenitor cells.[133,135] With intramuscular injection of TRCs, improvement was seen in time to treatment failure and in amputation-free survival. There was also a nonsignificant trend toward wound healing in the treatment group.

Lasala et al.[136] also conducted a single-center, prospective, nonrandomized, placebo-controlled phase II clinical trial of the intramuscular injection of a similar combination bone marrow product. Their findings demonstrated improvement in walking time and ABI as well as increased perfusion when evaluated with technetium (Tc 99m) tetrofosmin scintigraphy. The purpose of using a BMC combination product, as in these two trials, is to provide growth factors, ECM molecules, and pericytes that are provided by MSC to interplay with EPCs for enhanced vascular growth and repair.[135-137]

A meta-analysis was conducted of 37 trials (controlled/noncontrolled and randomized/nonrandomized) using G-CSF–mobilized peripheral blood cells (PBCs) or autologous BMCs in patients with PAD.[138] Intramuscular administration, rather than intraarterial, and the use of BMCs, rather than PBCs, were found to be more effective and safe. BMCs were found to improve subjective symptoms, including pain and pain-free walking distance. There was also a significant improvement in ulcer healing. $tcPO_2$ was greater in the treatment group, as was ABI. Comparatively, only a slight and nonsignificant improvement in pain scale was seen with PBCs mobilized by G-CSF.[138]

Although early clinical trials using PBCs mobilized by G-CSF did not yield promising results, clinical trials using BMCs are continuing to demonstrate exciting and promising results in the treatment of CLI. Iafrati et al.[139,140] conducted a randomized, placebo-controlled, phase III trial using BM-MNCs in a group of 48 patients with Rutherford classification 4 and 5. Follow-up at 3 months showed an improvement in pain, quality of life, ABI, and Rutherford classification, as well as decreased rates of amputation in the study group. Further follow-up at 6 months demonstrated a decrease in amputation rates among study patients.[140]

Fully Differentiated Cells

There have been few studies evaluating the role of fully differentiated cells and their use in PAD. Grossman et al.[141] used a combination of fully differentiated autologous venous SMCs expressing VEGF-165 and endothelial cells expressing Ang-1 in a phase I trial. These cells were isolated from a short superficial vein segment, either basilic or cephalic, from the individual's arm. The endothelial and SMCs were transduced ex vivo using pseudo-typed retroviral vectors encoding Ang-1 and VEGF-165, respectively. Following cell processing, the therapeutic combination was administered intraarterially in the subject's most symptomatic leg, and they were monitored for 1 year. This trial demonstrated an increase in mean peak walking time and claudication onset time, as well as no decrease in ABI over the study period. Phase II trials using this unique combination, termed MultiGeneAngio (MGA), are currently ongoing.

Based on contributions from previous editions by R. Eugene Zierler and David S. Sumner.

Obstruction of the vessel lumen is the primary physiologic abnormality in arterial disease—whether it be the result of atherosclerosis, fibromuscular dysplasia, thrombi, emboli, dissection, trauma, or external compression. The consequences of arterial obstruction are related to the degree of narrowing and can be analyzed in terms of hemodynamic principles. Effects on the distal vascular bed depend not only on the severity of the local obstructive lesion but also on the ability of the body to compensate by increasing cardiac work, dilating peripheral arterioles, and recruiting collateral pathways. Except for thrombus formation and occasional dissection, aneurysms seldom produce symptoms of obstruction. The tendency for aneurysms to rupture is determined by both intraluminal pressure and arterial diameter.

BASIC CONCEPTS

Fluid Energy

Although the motion of the blood is generally attributed to pressure gradients, blood flows through the arterial system in response to differences in total fluid energy. The pressure in a fluid system is defined as force per unit area, with units such as dynes per square centimeter (dyn/cm^2) or millimeters of mercury (mm Hg). Intravascular arterial pressure (P) has three components: (1) dynamic pressure produced by cardiac contraction, (2) hydrostatic pressure, and (3) static filling pressure.[1] Hydrostatic pressure depends on the specific gravity of blood and the height of the point of measurement above or below a specific reference level, which is usually considered to be the right atrium. The hydrostatic pressure is given by

$$P(\text{hydrostatic}) = -\rho g h, \qquad \textbf{(8.1)}$$

where ρ is the specific gravity of blood (~1.056 g/cm^3), g is the acceleration due to gravity (980 cm/sec^2), and h is the distance in centimeters above or below the right atrium. The magnitude of hydrostatic pressure may be relatively large. For example, in a man 5 feet 8 inches tall, the hydrostatic pressure at ankle level is approximately 90 mm Hg. In contrast, static filling pressure is low, usually about 7 mm Hg, and is determined by the volume of blood and the elastic properties of the vessel wall.[2]

Total fluid energy (E) consists of potential energy (E_p) and kinetic energy (E_k). The components of E_p are intravascular pressure (P) and gravitational E_p. Gravitational E_p represents the ability of blood to do work because of its height above a

specific reference level. The formula for gravitational E_p is the same as that for hydrostatic pressure but with an opposite sign: $+\rho gh$. Because the static filling pressure is relatively low, and the gravitational E_p and hydrostatic pressure usually cancel each other out, the predominant component of E_p is the dynamic pressure of cardiac contraction. Potential energy can be expressed as

$$E_p = P + (\rho gh). \quad \textbf{(8.2)}$$

E_k represents the ability of blood to do work because of its motion and is proportional to the specific gravity of blood and the square of blood velocity (v):

$$E_k = \tfrac{1}{2}\rho v^2. \quad \textbf{(8.3)}$$

When fluid flows from one point to another, the total fluid energy (E) remains constant, provided that flow is steady and there are no frictional energy losses. This is in accordance with the law of conservation of energy and constitutes Bernoulli's principle. This explains some apparent paradoxes of fluid flow. For example, in Fig. 8.1A, fluid with the density of blood enters the top of an inclined tube at a pressure of 100 mm Hg and flows out at a pressure of 178 mm Hg. Thus fluid moves against a pressure gradient; however, the total fluid energy remains constant because the gravitational E_p decreases by an amount exactly equal to the increase in pressure. In the horizontal diverging tube shown in Fig. 8.1B, steady flow between the entrance and exit is accompanied by an increase in cross-sectional area and a decrease in flow velocity. The widening of the tube results in conversion of E_k to E_p in the form of pressure. Although the fluid moves against a pressure gradient of 2.5 mm Hg and therefore gains E_p, the total fluid energy remains constant because of the decrease in velocity and a proportional loss of E_k. This phenomenon is seldom observed in the human circulation, because associated energy losses effectively mask the rise in pressure. The fluid energy lost in moving blood through the arterial circulation is dissipated mainly in the form of heat.

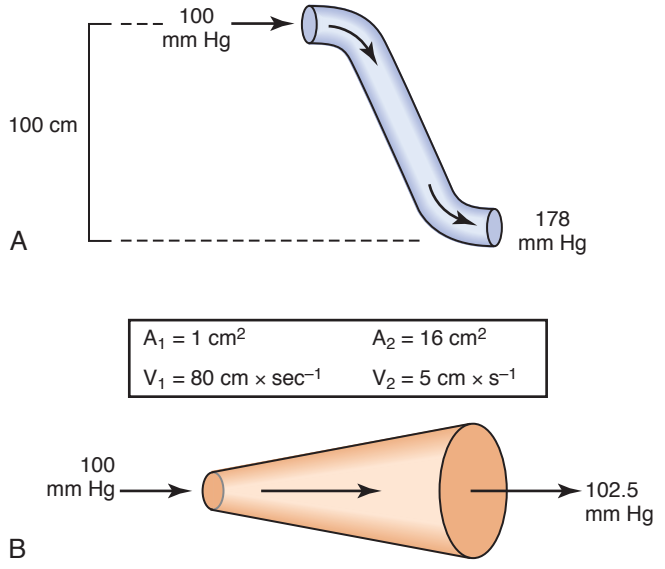

Figure 8.1 (A) Effect of vertical height on pressure in a frictionless fluid flowing downhill. (B) Effect of increasing cross-sectional area on pressure in a frictionless fluid system. A_1 and A_2, areas at the entrance and exit of the system, respectively; V_1 and V_2, velocities at the entrance and exit of the system, respectively.

Poiseuille's Law and Vascular Resistance

Energy losses in flowing blood occur either as viscous losses resulting from friction or as inertial losses related to changes in the velocity or direction of flow. The term *viscosity* describes the resistance to flow that arises because of the intermolecular attractions between fluid layers. Fluids with particularly strong intermolecular attractions offer a high resistance to flow and have high coefficients of viscosity. Because blood viscosity increases exponentially with increases in hematocrit, the concentration of red blood cells is the most important factor affecting the viscosity of whole blood. The viscosity of plasma is determined largely by the concentration of plasma proteins. Poiseuille's law describes the viscous energy losses that occur in an idealized flow model. This law states that the pressure gradient between two points along a tube (P_1–P_2) is directly proportional to the mean flow velocity ($\bar{V}$) or volume flow (Q), the tube length (L), and the fluid viscosity (η), and is inversely proportional to either the second or the fourth power of the radius (r):

$$P_1 - P_2 = \bar{V}\frac{8L\eta}{r^2} = Q\frac{8L\eta}{\pi r^4}. \quad \textbf{(8.4)}$$

This equation is often simplified to (pressure = flow × resistance), where the resistance term (R) is

$$R = \frac{8L\eta}{\pi r^4}. \quad \textbf{(8.5)}$$

The hemodynamic resistance of an arterial segment increases as the flow velocity increases, provided the lumen size remains constant, and these additional energy losses are related to inertial effects or changes in kinetic energy and are proportional to the square of blood velocity (Eq. 8.3).

The strict application of Poiseuille's law requires steady (nonpulsatile) laminar flow in a straight, rigid, cylindrical tube. Because these conditions do not exist in the arterial circulation, Poiseuille's law can only estimate the minimum pressure gradient or viscous energy losses that could be expected in arterial flow. Energy losses due to inertial effects typically exceed viscous energy losses, particularly in the presence of arterial stenoses. In the human circulation, approximately 90% of the total vascular resistance results from flow through the arteries and capillaries, whereas the remaining 10% results from venous flow. The arterioles and capillaries are responsible for over 60% of the total resistance, whereas the large and medium-sized arteries account for only about 15%.[3] Therefore the arteries that are most commonly affected by atherosclerotic occlusive disease are normally very low resistance vessels.

Normal Pressure and Flow

As the arterial pressure pulse moves distally, the systolic pressure rises, the diastolic pressure falls, and the pulse pressure becomes wider. The decrease in mean arterial pressure between the heart and the ankle is normally less than 10 mm Hg. In normal

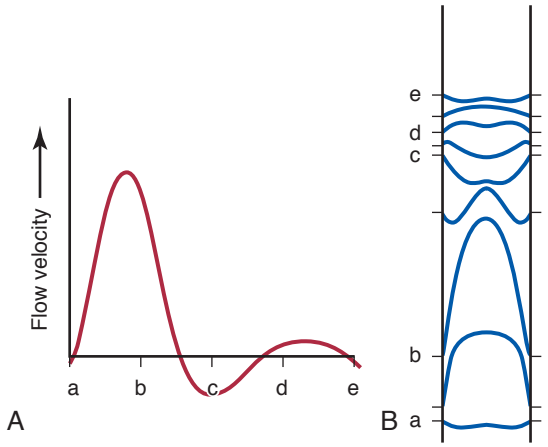

Figure 8.2 Phases of a normal femoral arterial flow pulse (A) and the corresponding velocity profiles (B). *Lowercase letters* indicate corresponding points in the cardiac cycle. For all profiles, the velocity at the wall is zero. At point *b,* forward flow is nearly maximal and the profile is almost parabolic. At the next point, flow near the wall is reversed but that in the center continues forward. Several profiles, both forward and reverse, are blunt in shape. (Adapted from McDonald DA. *Blood Flow in Arteries.* 2nd ed. Baltimore: Williams & Wilkins; 1974.)

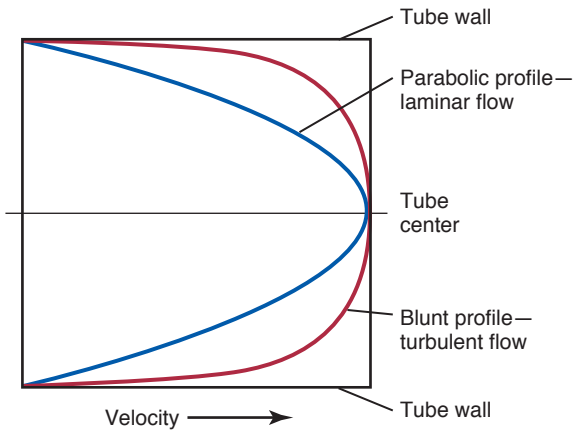

Figure 8.3 Velocity profiles of steady laminar and turbulent flow. Velocity is lowest adjacent to the tube wall and maximal in the center of the lumen. (From Sumner DS: The hemodynamics and pathophysiology of arterial disease. In Rutherford RB, ed. *Vascular Surgery.* Philadelphia: WB Saunders; 1977.)

individuals, the ratio of ankle systolic pressure to brachial systolic pressure (ankle-brachial index) has a mean value of 1.11 ± 0.10 in the resting state.[4] Moderate exercise in normal extremities produces little or no drop in ankle systolic pressure. Very strenuous effort may be associated with a relatively mild decrease in ankle systolic pressure; however, pressures return rapidly to resting levels after cessation of exercise.[5]

The velocity or flow pulse in the major arteries of the leg is normally described as *triphasic*, as shown in Fig. 8.2A. An initial large forward flow phase resulting from cardiac systole is followed by a brief second phase of reversed flow in early diastole and a third smaller phase of forward flow in late diastole. The phase of reversed flow is caused by reflected waves produced when the initial surge of forward flowing blood encounters the high resistance imposed by the arterioles, and these reflected waves subtract from the forward flow. As will be discussed, this triphasic flow pattern is modified by a variety of factors, including proximal arterial disease and changes in peripheral resistance. For example, body warming, which causes vasodilatation and decreased resistance, tends to eliminate the second phase of flow reversal; on exposure to cold, resistance increases and the reversed flow phase becomes more prominent.

The average blood flow in the normal human leg is in the range of 300 to 500 mL/minute under resting conditions.[6] Blood flow to the muscles of the lower leg is approximately 2.0 mL/100 g/minute. With moderate exercise, total leg blood flow increases by a factor of 5 to 10, and muscle blood flow rises to around 30 mL/100 g/minute. During strenuous exercise, muscle blood flow may reach 70 mL/100 g/minute.

Blood Flow Patterns

Laminar and Turbulent Flow

In the idealized flow conditions specified by Poiseuille's law, the flow pattern is *laminar*, with all flow streamlines moving parallel to the tube walls and the fluid arranged in a series of concentric layers or laminae. The velocity within each lamina remains constant, with the lowest velocity adjacent to the tube wall and increasing velocity toward the center of the tube. This results in a velocity profile that is parabolic in shape (see Figs. 8.2B and 8.3).

In contrast to the uniform, linear streamlines of laminar flow, *turbulence* is an irregular flow state in which velocity varies randomly with respect to location and time. These irregular velocity changes result in the dissipation of fluid energy as heat. When turbulence is the result of a stenotic arterial lesion, it generally occurs immediately downstream from the stenosis and may be present only during the systolic portion of the cardiac cycle when velocities are highest. Under conditions of turbulent flow, the velocity profile changes from the parabolic shape of laminar flow to a rectangular or blunt shape (see Fig. 8.3). Because of the random velocity changes, energy losses are much greater for a turbulent flow state than for a laminar flow state.

Boundary Layer Separation

When fluid flows through a tube, the portion of fluid adjacent to the tube wall is referred to as the *boundary layer*. This layer is subject to both frictional interactions with the tube wall and viscous forces generated by the more rapidly moving fluid toward the center of the tube. When the tube geometry changes, such as at points of curvature, branching, or alteration in lumen diameter, small pressure gradients are created that cause the boundary layer to stop or reverse direction. This results in a complex, localized flow pattern known as an *area of flow separation* or *separation zone*.[7,8] Boundary layer separation has been observed in models of arterial anastomoses and bifurcations (Fig. 8.4).[8-10] In the diagram of a carotid bifurcation shown in Fig. 8.5, the central rapid flow stream of the common carotid artery is compressed along the inner wall of the bulb, producing a region of high shear stress, with an area of flow separation along the outer wall of the carotid bulb that includes helical flow patterns and flow reversal. The region of the carotid bulb adjacent to the separation zone is subject to relatively low shear

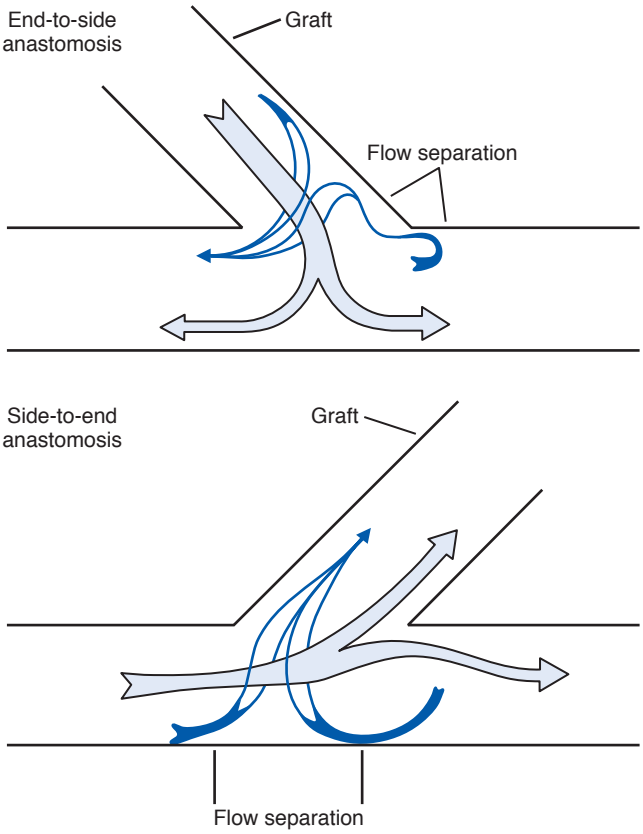

Figure 8.4 Flow patterns at end-to-side and side-to-end anastomoses. Near the wall, blood flow may reverse and travel circumferentially to reach the recipient conduit. Areas of flow separation are prone to the development of neointimal hyperplasia. (Redrawn from Sumner DS: Hemodynamics of abnormal blood flow. In: Veith FJ, et al., eds. *Vascular Surgery: Principles and Practice.* 2nd ed. New York: McGraw-Hill; 1994.)

stresses. Within the internal carotid artery distal to the bulb, flow reattachment occurs and a more laminar flow pattern is present.

The complex flow patterns described in models of the carotid bifurcation have also been documented in human subjects by pulsed Doppler studies.[9,10] As shown in Fig. 8.6A, the Doppler spectral waveform obtained near the inner wall of a normal carotid bulb is typical of the forward flow pattern found in the internal carotid artery. However, sampling of flow along the outer wall of the bulb demonstrates lower velocities with periods of both forward and reverse flow that are consistent with flow separation. Flow separation in the carotid bulb can also be seen with color-flow imaging, as shown in Fig. 8.6B. This is considered to be a normal finding and is particularly common in young individuals.[5] Wall-thickening in the carotid bulb and alterations in arterial distensibility with increasing age make flow separation less prominent in older individuals.[11]

The clinical importance of boundary layer separation is that these localized flow disturbances may contribute to the formation of atherosclerotic plaques.[12] Examination of human carotid bifurcations, both at autopsy and during surgery, indicates that intimal thickening and atherosclerosis tend to occur along the outer wall of the carotid bulb, whereas the inner wall is relatively spared. These findings suggest that atherosclerotic lesions form near areas of flow separation and low shear stress.

Pulsatile Flow

In a pulsatile system, pressure and flow vary with time, and the velocity profile changes throughout the cardiac cycle. The hemodynamic principles that have been discussed are based on steady flow, and they cannot be applied to pulsatile flow in the arterial circulation; however, they can be used to determine the minimum energy losses that would be expected in a specific flow system. The resistance term of Poiseuille's law (Eqs. 8.4 and 8.5) estimates viscous energy losses in steady flow, but it does not account for the inertial effects, arterial wall elasticity, and wave reflections that influence pulsatile flow. The term *vascular impedance* is used to describe the resistance or opposition offered by a peripheral vascular bed to pulsatile blood flow.[6]

Bifurcations and Branches

Although the branches of the arterial system produce sudden changes in the flow pattern that are potential sources of energy loss, the effect of branching on the total pressure drop in normal arterial flow is relatively small. Arterial branches commonly take the form of bifurcations. Flow patterns in a bifurcation are determined mainly by the area ratio and the branch angle. The area ratio is defined as the combined area of the secondary

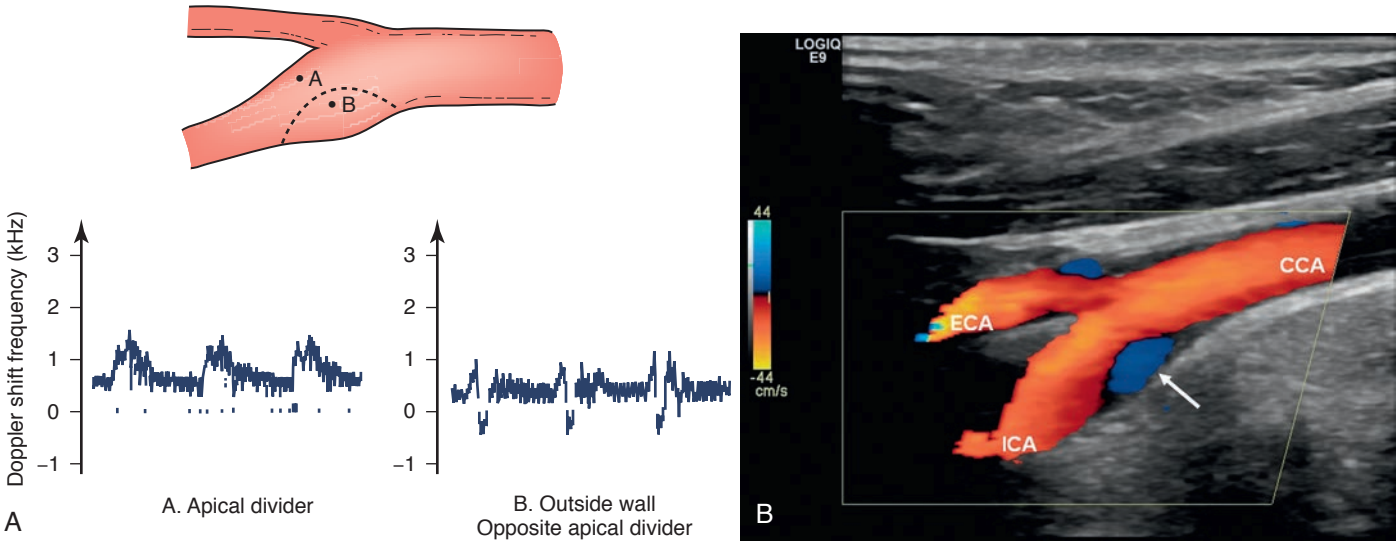

Figure 8.6 (A) Flow separation in a normal carotid bulb shown by pulsed Doppler spectral analysis. The flow pattern near the apical divider *(point A)* is forward throughout the cardiac cycle, but near the opposite wall *(point B)*, the spectral waveform contains both forward (positive) and reverse (negative) components. The latter pattern indicates an area of flow separation. (B) Color-flow image of a normal carotid bifurcation showing an area of flow separation *(white arrow)* adjacent to the outer wall of the proximal internal carotid artery *(ICA)*. The area of flow separation appears blue owing to the presence of reverse flow. *CCA,* Common carotid artery; *ECA,* external carotid artery.

branches divided by the area of the primary artery. Bifurcation flow can be analyzed in terms of pressure gradient, velocity, and transmission of pulsatile energy. According to Poiseuille's law, an area ratio of 1.41 would allow the pressure gradient to remain constant along a bifurcation. If the combined area of the branches equals the area of the primary artery, then the area ratio is 1.0 and there is no change in the velocity of flow. For efficient transmission of pulsatile energy across a bifurcation, the vascular impedance of the primary artery should equal that of the branches, a situation that occurs with an area ratio of 1.15 for larger arteries and 1.35 for smaller arteries.[13] Human infants have a favorable area ratio of 1.11 at the aortic bifurcation, but the ratio gradually decreases with age. This decline in the area ratio of the aortic bifurcation leads to an increase in both the velocity of flow in the secondary branches and the amount of reflected pulsatile energy. For example, with an area ratio of 0.8, approximately 22% of the incident pulsatile energy is reflected back to the infrarenal aorta. This mechanism may play a role in the localization of atherosclerosis and aneurysms in this arterial segment.[14]

The curvature and angulation of an arterial bifurcation can also contribute to the development of flow disturbances and energy loss. As blood flows around a curve, the rapidly moving fluid in the center of the vessel tends to flow outward and be replaced by the slower fluid originally located near the arterial wall. This can result in complex helical flow patterns, such as those observed in the carotid bifurcation.[9] As the angle between the secondary branches of a bifurcation widens, the tendency to develop turbulent or disturbed flow increases. The average angle between the human iliac arteries is 54 degrees; however, with diseased or tortuous iliac arteries, this angle can approach 180 degrees, and flow disturbances are particularly likely to develop.

ARTERIAL STENOSIS

Energy Losses

According to Poiseuille's law (Eq. 8.4), the radius of a stenosis has a much greater effect on viscous energy losses than its length. Inertial energy losses, which occur at the entrance (contraction effects) and exit (expansion effects) of a stenotic segment, are proportional to the square of blood velocity (Eq. 8.3). Energy losses are also influenced by the geometry of a stenosis. A gradual vessel tapering results in less energy loss than an irregular or abrupt change in lumen size. The energy lost at the exit of a stenosis may be quite significant because of the sudden expansion of the flow stream and dissipation of kinetic energy in a zone of turbulence. Fig. 8.7 illustrates the energy losses related to a 1-cm-long stenosis. The viscous energy losses are relatively small and occur within the stenotic segment. Inertial losses due to entrance and exit effects are much greater. Because most of the energy loss in this example results from inertial effects, the length of the stenosis is relatively unimportant.

Critical Stenosis

The extent of arterial narrowing required to produce a significant reduction in blood pressure or flow is called a *critical stenosis*. Because the energy losses associated with a stenosis are inversely proportional to the fourth power of the radius (Eq. 8.4), there is an exponential relationship between pressure drop and reduction in lumen size. When this relationship is illustrated graphically (Fig. 8.8), the pressure curves have a single sharp bend, and further narrowing results in a rapid increase in the magnitude of the pressure drop.[15,16] In peripheral arteries with physiologic flow rates, the critical stenosis value is reached at approximately

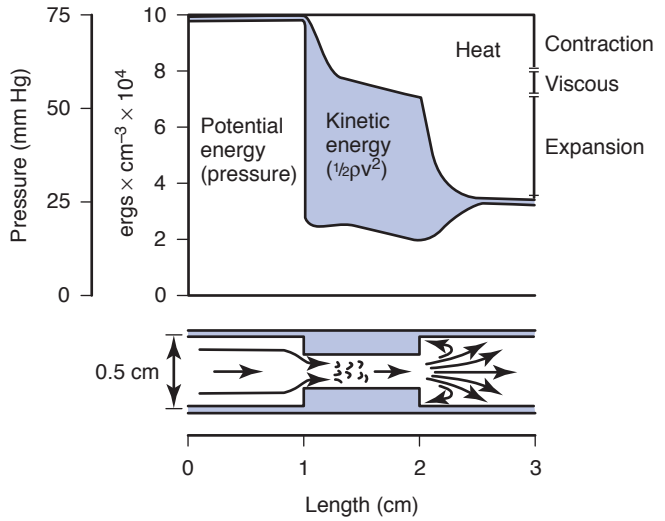

Figure 8.7 Diagram illustrating the energy losses that occur when blood passes through a stenosis 1 cm long. Flow is assumed to be unidirectional and steady. Very little of the total energy loss is attributable to viscous effects, so application of Poiseuille's law will greatly underestimate the drop in pressure across an arterial stenosis. Inertial energy losses due to entrance and exit effects are much greater.

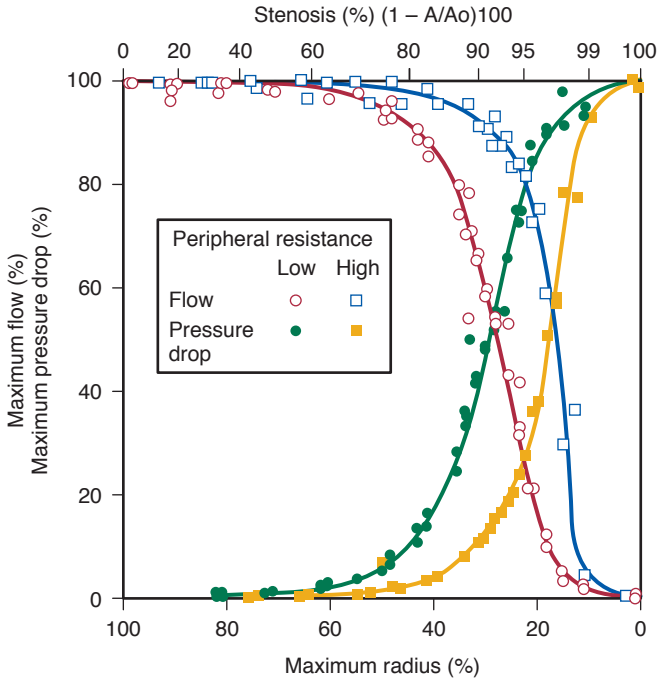

Figure 8.8 Relationship of pressure and flow to the degree of stenosis in a canine femoral artery. When peripheral resistance is high, the curves are shifted to the right. The percentage change in flow through the stenosis is essentially a mirror image of the percentage maximal drop in pressure across the stenosis.

a 50% reduction in lumen diameter or a 75% reduction in cross-sectional lumen area.

Whereas lumen size is the most prominent feature of an arterial stenosis, blood flow velocity is also a major determinant of fluid energy losses, and the pressure drop across a stenosis varies with the flow rate (Eq. 8.4). Consequently, a stenosis that is not significant at low or resting flow rates may become critical when flow rates are increased by reactive hyperemia or exercise. Because flow velocity depends on the distal vascular resistance, the critical stenosis value varies with the resistance of the runoff bed. In Fig. 8.8, a system with a high flow velocity (low resistance) shows a reduction in pressure with less narrowing than a system with low flow velocity (high resistance). The higher flow velocities produce curves that are less sharply bent, making the point of critical stenosis less distinct.

The decrease in flow with progressive arterial narrowing is linearly related to the increase in pressure gradient, as long as the peripheral resistance remains constant.[16] In this situation, the curves for pressure drop and flow reduction are mirror images of each other, and the critical stenosis value is the same for both (see Fig. 8.8). Many vascular beds are able to maintain a constant level of blood flow over a wide range of perfusion pressures by the mechanism of autoregulation. This is achieved by constriction of resistance vessels in response to an increase in blood pressure and dilatation of resistance vessels when blood pressure decreases (Fig. 8.9). For example, autoregulation permits the brain to maintain normal flow rates down to perfusion pressures in the range of 50 to 60 mm Hg.[17]

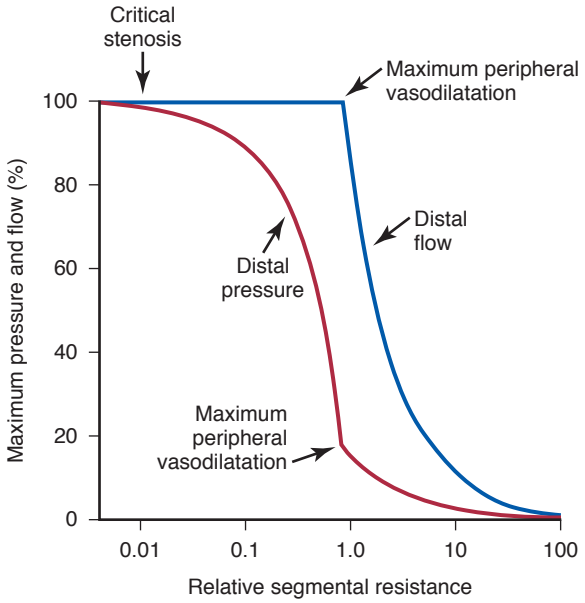

Figure 8.9 Although blood pressure distal to a critical stenosis falls progressively with increasing stenosis severity, autoregulation maintains normal blood flow until maximum peripheral vasodilatation is reached. Beyond this point, pressure and flow are linearly related; increasing stenosis results in marked decreases in both pressure and flow (compare with Fig. 8.8). (Redrawn from Sumner DS: Correlation of lesion configuration with functional significance. In: Bond MG, Insull WJ, Glagov S, et al., eds. *Clinical Diagnosis of Atherosclerosis: Quantitative Methods of Evaluation.* New York: Springer-Verlag; 1983.)

Stenosis Length and Multiple Stenoses

Poiseuille's law predicts that the radius of a stenosis has a much greater effect on viscous energy losses than its length (Eq. 8.4). Doubling the length of a stenosis results in a doubling of the

associated viscous energy losses; however, reducing the radius by half increases energy losses by a factor of 16. Because inertial energy losses are primarily due to entrance and exit effects, they are independent of stenosis length (see Fig. 8.7). Thus separate short stenoses tend to be more significant than a single longer stenosis. It has been shown experimentally that when stenoses that are not significant individually are arranged in series, large reductions in pressure and flow can occur.[18] In other words, multiple subcritical stenoses may have the same effect as a single critical stenosis.

Effect of Stenosis on Waveforms

As shown in Fig. 8.10, the compliant arterial wall and a stenosis create a situation analogous to a "low-pass filter." Passage of a pressure or flow pulse through this circuit attenuates the high-frequency or rapidly changing components of the pulse and results in a damped waveform. The arterial pulse pressure distal to a stenosis is reduced to a greater extent than the mean pressure.[19] In addition to the reduction in pulse pressure, the contour of the pressure pulse is changed radically: the upslope is delayed, the peak becomes more rounded, the "notch" on the downslope disappears, and the downslope becomes bowed away from the baseline. These changes are reflected in the plethysmographic (volume pulse) waveform and thus provide a sensitive indicator of the presence of arterial disease.[20] Similar changes are observed in the flow pulse waveform distal to a stenosis. In contrast to the normal flow pattern, the upslope rises more slowly in systole, the peak is rounded, and the downslope declines more gradually toward the baseline during diastole. The normal reverse flow component of the triphasic waveform also tends to disappear, and the waveform becomes monophasic.[21]

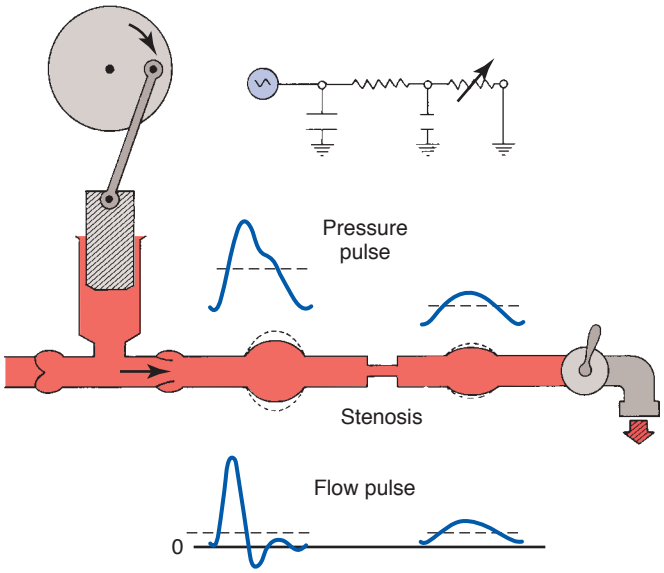

Figure 8.10 Effect of a stenosis and compliant vessels on the contour of arterial pressure and flow pulses. Mean pressure (*dashed lines* on the pressure pulses) is reduced, but mean flow (*dashed lines* on the flow pulses) is unchanged. The faucet represents the variable peripheral resistance. (Redrawn from Sumner DS: Correlation of lesion configuration with functional significance. In: Bond MG, Insull W Jr, Glagov S, et al., eds. *Clinical Diagnosis of Atherosclerosis: Quantitative Methods of Evaluation.* New York: Springer-Verlag; 1983.)

Abnormal Pressure and Flow

If an arterial lesion is hemodynamically significant at resting flow rates, there will be a measurable reduction in distal blood pressure. In general, limbs with a lesion at one anatomic level (e.g., aortoiliac, femoropopliteal, or tibioperoneal) have ankle-brachial indices between 0.90 and 0.50, whereas limbs with lesions at multiple levels have ankle-brachial indices less than 0.50. The ankle-brachial index also correlates to some extent with the clinical severity of disease; in limbs with intermittent claudication, the index has a mean value of 0.59 ± 0.15; in limbs with ischemic rest pain, 0.26 ± 0.13; and in limbs with impending gangrene, 0.05 ± 0.08.[4] Because of the increased vascular resistance produced by an arterial lesion and any associated collateral vessels, the ankle systolic pressure falls dramatically during leg exercise. The extent and duration of this pressure drop are proportional to the severity of the arterial lesions (Figs. 8.11 and 8.12).[22]

As mentioned previously, when blood flows through an arterial stenosis or a high-resistance collateral bed, the distal pulse pressure is reduced to a greater extent than the mean pressure.[19] This suggests that the systolic pressure distal to a lesion is a more sensitive indicator of hemodynamic significance than the mean pressure. It is well known that patients with superficial femoral artery stenosis can have palpable pedal pulses at rest that disappear after leg exercise; this occurs when increased flow through abnormal high resistance vessels causes a reduction in systolic pressure.

Resting leg or calf blood flow in most patients with intermittent claudication is not significantly different from values obtained in normal individuals. However, the capacity of these patients to increase limb blood flow during exercise is quite

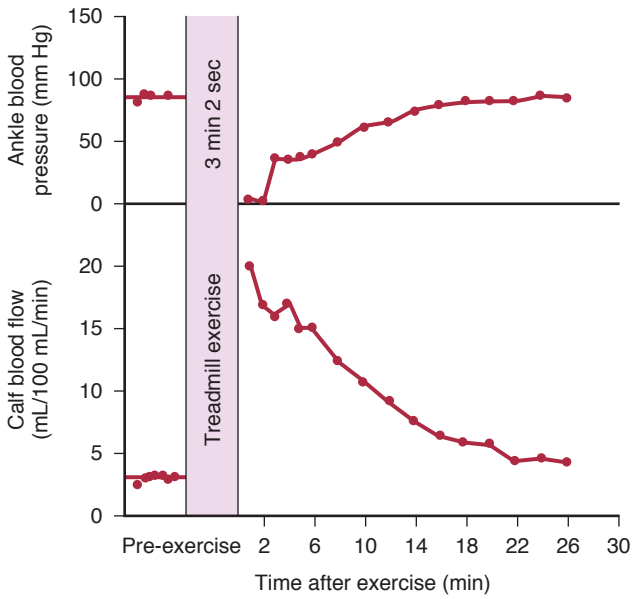

Figure 8.11 Ankle blood pressure and calf blood flow before and after exercise in a patient with stenosis of the superficial femoral artery. (Redrawn from Sumner DS, Strandness DE Jr. The relationship between calf blood flow and ankle blood pressure in patients with intermittent claudication. *Surgery.* 1969;65:763.)

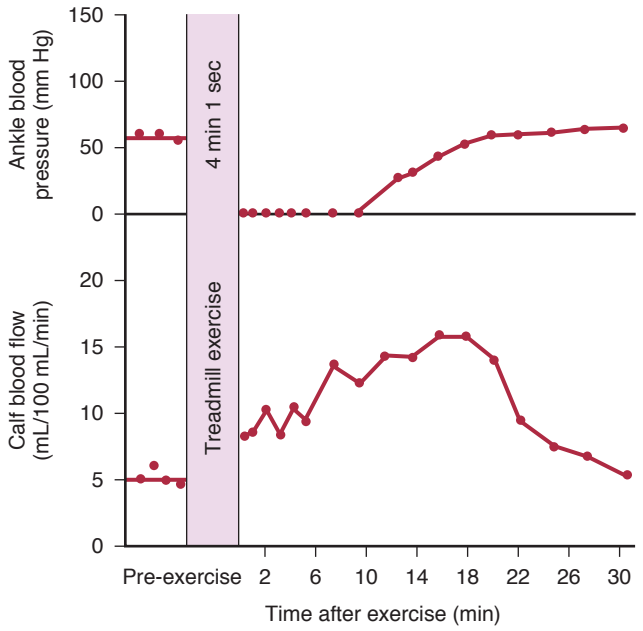

Figure 8.12 Ankle blood pressure and calf blood flow before and after exercise in a patient with stenosis of the iliac artery and occlusion of the superficial femoral artery. Note the more prolonged decrease in ankle pressure and slow return to resting baseline pressure compared to Fig. 8.11. (Redrawn from Sumner DS, Strandness DE Jr. The relationship between calf blood flow and ankle blood pressure in patients with intermittent claudication. *Surgery.* 1969;65:763.)

limited, and pain occurs in the muscles that have been rendered ischemic. As the occlusive process becomes more severe, a decrease in peripheral vascular resistance can no longer compensate, and resting flow drops below normal levels. When this occurs, signs and symptoms of ischemia at rest appear. With increasing degrees of disease, the hyperemia that follows exercise becomes more prolonged, and the peak calf blood flow is both decreased and delayed.[22]

Collateral Circulation

The development of collateral circulation is one of the major mechanisms that compensates for the hemodynamic effects of an obstructed artery. Collateral vessels are preexisting pathways that enlarge when flow through the parallel major artery is reduced. The functional capacity of a collateral system depends on the level and extent of the occlusive lesions. For example, the profunda-geniculate network can compensate to a large degree for an isolated superficial femoral artery occlusion; however, the addition of an iliac artery lesion severely limits collateral flow.

A collateral system consists of three components: (1) stem arteries, which are large distributing branches, (2) a midzone of smaller intramuscular channels, and (3) reentry vessels that join the major artery distal to the point of obstruction.[6] The main stimuli for collateral development are an abnormal pressure gradient across the collateral system and increased velocity of flow through the midzone vessels. Collateral vessels are smaller, longer, and more numerous than the major arteries that they replace. Although considerable enlargement may occur in the midzone vessels, collateral resistance is always greater than that of the original unobstructed major artery. In addition, the acute changes in collateral resistance during exercise are minimal.[23] Therefore the resistance of a collateral system can be considered as fixed. Unlike collateral resistance, the resistance of the peripheral runoff bed is quite variable.

Building on these concepts, vascular resistance in the lower limb can be divided into *segmental* and *peripheral* components. Segmental resistance consists of the relatively fixed parallel resistances of the major artery and any bypassing collateral vessels. Peripheral resistance includes the highly variable resistances of the distal arterioles and cutaneous circulation. The total vascular resistance of the limb can be estimated by adding the segmental and the peripheral resistances. Normally, the resting segmental resistance is very low and the peripheral resistance is relatively high.

Using the superficial femoral artery and profunda-geniculate collateral system as an example, the pressure drop across a normal femoropopliteal arterial segment is minimal. With exercise, the peripheral resistance falls, and flow through the segmental arteries increases by a factor of up to 10, with little or no pressure drop. With moderate arterial disease, such as an isolated superficial femoral artery occlusion, the segmental resistance is increased as a result of collateral flow, and an abnormal pressure drop is present across the thigh. Because of a compensatory decrease in peripheral resistance, the total resistance of the limb and the resting blood flow often remain in the normal range.[24] During exercise, the segmental resistance remains high and fixed, whereas the peripheral resistance decreases further. However, the capacity of the peripheral circulation to compensate for a high segmental resistance is limited, and exercise flow is less than normal. In this situation, exercise is associated with a still larger pressure drop across the diseased arterial segment, and the clinical consequence is calf muscle ischemia and claudication.

Vascular Steal

A vascular "steal" may arise when two runoff beds with different resistances must be supplied by a limited source of arterial inflow. One example of the steal phenomenon involves a limb with lesions in both the iliac and superficial femoral arteries. Between the fixed resistances of these two arterial lesions is the orifice of the profunda femoris artery, which supplies the variable resistance of the thigh. The resistance of the distal calf runoff bed is also variable. Under resting conditions, normal leg blood flow can be maintained by a nearly maximal decrease in calf resistance and a moderate decrease in thigh resistance. This is apparent clinically as abnormally low ankle systolic pressure. With the greater metabolic demands of exercise, thigh resistance can decrease further, but calf resistance has already reached its lower limit. The result is a further drop in pressure across the proximal iliac lesion, which reduces the pressure perfusing the calf. Blood flow to the calf is decreased until thigh resistance rises and thigh blood flow begins to fall. In this situation, the effect of exercise is to increase thigh blood flow, decrease calf blood flow, and decrease distal blood pressure. The thigh steals

blood from the calf because the proximal iliac lesion restricts inflow to both runoff beds.

When an extraanatomic bypass graft is performed, a single donor artery must supply several vascular beds. In the case of a femoral-femoral crossover graft, one iliac artery is the donor artery, the leg ipsilateral to the donor artery is the donor limb, and the contralateral leg is the recipient limb. Studies of crossover grafts in animal models have shown that the immediate effect of the graft is to double flow in the donor artery.[25] These experimental observations are consistent with hemodynamic data from patients with femoral-femoral grafts.[26] Improvement in the ankle-brachial index on the recipient side can be achieved, even when there is significant occlusive disease in both the donor and recipient limbs. Although the ankle-brachial index may decrease slightly on the donor side, a symptomatic steal is uncommon. The most important factor contributing to vascular steal with a femoral-femoral graft is stenosis of the donor iliac artery. With iliac artery stenosis, steal is most likely to occur during exercise, when flow rates are increased. A mildly stenotic iliac can be used as a donor artery when high flow rates are not needed, such as in the treatment of ischemic rest pain. However, when increased flow rates are required to improve the walking distance of a patient with claudication, stenosis of the donor iliac artery may result in steal from the donor limb. Occlusive disease in the arteries of the donor limb distal to the origin of the graft does not result in steal, provided that the donor iliac artery is normal.

Therapeutic Considerations

Arterial Occlusive Disease

Based on the preceding discussion, it is apparent that the high fixed segmental resistance of the diseased major arteries and collaterals is responsible for decreased peripheral blood flow. Therefore, to be most effective in improving peripheral blood flow and relieving ischemic symptoms, therapy must be directed toward lowering this abnormally high segmental resistance. Because the peripheral resistance has already been lowered to compensate for the increased segmental resistance, attempts to further reduce the peripheral resistance will not result in a significant increase in flow.[27]

Walking exercise therapy can lead to an increase in the speed, distance, and duration of walking, with decreased claudication symptoms.[28] Although walking exercise programs can improve walking ability, there is usually little change in the ankle pressure.[29] This finding suggests that the benefits of exercise are due in large part to metabolic changes and alterations in gait, rather than the development of new collateral vessels. In general, exercise therapy is best suited for patients with mild, stable claudication who are not considered as candidates for direct intervention.

A historical method for improving peripheral blood flow in limbs with arterial disease is medically induced hypertension.[27] The administration of mineralocorticoid and sodium chloride raises systemic blood pressure and increases the head of pressure perfusing the diseased arterial segment. Due to the obvious adverse effects of hypertension, this technique has not been widely applied; however, it has been used successfully in patients with severe distal ischemia and ulceration.

Arterial Grafts and Anastomoses

The most effective approach to reducing the abnormally high fixed segmental resistance is direct intervention on the obstructed arterial segments by open surgical or catheter-based techniques. In patients with occlusive disease involving a single anatomic level, a successful procedure should return all hemodynamic parameters to normal or near normal. This should be evident as an increase in the ankle-brachial index and an improvement in the ankle pressure response to leg exercise.[30] When occlusions involve multiple levels, the treatment of one level should result in significant improvement, and the persisting hemodynamic abnormality should then reflect the remaining untreated disease. In such cases, the improvement is usually sufficient to increase claudication distance or relieve ischemic rest pain.

When an arterial graft is required, decisions must be made regarding the choice of graft material, graft diameter, and anastomotic configuration (end-to-end or end-to-side). The factors required for optimal function of arterial grafts can be analyzed in terms of hemodynamic principles. As previously noted, vessel diameter is the main determinant of hemodynamic resistance, so the diameter of a graft is considerably more important than its length. Therefore the graft selected should be large enough to carry all the flow required at rest without causing a drop in pressure, and it should also be large enough to accommodate any increased flow likely to be required during exercise. Another factor to consider is that prosthetic grafts typically develop a thin layer (0.5 to 1.0 mm) of pseudointima on the luminal surface, so after implantation, a 6-mm prosthetic graft might have an internal diameter of only 4 to 5 mm.

Graft diameter is often limited by the size of the native arteries. To minimize energy losses associated with entrance and exit effects, the diameter of a graft should approximate that of the adjacent artery. When arteries of unequal size must be joined, a gradual transition is preferable. Thus the graft should be slightly smaller than the proximal artery and slightly larger than the distal artery. Theoretically, end-to-end anastomoses are preferable to those done end-to-side, because the end-to-end configuration eliminates energy losses due to curvature and angulation. However, these losses appear to be relatively small under physiologic conditions, and in most clinical situations the anastomotic angle is determined by local technical factors. For example, reversed angulation has been used successfully in the construction of aortorenal and femorofemoral bypass grafts. Nevertheless, as a general rule, the smallest anastomotic angle that is technically feasible should be used. The width of an end-to-side anastomosis should be approximately equal to the diameter of the graft; the length of an anastomosis is less important but does serve as the main determinant of anastomotic angle.

Bifurcation grafts, such as those used for aortobifemoral bypass, are subject to the same general hemodynamic considerations as arterial bifurcations and branches. Most commercially available bifurcation grafts have limbs with diameters that are

one-half that of the main body, resulting in an area ratio of 0.5. In this configuration, each of the limbs has 16 times the resistance of the main body of the graft, and in parallel they offer 8 times the main body resistance. The flow velocity in the limbs is doubled, and almost 50% of the incident pulsatile energy is reflected at the graft bifurcation.[6] As previously discussed, the area ratio determines the hemodynamic characteristics of a bifurcation with respect to pressure gradient, flow velocity, and transmission of pulsatile energy. However, the optimal area ratio for bifurcation grafts has not been established, and the geometry of bifurcation grafts has received relatively little attention. Despite their theoretical disadvantages, commercially available bifurcation grafts have functioned extremely well in a variety of clinical applications.

Aneurysms and Arterial Wall Stress

When the structural components of the arterial wall are weakened, aneurysms may form. Rupture occurs when the tangential stress within the arterial wall becomes greater than the tensile strength. The tangential stress (τ) within the wall of a fluid-filled cylindrical tube can be expressed as:

$$\tau = P\frac{r}{\delta}, \qquad \textbf{(8.6)}$$

where P is the pressure exerted by the fluid, r is the internal radius, and δ is the thickness of the tube wall. Thus tangential stress is directly proportional to pressure and radius but inversely proportional to wall thickness. Stress (τ) has the dimensions of force per unit area of tube wall (dynes per square centimeter). Eq. 8.6 is similar to Laplace's law, which defines tangential tension (T) as the product of pressure and radius:

$$T = Pr. \qquad \textbf{(8.7)}$$

Tension is given in units of force per tube length (dynes per centimeter). The terms *stress* and *tension* have different dimensions and describe the forces acting on the tube wall in different ways. Laplace's law can be used to characterize thin-walled structures such as soap bubbles; however, it is not suitable for describing the stresses in arterial walls.

Fig. 8.13 shows a tube with an outside radius of 1.0 cm and a wall thickness of 0.2 cm, dimensions similar to those of atherosclerotic aortas. If the internal pressure is 150 mm Hg, the tangential wall stress is 8.0×10^5 dynes/cm^2. Expansion of the tube to form an aneurysm with an outside radius of 3.0 cm results in a decrease in wall thickness to 0.06 cm. The increased radius and decreased wall thickness increase the wall stress to 98.0×10^5 dynes/cm^2, assuming that the pressure remains constant. In this example, the diameter has been enlarged by a factor of 3, and the wall stress has increased by a factor of 12.

Although the tensile strength of collagen is very high, it constitutes only about 15% of the aneurysm wall.[31] Furthermore, the collagen fibers in an aneurysm are sparsely distributed and subject to fragmentation. The tendency of larger aneurysms to rupture is readily explained by the effect of increased radius on tangential stress (Eq. 8.6) and degenerative changes in the arterial wall. The relationship between tangential stress and blood pressure accounts for the contribution of hypertension to the risk of rupture. Another factor is that in about 55% of ruptured abdominal aortic aneurysms, the site of rupture is in the posterolateral aspect of the aneurysm wall.[32] The posterior wall of the aorta is relatively fixed against the spine, and repeated flexion in that area could result in structural fatigue and a localized area of weakness that might predispose to rupture.

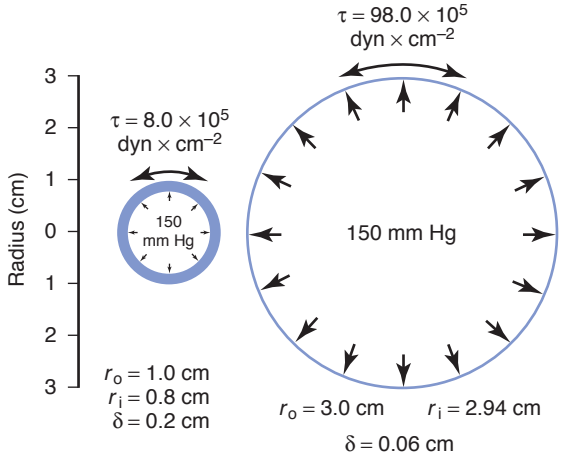

Figure 8.13 End-on view of a cylinder 2 cm in diameter before *(left)* and after *(right)* expansion to a diameter of 6 cm. Wall area remains the same in the two cases, but wall stress (τ) is greatly increased because of both the decrease in wall thickness (δ) and the increase in inside radius (r).

INTRODUCTION

The veins are complex "organs" and much like arteries are well suited to their physiologic purpose. Venous diseases represent a major concern in the general population and are influenced by genetics, environment, and acquired conditions. Understanding the basic physiologic and molecular responses to venous injury is essential for designing effective and safe therapies. Deep vein thrombosis (DVT) refers to the formation of one or more thrombi within the deep veins, most commonly in the lower limbs. The thrombus may cause partial or complete blockage of the circulation, which may lead to characteristic symptoms such as pain, swelling, tenderness, discoloration, or redness of the affected area, and skin ulcers. In 2008 The Surgeon General's Call to Action to Prevent DVT and pulmonary embolism (PE), states *"**the disease disproportionately affects older Americans, and we can expect more suffering and more deaths in the future as the population ages, unless we do something about it,**"* inviting multiple stakeholders, to come together in a coordinated effort to reverse this dramatic projected trend.[1]

BASIC CONSIDERATIONS

Endothelium and Hemostasis

The endothelium forms the inner cell lining of all blood vessels in the body and is a spatially distributed tissue. In an average individual the endothelium weighs approximately 1 kg and covers a total surface area of 4000 to 7000 square meters.[2] The endothelium has been described as a primary determinant of pathophysiology or as a target for collateral damage in most, if not all, disease processes.[2,3] Endothelial cells play a critical role in the balance between procoagulant and anticoagulant mechanisms in healthy individuals. The endothelium is integrally involved in mediating hemostasis.[4]

Most of the thrombosis-thrombolysis processes occur in juxtaposition to the endothelium, and hence the endothelium is one of the pivotal regulators of homeostasis. Under normal conditions, endothelial cells maintain a vasodilatory and local fibrinolytic state in which coagulation, platelet adhesion, and activation are suppressed. A nonthrombogenic endothelial surface is maintained by a number of mechanisms, including

(1) endothelial production of thrombomodulin and subsequent activation of protein C; (2) endothelial expression of heparan sulfate and dermatin sulfate, which accelerate antithrombin (AT) and heparin cofactor II activity; (3) constitutive expression of tissue factor pathway inhibitor (TFPI); and (4) local production of tissue plasminogen activator (tPA) and urokinase-type plasminogen activator (uPA). In addition, the production of nitric oxide (NO) and prostacyclin by the endothelium inhibits the adhesion and activation of leukocytes and produces vasodilation.[5] Tissue factor (TF) production is also inhibited by NO.[6]

In addition, von Willebrand factor (vWF) is expressed to a greater extent on the endothelium of veins compared with arterial endothelium, and tPA is less commonly expressed in venous endothelium.[7] Systemic inflammatory insults, such as conferred by tumor necrosis factor-α (TNF-α), may cause endothelial activation and result in increased surface expression of cell adhesion molecules (CAMs) such as P-selectin, E-selectin, and intracellular CAM (ICAM), thereby promoting the adhesion and activation of leukocytes as well as platelets.[8]

Venous Biomechanics

Veins allow a very large volume capacitance and tonal regulation to rapidly redistribute overall blood volume. Approximately 60% to 80% of circulating blood is stored in the venules and systemic veins at any given time. The function of the blood capacitance system via vasoregulation is to maintain the filling of the heart, as well as to compensate for orthostatic changes. The physiology of venous blood flow in the limb related to the calf muscle pump and other actions is detailed in Chapter 22.

Everyday activities and changes in body position cause large changes in venous pressure. The average venous pressure at the foot is approximately 100 mm Hg in a person 5 feet 10 inches tall weighing 75 kg. This pressure drops significantly with ambulation and during recumbence. The venous valves are endothelium-lined folds of tunica intima that allow unidirectional flow, contribute to this pressure reduction, and maintain blood flow. To accommodate pressure and volume changes, veins undergo complex alterations in shape, depending on the blood volume, resistance, and the amount of blood flow within the system. Less vascular resistance occurs with a circular shape than an elliptical shape, and thus as venous volume increases, resistance to flow lessens.

Unlike arteries, large veins lack an extensive elastic lamella (composed of elastin) but exhibit marked distensible properties. Veins have a much smaller ratio of wall thickness to radius and higher incremental distensibility in the low-pressure range than arteries, thus indicating that the elastic modulus of veins can greatly exceed the stress modulus of arteries. As a result, veins have a high breaking pressure, nearly four atmospheres.[9] Much of the stress-bearing function of the vein wall may depend on its smooth muscle cell and elastin content, in contrast to the abundance of collagen in the arterial wall. Indeed, vein wall compliance is decreased after experimental venous thrombosis (VT) injury, which correlates with its increased collagen content,[10] and disrupted elastin, as measured histologically.[11]

Deep Venous Thrombosis

Venous thromboembolism (VTE) is a significant healthcare problem in the United States, with an estimated 900,000 cases of VT and PE, causing approximately 300,000 deaths yearly.[12] For the past 150 years, understanding the pathogenesis of VTE has centered on Virchow triad of stasis, changes in the vessel wall (now recognized as injury), and thrombogenic changes in the blood. Stasis is probably permissive, and not a direct cause, whereas systemic infection and systemic inflammation may be more causal than previously thought.[13,14]

Venous Thrombosis Pathways

Coagulation Cascade

Hemostasis is typically initiated by damage to the vessel wall and disruption of the endothelium, although it may be initiated in the absence of vessel wall damage, particularly in VT (Fig. 9.1).[15] Vessel wall damage simultaneously results in release of TF, a cell membrane protein, from injured cells and circulating blood, with subsequent activation of the extrinsic pathway of the coagulation cascade. These two events are critical to the activation and acceleration of thrombosis. Differences in local organ mechanisms may cause region-specific susceptibility to thrombosis. For example, hemostasis in cardiac muscle may be more dependent on the extrinsic pathway for thrombosis, whereas skeletal muscle may be more dependent on the intrinsic pathway for thrombosis (see Fig. 9.1).[16]

Coagulation can be activated through the intrinsic pathway with activation of factor XI to XIa, which subsequently converts factor IX to IXa and promotes formation of the Xase complex and ultimately thrombin. Another mechanism by which this occurs in vitro is through the contact activation system, whereby factor XII (Hageman factor) is activated to XIIa when complexed to prekallikrein and high-molecular-weight kininogen (HMWK) on a negatively charged surface; factor XIIa then activates factor XI to XIa. Both thrombin and factor XIa are also capable of activating factor XI.[17]

Thrombin (factor II) is central to coagulation through its action of cleavage and release of fibrinopeptide A (FPA) from the α chain of fibrinogen and fibrinopeptide B (FPB) from the β chain of fibrinogen. This causes fibrin monomer polymerization and cross-linking, which stabilizes the thrombus and the initial platelet plug (see Fig. 9.1). Thrombin also activates factor XIII to XIIIa, which catalyzes the cross-linking of fibrin, as well as that of other plasma proteins, such as fibronectin and α_2-antitrypsin, resulting in their incorporation into the thrombus and increasing resistance to thrombolysis.[18] In addition, factor XIIIa activates platelets, as well as factors V and VIII, further amplifying thrombin production (see Fig. 9.1).

Platelets

Platelet activation and the formation of an effective hemostatic "platelet plug" is a primary thrombotic event, extensively studied in both arterial thrombosis but VT. Two platelet activation routes are thought to exist physiologically.[19] Without direct vessel damage, platelet activation may occur via TF de-encryption

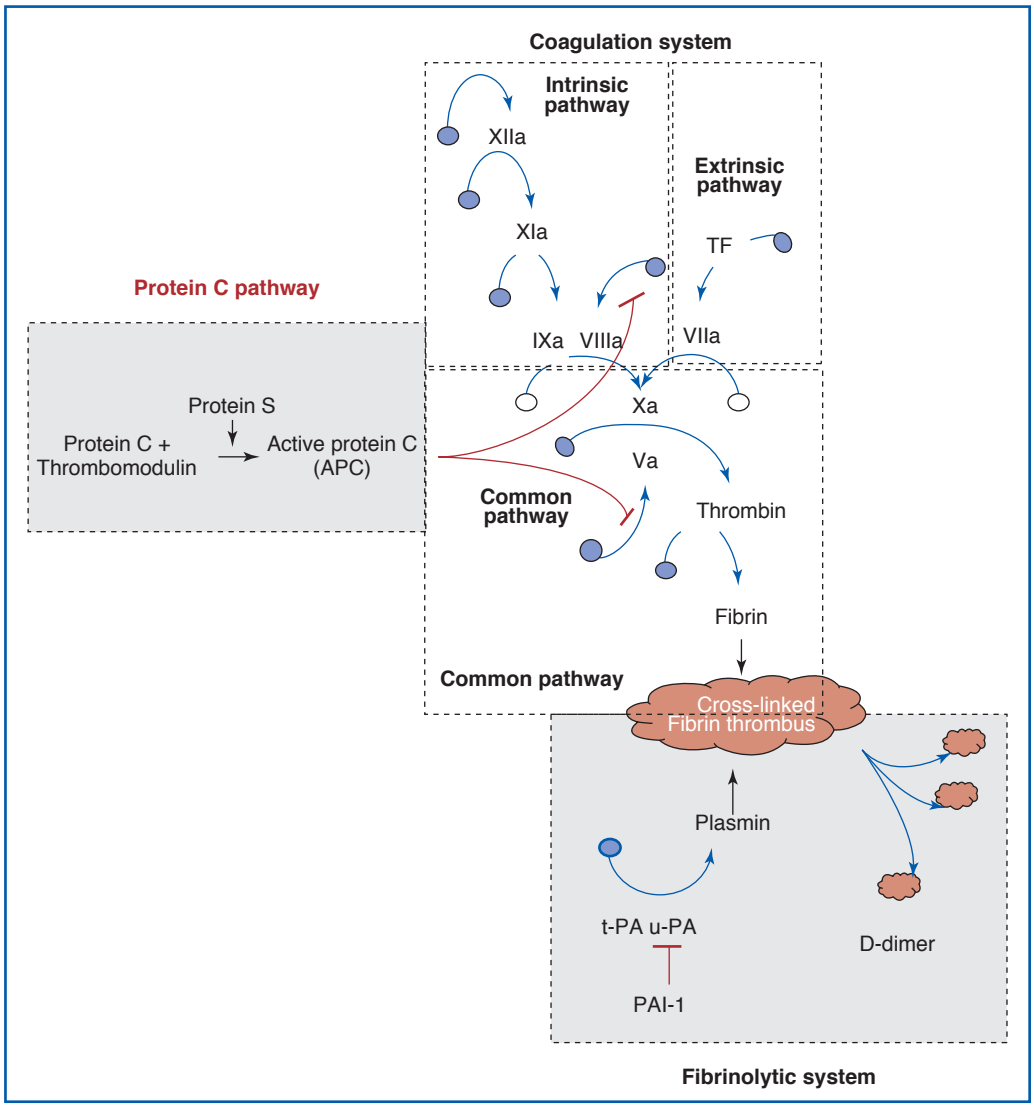

Figure 9.1 Fig. 9.1 shows an integrated representation of the coagulation cascade and the main players for the intrinsic, extrinsic, and common pathways, the natural anticoagulant protein C pathway, and the fibrinolytic system with the degradation product D-dimer. *PAI-1*, Plasminogen activator inhibitor-1; *TF*, tissue factor; *tPA*, tissue plasminogen activator; *uPA*, urokinase-type plasminogen activator.

and activation by protein disulfide isomerase, with factor VIIa generation and activation of platelets. Alternatively, subendothelial collagen may directly bind to glycoprotein (GP) VI and vWF, leading to platelet capture and activation.

Platelet interactions and activation are mediated by vWF, whose receptor is GPIb, via GPIIb/IIIa to fibrin.[20] Activation of platelets leads to the release of the prothrombotic contents of platelet granules, which contain receptors for coagulation factors Va and VIIIa. In addition, platelet activation also leads to the elaboration of arachidonic acid metabolites, such as thromboxane A_2, further promoting platelet aggregation (as well as vasoconstriction). Changes in platelet shape result in exposure of negatively charged procoagulant phospholipids normally located within the inner leaflet of the platelet membrane.[21] Platelets also release microparticles (MPs), rich in TF and other procoagulants, which accelerate and concentrate the thrombus generation. Interestingly, circulating TF may be more important in VT than in arterial thrombosis.[15,22]

Natural Anticoagulants

Several interrelated processes localize thrombotic activity to sites of vascular injury. First, AT is a central anticoagulant protein that binds to thrombin and interferes with coagulation by three major mechanisms: (1) inhibition of thrombin prevents removal of FPA and FPB from fibrinogen, limiting fibrin formation; (2) thrombin becomes unavailable for activation of factors V and VIII, thus slowing the coagulation cascade; and (3) thrombin-mediated platelet activation and aggregation are inhibited. In the presence of heparin the accelerated inhibition of thrombin by AT results in systemic anticoagulation. AT has been shown to directly inhibit factors VIIa, IXa, Xa, XIa, and XIIa. Thus patients with a genetic deficiency of AT are at much higher risk for development of VTE than the normal population.

A second natural anticoagulant is activated protein C (APC), which is produced on the surface of intact endothelium when thrombin binds to its receptor, thrombomodulin, and endothelial

protein C receptor (EPCR; see Fig. 9.1). The thrombin-thrombomodulin complex inhibits the actions of thrombin and also activates protein C to APC. APC, in the presence of its cofactor protein S, inactivates factors Va and VIIIa, therefore reducing Xase and prothrombinase activity (see Fig. 9.1).[23]

The third innate anticoagulant is TFPI. This protein binds the TF-VIIa complex, thus inhibiting the activation of factor X to Xa and formation of the prothrombinase complex. Interestingly, factor IX activation is not inhibited. Finally, heparin cofactor II is another inhibitor of thrombin whose action is in the extravascular compartment. The activity of heparin cofactor II is augmented by glycosaminoglycans, including both heparin and dermatan sulfate, but its deficiency is not associated with increased VTE risk.[24]

Thrombolysis

Physiologic thrombus formation is balanced by controlled thrombolysis to prevent pathologic intravascular thrombosis. Plasmin, the central fibrinolytic enzyme, is a serine protease generated by the proteolytic cleavage of the proenzyme plasminogen. Its main substrates include fibrin, fibrinogen, and other coagulation factors. Plasmin also interferes with vWF-mediated platelet adhesion by proteolysis of GPIb.[25]

Activation of plasminogen occurs through several mechanisms. In the presence of thrombin, vascular endothelial cells produce and release tPA as well as α_2-antiplasmin, a natural inhibitor of excess fibrin-bound plasmin (see Fig. 9.1). As a thrombus is formed, plasminogen, tPA, and α_2-antiplasmin become incorporated into it. In contrast to free circulating tPA, fibrin-bound tPA is an efficient activator of plasminogen. A second endogenous activator of plasminogen is through the uPA, also produced by endothelial cells but with less affinity for fibrin. Activation of uPA in vivo is not completely understood. However, it is hypothesized that plasmin in small amounts (produced through tPA) activates uPA, leading to further plasminogen activation and amplification of fibrinolysis.[26]

The third mechanism of plasminogen activation involves factors of the contact activation system; activated forms of factor XII, kallikrein, and factor XI can each independently convert plasminogen to plasmin. These activated factors may also catalyze the release of bradykinin from HMWK, which further augments tPA secretion. Finally, APC has been found to proteolytically inactivate plasminogen activator inhibitor type 1 (PAI-1), an inhibitor of plasmin activators that is released by endothelial cells in the presence of thrombin.[27]

The degradation of fibrin polymers by plasmin ultimately results in the creation of fragment E and two molecules of fragment D, which are released as a covalently linked dimer (D-dimer).[28] Detection of D-dimer in the circulation is a marker for ongoing thrombus metabolism and has been shown to accurately predict ongoing risk of recurrent VTE.[29] Interestingly, the resting state of the fibrinolytic system within the vein wall is lower in the area of the valvular cusps.[30] In comparison with other anatomic locations, the deep veins of the lower limb have the lowest fibrinolytic activity in soleal sinuses, as well as in the popliteal and femoral vein regions. This observation underlies a popular hypothesis as to why DVT most commonly originates in the lower limb.

Plasminogen Inhibitors and Thrombosis

Activation of plasminogen provides localized proteolytic activity,[31–33] and in plasma, PAI-1 is the primary inhibitor of plasminogen activators. It is secreted in an active form from liver and endothelial cells and is stabilized by binding to vitronectin (and inhibits thrombin in this form). PAI-1 is stored in the alpha granules of quiescent platelets.[34] PAI-1 levels are elevated by hyperlipidemia, and PAI-1 elevation appears to synergize with factor V Leiden genetic abnormalities.

Studies on the role of elevated PAI-1 in VT have been contradictory,[35,36] although it is plausible that elevated PAI-1 could suppress fibrinolysis and increase thrombosis potential. In humans, genetic polymorphisms correlate with increased risk of VTE. The highest levels of PAI-1 have been noted in those individuals carrying the 4G/4G polymorphism. Studies have found an eightfold higher risk for VTE in patients with the 4G allele in combination with other thrombophilic markers,[37] and a 4.5-fold higher risk for PE in patients with 4G/4G polymorphism and protein S deficiency.[38]

Inflammation and Thrombosis

The relationship between thrombosis and inflammation was first suggested in the early 1970s.[39] Inflammation increases TF, membrane phospholipids, fibrinogen, and the reactivity of platelets while decreasing thrombomodulin and inhibiting fibrinolysis (Fig. 9.2).[40]

Several circulating markers of inflammation once thought to be soluble are actually carried by small (<1 μm) phospholipid vesicles called MPs.[41] MPs, which are shed from platelets, leukocytes, and endothelial cells in a calcium-dependent fashion, are involved in the initiation and amplification of thrombosis (see Fig. 9.2).[42] MPs lack DNA and RNA, but subpopulations of MPs rich in TF and phosphatidylserine have been identified.[43] Fusion of MPs with activated platelets results in decryption of TF and the initiation of thrombosis.[44] These vesicles have direct exogenous procoagulant activity, as shown by normalization of tail bleeding times in hemophilic mice.[45] Moreover, MPs shed from platelets express PAI-1, and these MPs add to the growing thrombus via interactions between P-selectin and its receptor, P-selectin glycoprotein ligand-1 (PSGL-1; see Fig. 9.2). In this manner, platelet MPs not only are prothrombotic but also inhibit fibrinolysis, facilitating thrombus growth.[46] The results of these studies provide evidence that MPs are associated with VT; however, their role in thrombogenesis and also their potential role as biomarkers for VT was recently studied.[47]

Galectin 3 (gal3) and galectin 3 binding protein (gal3bp) play important roles in a number of pathologies, such as cancer, infections, diabetes, atherosclerosis, and wound healing, and in inflammatory disorders, such as asthma and rheumatoid arthritis, but their role in VT has not been defined.[48–56] Gal3bp was found to be upregulated in MPs collected from human patients diagnosed with DVT (see Fig. 9.2).[57] Gal3bp is a

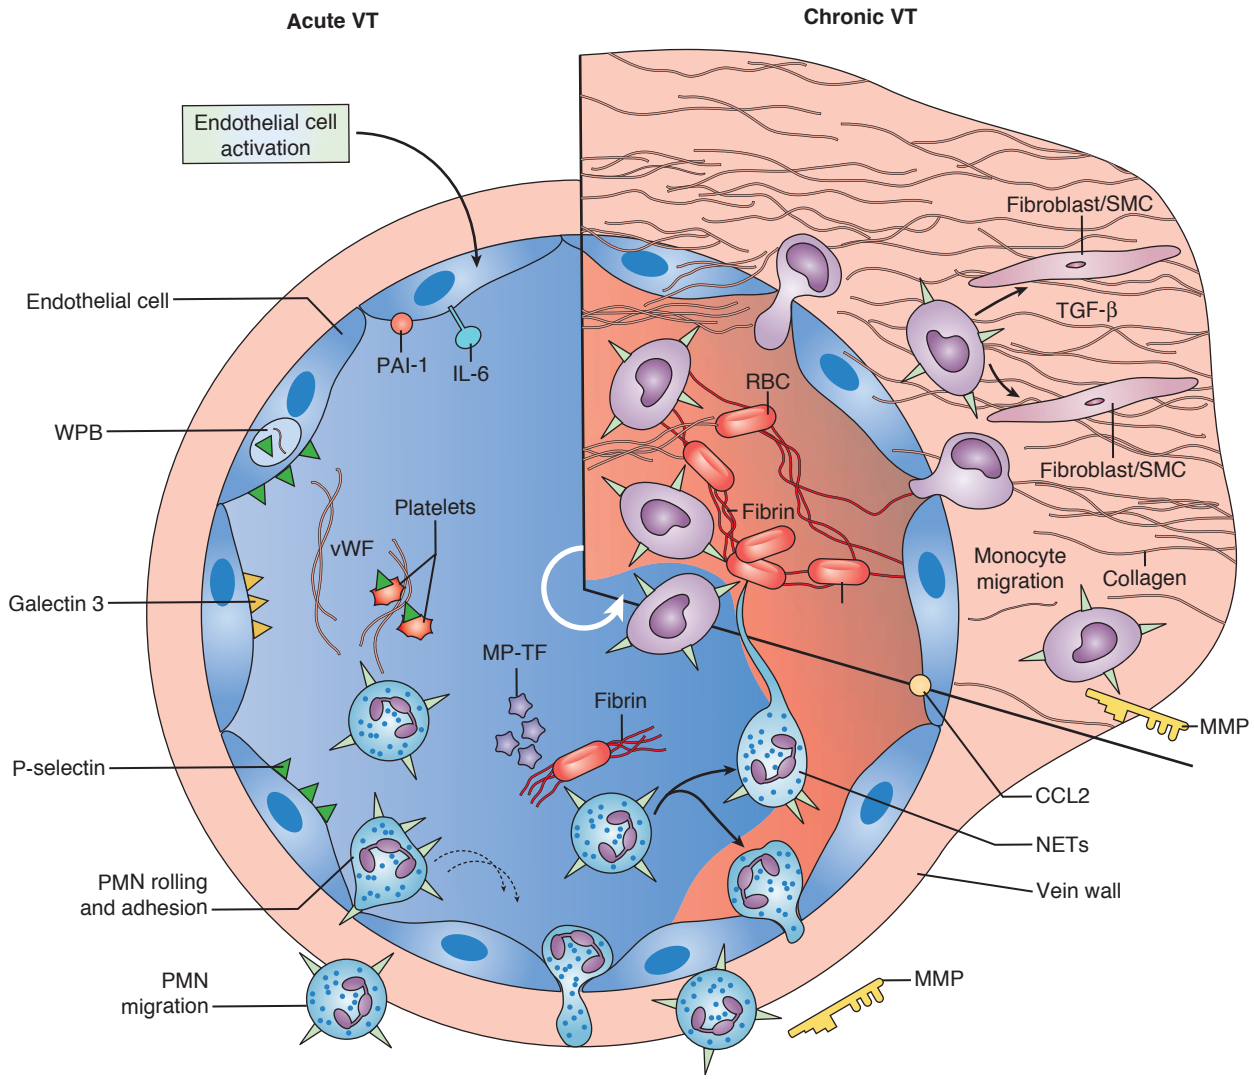

Figure 9.2 Fig. 9.2 shows a schematic representation of the inflammatory events during acute and chronic venous thrombosis in an anticlockwise fashion. The initial inflammatory events involve endothelial activation with secretion of cytokines and plasminogen activator inhibitor-1 (PAI-1) and release of von Willebrand factor (vWF) and P-selectin. This platform favors polymorphonuclear (PMN) recruitment. Platelet activation also contributes to the initial steps, and the fibrin red blood cell (RBC)-rich thrombus *(in light red)* forms. Vein wall, in *gray*, increases thickness over time. *CCL2*, CC motif ligand 2; *IL-6*, interleukin-6; *MMP*, matrix metalloproteinase; *MP-TF*, microparticle-tissue factor; *NETs*, neutrophil extracellular traps; *SMC*, smooth muscle cell; *TGF-β*, transforming growth factor-β; *VT*, venous thrombosis; *WPB*, Weibel-Palade body.

member of the lectin family, associated with integrin-mediated cell adhesion.[58] Gal3 and gal3bp were discovered to be associated with murine thrombogenesis. In addition, gal3 could be a potential biomarker in patients with acute DVT.[47] Gal3bp and gal3 were found in all tissue and blood elements pertinent to the thrombi that were examined (MPs, red blood cells, platelets, vein wall, thrombus), with the exception of leukocytes. In addition, increased circulating gal3bp and gal3 were observed during VT conditions in both mice and humans, showing parallelism between these two species and their potential to be biomarkers.[47] A detailed review of galectins and their potential role in venous thrombogenesis, inflammation, and fibrosis was published.[59]

Thrombus Resolution and Vein Wall Remodeling

Regardless of the location and extent of acute DVT, the resolution process is complex.[60] In humans the natural fibrinolytic mechanisms break down the thrombus over time at variable rates.[61] Resolution of experimental VT resembles wound healing, involving profibrotic growth factors, collagen deposition, and activation of matrix metalloproteinase (MMP; see Fig. 9.2). The fact that leukocytes invade the thrombus in a specific sequence suggests their importance in normal thrombus resolution.[62] Real-time in vivo imaging has also shown that leukocyte concentration and MMP activity colocalize to areas of recanalization.[63,64]

The first leukocyte subtype arriving to the thrombus is the polymorphonuclear neutrophil (PMN; see Fig. 9.2). Although PMNs may cause vein wall injury, they contribute to both early thrombus amplification and early thrombus resolution. The role of PMNs in promoting early DVT by release of neutrophil extracellular traps (NETs) has been shown in primate and murine models of thrombosis.[65] Inflammatory activation of PMNs causes degranulation of nucleic DNA, which is complexed with antimicrobial peptides and allows platelets and coagulation factors to assemble in juxtaposition to the vein wall. Consistently, DNAse treatment can directly accelerate VT resolution.

The monocyte is likely the most important cell for later DVT resolution (see Fig. 9.2).[62] In mice, monocyte influx into the thrombus correlates with elevations of monocyte chemotactic protein-1 (MCP-1), one of the primary CC chemokines that direct monocyte chemotaxis and activation[66,67]; MCP-1 has also been associated with DVT resolution.[68] Targeted deletion of CC receptor 2 (CCR2 KO) in the mouse model of stasis thrombosis is associated with late impairment of thrombus resolution, probably via impaired interferon-γ–inducible proteinase activity, which may be independent of monocytes.[69]

The local venous environment is by definition hypoxic. A major angiogenic growth factor is hypoxia-inducible factor-1α (HIF-Iα). Murine stasis models of VT have shown that thrombosis stimulates HIF-Iα, which thus accelerates thrombus resolution.[70] VEGF has also been associated with increased thrombus recanalization in smaller venous thrombi from rat models of DVT. VEGF was also correlated with higher numbers of thrombus monocytes.[71] Thus thrombus resolution is in part dependent on neovascularization. The effect of mechanical stretch, such as by a venous thrombus, may also stimulate HIF-Iα as well as MMP-2 and MMP-9, all of which lead to reduced vein contractility.[72]

As the thrombus resolves, a number of proinflammatory factors are released into the local environment, including interleukin-1β (IL-1β) and TNF-α.[73] The cellular sources of these different mediators have not been specifically defined but probably include leukocytes and smooth muscle–like cells within the resolving thrombus and adjacent vein wall. Leukocyte kinetics in the vein wall during DVT are similar to what is observed in the thrombus, with an early influx of PMNs followed by monocytes (see Fig. 9.2). On the basis of experimental studies, elastinolysis and collagenolysis seem to occur early, as measured by an increase in vein wall stiffness persisting through 14 days, and are accompanied by elevated MMP-2 and MMP-9 activities.[10,11] In addition, the protective effect of P-selectin inhibition is not yet know but probably does not involve leukocyte migration blockage, because no differences in influx of monocytes into the vein wall were observed.[74]

Loss of venous endothelium likely also contributes to vein wall fibrosis, as well as the predisposition to recurrent thrombosis. An experimental model of DVT showed lower expression of homeostatic endothelial gene products such as NO and thrombomodulin compared with controls, which correlated with loss of vWF-positive cell luminal staining.[75] Other investigators have found that prolonged venous stasis is associated with decreased plasminogen activators, probably related to the loss of endothelium.[76]

The profibrotic growth factor TGF-β is present in the thrombus and is activated with normal thrombolysis (see Fig. 9.2).[76] TGF-β may be a key mechanism promoting vein wall fibrosis. Late fibrosis has been observed in a mouse model of DVT, which demonstrated a significant increase in vein wall collagen.[59] Correlating with this increase in fibrosis is an increase in collagen I and III gene expression, as well as increases in MMP-2 and MMP-9 gene expression and activity. Genetic deletion of MMP-2 or MMP-2/9 is associated with decreased vein wall fibrosis, possibly by modulating vein wall elastin/collagen metabolism as well as monocyte influx.[77] Thus early vein wall injury is associated with active matrix remodeling that seems to promote late fibrosis, not unlike many organ responses to inflammation burnout.[78]

Chronic Venous Insufficiency

The common mechanism of chronic venous insufficiency (CVI) is venous reflux between the superficial and deep systems, either at the site of perforators or through other deep and superficial system connections, which accounts for the increased venous hydrostatic pressure transmitted to the superficial veins and tissues. An obstructed vein segment worsens this process. Experimentally, venous hypertension activates leukocytes,[79] although the activation is probably a local phenomenon.[80] The process of vein wall fibrosis plays a contributing role in valvular damage, which then worsens the hydrostatic pressure regulation and consequently promotes greater venous hypertension while in the upright position. Molecular and cellular events seem to point to adaptive responses to injury, as well as abnormal healing.

Historical Perspective and General Background

Several important theories have been postulated regarding the etiology and pathophysiology of CVI. In 1917 John Homans[81] produced a clinical treatise on the diagnosis and the management of patients with CVI and coined the term "post thrombotic syndrome." Alfred Blalock[82] put forth the hypothesis that local hypoxia precipitated CVI. Local tissue hypoxia and alterations in nutrient blood flow were proposed as an underlying etiology by Browse and Burnand.[83] Their important study directly demonstrated the effect of venous hypertension on the venous microcirculation, and they observed histologically the occurrence of pericapillary fibrin deposition in large capillaries, which they called the "fibrin cuff." Coleridge proposed that leukocyte trapping in slow-flow and distended venous segments may underlie much of CVI development.[84] Burnand et al.[85] also showed a positive correlation between the number of capillaries in the skin and the inability of the calf pump to reduce foot vein pressure during exercise.

Varicose Veins

Varicose veins (VVs) have been described since before the Common Era and are obvious on the lower limbs of many

people. The fact that VVs primarily affect the lower limb directly implicates the upright nature of humans—specifically, the effect of hydrostatic pressure on the pathophysiology of such veins. The relationship between body weight and the extent/symptoms of VVs is variable. Limb symptoms are generally local and consist of pruritus and swelling. Occasionally, VVs can erode and bleed. Conversely, most such veins do not thrombose, despite relatively slow blood flow through these torturous structures, pointing to the natural anticoagulant nature of venous endothelium even in structurally abnormal vessels.

Initially, VVs are typically located in the great and small saphenous distributions and their tributaries in the superficial system.[86] Related risk factors are multiple, including primary etiologies associated with pregnancy, prolonged standing, female gender, and, rarely, congenital absence of valves.[87] In addition, varicosities may develop as a result of prior DVT or trauma. Studies support a genetic predisposition to VVs.[88] In a prospective study of 402 subjects the risk of development of VVs was 90% if both parents were affected, 25% for males and 62% for females if one parent was affected, and 20% if neither parent was affected.[89] These data suggest an autosomal dominant with a variable penetrance mode of genetic transmission.

VVs lead to matrix dysregulation with altered expressions of collagen types I and III, with varying dysregulation patterns. The observed pathology suggests a net effect of matrix deposition. One mechanism for these changes may be local upregulation of MMPs and fibrinolytic activity within the microenvironment.[90] Overall differences in MMP-9 protein have also been identified, and it is likely, with the inflammatory influx, that MMP-9 is released primarily from PMNs and may be less important than MMP-2.[91]

This disordered vein structure also correlates with altered vasoreactivity. The contractual response of varicose and normal great saphenous rings to various alpha-adrenergic and non–alpha-adrenergic receptors has shown decreased contractility as compared with controls.[92] This lower contractility may be due to repeated overdistention or impaired contractility related to persistent vein wall tension. However, the response is segmental and likely adaptive.[93] Defining whether VVs involve an initial wall defect and a secondary hemodynamic factor or vice versa is still under debate.

Pathophysiology of Stasis Dermatitis and Dermal Fibrosis

Stasis venous dermatitis is a disease of chronic dermal inflammation due to persistent and sustained cutaneous and dermal injury secondary to venous hypertension. The primary injury may be extravasation of macromolecules and red blood cell products into the dermal interstitium, which creates a secondary inflammatory response, and multiple pathophysiologic hypotheses have been proposed.[94] The clinical appearance is that of brawny induration, skin thickening, swelling, and tissue breakdown with ulceration in the gaiter regions. Alteration in the extracellular matrix is clear on histologic assessment, with extracellular disorganized collagen deposition in the dermal space and perivascular tissue cuffs.

Skin hypoxia occurs on the gaiter areas of limbs with severe venous disease and is significantly different from controls, oxygen tension ($tcPo_2$) differing by more than 20 mm.[95] Although leukocyte trapping within the capillaries is probably not the sole cause, it is likely that leukocytes become activated, transmigrate into the vein walls, and mediate some of the observed tissue damage. Consistently, findings in punch biopsy specimens of ulcers suggest that leukocytes play a role in the dermal manifestations of CVI.[96] Leukocytes, macrophages, and mast cells have all been observed in immunohistochemical and electron microscopic examinations of affected dermal tissue.[97]

The dermal fibroblast may also be dysfunctional and allow perpetuation of the ulcer. Decreased motility, in part mediated by the microenvironment, plays a role in the impaired healing process of ulcer tissue.[98] Comparison of venous ulcer fibroblasts with control fibroblasts with stimulation with TGF-β suggested that there are differences in collagen production.[99]

An interesting but unanswered question is "why are patients with similar degrees of reflux and hydrostatic pressures from CVI more predisposed to venous ulcers?" Data now suggest that iron metabolism and ulcer development are interrelated. Although commonly thought of as a consequence of all the other mechanisms of CVI, the iron deposition itself may cause tissue damage.[100] More convincingly, the risk of ulcer development among patients with class 4 to 6 CVI was sevenfold higher in those with the C282Y genotype, a mutation related to iron processing.[101] This is an interesting area where the efforts between basic scientists and clinicians are devoted to providing new information to better understand the disease and improve patient treatment.

THROMBOPHLEBITIS

Thrombophlebitis, or venous wall inflammation associated with thrombosis, may be sterile or associated with a bacterial infection.[102] Most often it involves the superficial venous system, such as the great saphenous or cephalic vein, and occurs after placement of an intravenous catheter or other superficial trauma. Symptoms include pain, redness, swelling, and tenderness to palpation (often like a cord) present in the affected limb. A systemic febrile response is usually absent in noninfected cases, whereas bacterial thrombophlebitis may be a source of postoperative fever.

It is unclear whether there is a specific genetic predisposition to thrombophlebitis, but clinical factors and environment likely play the biggest roles. Migratory thrombophlebitis is a special case, which was described by Trousseau in the 1800s, and is specifically linked to patients with pancreatic cancer. Thrombophlebitis can also manifest superficially through Mondor disease, in which the veins of the breast tissue particularly in the upper outer quadrant are affected.

Sterile phlebitis may occur in varicosities, as well as after venous stripping or endovenous ablation. An experimental study of sterile thrombophlebitis showed a typical sequence of early PMN attachment followed by transmigration and inflammatory changes. Approximately 25% of the time, thrombosis occurs before symptoms. The histologic pathology is an acute vasculitis

with marked thickening, inflammatory cells, and fibrin deposition.[103] Later resolution involves fibrotic changes and recanalization of the venous segment at variable rates over weeks to months. One study has shown that anticoagulation for 45 days significantly decreased proximal venous thrombus propagation by approximately 85%.[104]

The role of bacterial infection in directly promoting thrombosis has been described in various clinical settings.[105] The pathophysiology of infectious thrombophlebitis is similar to that of any closed-space infection, and bacterial antigens and proteins may directly stimulate VT and the extrinsic pathway. Organisms can be diagnosed by cultured from infectious thrombophlebitis, including both gram-positive and gram-negative species.

CONCLUSION

It is an exciting time to study venous thrombogenesis and the pathophysiology of the resulting vein wall damage, in part because it has been relatively neglected compared with arterial disease. Fortunately, the National Institutes of Health has put forth two requests for funding applications in the past several years to better study the clinical and basic pathobiology of venous disease and the surgeon general has approved a call to action against VTE. Adjuncts to or replacement therapies for anticoagulants hold tremendous promise and will hopefully decrease the early risk of PE and the late complications of PTS for the benefit of the patient.

In a narrow sense, the lymph circulation is a unidirectional vascular system that merely transports surplus tissue fluid back to the bloodstream. In a broader sense, however, this network stabilizes the mobile intercellular liquid and extracellular matrix microenvironment to ensure parenchymal cellular integrity and function.

In its entirety, the lymphatic system is composed of vascular conduits: lymphoid organs, including the lymph nodes, spleen, Peyer patches, thymus, and nasopharyngeal tonsils; and cellular elements that circulate in the liquid lymph, such as lymphocytes and macrophages. These migrating cells cross the blood-capillary barrier along with a multitude of immunoglobulins, polypeptides, plasma protein complexes, and cytokines and enter the lymphatics to return to the bloodstream. Although body water circulates very rapidly as a plasma suspension of red blood cells within the blood vascular compartment, it percolates slowly outside the bloodstream as a tissue fluid-lymph suspension of lymphocytes through lymph vessels and lymph nodes. As a specialized subcompartment of the extracellular space, therefore, the lymphatic system completes a closed loop for the circulation by returning liquid, macromolecules, and other blood elements that "escape" or "leak" from blood capillaries (Fig. 10.1).

ANATOMY

Although, historically, identification of lymphatic vessels has long been hampered by lack of readily identifiable structures, early physicians from Hippocrates (460–377 BC) to Aristotle (384–322 BC) and Erasistratus (310–250 BC) did describe vessels and nodes and on occasion visible intestinal lymphatic vessels in recently fed animals (see Kanter[1] for details). After a period of little scientific advancement, discovery of chylous mesenteric lacteals in a well-fed dog by Gasparo Asellius early in the 17th century set off a flurry of anatomic dissections in England and continental Europe that established the nearly ubiquitous presence of lymphatics throughout the body and their

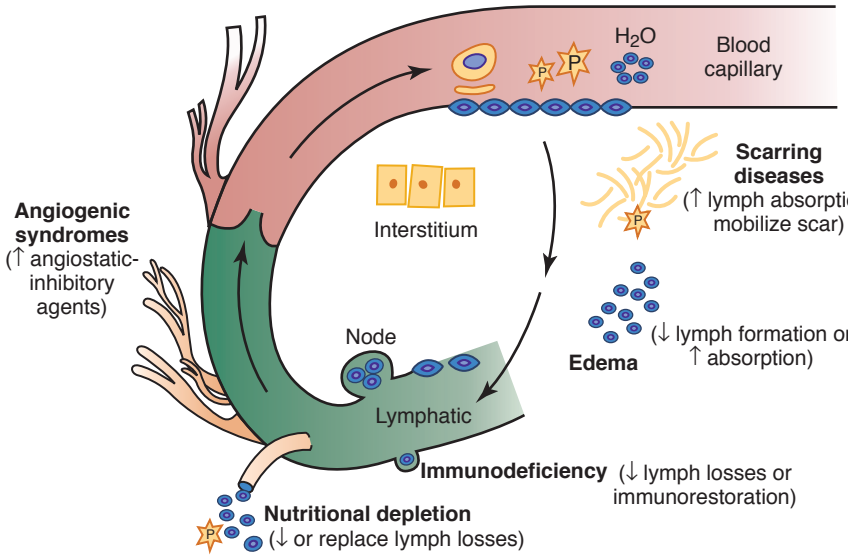

Figure 10.1 Blood-Lymph Circulatory Loop. Within the bloodstream, liquid flows rapidly as a plasma suspension of erythrocytes; outside the bloodstream, it flows slowly as a tissue fluid–lymph suspension of immunocytes through the lymphatics and lymph nodes. Small and large molecules, including plasma protein, trafficking cells, particulates, and respiratory gases, cross the blood–capillary endothelial barrier, percolate through the tissues, enter the lymph stream, and return to the central venous system to complete the loop. Clinical disorders of the blood-lymph circulatory loop are manifested as swelling, scarring, immunodeficiency, nutritional depletion, and uncontrolled lymphangiogenesis and angiotumorigenesis. Current and potential future therapeutic approaches are in parentheses.

important role in absorption of nutrients (Box 10.1).[2] These lymphatic "absorbents" accompany venous trunks everywhere, except in the central nervous system and cortical bony skeleton.

Macroscopic Anatomy

In general, lymph from the lower part of the torso and viscera enters the bloodstream via the thoracic duct at the left subclavian-jugular venous junction (see Figs. 10.1 and 10.2). Lymphatics from the head and neck and from the upper extremities enter the central veins either independently or by a common supraclavicular cistern. Numerous interconnections exist within this rich vascular network, and subvariant anatomic pathways are plentiful. For example, the bulk of cardiac and pulmonary lymph empties into the great veins in the right side of the neck. In contrast, intestinal lymph, which transports cholesterol, fat-soluble vitamins, and long-chain triglycerides as chylomicra, courses retroperitoneally to the aortic hiatus and with other visceral and retroperitoneal lymphatics forms the multichannel cisterna chyli and thoracic duct. The bulk of lymph formed in the liver flows retrograde or countercurrent to portal blood and joins intestinal lymph collectors just before the origin of the thoracic duct. Although these topographic variants influence development and progression of peripheral (lymph) edema only indirectly, they are nonetheless essential for a broad understanding of edema syndromes, including those accompanied by abnormal visceral lymphatics, celomic effusions, and chylous reflux.

Although the retina and brain do not technically have lymphatic apparatuses, they possess analogous circulations, such as the aqueous humor canal of Schlemm (the anterior chamber of the eye) or the cerebrospinal fluid/subarachnoid villus (pacchionian bodies) connections (the brain). Glial elements and non–endothelial-lined intracerebral perivascular (Virchow-Robin) spaces probably also serve to transport interstitial fluid to nearby intracranial venous sinuses. Extensive interruption of the cervical lymphatic trunks (e.g., after bilateral radical neck dissection) therefore causes prominent facial suffusion and a transient neurologic syndrome resembling pseudotumor cerebri,[3] whereas an infusion of crystalloid solution directly into the canine cisterna magna causes an elevation in intracranial pressure and increases lymph flow from draining neck lymphatics.[4,5] Although abundant lymphatic pathways thus exist for surplus tissue fluid to return to the bloodstream, homeostasis still depends on an unimpeded, intact, interstitial-lymph fluid circulatory system (see Figs. 10.1 and 10.2).

On the origin and development of the lymphatic system from the veins and the development of the lymph hearts and the thoracic duct in the pig. *Am J Anat.* 1902;1:367, and Yoffey JM, Courtice FC. *Lymphatics, Lymph and the Lymphomyeloid Complex.* New York: Academic Press; 1970.)

Embryonic Development

Controversy has persisted since the early 1900s about the embryologic origin of lymphatics, that is, lymphovasculogenesis (endothelial precursors or stem cells, such as lymphangioblasts, differentiate and proliferate into a primitive tubular network) and subsequent lymphangiogenesis (sprouting from existing vessels; see Box 10.1).[6] According to Sabin, the primary lymphatic plexuses derive from central veins and their growth progresses centrifugally by sprouting toward the periphery and ultimately forming the superficial lymphatic system (Fig. 10.3).[7] In contrast, Kampmeier,[8] after a review of serial tissue sections, including Sabin's original human embryo preparations, and phylogenetic considerations, proposed the centripetal theory that the lymphatic system arises independently from tissue mesenchyme in peripheral tissues and the surrounding primary lymph sacs and only later joins the central venous system.

Although recent studies of the growth regulatory gene *PROX1*[9] and the receptor for lymphatic vascular endothelial growth factor (VEGFR-3)[10] have tended to support the centrifugal theory (origin from venous spouting), other elegant work has demonstrated a substantial centripetal contribution from mesenchymal lymphangioblasts in the engrafted wing lymphatic system of chimeric quail chick embryos[11] and early avian embryos through *PROX1* staining.[12] Both processes may contribute in various degrees to the ultimate link between the lymph and blood vasculature (e.g., the cervical thoracic duct/venous junction in humans).

Light Microscopic Anatomy

As an afferent vascular system, the lymphatics originate within the interstitium as specialized capillaries, although in certain organs, such as the liver, they seem to emanate from nonendothelialized precapillary channels (e.g., the spaces of Disse).[13] Lymphatic capillaries are remarkably porous and readily permit the entry of even large macromolecules (molecular weight >1000 kD). In this respect, they resemble the uniquely "leaky" fenestrated sinusoidal blood capillaries of the liver but are in distinct contrast to most other blood capillaries, which are relatively impervious to macromolecules even the size of albumin (molecular weight, 69 kD).[14]

Under light microscopy without treatment, it is difficult to distinguish between blood and lymph vessels, although the latter are usually thin walled and tortuous, have a wider, more

irregular lumen, and are largely devoid of red blood cells. Many staining features have been advocated to differentiate between blood and lymph microvasculature, such as the endothelial marker factor VIII–related antigen: von Willebrand factor (vWF). Although staining characteristics vary in both normal and pathologic states and at different sites (perhaps related to endothelial cell de-differentiation), in general, lymphatic staining resembles but is less intense than its blood vessel counterpart. In other words, the staining differences have been more quantitative than qualitative.[15-17] Most recently, several new markers have been proposed that appear to be more lymphatic specific, particularly antibodies to lymphatic endothelial hyaluronan receptor-1 (LYVE-1; a homologue of CD44 glycoprotein),[18] podoplanin,[19] PROX1,[9] and to less degree, VEGFR-3 (the endothelial receptor for VEGF-C, the so-called lymphatic growth factor),[20,21] as well as 5′-nucleotidase.[22]

Lymphatic-Specific Markers

Lymphatic vessels can increasingly be distinguished from blood vessels in tissue sections by whole-mount staining with specific markers. Only 15 years ago, little histochemical specificity existed to distinguish lymphatic vessels from blood capillaries and veins, and identification was based primarily on morphology, distinctive ultrastructure, or both. One of the most commonly used and most specific markers in use today is LYVE-1.[19,23] It has been applied to tissues ranging from early mouse embryo to adult human and highlights collecting vessels and lymphatic capillaries (but not larger-caliber vessels). Another strong marker localizing to the nucleus of lymphatic endothelial cells and adaptable to multiple tissues is the transcription factor PROX1.[23] Podoplanin recognizes a transmembrane glycoprotein[24] in lymphatics but not blood vessel endothelial cells in the mouse, whereas its human analogue, D2-40,[25] also sharply distinguishes lymphatic from blood vessel endothelium but stains other distinguishable cells. This feature has been useful in identifying preexisting and new lymphatics in tumor specimens and in generating quantitative differentials from blood vessels and indices of lymphatic invasiveness and tumor dissemination.[26] 5′-Nucleotidase staining is used by research laboratories for its lymphatic specificity[22,27] and other common markers showing some cross reactivity to veins include VEGFR-3[10] and neuropilin-2[28] (reviewed elsewhere).[29,30] Thus an array of lymphatic markers are now available to distinguish lymphatic from blood vessels, although there is overlap of cell types in normal conditions and even more so in pathologic states.

Ultrastructure

Ultrastructurally, lymph capillaries display both "open" and "closed (tight)" endothelial junctions, often with prominent convolutions[31] and these capillaries can dramatically adjust their shape and lumen size. Unlike blood capillaries, a basal lamina (basement membrane) is tenuous or lacking altogether in lymph capillaries.[31,32] Moreover, complex elastic fibrils, termed *anchoring filaments,* tether the outer portions of the endothelium to a fibrous gel matrix in the interstitium.[33-35] These filaments allow the lymph microvessels to open wide, which causes a sudden increase in tissue fluid load and pressure, in contrast to the simultaneous collapse of adjacent blood capillaries (Fig. 10.4). Just beyond the lymph capillaries are the terminal lymphatics. In contrast to more proximal and larger lymph collectors and trunks, the terminal lymphatics are devoid of smooth muscle, although the endothelial lining is rich in the contractile protein actin.[15] Intraluminal bicuspid valves are also prominent features and serve to partition the lymphatic vessels into discrete contractile segments termed *lymphangions*.[36] These specialized microscopic features support the delicate lymphatic apparatus's functions of absorbing and transporting elements and the large protein moieties, cells, and foreign agents of the bloodstream (e.g., viruses, bacteria) that gain access to the interstitial space (Figs. 10.5 and 10.6).

Structural-Functional Imaging

Early physicians were able to visualize the lymphatic system only by observing chyle-filled mesenteric lymphatics. Asellius's initial publication[37] included what has been reported as the first color anatomic plate in history.[1] This was followed by intralymphatic injection of mercury into cadavers by Nuck in 1692, which depicted fine channels,[38] then the detailed and elegant work of Mascagni in 1787,[39] and subsequently, the classic images of both subcutaneous and deep vessels by Sappey in 1874.[40] von Recklinghausen used silver nitrate, which allowed imaging to take place without removal of surrounding tissue and facilitated visualization of lymphatic vessels as distinct from blood capillaries.[41] Gerota developed a technique in 1896 of injecting a mixture of Prussian blue and turpentine to highlight the vessels,[42] and this was followed in 1933 by the intracutaneous injection of vital dyes that bind to tissue proteins by Hudack and McMaster,[43] which is a technique still used today for investigation and in the clinic (Fig. 10.7).

Modern imaging techniques also include direct (intralymphatic) injection of oily contrast agents, termed lymphangiography, first described by Kinmonth in 1954,[44] and whole-body lymphangioscintigraphy after subcutaneous or intradermal injection of protein-bound radiotracers (see Witte et al.[45] for an overview; see Fig. 10.7). Other agents used for indirect lymphography include various fluorescent or magnetic particles,[46,47] infrared particles and dyes,[48-50] immunoglobulin conjugates,[51] and microbubbles[52] for detection with fluorescent microscopes, optical imaging systems, computed tomography (CT), magnetic resonance imaging (MRI; with and without contrast),[53] and ultrasound,[54,55] with an expanding potential for highly specific molecular imaging. New contrast agents and techniques continue to be developed.[56-58]

PHYSIOLOGY

Any protein which leaves these vessels…is lost for the time to the vascular system…it must be collected by lymphatics and restored to the vascular system by way of the thoracic or right lymphatic duct.

–PHYSIOLOGIST ERNEST STARLING, 1897

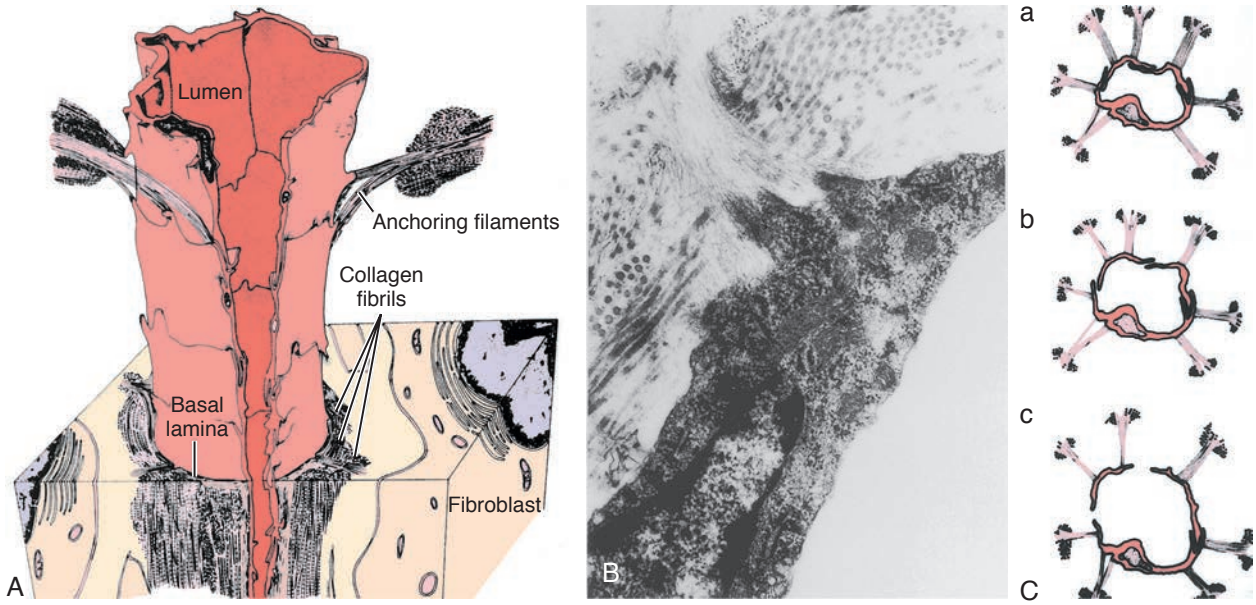

Figure 10.4 (A) Lymphatic capillary reconstructed from collated electron micrographs. The lymphatic anchoring filaments originate from the albumin surface of the endothelial cells and extend into adjacent collagen bundles, thereby forming a firm connection between the lymphatic capillary wall and the surrounding interstitium. (B) Transmission electron micrograph demonstrating anchoring filaments (AF) that derive from the lymphatic endothelium and join nearby collagen bundles. (C) Response of lymphatic capillaries to an increase in interstitial fluid volume. As the tissue matrix expands, tension on the AF rises, and the lymph capillaries open widely to allow more rapid entry of liquid and solute (*a* to *c*). In contrast to stretching of the lymph capillaries, a rise in matrix pressure collapses the blood capillaries, thereby restricting further plasma filtration. (From Leak LV, Burke JF. Ultrastructural studies on the lymphatic anchoring filaments. *J Cell Biol.* 1968;30:129–149; and Leak LV. Electron microscopic observation on lymphatic capillaries and the structural components of the connective tissue–lymph interface. *Microvasc Res.* 1970;2:361–391.)

General Principles

As a fine adjuster of the tissue microenvironment, the lymphatic system is often neglected in most treatises on vascular diseases. Yet this delicate system, so inconspicuous during life and collapsed after death, helps to maintain the liquid, protein, and osmotic equilibrium around cells and aids in absorption and distribution of nutrients, disposal of wastes, and exchange of oxygen and carbon dioxide in the local milieu intérieur.

Interstitial (Lymph) Fluid

Two-thirds of the body is composed of water, and most of this liquid volume is contained within cells. However, the remainder that exists outside cells continuously circulates. In a series of epochal experiments conducted more than a century ago, the English physiologist Ernest Starling outlined the pivotal factors that regulate partitioning of the extracellular fluid.[59,60] In brief, the distribution of fluid between the blood vascular compartment and tissues and the net flux of plasma escaping from the bloodstream depends primarily on the transcapillary balance of hydrostatic and protein osmotic pressure gradients as modified by the character (i.e., hydraulic conductance) of the filtering microvascular surface (Fig. 10.8; also see Box 10.1). Normally, a small excess of tissue fluid forms continuously (net capillary filtration), and this surplus enters the lymphatic system and returns to the venous system. In contrast to blood, which flows in a circular pattern at several liters per minute, lymph flows entirely in one direction and at rest at a rate of only 1.5 to 2.5 L/24 hour. This limited volume derives from a slight hydrodynamic imbalance that favors movement of fluid, salt, and macromolecules from plasma into tissue spaces. Although blood capillary beds vary in hydraulic conductance, in general, disturbances in the transcapillary hydrostatic and protein osmotic pressure gradients (Starling forces) tend to promote edema that is low in protein content (<1.0 g/dL [10 g/L]), whereas impedance to lymph flow (lymph stasis) promotes (lymph) edema that is high in protein content (>1.5 g/dL [15 g/L]).

Unlike blood flow, which is propelled by a powerful and highly specialized muscular pump (the heart), propulsion of lymph originates predominantly from spontaneous intrinsic segmental contractions of larger and probably also small lymph trunks,[61-63] and to less extent, from extrinsic "haphazard forces" such as breathing, sighing, yawning, muscular squeezing (e.g., alimentary peristalsis), and transmitted arterial pulsations (Table 10.1).[63,64] As noted, the contractions of lymphatic segments between intraluminal valves (i.e., the lymphangions) are highly responsive to lymph volume. Thus an increase in lymph formation is accompanied by more frequent and more powerful lymphangion contractions, a lymphodynamic response that resembles Starling's other major physiologic principle, the law of the heart.[36,65]

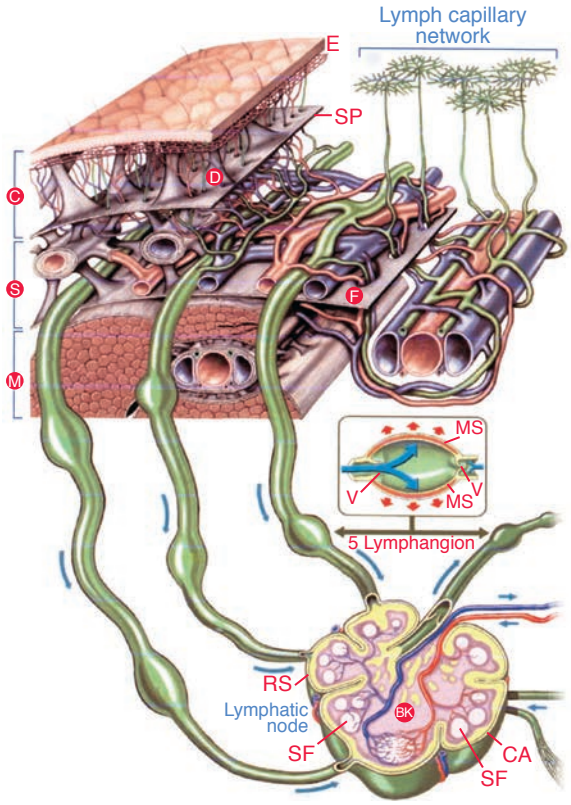

Figure 10.5 The lymphatic system consists of an initial superficial valveless network of endothelium-lined vessels connected to a deep valved collector system (lymphangion pumping segments defined by the valves). The deeper vessels run alongside major blood vessels and drain through lymph nodes to the main collectors; they ultimately empty into the thoracic duct or the right lymphatic duct. *BK*, Blood capillary network; *C*, cutis; *CA*, capsule; *D*, dermis; *E*, epidermis; *F*, fascia; *M*, musculature; *MS*, muscle layer; *RS*, marginal sinus; *S*, subcutis; *SF*, second follicle; *SP*, subcutaneous pseudofascia; *V*, lymphatic valves. (Modified with permission from BSN-Jobst Emmerich Conception, 2002.)

Lymphatic truncal contraction, like venous and arterial vasomotion, is mediated by sympathomimetic agents (both α- and β-adrenergic agonists),[66,67] byproducts of arachidonic acid metabolism (thromboxanes and prostaglandins),[68-71] and neurogenic, even pacemaker stimuli.[72,73] Oddly, in different regions of the body, lymphatic trunks exhibit varying sensitivity to different vasoactive and neurogenic stimulants.[67,74,75] Although the importance of truncal vasomotion as mediated by tunica smooth muscle is well established, it remains unclear whether terminal lymphatics or capillaries are also capable of vasomotion or are simply passive channels.

Lymph Nodes

In addition to their central immunologic role, lymph nodes are a potential site of impediment to the free flow of lymph. Unlike frogs, which lack lymph nodes but possess four or more strategically placed lymph hearts that propel large quantities of peripheral lymph back to the bloodstream,[76,77] mammals possess immunoreactive lymph nodes, which, when swollen, fibrotic, or atrophic, may act to initiate or perpetuate lymph stasis.[78,79]

Flow-Pressure Dynamics

Although lymphatic vessels, like veins, are thin-walled flexible conduits that return liquid to the heart, the flow-pressure relationships in the venous system and the lymphatic system are different. The energy to drive blood in the venous system derives primarily from the thrust of the heart. The cardiac propulsive boost maintains a pressure head through the arteries and blood capillaries into the veins. In contrast, lymph vessels in tissues are not directly contiguous with the blood vasculature, and the chief source of energy for propulsion of lymph emanates from the intrinsic lymphatic truncal wall

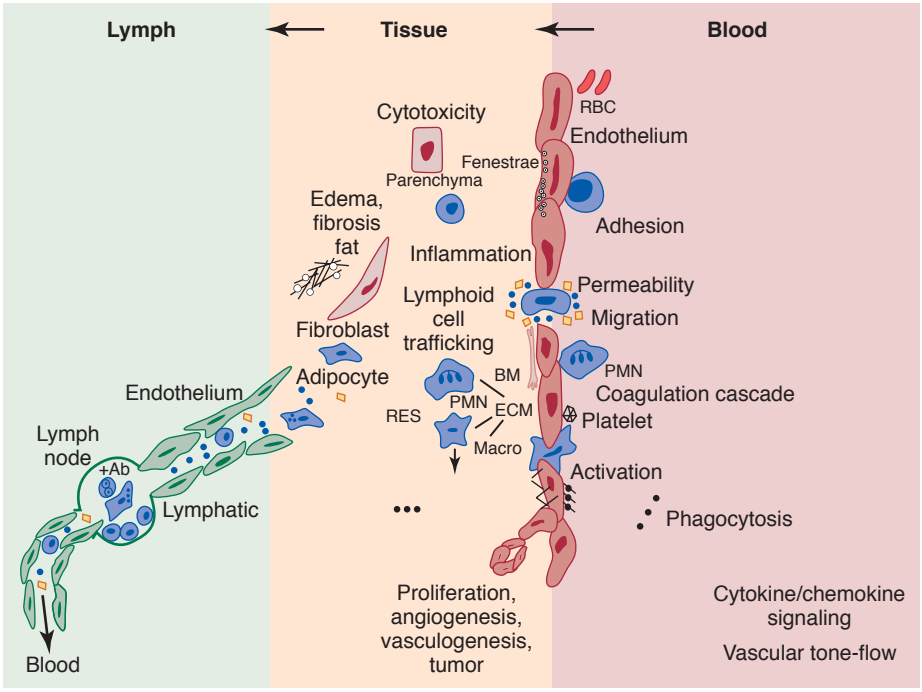

Figure 10.6 The postulated role of endothelial processes in microcirculatory events that have a bearing on angiogenesis in the blood-lymph loop. Such processes include macromolecular and liquid permeability, vasoresponsiveness, leukocyte adhesion and transmigration, coagulation cascading, particulate phagocytosis, antigen presentation and cytokine activation, lymphoid cell trafficking, and proliferative events leading to new vessel or tumor growth. Many mediators of these events have been identified by studying processes implicated at the blood vascular endothelial surface, which are likely to also occur at the lymphatic endothelial interface. The relative anatomic and dynamic relationships between blood and lymph vascular endothelium, parenchymal and extravascular connective tissue, and transmigrating leukocytes are shown. *Black circle*, exogenous particulates; *black square*, macromolecules; *open circles*, fluid (plasma, interstitial, or lymph). *Ab*, Antibody; *BM*, basement membrane; *ECM*, extracellular matrix; *macro*, macrophage; *PMN*, polymorphonuclear neutrophil; *RBC*, red blood cell; *RES*, reticuloendothelial system. (Modified from Witte MH, Dellinger MT, Papendieck CM, Boccardo F. Overlapping biomarkers, pathways, processes and syndromes in lymphatic development, growth, and neoplasia. *Clin Exp Metastasis.* 2012;29:707–727.)

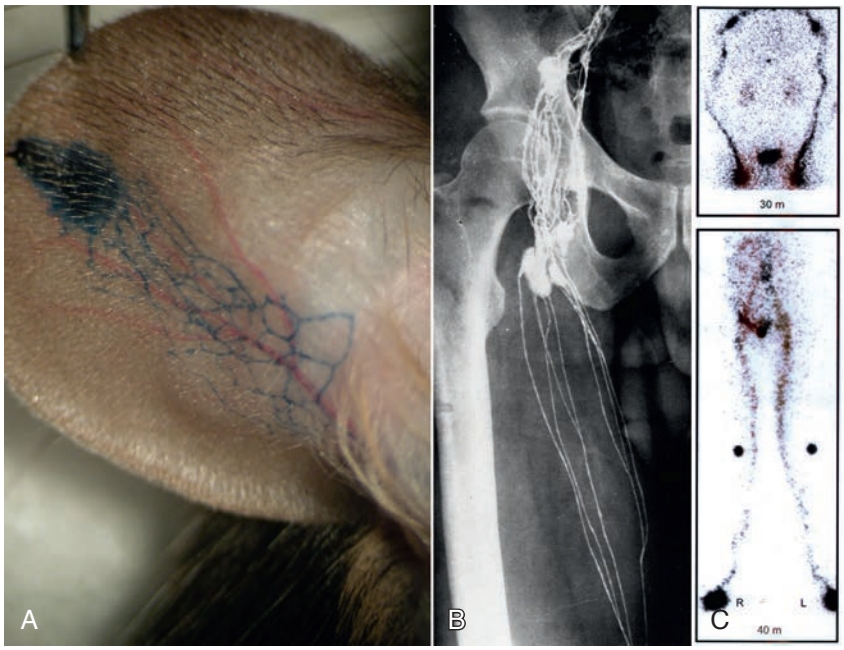

Figure 10.7 Imaging Techniques to Delineate the Structure and Function of the Lymphatic System. (A) Evans blue dye injected intradermally in the tip of a mouse ear rapidly displays the draining lymphatic channels. A similar vital dye (lymphazurin blue or isosulfan blue) is used in the clinic. (B) Classic lymphography image from Kinmonth clearly depicting the fine lymphatic vessels of the upper part of the thigh in an adult human.[44] (C) Radioisotope lymphangioscintigraphy displaying normal lymphatic tracer transport in the arms *(upper panel)* and the legs *(lower panel)*. A single injection into each hand or foot is seen at the bottom of each image, with markers at the knees in the lower panel. (Modified from Witte CL, Witte MH, Unger EC. Advances in imaging of lymph flow disorders. *Radiographics.* 2000;20: 1697–1719.)

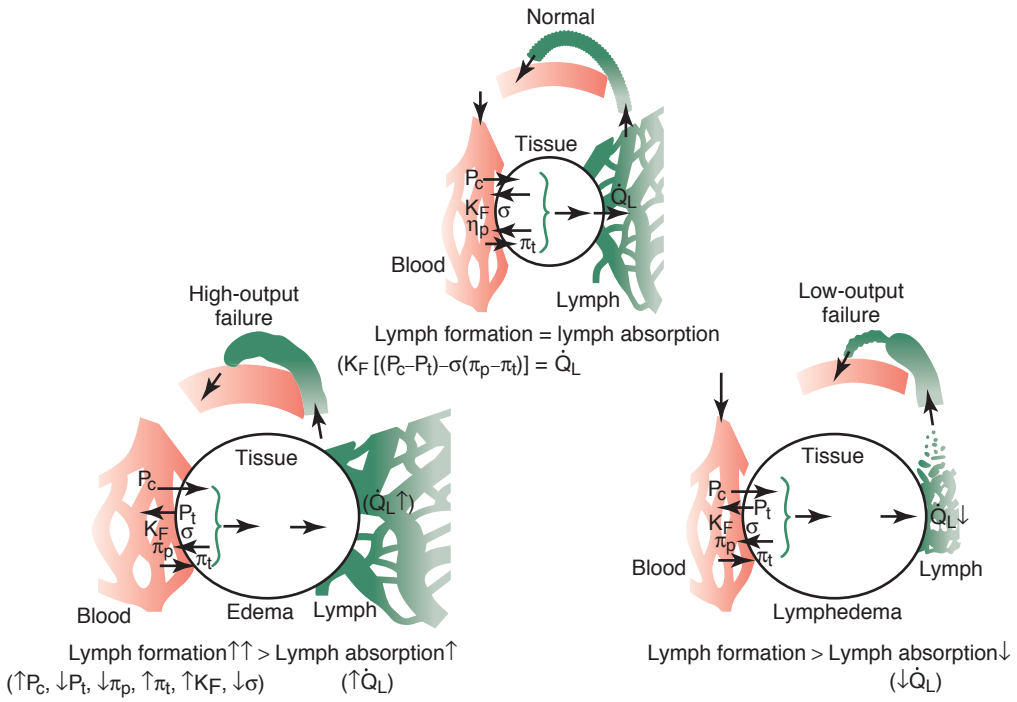

Figure 10.8 Primary forces regulating fluid flux into the interstitium and the importance of lymph flow in maintaining steady-state interstitial fluid volume, and hence, stable partitioning of extracellular fluid between the bloodstream and the interstitium (Starling's equilibrium). Edema may occur as a result of high-output failure of lymph circulation (lymph overload with increased lymph flow) *(lower left)* or, less commonly, low-output failure (lymphedema) caused by interruption in lymph transport capacity *(lower right)*.

contractions (propulsor lymphaticum).[61-77,80] Like amphibian lymph hearts (cor lymphaticum), mammalian lymphatic smooth muscle beats rhythmically, and in the presence of a well-developed intraluminal valve system, facilitates transport of lymph.[81] In a sense, the lymphatic structures function as micropumps that respond to fluid challenges with increases in both rate and stroke volume.[36,68] Ordinarily, resistance to flow in the lymphatic vessels is relatively high in comparison to the low resistance in the venous system,[82] but the pumping capacity of the lymphatics is able to overcome this impedance by generating intraluminal pressures of 30 to 50 mm Hg and sometimes even equaling or exceeding arterial pressure.[61,82,83] This formidable lymphatic ejection force is modulated not only by filling pressure but also by temperature, sympathomimetics, neurogenic stimuli, circulating hormones, and locally released paracrine and autocrine cytokine secretions.[84]

It is often mistakenly thought that lymph return, like venous return, is directly enhanced by truncal compression from skeletal muscle and other adjacent structures. Although muscular contraction and external massage clearly accelerate lymph return in the presence of edema,[83] under normal conditions, peripheral lymph flow is regulated primarily by spontaneous contraction

TABLE 10.1 Circulatory Dynamics of Vascular Conduits

	Lymphatic	Vein	Artery
Primary propulsive unit	Lymphangion	Heart	Heart
Secondary propulsive force	Haphazard[a]	Skeletal muscle	Vasomotion
Distal (upright) pressure (mm Hg)	2-3	90-100	20
Central pressure (mm Hg)	6-10	0-2	100
Flow rate	Very low	High	High
Vascular resistance	Relatively high	Very low	High
Intraluminal valves	Innumerable	Several	None
Impediment to flow	Lymph nodes	None	None
Conduit fluid column	Incomplete	Complete	Complete
Conduit failure	Edema (>1.5 g/dL) with brawny induration and acanthosis	Edema (<1.0 g/dL) with skin pigmentation and "stasis" ulceration	Claudication, rest pain, tissue necrosis

[a]Breathing, sighing, yawning, peristalsis, and transmitted arterial pulsation; skeletal muscle contraction also increases the amplitude and frequency of lymphatic contractions and squeezes interstitial fluid into the initial lymphatics (i.e., lymph capillaries).

of the lymphatics themselves.[83,84] In peripheral lymphatics, unlike peripheral veins, the column of liquid is incomplete. Accordingly, with normal intralymphatic pressure, external compression is ineffective in propelling lymph onward, although it may increase the frequency and amplitude of lymphatic contractions. In other words, lymphatics, in contrast to veins, are not sufficiently "primed."[85] During lymphatic obstruction and persistent lymph stasis, the fluid column in the lymphatics becomes continuous, and skeletal muscle or forceful external compression then becomes an effective pumping mechanism that aids lymph transport.[83,85]

Studies of the effect of gravity on peripheral lymphatic and venous pressure confirm these findings. Although assuming an erect position sharply raises distal venous pressure, peripheral intralymphatic pressure is unaffected, although lymphatic truncal pulsation increases in both frequency and amplitude.[85] This arrangement favors removal of tissue fluid by the lymphatics during dependency because, unlike veins, the lymphatics operate at much lower hydrostatic pressure. After the lymphatics become obstructed, truncal contractions quicken at first, but then the intraluminal valves gradually give way, and as the lymph fluid column becomes continuous, this mechanical advantage is lost, and chronic lymphedema supervenes.

Lymphatic Transport Route

The lymphatic route of transport of liquid, protein, and macromolecules, particularly chylomicra originating in the small intestine, is well recognized, albeit underappreciated, and the lymphogenous route of cancer spread forms the conceptual basis for most current treatment approaches to solid organ cancers. The role of lymphatic uptake and clearance of microorganisms in the clinical manifestations (e.g., lymphangitic streaking), pathogenesis, inflammatory and other tissue responses, and immune defense has been underemphasized, particularly in recent years. From the 1930s to the 1960s (see Box 10.1), a number of carefully performed studies examined the critical lymphatic route in the initial and later phases of viral and bacterial infection and the dynamic physiology of the afferent and efferent arms of the immune response.[86] The lymphologist Joseph Yoffey laid the groundwork for recognition of the importance of the "inert" lymphocyte and the discovery of lymphoid cell trafficking, which are fundamental to the principles of modern immunology.[87,88] Recasting these older investigations with more modern physiologic techniques and molecular tools may yield new translational insight into disorders ranging from AIDS and tuberculosis to parasitic disorders while also elucidating the lymphatic spread of cancer (Fig. 10.9).[81,89-92]

MOLECULAR LYMPHOLOGY

With improvement in methods of studying chromosomes, unexpected light may be shed on Milroy's disease and other hereditary lymphedemas.

–Lymphatic/Vascular Surgeon John Kinmonth, 1972

Advances in molecular biology and the development of new techniques from the Human Genome Project have ushered in the era of molecular lymphology.

Lymphangiogenesis

In contrast to uncontrolled new growth (lymphangiosarcoma), programmed proliferation of lymphatic endothelium with tube formation (lymphangiogenesis) is critical to a host of physiologic and pathologic processes. During the past several decades, since the phenomenon of angiogenesis was first reproduced in endothelial cell and mixed vascular tissue cultures,[93,94] considerable attention has been directed toward furthering understanding of this process, but largely in the context of blood vessel growth (hemangiogenesis).[95,96] The lymphatic counterpart (i.e., lymphangiogenesis) has received scant attention until recently,

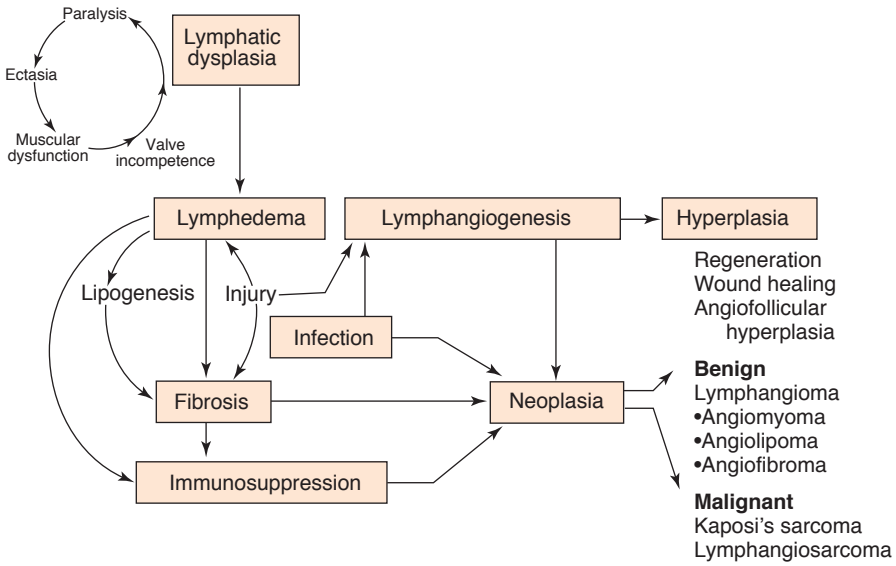

Figure 10.9 The Pathogenesis of Peripheral Lymphedema and Some of Its Sequelae. According to this scheme, congenitally deficient or obstructed lymphatics promote lymph stasis, which is accompanied by deranged truncal contractility, progressive valve incompetence, destruction of contractile elements (lymphangioparalysis), and gradual ectasia of lymphatic collectors. After a variable period (occult lymphedema), sometimes aggravated by environmental trauma, a series of events is set into motion that culminates in chronic lymphedema. This clinical state is characterized not only by progressive swelling but also by fat and scar deposition, immunodysregulation, a propensity for cellulitis, and microvascular proliferation; these processes are essential for repair and regeneration but may result in bizarre and poorly understood new vascular growths.

although lymphatic (re)generation is essential to health, and disorders of lymph flow and lymphatic growth are common, often disfiguring, and sometimes life- and limb-threatening.[95]

In now classic studies, Clark and Clark documented the extension of lymphatic capillaries by outgrowth from preexisting lymph vessels in rabbit ear transparent chambers (Fig. 10.10A).[97] Later, Pullinger and Florey emphasized that despite the similar appearance of each vascular endothelium, lymphatics are consistently connected to lymphatics, veins to veins, and arteries to arteries without intermingling (see Fig. 10.10B).[98]

After experimental hind limb circumferential skin incision, new lymphatics traverse the integumentary gap by postoperative day 4. By the eighth day, lymphatic continuity is restored anatomically (delineated by distribution of intradermal India ink particles) and physiologically (remission of transient peripheral edema).[99,100] Bellman and Odén meticulously documented, by Thorotrast microlymphangiography, the time course and extent of newly formed lymphatics in circumferential wounds in the rabbit ear, including lymphatic bridging through newly formed scar (see Fig. 10.10C).[101,102] As lymphatics increased in caliber, intraluminal valves and sinuous dilatations appeared. Subsequent studies documented restoration of distinctive ultrastructural features in newly regenerated lymphatic vessels, including characteristic overlapping junctions and Weibel-Palade bodies (storage depots for vWf [factor VIII–related antigen]).[103-105]

Like the more than 1 trillion blood vascular endothelial cells that are normally dormant,[106,107] lymphatic endothelial cell turnover is also miniscule.[108] However, with injury, incorporation of tritiated thymidine into proliferating lymphatic endothelium sharply increases.[108] Moreover, fetal lymphatics show greater labeling than do neonatal and adult lymphatics, whereas visceral lymphatic endothelium proliferates more rapidly than does peripheral lymphatic endothelium.[109]

Lymphatic endothelium was first isolated in vitro from bovine mesenteric lymphatics[17] and in the same year, from a patient with a large cervicomediastinal hygroma,[110] and subsequently, from another patient with a retroperitoneal lymphangioma,[15] as well as from canine and human thoracic ducts.[16] Lymphatic endothelial cells from sheep, dog, mouse, rat, and ferret lymphatic collectors have now been isolated, passed in culture, and studied by techniques similar to those used for blood large-vessel and microvessel isolation. Putative lymphatic endothelium has also been isolated from mixed microvascular cultures of human foreskin and skin by separation with magnetic beads and labeling with lymphatic markers such as LYVE-1.[111] Lymphangiogenesis in vitro was first demonstrated more than 2 decades ago with the formation of tubes and cystlike structures spontaneously[110] or after the addition of collagen matrix to tissue culture.[112]

Lymphovascular Genomics

Growing evidence has confirmed that lymphangiogenesis is under genetic control (Fig. 10.11 and Table 10.2; also see recent reviews).[6,29,30] For example, a gene or genes expressed from nonactivated portions of the inactivated X chromosome or from the Y chromosome are probably involved in lymphatic development, and a deficiency in this gene or its product(s) is responsible for Turner syndrome (XO ovarian dysgenesis), which exhibits a variety of lymphatic and other cardiovascular anomalies. Other chromosomal aneuploidies, such as trisomy 21 (Down syndrome), and rearrangements (additions, deletions, translocations) also occasionally manifest as strangulating fetal cystic hygroma, lymphedema, and intestinal lymphangiectasia and are commonly associated with early fetal demise (see Fig. 10.11).[113]

Both forward and reverse genetic techniques have provided clues to sites of "lymphangiogenesis genes," and a spectrum of developmental and other hereditary lymphedema-angiodysplasia syndromes (often with autosomal dominant inheritance) have been catalogued (see Fig. 10.11).[6,12,114-117] They include mutations in a subpopulation of patients with Milroy syndrome *(VEGFR-3)*,[118] mutations in the transcription factor *SOX18*[119] in two families with autosomal recessive and dominant forms of hypotrichosis-lymphedema-telangiectasia syndrome, and mutations in the transcription factor *FOXC2*[120] uniformly

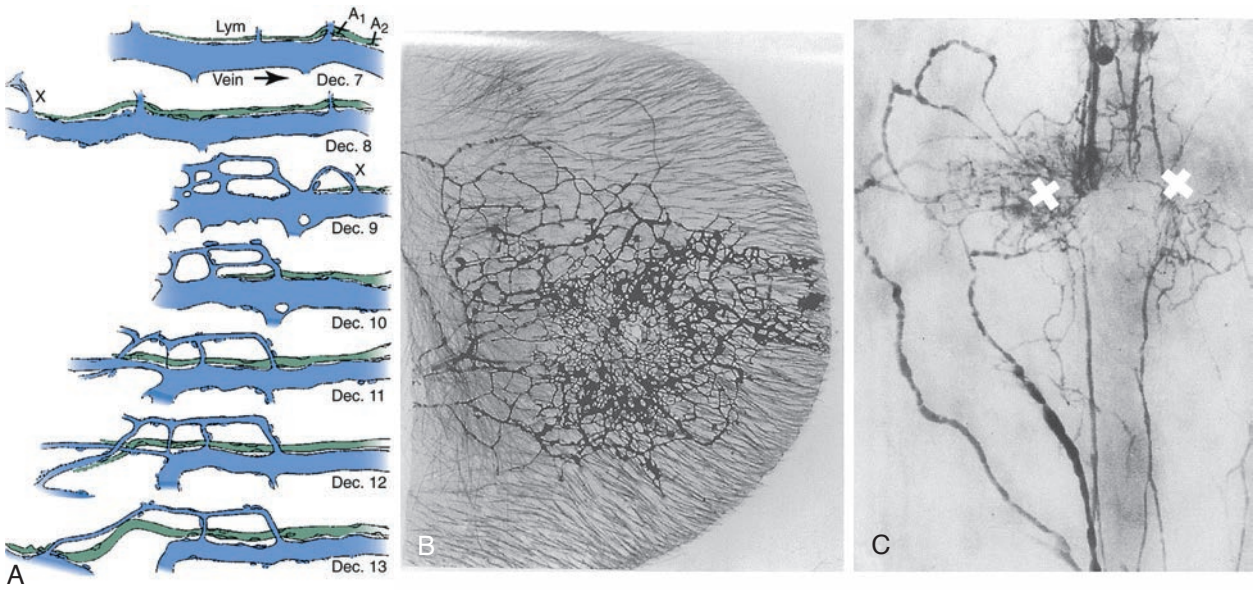

Figure 10.10 Classic Observations on Lymphangiogenesis in vivo. (A) Series of camera lucida, oil immersion records showing growth of an individual lymphatic capillary in the rabbit ear (LYM). Corresponding parts of a lymphatic and vein have been placed below one another in drawings of December (Dec) 7, 8, and 9 to 13. The drawings of Dec 9 to 13 have been moved to the right so that X represents the same spot on Dec 8 and 9. During growth of the lymphatic, there has been conspicuous retraction and disappearance of branches and loops of the blood vessel. Retraction of a short lymphatic tip is seen between Dec 11 and 13. Lymphatic endothelial nuclei are stippled. A1 and A2 are two daughter nuclei after a mitotic division (×177; magnification of original drawing, ×700). (B) Twenty-one days after making a turpentine abscess that perforated a mouse's ear, a dense new network of lymphatic capillaries surrounds the hole (×8). (C) In vivo microlymphangiogram 24 days after a short transverse incision in the skin of a rabbit ear. The extent of the incision is depicted by the *crosses*. The distal part of the ear is uppermost. Several arcading vessels around the incision and numerous fine connections through the scar are seen. ([A] From Clark ER, Clark EL. Observations on the new growth of lymphatic vessels as seen in transparent chambers introduced into the rabbit's ear. *Am J Anat.* 1932;51:49–87. [B] From Pullinger DB, Florey WH. Proliferation of lymphatics in inflammation. *J Pathol Bacteriol.* 1937;45:157–170. [C] From Bellman S, Oden B. Regeneration of surgically divided lymph vessels: an experimental study on the rabbit's ear. *Acta Chir Scand.* 1959;116:99–117.)

in hundreds of patients with lymphedema-distichiasis (LD) syndrome. Interestingly, the genetically engineered haploinsufficient (±) Foxc2 mouse[121] exhibits a double row of eyelashes and a hyperplastic lymphatic phenotype like human LD. More recently, additional mutations have been identified, including inherited generalized lymphatic dysplasia (Hennekam syndrome; *CCBE1*),[122] lymphedema type 1C *(GJC2),*[123] lymphedema-choanal atresia *(PTPN14),*[124] Emberger syndrome *(GATA2),*[125] microcephaly-lymphedema-chorioretinopathy *(KIF11),* Milroy-like lymphedema *(VEGF-C),* and oculodentaldigital lymphedema *(GJA1)* (see review)[117] Other genes (*HGF* and *MET*) have been associated with inherited lymphedema; however, no syndrome has been linked with these genes.[126] These known mutations pinpoint just a small portion of the more than 45 distinct Online Mendelian Inheritance in Man (OMIM) and non-OMIM familial disorders affecting the lymphatic segment of the "vasculature,"[112,127] suggesting that genes involved in normal and pathologic lymphatic growth and development span the entire genome (see Fig. 10.11).

Growth/Inhibitory Factors

Although the underlying mechanisms governing lymphangiogenesis are only beginning to be understood, a variety of stimulatory (e.g., VEGF-C and VEGF-D) and inhibitory factors, including the angiopoietin-1–angiopoietin-2 yin-yang interaction, modulate growth, development, and remodeling of the lymphatic vasculature (see Table 10.2),[29,30,128,129] and others modulate vascular development, with dysfunction/function of the lymphatic vasculature in common with or distinct from the blood vasculature.[6,12] Insights have been gained from the invaluable transgenic, spontaneous, and chemical- and/or radiation-induced mutant mouse models (see Table 10.2). These angiomodulatory factors should be crucial to understanding clinical conditions as diverse as cystic hygroma, Klippel-Trénaunay syndrome, (lymph)angiosarcoma, elephantiasis, and a constellation of peripheral and visceral disorders characterized by swelling, scarring, immunodysregulation, and malnutrition (Fig. 10.12; also see Figs. 10.1 and 10.9).

PATHOPHYSIOLOGY

Overview

Because both congenital absence and radical excision of regional lymph nodes (and hence, lymphatics) are associated with edema, it seems straightforward that lymphedema is simply the end result of insufficient lymphatic drainage (low-output failure of the lymphatic circulation). This scenario contrasts with the

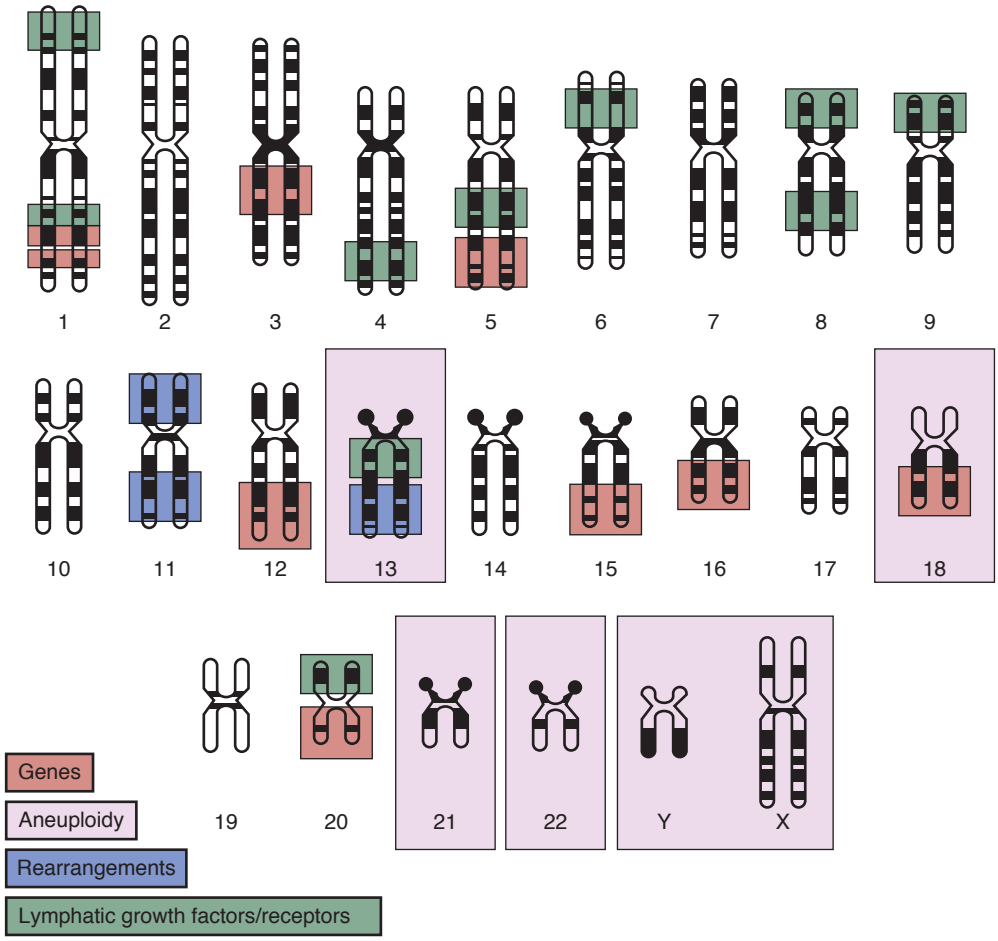

Figure 10.11 Genomics-proteomics of lymphedema-angiodysplasia syndromes displaying mutations of known genes *(pink boxes)* for a familial Milroy lymphedema subpopulation (VEGFR3 at chromosome 5q34-35), lymphedema-distichiasis (FOXC2 at chromosome 16q24), hypotrichosis, lymphedema, and telangiectasia (SOX18 at chromosome 20q13), generalized lymphatic dysplasia (Hennekam syndrome) (CCBE1 at 18q21), inherited lymphedema type 1C (GJC2 at 1q41), lymphedema-choanal atresia (PTPN14 at 1q32), and Emberger syndrome (GATA2 at 3q21) as well as linkage locations for Aagenaes syndrome (chromosome 15) and Noonan syndrome (chromosome 12). In addition, aneuploidies *(purple boxes)* and rearrangements *(blue boxes)* involving other chromosomes are associated with additional lymphedema-angiodysplasia syndromes. Examples include trisomy 13, 18, 21, and 22; Klinefelter XXY; Turner XO; and chromosomal abnormalities of addition 11p and deletions 11q and 13q, all associated with lymphedema-angiodysplasia syndromes. Locations of lymphatic-specific growth and/or modification proteins and receptors *(green boxes)* involved in development of the lymphatic system are also displayed. (Modified from Northup KA, Witte MH, Witte CL. Syndromic classification of hereditary lymphedema. *Lymphology.* 2003;36:162–189.)

TABLE 10.2 Mouse Lymphedema-Angiodysplasia Syndromes From Abnormalities and/or Altered Levels of Specific Proteins and/or Chromosomes

Molecular Description		Lymphatic Phenotype
Extracellular Proteins		
Angiopoietin-2	Ligand for the receptor tyrosine kinase Tie-2	*Ang2*$^{-/-}$ mice exhibit chylous ascites, lymphedema, and lymphatic hypoplasia. The mesenteric collecting lymphatic vessels of *Ang2*$^{-/-}$ mice lack complete coverage with smooth muscle cells, and the lymphatic capillaries in the digestive organs are associated with pericytes (Gale et al., 2002; Shimoda et al., 2007). Ang-1 can correct these mutant phenotypes (Gale et al., 2002; Shimoda et al., 2007)
Fasting-induced adipose factor	Glycosylated secreted protein	*Fiaf*$^{-/-}$ mice have dilated, blood-filled lymphatics in the small intestine. This phenotype begins postnatally and is not observed in *fiaf*$^{-/-}$ embryos (Bäckhed et al., 2007)
VEGF-C	Ligand for VEGFR-2 and VEGFR-3	*Vegfc*$^{-/-}$ mice lack jugular lymph sacs. *Vegfc*$^{+/-}$ mice have chylous ascites, lymphedema, and lymphatic hypoplasia (Karkkainen et al., 2004)

Continued

TABLE 10.2 Mouse Lymphedema-Angiodysplasia Syndromes From Abnormalities and/or Altered Levels of Specific Proteins and/or Chromosomes—cont'd

	Molecular Description	Lymphatic Phenotype
VEGF-D	Ligand for VEGFR-3	*Vegfd*$^{-/-}$ mice do not exhibit a striking lymphatic phenotype (Baldwin et al., 2005)
TgVEGF-C156S	Overexpression of the VEGFR-3–specific form of VEGF-C in the skin of mice using the keratin-14 promoter	Transgene-induced hyperplasia of lymphatic vessels (Veikkola et al., 2001)
TgVEGF-D	Overexpression of VEGF-D in the skin of mice using the keratin-14 promoter	Transgene-induced hyperplasia of lymphatic vessels (Veikkola et al., 2001)
Membrane and Intracellular Proteins		
Ephrin B2	Transmembrane ligand for the Eph receptor	*EphrinB2*$^{\Delta V/\Delta V}$ mice develop chylothorax and fail to undergo proper postnatal lymphatic remodeling (Mäkinen et al., 2005)
$\alpha_9\beta_1$ Integrin	Receptor for extracellular matrix	$\int 9^{-/-}$ mice develop chylothorax (Huang et al., 2000)
LYVE-1	Lymphatic hyaluronan receptor	The lymphatic system develops normally in *Lyve1*$^{-/-}$ mice (Gale et al., 2007)
Neuropilin-2	Receptor for semaphorins and VEGF family members	*Nrp2*$^{-/-}$ mice have a reduction in lymphatic capillaries during development (Yuan et al., 2002)
Podoplanin	Membrane glycoprotein	*Podoplanin*$^{-/-}$ mice have lymphedema, defects in lymphatic patterning, and dilated lymphatic vessels (Schacht et al., 2003)
SLP-76 and Syk	Adaptor protein and tyrosine kinase, respectively	Proposed that lymphatic and blood vessels in SLP-76 and Syk mutant mice fail to separate (Abtahian et al., 2003; Sebzda et al., 2006)
Spred1/2	Signaling proteins that negatively regulate ERK activation	*Spred1/2* double-knockout embryos die because of severe hemorrhage and edema. The lymphatic vessels of *Spred1/2* double-knockout mice appear dilated and contain blood (Taniguchi et al., 2007)
VEGFR-3	Receptor tyrosine kinase for VEGF-C and VEGF-D	*Chy* mice have chylous ascites, lymphedema, and hypoplasia of cutaneous lymphatic vessels (Karkkainen et al., 2001)
Connexin 37 and Connexin 43	Gap junction proteins	Connexin 37 and 43 deficiencies in mice disrupt lymphatic valve development and result in lymphedema and chylothorax (Kanady et al., 2011)
PI3K	Regulatory subunit of PI3-kinases	Organ-specific (gut) lymphangiectasia, arrested lymphatic sprouting, and maturation defects (Mouta-Bellum et al., 2009)
Tie1 receptor	Receptor for Tie1	Loss of Tie1 receptor impairs lymphatic vessel development, resulting in developmental edema (D'Amico et al., 2010)
Nuclear Proteins		
Foxc2	Transcription factor	*Foxc2*$^{+/-}$ mice exhibit lymphatic reflux, extralymphatic vessels and lymph nodes, and distichiasis (Kriederman et al., 2003). *Foxc2*$^{-/-}$ mice show defective lymphatic valves and abnormal mural cell coverage of lymphatic vessels (Petrova et al., 2004)
Net	Transcription factor. Net$^{\delta/\delta}$ mice lack a specific DNA-binding domain	*Net*$^{\delta/\delta}$ mice develop chylothorax and have dilated lymphatic vessels (Ayadi et al., 2001)
Prox1	Transcription factor	*Prox1*$^{-/-}$ mice fail to develop lymphatic vessels (Wigle and Oliver, 1999). *Prox1*$^{+/-}$ mice exhibit lymphedema, chylous ascites, mispatterned lymphatic vessels, and generalized obesity (Harvey et al., 2005)
Sox18	Transcription factor	*Sox18*$^{-/-}$ mice manifest chylous ascites, depending on the genetic background (Pennisi et al., 2000)
Vezf1	Zinc finger transcription factor	Lymphatic hyperplasia is observed in the jugular region of E13.5 *Vezf1*$^{+/-}$ embryos. Lymphatic abnormalities were not observed at later time points (Kuhnert et al., 2005)
Tbx1	Transcription factor	Lymphatic hyperplasia and chylous ascities. Regulates Vegfr3 (Chen et al., 2010)
Chromosomal Abnormalities		
Chy3	Large deletion of chromosome 8. The gene for VEGF-C is located within this deleted region	*Chy3* mice show chylous ascites, lymphedema, and lymphatic hypoplasia (Cattanach et al., 1993; Dellinger et al., 2007)
Ts16	Trisomy 16	Nuchal edema and distended jugular lymph sacs (Gittenberger-De Groot et al., 2004)

ERK, Extracellular signal–related kinase; *VEGF*, vascular endothelial growth factor; *VEGFR*, vascular endothelial growth factor receptor.

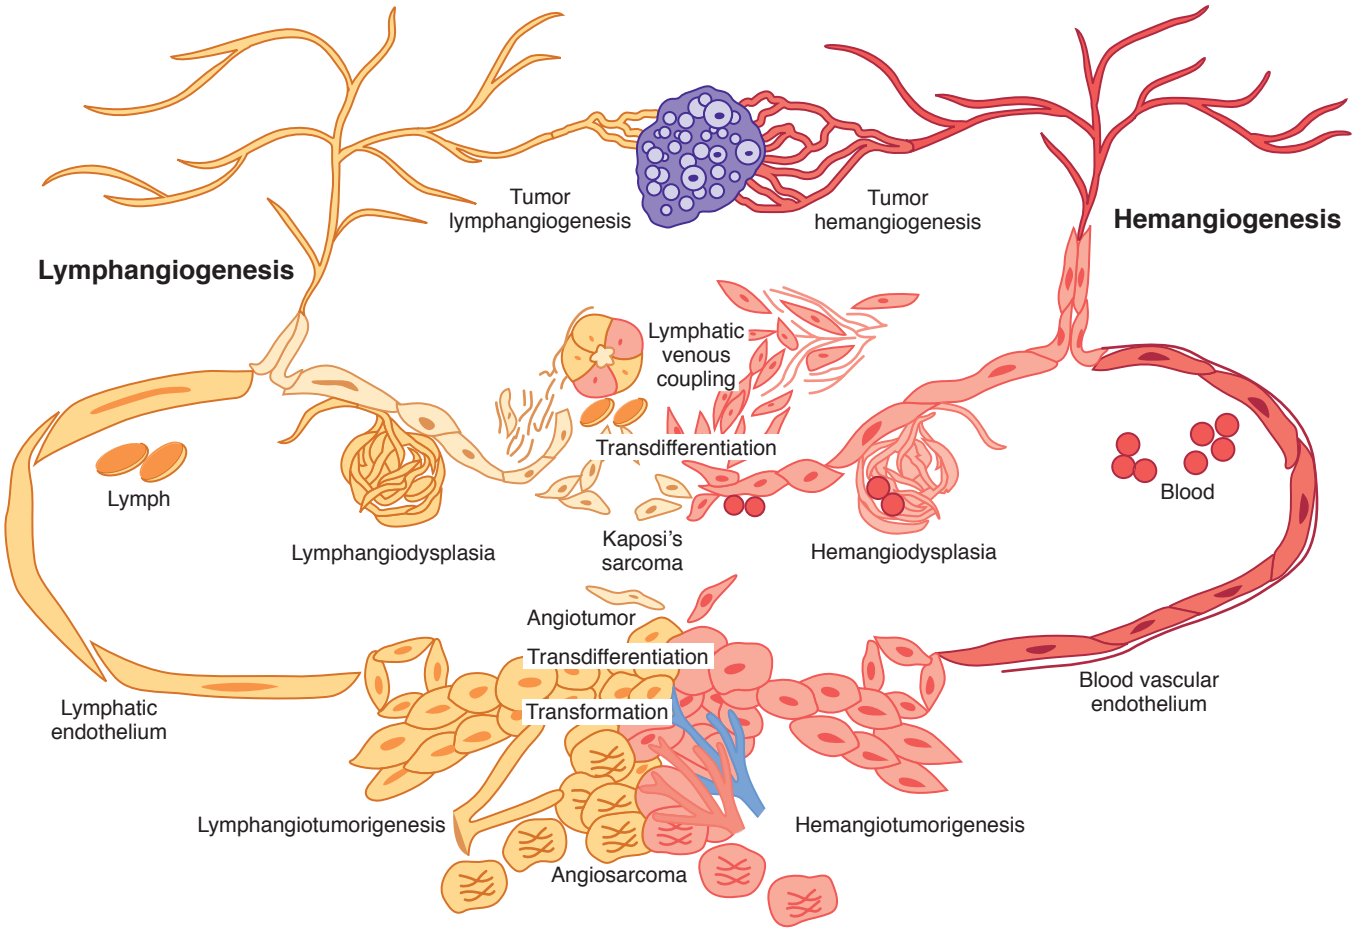

Figure 10.12 Physiologic and pathologic processes common to and linking the lymphatics with blood vessels and involving the growth of lymphatic vessels (lymphangiogenesis) analogous to and often accompanied by the growth of blood vessels (hemangiogenesis). Normally, these two vasculatures remain separate and connect directly only at a few strategic sites. In a variety of disorders, including tumor-associated angiogenesis, angiodysplasias, Kaposi sarcoma, and angiotumorigenesis, the two vasculatures come to resemble one another, interdigitate, and even merge indistinguishably. (Modified from Witte MH, Dellinger M, Bernas M, et al. Molecular lymphology and genetics of lymphedema-angiodysplasia syndromes. In: Földi M, Földi E, eds. *Textbook of Lymphology.* 6th ed. Munich, Germany: Urban & Fischer; 2006:497–523.)

more common local or generalized edemas (high-output; see Fig. 10.7) from venous occlusion, heart failure, and hepatic cirrhosis. Despite this reasonable conclusion and its pathophysiology, peripheral lymphedema has proved both hard to reproduce experimentally and difficult to treat. Initial experimental attempts to simulate the clinical condition by lymphatic sclerosis and radical excision were notoriously unsuccessful and revealed a remarkable capacity of obstructed lymphatics to regenerate and "bridge the gap" or bypass the induced blockage with spontaneous opening of auxiliary lymphatic-venous shunts.[98,130] Although transient swelling was common, these compensatory mechanisms precluded the development of chronic lymphedema solely based on obstruction of lymphatic drainage.

The general failure of early lymph stasis experiments to reproduce unremitting peripheral edema reinforced a long-held theory that overt or subclinical bacterial infection (lymphangitis) was indispensable for evolution of chronic lymphedema.[131] By disrupting microvascular integrity and promoting lymphatic obliteration, recurring infection was thought to exaggerate tissue scarring and cause unremitting lymphedema. This widely held belief was consistent with the commonly observed delayed onset and unpredictability of arm and leg edema after radical mastectomy and groin dissection, respectively, and the grotesque deformities of tropical lymphedema (so-called elephantiasis) from filariasis (Wuchereria bancrofti and Brugia malayi).

Lymphedema and Lymphangiodysplasia

Although understanding is still incomplete, it is now nonetheless clear that nonpitting, brawny extremity edema can arise from lymph stasis alone and by the unremitting accumulation of protein-rich fluid in the extracellular matrix. By using repeated intralymphatic injection of silica particles, Drinker et al.[132] first succeeded in simulating chronic lymphedema in dogs through extensive lymphatic sclerosis. Subsequently, Danese

et al.,[133] Olszewski,[79] and Clodius and Altorfer[134] established that refractory lymphedema could result solely from mechanical interruption of peripheral lymphatics. In an experimental model of circumferential lymphatic transection, tissue swelling was found to be prompt at first (acute lymphedema), disappeared by 4 to 6 weeks, and remained absent for months to years (latent lymphedema), but thereafter reappeared and persisted (chronic lymphedema). If radiation is combined with circumferential excision, the lymphedema is more severe and persists, as shown in rodent models of secondary lymphedema.[135-137] A similar sequence of events occurs in experimental filariasis (caused by Brugia malayi).[138] During the latent phase, when edema is not visible, conventional oil lymphography corroborates ongoing lymphatic destruction.[79] Progressive truncal tortuosity and dilatation give way to massive lymphangiectasis, valvular incompetence, and retrograde flow (dermal backflow). Serial microscopy discloses mononuclear cell infiltration, intramural destruction of lymphatic collectors, and collagen deposition throughout the soft tissues. Eventually, the lymph trunks lose their distinctive smooth muscle and endothelial lining, and the boundary lines between lymph collectors and the surrounding matrix progressively blur.[79,134]

These studies definitively demonstrate that extensive impairment of lymph drainage is sufficient by itself to cause chronic lymphedema (see Fig. 10.9). The key observation is the long interval between disruption of the lymph trunks and the development of refractory edema, which helps to explain the inconstancy and unpredictability of limb swelling after radical operations for treatment of cancer and other disorders of defective lymphatic drainage. As with deep venous occlusive disease, which is associated with valve destruction, venous stasis, and eventually overt edema (post-thrombotic syndrome) with characteristic trophic skin changes (hyperpigmentation and ulceration), absence or obliteration of the lymphatic vessels is associated with lymphatic valve incompetence, lymph stasis, and eventually, intractable edema (postlymphangitic syndrome) with its characteristic trophic skin changes (thickened toe skin folds or Stemmer sign, warty overgrowth, and brawny induration).[139]

Other lymphangiodysplasias were described long ago but remain poorly understood and treated. They often involve both the lymphatic and blood vascular systems and range from simple birthmarks to syndromes consisting of mixed lymphatic and venous components with benign tissue overgrowth to malignant lymphangiosarcoma (Box 10.2; also see Fig. 10.12).

These pathologic conditions and the biochemical and/or tissue composition changes (see Fig. 10.9 and Box 10.2) can be evaluated and imaged for diagnosis, prognosis, and intervention by a variety of modalities (e.g., circumferential measurements for limb volume, bioimpedance spectroscopy for fluid measurement, tonometry for tissue hardness, CT, MRI, dual energy x-ray absorptiometry [DEXA], and ultrasound for deep and superficial tissue analysis), depending on the clinical findings (Fig. 10.13). The current "gold standard" for lymphatic system imaging is whole-body lymphangioscintigraphy (Fig. 10.14), which provides both anatomic and functional imaging and is useful for most clinical manifestations.[45]

BOX 10.2 Clinical Examples of Hemangiodysplasia/Lymphangiodysplasia

A bewildering, poorly classified constellation of angiogenic, angioproliferative, and angiotumorigenic (benign/malignant) manifestations consisting of the following:

- Vascular "birthmarks"
- Capillary, cavernous, etc., hemangiomas, lymphangiomas, and mixed angiomas
- Angiomatosis, including "benign metastasizing" lymphangioma
- Histiocytoid hemangioma
- Malignant endovascular papillary angioendothelioma
- Epithelioid hemangioendothelioma(tosis)
- Kaposi sarcoma, kaposiform eruptions
- (Lymph)angiosarcoma

Chylous and Nonchylous Reflux

Abnormal retrograde transport of lymph is termed reflux. When the lymph fluid derives from outside the intestine (e.g., from the limbs, where it is generally straw-colored to clear), it is termed nonchylous reflux, whereas lymph arising from the intestines (generally milky in color) and flowing retrograde is termed chylous reflux. The phenomena of lymph reflux was observed and recorded as far back as Cruikshank,[140] but he was not sure of its significance and speculated that it was a post-mortem event in cadavers. In 1878 Busey described patients with both chylous and nonchylous reflux syndromes with accompanying lymphedema.[141] His failure to cure or even substantially benefit these patients persists even nowadays for many of these complicated conditions. Because cholesterol and long-chain triglycerides in the form of chylomicra are absorbed exclusively by the lymphatic system, dysfunction (in the form of disruption, compression, obstruction, or fistulization) of mesenteric lacteals, the cisterna chyli, and the thoracic duct is directly linked to chylothorax, chylous ascites, chyluria, chylometrorrhagia, and protein-losing enteropathy. In some patients with high-grade blockage of intestinal lymph flow, the peripheral lymphatics gradually dilate, and with progressive valvular incompetence, lactescent lymph refluxes into the soft tissues of the pelvis, scrotum, and lower extremities (chylous vesicles and chyledema) or even into the bronchial tree, manifesting as chyloptysis (see Fig. 10.14). Transgenic (particularly the angiopoietin-2 knockout mouse),[142] radiation-induced,[128] and spontaneously arising mouse models with chylous effusions are available to further study these chylous reflux syndromes (see Table 10.2). Dynamic imaging of both chylous and nonchylous lymph reflux can usually be accomplished by adjusting the whole-body protocol for lower, and rarely, upper limb lymphangioscintigraphy and can be applied in newborn infants to adults to identify the source, timing, and locations of the lymph reflux (see Fig. 10.14).[45]

Infection

Recurrent cellulitis is a devastating sequela of peripheral lymphedema. Erysipelas resulting from β-hemolytic streptococcal

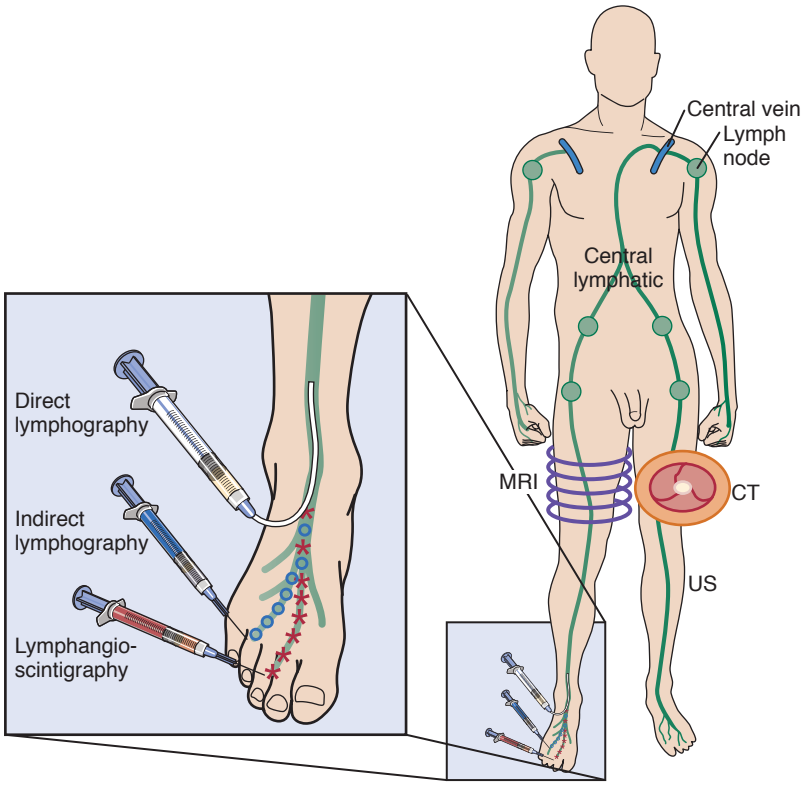

Figure 10.13 Techniques used for structural and functional imaging of the lymphatic system include direct lymphography with an oily contrast agent directly instilled into a lymphatic vessel and indirect lymphography with color vital dyes, fluorescent particles, or radioactive isotope (lymphangioscintigraphy) injected intradermally. Other useful techniques include magnetic resonance imaging (MRI), computed tomography (CT), and ultrasound (US), including photoacoustic refinements.

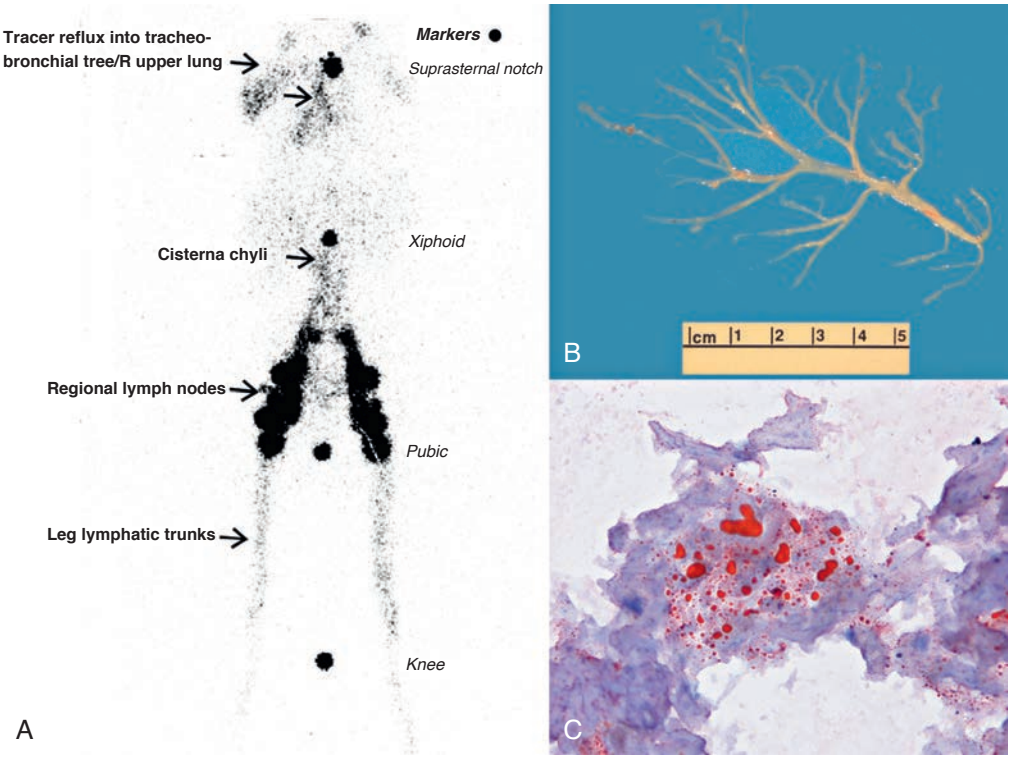

Figure 10.14 Chylous Reflux Syndrome Manifesting as Chyloptysis in an 11-Year-Old Boy With Congenital Heart Disease Following Fontan Repair. (A) Bilateral lower extremity technetium 99m sulfacolloid lymphangioscintigram. Note prompt cephalad tracer transport from foot injection sites into peripheral and central lymphatic trunks and regional inguinal and retroperitoneal lymph nodes up to the level of the cisterna chyli with demonstrable retrograde reflux of tracer *(arrow)* into the tracheobronchial tree and right upper lung field. Radioactive markers placed at key anatomic landmarks: knee, pubic, xiphoid, and suprasternal notch. (B) Large arboreal bronchial cast preserved following expectoration. (C) Acellular cast with oil red O positive lipid droplets, original magnification ×200. (Modified from Parikh K, Witte MH, Samson R, et al. Successful treatment of plastic bronchitis with low fat diet and subsequent thoracic duct ligation in child with Fontan physiology. *Lymphology.* 2012;45(2):47–52.)

infection is most common, but fulminant infection occurs with a variety of microorganisms.[143] To a certain extent, vulnerability to superimposed infection exists whenever tissue fluid stagnates. Patients with lymphedema (in contrast to edematous states arising from imbalances in transcapillary hydrodynamic forces) are so prone to recurring dermatolymphangitis that at one time it was mistaken as the sine qua non of lymphedema.

The reasons for extraordinary susceptibility of a lymphedematous extremity to bacterial infection remain perplexing. Studies

of canine-induced and human filarial lymphedema implicate defective complement activation and immunodysregulation.[79] In addition, dampened monocyte function has been reported in microfilaremic patients.[144] Alternative hypotheses include depopulation of regional lymph nodes with replacement by fat and scar[47] and deficient protease activity of extravascular macrophages.[145] Notwithstanding, the onset of overt lymphedema is often precipitated by sudden infection or injury in an extremity already exhibiting defective lymphatic function. In other words, in an extremity with marginal lymphatic drainage (and therefore dysregulated lymphocyte, monocyte, and dendritic cell trafficking and/or recirculation), even minor trauma and infection may initiate a protracted pernicious cycle that in the extreme culminates in a pachyderm-like deformity, and on rare occasion, leads to a highly aggressive vascular malignancy (see Fig. 10.9). Some strategies for bacterial and/or fungal prophylaxis, particularly in endemic filarial regions, have been undertaken. However, the value of long-term prophylaxis in Western and/or nontropical countries (demonstrating lower rates of infections) has not been well studied, nor has prophylaxis been widely practiced.

Fibrosis

Like the sequelae of superimposed infection, the complications of progressive interstitial fibrosis also set lymphedema apart from other edematous states. Although the pathogenetic sequence is still unclear, it has long been recognized that conditions associated with edema high in protein content (e.g., lymphedema) are characterized by fibrous proliferation and propagation of other cell types, including adipocytes. Altered cytokine production, perturbed immunoreactivity, accumulation of abnormal complexed plasma protein moieties, including growth factors in the extracellular matrix, proliferation of mast cells with release of vasomediators such as histamine,[146,147] alteration in the matrix sol-gel state, and activation of a complement cascade with "fixation" to immunocomplexes may exert, singly or with both microvascular and chemotactic effects that facilitate cell mobility and tissue infiltration of chronic inflammatory cells (e.g., lymphocytes and macrophages).[148] As fibrin- and cell-binding circulating fibronectins accumulate in the stagnant edema fluid, they act as the scaffolding and support glue for the migration of fibroblasts and deposition of collagen.[149] In addition, lymph stasis and the buildup of plasma proteins trapped in the interstitium overwhelm intrinsic neutrophil and macrophage proteases and provoke diffuse scarring.[150] Ironically, these same processes are also critical for the repair of wounds, for which scar formation is also the final common pathway.

Adipogenesis

Although the connection between the lymphatic system and fat absorption and/or deposition has been recognized by clinicians for well over a hundred years, the subject received relatively little interest until publications suggested mechanisms. It has long been recognized that a lymphedematous limb accumulates fat at an increased rate in comparison with the rest of the body and that, conversely, when weight loss is undertaken, the lymphedematous limb loses fat at a slower rate than the body does. The reasons for these observations are not understood. A report and accompanying comment studying Prox1 haploinsufficient mice proposed that lymph itself is stimulatory to fat cells.[151,152] More recent studies using the mouse tail have reported that lymph stasis stimulates adipogenesis and upregulation of fat differentiation genes.[153,154] Questions that still need to be answered include why other transgenic mouse models (e.g., angiopoietin-2 knockout) with more severe and sustained lymph accumulation do not exhibit the obesity phenotype and why severely obese (leptin knockout) mice have normal lymphatics.

In humans, it is known that adipogenesis occurs both prenatally and postnatally (particularly in relation to the modern lifestyle of excessive caloric consumption and epidemic obesity).[155] Obesity also can lead to significant changes in the skin, microcirculation, collagen structure and function, and lymphatics.[156] In humans, there is evidence that the presence of static lymph itself can also influence localized adipocyte hypertrophy.[157]

Adipocytes vary in function and growth potential. The fat pads on the soles of the feet rarely enlarge, whereas those in the midsection can enlarge greatly in number and size. These distinct regions also are likely to have different profiles of cytokine production and growth factors in response to the local environment and in turn to influence it. A factor from human preadipocytes has been shown to preferentially stimulate lymphatic endothelial cell growth in vitro,[158] and other work in rabbits has demonstrated that preadipocytes differentiate more completely when lymph is added to the culture medium.[159] In addition, multipotent mesenchymal stem cells give rise to adipocytes (as well as bone, muscle, and cartilage).[160]

The permanent accumulation of large amounts of fat in limb lymphedema is a poor prognostic factor for physical treatment methods and has given rise to therapeutic approaches such as liposuction to directly and effectively remove the fat.[161]

Lymphatic Tumors and Tumor Lymphatics

A rare but revealing sequela of long-standing peripheral lymphedema is the occurrence of lymphangiosarcoma and/or angiosarcoma and perhaps also other opportunistic neoplasms. This aggressive vascular malignancy was once thought to arise exclusively after radical mastectomy and irradiation for local control of breast cancer (Stewart-Treves syndrome).[162,163] However, lymphangiosarcoma has now been documented in other secondary lymphedemas and even in congenital or primary lymphedema.[164] Because preexisting swelling has usually persisted for many years and may occur in either primary or secondary lymphedema or in the presence or absence of previous radiotherapy, the lymphedema process itself has been thought to be the prime cause. More recently, Kaposi sarcoma, a vascular tumor akin to Stewart-Treves syndrome and allied closely with AIDS, has been linked to an origin from virally transformed lymphatic endothelium.[165-168] Perhaps immunodysregulation underlies a wide range of common and bizarre vasoproliferative and lymphologic syndromes, including hemolymphangioma (representing "angiotumorigenesis"), Klippel-Trénaunay syndrome, Gorham-Stout

syndrome (bony lymphangiomatosis or "disappearing bone disease"), angiofollicular hyperplasia (epithelioid hemangioma), lymphangioleiomyomatosis, and tumor lymphangiogenesis and lymphangitic metastatic carcinomatosis (see Fig. 10.12).[169,170]

Tumor angiogenesis, which generally refers to hemangiogenesis, has been extensively studied since Folkman's original observations[171] and has also become a major therapeutic target, including a target of blockbuster drugs such as Genentech's bevacizumab (Avastin).[172,173] Tumor lymphangiogenesis,[174] a phenomenon whose very existence until recently was questioned, has now become a hot topic. Yet cells giving rise to the two vasculatures overlap and may interchange in specific pathologic settings and resemble each other more in regional settings. Now, various biotechnology companies, stimulated by thought leaders in the angiogenesis field, are vigorously pursuing pharmaceuticals with antilymphangiogenic properties and testing them in preclinical models for application to patients with cancer.[169,170,172,175]

Other Lymphangiogenic Disorders

Although the specific disturbances in lymphangiogenic processes have not been pinpointed for a variety of syndromes and disorders, likely lymphatic growth and remodeling initiating or secondary events are affected in inflammation, infection, and immunodysregulation. In primary disorders such as lymphangioleiomyomatosis, lymphangiectasia, and lymphangiomas, the lymphatic disturbances are clear, but their lymphatic structural and functional details, range of clinical phenotypes, and molecular bases have not been well delineated.

CLINICAL OVERVIEW

Disturbances in microcirculatory perfusion and exchange of liquid, macromolecules, and cells across intact and abnormal microvessels and deranged lymphatic growth patterns and lymph kinetics are, individually and together, associated with disorders of tissue swelling. Low-output failure of the lymph circulation manifested as peripheral lymphedema is characteristically indolent for many years before lymphatic insufficiency and tissue swelling accelerate and become persistent. Nonetheless, impedance of lymph flow by itself is sufficient to explain at least mild to moderate forms of lymphedema. Chronic lymphedema is characterized by trapping of fluid and extravasation of plasma proteins and other macromolecules in the skin and subcutaneous tissues. It is typical to find impaired immune cell trafficking (lymphocytes, Langerhans cells, monocytes), abnormal transport of autologous and foreign antigens, probably intact hydrodynamic (Starling) transcapillary forces,[176] and an increased propensity for superimposed infection. Additional characteristics include progressive obliteration of lymphatics (lymphangiopathy "dieback" or lymphangitis), defective lymphangion contractility, mononuclear cell infiltrates (chronic interstitial inflammation), epidermal cell-fibroblast proliferation, collagen deposition, altered immunoreactivity, and vasoactive mediator imbalance with increased production of local cytokines and growth factors, including autocrine and paracrine hormones.

Transdifferentiation and transformation of endothelium and other vascular accessory cells associated with lymph stasis may also be pivotal factors in a wide range of dysplastic and neoplastic vascular disorders, including Stewart-Treves syndrome, AIDS-associated Kaposi sarcoma, recurrent lymphangiomatosis, and lymphangitic metastatic carcinomatosis. These phenomena have their origin in controlled and uncontrolled lymphangiogenesis and apparently are regulated at specific sites across the genome. Their manipulation may offer new avenues of therapy for both primary and secondary lymphedema and related angiodysplasia syndromes, as well as a variety of neoplasms. These new approaches include gene therapy to supply the normal gene and angiomodulatory therapy to promote lymphangiogenesis when inadequate (as in lymphedema) or inhibit lymphatic growth when excessive (as in lymphangioma). Stem cell therapy to grow new vessels from undifferentiated embryonic or adult stem cells (e.g., lymphangioblasts) and new biomaterials for artificial lymphatics and scaffolding to drain the tissues also hold promise for the future (Fig. 10.15).

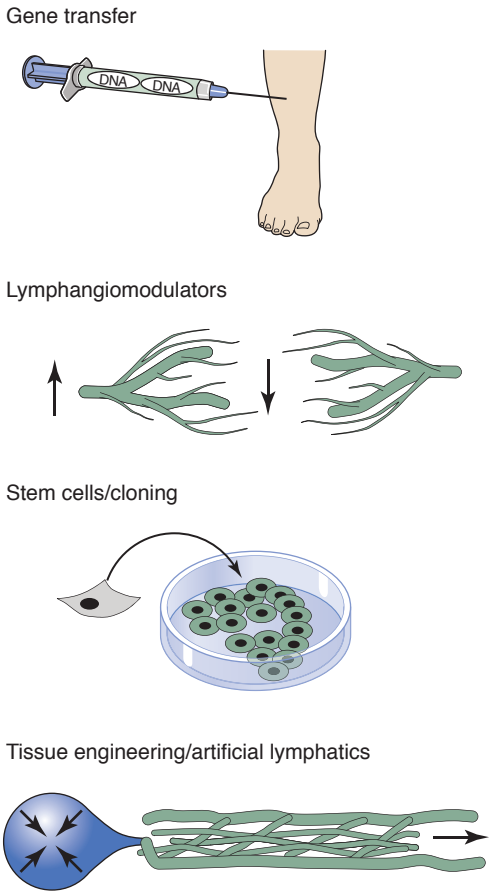

Figure 10.15 Future approaches to the treatment of patients with lymphedema-angiodysplasia disorders may include gene and/or protein transfer, modulation of growth and/or inhibitory factors, "reprogramming" with stem cells, or artificially engineered vessels/systems. SMOKING CESSATION 125

Called "one of the greatest public health catastrophes" of the 20th century in the Surgeon General's semicentennial report, smoking has had profound health consequences that continue to be felt even as its North American prevalence decreases.[1] For vascular surgeons in particular the association with aneurysm formation and arterial occlusive disease means that smoking remains one of the most critical modifiable risk factors.

EPIDEMIOLOGY

Smoking is the foremost cause of preventable morbidity and mortality in the United States. Annually, more than 480,000 premature deaths and more than $300 billion dollars in lost productivity and direct costs are attributed to smoking.[2]

Although the prevalence of smoking in the United States has decreased by more than half since the Surgeon General's seminal report on smoking in 1964, it remains significant.[1] Based on the National Health Interview Survey of almost 37,000 Americans at least 18 years of age, 16.8% smoked regularly in 2014. The prevalence was higher in males than females (18.8% vs. 14.8%). Adults aged 25 to 44 years had the highest rate of 20.0% compared with the lowest rate of 8.5% in those who were 65 years or older. There were also differences based on racial groups, education, and economic status. Namely, cigarette use was highest among American Indian/Alaska natives (29.2%) and lowest among Asians (9.5%). Caucasians had an intermediate rate of 18.2%. Americans with graduate degrees had a mere 5.4% use compared with 43% in those with a general equivalency diploma. Finally, people living below the poverty line had a use rate of 26.3% versus 15.2% in those living above the poverty line.[2]

It is important to recognize that patients may use tobacco products besides cigarettes. The 2012–2013 National Adult Tobacco Survey demonstrated that the following products were used daily or some days: snuff, dip, and other smokeless tobacco (2.6%); cigars and cigarillos (2.0%); water pipes and hookahs (0.5%); and pipes (0.3%).[3]

A recent increasingly popular cigarette alternative is the electronic cigarette or e-cigarette, used by 3.7% of adults daily or on some days.[4] E-cigarettes, while tobacco-free, are battery-operated devices that deliver aerosolized nicotine. They are marketed both as cigarette alternatives and as smoking cessation tools. Although more than half of smokers who attempted to quit had used e-cigarettes in 2014,[4] no such device has been FDA approved for smoking cessation, and the United States Preventative Services Task Force has found inadequate evidence to support e-cigarettes as cessation tools.[5] As a corollary, data regarding potential long-term harms from inhaling nicotine vapors are also absent. Finally, there is concern that e-cigarette use in minors may translate into long-term nicotine addiction for future generations.

Abstract

Despite the declining prevalence in American tobacco use, it remains a significant and relevant risk factor for the development of aneurysms and arterial occlusive disease. The epidemiology, molecular mechanisms, and clinical effects on arterial vasculature are reviewed. In addition, we consider approaches to smoking cessation.

smoking
smoking cessation
nicotine

BIOLOGIC EFFECTS OF SMOKING ON THE VASCULATURE

Cigarette smoke has adverse effects on vascular biology through a variety of mechanisms. First, it creates endothelial dysfunction, including reduction of the availability of nitric oxide, and activation of enzymes leading to the increased production of reactive-oxygen species. Flow-mediated dilation, a common measure of endothelial function, is diminished in active smokers and even nonsmokers exposed to secondhand smoke for less than 1 hour.[1]

Second, smoking creates a prothrombotic environment. Smoking leads to the increased production of thromboxane A2 and decreased levels of prostacyclin, thus overall promoting platelet aggregation. Smoking is also associated with elevated levels of prothrombotic substances such as von Willebrand factor, thrombin, and fibrin, while simultaneously reducing antithrombotic and fibrinolytic substances such as tissue plasminogen activator and plasminogen activator inhibitor-1. Smokers also have higher markers of platelet activation, which decline after smoking cessation.[1]

Last, smoking promotes an inflammatory state, which has been associated with vascular disease. Compared with nonsmokers, smokers have higher levels of leukocytes, C-reactive protein, interleukin-6, tissue necrosis factor-α, interleukin-1-β, and other inflammatory markers.[1]

It should also be noted that nicotine itself plays an important role in known drivers of vascular disease. Not only does it act as a sympathomimetic substance that raises blood pressure, but it is also associated with insulin resistance, altered lipid metabolism, and endothelial dysfunction.[1] Finally, vascular surgeons have for generations passed on the observation of differential disease distributions patterns between patients who smoke versus those with diabetes. Smokers tend to have aorto-iliac and superficial femoral disease, while occlusive atherosclerosis generally strikes the profunda and tibials in diabetic patients.[6] However, rigorous documentation of these broad and frequently variable differential disease patterns is sparse.

NONVASCULAR CLINICAL EFFECTS

Smoking has causal links with numerous diseases across several organ systems. Most prominently, smoking is associated with cancers of the lungs, oropharynx and larynx, esophagus, stomach, pancreas, kidney, bladder, and cervix. More recently, it has been implicated in liver and colorectal cancers as well.[1]

Cigarette smoking also has been linked to diabetes, cataracts, macular degeneration, chronic obstructive pulmonary disease, asthma, and rheumatoid arthritis, among others.

VASCULAR CLINICAL EFFECTS

Development of Peripheral Arterial Disease

Cigarette smoking has an unequivocal positive association with the development of peripheral vascular disease in multiple large epidemiologic studies. For example, the original Framingham Study, which followed 5209 subjects, showed that smoking was more allied with the development of intermittent claudication than even coronary artery disease and stroke.[7] Similarly, the Speedwell study followed 2348 men starting in 1979 and found that smoking was the strongest risk factor for the development of claudication, more so than diabetes and hypertension.[8]

The Women's Health Study provided additional insights into the development of PAD. This study prospectively followed nearly 40,000 healthy women health professionals at least 45 years of age beginning in 1993.[9] During a median follow-up of 12.7 years, 178 subjects developed symptomatic peripheral arterial disease. Multivariate analysis showed that the risk of this developed in stepwise fashion with smoking. Compared with never smokers, the hazard ratio for symptomatic PAD development was 3.16 for former smokers, 11.94 for current smokers using fewer than 15 cigarettes, and 21.08 for those using 15 or more cigarettes daily.

Interestingly, the Women's Health Study also showed that smoking cessation was beneficial with respect to PAD development, and that these benefits were proportional to the duration of cessation. Using current smokers as the reference group, the hazard ratios for PAD development in those who had fewer than 10 years of cessation, 10 to 19 years of cessation, 20 or more years, and never smokers were 0.39, 0.28, 0.16, and 0.08, respectively.[9] Not all studies, however, have found that cessation reduces atherosclerotic disease burden risk. The Atherosclerosis Risk in Communities study showed that after controlling for pack-years of smoking, there was no difference in atherosclerotic disease between past and current smokers as measured by carotid artery intimal-medial thickness.[10]

Graft Failure and Amputation

Willigendael et al. conducted a meta-analysis to determine the effects of smoking on the patency of lower extremity arterial grafts.[11] On basis of a total of 20 prospective and retrospective studies, the hazard ratio for graft failure was 2.35 in smokers compared with nonsmokers. Studies that used biochemical tests to determine smoking status found an even higher hazard ratio of 3.8, implying that studies based on self-reported smoking status may underestimate effects. Interestingly, three component studies that looked at the effect of patient age all found that smoking in patients less than 65 years old had a higher risk of graft failure than older patients. Smoking had similarly negative effects on autogenous grafts and polyesters grafts.

Willigendael's meta-analysis also found that there was a graft patency benefit to smoking cessation. Former smokers had patencies superior to those of current smokers and comparable to never smokers.[11]

In a corollary study, Lassila et al. prospectively examined the impact of heavy smoking, defined as 15 or more cigarettes daily on amputation risk and survival in 190 patients undergoing lower extremity arterial reconstruction for PAD. At 3 years, heavy smokers had diminished survival and increased major amputation rates (21% vs. 2% in non–heavy smokers, $P < .001$).[12]

Smoking and Other Vascular Disease

Although this chapter focuses on atherosclerotic occlusive peripheral vascular disease, it should be noted that smoking is also intimately associated with two other diseases of concern to the vascular surgeon: thromboangiitis obliterans (Buerger disease) and aortic aneurysms. Both of these are common and important pathologies worldwide and are described in more detail in separate chapters.

SMOKING CESSATION

Smoking cessation can have positive health effects, including an improvement in all-cause mortality.[13] Although duration of cessation counseling from a healthcare provider correlates with likelihood of abstinence, providers would be mistaken to believe that extensive time investments are necessary to have an impact: even individualized interventions as short as 1 minute have been shown to increase quitting success.

Although a full treatment of cessation interventions is beyond the scope of this work, some essential guidelines follow. The Agency for Healthcare Research and Quality recommends that smoking interventions should consists of five key elements, the five As: ask, advise, assess, assist, and arrange.[13] Physicians should ask about and document tobacco use at every patient visit. They should directly advise every tobacco user to quit. Each tobacco user should be assessed for his or her willingness to quit. Patients willing to quit should receive assistance, detailed below, and finally healthcare providers should arrange for follow-up.

For patients who are unwilling to quit, physicians should be sure to use motivational interview strategies along with the five R's.[13] Physicians should point out the **r**elevance of quitting to the patient with regard to his or her social situation, health concerns, and so forth. They should delineate the **r**isks of ongoing tobacco use and point out the manifold **r**ewards of quitting. Finally, the physician should ask the patient to identify **r**oadblocks to success and attendant solutions, and **r**epeat this intervention at each visit.

For patients interested in quitting, physicians should provide contemporary practical advice (Table 11.1), and select medication adjuncts. There are currently seven FDA-approved first-line therapies consisting of five nicotine-replacement medications—gum, inhaler, lozenge, nasal spray, and lozenge—and two nonnicotine pharmaceuticals, bupropion SR, and varenicline (Table 11.2).[13] Bupropion SR blocks neuronal reuptake of dopamine and norepinephrine while also serving as a nicotinic acetylcholinergic

TABLE 11.1 Practical Advice in Smoking Cessation

- Aim for total abstinence after the chosen quit date.
- Alcohol decreases success rates; consider reducing alcohol intake.
- Others in the patient's household should consider attempting to quit or not smoking in the presence of the patient to maximize success.
- Identify triggers for smoking and avoid them.
- Anticipate withdrawal symptoms—problems with mood and concentration, nausea, headache—which will peak at 1-2 weeks but may persist for longer periods.

TABLE 11.2 Nicotine and Non-Nicotine Therapy for Smoking Cessation[15-19]

Medication	Directions	Dosing	Major Side Effects
Nicotine Replacement Therapy for Smoking Cessation			
Gum Nicorette (available over the counter in generic form)	Chew gum until it tingles, then park between cheek and gums until tingle disappears, then chew again until tingle returns. Repeat until most of tingle is gone (~30 min).	Use 2-mg pieces for <25 cigarettes daily or 4-mg pieces for >25 cigarettes daily. Smokers should use at least one piece every 1-2 h for the first 6 weeks; the gum should be used for up to 12 weeks with no more than 24 pieces to be used per day.	Throat and mouth irritation, increased salivation, hiccupping, jaw muscle ache Use with caution in patients with oral or pharyngeal inflammation and in patients with a history of esophagitis or peptic ulcer.
Lozenge Commit (available over the counter in generic form)	Use 2-mg lozenges for first cigarette use >30 min after waking or 4-mg pieces for <30 min after waking. Allow lozenge to dissolve (~20-30 min) in mouth. Do not chew or swallow lozenge. Occasionally move lozenge from one side of mouth to the other.	Use at least 9 lozenges per day in the first 6 weeks; the lozenge should be used for up to 12 weeks, with no more than 20 lozenges per day.	Throat and mouth irritation, increased salivation, hiccupping, indigestion Use with caution in patients with oral or pharyngeal inflammation and in patients with a history of esophagitis or peptic ulcer.

Continued

TABLE 11.2 Nicotine and Non-Nicotine Therapy for Smoking Cessation—cont'd

Medication	Directions	Dosing	Major Side Effects
Inhalation Nicotrol	10-mg cartridges (4 mg is delivered) to be used for inhalation	Initial 12 weeks, 6-16 cartridges per day, then gradual reduction during 6-12 weeks	Throat and mouth irritation, coughing, rhinitis, sinusitis, pain in jaw and neck
	Inhale deeply into back of throat or puff in short breaths. Nicotine in cartridge is used up after 20 min of active puffing.		
			Use with caution in patients with bronchospastic disease.
Nasal spray Nicotrol NS	50-μL spray containing 0.5 mg of nicotine per actuation. One dose is 1 mg of nicotine (2 sprays, one in each nostril).	Initially 1-2 doses per hour up to 5 doses per hour (40 doses per day) for 8 weeks, with tapering during next 4-6 weeks.	Use with caution in patients with bronchospastic disease, known chronic nasal disorders (allergy, rhinitis, nasal polyps, sinusitis).
	Spray once in each nostril, do not sniff or inhale while spraying.		
Transdermal patch Habitrol Nicoderm CQ (available over the counter in generic form)	Wear patch 16 or 24 hours, 24 h if cravings on awakening, otherwise remove at bedtime and apply fresh patch on a clean, nonhairy area of skin between neck and waist in the morning. Do not reapply patch to a previously used skin site for at least 1 week. Do not cut patch into smaller pieces.	10-week therapy for >10 cigarettes a day, 8-week therapy for <10 cigarettes a day	Skin irritation
		10-week therapy: 21 mg for 6 weeks, 14 mg for 2 weeks, 7 mg for 2 weeks	
		8-week therapy: 14 mg for 6 weeks, 7 mg for 2 weeks	

Medication	Mechanism of Action	Dosing	Major Side Effects
Nicotine- and Nonnicotine Therapy for Smoking Cessation[12,14]			
Bupropion (Zyban)	Atypical antidepressant with dopaminergic and adrenergic actions	Start with 150 mg daily for first 3 days and increase to 150 mg twice daily. The maximum dose of bupropion is 300 mg per day.	Seizures, worsening depression, anxiety, agitation, irritability, insomnia, unusual changes in behavior, development of suicidal ideation/behavior, hypertension, dry mouth
		Treatment should be started while the patient is still smoking; the patient should set a target quit date, usually for the second week of treatment.	Contraindicated in patients with seizure disorder already taking bupropion for another reason as risk of seizures are dose dependent with bulimia or anorexia undergoing abrupt discontinuation of alcohol or sedatives taking monoamine oxidase inhibitors allergic to bupropion.
		Continue treatment for 7-12 weeks. Patients abstinent within 7-12 weeks may continue with 300 mg daily maintenance therapy.	
			Use with extreme caution in patients with hepatic dysfunction.
		May be used in combination with nicotine replacement therapy.	
			Boxed warning: Patients should be closely monitored for signs of serious neuropsychiatric side effects.

TABLE 11.2 Nicotine and Non-Nicotine Therapy for Smoking Cessation—cont'd

Medication	Mechanism of Action	Dosing	Major Side Effects
Varenicline (Chantix)	$\alpha_{4\beta2}$ Nicotinic acetylcholine receptor partial agonist	Treatment should be started while the patient is still smoking; the patient should set a target quit date, usually for the second week of treatment. Days 1-3: 0.5 mg once daily 4-7: 0.5 mg twice daily 8-end: 1 mg twice daily Adjust dosage for severe renal impairment or side effects to maximum dose of 0.5 mg twice daily. Initial therapy for 12 weeks with an optional additional 12 weeks for maintenance therapy	Nausea, insomnia, unusual or vivid dreams, constipation, headaches, weight gain, gas, changes in behavior, agitation, depressed mood, suicidal ideation. Boxed warning: Patients should be closely monitored for signs of serious neuropsychiatric side effects.

TABLE 11.3 Outcomes of Selected Smoking Cessation Interventions[13]

Medication	Estimated Odd Ratio of Abstinence Success (95% CI)	Estimated abstinence rate (95% CI)
Placebo	1.0	13.8
Varenicline (2 mg/day)	3.1 (2.5-3.8)	33.2 (28.9-37.8)
Bupropion SR	2.0 (1.8-2.2)	24.2 (22.2-26.4)
Nicotine Patch (6-14 weeks)	1.9 (1.7-2.2)	23.4 (21.3-25.8)
Long-Term Nicotine Patch (>14 weeks)	1.9 (1.7-2.3)	23.7 (21.0-26.6)
Nicotine Nasal Spray	2.3 (1.7-3.0)	26.7 (21.5-32.7)
Nicotine Inhaler	2.1 (1.5-2.9)	24.8 (19.1-31.6)
Nicotine Gum	1.5 (1.2-1.7)	19.0 (16.5-21.9)
Nicotine Patch (>14 weeks) + Nicotine Gum or Spray	3.6 (2.5-5.2)	36.5 (28.6-45.3)
Nicotine Patch + Bupropion SR	2.5 (1.9-3.4)	28.9 (23.5-35.1)
Nicotine Patch + Nicotine Inhaler	2.2 (1.3-3.6)	25.8 (17.4-36.5)

receptor antagonist. Varenicline functions as a partial mixed nicotine receptor agonist and antagonist. Unfortunately, there is no consensus on how to choose among first-line therapies, and the final decision may ultimately reflect personal preference and practical matters such as insurance coverage.

It should be noted that evidence does not support the use of any of these therapies in smokers who use fewer than 10 cigarettes daily. Also, several combinations of first-line therapies have been demonstrated to be effective: nicotine patch for more than 14-weeks and nicotine gum or spray, nicotine patch and nasal inhaler, and nicotine patch and bupropion SR.[13] Effectiveness of individual therapies and combinations are listed in Table 11.3.

Since the first evidence linking smoking and lung cancer more than 60 years ago, there have been extraordinary efforts to elucidate the clinical effects, mechanisms of disease, and public health impact of smoking. Concerted efforts to curb smoking rates based on broad scientific consensus on the adverse effects of smoking have produced steady declines in smoking rates. Nevertheless, there remains much to be done. As surgeons, we are uniquely positioned and obligated to counsel patients not only during "teachable moments" in their lives, as before surgery, but also longitudinally.[14] Indeed, smoking cessation must be seen by surgeons to be as crucial to improving patients' health as any surgical intervention.

SUMMARY AND FUTURE DIRECTIONS 137

Diabetes is characterized by chronic hyperglycemia resulting either from a lack of insulin production (type 1) or from insulin resistance (type 2). In the past several decades an alarming rise in the global prevalence of diabetes has been seen. The cost to the health care system is enormous because the medical expenditures of people with diabetes are 2 to 3 times higher than those of the rest of the population. In 2012 the total cost of diabetes in the United States alone was estimated at $245 billion, including $176 billion in direct medical costs and $69 billion in indirect costs due to disability, work loss, and premature death.[1]

The health consequences of diabetes are primarily vascular and are routinely divided into microvascular and macrovascular categories. The most important microvascular complications are retinopathy and nephropathy; people with diabetes have a 20-fold increased relative risk of blindness and a 25-fold higher relative risk of end-stage renal disease compared with people without diabetes. Macrovascular disease is characterized by atherosclerosis.[2] Diabetes is an important risk factor for the development and severity of all forms of atherosclerosis, including peripheral artery disease (PAD), coronary artery disease (CAD), and cerebrovascular disease (CVD). Most of the 230,000 diabetes-related deaths in the United States every year are due to CAD.[1] Diabetes also increases the risk of ischemic stroke twofold to threefold and accounts for 60% of nontraumatic lower-limb amputations.[3-7] These financial and physical costs are expected to increase in the next few decades as the prevalence of diabetes continues to rise worldwide.

EPIDEMIOLOGY

Over the past several decades, the global prevalence of diabetes has nearly quadrupled, with an estimated 422 million people worldwide currently diagnosed with the condition.[8] This number is predicted to exceed 500 million by 2030, which equates to an annual increase in diabetes prevalence that is 1.7 times faster

than the annual growth of the world's population. In the United States 9.3% of the population, or 29.1 million people, have diabetes and 86 million people have prediabetes (characterized by insulin resistance).[1] Although the prevalence of diabetes is shifting to a younger demographic as the overall population becomes more obese, the risk of diabetes continues to increase with age, and as many as 25.9% of all Americans over the age of 65 have diabetes.[1] The prevalence rate is highest for American Indians/Alaska Natives (15.9%), followed by non-Hispanic blacks (13.2%) and Hispanics (12.8%), and lowest for Asian Americans (9%) and non-Hispanic whites (7.6%).[1]

Global demographic changes and lifestyle factors that directly affect the incidence of diabetes are the major contributors to the increasing prevalence of diabetes worldwide. More than one-third of the increase in number of persons with diabetes worldwide over the past 30 years can be attributed to increases in population size and aging of populations, particularly in India and China. Lifestyle changes related to increasing industrialization and economic development, and the interaction between demographic changes and lifestyle factors explain the remainder of this trend.[8] Industrialization has led to both the abundance of cheap high-calorie food and adoption of a sedentary lifestyle in the same countries with the greatest population growth, leading to an epidemic of obesity worldwide. The prevalence of obesity in the United States is increasing at an alarming rate and directly corresponds to the number of new diagnoses of diabetes. In fact, from 2000 to 2005 the rate of obesity increased by 24%. During that same time period, the prevalence of diabetes in the United States increased from 12% to 16.3%.[1] However, recent data point to the specific role and direct relationship of sugar consumption and other types of food intake, independent of obesity and the risk of development of diabetes.[9]

CLASSIFICATION OF DIABETES

Type 1

Type 1 diabetes is characterized by an absolute deficiency in insulin secretion and accounts for 5% to 10% of diabetes diagnoses.[10] It results from cellular-mediated autoimmune destruction of the pancreatic beta cells and requires both genetic and environmental factors to cause the disease state. Markers of immune destruction of the beta cell are present in 70% to 90% of patients and can aid in the diagnosis. These include islet cell autoantibodies, autoantibodies to insulin, antiglutamic acid decarboxylase antibodies, and autoantibodies to tyrosine phosphatase IA-2 and IA-2β.[11]

Typically, type 1 diabetes presents with acute hyperglycemia or ketoacidosis as the first disease manifestation. Type 1 diabetes (previously known as "juvenile-onset" diabetes) often presents in children and adolescents but can present at any age. It also frequently develops in patients who have other autoimmune diseases such as lupus, rheumatoid arthritis, and Hashimoto thyroiditis.[10] Because patients with type 1 diabetes have an absolute deficiency in insulin secretion, their treatment is reliant on insulin replacement therapy.

Type 2

Type 2 diabetes results from a combination of insulin resistance and inadequate compensatory insulin secretion, accounting for 90% to 95% of patients with diabetes.[10] Although type 2 was previously referred to as either "adult-onset" or "noninsulin-dependent" diabetes, these terms are less accurate because many patients may require insulin treatment and because it can develop at practically any age. In the United States more than 20% of new diagnoses of diabetes in people under the age of 20 are due to type 2.[1]

The pathogenesis of type 2 diabetes is heterogeneous, with both environmental and genetic causes. Obesity is strongly related to insulin resistance and is the most important environmental factor. The heritability of insulin sensitivity is approximately 40% to 50%. Although insulin resistance is clearly necessary for the development of type 2 diabetes, incomplete compensatory rise in insulin secretion (relative deficiency) must also be present for hyperglycemia to result. This concept was illustrated by DeFronzo et al., who demonstrated that plasma insulin response to ingested glucose increases progressively in individuals who have fasting glucose concentration less than 120 mg/dL. Having a fasting glucose greater than 120 mg/dL is progressively associated with a corresponding decline in insulin secretion.[12] Genomic studies have identified more than 88 gene loci associated with the risk of developing type 2 diabetes. Most of these loci are primarily associated with insulin secretion and beta cell function, with few genes (e.g., *NAT2*) linked to insulin resistance that is independent of obesity.[13] In type 2 diabetes the hyperglycemia tends to develop slowly, and therefore the symptoms are more subtle. These include polyuria, polydipsia, weight loss, and polyphagia. Because people with type 2 diabetes have varying levels of insulin resistance and deficiencies in insulin secretion, they require the titration of different medications to achieve appropriate glycemic control.

DIABETES AND VASCULAR DISEASE

Vascular disease is the most significant cause of morbidity and mortality in people with diabetes.[3] There is a direct relationship between level of hyperglycemia and disease severity in microvascular diseases such as retinopathy, nephropathy, and neuropathy; thus these diseases are more prominent in type 1 diabetes, with its long duration of hyperglycemia exposure.[3] On the other hand, macrovascular complications such as CAD, PAD, and CVD, although responsible for the majority of deaths in patients with diabetes, have a modest relationship to glycemia.[14]

Coronary Artery Disease

Diabetes is associated with a significantly increased risk of developing CAD, and patients with diabetes and CAD have been shown to have worse outcomes. People with diabetes tend to present with CAD at a younger age than patients without diabetes. It is estimated that diabetes leads to clinically evident CAD as much as 15 years earlier than otherwise expected.[15]

Once diagnosed with CAD, persons with diabetes have a higher risk of cardiovascular death, recurrent myocardial infarction (MI), stroke, and coronary stent thrombosis.[16] Furthermore, people with diabetes account for a disproportionate number of those presenting with acute coronary syndromes.[17] Following MI, people with diabetes have higher rates of morbidity and mortality, with a 58% higher mortality than in nondiabetics at 30-days[18] and nearly 50% higher mortality at 1 year.[19]

Cerebrovascular Disease

There are more than 2 million people with diabetes in the United States who have survived a stroke.[1] Diabetes is associated with at least twice the risk for stroke, a 2-year earlier age of onset of CVD symptoms, and worse functional outcomes compared with nondiabetics.[17] The duration of diabetes, but not the quality of glycemic control, is an independent predictor for risk of ischemic stroke. For patients treated with thrombolytic therapy for acute stroke, hyperglycemia is associated with a higher failure of recanalization and increased risk for hemorrhagic conversion.[20] After a completed stroke, diabetes doubles the risk for a recurrent event.[21] Although stroke is responsible for 20% of mortalities among people with diabetes, no significant difference has been demonstrated in the mortality rate after stroke among diabetics compared with nondiabetics. Among diabetic survivors of ischemic stroke, half will have long-term disability and are less likely than nondiabetics to be discharged home and are more likely to suffer loss of independence in the short and long term (3, 6, and 18 months).[21]

Peripheral Artery Disease

An estimated 10 million Americans are affected by PAD, and more than 80,000 are hospitalized each year for the condition.[1,22] The prevalence of PAD varies significantly based on the age of the population studied, from 0.9% in patients between 40 and 49 years old to 14.5% in patients older than 69 years in the National Health and Nutrition Examination Survey (NHANES)[23] Targeted screening can more clearly identify a population at risk. In the PAD Awareness, Risk, and Treatment: New Resources for Survival (PARTNERS) trial, nearly 7000 subjects were screened in primary care practices, provided they met one of the following criteria: age 70 years or older or ages 50 to 69 years with a history of diabetes and/or smoking.[24] Using these criteria, 29% of subjects were found to have PAD. In patients with diabetes, risk of PAD is increased by older age, smoking, duration of diabetes, and presence of peripheral neuropathy. In patients with diabetes the prevalence of PAD may be as high as 40%.[25] The risk of PAD is also known to be higher in African Americans and Hispanic Americans with diabetes.[5]

Diabetes significantly increases both the incidence and severity of limb ischemia because of several associated factors.[26] Insulin resistance is independently associated with PAD, after adjustment for demographic factors and medical comorbidities.[27] The distribution of PAD is different in patients with diabetes compared with those without it. Patients with diabetes and PAD tend to have involvement of the more distal arteries, particularly the popliteal and tibial arteries, making limb-salvage revascularization more challenging.[5,6] The neuropathy that often develops in people with diabetes presents several additional challenges. First, sensory neuropathy reduces the ability to avoid injury by decreasing normal sensation and withdrawal to pain. In addition, symptoms common to advanced ischemic disease may be less appreciated and may lead to delay in diagnosis.[6] Diabetic peripheral neuropathy also leads to limited joint mobility (due to motor neuropathy), decreased proprioception and pain sensation (due to sensory neuropathy), and decreased sweating (due to autonomic neuropathy). The motor neuropathy fosters the formation of a swan neck foot deformity, resulting in disproportionate increases in pressure points to the metatarsal heads and other parts of the foot, making ulceration more likely.[28,29]

As a result, diabetes is the most common cause of nontraumatic lower extremity amputation in the United States, accounting for 55% of amputation-related hospitalizations.[30] For people 65 to 74 years old, the risk of amputation is increased more than 20-fold compared with those without PAD and diabetes.[31] The combination of PAD and diabetes is of additional clinical importance given its association with cardiovascular events. Patients with both diabetes and PAD are at extremely high risk of adverse cardiovascular events. In the Linz Peripheral Arterial Disease (LIPAD) study, the mortality rate from cardiovascular disease over a 10-year period was 5% for people with diabetes, 14% for those with PAD, and 31% for patients with both.[32] The mortality for patients with diabetes and PAD who require a lower extremity amputation is 50% at 2 years.[25]

PATHOPHYSIOLOGY OF VASCULAR DISEASE IN DIABETES

Diabetes leads to increased atherosclerotic vascular disease by a number of mechanisms, including metabolic derangements, hypercoagulability, inflammation, vascular dysfunction, and neuropathy. These alterations result in a phenotypic change in the blood vessel from one of homeostasis to an atherogenic phenotype characterized by endothelial cell dysfunction, oxidative stress mediated by increased production of free radicals, and vascular smooth muscle dysfunction.[33]

Dysmetabolism and Vascular Dysfunction

The cardinal metabolic derangements in diabetes are each associated with a wide variety of insults that attenuate the vasculature's ability to maintain equilibrium and foster an environment permissive for the development of atherosclerosis. The two fundamental derangements include hyperglycemia and insulin resistance, which are both associated with the development of atherosclerosis. Increases in the rate of atherosclerotic events begin with modest increases in fasting glucose levels in the normal range. Insulin resistance, independent of hyperglycemia, is associated with atherosclerosis and predicts cardiovascular events.[33]

The impact of diabetes on the vascular endothelium represents an important link between the dysmetabolism of diabetes and

the atherosclerosis that causes the majority of morbidity and mortality. The vascular endothelium plays a fundamental role in vascular homeostasis, regulating vascular tone, platelet activity, leukocyte adhesion and diapedesis, and vascular smooth muscle cell migration and proliferation.[34] The endothelium regulates vascular homeostasis through the elaboration of autocrines and paracrines that modulate the structure and function of vascular cells. An endothelium-derived vasodilator, nitric oxide (NO), is constitutively produced in healthy endothelial cells by endothelial NO synthase (eNOS). The production of NO is closely adjusted by a wide variety of chemical and biomechanical stimuli. In addition to its potent vasodilatory properties, NO reduces production of proinflammatory chemokines and cytokines through inhibition of inflammatory transcription factors, which subsequently limits platelet activation. In contrast, decreased bioavailability of NO enhances an environment of vascular injury and atherogenesis.[35] NO bioavailability is reduced in basic investigations, animal models, and humans with insulin resistance and frank diabetes mellitus.[36-39] Endothelial dysfunction, found in both hyperglycemia and impaired endothelial insulin signaling, may link insulin resistance to its heightened risk of atherosclerosis, MI, and death. Thus endothelial dysfunction participates in the development and progression of atherosclerosis and may facilitate its adverse sequelae.

Hyperglycemia impairs vascular function through an increase in the production of reactive oxygen species (ROS), oxidative stress, and consequent impairment in endothelial function.[40] Hyperglycemia-induced ROS inactivates endothelium-derived NO.[40] Reduced NO bioavailability fosters atherogenesis and predicts a heightened risk of cardiovascular outcomes.[41,42] Through a variety of mechanisms, hyperglycemia increases ROS production and impairs endothelial function. Hyperglycemia increases mitochondrial generation of the superoxide anion, leading to cellular mitogenic pathway activation including polyol and hexosamine flux, advanced glycation end products (AGEs), protein kinase C (PKC) activation, and nuclear factor kappa B (NF-κB)-mediated vascular inflammation.[43,44] Indeed, ROS lead to upregulation and nuclear translocation of NF-κB subunit p65 and transcription of proinflammatory genes encoding for monocyte chemoattractant protein-1 (MCP-1), selectins, vascular cell adhesion molecule-1 (VCAM-1), and intracellular adhesion molecule-1 (ICAM-1). These events facilitate adhesion of monocytes to the vascular wall and their translocation into the subendothelium with subsequent formation of foam cells (Fig. 12.1).

The second cardinal marker of dysmetabolism in diabetes is insulin resistance. Insulin resistance likely precedes the onset of hyperglycemia by many years. In diabetes, insulin resistance affects many tissues, including skeletal muscle, liver, adipose, and blood vessels. One possible mechanism by which insulin resistance can impair vascular function is the byproduct of the resistance on adipose tissue. Adipose tissue is an important source of inflammatory mediators and free fatty acids (FFAs),[45] which are elevated in the plasma of obese patients with type 2 diabetes.[46] Impaired endothelial cell insulin signaling may also be salient in insulin resistance. In mice a loss of insulin signaling in the vascular endothelium leads to diminished endothelial

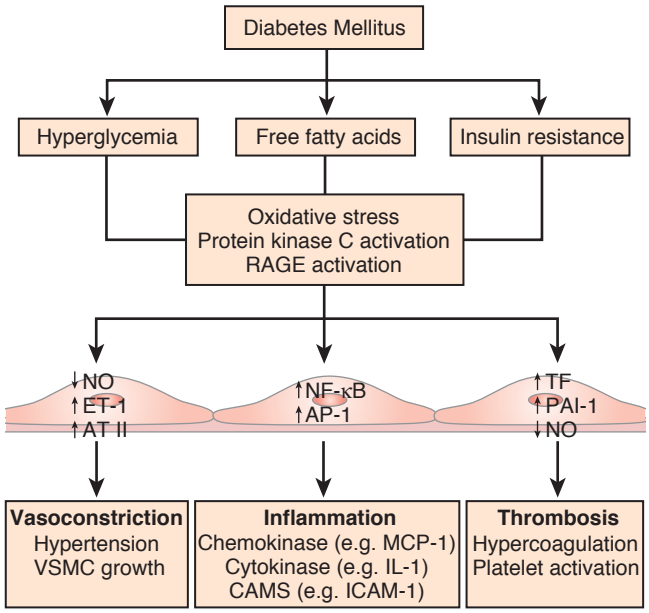

Figure 12.1 The metabolic abnormalities that characterize diabetes—particularly hyperglycemia, free fatty acids, and insulin resistance—provoke molecular mechanisms that alter the function and structure of blood vessels.

NO synthase levels, endothelial dysfunction, expression of adhesion molecules, and atherosclerotic lesions.[47] Another study confirmed the importance of endothelial insulin signaling by showing that genetic disruption of endothelial insulin receptor substrate 2 (IRS-2) reduces glucose uptake by skeletal muscle, whereas restoration of insulin-induced eNOS phosphorylation restored capillary recruitment as well as insulin delivery.[48] These novel findings strengthen the central role of endothelium in obesity-induced insulin resistance, suggesting that blockade of vascular inflammation and oxidative stress may be a promising approach to prevent metabolic disorders. Notably, pharmacologic improvement of insulin sensitivity in patients with type 2 diabetes and metabolic syndrome is associated with restoration of flow-mediated vasodilation.[49-51]

The atherogenic effects of insulin resistance are also due to changes in lipid profile such as high triglycerides, low HDL cholesterol, increased remnant lipoproteins, elevated apolipoprotein B (ApoB), and small and dense LDL.[52] Once circulating FFAs reach the liver, VLDL are assembled and made soluble by increased synthesis of ApoB. VLDL are processed by cholesteryl ester transfer protein (CETP), allowing transfer of triglycerides to LDL, which become small and dense and hence more atherogenic. Atherogenic dyslipidemia is a reliable predictor of cardiovascular risk, and its pharmacologic modulation may reduce vascular events in subjects with type 2 diabetes and metabolic syndrome.[53-55]

Platelet Dysfunction and Coagulation Cascade

Platelet dysfunction has also been shown to play a role in thrombosis, complicating atherosclerotic plaque rupture in diabetes. Glycoprotein Ib and IIb/IIIa expression is upregulated in diabetes, which leads to increased amounts of von Willebrand

factor and platelet-fibrin interaction.[56] Hyperglycemia also impairs calcium homeostasis, which alters calcium-dependent platelet aggregation and activation.[57] Procoagulant factors (factor VIII, thrombin, and tissue factor) are increased and endogenous anticoagulants and fibrin inhibitors (thrombomodulin, protein C, plasminogen activator inhibitor 1) are decreased in a chronic hyperglycemic state.[58-61] Diabetes therefore leads to increased platelet aggregation and a shift in favor of the procoagulant portion of the thrombotic cascade. These alterations contribute to the propensity not only for atherosclerosis, but also for thrombosis in pathologic plaque rupture resulting in acute coronary syndrome, ischemic stroke, and acute limb ischemia, which are known to be more common in people with diabetes.

VASCULAR EVALUATION OF PATIENTS WITH DIABETES

The vascular evaluation of patients with diabetes is a challenge for providers and requires additional evaluation for a comprehensive assessment, particularly regarding the evaluation of neuropathy, thorough foot examination, and noninvasive physiologic testing. The examination should focus on inspection of the extremities and feet for signs of skin change, hair loss, ulceration, or increased dryness. Full sensory and motor exam should then be performed with the addition of monofilament testing plus vibration sensation (using 128-Hz tuning fork), pinprick sensation, or ankle reflexes.[62]

The presence of neuropathy is an important risk multiplier not seen with other risk factors. Diabetic peripheral neuropathy is characterized by a symmetric sensorimotor polyneuropathy.[63] It starts distally, moves proximally, and results in a typical "glove and stocking" distribution.[64] Motor deficits are rare in the early stages of diabetic peripheral neuropathy. Burning, tingling, and shooting pains are frequently described and are typically worse at night.[64] Of note, the degree of pain and subjective symptoms are not reliable indicators of sensory nerve damage. Careful peripheral neurologic examination is recommended annually in patients with diabetes.[62]

The American Podiatric Medical Association and the Society for Vascular Surgery recommend that patients with diabetes have ankle-brachial index (ABI) measurements performed when they reach 50 years of age. Furthermore, patients with a prior history of diabetic foot ulcer, known atherosclerotic cardiovascular disease, prior abnormal vascular examination, or prior intervention for PAD should have a clinical examination of the lower extremities and noninvasive physiologic testing (ABI and/or toe pressures) annually.[25] However, one important diagnostic consideration is the increased likelihood of noncompressible pedal vessels and subsequent falsely elevated ABI results in patients with diabetes.

The Wound, Ischemia, and foot Infection (WIfI) classification system is a framework for stratifying amputation risk and revascularization benefit in patients with PAD that is useful in the evaluation of diabetic foot ulcers which is reviewed in Chapter 116.[65]

TREATMENT OF PATIENTS WITH DIABETES AND PERIPHERAL ARTERY DISEASE

The two most important goals in the treatment of patients with PAD and diabetes are improving limb outcomes (i.e., improving claudication symptoms and preventing progression to critical limb ischemia) and decreasing morbidity and mortality from cardiovascular disease and stroke. An aggressive approach to risk factor modification and medical treatment is the cornerstone to achieve both goals. Target-driven medical intervention can reduce the risk of cardiovascular events by as much as 50% in patients with type 2 diabetes.[66] A sample treatment algorithm for patients with PAD and diabetes is available in Box 12.1.

Preventive Foot Care

Peripheral neuropathy, ischemia, and infection form the etiologic triad of diabetic foot complications.[67] Proper foot care and hygiene are the hallmarks of preventive therapy. Commonly, diabetic foot ulcers and infections begin as small wounds that are not recognized and treated in the early stages because symptoms may be masked by sensory neuropathy. Therefore careful screening and early intervention are important in preventing diabetic foot complications. The American Diabetes Association (ADA) recommends annual foot examination to identify high-risk conditions before complications develop.[68] The SVS and APMA provide more specific recommendations for prevention of diabetic foot ulceration including: (1) annual foot

BOX 12.1 Treatment Algorithm for Peripheral Artery Disease in Patients With Diabetes

1. Refer to smoking cessation program
2. Treatment of hypertension with blood pressure reduced to <140/90 mm Hg
3. Control diabetes mellitus with hemoglobin A1c level reduced to <7.0%
4. Treat dyslipidemia and reduce serum LDL level to <70 mg/dL
5. Antiplatelet drug therapy with aspirin or clopidogrel
6. Treatment with angiotensin-converting enzyme inhibitor
7. Treatment with beta blockers in patients with coronary artery disease in the absence of contraindications
8. Use of statins
9. Treatment with cilostazol in patients with intermittent claudication
10. Exercise rehabilitation program
11. Foot care
12. Consider percutaneous angioplasty or bypass surgery for
    - Incapacitating claudication interfering with work or lifestyle
    - Limb salvage in persons with limb-threatening ischemia
    - Vasculogenic impotence
13. Amputation of lower extremities should be performed if tissue loss has progressed beyond the point of salvage, if surgery is too risky, if life expectancy is very low, or if functional limitations diminish the benefit of limb salvage

Adapted from Aronow WS. Peripheral arterial disease of the lower extremities. *Arch Med Sci*. 2012;8:375-388.

examination by a provider with training in foot care, (2) inclusion of the Semmes-Weinstein test for peripheral neuropathy as a component of the foot exam, (3) patient and family education about preventative foot care, (4) custom therapeutic footwear in high-risk patients, including those with significant neuropathy, foot deformities, or previous amputation, and (5) glycemic control (hemoglobin A1c <7%).[25]

Glycemic Control

The study of glycemic control and the impact on macrovascular events has been investigated in three large trials performed to determine whether tight glucose control (hemoglobin A1c <6.5%) was better than standard control (hemoglobin A1c of 7%). In the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial, a strategy of targeting a hemoglobin A1c of 6% versus 7% to 7.9% to reduce adverse cardiovascular events was evaluated in 10,251 patients.[69] The study was stopped early because the intensive glucose-lowering strategy was found to increase cardiovascular mortality without reducing other major cardiovascular events. The Action in Diabetes and Vascular Disease (ADVANCE) study and the Veterans Affairs Diabetes Trial (VADT) both also failed to demonstrate a reduction in cardiovascular outcomes in patients with improved glycemic control.[70,71] Based on the lack of success in these large trials, the ADA recommended targeting a hemoglobin A1c of 7.0%.[72]

In addition to lowering glucose, insulin-sensitizing agents have been studied in relation to cardiovascular events. Metformin, a biguanide, has demonstrated improvements in cardiovascular outcomes. In United Kingdom Prospective Diabetes Study (UKPDS), among obese subjects, metformin reduced diabetes-related death and all-cause mortality by 42% and 36%, respectively.[3] In the 10-year follow-up of UKPDS, metformin reduced MI by 33% and mortality by 27% compared with subjects treated with sulfonylureas, despite a lack of difference in glycemic control.[73] In a Danish study, patients treated with insulin secretagogues had an approximate 20% increase in all-cause mortality compared with patients treated with metformin.[74] Thus metformin is the recommended first line hypoglycemic agent to be used in patients with type 2 diabetes. The thiazolidinediones have a mixed cardiovascular outcomes record. In the Prospective Pioglitazone Clinical Trial in Macrovascular Events (PROactive), pioglitazone did not demonstrate macrovascular benefits in terms of reduction of cardiovascular events at 10-year follow-up.[75] Rosiglitazone, on the other hand, was shown to be associated with a reduction in overall cardiovascular events and cardiovascular death in the VADT.[76] Table 12.1 briefly reviews the different classes of medications available to treat hyperglycemia.

Although it has not been proven to improve PAD symptoms or amputation rates, the ACC/AHA consensus guidelines on PAD treatment also support a hemoglobin A1c goal of 7.0%.[77] When insulin-providing therapy was compared with insulin sensitization therapy for glycemic control in the Bypass Angioplasty Revascularization Investigation 2 Diabetes (BARI 2D) trial, the insulin sensitization strategy was shown to be superior in the reduction of PAD, need for lower extremity revascularization, and lower extremity amputation.[78] The PROactive trial, despite failing to demonstrate an effect of pioglitazone on cardiovascular outcomes, did show a significant decrease in leg amputations at 10-year follow up (4.1% for pioglitazone compared with 5.6% for placebo).[75]

With so many medication classes, the choice of agent for each patient may seem daunting. The ADA published *A Consensus Algorithm for the Initiation and Adjustment of Therapy* in 2009 to aid in these decisions. According to this algorithm, lifestyle interventions are the first step of treatment, followed by metformin, if still necessary. If lifestyle interventions and maximal tolerated dose of metformin do not achieve a hemoglobin A1c less than 7%, another medication should be added. Either sulfonylurea or insulin is the suggested second medication for this step. If glycemic control is still not achieved, insulin therapy should be started or intensified until goal hemoglobin A1c is achieved. The ADA therefore relegates the other oral and subcutaneous medications to a "second-tier" algorithm, which it states is appropriate in certain individualized circumstances.[72]

Risk Factor Control

Aggressive risk factor modification is the cornerstone for reductions in atherosclerosis-related events. Much of this therapy is discussed in other chapters in the text; here we provide diabetes-specific data for risk factor reduction.

Dyslipidemia

The American College of Cardiology and American Heart Association guidelines on the treatment of blood cholesterol strongly recommend the use of moderate-intensity statin therapy for primary prevention of atherosclerotic cardiovascular disease in diabetics 40 to 75 years of age with LDL greater than 70 mg/dL.[79] This recommendation is based on numerous large-scale clinical trials which have shown a significant benefit of statin therapy in patients with diabetes and elevated LDL or even average LDL.[80,81] In the Heart Protection Study (HPS), 3000 subjects with diabetes and without evidence of atherosclerotic disease at entry but with total cholesterol greater than135 mg/dL were randomized to simvastatin or placebo. A 34% risk reduction was observed in the combined endpoint of coronary heart disease, stroke, and revascularization in simvastatin-treated group.[82] The Collaborative Atorvastatin Diabetes Study (CARDS) enrolled participants with diabetes without evidence of vascular disease but with one other cardiovascular risk factor (hypertension, retinopathy, smoking, or microalbuminuria or macroalbuminuria) and randomized these subjects to 10 mg/day of atorvastatin versus placebo.[83] The mean LDL level in this trial was 117 mg/dL. The results showed a 30% reduction in the composite primary endpoint of major cardiovascular events in the atorvastatin-treated group. The most significant finding of this trial is that the benefit occurred irrespective of baseline LDL levels in both treated and placebo patients. Despite numerous trials and recent efforts at targeted drug development, to date, no lipid-lowering medications other than statins have been shown to reduce the incidence of stroke, MI, or cardiovascular mortality. Indeed, niacin, fenofibrate, and novel agents

TABLE 12.1 Summary of the Most Common Oral Hypoglycemic Agents

Agent	Mechanism of Action	Expected A1C Reduction	Adverse Effects	Outcome Data/CV Safety Concerns
Biguanides Metformin	Decrease hepatic glucose production	≈1%-2%	Diarrhea, nausea, lactic acidosis, decreased B12 levels	May improve CVD outcomes; contraindicated in decompensated or unstable HF due to risk of lactic acidosis
Sulfonylureas Glyburide Glipizide Glimepiride	Bind to sulfonylurea receptors on pancreatic islet cells, cardiac K_{ATP}, stimulating insulin release	≈1%-2%	Hypoglycemia, weight gain	Hypoglycemia may precipitate ischemia or arrhythmia; cardiac K_{ATP} channel closure may impair ischemic preconditioning
Glinides Nateglinide	Bind to sulfonylurea receptors on pancreatic islet cells	≈1%-2%	Hypoglycemia, weight gain	Hypoglycemia may precipitate ischemia or arrhythmia; cardiac K_{ATP} channel closure may impair ischemic preconditioning
α-Glucosidase inhibitors Acarbose Miglitol	Slow gut carbohydrate absorption	≈0.5%-1%	Gas, bloating	Improves postprandial glucose excursions, which are more tightly associated with CVD than fasting glucose
Thiazolidinediones Rosiglitazone Pioglitazone	Activates the nuclear receptor PPAR-γ, increasing peripheral insulin sensitivity and reduces hepatic glucose production	≈1%-1.5%	Weight gain, edema, possible bone loss in women	May precipitate clinical HF in predisposed individual;
Incretin modulators GLP-1 mimetics Exenatide	Increase glucose-dependent insulin secretion, decrease glucagon, and delay gastric emptying	≈1%	Nausea, vomiting	
DPP-4 inhibitors Sitagliptin Saxagliptin	Inhibit degradation of endogenous GLP-1, thereby enhancing the effects of incretins	≈0.6%-0.8%		
Amylin analogues Pramlintide	Decrease glucagon secretion and delay gastric emptying	≈0.4%-0.6%	Nausea, vomiting	
Insulins	Increased insulin supply	No limit (theoretically)	Hypoglycemia, weight gain, edema (at high doses)	

CVD, Cardiovascular disease; *GIP-1*, glucose-dependent insulinotropic peptide; *GLP-1*, glucagon-like peptide 1; *HF*, heart failure; *MI*, myocardial infarction.
Adapted from Inzucchi SE, et al. New drugs for the treatment of diabetes: part II: incretin-based therapy and beyond. *Circulation*. 2008;117:574.

that raise HDL (CETP inhibitors) have all been shown in large-scale clinical trials to provide no benefit beyond statins in cardiovascular risk reduction.[84-86]

Hypertension

Control of hypertension has been shown in multiple studies to decrease the risk of macrovascular disease and death in patients with diabetes. Indeed, blood pressure control was the first treatment to show reductions in mortality. In UKPDS, "tight blood pressure control" (a mean blood pressure of 144/82 mm Hg in the treatment arm compared with 154/87 mm Hg in the control arm) was associated with a 32% risk reduction in death related to diabetes and 44% risk reduction in strokes.[87] In the Appropriate Blood-Pressure Control in Diabetes (ABCD) trial, normotensive patients with diabetes were randomized to intensive diastolic blood pressure control (with a goal of decreasing the diastolic blood pressure by 10 mm Hg from the baseline value) or moderate blood pressure control.[88] The intensive blood pressure control group was treated with either nisoldipine (a calcium-channel blocker) or enalapril (an angiotensin-converting enzyme [ACE] inhibitor). Intensive diastolic blood pressure control resulted in improved cardiovascular outcomes in the ACE inhibitor group and had a beneficial effect on albuminuria, retinopathy, and strokes in patients treated with either medication.[89] When patients with PAD were specifically analyzed, a significant and dramatic reduction (38.7% compared with 13.6%) was seen in MI, stroke, and cardiovascular death in the patients in the intensive blood pressure control groups.[90] In response to these and other studies showing similar outcomes, the current Joint National Committee (JNC) guidelines for the management of hypertension involves pharmacologic therapy with a goal blood pressure lower than 140/90 mm Hg for all adult patients with diabetes.[91]

Further studies have shed light on the importance of the renin-angiotensin axis in patients with diabetes. More than 20 high-quality studies have investigated the effect of ACE inhibitors on cardiovascular events in patients with diabetes, and meta-analysis of these data demonstrates that ACE inhibitor therapy significantly reduces the risk of all-cause mortality by 13%, cardiovascular deaths by 17%, and major cardiovascular events by 14%, including MI (reduced by 21%) in patients with diabetes.[92] The effect of ACE inhibitors and angiotensin II

receptor blockers on diabetic foot ulcers and lower extremity amputations in patients with diabetes and PAD was studied by Margolis et al.[93] They found significant reduction in diabetic foot ulcers and lower extremity amputations in patients treated with angiotensin II receptor blockers for 1 year compared with those who received ACE inhibitors. However, this finding requires further validation.

Antiplatelet Therapy

Antiplatelet therapy is a key component of secondary prevention measures in patients with diabetes and known atherosclerotic vascular disease. However, the role of aspirin therapy for primary prevention of cardiovascular disease is less clear. Three trials have been conducted specifically in patients with diabetes (Early Treatment Diabetic Retinopathy Trial, Prevention of Progression of Arterial Disease and Diabetes [POPADAD], and Japanese Primary Prevention of Atherosclerosis with Aspirin for Diabetes [JPAD]), and six trials included large proportions of patients with diabetes with a wide range of study duration and aspirin dosage.[94] Meta-analysis of these data suggests a modest (9%) relative risk reduction in risk for cardiovascular events and more than twofold increased risk of bleeding. Based on this evidence, in 2015 the ADA and the AHA jointly recommended low-dose aspirin therapy (75 to 162 mg/day) for primary prevention in patients with diabetes when the 10-year risk of cardiovascular events is greater than 10% and the baseline risk of gastrointestinal bleeding is not increased.[95] This includes men older than 50 years and women older than 60 years with one or more of the following risk factors: smoking, hypertension, dyslipidemia, family history of premature CVD, or albuminuria.

Numerous studies have demonstrated the benefit of antiplatelet therapy in patients with known PAD for reducing cardiovascular events. A subgroup of the Antithrombotic Trialists' Collaboration meta-analysis included 9214 patients with PAD and found a significant reduction in serious vascular events with aspirin therapy.[96] In the Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) trial, patients with non–ST-elevation MI, ischemic stroke, or PAD were randomized to treatment with aspirin versus clopidogrel. A subset analysis demonstrated that the 3866 patients with diabetes had a 12.5% reduction in major cardiovascular events with clopidogrel versus aspirin.[97] The SVS guidelines recommend antiplatelet therapy with either aspirin 75 to 325 mg or clopidogrel 75 mg in individuals with PAD with a grade 1 level of evidence.[22] However, more recent data question the benefits of this therapy specifically in patients with diabetes. In the JPAD trial, patients with diabetes were randomized to low-dose aspirin (81-100 mg) versus placebo, with no reduction found in the risk of major cardiovascular events.[98] The POPADAD trial evaluated aspirin efficacy in patients with both diabetes and PAD. The 1276 patients with diabetes and PAD (based on ABI <0.99) were randomized to low-dose aspirin plus antioxidant treatment, low-dose aspirin plus placebo, antioxidant plus placebo, or double placebo. No significant difference was seen among the four groups in death from coronary heart disease, nonfatal MI, stroke, above-the-ankle amputation, or critical limb ischemia.[99] The clinical standard will likely be to continue aspirin or other antiplatelet therapy in these patients pending further studies in a larger number of patients.

Medical Treatment for Symptomatic Improvement of Peripheral Artery Disease

After a diagnosis of PAD has been made, therapies to preserve exercise tolerance and improve symptoms should be initiated. Exercise therapy is the most beneficial intervention for these goals, and cilostazol may also improve exertional capacity and symptoms.

Exercise Therapy

Exercise therapy is effective in improving the symptoms of intermittent claudication. Randomized controlled trials of supervised exercise training programs have repeatedly supported this benefit, including increasing the distance to onset of claudication and increasing the distance to maximum claudication pain.[100,101] The optimal exercise program, based on a meta-analysis by Gardner et al., includes walking for at least 30 minutes, more than 3 times per week for 6 months.[102] In another meta-analysis of supervised exercise for PAD, Bendermacher et al. found an average improvement in maximum walking time of 6.5 minutes with supervised exercise, which is superior to any medication studied to date.[103] Although patients with diabetes typically have more impairment at baseline, exercise therapy increases walking distance in patients with diabetes as well as in claudicants without diabetes.[104] The Claudication: Exercise versus Endoluminal Revascularization (CLEVER) study randomized patients (approximately 25% of whom had diabetes) with aortoiliac PAD to optimal medical care, optimal medical care plus supervised exercise, or optimal medical care plus stent revascularization.[105] The primary endpoint was a graded treadmill test at 6 months compared with baseline. The supervised exercise group had the greatest improvement in walking time, but quality of life assessment by questionnaire was most improved in the stenting group. This finding will be further evaluated in the larger SUPERvised Exercise Therapy or Immediate PTA for Intermittent Claudication In Patients with an Iliac Artery Obstruction (SUPER) trial, which is ongoing.[106] Consistent with these data, the SVS recommends a supervised exercise program as the initial treatment modality for patients with intermittent claudication consisting of walking a minimum of 3 times per week (30 to 60 min/session) for at least 12 weeks or a home-based exercise program of similar intensity when a supervised exercise program is unavailable or has been completed.[22]

Cilostazol

Cilostazol is a phosphodiesterase-3 inhibitor that has vasodilator, antiproliferative, and antiplatelet effects.[107] Although it has not been shown to have any effect on mortality, it improves symptoms of claudication in approximately 50% of patients with and without diabetes.[108] A Cochrane Review of seven randomized double-blind trials evaluating the use of cilostazol found significantly increased walking times in patients with stable intermittent claudication.[109] The SVS guidelines for treatment

of PAD state that a 3-month trial of cilostazol at a dose of 100 mg twice daily is recommended to alleviate symptoms and improve walking distance in patients with lifestyle-limiting symptoms who do not have congestive heart failure.[22] In one study that compared the effects in subjects with and without diabetes, cilostazol increased walking distance similarly in both groups.[110] Cilostazol is generally well tolerated, with adverse effects of headaches, nausea, diarrhea, pain, infection, upper respiratory symptoms, palpitations, arrhythmias, and peripheral edema occurring in approximately 5% of people based on a meta-analysis.[109] Cilostazol is contraindicated in patients with congestive heart failure or moderate to severe renal or hepatic impairment.

Pentoxifylline

Pentoxifylline is a methylxanthine derivative that acts by inhibiting phosphodiesterase and by potentiating the effects of endogenous prostacyclin.[111] Numerous studies have been performed comparing pentoxifylline treatment with both placebo and other therapies. A Cochrane Review of these studies concluded that the data were poor, the results varied widely, and definitive evidence of efficacy was lacking.[111] When evaluated head to head, cilostazol significantly improved walking distances compared with placebo, whereas pentoxifylline was no different from placebo.[112] The SVS guidelines state that a trial of pentoxifylline may be considered for patients who cannot tolerate or have a contraindication to cilostazol to improve pain-free walking in patients with intermittent claudication.[22]

Statins

Beyond their reduction of cardiovascular events, statins have also been shown to improve walking distance and reduce the progression of symptomatic claudication. In one prospective trial of patients with PAD randomized to atorvastatin 10 mg/day, atorvastatin 80 mg/day or placebo, the patients in the high-dose atorvastatin group experienced improvement in pain-free walking distance and subjective physical activity questionnaire scores.[113] A retrospective analysis of the Scandinavian Simvastatin Survival Study (4S) found that patients with dyslipidemia and CAD had a 38% risk reduction in developing new or worsening claudication symptoms when treated with simvastatin.[114] A randomized trial of simvastatin versus placebo for intermittent claudication found that at 6 months the pain-free walking distance had increased 90 m more in the stimvastatin group.[115] With these data in mind, the SVS recommends the inclusion of statin pharmacotherapy for patients with symptomatic PAD.[22]

Angiotensin-Converting Enzyme Inhibitors

Six small randomized controlled trials have evaluated the role of ACE inhibitors in pharmacologic therapy to improve symptoms of PAD. Meta-analysis of these studies demonstrates that treatment with ACE inhibitors improves maximum walking distance by 121 m and pain-free walking distance by 75 m compared with placebo.[116] The greatest benefits were seen in the three trials that used ramipril. The most common side effect of treatment with ACE inhibitors is persistent cough.

Referral for Revascularization

When medical therapy fails, revascularization (either surgical or percutaneous) may be necessary. Indications for peripheral revascularization procedures for PAD are the same in patients with and without diabetes. In PAD, these include disabling claudication, critical limb ischemia (rest pain or tissue loss), or nonhealing or infected foot ulcers that are expected to benefit from revascularization, which is reviewed in Chapter 105.

SUMMARY AND FUTURE DIRECTIONS

Diabetes increases the risk of vascular disease, including cardiovascular, cerebrovascular, peripheral vascular, and microvascular diseases. CAD is responsible for the majority of the deaths in patients with diabetes, but stroke, claudication, critical limb ischemia, diabetic foot ulcers, retinopathy, and nephropathy all contribute to the overall health care expenditures and morbidity in patients with diabetes. Numerous metabolic, thrombotic, and vascular derangements occur in diabetes and explain the accelerated atherosclerosis and increased rate of thrombosis characteristic of diabetic vascular disease. Treatment of PAD in patients with diabetes involves therapies to improve claudication symptoms and aggressive risk factor modification aimed at improving cardiovascular outcomes and overall mortality. As the worldwide incidence of diabetes grows, these complications will become more and more important to global health care delivery.

Cardiovascular disease is the leading cause of death in industrialized countries and accounts for over 31% of deaths globally.[1] Over the last century, a multitude of discoveries and intense research have elucidated the mechanisms of atherosclerosis, a word derived from the Greek *atheros*, meaning gruel and *sclerosis*, meaning hard. It has been well established, for over six decades now, that the major atherosclerotic risk factors include hyperlipidemia, hypertension, cigarette smoking, and a positive family history of the disease.[2-4] Diabetes mellitus, obesity, lack of exercise, and poor dietary habits can also be added to the previous list (Box 13.1). At the molecular level, hypercholesterolemia and inflammatory cells play a key role in the development of atherosclerotic plaque.[5,6] Numerous large-scale studies have confirmed that lowering low-density lipoproteins (LDL) levels by 30% to 50% will significantly reduce cardiovascular mortality. Between 1980 and 2000, therapeutic cholesterol reduction has decreased mortality from atherosclerotic cardiovascular disease (ASCVD) by one third. The focus of this chapter is on the

Abstract

Hyperlipidemia is a recognized risk factor for the development of atherosclerosis. Over the last century, lipid metabolism and the pathophysiology of plaque formation have been elucidated. Low-density lipoprotein (LDL) level in the blood is the most important determinant for the development and progression of atherosclerosis. Therapeutic interventions have been devised to lower LDL serum levels in patients at risk. Several pharmaceuticals agents have been developed to treat hyperlipidemia but statins play a dominant role in this therapeutic goal. Lowering LDL serum levels <70 mg/dl in high-risk patients is associated with a decreased risk of stroke and coronary events, as well as improved survival. In addition to lipid-lowering agents, diet and exercise have been shown to be effective in managing hyperlipidemia. Recently, PCSK9 inhibitors were approved to treat patients who are refractory to the other lipid lowering therapies.

pathophysiologic role of hyperlipidemia in causing atherosclerosis, the physiology and metabolism of lipids, and the diagnosis and management of hyperlipidemia.

HISTORICAL PERSPECTIVE

The notion that dietary fat had something to do with atherosclerosis has existed for some time. In 1910, a German scientist found that human aortic plaque had 25 times more cholesterol than a "normal" aorta. Three years later, a Russian pathologist induced atherosclerosis in rabbits fed a high cholesterol diet. In 1919, an American clinician correlated electrocardiographic changes in patients suffering from angina caused by ASCVD.[2] Subsequently, familial hypercholesterolemia was diagnosed and the cholesterol synthesis pathway described. Over the last 50 years, the LDL receptor was discovered and pharmaceutical agents, the statins which inhibit 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, were approved and prescribed to treat patients with hyperlipidemia (Table 13.1). More recently, the transcription factor sterol regulatory element-binding protein-1 (SREBP-1) was identified as well as its complex interaction with intracellular and nuclear elements to regulate LDL.

BOX 13.1 A Century of Cholesterol and Coronaries

First Half—The Era of Cholesterol

1910 Human and atherosclerotic plaques contain cholesterol
1913 High cholesterol diet causes atherosclerosis in rabbits
1919 Heart attacks recognized in humans
1933 Feedback inhibition of cholesterol synthesis demonstrated
1938 Familial hypercholesterolemia described
1950 Cholesterol biosynthetic pathway elucidated
1951 High-fat diets raise plasma cholesterol in humans
1953 Risk factor concept advanced

Second Half—The Era of LDL

1955 LDL identified as risk factor for CHD
1973 LDL receptor discovered
1976 HMG CoA reductase inhibitors (statins) discovered
1981 Statins increase LDL receptors in vivo
1987 First statin (Mevacor) approved for human use
1994 Statins decrease heart attacks and prolong life
1997 SREBP pathway elucidated
2006 PCSK9: Destroyer of LDL receptors

PHYSIOLOGY AND METABOLISM OF LIPIDS

Lipids are hydrophobic and are chemically insoluble in blood. They are transported as lipoproteins in which the hydrophobic lipid components are surrounded by an envelope of hydrophilic phospholipids and proteins known as apolipoproteins (apo). This creates a water-soluble spherical particle that can be carried in the blood (Fig. 13.1). The principal function of lipoprotein particles is transporting lipids from the intestine and liver through the bloodstream to the cells of the body, where they can be stored, used for synthetic processes, and metabolized to yield energy. The various apolipoproteins, such as apo B, apo A, apo E, and apo C, serve as cofactors in metabolism of the contained lipid and as ligands to facilitate binding of lipoproteins to receptors on the surface of cells throughout the body. Five major lipoproteins are recognized.

TABLE 13.1 Critical Historical Events That Led to the Discovery and Development of the Statins

Year	Scientist(s)	Discovery
1913	Nikolai Anitschkow	Fed pure cholesterol to rabbits and demonstrated development of hypercholesterolemia and extensive aortic atherosclerosis
1950	John Gofman	Described the major classes of plasma lipoproteins using ultracentrifugation. Demonstrated direct and inverse association of LDL-C and HDL-C levels respectively, with incidence of myocardial infarction
1964	Konrad Bloch and Feodor Lynen	Received Nobel Prize for unraveling the metabolic pathway of cholesterol synthesis
1972	Akira Endo	Discovered compactin, the forebearer to the first statin, from a blue-green mold
1973	Michael Brown and Joseph Goldstein	Received the Nobel Prize for the discovery of the LDL receptor and its feedback regulation

HDL-C, High-density lipoprotein cholesterol; *LDL-C,* low-density lipoprotein cholesterol.

Chylomicrons

Lipoprotein metabolism can be divided into exogenous and endogenous phases. During the exogenous phase, both dietary lipids and recirculated lipids within bile are absorbed into enterocytes and packaged as very large lipoproteins called chylomicrons. Although dietary cholesterol and triglycerides are absorbed by different mechanisms within the gastrointestinal (GI) tract, they are combined in this single chylomicron particle for transport from the GI tract through the thoracic duct and into the circulation to the rest of the body. Triglycerides constitute approximately 90% of the chylomicron's lipid content. When present in significant concentration, chylomicrons account for the turbidity or "milkiness" of plasma, known as postprandial lipemia, which is seen in some individuals with metabolic and inherited disorders of lipid metabolism. Chylomicrons are distinguished by the presence of one apo B-48 molecule in each particle. In the bloodstream, the enzyme lipoprotein lipase (LPL) hydrolyzes the triglyceride contained within the chylomicron into free-fatty acids (FFAs). FFAs are taken up by peripheral tissues and used for energy. In adipose and muscle cells, FFAs can also be re-esterified into triglycerides and stored for future energy production. The remaining triglyceride-poor chylomicron remnant contains only the absorbed dietary cholesterol, which is then transported to the liver for storage. Although chylomicrons are typically considered a transport lipoprotein, evidence suggests atherosclerotic lesions contain apo B-48 within plaque, thus implicating these chylomicron remnants as atherogenic particles.[7,8]

Very-Low-Density Lipoproteins

The endogenous phase of lipoprotein metabolism involves the hepatic formation of very-low-density lipoproteins (VLDLs) containing cholesterol and triglycerides derived from stores within the liver and adipocytes (Table 13.2). Each VLDL particle contains apos C and E as well as one molecule of apo B-100 per particle. Similar to chylomicrons, the predominant lipid component of VLDL is triglyceride, which accounts for approximately 70% of its lipid content. Although not as large as chylomicrons, VLDL is large enough to cause lipemia when present in very high concentrations. VLDL is released from the liver into the bloodstream, where LPL again facilitates removal of the triglyceride component of VLDL and presents it to the muscle cell as fuel for energy production. Through this endogenous mechanism, triglycerides stored in adipocytes, hepatocytes, and muscle cells can be used for energy during fasting or starvation as a more energy-rich alternative to glucose. As the triglyceride is removed, two additional atherogenic lipoprotein particles are formed: VLDL remnants and intermediate-density lipoproteins (IDLs).

Intermediate Density Lipoprotein (Remnant Lipoprotein)

IDLs carry cholesterol esters and triglycerides. IDLs, similar to LDL, have been shown to increase the risk of cardiovascular disease. These triglyceride-rich lipoprotein particles are present in patients with metabolic syndrome and type 2 diabetes mellitus. The MARS study showed that IDL is associated with increased carotid artery intima-media thickness (CIMT).[9]

TABLE 13.2 Adult Treatment Panel III Guidelines for the Evaluation of Fasting Lipid Profile

	Conventional Units (mg/dL)	SI Units (mmol/L)
Low-Density Lipoprotein Cholesterol		
Optimal	<100	<2.59
Near optimal	100-129	2.59-3.34
Borderline high	130-159	3.37-4.12
High	160-189	4.14-4.90
Very high	>190	>4.92
High-Density Lipoprotein Cholesterol		
Low	<40	<1.04
High	>60	>1.55
Triglycerides		
Normal	<150	<1.70
Borderline	150-199	1.70-2.25
High	200-499	2.26-5.64
Very high	>500	>5.65

SI, Standard international.

Low-Density Lipoprotein

In addition to LPL, hepatic lipase participates in the conversion of IDL to LDL, the most atherogenic of all lipoprotein particles. Although a number of other apolipoproteins are attached to the original VLDL particle, only one, apo B-100, is present in each LDL particle (see Fig. 13.1). LDL binds to specific LDL receptors on the surface of each cell, facilitating transfer of the remaining cholesterol to these cells, where it can be stored and used as cell membranes, steroid hormones, and bile acids. The number of exposed LDL receptors is regulated by the intracellular concentration of cholesterol within each cell. When excess plasma LDL is present, atherosclerosis can possibly increase in proportion to the concentration of circulating LDL.

Nabel and Braunwald received the Nobel Prize in 1985 for discovering the LDL receptor.[10,11] They were able to demonstrate that the circulating LDL concentration in plasma is determined by the number of LDL receptors on the various cells of the body, with the liver accounting for more than 70% of this total receptor number.[12] When the intracellular cholesterol content of the cells is low, LDL receptor synthesis is upregulated, receptor numbers increase, and the LDL plasma concentration decreases. In contrast, when intracellular cholesterol is increased, LDL receptor synthesis is downregulated, receptor numbers diminish, and circulating LDL rises. Humans are born with a maximum number of LDL receptors and a very low circulating LDL level

of 25 to 30 mg/dL (0.65 to 0.78 mmol/L).[13] Over a lifetime, the Western lifestyle of excessive calories, cholesterol, and saturated fat intake, along with inactivity, results in increasing intracellular cholesterol levels, causing secondary downregulation of LDL receptors. Therefore observed increases in excess plasma LDL-C levels coincide with the epidemic of atherosclerosis seen worldwide.

High-Density Lipoproteins

High-density lipoprotein (HDL) is synthesized by the liver and intestine as apo A-I, which is released into the bloodstream as a lipid-poor discoid particle. Stored cholesterol released from peripheral cells through the action of a specific transporter known as adenosine triphosphate–binding cassette (ABC) transporter A1 is absorbed by the discoid apo A-I and converted to cholesterol ester under the influence of lecithin-cholesterol acyltransferase (LCAT).[14] During this process, HDL becomes a spherical particle. Additional cellular cholesterol is then added by another cassette transporter, ABCG1, and through the action of the scavenger receptor B1 (SR-B1). The HDL particle can then return to the liver, where it binds to hepatic SR-B1 and releases its cholesterol, or it can exchange a portion of its cholesterol content for triglyceride from VLDL through the chemical action of the cholesterol ester transfer protein (CETP). This removes triglyceride from VLDL, converting it into LDL, which is then removed from circulation through the hepatic LDL receptor. This process is known as "reverse cholesterol transport" and plays an important role in the antiatherogenic properties of the HDL particle.[15,16]

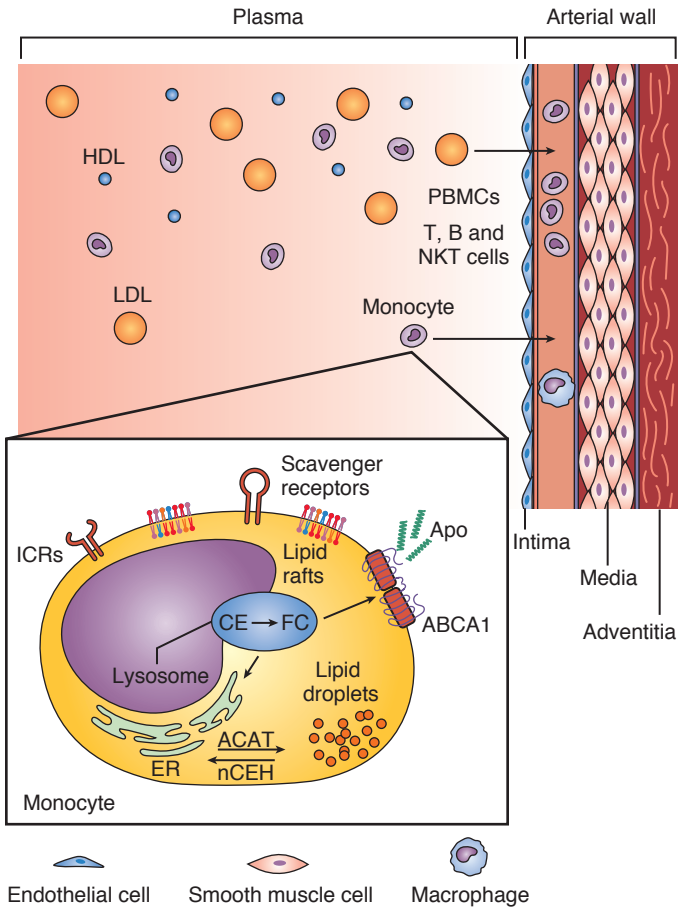

Figure 13.2 Low-density lipoprotein and monocytes invade the endothelial layer. *Apo,* Apolipoproteins; *ER,* extended-release; *HDL,* high-density lipoprotein; *LDL,* low-density lipoproteins. (Sorci-Thomas MG, Thomas MJ. Microdomains, inflammation, and atherosclerosis. *Circ Res.* 2016;118(4):679-691.)

PATHOPHYSIOLOGY OF ATHEROSCLEROSIS

Atherosclerosis is a pathologic process that begins in the arterial endothelial layer. Normal endothelium is smooth and repels circulating blood elements. On the other hand, damaged endothelium attracts various cellular elements. After the initiation of an atherogenic diet, patches of endothelial cells express selective adhesion molecules that bind to various classes of leucocytes.[5] Vascular cell adhesion molecule-1 (VCAM-1) binds to monocytes and T-lymphocytes detected in human atheromas.[3] In the setting of elevated LDL and low HDL, peripheral blood mononuclear cells become cholesterol enriched (Fig. 13.2). Intracellular droplets of cholesterol ester accumulate in these engorged cells, and give them a characteristic appearance, "foam cells."[17] Foam cells are more apt to adhere to damaged endothelium and then migrate into the intima layer and become macrophages. In response to this, VSMC proliferate and cause thickening of the intima.[6] As the process is repeated, plaque thickness increases and a fibrous cap is formed (Fig. 13.3).[18] This pathologic process is the same in the peripheral and cerebrovascular circulation as it is in the coronary arteries. To varying degrees, the traditional risk factors are also similar, regardless of the location of atherosclerotic disease, including hyperlipidemia.[19]

Damaged endothelium also becomes permeable to LDL and other circulating atherogenic lipoproteins (VLDL remnants, IDL, and chylomicron remnants). Once inside the vessel wall, LDL is oxidized by free radicals, furthering the inflammatory immune response and initiating the pathologic process of atherosclerosis. Oxidized LDL is subsequently absorbed through specific scavenger receptors into fixed tissue macrophages, thereby transforming them into lipid-filled foam cells (Fig. 13.4). Groups of foam cells accumulate underneath the endothelium and become the initial lesion of atherosclerosis (the fatty streak).[4] As this process continues, the foam cells undergo apoptosis (programmed cell death) allowing the lipid contained in them to spill out to form the lipid core of an atherosclerotic plaque. The initial response of the arterial wall is to expand, a process known as positive remodeling. As the plaque increases in thickness, it begins to encroach on the arterial lumen, thereby reducing the blood flow to points distal.[20] The concept of stable and unstable plaque has been developed, with stable plaques possessing a thick fibrous cap and solid lipid core. Plaques accumulating a large lipid core trigger an intense local inflammatory reaction as this lipid is oxidized resulting in the infiltration of additional macrophages and inflammatory cells. The vulnerable or unstable plaque usually remains small and does not critically

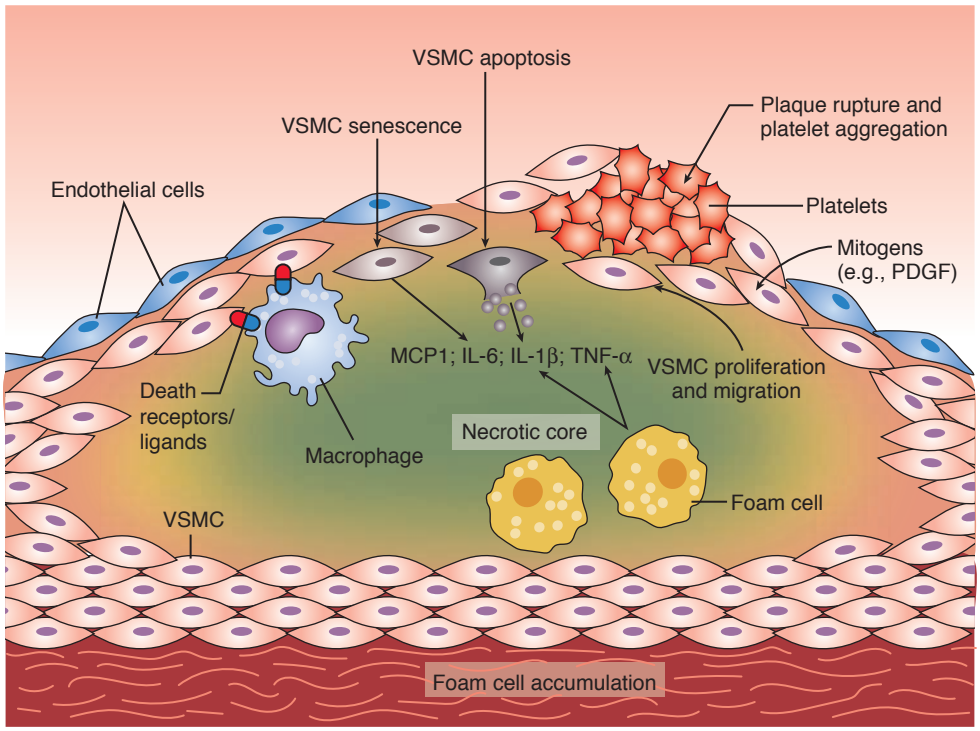

Figure 13.3 Interaction of cellular elements to form the lipid core and fibrous cap. (Bennett MR, Sinha S, Owens GK. Vascular smooth muscle cells in atherosclerosis. *Circ Res.* 2016;118(4):692-702.)

compromise the luminal diameter (Fig. 13.5). However, the thin fibrous cap is prone to ulceration or rupture. When this occurs, a platelet-rich clot rapidly forms on top of the plaque and produces complete obstruction of the involved artery and subsequent acute clinical infarction or ischemia.

DIAGNOSIS OF ATHEROGENIC LIPID DISORDERS

The Adult Treatment Panel III (ATP III) of the National Cholesterol Education Program (NCEP) recommended that all adults older than 20 years be screened for hyperlipidemia every 5 years with a fasting lipoprotein profile.[21,22] Blood levels should include total cholesterol (TC), triglycerides, HDL cholesterol (HDL-C), and LDL-C. It is recommended that patients be in their usual state of health and fast for 12 hours before testing. Blood should be drawn after sitting comfortably for 5 minutes and with less than 1 minute of tourniquet time. If TC is greater than 200 mg/dL (5.18 mmol/L) or HDL is less than 40 mg/dL (1.04 mmol/L), a fasting lipoprotein profile should be obtained to better quantify the patient's atherosclerotic risk.

Fasting Lipid Profile

ATP III recommended new guidelines for the evaluation of a fasting lipid profile (see Table 13.2). TC is not a good risk predictor because it can be increased by elevated HDL, which is usually a lower risk lipid profile, or decreased by low HDL, which is a higher risk lipid profile. The presence of very high triglyceride levels can also elevate TC and suggest a higher risk lipid profile than actually may be present.

LDL-C has been shown to be the most predictive lipoprotein fraction for determining atherosclerosis risk in both epidemiologic and interventional studies, and the associated risk is directly proportional to the LDL-C concentration over a wide range of values.[23,24] HDL-C is equally predictive in epidemiologic studies, with an inverse relationship between the HDL-C concentration and risk for atherosclerosis. The risk associated with each of these lipoprotein fractions is additive in individuals with increased LDL-C and decreased HDL-C.[25] The role of elevated triglycerides in risk assessment is tougher to discern. When very sophisticated analyses of triglyceride-rich lipoproteins are performed, it is evident that large chylomicrons and VLDLs are not atherogenic, but the smaller remnant forms of both these lipoproteins and the presence of IDL definitely confer increased atherogenicity.[26]

Clinically, elevated triglycerides in the presence of type 2 diabetes, metabolic syndrome, or familial combined dyslipidemia should indicate an increase in the risk for ASCVD. Very high levels of triglycerides (>1000 mg/dL [11.3 mmol/L]) are also associated with an increased risk for pancreatitis. Atherogenic dyslipidemia is a characteristic lipoprotein pattern frequently observed in patients with type 2 diabetes mellitus and the metabolic syndrome. In this condition, the LDL-C is often unimpressive or frankly low, but it is associated with elevated triglycerides with a decreased HDL-C concentration. More important, however, is the change in the number and composition of LDL particles associated with the metabolic syndrome

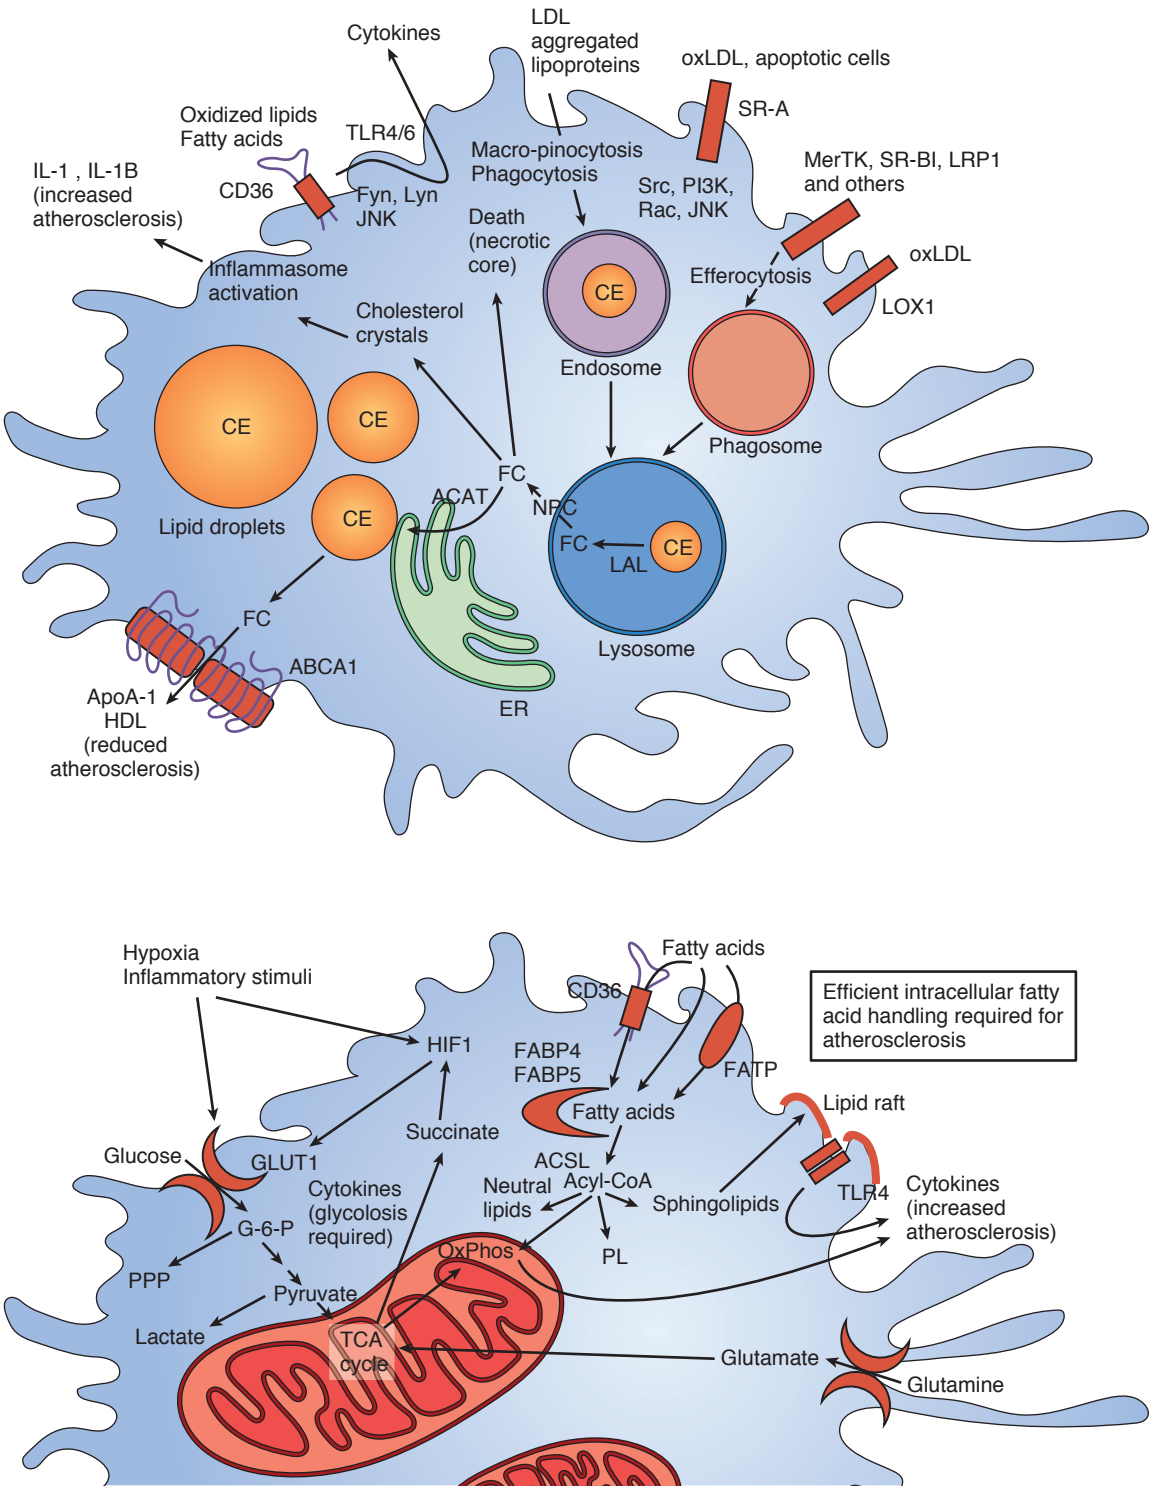

Figure 13.4 Complex interaction of lipids and macrophages in atherosclerosis. *ApoA-1,* Apolipoproteins A-1; *ER,* extended-release; *HDL,* high-density lipoprotein; *LDL,* low-density lipoproteins. (Tabas I, Bornfeldt KE. Macrophage phenotype and function in different stages of atherosclerosis. *Circ Res.* 2016;118(4):653-667.)

and type 2 diabetes, rendering them more atherogenic. This LDL is described as "small, dense LDL," which is an increased number of particles that contain less cholesterol per particle. Studies have shown that it is the number of LDL particles (LDL-P) that truly reflects the risk related to this profile.[27] LDL-P can be determined by lipid analysis using nuclear magnetic resonance (NMR) studies. Because each LDL-P contains one apo B-100 molecule, another method of more accurately assessing the risk conferred by an individual's LDL profile is to measure the apo B-100 level. Complete analysis

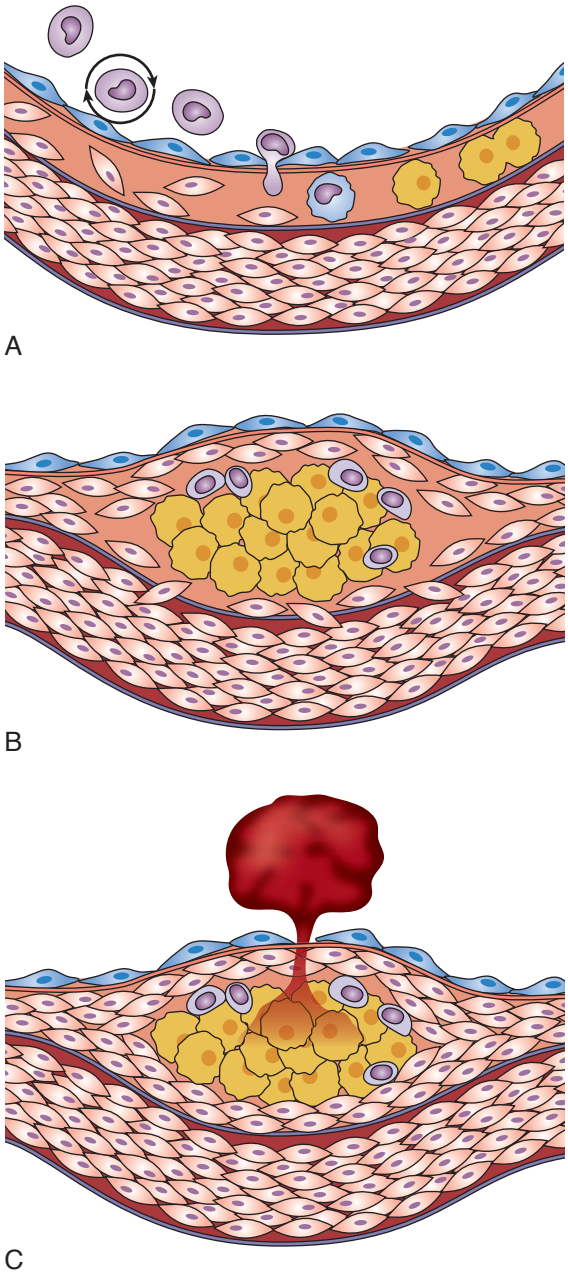

Figure 13.5 Initiation of plaque: the stable versus vulnerable plaque. A, Recruitment of leucocytes in a developing plaque; B, t-lymphocytes and macrophages in the intima and plaque formation; C, plaque rupture and thrombus formation, may lead to vessel occlusion. (Libby P, Ridker PM, Maseri A. Inflammation and atherosclerosis. *Circulation*. 2002;105(9):1135-1143.)

may provide a better risk assessment because the individual risks associated with each lipoprotein abnormality in type 2 diabetes mellitus and metabolic syndrome are additive.

Non–High-Density Lipoprotein Cholesterol in Risk Assessment

Non-HDL-C has been recognized in epidemiologic studies as one of the better predictors of atherosclerotic risk.[28] Non-HDL-C is easily calculated by subtracting HDL-C from TC. ATP III recommended the use of non-HDL-C (Box 13.2) as a way to more accurately assess risk in patients with increased triglycerides and made this a secondary target of therapy after the primary therapeutic goal for LDL-C is attained (vide infra). Non-HDL-C essentially represents the cholesterol content in all of the apo B–containing atherogenic lipoproteins: non-HDL-C = LDL-C + IDL cholesterol + VLDL-C + lipoprotein (a) (Lp[a]). However, these more specialized studies of cholesterol fractions are significantly more expensive than a routine lipid profile. Therefore it is recommended that the initial risk evaluation and lipid management be performed with the standard LDL-C, HDL-C, and non-HDL-C measurements and that specialized testing be reserved for unusual situations or for fine tuning of therapy.

BOX 13.2 Importance of Non–High-Density Lipoprotein Cholesterol

- Known predictor of CHD in epidemiology
- Equivalent to total apo B-100 and TC/HDL
- Represents the sum of LDL, Lp(a), IDL, and VLDL: all atherogenic apo B–containing lipoproteins
- Lipid equivalent of hemoglobin A_{1c}

Non-HDL cholesterol = TC – HDL cholesterol.
CHD, Coronary heart disease; *HDL,* high-density lipoprotein; *IDL,* intermediate-density lipoprotein; *Lp(a),* lipoprotein (a); *TC,* total cholesterol; *VLDL,* very low-density lipoprotein.

Lipoprotein (a)

Epidemiologic studies have established that Lp(a) is associated with increased atherosclerotic risk and risk of cardiovascular events, particularly ischemic stroke.[29,30] However, little is known about the metabolism of this hybrid lipoprotein particle. There is a lack of interventional data to establish Lp(a) as a legitimate modifiable atherosclerotic risk factor, and there are few effective therapies for lowering levels of this lipoprotein. The European Atherosclerosis Society recommends checking Lp(a) levels in patients at moderate or high risk of cardiovascular disease, including patients with a personal or family history of premature atherosclerosis, familial hypercholesterolemia, family history of elevated Lp(a), recurrent atherosclerotic events despite statin therapy and meeting accepted goals for therapy, and patients with increased 10-year risk for major cardiovascular events according to European or U.S. guidelines.[30]

EVOLUTION OF THE GUIDELINES FOR MANAGEMENT AND THERAPEUTIC GOALS FOR LIPOPROTEIN DISORDERS

Adult Treatment Panel I

The NCEP was launched in 1988. It has served as the driving force for lipid management guidelines since the publication of the ATP I report and recommendations for standardization of clinical measurement of lipids.[31] ATP I sought to educate the

BOX 13.3 Risk Factors for Coronary Heart Disease in Addition to Low-Density Lipoprotein Cholesterol

- Cigarette smoking
- Hypertension (>140/90 mm Hg)
- Low HDL cholesterol (<40 mg/dL) (1.04 mmol/L)
- Family history:
  - CHD in male first-degree relative younger than 55 years
  - CHD in female first-degree relative younger than 65 years
- Age (men older than 45 years, women older than 55 years)

CHD, Coronary heart disease; *HDL*, high-density lipoprotein.

U.S. population regarding coronary heart disease (CHD) risk and to encourage cholesterol reduction. The focus of ATP I was education and lifestyle intervention. Interventional therapy was reserved for individuals at increased risk, including those with an LDL greater than 190 mg/dL (4.92 mmol/L) or those with an LDL-C greater than 160 mg/dL (4.14 mmol/L) and two or more additional CHD risk factors (Box 13.3).

Adult Treatment Panel II

The NCEP published the ATP II report in 1993 after the introduction of HMG-CoA reductase inhibitors (statins).[22] The NCEP guidelines adopted the ATP I recommendations and added secondary prevention of CHD in patients with known CAD. Several small trials verified the benefit of modifying diet and using statins. Lowering LDL-C was the main goal; however, significant increases in HDL-C were observed, and this lipid change was thought to contribute to the positive outcomes of these surrogate endpoint trials. On the basis of these secondary prevention studies, ATP II recommended that patients with known CHD have the more aggressive therapeutic goal for LDL-C of 100 mg/dL or less.[32]

Another observation made in these trials was that coronary events were frequent in patients with coronary stenosis less than 70%. This introduced the concept of a "vulnerable plaque."[33] This is a small plaque with a large lipid core and a thin fibrous cap, with less than critical stenosis but a potential for inducing intraluminal thrombosis. It was suggested that statin therapy "stabilized" this plaque by helping prevent rupture or ulceration of the fibrous cap.

On the basis of these secondary prevention studies, ATP II recommended that patients with known CHD have the more aggressive therapeutic goal for LDL-C of 100 mg/dL or less.

Adult Treatment Panel III

Initially published as an executive summary and later as a full report in 2002, ATP III was the first evidence-based report from the NCEP that focused on large clinical trial data.[21] Four large trials examined primary and secondary prevention strategies.[34-37] As a result, ATP III recommended a more aggressive approach to risk assessment and management of lipid levels. Table 13.2 shows the new classification recommended by ATP III for LDL-C, HDL-C, and triglyceride levels in the initial risk assessment of individuals based on lipid levels. ATP III also recommended more aggressive goals of therapy for lipid management in patients with both established CHD and CHD risk equivalents. In addition to continuing the evaluation of additional risk factors (see Box 13.3) recommended by ATP I and II, ATP III added an emphasis on 10-year risk assessment for CHD by using the Framingham risk assessment algorithm.[38]

BOX 13.4 Coronary Heart Disease Risk Equivalents

- Other clinical forms of atherosclerotic disease (peripheral arterial disease, abdominal aortic aneurysm, and symptomatic carotid artery disease)
- Diabetes
- Multiple risk factors that confer a 10-year risk for coronary heart disease greater than 20%

Coronary Heart Disease Risk Equivalents

Another feature of ATP III was the designation of three conditions as "CHD risk equivalents," in that each carried a 10-year risk for a major coronary event that was equal to that of patients with established CHD (>20% per 10 years). Diabetes mellitus, other atherosclerotic diseases including PAD, carotid artery disease, and abdominal aortic aneurysm, and the presence of multiple cardiovascular risk factors that conferred a 10-year risk of greater than 20%, as judged by the Framingham risk assessment tool, received the designation of "CHD risk equivalent" (Box 13.4). Although discussed in the ATP II report, ATP III was the first formal recognition of the importance of PAD as a significant indicator of CHD.

Risk Stratification

ATP III suggested patients be categorized into one of three risk strata and that aggressiveness matched therapeutics to the assessed risk level. These three categories are as follows: (1) high risk—established CHD and CHD risk equivalents; (2) intermediate risk—multiple (2+) risk factors; and (3) low risk—0 to 1 risk factor. In addition to the goals recommended for LDL-C, in individuals with triglyceride levels greater than 200 mg/dL, a secondary goal was recommended for management of non-HDL-C (discussed previously). Table 13.3 shows the LDL and non-HDL-C goals for the treatment of individuals in each of these three risk categories. Although ATP III introduced the issue of basing lipid management on an individual's 10-year risk assessment, management of individuals with very high LDL levels or severe individual risk factors that conferred a high lifetime risk was continued as recommended by ATP I and II.

The 2013 ACC/AHA Guidelines

After ATP III was published, trials of very aggressive lipid lowering in very high-risk individuals were conducted, and the LDL-C levels reached were considerably lower than those recommended by ATP III.[39,40] The positive clinical outcomes of these aggressive lipid-lowering trials resulted in an addendum to

TABLE 13.3 Comparison of Low-Density Lipoproteins Cholesterol and Non–High-Density Lipoprotein Cholesterol Therapeutic Goals by Categories of Risk

	LDL CHOLESTEROL GOAL		NON-HDL CHOLESTEROL GOAL	
Risk Category	(mg/dL)	(mmol/L)	(mg/dL)	(mmol/L)
CHD and CHD risk equivalent (10-year risk for CHD >20%)	<100	<2.59	<130	<3.37
Multiple (2+) risk factors and 10-year risk <20%	<130	<3.37	<160	<4.14
0-1 Risk factor	<160	<4.14	<190	<4.92

Modified from National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on detection, evaluation, and treatment of high blood cholesterol in adults (Adult Treatment Panel III) final report. *Circulation.* 2002;106:3143-3421.

the ATP III report published in 2004 that recommended lower therapeutic goals for LDL-C and non-HDL-C in patients with very high-risk CHD (Table 13.4).[41] In 2005, the ACC/AHA published guidelines specifically directed to the management of patients with PAD. Patients with established PAD should be treated with statins to achieve a target LDL of less than 100 mg/dL (class I recommendation). Treatment goals of less than 70 mg/dL are reasonable in patients with lower extremity PAD who are at high risk for events (class IIa recommendation).[19]

The most recent guidelines and recommendations from the ACC/AHA were published in 2013.[42] These guidelines reaffirmed the more aggressive therapeutic goals for LDL-C and non-HDL-C and recommended targeting 4 statin benefit groups: individuals with clinical ASCVD, those with LDL >190 mg/dL, diabetics and non-diabetics between 40 and 75 years, and LDL in the 70 to 189 mg/dL and ASCVD risk >7.5%.

CLINICAL TRIALS OF THE MANAGEMENT OF DYSLIPIDEMIA IN PERIPHERAL ARTERIAL DISEASE

Most clinical trials were designed to test the efficacy of statins and the benefit of driving down LDL levels in reducing cardiovascular mortality. The secondary benefit of improving PAD was realized post hoc. Patients with PAD generally receive less intensive risk factor modification than do patients with coronary disease, although they share similar vascular risk profiles.[43] As few as a third of patients with PAD receive statin therapy. The Heart Protection Study (HPS) data are provocative (see the next section); they indicate that aggressive lipid management produces a definite reduction of approximately one sixth in the risk for peripheral vascular events not only in patients with preexisting PAD but also in high-risk individuals without previously diagnosed PAD. This finding highlights the need for further clinical trials that have prevention of peripheral vascular disease as their primary endpoint. These additional trials should also include patients with early forms of PAD.

Early Trials Linking Lipid Therapy to Atherosclerosis

The Program on the Surgical Control of the Hyperlipidemias (POSCH) and the Cholesterol Lowering Atherosclerosis Study (CLAS) established the basis for future studies examining dyslipidemia.[44,45] Both studies used angiographic evidence to support the conclusion that lipid therapy is effective in controlling the progression of atherosclerosis.

POSCH used ileal bypass surgery to lower lipid levels and demonstrated a reduction in the progression of atherosclerosis. At the formal closure of the POSCH trial, no significant difference was noted between the control and active therapy groups in the progression of PAD. However, all participants were observed for an additional 5 years after the trial ended. At the 5-year follow-up evaluation, an ankle-brachial index (ABI) of less than 0.95 was present in 41 of 120 control patients and in 24 of 126 ileal bypass patients, thus conferring a 44% risk reduction for development of an abnormal ABI. Furthermore, the risk of development of clinical manifestations of PAD was reduced by 30%.[46]

TABLE 13.5 ATP III Low-Density Lipoproteins Cholesterol Goals and Cutpoints for Therapeutic Lifestyle Change and Drug Therapy in Different Risk Categories and Proposed Modifications Based on Recent Clinical Trial Evidence

Risk Category	LDL Cholesterol Goal	Initiate TLC	Consider Drug Therapy[a]
High risk: CHD[b] or CHD risk equivalents[c] (10-year risk >20%)	<100 mg/dL (2.59 mmol/L) (optional goal: <70 mg/dL [1.81 mmol/L])[d]	≥100 mg/dL (2.59 mmol/L)[e]	≥100 mg/dL (2.59 mmol/L)[f] (if <100 mg/dL, consider drug options)[a]
Moderately high risk: 2+ risk factors[g] (10-year risk of 10%-20%)[h]	<130 mg/dL (3.37 mmol/L)[i]	≥130 mg/dL (3.37 mmol/L)[j]	≥130 mg/dL (3.37 mmol/L) (if 100-129 mg/dL [2.59-3.34 mmol/L], consider drug options)[j]
Moderate risk: 2+ risk factors[g] (10-year risk <10%)[h]	<130 mg/dL (3.37 mmol/L)	≥130 mg/dL (3.37 mmol/L)	≥160 mg/dL (4.14 mmol/L)
Lower risk: 0-1 risk factor[k]	<160 mg/dL (4.14 mmol/L)	≥160 mg/dL (4.14 mmol/L)	≥190 mg/dL (4.92 mmol/L) (if 160-190 mg/dL [4.14-4.92 mmol/L], LDL-lowering drug optional)

[a]When LDL-lowering drug therapy is used, it is advised that the intensity of therapy be sufficient to achieve at least a 30%-40% reduction in LDL cholesterol levels.
[b]CHD included a history of myocardial infarction, unstable angina, stable angina, coronary artery procedures (angioplasty or bypass surgery), or evidence of clinically significant myocardial ischemia.
[c]CHD risk equivalents include clinical manifestations of noncoronary forms of atherosclerotic disease (peripheral arterial disease, abdominal aortic aneurysm, and carotid artery disease [transient ischemic attacks, stroke of carotid origin, or >50% obstruction of a carotid artery]), diabetes, and 2+ risk factors with a 10-year risk for hard CHD >20%.
[d]Very high risk favors the optional LD cholesterol goal of <70 mg/dL (1.81 mmol/L) and, in patients with high triglyceride levels, non-HDL cholesterol <100 mg/dL (2.59 mmol/L).
[e]Any person at high risk or moderately high risk who has lifestyle-related risk factors (e.g., obesity, physical inactivity, elevated triglycerides, low HDL cholesterol, or metabolic syndrome) is a candidate for TLCs to modify these risk factors regardless of LDL cholesterol level.
[f]If baseline LDL cholesterol is <100 mg/dL (2.59 mmol/L), institution of an LDL-lowering drug is a therapeutic option on the basis of available clinical trial results. If a high-risk person has high triglyceride levels or low HDL cholesterol, combining a fibrate or nicotinic acid with an LDL-lowering drug can be considered.
[g]Risk factors include cigarette smoking, hypertension (blood pressure ≥140/90 mm Hg or taking antihypertensive medication), low HDL cholesterol (<40 mg/dL [1.04 mmol/L]), family history of premature CHD (CHD in male first-degree relative <55 years of age, CHD in female first-degree relative <65 years of age), and age (men ≥45 years; women ≥65 years).
[h]Electronic 10-year risk calculators are available at www.nhlbi.nih.gov/guidelines/cholesterol.
[i]Optional LDL cholesterol goal, <100 mg/dL (2.59 mmol/L).
[j]For moderately high-risk persons, when the LDL cholesterol level is 100-129 mg/dL (2.59-3.34 mmol/L) at baseline with lifestyle therapy, initiation of an LDL-lowering drug to achieve an LDL cholesterol level of <100 mg/dL (2.59 mmol/L) is a therapeutic option on the basis of available clinical trial results.
[k]Almost all people with zero or one risk factor have a 10-year risk of <10%, and 10-year risk assessment in people with zero or one risk factor is thus not necessary.
ATP III, Adult treatment panel III; *CHD,* coronary heart disease; *HDL,* high-density lipoprotein; *LDL,* low-density lipoprotein; *TLC,* therapeutic lifestyle change.
From Grundy SM, Cleeman JI, Merz CN, et al. Implications of recent clinical trials for the National Cholesterol Education Program Adult Treatment Panel III Guidelines. *Circulation.* 2004;110:227-239.

Anatomic assessment of the effect of lipid-lowering therapy was also evaluated in the CLAS trial.[47] One hundred sixty-two nonsmoking men between the ages of 40 and 59 years who had previously undergone coronary artery bypass graft surgery were randomized to a combination of colestipol, niacin, and diet, or to placebo and diet. Coronary angiography after 2 years demonstrated a significant reduction in the progression of atherosclerosis in the group that received therapy with colestipol plus niacin.

NONPHARMACOLOGIC THERAPY FOR DYSLIPIDEMIA

ATP III issued evidence-based guidelines on cholesterol management.[41] Therapeutic lifestyle change (TLC) was recommended as an essential modality in the clinical management of hypercholesterolemia. The ATP III report recommends initiation of TLC based on the LDL goal stratified by risk category (Table 13.5). Any person at high risk or moderately high risk who has lifestyle-related risk factors is a candidate for TLC to modify these risk factors, regardless of LDL-C level.

Dietary Changes

Individuals at low risk should initiate TLC at an LDL-C level of greater than 160 mg/dL (4.14 mmol/L); those with two or more risk factors and a Framingham 10-year CHD risk assessment of less than 10% should initiate TLC at an LDL-C level of greater than 130 mg/dL (3.37 mmol/L); and individuals with two or more risk factors and a 10-year CHD risk assessment of 10% to 20% should initiate TLC at an LDL-C level of 130 mg/dL (3.37 mmol/L). Finally, any high-risk patient with CHD or a CHD risk equivalent and a 10-year CHD risk assessment of greater than 20% should initiate TLC at an LDL-C level of greater than 100 mg/dL (2.59 mmol/L).

TABLE 13.6 Essential Components of Therapeutic Lifestyle Changes

Component	Recommendation
LDL-Raising Nutrients	
Saturated fats[a]	<7% of total calories
Dietary cholesterol	<200 mg/day
Therapeutic Options for LDL Lowering	
Plant stanols/sterols	2 g/day
Increased viscous (soluble) fiber	10-25 g/day
Total calories (energy)	Adjust total caloric intake to maintain desirable body weight/prevent weight gain
Physical activity	Include enough moderate exercise to expend at least 200 kcal/day

[a]*Trans* fatty acids are another LDL-raising fat that should be kept at low intake.

LDL, Low-density lipoprotein.

From National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III) final report. *Circulation.* 2002;106:3143-3421.

Dietary modifications include high amounts of fruits and vegetables, legumes, and whole grains as part of a low-fat diet. These modifications have been shown to reduce LDL and TC.[48] ATP III recommends a reduction in saturated fats to less than 7% of total calories and cholesterol to less than 200 mg/day. The addition of other dietary products containing plant sterols or stanols, which are available on the shelves of most grocery stores, has been shown to reduce TC and LDL-C by 10% to 15%.[49] Soluble fiber supplements are also suggested as adjuncts to dietary therapy. ATP III outlines maximal dietary therapy, including balancing energy intake and expenditure to maintain desirable body weight and prevent weight gain, which together can reduce LDL-C by 25% to 30% (Table 13.6). The PREDIMED study in Spain enrolled 7447 with increased CVD risk and demonstrated that a Mediterranean diet supplemented with olive oil or nuts decreased the incidence of major cardiovascular events.[50] A meta-analysis of gastric bypass studies showed an improved lipid profile in a majority of patients.[51]

Exercise

At least moderate daily physical activity, to expend approximately 200 kcal/day is recommended. Physical activity has been reported to lower LDL and triglyceride levels, raise HDL-C, and improve insulin sensitivity. Inactivity impairs cardiovascular fitness and coronary blood flow. These effects can be readily reversed by regular activity. Physical activity in accord with a patient's overall health status should be encouraged. Additional benefits may be realized in the management of metabolic syndrome. Exercise specialists in addition to nutrition and diet professionals may be able to assist patients in achieving TLC (see Table 28.5). The ACC/AHA goals for exercise include 30 to 60 minutes of moderate physical activity 5 to 7 days a week in addition to increased activity in daily lifestyle activities.[52,53]

PHARMACOLOGIC THERAPY FOR DYSLIPIDEMIA

There are many classes of drugs available for treating dyslipidemia. Newer drugs and classes of drugs are under development and briefly mentioned.

Statins

The HMG-CoA reductase inhibitors (statins) are the most effective class of drugs for treating elevated LDL-C levels. This class of drugs has been shown to reduce LDL-C by 18% to 60%, raise HDL-C by 5% to 20%, and decrease triglycerides by 7% to 30%. Statins have been proven to reduce the risk of CHD, stroke, and PAD, as well as improve mortality. They have also proved to be safe, with very low occurrences of major adverse events. The reduction in LDL-C is dose-dependent and log-linear. The starting dose of each statin produces 75% to 80% of the maximal reduction in LDL-C, and with each subsequent doubling of the dose, an additional 6% reduction is LDL-C is typically achieved.

Statin therapy has been demonstrated to be safe and effective in lipid management. Transient elevation of transaminase level occurs infrequently and is usually self-limiting. Minor musculoskeletal side effects (myalgia without CPK elevation) have been reported in clinical practice but not detected in randomized trials. Rhabdomyolysis is rare (4 in 10,000) and if strongly suspected, warrants measurement of total creatine phosphokinase, and if significantly elevated (>10× the upper limit of normal), discontinuation of the medication (Table 13.7). Excess risk of myopathy with the 80-mg dose of simvastatin was identified in the Study of the Effectiveness of Additional Reductions in Cholesterol and Homocysteine (SEARCH) trial, especially in the first 12 months of use.[54] This led the Food and Drug Administration (FDA) to recommend safety label changes, with recommendations regarding the prescription of the 80-mg dose of simvastatin, as well as adjusting the list of drugs to which the use of simvastatin is contraindicated.

Statin therapy is associated with an increased risk of new onset diabetes, and appears to be dose-dependent, with higher incidence in patients receiving high doses. In randomized trials, there was no evidence of a causal relationship between statins and malignancy or cognitive dysfunction.[1,55]

Statin therapy has also proved to be effective in improving pain-free walking time in patients with intermittent claudication.[56,57] In a multicenter randomized controlled trial of 354 people with claudication attributable to PAD, patients were randomized to placebo or to 10- or 80-mg doses of atorvastatin. There was an improvement in pain-free walking in 63% of patients but significant change in ABI.[58]

TABLE 13.7 Summary of 3-Hydroxy-3-Methylglutaryl Coenzyme A Reductase Inhibitors

Available Drugs	Lovastatin, Pravastatin, Simvastatin, Fluvastin, Atorvastatin, Rosuvastatin
Lipid/lipoprotein	LDL cholesterol: decrease of 18%-60%
Effects	HDL cholesterol: increase of 5%-25%
	Triglycerides: decrease of 7%-30%
Major use	To lower LDL cholesterol
Contraindications	
Absolute	Active or chronic liver disease
Relative	Concomitant use of cyclosporine, macrolide antibiotics, various antifungal agents, and cytochrome P-450 inhibitors (fibrates and nicotinic acid) should be undertaken with appropriate caution
Efficacy	Reduce risk for CHD and stroke
Safety	Side effects minimal in clinical trials
Major side/adverse effects	Myopathy, increased liver transaminases
Usual Starting Dose	**Maximum FDA-Approved Dose**
Lovastatin: 20 mg	Lovastatin: 80 mg
Pravastatin: 20 mg	Pravastatin: 80 mg
Simvastatin: 20 mg	Simvastatin: 40 mg[a]
Fluvastatin: 20 mg	Fluvastatin: 80 mg
Atorvastatin: 10 mg	Atorvastatin: 80 mg
Rosuvastatin: 5 mg	Rosuvastatin: 40 mg
Pitavastatin: 2 mg	Pitavastatin: 4 mg
Available dosing	Lovastatin: 10-, 20-, 40-mg tablets Pravastatin: 10-, 20-, 40-mg tablets Simvastatin: 5-, 10-, 20-, 40-, 80-mg tablets Fluvastatin: 20-, 40-mg capsules; 80-mg XL tablets Atorvastatin: 10-, 20-, 40-, 80-mg tablets Rosavustatin: 5-, 10-, 20-, 40-mg tablets Pitavastatin: 1-, 2-, 4-mg tablets

[a]Patients already on the 80-mg dose for more than 12 months may continue at this dose. New patients started on simvastatin should not exceed 40 mg daily.

CHD, Coronary heart disease; *FDA,* Food and Drug Administration; *HDL,* high-density lipoprotein; *HMG-CoA,* 3-hydroxy-3-methylglutaryl coenzyme A; *LDL,* low-density lipoprotein.

The Scandinavian Simvastatin Survival Study (4S) was the first trial of lipid-lowering therapy in patients with established CHD to show a decrease in all-cause mortality and a reduction in CHD mortality and morbidity with statins compared with placebo. Patients exhibited a 30% reduction in CHD mortality and a 42% reduction in the incidence of nonfatal coronary events, with both outcomes being directly proportional to the reduction in LDL-C and TC levels. In addition, new or worsening intermittent claudication symptoms were reduced by 38% in patients who received statin therapy versus those given placebo in 4S.[59]

The HPS, a trial of simvastatin, 40 mg/day, versus antioxidant vitamins or placebo in 20,536 participants at high risk for a CHD event, demonstrated an overall 19.8% risk for a first major vascular event on statin treatment compared with a 25.2% risk in the placebo group (a 24% relative risk reduction).[39] The average LDL-C difference between the two groups was 39 mg/dL (1.01 mmol/L) during a mean follow-up of 5 years. The event reduction was due mainly to a 20% reduction in noncoronary revascularization, including a decrease in the number of carotid endarterectomies. The HPS was also the most comprehensive evaluation of the effects of cholesterol-lowering therapy on major vascular events in patients with PAD. More than 6000 patients with PAD were included in this study. Risk reduction benefits were similar between PAD patients and CHD patients, and were reported in a separate subset analysis.[60] The HPS included more than 5900 diabetics who experienced similar benefits in clinical outcomes as nondiabetics. HPS was a landmark trial in the treatment of patients with PAD, given the large number of participants with preexisting disease. The results of HPS support the treatment of all patients with PAD with a statin agent for lipid-lowering therapy.

The high-risk elderly population was examined in the Prospective Study of Pravastatin in the Elderly at Risk (PROSPER) study.[61] A total of 5800 patients, ages 70 to 82 years, with a history of preexisting vascular disease (coronary, cerebral, or peripheral), or at increased risk for such disease because of smoking, hypertension, or diabetes, were randomized to 40 mg/day of pravastatin or placebo. Treated patients had a 34% reduction in their LDL-C level and a reduction in the rate of major coronary events by 19% and CHD mortality by 24%. The authors concluded that the study results allowed statin therapy to be safely extended to older persons.

The Treating to New Targets (TNT) study examined the safety and efficacy of aggressive LDL lowering. More than 10,000 patients with established CHD and LDL less than 130 mg/dL were randomized to atorvastatin either 10 or 80 mg daily. After nearly 5 years of follow-up, LDL levels were substantially lower in the patients treated with 80 mg daily (77 mg/dL) compared with patients taking atorvastatin 10 mg daily (101 mg/dL; $P < .001$). In addition, major cardiovascular events were 22% lower in the patients taking atorvastatin 80 mg (8.7%) versus 10 mg (10.9%) ($P < .001$).[62]

The Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin (JUPITER) trial enrolled 17,802 apparently healthy people with LDL levels less than 130 mg/dL and hs-CRP levels equal to or more than 2.0 mg/L to rosuvastatin or placebo. The trial was terminated early after a median 1.9 years of follow-up. Rosuvastatin reduced LDL-C by 50%; hs-CRP was decreased by 37%. The primary endpoint of major cardiovascular events or cardiovascular death decreased from 1.36 per 100 person-years with placebo to 0.77 per 100 person-years with rosuvastatin ($P < .00001$).[63]

Niacin

Niacin (nicotinic acid) was the first pharmacologic agent demonstrated to reduce cholesterol in clinical trials. It favorably affects all lipids and lipoproteins, with 15% to 35% increases in HDL-C and 5% to 25% decreases in LDL-C. Niacin inhibits lipoprotein synthesis, improves the clearance of triglyceride-rich lipoproteins from the circulation, and is also the most effective agent for raising HDL-C levels.

Adverse events are more common with niacin than with other lipid-lowering agents, and regular evaluation of liver function, glucose, and uric acid is indicated. Aspirin 30 minutes before niacin administration helps prevent flushing.[64] In addition, extended-release (ER) and enteric-coated ER niacin in which the frequency and intensity of flushing is reduced are available. Niacin is available over the counter, although over-the-counter forms of delayed-release or long-acting niacin should not be used because of a significant increase in hepatotoxicity.

Niacin is typically poorly tolerated at higher doses and is often used in combination with statins or other pharmacologic agents. The initial dosage should be 500 mg ER niacin by mouth nightly for 4 weeks and then increased by 500 mg/day every 4 weeks based on effect and tolerance. The maximum dose is 2 g/day ER niacin. Data from the Comparative Effects on Lipid Levels of Niaspan and Statins versus Other Lipid Therapies (COMPELL) study of 292 patients at high risk of MI and with mixed dyslipidemia (mean baseline LDL-C, 197 mg/dL [5.10 mmol/L]; HDL-C, 49 mg/dL [1.27 mmol/L]; and triglycerides, 168 mg/dL [4.35 mmol/L]) support this combination.[65] In this study, patients were randomized to treatment with either ER niacin (1 to 2 g daily) plus moderate doses of a statin (rosuvastatin, 10 to 20 mg daily, or atorvastatin, 20 to 40 mg daily), high-dose statin therapy (rosuvastatin, 20 to 40 mg daily), or combination therapy with simvastatin and ezetimibe (20/10 mg increasing to 40/10 mg daily). Although all treatments lowered LDL-C and non-HDL-C levels by about 50% or more, the combination of niacin plus statins resulted in substantially greater decreases in triglyceride levels and up to 3.5-fold greater increases in HDL-C levels than with the other regimens. Despite demonstrable improvements in the lipid profile, the role of niacin in lipid management has been questioned. Several large trials failed to show significant improvement.[66]

Fibrate

The fibrates, gemfibrozil and fenofibrate, are peroxisome proliferator receptor-α agonists used for treating hypertriglyceridemia and to increase HDL-C.[67] The therapeutic effect of these drugs is a 25% to 50% decrease in triglyceride levels and a 5% to 15% increase in HDL-C. In addition, fenofibrate may also decrease LDL-C by 10% to 20%, whereas an increase in LDL-C is often seen when gemfibrozil is used to treat very high levels of triglycerides. Gemfibrozil is taken 30 minutes before morning and evening meals as a 600-mg tablet. Fenofibrate is started at 54 mg by mouth with food once daily, and the dosage can be increased to 160 mg daily. Several trials demonstrated reduction in the progression of atherosclerosis but had no impact on decreasing mortality.[68,69]

Bile Acid Sequestrants

Bile acid sequestrants include colestipol, cholestyramine, and a more recently developed form, colesevelam. Historically, cholestyramine and colestipol were among the first drugs available to treat high TC and LDL-C. These drugs may be used as monotherapy in concert with dietary modification to achieve enhanced LDL-C lowering, but are more often used in combination with statin therapy. As noted earlier, doubling the dose of a statin may achieve only a 6% further reduction in LDL-C, but adding a sequestrant to a statin can further lower LDL-C by 12% to 16%.[70] Sequestrants have extremely low rates of systemic toxicity. Dyspepsia and constipation are known side effects. Colesevelam (WelChol, Daiichi-Sankyo, Inc., Basking Ridge, New Jersey) has significantly reduced these side effects and increased the compliance in the use of these drugs. It also has the advantage of being formulated as a tablet. Colesevelam comes in 625-mg tablets and should be started at three tablets twice daily with meals followed by liquid. In addition to the previously listed GI side effects, bile acid sequestrants may significantly increase triglycerides and are known to bind certain other drugs in the GI tract.

Ezetimibe

Ezetimibe is the first in a new class of pharmacologic agents for reducing TC and LDL-C. It specifically interferes with the absorption of cholesterol from the GI tract and results in a 15% to 20% reduction in LDL-C as monotherapy.[71] Ezetimibe is often used with a statin to achieve a further reduction in LDL-C of 20% to 25%, with added beneficial effects on triglycerides and HDL-C. The efficacy of ezetimibe in reducing atherosclerosis has been questioned, but the National Lipid Association endorsed its use because of its proven efficacy.[72]

Omega-3 Fatty Acids

Polyunsaturated fatty acids of the omega-3 type are found in fish and other marine animals, as well as in soybeans and other vegetables. Varying strength of evidence exists to support consumption of omega-3 fatty acid. ATP III supports the AHA's recommendation that fish, particularly fish high in omega-3 fatty acids, be included as part of a CHD risk reduction diet.[73] Fish is also low in saturated fat and may be cardioprotective. A number of observational studies have suggested that regular consumption of fish reduces the risk for CHD.[74,75] An Italian trial showed that the omega-3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) at a dose of 1 g daily reduced the risk of sudden death.[76] Other trials showed mixed results.[77-79] It is important to note that higher doses of EPA and DHA, 3 g or more daily, have a significant hypotriglyceridemic effect without significant adverse events. However, more definitive trials are necessary before strongly recommending high doses of omega-3 fatty acids.

Cholesterol Ester Transfer Protein Inhibitors

In addition to lowering LDL-C, the ability to raise HDL-C is a tangible therapeutic target. Endogenously, the transfer of cholesterol ester from HDL-C to apo B–containing lipoproteins, VLDL, and LDL, in exchange for triglycerides is mediated by CETP. This is deemed a heterotypic transfer. Homotypic transfer or the transfer of cholesteryl ester between HDL subtypes is also mediated by CETP. Of the developed CETP inhibitors, torcetrapib and anacetrapib inhibit both homotypic and heterotypic transfer, whereas dalcetrapib inhibits only heterotypic transfer.[80]

Novel Therapeutic Agents

Proprotein convertase subtilisin/kexin type-9 (PCSK9) increases LDL by interfering with hepatic LDL receptor recycling (Fig. 13.6). Monoclonal antibodies directed against PCSK-9 have been developed and tested in trials. Alirocumab, evolocumab, and bococizumab, PCSK9 inhibitors, have been effective in lowering LDL in patients.[81] The FDA has recently approved alirocumab and evolocumab in patients with clinical ASCVD or heterozygous familial hypercholesterolemia.

Combination Drug Therapy

Combination therapy has been shown to be effective in obtaining LDL, HDL, and triglyceride targets in patients with dyslipidemia. A combination of a statin plus an agent that blocks the intestinal absorption of cholesterol is particularly effective in decreasing LDL-C levels. Both ezetimibe and the bile acid sequestrants can be safely added to the maximal dose of a statin or can be used with lower doses to reach LDL-C therapeutic goals. Some patients will not tolerate the maximal dose of any statin, and one or both of these intestinally acting agents will allow the attainment of LDL-C goals when added to a submaximal dose of a statin. In addition, ER niacin can be combined with a statin or one of the intestinally acting drugs, or can be used in combination with both classes of drugs to reach LDL-C targets in patients with very high LDL-C levels, such as those with heterozygous familial hypercholesterolemia. Statin therapy may also be combined with fenofibrate, niacin, or omega-3 fatty acids to achieve control in patients with combined hyperlipidemia; the combination yields superior results over monotherapy. In general, gemfibrozil should not be used with a statin because of its inhibition of statin metabolism, which increases the potential toxicity of all statins.[82] Fenofibrate is a better choice when statin and/or fibrate combination therapy is required.[83] The SANDS (Stop Atherosclerosis in Native Diabetics) trial used the endpoint of change in CIMT as a surrogate for the control of atherosclerosis. In the most aggressive group with lipid goals of less than 70 mg/dL (1.81 mmol/L) for LDL-C and less than 100 mg/dL (2.59 mmol/L) for non-HDL-C, CIMT regression was achieved. However, larger prospective studies with clinical endpoints that include cardiovascular morbidity and mortality and PAD-related outcomes are still needed to evaluate the outcome benefits of combination therapy.

(Shapiro MD, Fazio S. From lipids to inflammation: new approaches to reducing atherosclerotic risk. *Circ Res.* 2016;118(4):732-749.)

Homozygous Familial Hypercholesterolemia

In 1972, Goldstein and Brown treated two young siblings, aged 6 and 8, who were hospitalized at the NIH for acute coronary syndromes due to LDL levels eightfold above normal. They were diagnosed with homozygous familial hypercholesterolemia (HFH) and became the impetus for scientists to elucidate the LDL receptor mechanism.[2] Even with combination therapy, patients with HFH have a difficult time reducing LDL. LDL apheresis is available in some clinical centers and may be used when high-risk patients fail to meet target goals, despite dietary management and maximum tolerated lipid-lowering regimens. In addition, lomitapide, a microsomal triglyceride transfer protein inhibitor, and mipomersin, an antisense oligonucleotide inhibitor of apo B-100 synthesis, have been approved, but are presently available only through Risk Evaluation and Mitigation Strategy (REMS). Now PCSK9 inhibitors have been shown to effectively reduce LDL levels in HFH patients.[81]

The TNT trial demonstrated the benefit of aggressive LDL lowering in individuals with established coronary artery disease and modestly elevated LDL values (<130 mg/dL). Patients treated with high-dose atorvastatin, 80 mg daily, demonstrated a mean LDL of 77 mg/dL and a 22% reduction in relative risk for major cardiovascular events in comparison with patients treated with 10 mg atorvastatin and a mean LDL of 101 mg/dL.

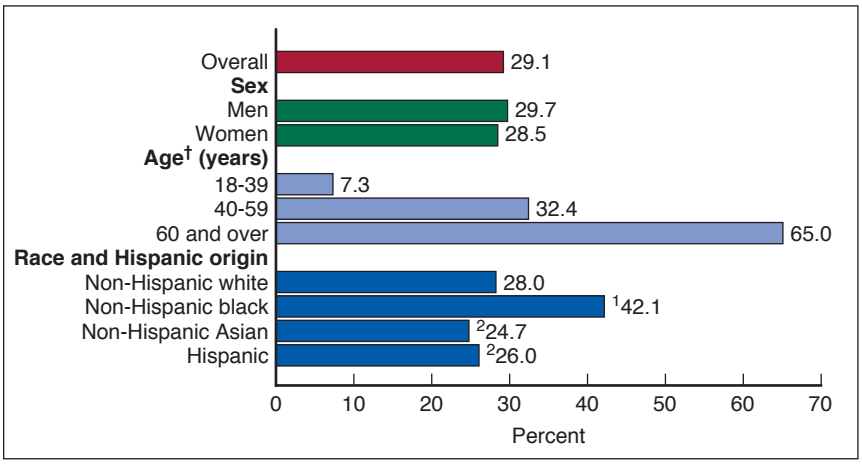
Hypertension is a key risk factor in the pathophysiology of atherosclerosis and the development of peripheral artery disease (PAD). Available evidence related to PAD and hypertension is largely extrapolated from subgroup analyses of larger trials of patients with atherosclerotic vascular disease and cardiovascular risk factors. Consequently, there are no current concrete within-class comparison studies of the effects of the treatment of hypertension on PAD-related disease outcomes. Patients with PAD have a high mortality from cardiovascular disease (CVD) and cerebrovascular disease, and thus treatment of hypertension is recommended in this population despite the lack of prospective, randomized clinical trial data showing that antihypertensive therapy alters the course of PAD.

EPIDEMIOLOGY

Scope of the Problem

The prevalence of hypertension is high in the United States, with nearly one-third of the US adult population affected.[1] The



† Significant linear trend. [1]Significantly different from non-Hispanic white.
[2]Significantly different from non-Hispanic black.

NOTE: Estimates were age-adjusted by the direct method to the Census 2000 population, using the age groups 18-39, 40-59, and 60 and over.

SOURCE: CDC/NCHS, National Health and Nutrition Examination Survey, 2011–2012.

Figure 14.1 Age-specific and age-adjusted prevalence of hypertension among adults aged 18 and over: United States, 2011–2012. (From Center for Disease Control and Prevention [CDC], http://www.cdc.gov/nchs/data/databriefs/db133.pdf; National Health and Nutrition Examination Survey [NHANES].)

National Health and Nutrition Examination Survey (NHANES, 2011–2012) estimates that the age-adjusted prevalence of hypertension among US adults aged 18 and over was 29.1% (Fig. 14.1).[2] In this study, hypertension was defined as either a systolic blood pressure (SBP) of 140 mm Hg or higher, a diastolic blood pressure (DBP) of 90 mm Hg or higher, or the current need for antihypertensive medications. The prevalence of hypertension is similar to recent NHANES data from 2009 to 2010, but overall, has increased compared to the previous data from 1988 to 1994.[3,4] Despite a higher awareness of the problem over the past decade, the prevalence of hypertension in the adult U.S. population has remained unchanged.

The prevalence of hypertension increases with increasing age, with approximately 7.3% of adults between the ages of 18 and 39 affected, as compared with 32.4% of adults between the ages of 40 to 59 affected, and 65.0% of adults aged 60 and older affected.[2] Similarly, PAD increases in prevalence with increasing age.[5] Hypertension is similarly prevalent between men and women (29.7% vs. 28.5%), and the prevalence is highest among non-Hispanic black adults (42.1%).[2] PAD also has a higher prevalence among non-Hispanic male and female black adults as compared with non-Hispanic white adults (men 33% vs. 11%, women 34% vs. 22%) based on data from the genetic epidemiology network of arteriopathy (GENOA) study.[6] A similar trend in ethnic differences in epidemiology of PAD was observed in data from the NHANES survey.[5]

Elevation of SBP, DBP, and pulse pressure (PP) are associated with increased cardiovascular risk.[7] The relative importance of each of these factors as a predictor of cardiovascular risk varies with age. Based on data from the Framingham Heart Study, in adults younger than 50 years of age, DBP is the strongest predictor of cardiovascular risk.[7] In adults between the ages of 50 and 59, all three factors (SBP, DBP, PP) are comparable predictors of risk, and SBP is the strongest predictor in adults 60 years of age and older.[7] Isolated systolic hypertension is more prevalent in an older population,[8] and this may be responsible for predictive value of SBP of cardiovascular risk in older adults. SBP rises more than DBP with aging, which results in a widened PP.[9]

Hypertension, along with smoking, diabetes, and dyslipidemia, is strongly associated with PAD.[10] The high prevalence of hypertension in the US adult population, particularly among older adults, makes hypertension a significant contributor to the overall burden of PAD in the US adult population. Quantifying the risk of PAD among patients with hypertension depends, in part, upon the manner in which PAD is defined. For example, data from the Framingham Heart Study, which defined PAD by intermittent claudication (IC), showed that the risk for PAD increases with increasing systolic and DBP in both men and women.[11] Long-term 38-year follow-up of data from the original Framingham Heart Study cohort demonstrated that hypertension was a risk factor for both symptomatic and noninvasively determined PAD in both men and women, and was associated with a greater than twofold increase in the risk of PAD.[12] Data from the NHANES study, which also used IC to define PAD, found that hypertension that was untreated, or hypertension that was treated but still uncontrolled were both associated with PAD.[5] Although these studies demonstrated the risk of both SBP and DBP on PAD, other studies that used ankle-brachial index (ABI) to define PAD have shown slightly different results and have implicated SBP more than DBP in hypertensive risk of PAD. This may be attributable to the fact that not all patients with PAD (as defined by an ABI of <0.9) exhibit classic symptoms of IC.[13]

Traditionally, an ABI of less than 0.9 has been considered diagnostic for PAD; however, several studies have used more conservative criteria using an ABI of less than 0.80 or less than 0.75. In addition, patients with an ABI of 0.91 to 0.99 are considered borderline. NHANES data has shown that hypertension was strongly associated with PAD (when defined as an ABI of <0.90) in patients 40 years of age and older.[14] In the Cardiovascular Heart Study, an inverse relationship was

demonstrated between hypertension and ABI (the higher the blood pressure, the lower the ABI, consistent with more significant PAD).[15] However, after the study investigators controlled for confounders, the inverse relationship persisted for SBP but not for DBP. In the Rotterdam Study of PAD (which defined PAD by ABI of <0.9), SBP, and not DBP, was strongly associated with PAD.[16] Overall, there appears to be a stronger association between PAD and SBP than PAD and DBP.

Unfortunately, hypertension tends to be undertreated in the general population. According to the NHANES 2011–2012 data, 82.7% of patients with hypertension were aware of their diagnosis and 75.6% were currently taking prescribed antihypertensives, but only 51.8% of patients had their blood pressure controlled.[2] In addition, there is some data to suggest that blood pressure control is worse in patients with PAD than in the general coronary heart disease population.[17] In the PAD Awareness, Risk and Treatment: New Resources for Survival (PARTNERS) study, hypertension was treated less frequently in PAD patients with both newly diagnosed hypertension as well as known PAD and hypertension, as compared with patients with hypertension and no PAD.[18]

A secondary cause of hypertension, renal artery stenosis (RAS), is prevalent in patients with PAD. In a prospective cohort of 629 consecutive patients with PAD undergoing digital subtraction angiography (DSA), renal artery disease was found in 33%, and 9.6% of patients had a significant RAS (> or = 60%).[19] In patients with PAD and hypertension, RAS is an important consideration in the diagnostic evaluation, as it has implications for subsequent blood pressure management.

In summary, hypertension is prevalent in the adult U.S. population, and is a major risk factor for atherosclerotic diseases—specifically PAD. The high prevalence of hypertension in the PAD population, the association of hypertension with risk of cardiovascular events, as well as the undertreatment of hypertension in this population, all make the identification and treatment of hypertension an important target for the management of patients with PAD.

DIAGNOSIS

Definition

Previous epidemiologic studies and therapeutic trials have used different criteria to define hypertension in populations. In December of 2013, the Joint National Committee (JNC) on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure released the eighth report and guidelines for the management of hypertension (JNC 8).[20] The JNC 8 guidelines did not address the definition of hypertension, but rather addressed the threshold for initiating pharmacologic treatment. In the previous guidelines (JNC 7), stage 1 hypertension was defined as a SBP of 140 to 159 mm Hg or a DBP of 90 to 99 mm Hg, and stage 2 hypertension was defined as a SBP of greater than or equal to 160 mm Hg or a DBP of greater than or equal to 100 mm Hg (Table 14.1).[21] JNC 8 guidelines recommend a blood pressure of less than 150/90 mm Hg in patients aged 60 years or older, and less than 140/90 mm Hg in patients aged 30 to 59 years of age.[20] The blood pressure should be based on the average of two or more properly measured, seated readings on each of two or more office visits.

TABLE 14.1 JNC 7: Definition of Hypertension

Stage	Systolic (mm Hg)	Diastolic (mm Hg)
Normal blood pressure	<120	<80
Prehypertension	120-139	>80-89
Stage 1 hypertension	140-159	>90-99
Stage 2 hypertension	>160	>100

Adapted from the National Heart Lung and Blood Institute: The Seventh Report of the Joint National Committee on Prevention, detection, Evaluation, and Treatment of High Blood Pressure (JNC-7). http://www.nhlbi.nih.gov/guidelines/hypertension/jnc7full.pdf.

Blood Pressure Measurement Technique

Routine blood pressure measurements should be made with an appropriate-sized cuff (cuff bladder encircling at least 80% of the arm) to ensure accuracy. At least two measurements should be made. The patient should be seated comfortably, with feet on the floor and back supported, for at least 5 minutes in a quiet room prior to taking measurements. The arm should be supported at the level of the heart. Ideally, patients should be free of caffeine and smoking for 30 minutes before measurements are taken.

Ambulatory blood pressure monitoring (ABPM) is another technique that can be used to verify the diagnosis of hypertension in certain situations. ABPM can be used to identify hypertension, masked hypertension, normotension, or white coat hypertension (WCH). In addition to suspected cases of WCH, the previous JNC 7 guidelines recommended ABPM for resistant hypertension (uncontrolled blood pressure despite adequate doses of three drugs including a diuretic), episodic hypertension, autonomic dysfunction, and those with symptoms of orthostasis on therapy.[21]

According to ABPM measurements, hypertension is defined as a 24-hour average of greater than 130/80 mm Hg or a daytime average of greater than 140/85 mm Hg.[22] WCH is defined as an elevated blood pressure in the physician's office of greater than or equal to 140/90 mm Hg and a 24-hour blood pressure of less than 130/80 mm Hg.[23] Although WCH has been traditionally thought to be a benign condition, there are now data indicating an increased, albeit small, risk of CVD.[23] No randomized trial data or guidelines exist addressing this group, so practitioners should use judgment in evaluating these patients from evidence of end-organ damage and counsel them regarding lifestyle modifications. Lastly, patients with masked hypertension have normal blood pressure in the office, but are hypertensive at home. This group of patients is more difficult to identify, and may be discovered by participation in research studies or through home blood pressure monitoring. These patients may also have an increased risk of CVD.[24]

Secondary Causes

Patients who have uncontrolled blood pressure despite adequate doses of three antihypertensive medications (including a diuretic) meet criteria for resistant hypertension. These patients should be evaluated for secondary causes of hypertension. First, patients with resistant hypertension should have a careful and detailed history taken, with specific attention paid to the use of exogenous substances that may lead to elevations in blood pressure (e.g., corticosteroids, weight loss supplements, herbal medication, NSAIDs). Next, the patient's current medication list should be reviewed to ensure that all antihypertensives are adequately dosed and include the use of a diuretic. The patient should also be assessed for adherence to the current medication regimen. If all of the above are unrevealing, then the patient should be evaluated for secondary causes of hypertension.[25]

The causes of secondary hypertension and association signs and symptoms are reviewed in Table 14.2. The physical examination of patients with suspected secondary hypertension should include auscultation for abdominal bruits, palpation of the thyroid gland, and assessment of pulses in the upper and lower extremities. The laboratory evaluation should include a complete blood count, serum blood urea nitrogen, glucose, calcium, creatinine, electrolytes, and a urinalysis.[26] A uric acid level may also be checked in patients that may undergo diuretic therapy, as this class of medications may cause hyperuricemia. Plasma renin activity may be checked in patients with hypokalemia with suspected primary hyperaldosteronism.

Renovascular hypertension is a cause of secondary hypertension and should be included in the evaluation of patients with difficult to control hypertension. It is most commonly due to the development of renal artery atherosclerosis and ultimately RAS. RAS leads to decreased blood flow to the kidney, and the renin-angiotensin-aldosterone system is thus activated. A proposed hypothesis of the model of renovascular hypertension is that humoral factors activated by the renin-angiotensin-aldosterone system in patients with RAS may accelerate and promote the atherosclerotic process in these patients, thus creating a vicious cycle.[27] In addition, studies of pigs with secondary hypertension due to RAS showed that increased oxidative stress resulted from this condition and was a stimulus for atherosclerosis independent of cholesterol levels.[28] Overall, clinical evidence is also supportive of this hypothesis, and this may explain the relatively high prevalence of RAS in patients with CVD and atherosclerosis in other arteries.

TABLE 14.2 Secondary Causes of Hypertension

Cause	Signs and Symptoms
Primary aldosteronism	Hypokalemia
Cushing syndrome	Striae, abdominal obesity
Pheochromocytoma	Labile blood pressure, tachycardia, sweats, headaches
Renal artery stenosis (atherosclerotic or due to fibromuscular dysplasia)	Smoking history, flash pulmonary edema, abdominal bruits
Thyroid disease	Goiter
Oral contraceptive pills	Women of child-bearing age
Obstructive sleep apnea	Snoring
Coarctation of the aorta	Children, disparate blood pressures in upper and lower extremities
Kidney disease	Elevated serum creatinine, proteinuria

PATHOLOGIC MECHANISMS OF HYPERTENSION AND ATHEROSCLEROSIS

The association of hypertension with the development of atherosclerosis has long been known, but the molecular mechanisms involved are not completely understood. This is likely due to the complex nature of the development of atherosclerosis. Many factors contribute to the development of atherosclerosis, including genetics, behavioral tendencies (e.g., smoking), and environmental factors.

Animal Models of Hypertension

Much insight into the interaction of hypertension and atherosclerosis has been gained from genetically engineered mouse models. Previous research has demonstrated that most mouse models of hypertension shown an increase in atherosclerotic lesion size.[29] It has also been demonstrated in mice that reducing blood pressure reduces atherosclerotic lesion size. Other studies have shown decreases in atherosclerosis without decreases in blood pressure.[29] These findings point to the complex interplay between blood pressure and development of atherosclerosis.

Renin-Angiotensin System and Atherosclerosis

A theme that has consistently been observed in the literature is that blood pressure alterations from the manipulation of the renin-angiotensin system has a direct impact on the size of atherosclerotic lesions.[29] The renin-angiotensin system is responsible for homeostatic control of arterial pressure, tissue perfusion, and extracellular volume. Renin is produced from the juxtaglomerular cells in the nephron. Angiotensinogen, which is primarily produced in the liver, is converted to angiotensin I by renin. Angiotensin I is converted to angiotensin II by angiotensin converting enzyme (ACE). Angiotensin II is a potent vasoconstrictor, specifically on the efferent arteriole, and mediator of aldosterone secretion.

Previous mouse models have shown that angiotensin II, via chronic infusion, promotes atherosclerosis independent of changes in arterial pressure.[30] In addition, other studies have shown that pharmacologic inhibition of the renin-angiotensin system decreases the development of atherosclerosis independent of blood pressure lowering.[29] Consequently, this axis is a

prime target for pharmacotherapy for both hypertension and atherosclerosis.

A correlation between hypercholesterolemia and hypertension has been observed in humans. Vascular angiotensin II receptor type 1 (AT1) expression is upregulated in patients with hypercholesterolemia, and this is associated with a more prominent blood pressure response to angiotensin II in these patients. In one study, angiotensin II was administered to patients with hypercholesterolemia and to patients with normocholesterolemia, and the blood pressure response was exaggerated in the hypercholesterolemia group.[31] Administration of statins mitigated this response.[31] Animal studies have shown that renin-angiotensin inhibition, along with statin therapy, reduces atherosclerosis as compared with renin-angiotensin inhibition alone.[32] In addition to improved reduction in atherosclerosis with both renin-angiotensin inhibition and statins, the combination may also result in better blood pressure control as compared with renin-angiotensin inhibition alone.[33] In addition, statins have a role in improving endothelial function and in vascular elasticity.[32]

Endothelial Dysfunction and Hypertension

Hypertension is associated with endothelial dysfunction in the coronary, renal, and peripheral circulation. Endothelial dysfunction occurs early in the atherosclerotic process. Maintenance of normal endothelial function and appropriate vasodilation is important to both blood pressure control as well as the development of atherosclerosis. Previous studies have shown that the presence of hypertension blunts the effects of an agonist-induced vasodilatory response.[34] Nitric oxide (NO) is important in maintaining normal endothelial function and is critical to the vasodilator response. Reductions in endothelial-derived NO result in a reduced vasodilatory response, and may also result in a proinflammatory, prothrombotic, and procoagulant phenotype (Fig. 14.2).

The enzyme responsible for generating NO is endothelial NO synthase. In a mouse knockout model, the deletion of this enzyme resulted in significantly increased SBP (128 ± 3 vs. 108 ± 5 mm Hg; $P < .001$), and decreased heart rate (531 ± 22 vs. 629 ± 18 bpm; $P < .001$), as compared with wild-type controls.[35]

Although endothelial dysfunction is related to hypertension and appears to be a consequence of it, the data regarding endothelial dysfunction as a precursor to hypertension is mixed. In one study, investigators evaluated forearm blood flow modifications by administering intrabrachial acetycholine (an endothelium-dependent vasodilator), and sodium nitroprusside (an endothelium-independent vasodilator) to offspring of patients with essential hypertension.[36] A blunted vasodilatory response was found in those who were offspring of hypertensive patients, suggesting that impairment in NO may precede the onset of essential hypertension.[36] However, another study of black young adults with and without a family history of hypertension did not show a significant difference in brachial artery reactivity, and there was no evidence of early endothelial dysfunction in the offspring of those with essential hypertension.[37] In this study, women did show more brachial artery vasodilation compared with men and irrespective of family history of hypertension. Overall, more research is needed to help identify subject who are predisposed to developing hypertension.

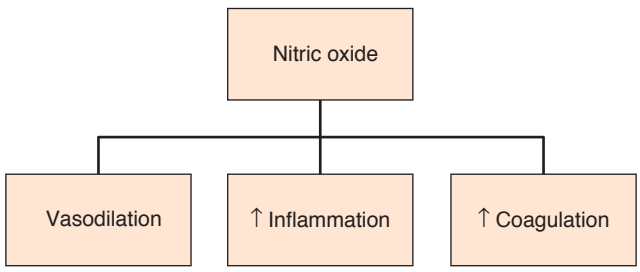


Figure 14.2 Pathologic mechanism of action associated with endothelial dysfunction. A reduction on nitric oxide may lead to reduced vasodilation, increased inflammation, and increased coagulation.

MANAGEMENT

General Principles

The goals of treating hypertension are to lower blood pressure and reduce CVD risk as well as to reduce progression of atherosclerosis. Effective treatment of hypertension includes lifestyle modifications as well as pharmacotherapy.

Lifestyle Modifications

Lifestyle modifications have been demonstrated to decrease blood pressure and to reduce CVD risk.[38] The relationship between weight loss and blood pressure reduction appears to be linear, and a reduction in every 1 kg of body weight is associated with an approximate reduction in blood pressure by 2/1 mm Hg.[39] Lifestyle modifications, including diet and exercise, can lead to improved overall health in addition to the benefits of blood pressure reduction. Most major medical societies recommend lifestyle modifications of weight loss, limiting sodium intake, engaging in aerobic physical activity for at least 30 minutes daily, and limiting alcohol intake to one to two servings daily. A diet that is commonly recommended and has been demonstrated to effectively lower blood pressure is the Dietary Approaches to Stop Hypertension (DASH) diet, which is low in fat and sodium and high in fruits and vegetables.[40]

Antihypertensive Therapy

CVD risk increases progressively with increasing blood pressure, beginning at 110/75 mm Hg.[41] Previous clinical trials have demonstrated that lowering blood pressure reduces the risk of CVD.[42,43] The benefits of treating hypertension with regards to lowering cardiovascular risk have also been demonstrated in patients with PAD. In the Heart Outcomes Prevention Evaluation (HOPE) study, the subset of patients with PAD (as defined by an ABI < 0.9), and treatment with an ACE inhibitor (specifically, ramipril), showed an overall reduction in cardiovascular events in patients with hypertension and PAD.[44] The Appropriate Blood Pressure Control in Diabetes study evaluated blood pressure control in patients with both diabetes and PAD. The

results demonstrated that a reduction in blood pressure to a mean of 128/75 mm Hg in this population was associated with a significant reduction in cardiovascular events.[45]

Although it is known that treatment of blood pressure reduces the risk of cardiovascular events in patients with hypertension and PAD, there is no clear data that antihypertensive treatment significantly modifies the disease process of PAD. The United Kingdom Prospective Diabetes Study Group (UKPDS) trial evaluated tight blood pressure control in patients with diabetes and hypertension, and there was an association in this study with reductions in cardiovascular endpoints, but not in the risk of incident PAD.[46] There is some evidence that treatment with ACE inhibitors may improve symptoms of PAD, including improved walking times.[47]

The 2005 American College of Cardiology and American Heart Association guidelines on the management of patients with PAD recommend treating blood pressure with antihypertensive therapy to a goal of less than 140/90 mm Hg.[48] The 2011 focused update to these guidelines did not address blood pressure control.[49] The Inter-Society Consensus for the Management of Peripheral Arterial Disease (TASC-II) also recommends treating to a goal blood pressure of less than 140/90 mm Hg.[50] As previously described, the JNC 8 guidelines for the management of hypertension recommend treating a blood pressure to less than 150/90 mm Hg in patients aged 60 years or older, and to less than 140/90 mm Hg in patients aged 30 to 59 years of age.[20] More recently, the results of a large, randomized trial, the SPRINT study, were published, which call into question the appropriate treatment goals for blood pressure in adults.[51] In this study, 9361 patients with hypertension and an increased cardiovascular risk (but without diabetes), were assigned to a blood pressure target of less than 120 mm Hg versus a target of less than 140 mm Hg. The primary outcome was myocardial infarction, acute coronary syndrome, heart failure, or death from cardiovascular causes. The trial, notably and surprisingly, was stopped early due to a significantly lower rate of fatal and nonfatal major cardiovascular events, as well as death from any cause in the group of patients treated to a SBP of less than 120 mm Hg.[51] The results of this trial argue for more aggressive blood pressure control than what is in the current guidelines. Importantly, this trial excluded patients younger than 50 years of age, those with previous strokes, and those with diabetes which is important to note, as only approximately 20% of the adult hypertensive population would have been eligible for this trial.[52] If this more aggressive approach to management of hypertension based on the SPRINT study is pursued, then it is important to discuss the possible side effects with patients such as presyncope or even syncope that may occur with lower blood pressure targets.

Pharmacotherapy

General Considerations

Patients with prehypertension (blood pressure >120-139/80-89) should be counseled regarding lifestyle modifications, as this group has a high risk for progression to hypertension. Currently, guidelines do not recommend treating pre-hypertensive patients with pharmacotherapy. However, a seminal study in 2006 demonstrated that treatment of prehypertensive patients with an angiotensin receptor blocker (ARB) reduced the incidence of hypertension.[53]

The first step in treatment of hypertension is lifestyle modifications. For patients who are unable to reach blood pressure goals with lifestyle modifications alone, or if there is evidence of end-organ injury, then antihypertensive medications should be initiated. The first-line therapy for most patients with uncomplicated, essential hypertension is a thiazide diuretic (typically chlorthalidone). If blood pressure is greater than 160/90 mm Hg on presentation, then combination therapy should be initiated with at least two antihypertensive agents. With the goal of patient adherence in mind, consideration should be given by the clinician to fixed-dose combination pill therapy. The second agent, after a thiazide diuretic, depends on the patient's other co-morbid conditions. In patients with uncomplicated, essential hypertension, the second-line agent may be an ACE inhibitor, an ARB, a beta blocker, or a calcium channel blocker.

For patients with other co-morbid conditions, the second medication chosen should be picked for specific benefits related to the co-morbid conditions. For example, in patients who have diabetes mellitus or chronic renal disease in addition to hypertension, ACE inhibitors and ARBs have superior benefit to the other medication classes. In addition, patients with coronary artery disease or heart failure derive greater benefits from beta blockers.

No specific antihypertensive medication class has shown superior benefit in patients with PAD.[54] Therefore medications should be chosen based on the patient's other comorbidities. The available agents for antihypertensive therapy, organized by medication class, are listed in Table 14.3.

Thiazide Diuretics

Thiazide diuretics act in the distal convoluted tubule by blocking sodium and chloride transport. Thiazides tend to be more effective in patients with lower renin levels, and this situation tends to be more common in African American patients and older hypertensive patients.[55] The landmark trial that demonstrated the beneficial effects of thiazides was the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), and this largely led thiazides to be considered as first-line treatment for hypertension in most patients.[56,57] The ALLHAT study was a large, randomized, double-blind controlled trial of more than 33,000 participants with hypertension. Patients were assigned to receive either chlorthalidone (a thiazide diuretic), amlodipine (a calcium channel blocker), or lisinopril (an ACE inhibitor). In this study, patients treated with chlorthalidone had a lower average blood pressure, and was shown to be equivalent to both lisinopril and amlodipine. Given the low cost of thiazide diuretics, coupled with their sustained clinical benefits, the authors of the ALLHAT study concluded that thiazide diuretics should be considered as first-line therapy.[57]

In addition, thiazide diuretics lead to decreased calcium excretion, and therefore can be of benefit in preventing calcium-containing kidney stones. The positive calcium balance associated with thiazides may also be beneficial in patients with osteoporosis.

TABLE 14.3 List of Available Antihypertensive Agents by Class

Class	Drugs	Indications	Side Effects
Thiazide diuretics	Chlorthalidone Hydrochlorothiazide Indapamide Metolazone	First-line therapy Low renin Blacks Elderly	Hyperuricemia, hypokalemia, insulin resistance, erectile dysfunction
Loop diuretics	Bumetanide Ethacrynic acid Furosemide Torsemide	CHF Impaired kidney function	Hypokalemia, volume depletion
Potassium-sparing diuretics and aldosterone antagonists	Amiloride Eplerenone Spironolactone Triamterene	Hypokalemia from thiazide diuretics Primary aldosteronism CHF Proteinuria	Hyperkalemia, GI side effects, gynecomastia
Beta blockers	Acebutolol Atenolol Betaxolol Bisoprolol Carvedilol Labetalol Metoprolol Nadolol Nebivolol Pindolol Propranolol Sotalol	CAD Atrial fibrillation CHF	Hyperlipidemia, bradycardia, insulin resistance, depression?
ACE inhibitors	Benazepril Captopril Enalapril Fosinopril Lisinopril Moexipril Perindopril Quinapril Ramipril Trandolapril	CAD CHF LVH Proteinuria Younger patients	Angioedema, cough, hyperkalemia, acute kidney injury
ARBs	Candesartan Eprosartan Irbesartan Olmesartan Losartan Telmisartan Valsartan	CAD CHF LVH Proteinuria	Angioedema, hyperkalemia, acute kidney injury
Renin inhibitor	Aliskiren	Hypertension with elevated renin, (see ACE, ARB)	Angioedema, hyperkalemia, GI side effects
CCB	Dihydropyridine: Amlodipine, felodipine, isradipine, nicardipine, nimodipine, nifedipine Nondihydropyridine: Diltiazem, Verapamil	Blacks Elderly	Lower extremity edema, constipation, bradycardia
Alpha blockers	Doxazosin Terazosin	Hypertension with benign prostatic hypertrophy	Dizziness, fatigue
Central alpha agonists	Clonidine Methyldopa	Resistant hypertension Pregnancy	Rebound hypertension, fatigue, dry mouth, erectile dysfunction
Vasodilators	Hydralazine Minoxidil	Resistant hypertension with CHF or impaired kidney function	Fluid retention, tachycardia

ACE, Angiotensin converting enzyme; *ARB*, angiotensin receptor blockers; *CCB*, calcium channel blockers.

In patients with impaired renal function, thiazide diuretics are generally not effective (serum creatinine >1.5 mg/dL). In patients with decreased renal function, loop diuretics are preferred. Lastly, the efficacy of thiazide diuretics is reduced in the presence of excessive dietary sodium intake, as well as nonsteroidal anti-inflammatory drug use.

Complications/Side Effects

Thiazide diuretics must be used with caution, as they can lead to hypokalemia. Hypokalemia associated with thiazide diuretics is dose-dependent. This class is also associated with an increased risk of hypercalcemia, hyperuricemia, hyperlipidemia, and hyperglycemia. In addition, caution must be taken with the use of thiazide diuretics in elderly patients as they may cause volume depletion, and in patients with RAS. Lastly, there is an association of thiazide diuretics with erectile dysfunction.

Overall, thiazide diuretics are efficacious in the lowering of blood pressure and are considered to be first-line therapy. The use of this class must be balanced with the risks associated with their many metabolic side effects. Many of the side effects listed above are dose-dependent, and may be reduced and/or avoided by using low to moderate doses of these medications.

Angiotensin Converting Enzyme Inhibitors

ACE inhibitors block the enzyme that is responsible for converting angiotensin I to angiotensin II (Fig. 14.3). As previously discussed, angiotensin II is a potent vasoconstrictor. ACE inhibitors lack many of the metabolic side effects that are more commonly present with thiazide diuretics as well as beta blockers. This class is considered first-line therapy for patients with certain comorbid conditions, including congestive heart failure, anterior wall myocardial infarction, left ventricular hypertrophy, diabetes mellitus, and proteinuric renal disease.

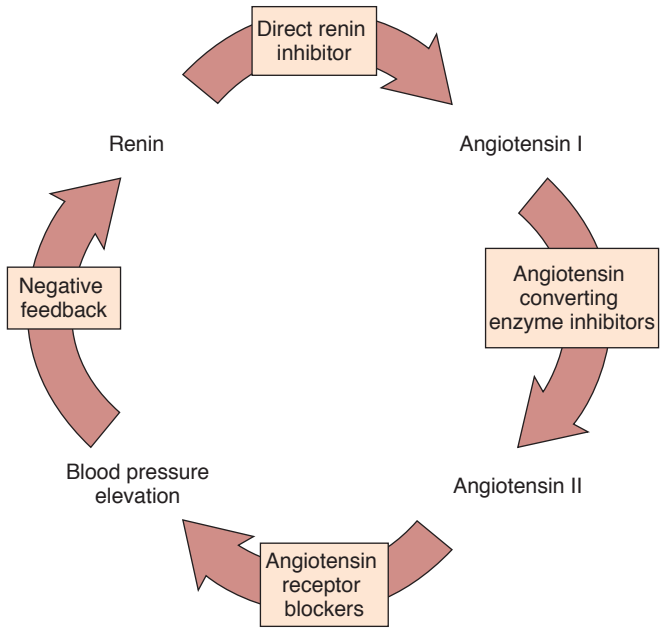

Figure 14.3 Site of action of angiotensin converting enzyme inhibitors, angiotensin receptor blockers, and direct renin inhibitors within the renin-angiotensin system.

ACE inhibitors work synergistically with thiazide diuretics. In addition to the blood pressure lowering effects of ACE inhibitors, this class may be of particular benefit in patients with PAD, as they have been shown to improve endothelial dysfunction and vascular remodeling.[58] ACE inhibitors reduce cardiovascular morbidity and mortality, as has been observed in several randomized clinical trials.[42] In the HOPE study, patients with atherosclerotic vascular disease or diabetes had a reduction in the endpoints of acute myocardial infarction, stroke, and all-cause mortality when treated with an ACE inhibitor (ramipril), as compared with placebo.[59] This class of antihypertensives is of particular benefit for patients with hypertension and diabetes mellitus. In the UKPDS trial, which examined tight blood pressure control in patients with hypertension and diabetes, there was a reduction in the risk of death related to diabetes, as well as complications related to diabetes including progression of diabetic retinopathy and deterioration in visual acuity.[46] In addition, ACE inhibitors are beneficial to patients with diabetes, as they increase insulin sensitivity and may delay the onset of overt diabetes in patients with impaired fasting glucose.

Complications/Side Effects

A common side effect of ACE inhibitors is a dry cough, which is thought to be bradykinin mediated. ACE inhibitors are also associated with the rare, but potentially life-threatening, side effect of angioedema. Due to the common co-existence of renovascular disease in patients with PAD, caution must be used with the initiation of ACE inhibitors in this population to avoid the complication of acute kidney injury.[60] Hyperkalemia may also result from ACE inhibitor therapy, and this is of specific concern in patients with impaired renal function. Lastly, ACE inhibitors are contraindicated in pregnancy due to the known increased risk of cardiovascular and central nervous system congenital malformations.[61]

Angiotensin Receptor Blockers

Angiotensin II binds to the angiotensin (AT1) receptor, which triggers its downstream vasoconstrictive effects. ARBs work by inhibiting AT1 receptor. ARBs have similar indications to ACE inhibitors in regard to patient co-morbidities. Like ACE inhibitors, ARBs have significant benefits in regard to reduction in cardiovascular endpoints. The ARB, losartan, was studied in the Losartan Intervention for Endpoint reduction in hypertension (LIFE) trial, and in this large, randomized trial, patients with hypertension and left ventricular hypertrophy treated with losartan had a lower incidence of cardiovascular morbidity and mortality as compared with those treated with the beta blocker atenolol.[62] The ONgoing Telmisartan and in combination with Ramipril Global Endpoint Trial (ONTARGET) evaluated the ARB telmisartan in comparison to ramipril, and patients treated with telmisartan had equivalent outcomes with regard to cardiovascular events, and had a lower risk of angioedema.[63] The combination use of ACE inhibitors and ARBs was also evaluated in the ONTARGET study, and the combination was associated with an increased risk of adverse events without an improvement in clinical benefit.[63] In general, ARBs are better tolerated than

ACE inhibitors due to lower incidence of cough, and they carry a lower overall risk of hyperkalemia and angioedema.

Complications/Side Effects

Similarly to ACE inhibitors, ARBs have a risk of congenital malformations, and are therefore contraindicated during pregnancy.[64]

Calcium Channel Blockers

Calcium channel blockers (CCBs), work by interacting with the L-type voltage gated plasma membrane calcium channels to disrupt calcium transport. CCBs are subdivided into two groups: the dihydropyridines and the non-dihydropyridines. The dihydropyridines (e.g., amlodipine, nifedipine) are potent vasodilators. The non-dihydropyridines (e.g., diltiazem, verapamil) are negative chronotropic and inotropic agents. The dihydropyridines increase salt excretion and thus may be effective in patients who are unable to adhere to salt-restricted diets or those taking nonsteroidals (for which thiazide diuretics would be less effective). In addition, there is some evidence that CCBs may be of benefit to patients with claudication.[65] However, clinical guidelines do not support the use of CCBs as treatment for claudication. Patients with Raynaud's phenomenon also benefit from CCB treatment.

Complications/Side Effects

CCBs, specifically the non-dihydropyridines, must be used with caution in patients with underlying cardiac conduction abnormalities, as they will lower the heart rate. In addition, the dihydropyridines may cause lower extremity edema. The side effect of lower extremity edema can be reduced when CCBs are used in combination with a diuretic. Clinicians should be cautious when using these agents in combination with beta blockers due to the risk of bradyarrhythmia. Other common side effects include constipation and flushing.

Beta Blockers

The mechanism of action of beta blockers is to inhibit the beta adrenergic receptors. There are different categories of beta blockers, including nonselective beta blockers (e.g., propranolol), cardioselective beta blockers (e.g., atenolol, metoprolol), and beta blockers with alpha blocking properties (e.g., carvedilol). Beta blockers were previously considered first-line therapy for essential hypertension. However, several meta-analyses have been conducted that have called into question the role of beta blockers in the treatment of hypertension, and consequently, they are no longer recommended as first-line therapy.[66-70] Although no longer considered first line for treatment of hypertension, beta blockers are indicated for patients with the coexisting co-morbidities of coronary artery disease, congestive heart failure, angina, and atrial fibrillation. In addition, beta blockers may be useful in patients with hyperthyroidism as well as migraine headaches.

Complications/Side Effects

Beta blockers may cause reduced exercise tolerance and fatigue, which may be treatment limiting. Beta blockers also antagonize the bronchial beta receptors that mediate bronchodilation, and consequently, they may not be tolerated in patients with co-existing asthma or severe chronic obstructive pulmonary disease. Beta blockers also may cause metabolic derangements, including dyslipidemia and worsening insulin resistance. Caution must be used with regard to heart rate, especially in patients with underlying cardiac conduction abnormalities. This class of medications can mask hypoglycemic symptoms in diabetic patients, and may also predispose patients to depression. Previously, beta blockers were thought to be contraindicated in PAD due to the risk of exacerbating peripheral vasoconstriction; however, there is now evidence that beta blockers are safe in PAD.[71]

Loop Diuretics

Loop diuretics work in the thick ascending limb of the loop of Henle by blocking the reabsorption of sodium, chloride, and potassium. Because of their effectiveness at blocking sodium, and therefore water, reabsorption, and loop diuretics (e.g., furosemide, torsemide, bumetanide, ethacrynic acid), are particularly useful in patients in states of salt and volume excess (e.g., heart failure, renal failure). Generally, loop diuretics are thought to be less potent from an antihypertensive standpoint than thiazide diuretics, but they cause fewer metabolic derangements.

Complications/Side Effects

Volume depletion, as well as electrolyte abnormalities (specifically, hypokalemia), may occur with the use of loop diuretics. In addition, this class is associated with allergic reactions, especially in patients who are allergic to sulfa.

Potassium-Sparing Diuretics

The potassium-sparing diuretics, amiloride and triamterene, work in the distal convoluted tubule or collecting tubule, where they block the reabsorption of sodium without blocking potassium reabsorption. This class of medications is often used in combination therapy with diuretics to prevent the side effect of hypokalemia that is seen with diuretic therapy. These agents are frequently used in patients with hypertensive disorders associated with low potassium (e.g., primary aldosteronism).

Complications/Side Effects

Gastrointestinal side effects are associated with amiloride. Triamterene acts as a folate antagonist and is therefore contraindicated in pregnancy. Patients treated with this class of medications should be monitored for evidence of hyperkalemia.

Aldosterone Receptor Antagonists

Spironolactone and eplerenone, the aldosterone receptor antagonists, are effective at treating hypertension in patients particularly when it is associated with aldosterone excess. This class of medications is well studied in patients with heart failure with reduced ejection fraction, and has a mortality benefit in those patients.[72,73] Eplerenone is more selective than spironolactone, and has less of an impact on androgen and progesterone.

Complications/Side Effects

Spironolactone is associated with painful gynecomastia, erectile dysfunction, and irregular menses. These side effects may be treatment limiting. Eplerenone has an improved side effect

profile. Both medications are associated with hyperkalemia, and patients should be carefully monitored for this effect.

Alpha Blockers

Alpha blockers work by blocking the alpha adrenergic receptors. The use of this class of medications has decreased over time, particularly after the ALLHAT study showed an increased risk of heart failure in patients treated with the alpha blocker doxazosin.[56] The alpha blockers (e.g., terazosin, doxazosin) are of particular use in men who also have benign prostatic hypertrophy, as they have smooth-muscle relaxation properties and can relieve lower urinary tract obstructive symptoms. These medications may cause sodium retention, and concomitant use of a diuretic is often necessary. Nonselective alpha antagonists (e.g., phenoxybenzamine and phentolamine) are used primarily for the management of patients with pheochromocytoma.

Complications/Side Effects

The alpha blockers are associated with dizziness, orthostatic hypotension, fatigue, nasal congestion, and headache.

Centrally Acting Alpha Antagonists

The centrally acting alpha antagonists, clonidine and methyldopa, work to lower blood pressure by inhibiting sympathetic activity. Clonidine can be administered transdermally, which has the benefits of continuous drug delivery and improved adherence. Methyldopa is safe to use in pregnancy, and is most commonly used to manage hypertension in that setting.

Complications/Side Effects

Clonidine can cause fatigue and dry mouth, as well as impotence. The side effects of dry mouth and fatigue are attenuated with the transdermal preparation. An important consideration when using clonidine is the risk of rebound hypertension if the medication is abruptly stopped. Methyldopa also may cause fatigue, orthostatic hypotension, fluid retention, hepatotoxicity, and hemolytic anemia.

Direct Vasodilators

The role of direct vasodilators in the treatment of patients with hypertension is most commonly as a fourth-line agent in patients with refractory hypertension. These include direct arterial vasodilators like hydralazine. Hydralazine is commonly used in conjunction with nitrates for afterload reduction in patients with heart failure with reduced ejection fraction. It is approved as a fixed-dose combination drug with isosorbide dinitrate as BiDil, which is indicated in African American patients with systolic heart failure.[74] Another direct vasodilator, minoxidil, is generally used only in resistant hypertension and particularly in patients with impaired renal function. To prevent edema and tachycardia associated with minoxidil use, administration of alpha and beta blockers is frequently necessary.

Complications/Side Effects

Hydralazine is associated with sodium retention, reflexive tachycardia, and may also cause drug-induced lupus. Minoxidil is associated with fluid retention, tachycardia, and hirsutism.

Renin Inhibitors

Aliskiren, a direct renin inhibitor, was approved for use in the treatment of hypertension by the Food and Drug Administration in 2007. Aliskiren blocks the first step in the renin-angiotensin-aldosterone system. It has been shown to have equal efficacy in reducing blood pressure as compared to ACE inhibitors, ARBs, and diuretics.[75] When aliskiren is used in combination with ACE inhibitors or ARBs, the blood pressure reduction is greater than with monotherapy.[76,77] However, the use of combination therapy has been called into question, and as a result, the U.S. Food and Drug Administration (FDA) has cautioned against the use of aliskiren in combination therapy with ACE inhibitors or ARBs. This is largely based on the results of the Aliskiren trial in type 2 diabetes using cardiorenal endpoints (ALTITUDE) trial that showed that patients treated with combination therapy had a higher rate of adverse events (cardiovascular and renal events), and had higher rates of hyperkalemia.[78,79] Given the side effect profile of this medication, it is not commonly used.

Complications/Side Effects

Aliskiren is associated with angioedema, hyperkalemia, and diarrhea. This medication is also contraindicated in pregnancy.

Emerging Therapies

Experimental Invasive Therapies

In addition to lifestyle modifications and antihypertensive pharmacotherapy for hypertension, new technologies are currently being evaluated.

The carotid sinus baroreceptors play an important role in blood pressure regulation. Stimulation of the carotid sinus, via an implanted device, has been under investigation as an option for treatment of patients with resistant hypertension. The first generation of carotid sinus simulators, the Rheos device, is a surgically implanted pulse generator, bilateral carotid leads, and a programmer system.[80,81] The Rheos system was evaluated in the Phase III Rheos Pivotal Trial which was a double-blind, randomized, placebo-controlled trial.[82] This trial showed a significant benefit for patients who had the Rheos device implanted with regards to efficacy and device safety, but the trial did not meet the endpoints for acute responders or procedural safety.[82] As a result, the usage of this technology has been limited. Currently, a second-generation carotid sinus baroreceptor activation system is under evaluation, the Neos system. Further trials are necessary to evaluate the safety and role of carotid baroreceptor therapy for the treatment of patients with resistant hypertension.

In patients with resistant hypertension, increased sympathetic nervous system activity is present and can be difficult to treat pharmacologically.[83] A concept which grew out of this idea was that the sympathetic renal innervation could be interrupted, and thus blood pressure would be reduced due to the decrease in sympathetic activity. Renal denervation is a minimally invasive, catheter-based procedure that uses radiofrequency pulses in the adventitial layers of the renal arteries to ablate the nerves in the vascular wall and reduce sympathetic tone (Fig. 14.4). Renal

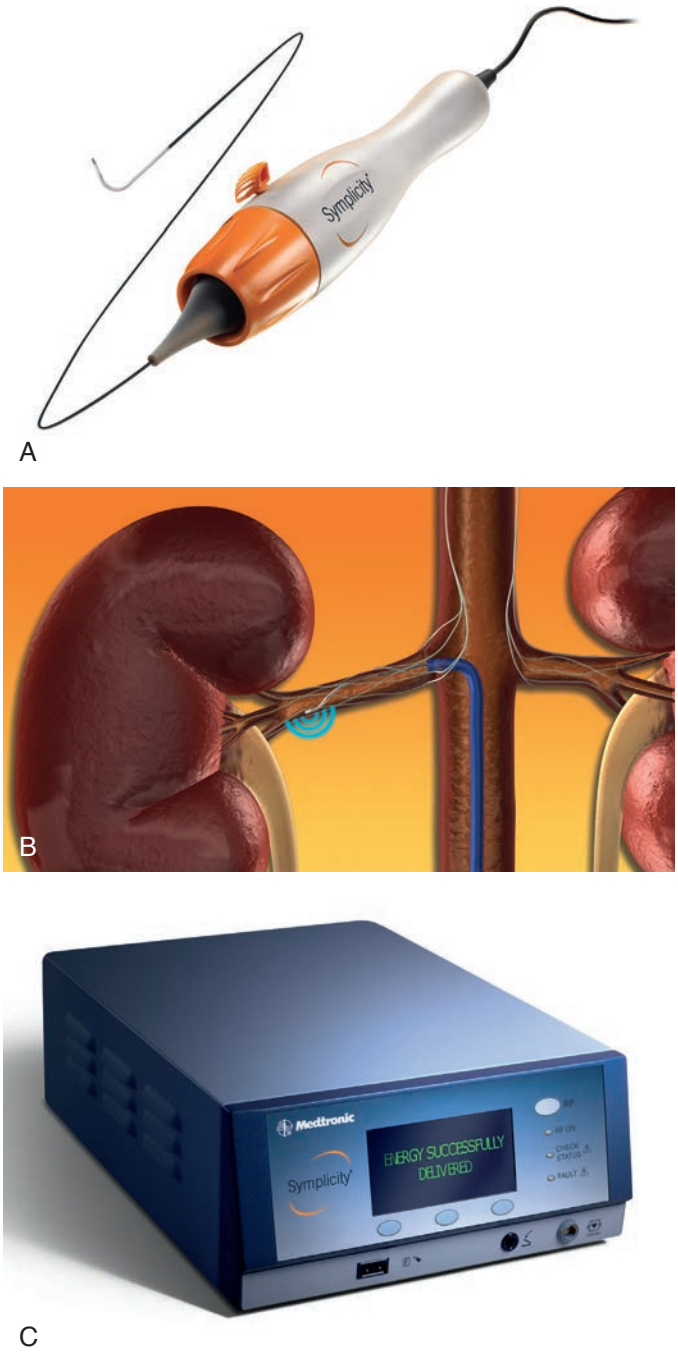

Figure 14.4 Ardian Symplicity Catheter System (A-C) which delivers radiofrequency energy from within the renal artery (B) to block conduction in the surrounding renal nerves, thereby counteracting chronic activation of the sympathetic nervous system. (Courtesy of Medtronic Simplicity Catheter System, www.whichmedicaldevice.com.)

denervation results in a decrease in renal sympathetic afferent and efferent activity, which indirectly results in a reduction in blood pressure.[84] The initial clinical trials involving catheter-based renal denervation, SYMPLICITY HTN-1 and -2, showed significant and sustained reductions in blood pressure.[84,85] These trials were open label, uncontrolled trials, which showed reductions in SBP by as much as 33 mm Hg for up to 3 years post-denervation. These initial results were very promising. To further evaluate the role of this technology, the SYMPLICITY HTN-3 was conducted, which was designed as a prospective, single-blinded randomized controlled trial with a sham procedure arm.[86] The results of SYMPLICITY HTN-3 stand in contrast to the previous two studies. In this trial, patients who received renal denervation had a reduction in SBP of only 2 mm Hg more than sham-operated patients at 6 months.[86] The explanation for the significant discrepancy between the first two SYMPLICITY trials and the third trial is not clear, but some have surmised that the extent of renal denervation may have not been adequate and there may have been significant variation in the extent of denervation within the trial.[87] Consequently, new technologies are currently being developed to improve the denervation procedure. Overall, catheter-based renal denervation is a novel, minimally invasive technique that may have a role in the future in the treatment of resistant hypertension.

Atherosclerosis is a disease in which plaque builds up inside of artery wall, causing the thickening and narrowing of arteries, thereby reducing blood supply to the end organs. Plaque is made up of fatty substances, cholesterol, cellular waste products and debris, calcium, fibrin, inflammatory cells, and platelets.[1,2] It can affect any artery in the body, including arteries in the heart, brain, kidneys, and legs.

Atherosclerosis is the result of nonresolving interactions of inflammation, oxidative stress, lipid deposition, and genetic predisposition.[3] In addition, a novel concept for atherosclerosis risk implicates a lack of endothelial progenitor cell (EPC)–dependent arterial repair in the development of the disease, secondary to the exhaustion of repair-competent EPCs. Molecular evidence derived from genetic techniques indicates that atherosclerotic lesions may begin to form as arterial repair fails, rather than merely following arterial injury. Thus chronic arterial injury may overwhelm the ability of EPCs to maintain arterial homeostasis, particularly when EPCs capable of arterial repair become exhausted. Imbalance between arterial damage and repair leads to atherosclerosis (Fig. 15.1).[4,5]

Atherosclerosis is probably one of the most complex of all disorders, with multiple genetic and environmental contributions. Of the major genetic risk factors, family history is the most significant independent one.[6-8] Familial hypercholesterolemia (FH), familial hypertension, familial diabetes, and familial obesity are at the top of the list of heritable and genetic risk factors. Moreover, these multiple heritable and genetic risk factors can cluster, in many cases, in families. Although FH is the best-characterized heritable risk factor in familial arteriosclerosis, it explains only a small percentage of disease susceptibility. Most of the clinical atherosclerotic diseases result from the interactions of multiple genetic and environmental factors, none of which usually can cause disease by itself.

FAMILIAL HYPERCHOLESTEROLEMIA

FH is an inherited metabolic disorder characterized by severe hypercholesterolemia due to the accumulation of low-density lipoprotein (LDL) in the plasma with cholesterol deposition in tendons and occasionally in skin and an increased risk of premature atherosclerosis manifesting almost exclusively as precocious CAD.

FH is an autosomal dominant disease caused by mutations in the genes encoding the LDL receptor (LDLR), which normally removes LDL from the circulation; apolipoprotein B (ApoB), which is the part of LDL that binds with the receptor; or proprotein convertase subtilisin/kexin type 9 (PCSK9), which induces degradation of LDLR; and the adaptor protein, or autosomal recessive hypercholesterolemia (ARH) protein (LDLRAP), which facilitates the clearance of circulating LDL

Abstract

Atherosclerosis is the principal cause of coronary artery disease (CAD), cerebrovascular disease (CVD), and peripheral artery disease (PAD) and represents a leading global cause of death and disability. Atherosclerosis is one of the most complex disorders with multiple genetic and environmental contributions. This chapter reviews numerous genetic and environmental risk factors for cardiovascular diseases associated with atherosclerosis. Of the major genetic risk factors, family history is the most significant independent one. Familial hypercholesterolemia, familial hypertension, familial diabetes and familial obesity are at the top of the list of heritable and genetic risk factors. Moreover, these multiple heritable and genetic risk factors also cluster, in many cases, in families. Although familial hypercholesterolemia is the best-characterized heritable risk factor in familiar arteriosclerosis, it explains only a small percentage of disease susceptibility. On the other hand, the major environmental risk factors are cigarette smoking, unhealthy diet, physical inactivity and infection. Most cases of myocardial infarction and stroke result from the interactions of multiple genetic and environmental factors, none of which can cause disease by itself.

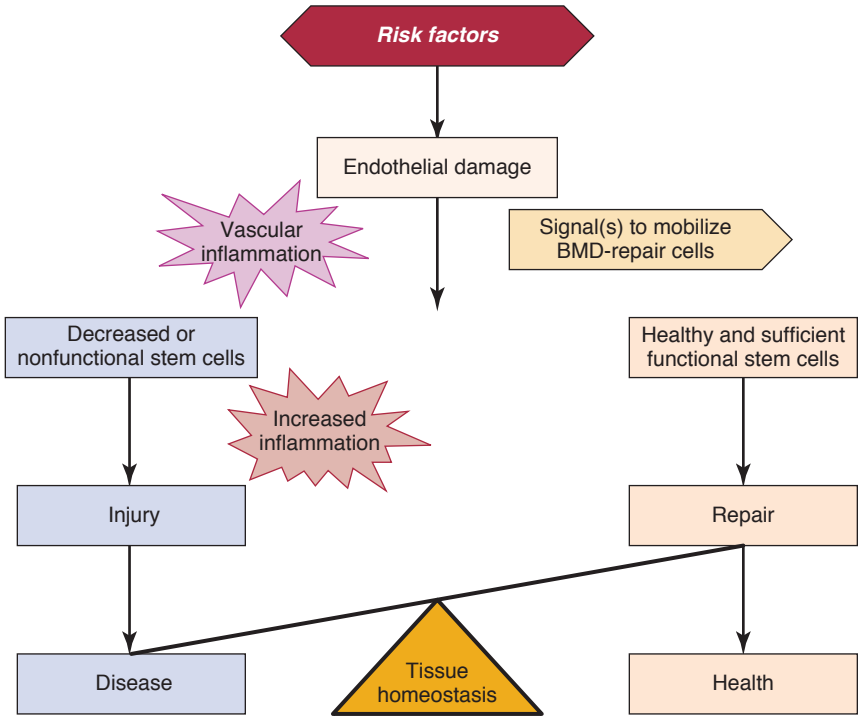

Figure 15.1 Imbalance between arterial damage and repair leads to atherosclerosis. Dysfunction of bone marrow–derived (BMD) stem cells or EPC-dependent arterial repair likely tips the balance toward the development of atherosclerosis.

(Fig. 15.2).[9] Mutations in these genes result in loss of function of these molecules and contribute to elevated plasma levels of LDL. Defects on the first three genes cause both homozygous and heterozygous phenotypes, whereas defects on the latter cause only the homozygous phenotype. People who have one abnormal copy (are *heterozygous*) in one of three genes *(LDLR, ApoB, PCSK9)* may have premature CAD at the age of 30 to 40. Having two abnormal copies (being *homozygous*), either biallelic pathogenic variants in one of these known genes or one pathogenic variant in each of two different genes, may result in severe CAD in childhood.

Heterozygous FH (HeFH) is more common and accounts for 60% to 80% of FH, with a prevalence estimated at 1 per 200 to 500 of persons with FH. Persons with untreated FH are at an approximately 20-fold increased risk for CAD. Untreated men are at a 50% risk for a fatal or nonfatal coronary event by age 50 years; untreated women are at a 30% risk by age 60 years. In contrast, homozygous FH (HoFH) is much rarer with a prevalence of about 1 per 160,000 to 1 million. Most individuals with HoFH experience severe CAD by their mid-20s. The rate of death or coronary bypass surgery by the teenage years is high. Severe aortic stenosis is also common.[10,11]

Cholesterol is a fatlike substance used by cells to synthesize hormones, vitamin D, and substances that help with food digestion. However, if too much cholesterol is present in the bloodstream, it builds up in artery walls and increases the risk of atherosclerosis. All nucleated cells can synthesize the enzymes to produce cholesterol. This synthetic pathway produces cholesterol as well as other isoprene products involved in the prenylation of proteins and the synthesis of ubiquinone. The rate-limiting enzyme in this pathway is 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase. The product of HMG-CoA reductase, mevalonic acid, appears in plasma and urine and may be used as a guide to cholesterol synthetic activity.

Cholesterol is carried in the bloodstream in small packages called lipoproteins, which are made up of lipid on the inside and proteins on the outside. There are two main kinds of lipoproteins: LDL and high-density lipoprotein (HDL). People who have FH have high levels of LDL because they cannot properly remove the LDL from the bloodstream. HDL carries cholesterol from other parts of the body to the liver, where it is removed from the body. Higher levels of HDL lower a person's chances for getting CAD.

LDL binds to LDLR, a well-characterized transmembrane protein that resides on the cell's surface.[12] Upon LDL binding with LDLR, the bound complex of LDL/LDLR is internalized. Once in the endosome, the LDLR dissociates from the lipoprotein during acidification. Thereafter, the lipoprotein proceeds to the lysosome for enzymic degradation into its constituent cholesterol, fatty acids, and amino acids. The dissociated LDLR can be retransported back to the cell surface and recycles approximately 150 times before degradation.[13]

The defect of LDLR results in accumulation of LDL in the bloodstream, leading to FH. Numerous defects in the LDLR have been divided into six classes, depending on the impact of the mutation on the presence of mRNA, receptor maturation in cells, disparity between LDL and immunoglobulin binding on the cell surface, and LDLR degradation and trafficking.[14] Class 1 defects, mainly due to promoter mutations, leave no detectable miRNA and no detectable LDLR. Class 2 defects are due to mutations that retard the maturation of the LDLR by glycosylation, either in a limited fashion (class 2B) or completely (class 2A). Mutations such as D206E have persistent folding defects, demonstrable on nuclear magnetic resonance

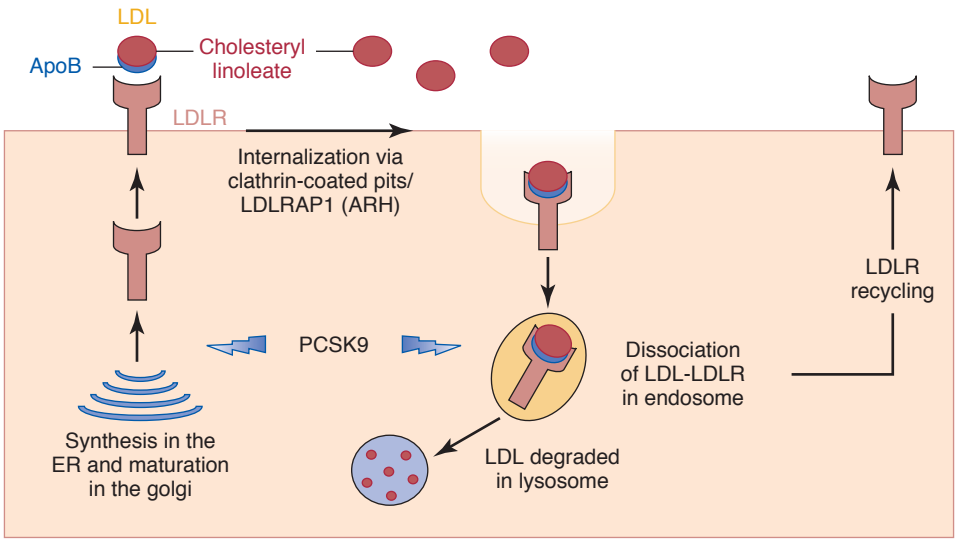

Figure 15.2 The LDL-receptor pathway for uptake and degradation of LDL. The LDL receptor is a cell-surface glycoprotein that is synthesized as an immature protein and processed in the Golgi apparatus, producing the mature form that is transported to the cell surface. There, the receptor specifically binds apoB in LDL particles present in the extracellular fluid. The receptor–ligand complex is then internalized by endocytosis via clathrin-coated pits through interactions involving LDLRAP1 (ARH). The complex is transported via early endosomes to the late endosomal compartment, where the acidic environment causes dissociation of the receptor–ligand complex. The receptor is recycled to the cell surface while the LDL particle is degraded in the lysosomal compartment. Accumulation of free cholesterol released by hydrolysis of cholesteryl esters in the core of LDL inactivates sterol regulatory element binding protein (SREBP), a transcription factor that drives expression of genes for enzymes involved in cholesterol synthesis and the LDL receptor. Thus the LDL-receptor pathway maintains intracellular cholesterol homeostasis. The PCSK9 normally reduces the LDL–protein content of cells by a post-translational mechanism that is not yet fully understood. Mutations in *LDLR, ApoB, LDLRAP1,* or *PCSK9* are known to result in FH. *ApoB,* Apolipoprotein B; *ARH,* autosomal recessive hypercholesterolemia; *FH,* familial hypercholesterolemia; *LDL,* low-density lipoprotein; *LDLRAP1,* low-density lipoprotein receptor 1; *PCSK9,* proprotein convertase subtilisin/kexin type 9.

spectroscopy, which will influence maturation.[15] In class 3, the defective LDLR mature normally but have defects in binding the ligand. In class 4, mutated LDLR mature normally to occupy the cell membrane but are not internalized, typically due to mutations in the cytoplasmic tail. Class 5 mutations relate to LDLR degradation that prevents receptors from reaching the cell surface and from recycling to the cell surface. Class 6 mutations are due to a failure of directing LDLR to the basolateral surface of polarized cells.[16] Although defective hepatic LDL uptake is the main and most direct consequence, other metabolic perturbations may contribute to the metabolic characteristics and accelerated atherosclerotic disease associated with FH.

The defective apoB100 is another common reason for FH. Compared with the numerous mutations found in the LDLR and its pathway, very few mutations have been reported in apoB100 that will disrupt the binding of LDL to the LDLR. Individuals with heterozygous familial binding defective apoB100 (FDB) exhibit cholesterol levels of about 300 mg/dL due to defective LDL clearance.[3] In homozygous FDB, there appears to be no significant gene dose effect.[17] Two homozygotes for FDB were reported to have cholesterol concentrations in the range of heterozygotes for LDLR mutations.[18] The binding affinity for LDLR of very low density lipoprotein (VLDL) was normal in these subjects, whereas LDL affinity was 10% of normal.

An alternative mechanism for FH is mutations in the *PCSK9* gene. PCSK9 protein binds to LDLR and induces LDLR degradation.[19] PCSK9 degrades LDLR by preventing the hairpin conformational change of LDLR.[20] Reduced LDLR levels result in decreased clearance of LDL, which can lead to hypercholesterolemia. Mutations in *PCSK9* have been known to cause autosomal dominant hypercholesterolemia.[21]

Mutations in ARH, the adaptor protein, can impair the internalization of LDLR.[22,23] Disruption of LDLR endocytosis in some FH patients affects the clearance of LDL by the liver and is therefore responsible for the HoFH phenotype.

FAMILIAL HYPERTENSION

Hypertension is a well-known risk factor for atherosclerosis.[24] Over time, this extra pressure can damage the arteries, making them more vulnerable to the plaque buildup associated with atherosclerosis. Hypertension tends to be familial and is likely to be the consequence of an interaction between genetic and environmental factors. About 30% to 50% of the variance in blood pressure readings is attributable to genetic heritability and about 50% to environmental factors.[25] The heritability of blood pressure frequently ranges about 50% to 70% in twins, with considerably lower estimates (around 20% to 25%) in family studies.[26-28] In spite of substantial efforts and progress

in elucidating the genetic basis for heritable hypertension, the genetic factors contributing to common forms of hypertension remain largely unknown. The genetics of hypertension is complex, with no known single gene playing a major role but rather many genes, each with mild effects, reacting to different environmental stimuli and thus contributing to elevated blood pressure. Early studies in hypertension identified specific enzymes, channels, and receptors implicating sodium handling in the regulation of blood pressure, including genes involved in the renin-angiotensin-aldosterone system (RAAS), controlling blood pressure and saltwater homeostasis, proteins in hormonal regulation of blood pressure (enzymes and receptors of the mineralo- and glucocorticoid pathways), and proteins coded by genes involved in the structure and/or regulation of vascular tone (endothelins and their receptors).[29] RAAS plays an important role in regulating blood pressure and during hypertensive crises (Fig. 15.3).[30] The enzyme renin acts on angiotensinogen (AGT) to generate angiotensin I (Ang I). Ang I is further converted to angiotensin II (Ang II) by angiotensin converting enzyme (ACE). Ang II exerts its effects by binding to two major types of receptors—AT1R and AT2R.[31] Functions like vasoconstriction, cellular proliferation, cellular hypertrophy, fibrosis, atherosclerosis, antinatriuresis, and the release of aldosterone, endothelin, norepinephrine, and vasopressin are initiated by the binding of Ang II to AT1R. In addition, Ang II directly stimulates vascular smooth muscle cell (SMC) growth and extracellular matrix production. Studies with spontaneously hypertensive rats indicate that raised blood pressure stimulates the expression of platelet-derived growth factor (PDGF), a potent mitogen for SMC.[32] Furthermore, both renin receptors (recently identified) and functionally active Ang II-derived peptides like Ang 1 to Ang 7 have been shown to play pathologic roles in the development of hypertension.[33] Both linkage and association studies have provided strong evidence for the role of the AGT gene in hypertension in Caucasian and African/Caribbean populations as well as in pregnancy-induced hypertension.[34]

The kidney is known to be the dominant, long-term regulator of blood pressure,[35-37] highlighting the need for an appreciation of its pathophysiology in considering genetic factors potentially contributing to hypertension. Moreover, pheochromocytoma is a rare cause of hypertension that may be familial.

FAMILIAL DIABETES

Cardiovascular disease (CVD) is more prevalent in type 1 and type 2 diabetes (T1D and T2D) and continues to be the leading cause of death among adults with diabetes. T2D, commonly referred to as insulin resistance, is partly inherited.[38]

Insulin resistance is also associated with the enhanced generation of reactive oxygen species (ROS). In addition, insulin resistance decreases NO production,[39-41] and increases the release of free fatty acids from adipose tissue. Increased circulating

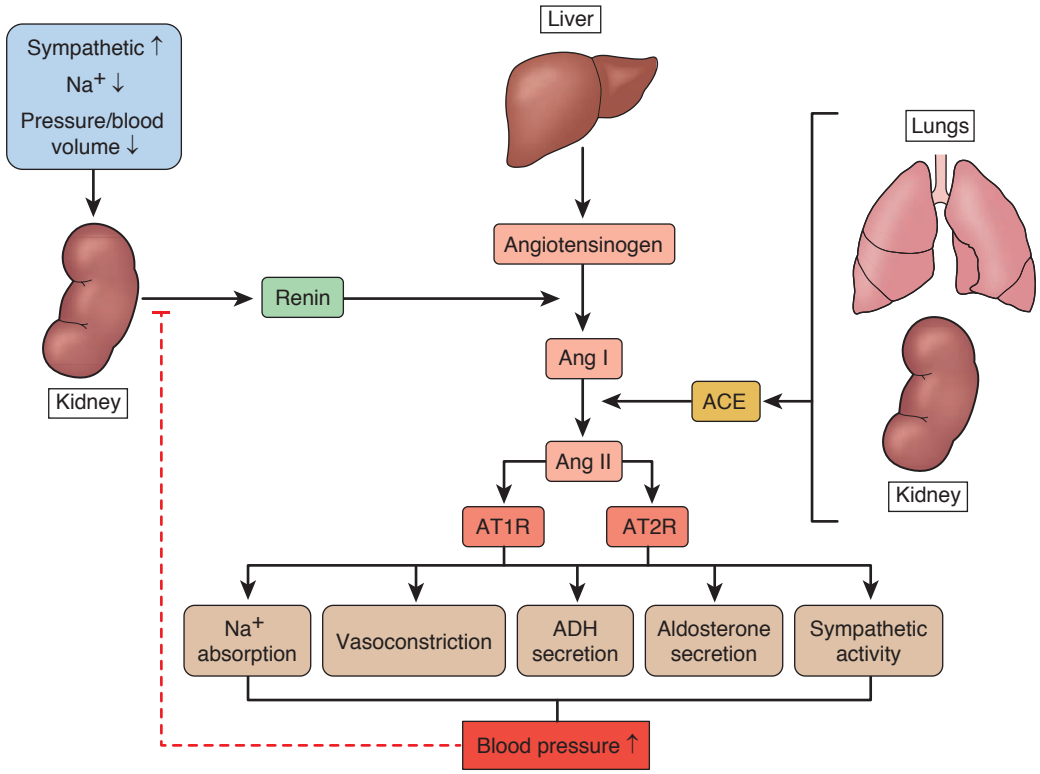

Figure 15.3 Renin-angiotensin-aldosterone system (RAAS). When renin is released into the blood, it acts upon angiotensinogen, which undergoes proteolytic cleavage to form Ang I. Vascular endothelium, particularly in the lung and kidney, produces ACE, which cleaves off two amino acids to form Ang II. Ang II binds with AT1R and AT2R to exert its effect on increasing blood pressure. High blood pressure inhibits renin production by kidney. *ACE,* Angiotensin converting enzyme; *Ang I,* angiotensin I.

levels of free fatty acids may impair endothelial function[40-42] and induce low-grade inflammation.[41,42] Hyperinsulinemia augments VLDL synthesis in liver; increases cholesterol transport/synthesis in cultured arterial SMCs; stimulates the proliferation of arterial SMCs; augments collagen synthesis and turns on multiple genes involved in inflammation.[43,44] Although insulin receptors are expressed on endothelial cells, vascular SMCs, and macrophages, it remains unclear whether the vascular insulin receptors contribute directly to the vascular pathology of metabolic insulin resistance.[45]

A subset of insulin-resistant individuals develop non–insulin-dependent diabetes mellitus (NIDDM), characterized by an insufficient insulin secretory capacity to maintain normal glucose levels. A genome scan identifies a major NIDDM susceptibility locus, designated NIDDM1, on chromosome 2q. Using linkage disequilibrium mapping, scientists have shown that an intronic polymorphism in the calpain-10 gene is strongly associated with the disease.[46] A second locus for diabetes has been identified on chromosome 1q.[47-50] It is interesting to note that the chromosome 1 locus was initially linked with familial combined hyperlipidemia (FCH) in a set of Finnish families, and that FCH overlaps with diabetes.[51]

Advances in genotyping technology have facilitated rapid progress in large-scale genetic studies. Genome-wide associated studies (GWAS) and linkage analyses have identified greater than 120 genetic variants associated with T2D and diabetes-related traits.[52-55] Most of these variants are noncoding variants; therefore, their functional consequences are challenging to investigate. However, many of the variants identified to date regulate insulin secretion and not insulin action in insulin-sensitive tissues.

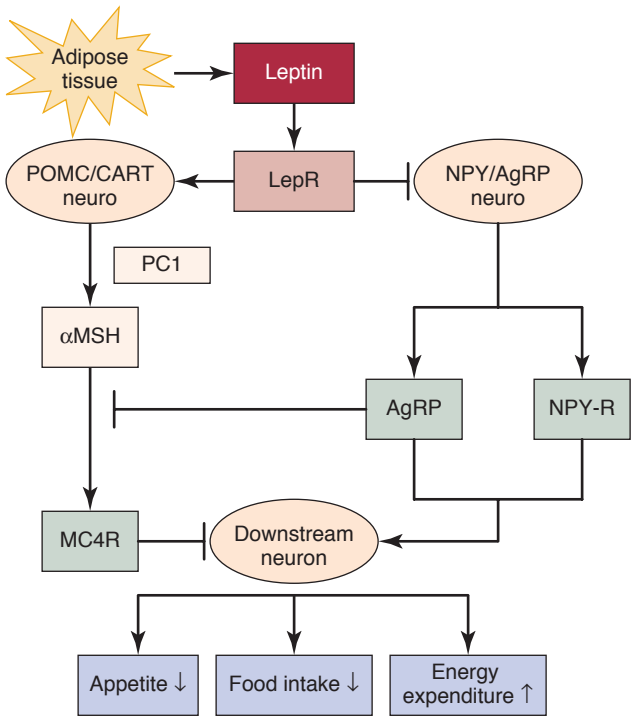

Figure 15.4 Influence of the leptin-melanocortin pathway on food intake and energy expenditure. Leptin secreted from adipose tissue binds to the leptin receptor (LepR) in the hypothalamus. Leptin binding inhibits the neuropeptide Y/agouti-related protein (NPY/AgRP) production and stimulates pro-opiomelanocortin (POMC) production, which undergoes posttranslational modifications to produce peptides such alpha-melanocyte-stimulating hormone (αMSH) via the processing of prohormone convertase 1 (PC1). αMSH binds to melanocortin 4 receptors (MC4R) and induce downstream events of food intake and energy consumption.

FAMILIAL OBESITY

Although some studies have suggested that obesity is not an important contributing cause of atherosclerosis and CAD,[56,57] recent evidence indicates that obesity is a major contributor to CVD risk and mortality.[58-60] Obesity exhibits considerable metabolic overlap with the abnormalities present in individuals with T2D and is associated with other cardiovascular factors such as hypertension, hyperlipidemia, and insulin resistance.[61,62]

Obesity is a complex disease resulting from the interaction of a wide variety of hereditary and environmental factors. Clustering of cases within a family, the congruence of body weight in monozygotic twins, and the discovery of genes associated with obesity all suggest genetic involvement in obesity. Obesity risk is 2-8 times higher for a person with a family history as opposed to a person with no family history of obesity, and an even higher risk is observed in cases of severe obesity. Occurrences of monogenic types of obesity are evidence that obesity may be caused by genetic mutations (http://obesity.ulaval.ca/obesity/generalities/genetic.php). Eight monogenic genes and four polygenic genes have been associated with obesity.[63] The cloning of the mouse ob gene and its human homologue, leptin,[64] has proved to be a paradigm for the field, resulting in the identification of many genes involved in the regulation of appetite, food intake, and energy expenditure via the leptin–melanocortin pathway (Fig. 15.4). These variants account for some 5% of morbid human obesity and include leptin[65] and its receptor,[66] the α-melanocortin–stimulating hormone receptor (MC4R),[67,68] pro-opiomelanocortin (POMC),[69] and prohormone convertase-1.[70] Moreover, the association of additional genes with obesity has recently been identified by GWAS (*SH2B1, KCTD15, MTCH2, NEGR1,* and *BDNF*) with dietary intake and nutrient-specific food preferences.[71] This is in line with the fact that food intake–related parameters are heritable[72] and are strongly correlated with body mass index (BMI).[73]

Other genes such as *fat mass and obesity-associated (FTO); PCSK1;* and *catenin, beta-like 1 (CTNNBL1)* are also associated with obesity. In addition, more than 150 loss-of-function coding mutations have been associated with monogenic obesity,[74] and two infrequent gain-of-function coding polymorphisms (V103I and I251L) have been associated with protection from obesity.[75,76]

GENETICS OF PERIPHERAL ARTERY DISEASE

PAD is a disease characterized by reduced blood flow to the lower extremities, most often because of atherosclerosis and

can be considered a marker of widespread atherosclerosis. However, PAD is a distinct subtype of atherosclerotic vascular disease that differs from CAD and CVD in its clinical manifestations. Thrombus formation resulting from acute rupture or erosion of a vulnerable plaque in the coronary or cerebral arterial beds leads to acute events such as myocardial infarction (MI) or stroke. Such acute events are relatively uncommon in PAD, and symptoms most often result from progressive arterial narrowing because of ongoing atherogenesis. The underlying reasons for the differences remain unknown. It is therefore likely that risk factors, both genetic and environmental, and the intermediate biochemical pathways through which they act contribute differently to PAD than to CAD or CVD. Although traditional cardiovascular risk factors have been associated with the development of PAD, relatively few genetic variants that influence susceptibility to PAD have been discovered. This may be partly because of the greater clinical and genetic heterogeneity in PAD.[77] Phenotypic heterogeneity seems to be a major challenge in investigating the genetic basis of PAD.

PAD is complex and heterogeneous; it is not a uniform entity. Two broad subtypes of PAD, proximal and distal, are associated with distinct risk factor and comorbidity profiles.[78] Female sex, smoking, hypertension, and dyslipidemia are more significantly associated with proximal disease, whereas older age, male sex, and diabetes are more significantly associated with distal, small vessel disease. The candidate genes include β-fibrinogen,[79] apoB,[80] endothelial nitric oxide synthase (eNOS), methylene tetrahydrofolate reductase,[81] G protein β3, α-adducin,[82] IL-6,[83] and glutathione S-transferase.[84] However, any reported associations between variants in these genes and PAD have not been confirmed in independent cohorts or in GWAS. Moreover, genetic analyses do not appear to be as useful as in CAD in determining progression of the disease or its tendency to remain stable.[85]

A linkage analysis using a 10-cM genome-wide scan in 272 PAD patients from 116 extended families has identified a region on chromosome 1 between 100 and 110 cM (logarithm of the odds score, 3.93; $P = 1.04 \times 10^{-5}$) associated with PAD. Several candidate genes (in pathways of inflammation, coagulation, lipid metabolism, blood pressure regulation, and vascular matrix regulation) for atherosclerosis are present under the linkage signals, but the causal variants cannot be identified.[86] Association studies using the GWAS approach identified only a few loci having weaker associations with PAD.[87]

Similar to CAD, several Mendelian disorders are associated with PAD. These include familial lipoprotein disorders, such as chylomicronemia resulting from mutations in the lipoprotein lipase gene and FH,[88,89] hyperhomocysteinemia,[90] and pseudoxanthoma elasticum.[91] In a family history study including 2296 PAD cases and 4390 controls, the prevalence of a family history of PAD was significantly higher among patients with PAD than in controls, resulting in a doubling of the odds of the presence of PAD in those with family history of PAD.[92] The association is stronger in individuals less than 68 years of age and in those with a greater number of affected relatives. In another study conducted in a twin population, the odds ratio of having PAD among individuals whose twins had PAD compared with individuals whose twins did not have PAD was 17.7 for monozygotic twins and 5.7 for dizygotic twins.[93]

INFLUENCE OF NONGENETIC FACTORS

Although the critical roles of genetic factors in atherosclerotic vascular disease have increasingly being recognized, the specific etiology in many cases remains unknown, with nongenetic risk factors believed to be important contributors. It is now generally considered that atherosclerosis results from a variety of genetic causes, with added epigenetic modulation and the interaction of genetic and environmental factors. None of these triggers is sufficient to cause atherosclerosis on its own.

Environmental Factors

Accumulating evidence strongly supports the existence of gene-environment interactions in atherosclerosis.[94-99] The genetics of atherosclerosis-induced CVDs involves a large number of genes having weak effects on disease risk, but possibly interacting with each other and with environmental factors could act synergistically in the pathogenesis of atherosclerosis and its complications. Gene-environment interactions can be either complementary or antagonistic.[100] Complementary gene-environment interactions may play a substantial role in CAD risk only when an individual with a high-risk genetic profile enters a high-risk environment; that is, the effect on risk will then be so great that premature CAD develops. Indeed, a large number of studies have shown significant gene-environment interactions in the etiology of obesity as well as in the pathogenesis of T2D and CAD.[101-103]

Epigenetic Factors

Epigenetics plays important roles in the modulation of gene expression and activity. Epigenetics represents a critical link between genomic coding and phenotype expression that is influenced by both underlying genetic and environmental factors. Epigenetic modifications may contribute to subclinical and clinical CAD, CVD, and PAD.[104] *Epigenetics* refers to changes in gene expression resulting from factors other than a direct change in the DNA sequence of the genome. Epigenetic mechanisms for the regulation of gene expression include DNA methylation, posttranslational histone modifications, and post-transcriptional modifications such as small noncoding miRNA (Fig. 15.5).[105] Alteration of gene expression regulated by epigenetics is heritable. Epigenetic inheritance is an essential mechanism that allows the stable propagation of gene activity states from one generation of cells to the next.[106]

RISK ASSESSMENT AND DIAGNOSIS

The Framingham Risk Score (www.bestsciencemedicine.com/chd/calc2.html) is a popular tool for risk assessment in patients without inherited CAD-associated diseases. For patients with

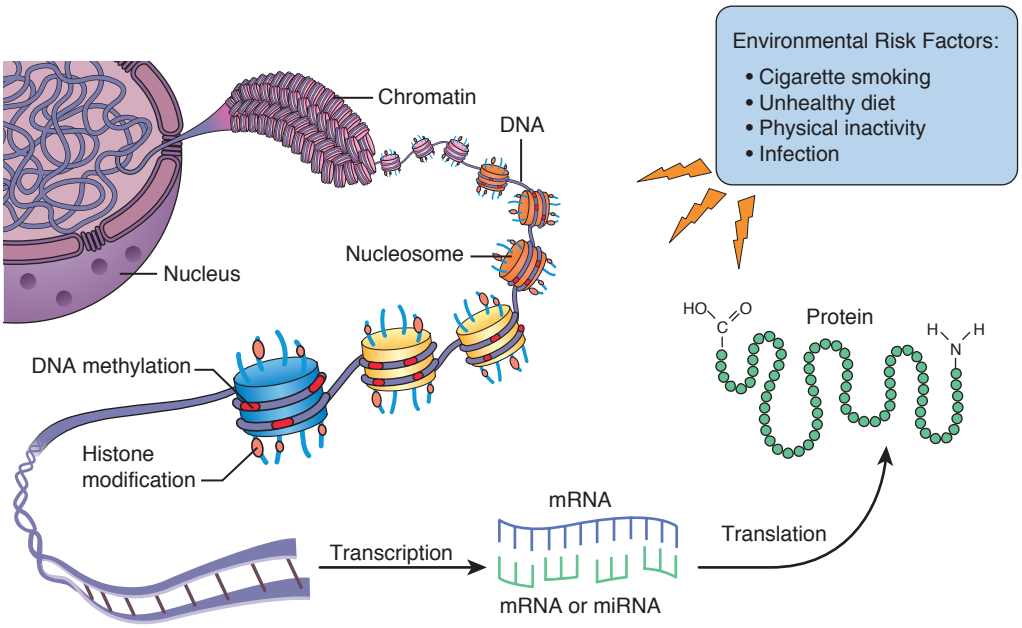

Figure 15.5 Overview of gene expression regulated by epigenetic mechanisms. Histone modifications, DNA methylation, and noncoding (micro)RNAs mediate influence from environment on gene transcription and translation. (Modified from Dr. Clarissa Gerhäuser. Cancer Prevention and Nutrition. *Lab&More int* 4, 2014.)

genetic susceptibility to CAD, family history plays a critical role in assessing the risk. Pedigree is a commonly used family history assessment tool. Family history along with emerging new genetic markers and traditional biomarkers—including lipid profile, glucose, and hormone level and established physiologic biomarkers such as serum ferritin, triglyceride-HDL ratio, lipophorin-cholesterol ratio, lipid-lipophorin ratio, lipophorins-LTPs ratio, LDL, HDL and apolipoprotein levels, sphingolipids, omega-3 index, and ST2 level—are employed in the prediction and diagnosis of a variety of familial inherited diseases.

Familial Hypercholesterolemia: The diagnosis of both HoFH and HeFH is based primarily on the finding of severe LDL elevations in the absence of secondary causes of hypercholesterolemia (Table 15.1). Findings on lipid analysis in patients with FH include the following:

Homozygous Familial Hypercholesterolemia: Severely elevated cholesterol levels (total cholesterol and LDL levels >600 mg/dL). Triglyceride levels remain within the reference range. A substantial increase in serum triglyceride levels should raise the possibility of another lipid disorder. Patients with a HoFH phenotype should be referred to specialized centers for diagnostic workup and management.

Heterozygous Familial Hypercholesterolemia: If the LDL level is commonly greater than 250 mg/dL, HeFH is suggested; in patients less than 20 years old, an LDL level greater than 200 mg/dL is highly suggestive of HeFH or, possibly, a familial ligand defective apoB-100; in adults, LDL levels greater than 300 mg/dL suggest HeFH. If tendon xanthomas are present in a patient with an LDL level above the 95th percentile, a probable diagnosis of HeFH can be made.

A careful family history is essential for the comprehensive assessment of possible FH in general and HoFH in particular. In the case of autosomal dominant mutations (in *LDLR*, *PCSK9*, and *APOB* genes), both parents are obligate heterozygotes and therefore display elevated LDL levels (frequently >95th percentile) and a strong positive family history of premature CVD (<55 years in men and <60 years in women among first-degree relatives). In the case of *LDLRAP1* mutation–induced ARH, parents may exhibit normal LDL levels, and determination of an extended family pedigree may reveal an autosomal recessive pattern of inheritance. Systematic cascade or opportunistic screening offers prospective parents with HeFH the possibility of making informed decisions prenatally and

TABLE 15.1 Diagnostic Criteria for Familial Hypercholesterolemia

Fm Family history	Premature CAD (>55 years in men and <60 years in women among first-degree relatives) >95 percentile for age and gender in first- or second-degree relatives)
Cli Clinical history	Pat Patient with premature CAD and/or CVD
La Laboratory examination	Ge High LDL levels (>250 mg/L in adult; >200 mg/L in patients <20 years old)
P Physical examination	Tendonxanthomas: arcus cornealis
Ge Genetic test	Ge Gene mutation in LDLR, ApoB, or PCSK9.
No No secondary causes of hyperlipidemia	Ge Normal liver enzymes, renal function, thyroid hormones No hyperglycemia or albuminuria

ApoB, Apolipoprotein B; *LDL,* low-density lipoprotein; *LDLR,* low-density lipoprotein receptor; *PCSK9,* proprotein convertase subtilisin/kexin type 9.

identifying HoFH patients at birth, thereby allowing for the early initiation of treatment. Identification of HoFH can also guide reverse cascade screening for parents and relatives to identify patients with FH.

Definitive diagnosis can be made only with gene or receptor analysis. The genetic diagnosis is popularly made by polymerase chain reaction (PCR) for LDLR and ApoB defects. Only a few mutations are known in ApoB, but there are more than 750 mutations in LDLR. New technology, such as next-generation sequencing and RNA-seq, may provide in-depth evaluation for many mutations. These new technologies are currently available in some medical centers for genetic diagnosis. In populations with founder effects, genetic diagnosis is easier. In other populations, where hospitals can sequence the genes in affected families, genetic diagnosis can be made in family members. Moreover, cell culture is more reliable in identifying LDLR defects. In fibroblast cultures, LDLR mutations will result in low binding, whereas adaptor protein mutations will not. It is worth considering measurement of plasma phytosterols for phytosterolemia and cholestanol for cerebrotendinous xanthomatosis and investigating the genes influencing the concentration of these products.

Familial Hypertension

A family history of hypertension is twice as common in the hypertensive population than in those who are normotensive. As described earlier, a polygenic model of inheritance has been found. Genetic factors include an inherited defect in cellular sodium transport as well as abnormal response to psychogenic stress. Therefore family history and genetic markers are included in the family hypertension workup. Other factors to be investigated include T2D, dyslipidemia, BMI, sex, age, smoking, and psychological factors (e.g., stress levels), as multiple factors are more often involved in high-risk CAD associated with family hypertension. Laboratory genetic test may consider *AGT*, which is the first gene to show linkage with human essential or primary hypertension,[107] ACE,[108] and α-adducin (ADD1).[109] More information about genetics and hypertension is available at the website of the Centers for Disease Control Office of Public Health Genomics.

Familial Diabetes

Family history is increasingly recognized as a powerful, cost-effective, and readily available tool for detecting diabetes. Such information can be used to classify individuals or groups of people according to different levels of familial risk, such as average, moderate, and high.

In most cases of T1D, people must inherit risk factors from both parents. In many people the development of T1D seems to take many years. Early onset suggests a major role for genetic factors, with a strong inverse association between age at diagnosis and prevalence of HLA alleles conferring susceptibility.[110,111] High genetic susceptibility in the proband implies increased genetic susceptibility and disease risk in his or her parents and siblings. This has been confirmed by many family studies.[112] Because genetic risk is inversely correlated with age at onset, it might be anticipated that this would also apply to familial risk. Most whites with T1D have genes called HLA-DR3 or HLA-DR4. If you and your child are white and share these genes, your child's risk is higher. (Suspect genes in other ethnic groups are less well studied. The HLA-DR7 gene may put African Americans at risk, and the HLA-DR9 gene may put Japanese at risk.) Individuals at high risk can be identified using immunologic, genetic, and metabolic parameters. In addition, circulating antibodies to pancreatic β-cell antigens are markers of islet autoimmunity. In first-degree relatives of persons with T1D, the levels and range of antigen specificities of these islet antibodies reflect the risk for clinical diabetes.[113] Besides, severe metabolic decompensation, rapid failure of C-peptide secretion, and high levels of glutamic acid decarboxylase are useful parameters.[110]

T2D accounts for some 90% of all cases of diabetes.[114] It has a stronger link to family history and lineage than T1D, although it also depends on multiple environmental.[115-118] T2D tends to run in families, based on sociologic and genetic factors. In general, the lifetime risk of developing the disease is about 40% in the offspring of one parent with T2D, greater if the mother is affected,[119] and approaching 70% if both parents have diabetes. It also shows that first-degree family history is associated with a twofold increased risk of future T2D.[120,121] People with certain rare types of T2D have different risks. If patients have the rare form called maturity-onset diabetes of the young (MODY), their child has a 50% chance of getting it too. The concordance of T2D in monozygotic twins is about 70%, compared with 20% to 30% in dizygotic twins.[122,123]

It should be noted that various single genetic variants have been found to be associated with increased risk for T2D, as mentioned earlier; however, the magnitude of increased risk conferred by each variant is relatively small. Thus genetic testing for the prediction of T2D in high-risk individuals is currently of little value in clinical practice.

Familial Obesity

Obesity also tends to run in families; hence family history is a basic tool in assessment.

BMI is the most common way to estimate body fat based on comparing a person's weight to height. Body fat can be measured in other ways in addition to BMI, including waist circumference, calculation of waist-to-hip circumference ratios, measuring the thickness of a skinfold (a pinch of skin and fat), and techniques such as ultrasound, which are more precise than BMI. Obesity is defined differently for children and teens than for adults. Children are still growing, and boys and girls mature at different rates. BMI for children and teens compares their heights and weights against growth charts that take age and sex into account. This is called a BMI-for-age percentile. A child's or teen's BMI-for-age percentile shows how his or her BMI compares with that of other boys and girls of the same age. For more details, see http://www.nhlbi.nih.gov/health/health-topics/topics/obe/diagnosis. Heritability estimates for obesity are high (typically >0.70). In addition, the use of

quantitative obesity subphenotypes that can be accurately measured has resulted in significant measures of heritability for skinfold thickness,[124-126] waist circumference,[127] and total and regional fat distribution.[128]

The location of fat deposition, variation in the secretion of adipokines, and other factors govern whether a particular obese person is more predisposed to obesity-associated diseases and thus is "at risk." Physiologically, metabolically deleterious and life-threatening forms of obesity are associated with a preferential accumulation of fat in the visceral adipose tissue and with ectopic fat deposition in insulin-sensitive tissues such as muscle, liver, and pancreas. This aberrant fat content strongly correlates with severe generalized insulin resistance and the development of a chronic inflammatory state, partly due to the infiltration of the adipose tissue by macrophages.[129] An anti-inflammatory adiponectin is known to strongly modulate the risk of the metabolic syndrome and T2D associated with obesity (diabesity).[130] Variation within the adiponectin gene is reported to modulate plasma adiponectin levels and also to predict risk for diabesity and associated CAD.[131] Paradoxically, the adiponectin variant alleles that protect against the development of diabesity by maintaining high adiponectin concentrations are also associated with obesity risk in both adults and children.[132] Individuals with high adiponectin levels can be severely obese but seem to enjoy metabolic protection.[133] The same alleles—together with the T2D protective PPARγ-12Ala allele—associate with a CAD-protective risk factor pattern, elevated adiponectin and insulin sensitivity, but also with a dramatic increase of 3 units of BMI.[134]

Several biomarkers have been used for assessing the development of obesity and its sequelae. These markers include ACE, AGEs, aldo-keto reductase family 1, member B10 (AKR1B10), alpha-methylacyl-CoA racemase (AMACR), cocaine- and amphetamine-regulated transcript (CART), collagen type I alpha 1, cannabinoid receptor 1 (CR1), ectonucleotide pyrophosphatase/phosphodiesterase 1 (ENPP1), MC4R, MTHFR (5,10-methylenetetrahydrofolate reductase [NADPH]), NRs (nuclear receptors), POMC, PPARγ (peroxisome proliferative activated receptor γ), TCF7L2 (transcription factor 7-like 2 [T-cell specific]), TGFβ1 (transforming growth factor β1), VDR (vitamin D3 receptor).[135] However, the value of these biomarkers in risk assessment remains limited.

RISK MANAGEMENT

Familial Hypercholesterolemia: If they are diagnosed and treated early in childhood, individuals with FH can have a normal life expectancy. Early treatment of FH can reduce LDL burden, improve endothelial function, substantially attenuate the progression of atherosclerosis, and offer health and socioeconomic benefits.[136-141] Furthermore, long-term follow-up from statin trials, albeit not specifically in FH patients, suggests a legacy effect—that is, better CAD outcomes in those initially randomized to statin treatment.[142,143]

Children with HeFH should be treated with a fat-modified, heart-healthy diet at diagnosis and begin statins at age 8 to 10 years. For children aged 8–10 years, it is recommended to reduce LDL by 50% from pretreatment levels. For children above age 10, especially if there are additional cardiovascular risk factors including elevated lipoprotein(a), the target LDL should be less than 3.5 mmol/L (130 mg/dL). In HoFH, pharmacologic treatment should start at diagnosis. Children with HoFH should be referred to and cared for at a specialized center.

Diet and lifestyle underpin the management of FH in children. In considering dietary fat content, the major dietary drivers of serum cholesterol levels are saturated fats and trans fats with a small contribution from dietary cholesterol.[144,145] Limitation of foods high in saturated fat will secondarily limit dietary cholesterol intake; cholesterol-containing foods without saturated or trans fats may be allowed (http://www.health.gov/dietaryguidelines/2015-scientific-report/). There should be annual or biannual monitoring of weight, growth, and developmental milestones. Physical activity should be promoted and smoking strongly discouraged. Identifying children with FH early ensures that adherence with lifestyle interventions is established before puberty. Other cardiovascular risk factors should be monitored and treated if indicated.

The most powerful cholesterol-lowering agents for FH are the statins. By inhibiting de novo cholesterol synthesis at HMG-CoA reductase, compensatory upregulation of LDLR lowers plasma LDL concentration. Statins are the cornerstone of FH management. Simvastatin, lovastatin, atorvastatin, pravastatin, fluvastatin, and rosuvastatin are approved in the United States and Europe for use in children with FH. Treatment should be initiated at the lowest recommended dose and titrated upward according to the LDL-lowering response and tolerability. Ezetimibe, a recently developed drug that limits cholesterol absorption, lowers LDL by about 15%. In addition, bile acid sequestrants that waste more bile acids for the patient result in a reduction of the cholesterol pool in cells. Thus the addition of ezetimibe or a bile-acid sequestrant may be required to attain the LDL goal in some patients.[146-148]

Modern pharmacotherapy can achieve desirable concentrations of LDL in HeFH, but treatment for HoFH remains problematic. Patients with HeFH respond as do normal subjects to lipid-modifying treatment as there is a functional LDLR that will clear LDL from plasma. In 2013, both mipomersen, an ApoB antisense oligonucleotide, and lomitapide, a microsomal triglyceride protein inhibitor, were approved for the treatment of HoFH in the United States.[149] Lomitapide was also approved in Europe. Also, PCSK9 inhibitors, including evolocumab and alirocumab, were approved in Europe and United States in 2015. Besides, liver transplantation (alone or in combination with a heart transplant) may be considered for young HoFH patients, although the disadvantages of this approach include the high risk of posttransplantation complications and mortality as well as the limited availability of donors. Other options, such as partial ileal bypass and portocaval shunting, are not recommended for this population but may be considered for patients with very severe disease in whom other conventional options are not effective.[150,151] In addition, several other novel options for the treatment of HoFH, such as gene therapy, are being investigated. Gene therapy is a strategy used to correct

defective genes responsible for the development of disease. For example, replacement of the *LDLR* gene has the potential to decrease LDL levels while also making patients with HoFH more responsive to conventional therapies.[152] Preclinical studies using mouse models of HoFH and HeFH have yielded promising results.[153] Additional studies and clinical trials of these gene replacement strategies are warranted before they can be considered for general use.

Familial Hypertension

Treatment of familial hypertension should comprise both lifestyle modification and pharmacologic therapy.

Pharmacologic therapy follows the guidelines for the treatment of essential hypertension. The best strategy is to formulate a combination therapy that targets different physiologic mechanisms and accounts for patient comorbidities. Based on either the approved responses of the family members to a given drug or genetic testing in the patient's family, the medication targets the factor related to the primary genetic alteration should be tested first rather than following the general guideline for hypertension treatment, in which the preferred initial drug choices are ACE inhibitor in patients less than 55 years old, or a dihydropyridine calcium channel blocker (CCB) in patients greater than 55 or black patients of any age. These options can then be trialed in combination and titrated as necessary before adding a thiazide, including a recently approved thiazide-like diuretic such as chlorthalidone and indapamide as the third medication. Spironolactone is recommended as the fourth antihypertensive drug.[154,155] Vasodilating β-blockers—that is, carvedilol and labetalol—are the fifth-line drug therapy.[156] Other options include α-blockers, clonidine, methyldopa, and direct vasodilators such as hydralazine or minoxidil. These seldom form part of the routine management and should be prescribed only with expert advice. Adequate monotherapy controls hypertension in 30% of cases.[156] If monotherapy is insufficient, the regimen could be modified by altering dose or adding an additional class of drug. Triple therapy must be optimized before selecting further add-on therapy because optimal dosing and drug selection can see blood pressure normalize in many patients. Patients must be approached in a stepwise manner, beginning with traditional antihypertensive therapy followed gradually by additional agents to reach a quadruple or five-drug compound regimen if necessary. In those who remain hypertensive despite thorough medical management, there are interventional options currently under development, such as renal denervation and carotid sinus stimulation, which are promising but require further research. The primary aim of antihypertensive treatment is to reduce the blood pressure to less than the 95th percentile and to less than the 90th percentile in the presence of comorbid conditions like diabetes, heart disease, or kidney disease.

Familial Diabetes

Risk management of familial diabetes requires continuous medical care with multifactorial risk reduction strategies beyond glycemic control. The management plan should be formulated as a collaborative therapeutic alliance among the patient and family, the physician, and other members of the healthcare team. The management plan should recognize the role of education in diabetes self-management and ongoing diabetes support as integral components of care.

Familial Obesity

The treatment of familial obesity should also focus on changing health behaviors to achieve effective weight management. Studies demonstrate modest weight loss of 5% to 10% with improvement in cardiometabolic parameters. Lifestyle interventions incorporating dietary change, increased physical activity, and decreased sedentary behaviors, with the involvement of family and adoption of a developmentally appropriate approach, should be used as the first line of treatment.

Drug treatment for obesity is an evolving branch of pharmacology. Several antiobesity drugs are under testing. Sibutramine (a centrally acting serotonin/noradrenaline reuptake inhibitor that mainly increases satiety), orlistat (a pancreatic lipase inhibitor that reduces fat absorption by partially blocking the hydrolysis of dietary triglycerides), and rimonabant (a selective antagonist of cannabinoid type 1 receptor) are three examples. When properly used, these medicines contribute to the reduction of body weight and undoubtedly improve cardiometabolic risk factors. Patients who might benefit from antiobesity treatment are those with a BMI ≥30 or 27 to 29.9 kg/m^2.[157] It should be pointed out that the pharmacologic approach is a complement to the behavioral strategy aimed at changing a person's lifestyle. But to treat extreme obesity—that is, in persons with an overweight of more than 100 lb (BMI > 40)—only bariatric surgery can be effective.

SUMMARY 179

Atherosclerotic disease is the leading cause of mortality in developed countries. Better understanding of the pathophysiology of atherosclerosis has led to successful therapies and preventative strategies; however, treatment of conventional risk factors for atherosclerotic disease may only prevent 50% of cardiovascular events.[1] A more complete understanding of atherosclerotic risk factors and the atherosclerotic process has the potential to yield improved therapies and preventative strategies. Several less commonly considered areas of investigation have added insights into the development and progression of atherosclerosis.

First, the atherosclerotic lesion itself appears to be more complex than previously described, and the roles of macrophages, vascular smooth muscle cells (VSMCs), and endothelial cells are not as distinct and static as once thought. Second, the effect of hyperlipidemia on atherosclerosis formation appears to involve more than just low- and high-density lipoprotein (HDL) levels. Finally, many less commonly considered environmental exposures seem to be associated with atherosclerosis and conventional atherosclerotic risk factors such as diabetes mellitus (DM; Table 16.1).

THE ATHEROSCLEROTIC LESION

The prevailing model for the progression of the atherosclerotic lesion from fatty streak to mature plaque has been well described.[2,3] In short, injury to the vascular endothelium allows for adherence and transmigration of bone marrow–derived monocytes into the arterial wall. Monocytes within the arterial wall differentiate into macrophages that phagocytose oxidized LDL (ox-LDL), and become lipid-rich foam cells. VSMCs within the arterial media migrate toward the luminal surface of the plaque to form a fibrous cap. The degree of inflammation, lipid content, and fibrous cap thickness within the lesion affect the stability of the plaque.

Recent evidence suggests that the roles of endothelial cells, VSMCs, and macrophages may not be as static as suggested by this model. Under atherogenic conditions, endothelial cells can transition into fibroblast-like cells, while VSMCs can transition to an inflammatory phenotype resembling macrophages.[4] The transition of endothelial cells into a fibroblast-like cell was first shown in cardiac fibrosis.[5] The role of endothelial

Abstract

Conventional atherosclerotic risk factors do not fully account for the development of atherosclerosis and atherosclerosis-related morbidity. Many less commonly considered environmental exposures seem to be associated with atherosclerosis and conventional atherosclerotic risk factors such as diabetes mellitus. The atherosclerotic lesion also appears to be more complex than previously described, and the roles of lipids, macrophages, vascular smooth muscle cells, and endothelial cells are not as distinct and static as once thought. Better understanding of the atherosclerotic lesion and interactions between conventional and less commonly considered risk factors for atherosclerotic development may lead to improved therapies and preventative strategies.

cell transformation in atherosclerosis formation is not clear, but it does highlights the phenotypic flexibility of cells within the arterial wall. On the other hand, the transition of VSMCs into a macrophage-like phenotype seems to be an important component of atherosclerotic plaque formation. Recent evidence suggests that VSMCs do more than proliferate to wall off the atherosclerotic lesion. VSMCs may also differentiate into an inflammatory phenotype that can phagocytose ox-LDL to become lipid-rich foam cells.[6,7] It is difficult to determine the degree to which foam cells are derived from macrophages versus VSMCs in vivo, as the two cells are difficult to distinguish based on traditional cell surface markers. VSMC-derived foam cells express cell surface markers typically seen on macrophages, such as CD68 and Mac-2 antigen, while downregulating typical VSMC markers, such as alpha-smooth muscle cell actin.[8-11] VSMC-derived macrophages may accelerate the pathogenesis of atherosclerosis due to the decreased uptake of ox-LDL, increased cellular apoptosis, and dysfunctional reverse cholesterol transport.[7,12] However, it also appears that premature senescence of VSMCs leads to decreasing thickness of the fibrous cap, increasing lesion size, and a larger necrotic core area.[13] Therefore it seems that VSMCs can undergo both compensatory and pathologic changes during the atherosclerotic process, and it is not clear whether the overall effect of changes in the VSMC phenotype are beneficial or detrimental in atherosclerotic disease. The varying effects of VSMCs in atherosclerotic lesions may be partially explained by the fact that VSMCs are not a homogenous population derived only from the arterial media. Rather, VSMCs can be derived from precursor cells in the bone marrow, adventitia, or arterial media, with VSMC of different origins producing different effects within the atherosclerotic lesion.[14-16] A better understanding of the role of various VSMC populations in the formation of atherosclerosis may potentially lead to new therapies that can enhance the protective effects of VSMCs while decreasing the harmful effects.

HYPERLIPIDEMIA

Hyperlipidemia is one of the most well-known risk factors for atherosclerotic disease and a primary target of pharmacologic intervention for preventing or slowing the atherosclerotic process. High LDL cholesterol and low HDL cholesterol have been the most-studied lipid components related to atherosclerotic disease. Total cholesterol and LDL reduction has been the cornerstone for medical treatment and prevention of ischemic heart disease with an abundance of randomized control trials that attest to efficacy of cholesterol lowering therapy in preventing ischemic heart disease.[17-20] However, additional lipid variables have emerged as risk factors for atherosclerotic heart disease and potential routes of residual risk reduction.

Lipoprotein a

Lipoprotein a, or Lp(a), is an LDL molecule linked to apolipoprotein (a), or Apo(a). There are several different isoforms of Apo(a) and therefore of Lp(a) as well. Lp(a) levels correlate with both primary and secondary cardiovascular events independent of LDL and HDL levels.[21-24] Statin medications and niacin can reduce Lp(a) levels modestly.[25-28] Further reductions in Lp(a) can be achieved through apheresis, which can be used to remove both LDL and Lp(a) particles or Lp(a) particles alone.[29] Apheresis can be considered for persistently high levels of LDL cholesterol despite maximal medical therapy or isolated Lp(a) elevation in the setting of progressive atherosclerotic disease. Given the powerful LDL-lowering effect of statins and newer proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors, apheresis is rarely needed for residual LDL reduction. However, Lp(a)-specific apheresis may be able to prevent progression of angiographically measured coronary atherosclerosis compared with medical therapy alone.[30] Major adverse cardiovascular events (MACEs) are also lower when apheresis is added to maximal medical therapy in patients with progressive cardiovascular disease.[31,32] Given that conventional therapy with statins may reduce only half of cardiac adverse events,[1] there seems to be a potential role for the consideration of lipid parameters beyond HDL and LDL and additional lipid-based interventions.

DIET

A diet low in meats and animal products is a component of a low-fat, low-cholesterol diet. However, there may be a link between diet and atherosclerosis beyond dietary cholesterol intake. Trimethylamine-N-oxide (TMAO) is a proatherogenic molecule that is derived from carnitine, which is predominantly found in red meats, and phosphaditylcholine (PC), which is found in most animal products including dairy and eggs. Intestinal bacteria synthesize trimethylamine (TMA) from

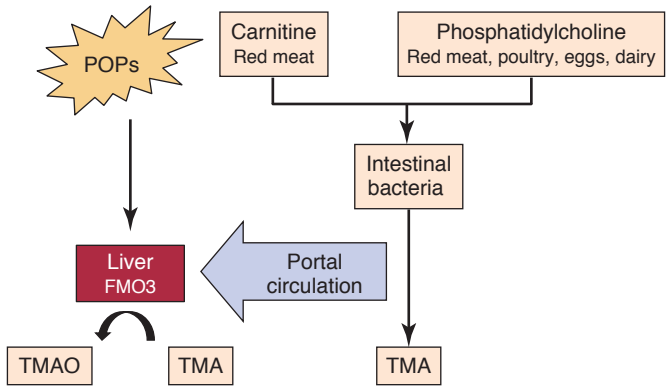

Figure 16.1 Interaction between diet and environment. Carnitine and phosphatidylcholine are converted into trimethylamine (TMA) by intestinal bacteria. TMA is oxidized by the flavin mono-oxygenase 3 (FMAO3) in the liver into trimenthylamine-N-oxide (TMAO). FMO3 is also upregulated by persistent organic pollutants (POPs).

carnitine and PCA. TMA is transported to the liver via the portal circulation, where it is converted to the proatherogenic molecule TMAO by a family of enzymes known as the flavin mono-oxygenases (FMO), particularly FMO3. The FMOs also oxidize a wide range of drugs and environmental toxins, such as persistent organic pollutants (POPs) in pesticides, and there may be a synergistic effect of diet and environmental toxins on atherosclerosis formation (Fig. 16.1).

The production of TMAO from dietary precursors is dependent on intestinal bacterial metabolism and can be suppressed by antibiotic administration.[33] The amount of animal products in the diet affects the intestinal microbiome and the amount of TMAO produced. Vegetarians and vegans produce significantly less TMAO than omnivores, and even short-term changes in diet can alter intestinal microbial populations.[34,35]

Blood TMAO levels are associated with increased rates of PAD, MI, and CAD.[33] Dietary TMA and choline supplementation also induce atherosclerosis in animal models.[36] TMAO levels are also associated with increased mortality or major adverse cardiac events (MACEs) in patients with heart failure, CAD, and renal failure.[37-39] Increased PC consumption has been associated with increased cardiovascular-specific mortality in the Nurses Health Study and the Health Professionals Study (encompassing over 110,000 participants).[40] Finally, carnitine and its immediate breakdown products, which are the TMAO precursors found in red meat, have also been shown to associate with atherosclerotic disease and cardiovascular mortality in both human and animal studies.[41,42]

On the whole, the observational and animal data are highly suggestive of a role for PC, carnitine, and TMAO in atherosclerosis formation. Some studies of meat consumption have suggested that an increased risk of cardiovascular disease and diabetes is not associated with fresh or frozen meat consumption, but is limited to consumption of processed meats.[43-45] However, determining the effect of TMAO production on cardiovascular risk may require assessment of all animal products that lead to TMAO production, not just meat consumption. Finally, there is some seemingly contradictory evidence that L-carnitine supplementation may prevent atherosclerosis in animal models,[46] and L-carnitine supplementation in patients with acute MIs decreases all-cause mortality.[47] Further studies and perhaps randomized interventional trials that assess TMAO as a risk factor for MACEs are needed to further clarify the link between diet, TMAO levels, and atherosclerotic disease.

INFECTION

Efforts to link atherosclerosis with infectious etiologies have spanned decades. Although enthusiasm for an infectious etiology of atherosclerotic disease may have waned after several negative trials of antibiotics, the association and potential causal link between infectious pathogens and atherosclerosis remains an active area of investigation. Numerous viral and bacterial pathogens have been examined as potential causes of atherosclerosis. The most commonly studied viral pathogens potentially linked to atherosclerosis are herpes simplex viruses 1 and 2 (HSV-1 and HSV-2), cytomegalovirus (CMV), Epstein-Barr virus (EBV), hepatitis C virus (HCV), and enteroviruses. The most commonly studied bacterial pathogens are *Chlamydia pneumoniae, Helicobacter pylori,* and the oral pathogens.

Potential mechanisms by which bacteria and viruses may cause atherosclerosis development include upregulation of adhesion molecules in vascular endothelium and foam cell formation.[48,49] The effect of many pathogens on foam cell formation seems partially dependent on Toll-like receptors (TLRs), which are present on inflammatory cells and bind to bacterial and viral pathogen–associated molecular patterns (PAMPs) as part of the innate immune system. However, they also bind endogenous compounds, such as ox-LDL, and cause macrophages to transform into foam cells (Fig. 16.2).[48-51]

Although the association between atherosclerosis and any single pathogen has been inconsistent, the concept of an increased pathogen burden may better explain the potential link between infection and atherosclerosis. The pathogen burden hypothesis postulates that exposure to an increased number of pathogens creates an increased systemic inflammatory response, which promotes the development of atherosclerosis. This hypothesis is supported by studies demonstrating a higher risk of CAD in patients with antibodies to a larger number of pathogens.[52-55]

Viruses

Herpes Simplex Viruses 1 and 2

Data linking HSV infection to atherosclerosis are mixed. A meta-analysis of 17 studies investigating the association of HSV-1 and 7 studies investigating HSV-2 seropositivity showed a significant association between both HSV-1 and HSV-2 with atherosclerotic disease. However, there was significant heterogeneity among studies with regard to the populations studied, the definition of exposure and disease outcomes, and the results.[56]

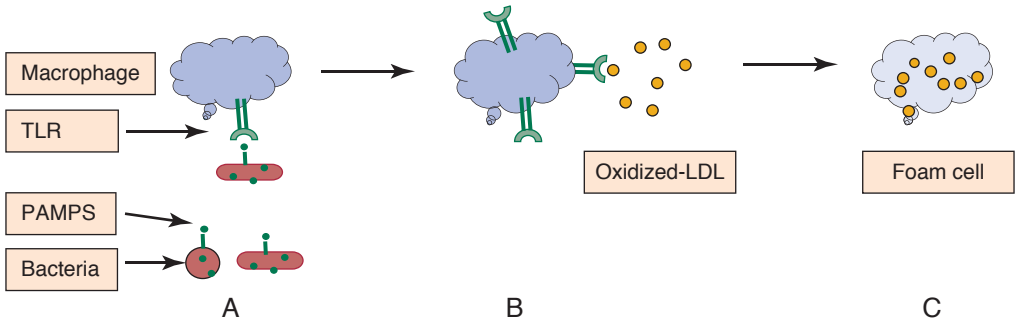

Figure 16.2 Potential mechanism of atherosclerosis formation by infectious pathogens. (A) Pathogens associated molecular patterns (PAMPs) are recognized by Toll-like receptors (TLRs) on macrophages. (B) Macrophages upregulate TLRs, which can also bind oxidized low-density lipoprotein (LDL). (C) Uptake of oxidized LDL by macrophages causes foam cell formation.

Enteroviruses, Hepatitis C, Cytomegalovirus

The association of cardiovascular events and antibodies to enteroviruses is also inconclusive, with some prospective studies showing a correlation between antibody levels and cardiovascular events[57] and others studies demonstrating no association.[58,59] Similarly, HCV infection has been shown to be associated with CAD in one study[60] and to have no association with MI in another.[61] The data regarding CMV infection are mainly composed of small case studies, with a meta-analysis of these studies suggesting a modest association between CMV exposure and CAD.[62]

Bacteria

Helicobacter pylori

H. pylori is best known as a cause of peptic ulcer disease, but it has also been associated with atherosclerotic disease. *H. pylori* DNA can be detected in up to 30% of coronary artery atherosclerotic plaques.[63] Its detection in coronary artery plaques by PCR techniques has been criticized for potential false-positive rates, but use of the internal mammary arteries as a control has lessened this concern.[63] *H. pylori* has been associated with increased risk of CAD, MI, and stroke, with the more virulent CAG A strains possibly conferring the highest risk.[64-68] However, the data are inconsistent, with several large studies not demonstrating a positive association between seropositivity to CAG A–positive *H. pylori* and cardiovascular mortality.[52,69] Inconsistent results may stem from variability in classifying exposure, disease endpoints, and confounding factors such as past and present socioeconomic status.[70]

Chlamydia pneumoniae

Many case-control[71-74] and a few prospective[75,76] studies have suggested an association between seropositivity or high serum titers to *C. pneumoniae* and atherosclerotic heart disease and ischemic stroke. However, other large prospective cohort trials have failed to show an association between seropositivity to *C. pneumoniae* in healthy individuals and the subsequent development of cardiovascular events.[77,78] Differences in the definition of exposure, definition of outcomes, and duration of follow-up in prospective trials may explain some of the differences between these trials.

Despite the possible association between *C. pneumoniae* infection and subsequent atherosclerosis, causation has been difficult to prove. The use of antibiotics effective against *C. pneumonia*, such as azithromycin[76,79-82] or gatifloxacin,[83] has not shown any benefit in the secondary prevention of cardiovascular events. The largest of these trials, totaling almost 16,000 patients,[81-83] had mean follow-up times of 2.0 to 3.8 years and included a fairly lengthy antibiotic regimen that continued for 1 to 2 years.[81,83] However, there may be a benefit in decreasing secondary cardiovascular event rates using broader antibiotic regimens of either azithromycin and metronidazole or amoxicillin and metronidazole[84] and in preventing the progression of carotid plaque using roxithromycin.[85] Interestingly, the benefit of using antibiotics to lower cardiovascular event rates appears to be independent of seropositivity to *C. pneumoniae*, suggesting that additional pathogens or mechanisms may be involved.[84]

Oral Pathogens

Oral pathogens have received substantial interest as a potential cause of atherosclerosis development and progression. Oral bacteria are detected in the blood after normal daily activities such as tooth brushing and therefore have access to the systemic circulation. There is a strong association between periodontitis, defined as chronic inflammation leading to bone loss, and clinical atherosclerosis. Periodontitis is associated with an increased risk of MI[86-91] and ischemic stroke.[91] Patient-specific oral bacteria have also been detected in and cultured from coronary atherosclerotic plaques.[92]

The relationship between oral pathogens and atherosclerosis appears to depend more on the entire oral microbiome rather than any specific pathogens, with an increasing number of oral pathogens exerting a synergistic effect on atherosclerosis development.[55] However, although the association between periodontitis and atherosclerosis is well established, causality is not clear.

The benefit of treating periodontitis with regard to cardiovascular events has been inferred through changes in cardiovascular disease biomarkers, such as C-reactive protein (CRP) levels but not demonstrated through decreases in clinical

endpoints, such as MI or stroke. Results of individual trials are mixed, with some showing no benefit in CRP and interleukin-6 (IL-6) reduction[93,94] whereas others demonstrate CRP and IL-6 reductions with periodontal therapy regimens.[95,96] Reductions in CRP levels occur regardless of whether antibiotics are added to the mechanical treatment of periodontitis, but the two modalities may exert synergistic effects.[95,97,98] Finally, the PAVE study[99,100] evaluated the effect of periodontal treatment on secondary prevention of cardiovascular events. This study did not show any benefit in CRP levels or cardiovascular event rates from treatment of periodontitis. However, a large portion (48%) of the "control group" also received treatment for periodontitis, and the treatment arm sustained only a short-term, modest improvement in the participants' periodontal disease status. Therefore despite the association between periodontitis and atherosclerosis, it is not known whether periodontitis causes atherosclerosis or if treatment of periodontitis will decrease major adverse cardiac events.

ENVIRONMENTAL TOXINS

Persistent Organic Pollutants

Emerging evidence suggests that some long-lasting environmental toxins, collectively known as POPs, are associated with both atherosclerosis and type II DM. POPs include many industrially produced compounds such as herbicides and dioxins. The toxic effects of 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), the dioxin contaminant in the Agent Orange herbicide used during the Vietnam War, are well characterized, and the toxic effects of all other dioxins are expressed in relation to that of TCDD. TCDD is found as a by-product of industrial waste incineration, a contaminant in herbicides, and a by-product of pulp and paper mills and metal production.[101] Dioxins are highly lipophilic substances that accumulate in the fat stores of animals and humans due to their long biological half-lives of 7 to 11 years.[102,103] Polychlorinated biphenyls (PCBs) are another well studied class of POPs with similar mechanism of action and disease associations as dioxins.

The National Academy of Science, Engineering and Medicine routinely examines evidence linking POPs to diseases, including ischemic heart disease, stroke, and type II DM. In 2000 this institution's report on veterans and Agent Orange exposure stated that there is "limited or suggestive" evidence of an association between these chemicals and type II DM, ischemic heart disease, hypertension, and stroke.[104] Subsequent updates of this report at 2-year intervals have upheld this conclusion, although not all individual studies confirmed the association between these chemicals, atherosclerotic disease, and DM.[98,105,106]

More recent studies have also supported the association between POP exposure, atherosclerotic disease, DM II, and metabolic syndrome. They have demonstrated that both estimated exposure and blood level concentrations of POPs are associated with type II DM and serum glucose abnormalities in military veterans.[107-110] Many studies also show an association between occupational and environmental exposure to POPs and DM,[111-117] although others show mixed results or no such association.[105,106,118,119] In addition, exposure to POPs appears also to be associated with metabolic syndrome and stroke.[110,118,120]

The aryl hydrocarbon receptor (AhR) is the most studied mediator of the proposed mechanism by which POPs exposure exerts toxic effects, including the development of type II DM. POPs can bind the AhR and cause downstream effects affecting the regulation of the cell cycle and promoting inflammation. There is also an AhR-independent pathway that affects results in the upregulation of inflammatory mediators by altering intracellular concentrations of calcium ions.[121,122] Another mechanism by which some POPs can contribute to atherosclerosis is via the upregulation of flavin monoxygenase-3 (FMO3), the hepatic enzyme responsible for producing the proatherogenic compound TMAO from dietary precursors (see the earlier section titled "Diet"). Exposure to some POPs has recently been shown to cause upregulation of FMO3 as well as increased TMAO production in response to PC supplementation,[123] indicating that diet and environmental contaminants may synergistically lead to atherosclerotic disease (see Fig. 16.1).

Heavy Metals

Heavy metals are another source of environmental contaminants that may negatively affect cardiovascular health and promote atherosclerosis. Activities such as the burning of coal, municipal waste incineration, smelting, and the production of paper have led to the accumulation of arsenic, cadmium, and mercury in the environment.

Arsenic

The contamination of drinking water with arsenic is a major problem in the developing world. Blood arsenic levels are associated with multiple atherosclerotic risk factors, such as DM II and hypertension. Initially, only high levels of exposure and prolonged exposure times were associated with DM II[124]; however, arsenic seems to be associated with DM II even at "low" levels of 50 to 100 μg/L in drinking water.[125,126] There is also an association between levels of arsenic in blood and urine and hypertension (HTN).[118,127,128] Exposure to arsenic is also linked with coronary artery disease, stroke, and PAD.[129]

Cadmium

Cadmium exposure can occur through the ingestion of contaminated vegetables or smoke inhalation. The association of between cadmium exposure and tobacco smoke had previously made it difficult to determine whether cadmium exposure is linked with atherosclerosis independent of exposure to tobacco.[130] However, subsequent studies have demonstrated that cadmium exposure is associated with an increased incidence of MI, stroke, CAD, and PAD independent of smoking status.[131-133]

Cadmium levels may also affect the progression of atherosclerotic plaques, with higher cadmium levels being associated with the progression of carotid atherosclerois.[134] High levels of cadmium in symptomatic carotid plaques and the association between cadmium levels and the increased density of macrophages in carotid plaques has led some investigators to suggest that cadmium exposure can affect plaque behavior and stability

as well.[135,136] The association between cadmium exposure and atherosclerotic disease may be more pronounced in women than in men.[131,133] Potential mechanisms by which cadmium exposure can lead to atherosclerosis may include disruption of vascular endothelial integrity and endothelial cell junctions[137,138] as well as free-radical production and the depletion of endogenous free-radical scavengers.[139,140]

Mercury

Mercury vapor from the burning of fossil fuels, waste incineration and other industrial causes is eventually deposited in lakes, rivers, and oceans, where it can be converted to organic methyl mercury. Methyl mercury bioaccumulates in aquatic life, especially large predatory fish, such as shark, swordfish, and tuna.[141] The protective effect of fish consumption on cardiovascular health due to omega-3 polyunsaturated fatty acids, has the potential to obscure some of the detrimental effects of exposure to organic mercury. However, a large, prospective study of a Finnish population has demonstrated a strong association between levels of mercury in hair and MI and death from CAD at 6-, 10-, and 14-year follow-up intervals.[142-144] In addition, mercury appears to attenuate the protective effect of omega-3 fatty acids on the incidence of MI.[143,144] However, not all studies have corroborated the association between mercury levels and CAD.[119,145-147]

Air Pollution

Air pollution from automobiles and industrial production consists of free radicals, reactive aldehydes, and particulate matter. The association between air pollution, atherosclerosis, and atherosclerotic risk factors is controversial. There are methodologic challenges, such as quantifying the length and intensity of pollution exposure, accounting for confounders, and determining the true rates of outcomes. However, overall, multiple studies suggest an association between air pollution and the development of DM II.[148-154] In addition, the association between air pollution exposure and DM may be exaggerated in women and nonsmokers.[148,150,154] Increased exposure to air pollution is associated with increased levels of high-sensitivity CRP (hsCRP) and other inflammatory markers[155-157] as well as an increased prevalence of coronary artery disease, stroke, ischemic heart disease, and congestive heart failure.[149,158]

Multiple theories exist regarding potential mechanisms by which air pollution can cause atherosclerosis. Animal and human studies demonstrate increased markers of systemic inflammation, insulin resistance, and activation of the innate immune system through the activation of TLRs.[159–162] Additionally, free-radical stress from air pollution has also been linked to signs of mitochondrial dysfunction, which may be associated with atherosclerosis through increased intracellular oxidative stress, mutations in mitochondrial DNA, and decreasing metabolic rates due to reduced mitochondrial numbers.[160]

SUMMARY

There continues to be progress in understanding atherosclerosis and its risk factors. The behavior of the atherosclerotic lesion, the role of various cells within the atherosclerotic lesion, and the effect of hyperlipidemia are more complex than previously demonstrated. Many less commonly considered factors such as infection and environmental exposures may also contribute to atherosclerotic disease. As our understanding of the links between diet, infection, environmental exposures, and traditional atherosclerotic risk factors expands, there will be opportunities to develop new therapies and preventive strategies through improved pharmacotherapy and public health measures.

The 21st century has ushered in a number of changes in the distribution of vascular disease worldwide, primarily due to demographic changes and trends in atherosclerotic risk factors. These global trends require concerted efforts at the patient, provider, and public health level to adequately care for the increasing burden of vascular disease worldwide. Similarly, significant advancements in the understanding of ethnic differences in the epidemiology of vascular disease, delivery of care, and outcomes of treatment modalities have also been made in the past decade. The disparities identified have prompted the development of a number of strategies to improve the care of the diverse population of patients with vascular disease.

INTERNATIONAL TRENDS

Globally, atherosclerosis is a leading cause of vascular disease, including ischemic heart disease (IHD), ischemic stroke, and peripheral arterial disease (PAD). Based on large-scale population-based studies, there is an increased burden of disease resulting primarily from the increasing trends of risk factors of atherosclerosis, primarily smoking and diabetes. A multifaceted approach including environmental and legislative interventions for health promotion, primary intervention, and access to affordable evidence-based evaluation and treatment of major risk factors are required to combat the growing burden of vascular disease worldwide.

Risk Factors

Smoking

There are currently more than 1 billion smokers worldwide.[1] Fortunately, the global prevalence of daily tobacco smoking has declined over the past 30 years but varies by gender and region (Fig. 17.1).[2] Men smoke more than women in all regions, with the largest disparity between the genders in the Western Pacific region and lowest in the Americas. Regionally, the highest smoking prevalence is in the European region, with nearly 30% daily tobacco use, followed by the Western Pacific (including China), Southeast Asia, Americas, then Eastern Mediterranean regions. The only region with smoking prevalence less than 10% is Africa.[1] The last quarter of the 20th century saw an increase in smoking in a number of developing regions, including parts of Latin America, the Eastern Mediterranean, and Southeast Asia.[3]

More than 6 million people die from tobacco use and exposure each year, which is projected to increase to 8 million by 2030. Smoking is estimated to cause nearly 10% of cardiovascular deaths worldwide. The highest proportion of cardiovascular deaths attributed to smoking is observed in North America (22%), Eastern Europe (17%), Western Europe (13%), and Southeast Asia (10%). Based on gender, the effects on men have demonstrated a relative risk of 1.6 for IHD mortality and 1.6 for stroke morality among current smokers compared with

Abstract

The 21st century has ushered in a number of changes in the distribution of vascular disease worldwide, primarily due to demographic changes and trends in atherosclerotic risk factors. These global trends require concerted efforts at the patient, provider, and public health level to adequately care for the increasing burden of vascular disease worldwide. Similarly, significant advancements in the understanding of ethnic differences in the epidemiology of vascular disease, delivery of care, and outcomes of treatment modalities have also been made in the past decade. The disparities identified have prompted the development of a number of strategies to improve the care of the diverse population of patients with vascular disease.

never-smokers.[4] Among women, current smokers were found to have 3 times the risk of mortality from IHD, 3 times increased risk of stroke mortality, and 6 times increased risk of death from aortic aneurysm compared with never-smokers.[5] Looking forward, it is expected that the countries with both the highest smoking prevalence rates and high consumption rates (>20 cigarettes per day) will likely face the greatest health consequences among current smokers: China, Greece, Ireland, Italy, Japan, Kuwait, Korea, Philippines, Uruguay, Switzerland, and Russia.[2]

Diabetes

The global epidemic of diabetes is expanding as rapidly growing populations, particularly in India and China, adopted Western lifestyles. These studies projected that the number of adults worldwide with diabetes will more than double from 2000 to 2030 due to the combined forces of improved survival from communicable diseases, abundance of food, and less physically demanding lifestyles.[6] As of 2004 the WHO estimated the prevalence of diabetes mellitus at 220.5 million, with the highest prevalence in the Western Pacific region and lowest in Africa (Fig. 17.2). By 2008 an estimated 10% of adults older than 25 years were living with diabetes worldwide.[1] Population growth and aging alone accounted for 70% of the 198 million new cases of diabetes between 1980 and 2008.[2] The prevalence of diabetes is relatively consistent among income groupings of countries, ranging from 8% in low-income countries to 10% in upper-middle-income countries.[1] The highest prevalence rates (>20%) were found in a mix of low- and high-income countries (HICs): Marshall Islands, Kiribati, Saudi Arabia, Cook Islands, and Samoa.[2] Large-scale meta-analysis of prospective observational studies quantified that diabetes mellitus increases vascular mortality rates by a factor of 2.[7] Therefore these regions with the greatest increase in diabetes prevalence can also anticipate an associated increase in vascular morbidity with its associated costs as the population ages.

Ischemic Heart Disease

IHD is the leading cause of death from noncommunicable diseases worldwide. In 2010 the highest mortality rates from IHD were reported for Eastern Europe (including Russia) and Central Asia, with these regions demonstrating nearly 10 times the mortality rate observed in the regions with the lowest rates: the high-income Asia Pacific region and Eastern Sub-Saharan Africa.[7]

Globally, the age-standardized incidence of acute myocardial infarction (AMI) and prevalence of angina and ischemic heart failure decreased from 1990 to 2010. Regionally, the greatest decline in age-standardized incidence of AMI during this period was observed in Australasia, Western and Central Europe, and North America high-income regions. However, Eastern Europe was noted to go against the trend of worldwide decline in age-standardized incidence of AMI, demonstrating an increased incidence of 62 per 100,000 in males and 17 per 100,000 in females during this time period.[8]

Cerebrovascular Disease

In 2004 the World Health Organization estimated a worldwide incidence of 9 million strokes per year, with the greatest incidence in populations of the Western Pacific (3.3 million), Europe (2 million), and Southeast Asia (1.8 million). Stroke incidence was lowest in the Eastern Mediterranean (0.4 million), followed by Africa (0.7 million) and the Americas (0.9 million).[9] The global trend in age-standardized incidence of stroke indicated a decrease from 1990 to 2010 by 12% in HICs but suggested an increase of the same degree in low- and middle-income countries (LMICs) (Fig. 17.3).[10]

Stroke is the second leading cause of death worldwide. Stroke-related mortality and disability-adjusted life-years (DALYs) lost also increased over the past 2 decades, with most of the burden in LMIC. These trends are represented in Fig. 17.3. Age-adjusted mortality rates for stroke decreased significantly globally and in both HIC and LMIC regions. This discrepancy between rising absolute numbers of stroke mortality and decreasing age-adjusted mortality rates for stroke globally can be explained by a 36% decrease in stroke-related mortality among persons older than 75 years.[10] Measures to improve stroke prevention and care (i.e., smoking cessation programs, blood pressure control, acute stroke units) that have been adopted in

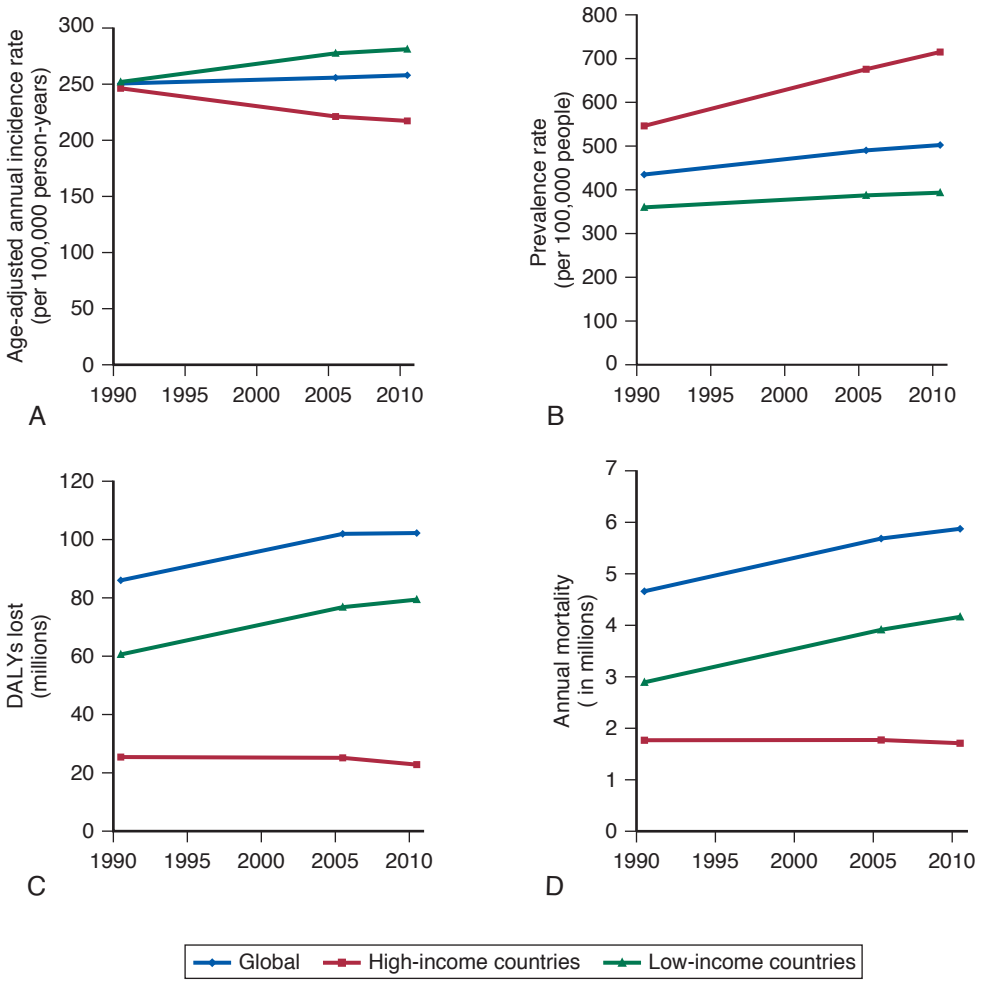

Figure 17.3 **Trends in Global Burden of Cerebrovascular Disease, 1990 to 2010.** (A) Age-adjusted annual incidence rate (per 100,000 person-years). (B) Prevalence rate (per 100,000 people). (C) Disability-adjusted life-years *(DALYs)* lost. (D) Annual mortality.

HIC are the most likely explanation for the decreasing incidence and mortality rates observed in the past 20 years. In countries like China, Russia, and India with very high stroke-related mortality attributable to tobacco use, even a modest reduction in the number of current smokers could prevent millions of deaths.[11]

Peripheral Arterial Disease

Lower extremity PAD, including intermittent claudication and critical limb ischemia, is the third leading cause of atherosclerotic vascular morbidity after IHD and stroke. Globally, more than 200 million people are living with PAD, with more than two-thirds of these persons residing in LMICs. In the past decade the number of people with PAD has increased both in HICs by 13%, and LMICs by 29%.[12] The regions with the highest incidence of PAD as of 2010 were Southeast Asia, LMIC Western Pacific, and Europe, whereas the lowest numbers of people living with PAD were in the Eastern Mediterranean, Sub-Saharan Africa, and HIC Western Pacific regions (Fig. 17.4). The increase in PAD prevalence over the past decade was highest in the elderly, thereby expecting the global prevalence of PAD to grow rapidly, because of an aging world population and increased prevalence of atherosclerotic risk factors, particularly smoking and diabetes.

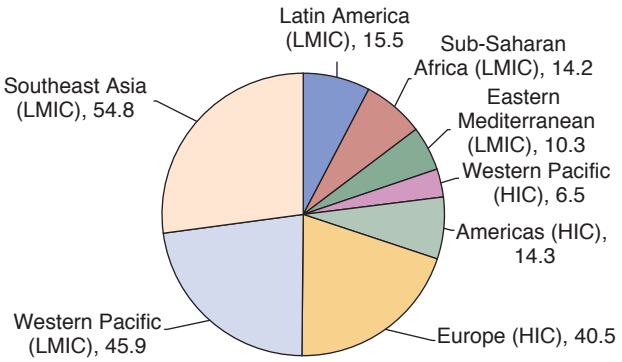

Figure 17.4 Prevalence (millions) of peripheral arterial disease by geographic regions, 2010. *HICs*, High-income countries; *LMICs*, low- and middle-income countries.

In addition, PAD, as opposed to IHD and stroke, has a lower associated mortality, accounting for only 1% to 2% of cardiovascular deaths globally each year.[7] The high-income

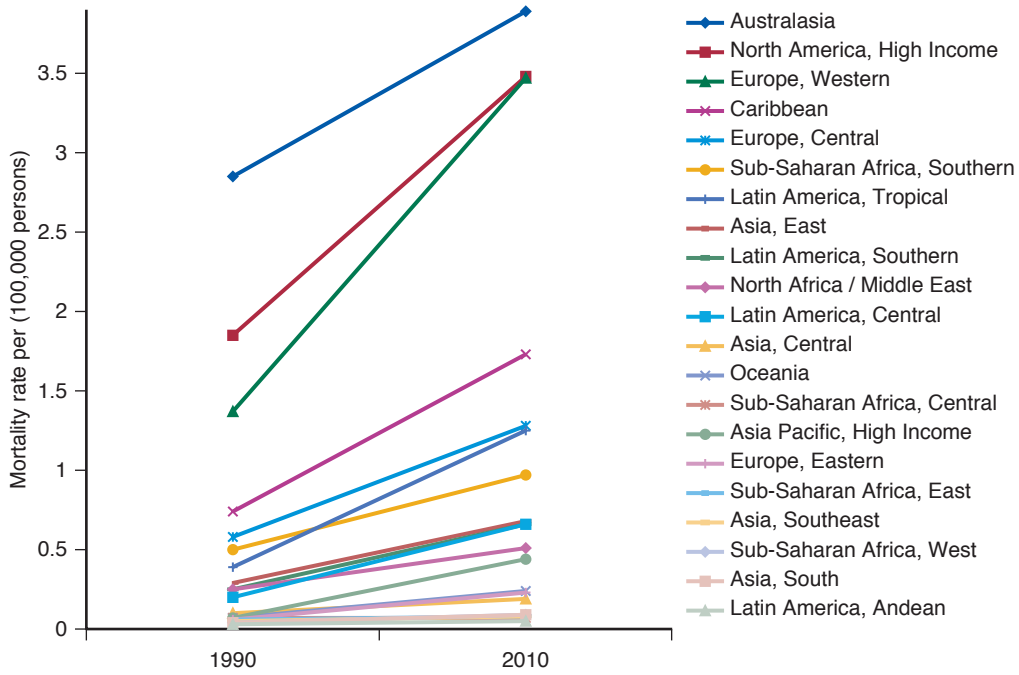

Figure 17.5 Trends in mortality rates attributed to peripheral arterial disease by geographic regions, 1990 to 2010.

regions of Australasia, North America, and Western Europe have consistently demonstrated the highest regional mortality rates from PAD but have also been noted in LMIC regions of the Caribbean, Central Europe, Southern Sub-Saharan Africa, tropical Latin America, and East Asia (Fig. 17.5).[13]

These trends pose a significant public health challenge in LMIC due to both the rapid rise in prevalence of PAD on healthcare resources and the dependence of the population on walking substantial distances for activities of daily living.[12] The limited availability of healthcare services in these regions is predicted to lead to significant number of limb amputations with their associated social needs in the coming decades.

Aortic Aneurysm

A consistent increase in the incidence and mortality from both thoracic and abdominal aortic aneurysm (AAA) were noted in many HICs during the second half of the 20th century, with a prevalence estimated at 5% by the turn of the century.[14] In 1990 to 2010 the highest global prevalence was in Australasia and North America HIC regions despite a decrease of prevalence over the past 20 years, whereas Oceania, tropical Latin America, Asia Pacific HIC, Central Asia, South Asia, and the Sub-Saharan African regions all demonstrated an increase in aortic aneurysm prevalence.[14]

Despite a net decline in the global prevalence of aortic aneurysm, mortality rates have increased worldwide over the same time period: from 2.49 per 100,000 in 1990 to 2.78 per 100,000 in 2010.[15] The highest mortality rates from aortic aneurysms have been consistently observed in the Australasia and Western Europe regions over the past few decades[15]; however, other studies have documented a decline in mortality rates in many HICs, likely due to a combination of comprehensive tobacco use reduction efforts and implementation of targeted screening programs.[14,16]

Global Strategies

A number of strategies have proven effective in decreasing the global burden of vascular disease. Public health measures to treat hypertension, high cholesterol, and diabetes and reduce smoking can further reduce the burden of IHD, cerebrovascular disease, PAD, and aortic aneurysm disease.

Interventions that are highly cost effective, feasible, and culturally acceptable to reduce tobacco use include increases in prices of tobacco products, policies designating smoke-free work and public spaces, mass media campaigns providing education about tobacco dependence and health effects, and bans on tobacco advertising, promotion, and sponsorship. The cost of implementation of these interventions is estimated at less than $0.50 per capita and has been effective when implemented; however, only 180 countries have ratified the WHO Framework Convention on Tobacco Control (Table 17.1). As of 2008, less than 10% of the world population was fully covered by any of these tobacco control reduction measures.[1]

Several evidence-based interventions for the management of diabetes have proven cost effective while improving health[1] and are reviewed in Chapter 12.

Approaches to improve cardiovascular health globally can be categorized as policy strategies, provider-level interventions, or patient-level interventions (Table 17.2). Primary prevention of atherosclerotic disease with a regimen of aspirin, statin, and blood pressure–lowering agents may significantly reduce the risk of mortality in people at high cardiovascular risk for a modest cost. In high-risk patients between 40 and 70 years of

TABLE 17.1 WHO Framework Convention on Tobacco Control

Price and Tax Measures to Reduce the Demand for Tobacco

- Tax increases that result in an increase of the sales price of tobacco products
- Prohibition or restriction of sales of tax- and duty-free tobacco products

Nonprice Measures to Reduce the Demand for Tobacco

- Comprehensive smoke-free policies to provide protection from exposure to tobacco smoke in indoor workplaces, public transport, and indoor and other public spaces
- Regulation of the contents and emissions of tobacco products and the methods by which they are tested and measured
- Disclosure of the constituents and emissions of tobacco products by manufacturers and importers
- Requirement that tobacco product packaging carry large health warnings and messages describing the harmful effects of tobacco (constituting more than 50% of the principal display areas)
- Education, communication, training, and public awareness campaigns
- Comprehensive ban on all tobacco advertising, promotion, and sponsorship
- Provision of support for reducing tobacco dependence and cessation, including counseling, psychological support, nicotine replacement, and education programs

Measures to Reduce the Supply of Tobacco

- Elimination of illicit trade in tobacco products by marking of tobacco packaging to enable tracking and tracing, monitoring of cross-border trade, and confiscation of proceeds derived from illicit trade in tobacco products
- Prohibition of sales of tobacco products to children and limitation of access of underage persons to tobacco products through elimination of distribution of free tobacco products, tobacco vending machines accessible to minors, and the sales of tobacco products individually or in small packets

TABLE 17.2 Comprehensive Strategy to Address Cardiovascular Disease[a]

Policy Approaches (Global, National, Local)

- Comprehensive tobacco control policies
- Food, agricultural, and trade policies that promote consumption of fruits and vegetables
- Environmental policies to limit meat, dairy, and palm oil production
- Urban planning policies to promote active transport to work and leisure-time activity

Healthcare Delivery—Provider-Level Approaches

- Creation of systemic infrastructure by establishment of disease management programs
- Adherence to clinical practice guidelines, with audit and feedback mechanisms to improve quality of care

Healthcare Delivery—Patient-Level Approaches

- Registration, recall, reminding, reinforcing, and review of patients with linked, simplified, stepped-care algorithms
- Fixed-dose combination or polypill therapy to increase adherence to multidrug regimen

[a]Modified from Huffman MD. Cardiovascular health in low- and middle-income countries. *Curr Probl Cardiol*. 2014;39:399–419.

age, providing this regimen has been estimated to avert approximately 20% of cardiovascular deaths over 10 years at a cost of less than $1 per person in low-income countries and less than $3 per person in middle-income countries.[1]

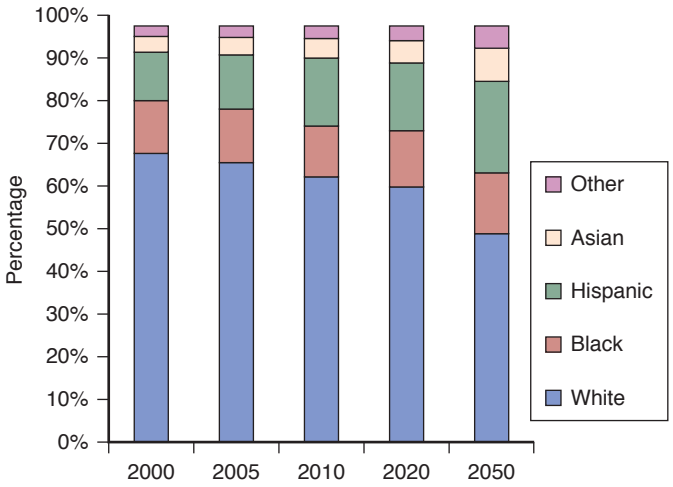

Figure 17.6 Percentages of projected US population by race/ethnicity.

ETHNIC TRENDS

Current demographic trends in the United States indicate that significant changes are occurring in the proportion of racial/ethnic groups represented in the overall population. Compared with estimates in 2000, the proportion of whites is expected to decrease, while proportions of Hispanics and Asians will nearly double by 2050 (Fig. 17.6).[17]

Trends in the Risks for Cardiovascular Disease

Racial and ethnic trends in the risk factors for and occurrence of cardiovascular and related diseases in the United States have been documented in the past few decades, and provide insights in the morbidity and mortality that can be expected in the years to come. It is important to note that the major broad racial/ethnic categories used to describe populations (white, black, Hispanic, Asian) represent genetically heterogeneous groups of diverse origins in these broad categories, resulting from migration and genetic intermixing. Rather than genetic factors, it is the psychosocial factors, particularly nutritional behaviors and disparities in access and delivery of healthcare, that have the most powerful effect on trends of vascular disease within these racial/ethnic constructs. Notable differences in cardiovascular risk factors—obesity, diabetes, hypertension, hypercholesterolemia, and smoking—have all been described.

The epidemic of obesity in the United States is not distributed equally among racial/ethnic groups. The highest obesity rates

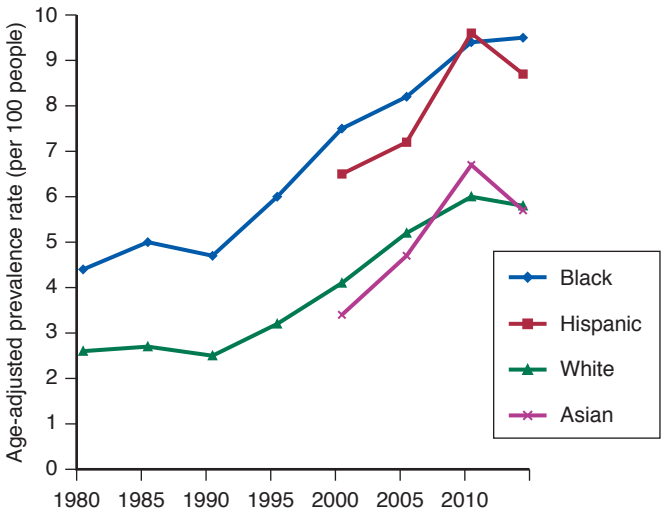

Figure 17.7 Racial/ethnic trends in age-adjusted rates of diagnosed diabetes per 100 persons in the United States, 1980 to 2014.

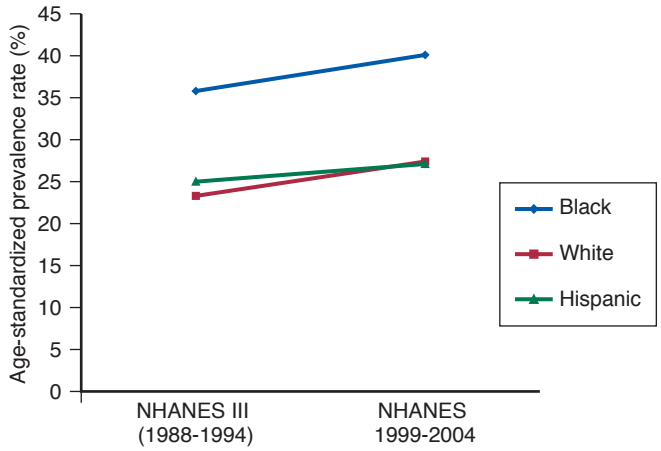

Figure 17.8 Racial/ethnic trends in age-standardized prevalence rates of hypertension in the United States, The National Health and Nutrition Examination Survey *(NHANES)*.

(BMI ≥ 30 kg/m^2) are seen among blacks (47.8%) and Hispanics (42%), followed by non-Hispanic whites (33.4%), whereas Asians have been much less affected (10.9%).[18] A parallel trend is seen in the age-adjusted prevalence of diabetes, which have risen at a similar rate in all racial/ethnic group categories (Fig. 17.7).[19,20] Trends for Asians may not accurately predict diabetes because the cutoff points of BMI indicating high risk for hypertension, dyslipidemia, and cardiovascular morbidity are lower than for other groups (obesity defined as BMI = 27.5 kg/m^2 for Asians).[21] However, after adjusting for age, gender, and BMI, Asians are 60% more likely to have diabetes than whites.[22]

The National Health and Nutrition Examination Survey (NHANES) noted an 18% relative increase in age-standardized prevalence rate of hypertension between the 1988–1994 survey and the 1999–2004 survey, with highest rates among blacks and lowest rates among Hispanics at both time points (Fig. 17.8).[23] Increases in BMI accounted for nearly all of the increase in hypertension in men, and much (but not all) of the increased prevalence in women. Greatest relative increases in prevalence rates were observed among white and black women. Among whites, awareness, treatment, and control of hypertension have improved significantly among men but not women between the survey periods. Blacks had the highest awareness and treatment rates in both surveys, and significant improvements were noted in both measures between the two time periods. However, rates of hypertension control among blacks have consistently lagged behind those of whites. Hypertension awareness, treatment, and control have been consistently lowest among Hispanics (60%, 39%, and 16%, respectively), and no demonstrable improvements have been made from 1988 to 2004.

NHANES has also tracked the prevalence of hypercholesterolemia among whites, blacks, and Hispanics and found that within these groups there has been no significant increase from 1999 to 2006. The prevalence of hypercholesterolemia in NHANES was highest for whites, at 57%, and similar for Hispanics (47%) and blacks (49%).[24] However, significant disparities existed in that blacks and Hispanics were less likely than whites to have had their cholesterol checked by their doctor, and if laboratory values demonstrated hypercholesterolemia, these groups were less likely to report having been told by a healthcare provider that they had high cholesterol, leading to substantially lower rates of treatment and control. Once told about their hypercholesterolemia, blacks, whites, and Hispanics were equally likely to report use of cholesterol-lowering medication.

Cigarette smoking has declined among US adults overall but still remains quite prevalent among American Indian/Alaska Natives (29.2%) (Fig. 17.9). Blacks and whites demonstrate similar rates of tobacco use and decline in prevalence. Despite studies suggesting that Hispanic smokers are half as likely as whites to be advised on or offered assistance with smoking cessation,[25] the largest reduction in smoking prevalence by racial/ethnic group has been seen among Hispanics.[26]

Cerebrovascular Disease

Stroke is a leading cause of death and disability in the United States,[27] with the highest age-adjusted prevalence in blacks (3.9%) compared with Hispanics (2.5%) and whites (2.5%).[25] A number of studies have suggested that there is a decreased utilization of surgical and nonsurgical interventions, as well as worse outcomes following these interventions, among racial/ethnic minority groups. The disparity in treatment of high-grade extracranial carotid artery stenosis with carotid endarterectomy is greatest for Asians compared with whites, where the ratio of intervention in Asians/whites is 0.08, whereas the Hispanic/white disparity ranges from 0.06 to 0.28, and the black/white ranges from 0.36 to 0.39.[27] These differences may result from unmeasured differences in patient preferences or disparities in access to care, the latter of which is substantiated by two large prospective cohort studies of racial/ethnic differences in carotid endarterectomy rates within the VA healthcare system (an equal access system). These studies did not find evidence of racial disparities in CEA use rates.[28,29] Negative outcomes after carotid endarterectomy have also disproportionately affected blacks and Hispanics, because studies have reported a higher rate of postoperative stroke and death in blacks and Hispanics

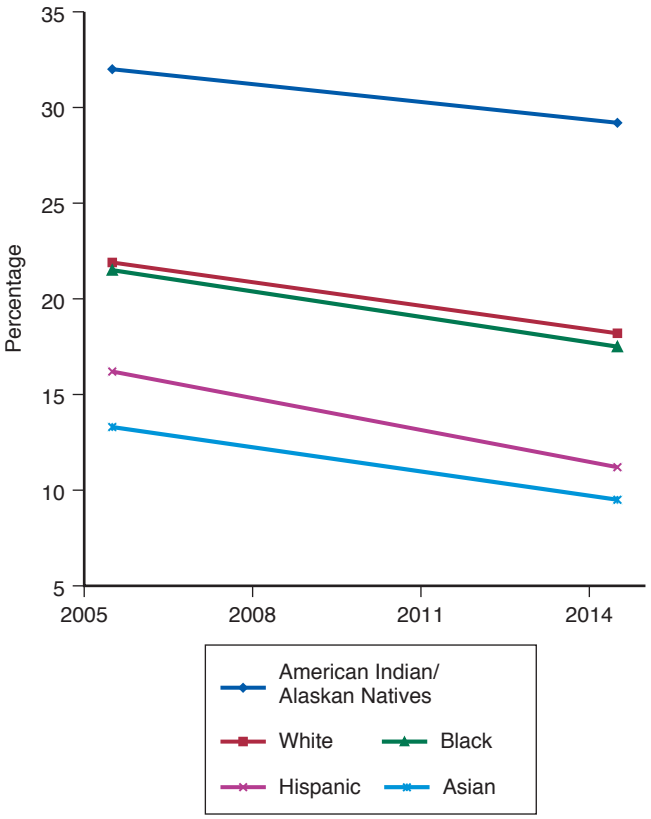

Figure 17.9 Racial/ethnic trends in prevalence of adult cigarette smokers in the United States, 2005 to 2014.

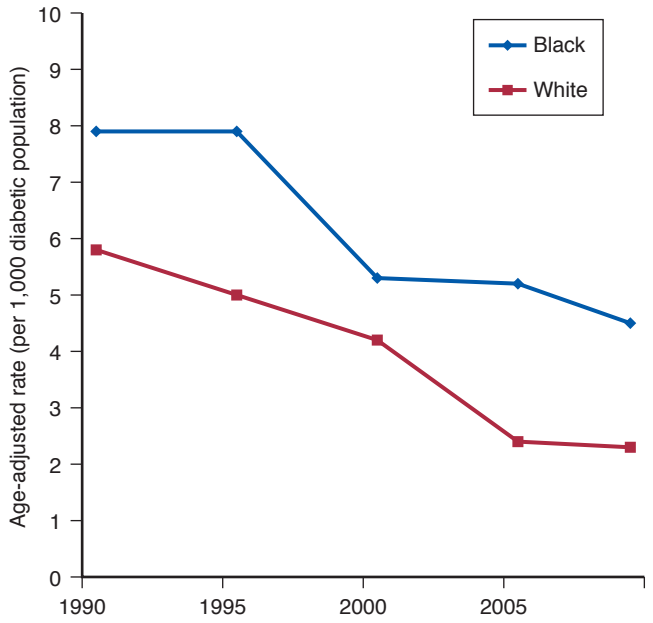

Figure 17.10 Racial trends in age-adjusted hospital discharge rates for nontraumatic lower extremity amputation per 1000 diabetic population in the United States, 1990 to 2009.

compared with whites.[30-32] Limited access to optimal surgical care may play a role in these racial/ethnic differences in outcomes after carotid endarterectomy, because these studies failed to adjust for hospital or surgeon volume.[27]

Peripheral Arterial Disease

The prevalence of PAD in the United States (defined by ankle-brachial index <0.9) is highest among blacks (7.2%), followed by whites (3.6%), Hispanics (2.4%), and Asians (2%).[25] There are more than 3.5 million people living in the United States with diagnoses of diabetes and PAD, and the diagnosis of PAD among diabetics has grown at a more rapid rate for blacks than for whites.[33] Approximately 2.5% of these patients undergo a vascular procedure each year. More white patients with claudication are treated with endovascular intervention compared with blacks and Hispanics.[34] Studies have demonstrated that, although 30-day mortality and complication rates are similar among blacks, whites, and Hispanics, a higher rate of early graft failure has been demonstrated among blacks and Hispanics.[34-36] Primary assisted patency and secondary patency are markedly inferior in black patients, suggesting a more aggressive process of neointimal hyperplasia leading to elevated rates of graft occlusion in the first postoperative year.[35] Biology has been postulated as a contributor to these poor outcomes, but no reliable histologic or genetic data exist to support this hypothesis.

Blacks and Hispanic Americans with PAD have a disproportionately high rate of 2 to 4 times higher nontraumatic lower extremity amputations, compared with whites (Fig. 17.10).[25,37] The incidence of lower extremity amputations is consistently reported as being higher in racial/ethnic minority populations even when controlled for atherosclerotic risk factors, severity of PAD, rate of infection, and income.[38-40] Because the decision to amputate is based in large part on the stage of disease at presentation, disparities in disease awareness, medical management, and access to tertiary care and vascular specialists may be key factors affecting these outcomes. Regarding optimal medical management, black patients with PAD are significantly less likely to have been treated with statins compared with whites.[35] A smaller proportion of black patients with diabetes report receiving recommendations on aspirin use from their physicians compared with whites (61% vs. 76%, respectively).[41] There is also evidence that blacks are less aggressively treated with lower extremity bypass and endovascular interventions for PAD.[37,38,42] Data from the Nationwide Inpatient Sample of patients admitted for PAD confirm that blacks and Hispanics are significantly less likely to undergo open vascular bypass or endovascular revascularization than whites when age, gender, comorbidities, and insurance status are controlled for.[40] Even among patients in the Medicare database, when patient characteristics are controlled for, black amputees were significantly less likely than whites to have undergone at least one lower extremity revascularization in the 2 years prior to major amputation.[37] There is no empiric evidence to suggest that black patients are less inclined to attempt limb salvage prior to proceeding with amputation; rather, differences in presentation or physician decision-making may explain these findings.[37]

Census data have consistently demonstrated higher levels of poverty and lower rates of insurance in black and Hispanic communities. Patients with less coverage face higher out-of-pocket costs for surgery and therefore may be less likely to opt

for intervention. Minorities are often treated in safety net hospitals, where providers may be overworked and less able to provide adequate treatment for patients with severe disease.[42] The role of hospital and physician volume has not been well explored, but data from the National Surgical Quality Improvement Program demonstrate that relatively more procedures performed in black patients involved resident trainees compared with procedures performed among white and Hispanic patients. This factor has previously been identified as a contributor to complication rates due to prolonged operative times.[36] Underinsurance may also lead to disparities in access to follow-up care after vascular intervention, including use of antiplatelet and lipid-lowering therapy postoperatively and surveillance duplex imaging.

Aortic Aneurysm

Population studies have shown that the disease burden of aortic aneurysm is greater among whites than Hispanics and blacks. However, even when the disease prevalence is controlled for, black and Hispanic patients are less likely to undergo elective repair of AAA and more likely to present emergently compared with whites.[43] This disparity may be secondary to lower rates of access to primary care and decreased rates of screening in minority communities. Blacks, Asians, and Hispanics are also more likely to receive treatment of AAA at low-volume facilities compared with whites. Numerous studies have demonstrated a higher morbidity and mortality from elective and ruptured endovascular aneurysm repair among blacks and Hispanics compared with whites, even when patient and facility factors are controlled for.[43-45]

When examining open repair of thoracic aortic aneurysms, blacks have a higher perioperative mortality compared with whites, even when adjusting for hospital volume.[46] Black, Hispanic, and Native American populations are more likely to undergo thoracic endovascular aortic repair compared with whites, with no racial/ethnic differences in complications or mortality rates.[47,48]

Hemodialysis Access

Blacks have more than 3 times the incidence of end-stage renal disease (ESRD) compared with whites.[48] A genetic basis for this difference has been identified. An increased risk for progression of chronic kidney disease (CKD) is seen among patients with high-risk variants of the gene encoding apolipoprotein L1 *(APOL1),* which appear at a high allele frequency in populations of West African ancestry.[49] Response to hypertension treatment does not differ by *APOL1* variant group. The risk of CKD progression among blacks even in the low-risk APOL1 variant group is higher than in whites, suggesting that genetic factors alone do not explain these racial disparities.[50] Limited access to specialist care and lack of medical insurance may explain why black and Hispanic patients with CKD are less likely to receive nephrology care prior to progression to ESRD compared with whites. As a result, white patients have a 22% greater chance than black patients and 32% greater chance than Hispanic patients of initiating hemodialysis with an arteriovenous fistula.[51]

Addressing Disparities

Addressing racial and ethnic disparities in the prevalence, delivery, and outcomes of care of vascular patients in the United States requires a multilevel approach. At the systems level, the Institute of Medicine has identified the operation of healthcare systems and the legal and regulatory climate in which they operate as a primary source of disparities in care. Federal, state, and institutional policies should be directed at changing the culture within healthcare facilities.[52] Addressing these disparities in access to healthcare at the policy level has been shown to reduce racial and ethnic disparities in outcome. In 2006 Massachusetts expanded healthcare coverage to include 98% of residents and noted significant reductions in racial disparities in vascular disease. Prior to healthcare expansion in that state, nonwhite patients were 12% more likely to present with severe PAD, 7% less likely to receive revascularization, and 9% more likely to receive an amputation compared with whites. After the insurance expansion to all Massachusetts residents, these measured disparities by patient race were no longer statistically significant.[53]

At the provider level, bias and uncertainty in clinical communication and decision-making have been identified by the Institute of Medicine as major sources of disparities. Healthcare providers must continue to develop cultural competency to improve clinical communication and therefore the provision of healthcare in cross-cultural situations. Cognitive shortcuts subconsciously introduce bias into medical decision-making. These rapid assessments of patients allow our minds to process complex environmental information in a short period of time by relying on preconceived notions of how a patient is expected to behave. However, they may be detrimental to the choice of the paradigm of care and ultimately affect the medical outcome of the patient.[52] The adherence to evidence-based guidelines allows physicians to rely on logical cognitive processes rapidly, thus reducing reliance on cognitive shortcuts to manage time pressures in the delivery of care. This may be particularly helpful for primary care providers to improve the use of antiplatelet and statin medications for risk reduction in patients with vascular disease. Much like how electronic clinical reminders have been shown to increase detection of AAA,[54] there is excellent evidence to support the use of tracking/reminder systems aimed at providers of racial/ethnic minority patients.[55] Protocols to alert providers to consider referral to a vascular specialist for specific diagnoses can help to address disparities in referral for timely vascular care among racial/ethnic groups.

Patient-level interventions include educational programs to improve patient awareness of interacting with and engaging the healthcare system.[52] Studies suggest that minority patients may be less communicative when the encounter is race discordant and more likely to report medical complaints with race-concordant providers.[56] This may contribute to decreased rates of intervention for claudication and rest pain if these symptoms are underreported by patients. Efforts have recently been made

to increase the presence of minorities in the health profession to facilitate members of minority communities to take advantage of treatment options.[42] Improving patients' knowledge of specialty services offered at high-volume centers particularly for aggressive limb salvage may be helpful to reduce outcome disparities if combined with efforts to improve the ability of patients to take advantage of these opportunities.

This chapter will focus on the role of patient history and physical examination in evaluating the various disease states associated with arterial, venous, and lymphatic pathology. In general, the lower extremities provide a model for the clinical evaluation of patients with peripheral vascular disease and can be used to demonstrate the value of an organized approach to the history and physical examination of the patient.

OVERVIEW OF THE CLINICAL EVALUATION

The patient's chief complaint should be determined; the physical examination should be correlated with the history and should provide a bridge to the pathophysiology of the disease process.[1-3] As an example, aortoiliac obstructive disease will often be associated with more proximal symptoms of claudication involving the buttock, hip, or thigh. If the clinical history is accurate, the examiner should expect that the femoral pulse will be absent or decreased. If it is not, the history and assumptions regarding pathophysiology should be questioned.

When the history and physical examination are completed, diagnostic studies can be ordered, if necessary, to further localize the disease or quantify the extent of the process. Therapy is ultimately driven by the natural history of the disease process and its impact on quality of life, as well as by the patient's risk factors and functional status. A relatively benign natural history or significant and unmodified patient risk factors may indicate an initial course of medical management, risk factor modification, and observation, whereas a threat of tissue loss may indicate the need for a more aggressive intervention.

Abstract

This chapter will focus on the role of patient history and physical examination in evaluating the various disease states associated with arterial, venous, and lymphatic pathology. This work will demonstrate the value of an organized approach to the history and physical examination of the patient.

Clinical History

Typically, the symptoms of arterial and venous disease can be broadly classified into the following categories: pain; weakness; neurosensory complaints, including warmth, coolness, numbness, and hypersensitivity; discoloration; swelling; tissue loss and ulceration; and varicosities. Critical elements include the initial onset of symptoms (acute or chronic); progression or changes since the initial onset; location (unilateral, bilateral, proximal, distal); character or quality of the symptom or complaint; some measure of the extent of disability or limitation; the context or factors precipitating or aggravating the symptoms (activity, position, temperature, menses, vibration, pressure); factors mitigating or relieving symptoms; and associated signs, symptoms, or risk factors. In the assessment of vascular disease, the history is important. As will be seen, variations from the expected history or pattern of findings may suggest additional disease processes that might be included in the differential diagnosis.

Physical Examination

The physical examination links the clinical history and the pathophysiology of the arterial, venous, or lymphatic disease process. The pathology associated with arterial disease can be broadly classified into inflammation-mediated arterial wall changes, arterial wall irregularity or ulceration, stenosis/occlusion, and dilation and aneurysmal degeneration. Veins are normally patent and competent, with functioning valves. Pathologically, intraluminal thrombus can partially or completely obstruct veins. With recanalization of thrombus, veins can become incompetent and lose their valvular function. Valvular incompetence can also develop primarily, independent of previous thrombosis. Finally, if flow through the lymphatic system is disturbed by obstruction, compression, or absence of the lymphatic channels, lymphedema may result.

The physical examination should progress from inspection, to palpation, to auscultation. On inspection, the extremity should be assessed for evidence of skin changes, including atrophy, cyanosis or mottling, pallor, and rubor; hair distribution; and abnormalities in nail growth. The presence and location of edema should be identified and quantified. Tissue loss and ulceration should be noted and fully described, including the location, size, and depth, and the presence of associated cellulitis and inflammation should be documented. Motor function should be documented. On initial palpation, changes in temperature and sensation should be noted and compared with the contralateral extremity. All accessible pulses should be evaluated. At a minimum, pulses should be classified as absent, decreased, or normal. A prominent or widened pulse may suggest aneurysmal degeneration.

Synthesis of the History and Physical Examination

Assessment of a patient with vascular disease is unique in that it is frequently possible to make a diagnosis and predict the underlying anatomic pathology on the basis of history and physical examination alone. This is important because the anatomy of the disease process can often correlate with the location of symptoms. The history and physical examination should be thought of as a system of checks and balances. Symptoms should correlate with the physical examination and suspected pathology.

The Evolving Role of Telemedicine in History and Physical Exam for Vascular Disease

As with many aspects of healthcare, technology has changed the landscape in which we practice. Many fields rely heavily on remote interaction between treating physicians and their patients. While many believe that telemedicine in vascular surgery is a new and evolving concept, it has been studied for more than 20 years. For example, Endean and colleagues described vascular evaluation by teleconference, remote Doppler assessment, and the use of physician extenders in a manuscript published in 2001.[4,5] The barriers they described at the time sound strikingly familiar to the challenges we all face, and electronic health records today comfort with technology and successful execution of technology-based assessment strategies. While this is an evolving strategy, future advances will undoubtedly change the way we perform physical examination in the future.

HISTORY IN PATIENTS WITH ARTERIAL DISEASE

Patients with peripheral arterial disease (PAD) may initially be seen after acute arterial occlusion or with symptoms of chronic arterial insufficiency. Regardless of whether the onset of symptoms is acute or chronic, the chief complaint is generally pain or discomfort. As part of the initial history, it is important to determine the acuteness of onset, the character and intensity of the pain or discomfort, changes in the character and intensity since onset, and its location.

Acute Arterial Occlusion

Acute arterial occlusion may be either embolic or thrombotic in etiology (see Chapter 100 and Chapter 101). Classically, acute arterial occlusion is associated with the six P's: pain, pallor, pulselessness, paresthesias, paralysis, and poikilothermy (meaning changing to room temperature; i.e., a cold extremity). Symptoms can occur within minutes to hours after acute arterial occlusion and are associated with a sudden, dramatic decrease in perfusion. Classically, a patient will complain of generalized pain, severe, and not well localized. The patient will notice a change in the color of the extremity, a decrease in sensation, and coolness to touch. Absent motor function is consistent with severe limb-threatening ischemia.

Acute Arterial Occlusion of the Lower Extremity

As a rule, patients with acute arterial occlusion secondary to an embolic etiology will not have a history of claudication or symptoms suggestive of chronic occlusive arterial disease. Embolic

occlusion of the iliac, femoral, or popliteal arteries is frequently associated with a history of atrial fibrillation, and the patient may have had a previous embolic event. Patients with thrombotic occlusion of the iliac, femoral, or popliteal arteries will frequently have a history of claudication and may have previously undergone arterial bypass or intervention.

Atheroembolism: "Blue Toes Syndrome"

Atheroembolic debris arising from atherosclerotic plaque or ulcerations in the aorta, as well as the iliac, femoral, and popliteal arteries, can result in distal small-arterial occlusion (see Chapter 103). Progressive renal insufficiency can be associated with atheroemboli originating in the thoracic or suprarenal aorta. Patients may have undergone some form of catheter-based procedure involving manipulation of a catheter in the aortic arch or the thoracic and abdominal aorta, or the embolism may be spontaneous.

Acute Arterial Occlusion of the Upper Extremity

While less common, acute arterial occlusion may also occur in the upper extremities. The onset and symptoms are similar to those seen in the lower extremities. Emboli associated with atrial fibrillation or recent myocardial infarction are more common, but may also originate from aneurysmal disease of the arch or upper extremity arteries. Atheroemboli involving the hand or digits may arise from atherosclerotic irregularity and plaque in the aortic arch, or from thrombus associated with a subclavian artery aneurysm.

Chronic Obstructive Arterial Disease

Patients with PAD most commonly have long-standing symptoms. Chronic PAD can be categorized according to the Rutherford classification system of occlusive arterial disease, which encompasses a spectrum of symptoms, beginning with effort discomfort (claudication) and progressing to pain at rest and tissue loss.[6] Claudication is derived from the Latin word *claudicare*, which means to limp or be lame. Thus, claudication involves the lower extremities and is associated with walking. Effort-induced discomfort with activity involving the upper extremity can be associated with stenosis or occlusion of the subclavian and axillary arteries.[7] The Rutherford classification system—a clinical staging system—ranges from asymptomatic (Stage 0), to mild or moderate claudication (Stage 3), to severe (Stage 6).

Lower Extremity Claudication

Claudication symptoms are associated with walking, and relief occurs promptly after the cessation of activity. Complete relief of symptoms should occur within 5 to 10 minutes, and it should not be necessary for the patient to sit to obtain relief. Symptoms may be described as cramping, aching, fatigue, or numbness, and the common denominator is an association with exercise or activity.

Symptoms may have been present for months or years. Anatomically, lower extremity PAD is broadly classified as aortoiliac, femoropopliteal, or tibial. Depending on the location of the arterial obstruction, the patient may have pain in any of the three major muscle groups of the lower extremity: the buttock, thigh, or calf. Symptoms may involve one or more of these muscle groups and may progress from the proximal to the distal part of the extremity or from the calf to the thigh with continued activity. Symptoms will often occur in the muscle group immediately distal to the obstruction. Whereas obstruction of the superficial femoral artery will cause calf discomfort, aortoiliac disease will result in symptoms involving the buttock or thigh. However, patients with aortoiliac disease can also have associated or isolated discomfort of the calf because the calf is the most distal large muscle group and is used extensively in walking. The triad of intermittent claudication, impotence, and absent femoral pulses is associated with aortoiliac occlusion and is often referred to as Leriche's syndrome. In his initial descriptions of the disease process, Leriche also identified widespread atrophy of the lower extremities and a pale appearance of the extremities and foot.[8]

Some patients with PAD confirmed by noninvasive vascular testing may not complain of claudication because comorbid conditions may limit their exercise tolerance. Conversely, other patients may have classic symptoms of claudication but a normal pulse examination. Because initial assessment generally occurs while the patient is at rest on the examining table, it is important to remember that the claudication occurs with walking. In cases when there is a mismatch between the history and physical examination, the physical examination may need to be repeated after exercise.

Conditions Mimicking Arterial Claudication

Classically, claudication is associated with arterial stenosis or occlusion; it is induced by exercise and relieved by rest, and has an onset that is consistently reproducible. Inconsistencies in the history should suggest the possibility of other causes of the patient's symptoms. Included in the differential diagnosis of claudication are musculoskeletal, neurologic, and venous pathologies—the most common of which are osteoarthritis, spinal stenosis, and venous outflow obstruction. Symptoms that occur at rest, occur with standing, or are associated with positional changes may suggest osteoarthritis, spinal stenosis, radiculopathy, or venous claudication (Table 18.1).

Patients with atypical claudication of nonarterial etiology will often note pain with exertion, yet the pain does not stop the individual from walking, may not involve the calves or other major muscle groups in the leg, or does not resolve within 10 minutes of rest.[9-11] Patients may report the same type of pain in both legs regardless of the associated presence of occlusive disease. Frequently, patients with atypical symptoms often report walking impairment because of joint pain or shortness of breath.[9,10]

Ultimately, in the evaluation of an individual with leg pain, the examiner has to be cognizant of the patient's comorbid conditions in an effort to offer the most complete treatment. Newman and colleagues compared answers to the Rose Questionnaire in patients with and without arthritis, all of whom had a decreased ankle-brachial index and exertional leg pain.[11] Both groups had pain in the calf or calves on walking at a normal

TABLE 18.1 Differential Diagnosis of Claudication

Condition	Location of Pain or Discomfort	Characteristic Discomfort	Onset Relative to Exercise	Effect of Rest	Effect of Body Position	Other Characteristics
Arterial Conditions						
Intermittent claudication of the calf	Calf muscles	Cramping pain	After same degree of exercise	Quickly relieved	None	Reproducible
Intermittent claudication of the hip, thigh, buttock	Hip, thigh, buttocks	Aching discomfort, weakness	After same degree of exercise	Quickly relieved	None	Reproducible
Popliteal artery entrapment	Calf muscles	Cramping pain	After exercise	Quickly relieved	Aggravated by extension of the foot	Typically seen in younger patients
Venous Conditions						
Venous claudication	Entire leg, but usually worse in the thigh and groin	Tight, bursting pain	After walking	Subsides slowly	Relief speeded by elevation	History of iliofemoral deep venous thrombosis, signs of venous congestion, edema
Venous compartment syndrome	Calf muscles	Tight, bursting pain	After much exercise (e.g., jogging)	Subsides very slowly	Relief speeded by elevation	Typically, heavily muscled athletes
Neurologic Conditions						
Nerve root compression (e.g., herniated disk)	Radiates down leg, usually posteriorly	Sharp lancinating pain	Soon, if not immediately after onset	Not quickly relieved (also often present at rest)	Relief may be aided by adjustment of back position	History of back problems
Neurospinal root compression	Hip, thigh, buttocks (follows dermatome)	Weakness more than pain	After walking or standing for same time	Relieved by stopping only if position changed	Relieved by lumbar spine flexion (sitting or stooping forward)	Common history of back problems; provoked by increased intra-abdominal pressure
Orthopedic Conditions						
Hip arthritis	Hip, thigh, buttocks	Aching discomfort	After variable degree of exercise	Not quickly relieved (and may be present at rest)	Patient is more comfortable sitting with weight taken off legs	Variable; may relate to activity level, weather changes

pace, while in a hurry, or when walking uphill. However, the patients with arthritis had a higher incidence of pain when standing still or sitting, were less likely to continue walking after the onset of pain, and required more than 10 minutes to obtain relief after they had stopped walking (Table 18.2).

Several prior reports have examined the sensitivity and specificity of the Rose Questionnaire for patients with intermittent claudication. Geoffrey Rose at the London School of Hygiene designed the original questionnaire, which was used to identify patients with intermittent claudication.[12] While the original questionnaire was highly specific (>90%), it was not very sensitive (<70%). Several investigators, including those described above, have worked to refine the sensitivity of this instrument and others like it. These tools are critical in the attempt to discern patients with and without significant claudication from those with other conditions that cause leg pain.

Neurogenic Claudication

Neurogenic claudication due to spinal stenosis can result from a wide range of conditions causing compression of the spinal cord or its nerve roots in the region of the lumbar spine. It may be associated with aging, arthritis, or inherited deformities of the spine. The symptoms of spinal stenosis are frequently inconsistent in their relationship to exercise or activity.

Venous Insufficiency/Venous Claudication

In an individual with venous claudication, the symptoms are associated with a proximal venous obstruction resulting in impaired venous outflow. When an individual begins to exercise or engage in some activity, venous outflow cannot accommodate the increase in arterial flow to the extremity, and high venous pressure develops. The veins become engorged and tense, which

TABLE 18.2 Answers to the Rose Questionnaire by Patients With or Without Arthritis, With a Low Ankle-Brachial Index and Exertional Leg Pain, but Without Positive Rose Questionnaire Findings for Intermittent Claudication (N 234)

	THOSE WITHOUT ARTHRITIS (N 73)		THOSE WITH ARTHRITIS (N 156)		
Question	Number	Percentage	Number	Percentage	*P* Value
Do you have pain in either leg on walking?	73	100	156	100	—
Does the pain begin when standing still or sitting? Answer = No	57	78.1	60	38.5	.001
Do you get this pain in your calf/calves? Answer = Yes	55	75.3	118	76.1	.897
Do you get it if you walk uphill or hurry? Answer = Yes	55	82.1	86	72.3	.133
Do you get it when you walk at an ordinary pace on the level? Answer = Yes	46	62.2	97	65.5	.620
Does it ever disappear while walking? Answer = No	22	29.7	76	50.7	.003
What do you do if you get it while walking? Answer = Stop or slow down	54	72.0	123	83.7	.041
What happens to the pain if you stand still? Answer = Relieved in 10 minutes or less	59	95.2	82	72.6	.001

From Newman AB, Naydeck BL, Sutton-Tyrrell K, et al. For the Cardiovascular Study Research Group. The role of comorbidity in the assessment of intermittent claudication in older adults. *J Clin Epidemiol*. 2001;54:294–300.

causes a bursting sensation or pain that is slowly relieved by rest. The same symptoms can be seen in individuals with chronic venous insufficiency, where persistent venous thrombosis or valvular insufficiency can cause an increase in ambulatory venous pressure that results in chronic lower extremity edema, as well as evidence of postphlebitic skin changes. In these patients, swelling is frequently minimal in the morning but progresses throughout the day with increased activity and dependency of the extremity.

Other Considerations in Young Patients

Claudication of a vascular etiology most commonly occurs in patients 50 years or older. In younger patients, symptoms of effort discomfort can be associated with popliteal artery obstruction from muscular or tendinous entrapment or mucinous degeneration of the artery. Popliteal artery entrapment[13] is a condition commonly seen in patients younger than 50 years (see Chapter 143). Another condition that can be seen in younger patients is chronic compartment syndrome, an overuse syndrome that is often symmetric and bilateral (see Chapter 197).[14,15] The most common complaints are muscle cramping and swelling, with focal paresthesias on the plantar or dorsal aspect of the foot. The pain or discomfort is associated with tightness in the calf and is precipitated by exercise. The patient is often an athlete or a runner with large calf muscles. Muscle swelling, increased compartment pressure, and impaired venous outflow constitute a vicious circle. The pain usually starts after considerable exercise and does not quickly subside with rest.

Rest Pain

Progressive, frequently multilevel atherosclerotic obstructive disease results in ischemic rest pain. In the absence of acute embolic or thrombotic arterial occlusion, the onset of symptoms is gradual. In most cases, the patient will have a history of claudication. With injury or minor trauma, the patient may have associated nonhealing ulcers. Pain at rest represents a significant decrease in circulation and involves the most distal aspect of the lower extremity, which is farthest from the central source of circulation and blood flow. The forefoot and digits are most commonly involved. In the absence of acute arterial occlusion, patients do not have pain in the thigh or calf at rest. The symptoms are classically relieved with dependency because gravity tends to facilitate circulation. The symptoms are aggravated if the patient lies down and elevates the extremity, which further increases the work of pushing blood against gravity to the foot. Patients will complain that the pain awakens them at night or develops soon after lying down. It is not uncommon for patients to be unable to describe the character of the pain. It is easiest to quantify the severity of rest pain relative to the sleep that patients are able to obtain. Early in the course, patients may awaken only occasionally and are able to get back to sleep after sitting up or walking about the room. With time, patients must sleep with their foot constantly hanging over the edge of the bed.

The clinical distinction between rest pain and tissue loss—which represent the two clinical conditions described as critical limb ischemia—is a matter of constant debate.[16] While both

syndromes require urgent attention, the clinical risk for amputation implied by the latter is presumed to be much higher. However, the magnitude of this difference remains a topic of discussion.[17]

Conditions Mimicking Rest Pain

Clinicians should note, and investigate, other etiologies of leg pain, especially when noninvasive tests fail to reveal evidence of PAD. As shown in several examples below, inconsistencies in the history can suggest an alternative diagnosis.

Diabetic Neuropathy

Diabetic patients are prone to a distal arterial occlusive process that frequently involves the tibial and digital arteries and can result in severe ischemia and pain at rest. Diabetic patients can also have associated peripheral neuropathy (see Chapter 12). Diabetic neuropathy can involve the forefoot and digits, and is often described as a burning pain, hyperesthesia, or a "pins and needles" sensation. A careful history should permit differentiation between ischemic rest pain and neuropathy because neuropathic pain is constant and unrelieved by dependency.

Complex Regional Pain Syndrome

Complex regional pain syndrome (or reflex sympathetic dystrophy or causalgia) is described in detail in Chapter 193. Often the pain originates after soft issue or nerve injury. Pain is the most common and prominent feature. The pain is frequently burning and can be worse in the distal aspects of the extremity.

Upper Extremity Effort Discomfort

Effort discomfort involving the upper extremity can be associated with stenosis or occlusion of the subclavian or axillary arteries. Like claudication, symptoms are induced by exercise and relieved by rest. A careful history should allow the examiner to make a distinction between symptoms related to arterial disease and those associated with thoracic outlet syndrome (see Chapter 120). In neurogenic thoracic outlet syndrome, the nerve roots that form the brachial plexus and its trunks are compressed within the scalene triangle (see Chapter 121). While the diagnosis of these patients can be especially difficult, careful attention to physical exam and a reliable history will add to the ability to decide whether or not surgical treatment is the best course.

PHYSICAL EXAMINATION IN PATIENTS WITH ARTERIAL DISEASE

Regardless of the suspected vascular pathology, physical examination of an individual with suspected arterial disease should be complete because of the systemic nature of the atherosclerotic process underlying the arterial disease.

Inspection

The examination begins with the observation or inspection of the extremities. Significant PAD can be associated with atrophy of the calf muscles; loss of hair growth over the lower part of the leg and foot is also a common sign of arterial insufficiency, as is thickening of the nails. With more advanced changes, atrophy of the skin is seen; there is a decrease in subcutaneous tissue, and the skin assumes a fragile, shiny appearance. With severe ischemia, dependent rubor is observed, and the distal part of the leg, the foot, and the digits may appear reddish. On elevating the lower extremity, the rubrous appearance is replaced with pallor.

Ischemic Ulcers

With increasing ischemia, the formation of ischemic ulcers can be observed. These ulcers are small and circinate, with pale, grayish granulation tissue in the base. They are noted specifically on the toes, heels, or fingertips, and if found more proximally, they are usually secondary to trauma. When examining the foot and digits for ischemic ulcers, care should be taken to examine between the toes because skin breakdown and small fissures can frequently begin in these intertriginous areas. Ischemic ulcers are usually painful and can progress to tissue necrosis and frank gangrene. Gangrene can consist of dry eschar, or be "wet" due to purulent or serous drainage at the margins of the eshar. Table 18.3 provides a model that can be used to describe and document ischemic ulcers and wounds in a uniform fashion.

Livedo Reticularis

Close examination of the skin may reveal abnormalities, such as livedo reticularis, which is a discoloration of the skin consisting of macular, violaceous, connecting rings that form a netlike or lacelike pattern. Decreased flow leading to hypoxia and collateral formation are thought to cause the cutaneous findings. Livedo reticularis can be due to PAD and be found in areas of ischemia. More often it is secondary to vasculitis, calciphylaxis, atheroemboli, hyperviscosity syndromes, endocrine abnormalities, infection, or any combination of these causes. In these latter forms, the lesions are usually more diffuse. In situations in which the microcirculation is affected, splinter hemorrhages, focal areas of cyanosis, or punctate violaceous lesions can be indicative of microemboli. These lesions can often be multiple, but they can also occur in single form. The lesions are generally

TABLE 18.3 Documentation of Wound Characteristics

Characteristic	Observations to Be Documented
Wound size	Length, width, depth, area, volume
Undermining	Presence, location, measurement
Appearance	Granulation tissue, sloughing, necrotic eschar, friability
Exudate	Amount, color, type (serous, serosanguineous, sanguineous, purulent), odor
Wound edge	Presence of maceration, advancing epithelium, erythema, even, rolled, ragged

From Lawrence PF, Caswell DR. The wound care center and limb salvage. In: Moore WS, ed. *Vascular and Endovascular Surgery. A Comprehensive Review*. 7th ed. Philadelphia: Saunders Elsevier; 2006:876–889.

small in overall diameter and are frequently found to be painful.[18,19]

Acrocyanosis

While a precise definition of acrocyanosis remains elusive, it is a generalized term used to describe painless, symmetric, cyanotic discoloration of the hands, feet, and occasionally face and central portions of the body, such as the tips of the ears or nose.[20] Episodes of acrocyanosis are often triggered by cold exposure.[21,22] Distinction from Raynaud's-like phenomena is difficult to discern.

Pulse Examination

Palpation of pulses should be performed in a relatively consistent manner and should be complete. Comparing a pulse with that in the contralateral extremity can demonstrate important relative differences. In addition to pulses in the neck and the upper and lower extremities, the abdominal aortic pulse also should be assessed. The carotid pulse can best be palpated in the midneck region, anterior to the sternocleidomastoid muscle. Superficial temporal artery pulses should also be documented, particularly when evaluating temporal arteritis. The subclavian pulse is usually found in the supraclavicular fossa, and the axillary pulse is found lateral to the clavicle along the course of the deltopectoral groove or in the axilla. Upper extremity pulses are examined in the antecubital fossa and at the wrist. Both the brachial and radial pulses can generally be felt with superficial palpation. The ulnar pulse, in contrast, does require firmer palpation because this artery follows a deeper course than the radial or brachial arteries. In the lower extremity, the common femoral, popliteal, dorsal pedal, and posterior tibial artery pulses are examined. The common femoral artery pulse can usually be found in the medial aspect of the groin, just below the inguinal ligament, and can be felt with light palpation in a thin person; but deeper palpation is necessary in an obese individual. Popliteal artery pulses are more difficult to palpate because they are generally located lateral to the popliteal fossa. The patient's knee should be partially flexed and relaxed to allow the examiner to palpate the pulse; firm pressure is required. The posterior tibial artery pulse is typically found in the hollow posterior to the medial malleolus, and usually, gentle pressure allows adequate palpation. Increased pressure, particularly in patients with poor arterial perfusion, can obscure the pulse. The dorsal pedal pulse is generally found on the dorsum of the foot between the first and second metatarsal bones. In 10% of patients, the dorsal pedal pulse is absent congenitally. In patients with suspected popliteal artery entrapment, tibial pulses should also be evaluated during active plantar flexion of the foot or during passive dorsiflexion.

Arterial Aneurysms

During the course of the pulse examination, the size of the artery should be assessed. Typically, an aneurysm is first suspected by a prominence of the palpated pulse. If a prominent pulse is appreciated, the artery should be further evaluated to determine whether aneurysmal dilation is present, and if it is, the size of the aneurysm should be estimated and noted. Peripheral aneurysms are most commonly found in the popliteal, common femoral, and subclavian arteries. The abdominal aorta can be palpated in thin individuals by having them relax their abdominal musculature and then palpating deeply.

Auscultation

After palpation, the arteries should be auscultated. Although, typically, nothing is heard on auscultation, the presence of a bruit, which is indicative of turbulent blood flow, is a marker of underlying pathology. Generally speaking, the pitch and duration of a systolic bruit are correlated with increasing severity of arterial narrowing, but it is difficult to quantify the degree of stenosis. Bruits extending into diastole may suggest the presence of an arteriovenous fistula. Although uncommon in the past, arteriovenous fistulae are being seen with increasing frequency because of the rising number of arterial catheterizations.

Palmar Circulation

In patients with upper extremity arterial disease, it may be of value to assess the patency of the palmar arch. Typically, circulation to the hand is supplied by both the radial and ulnar arteries. These two arteries merge to form the palmar arch. In approximately 10% of the population, the arch is congenitally incomplete. The Allen test can demonstrate the presence of an incomplete arch or occlusion of the arch. In this test, pressure is applied at the wrist to occlude the radial and ulnar arteries. The patient is asked to open and close the hand, making a fist. After several repetitions, the palmar aspect of the hand blanches and becomes pale. With release of pressure over the radial or ulnar artery, normal skin color should return within seconds.

THE ULCERATED LEG

Chronic ulcers can be associated with arterial ischemia, venous stasis, and neuropathy (Table 18.4). The history and physical examination are critical because the causes are not mutually exclusive. A history of arterial insufficiency, including claudication and rest pain, should be sought. Ischemic ulcers and tissue loss represent the far end of the spectrum of arterial disease. Diabetics can have arterial disease and peripheral neuropathy. Neuropathy can predispose diabetic patients to neurotrophic ulcers over the weight-bearing prominences of the plantar surface of the foot. Venous stasis disease can result in characteristic ulcerations, but associated arterial disease can affect healing and influence treatment. All areas of ulceration and tissue loss should be fully characterized with respect to location and size (Table 18.5).

Ischemic Ulcers

Ischemic ulcers are usually painful, and there is likely to be typical ischemic rest pain in the distal part of the forefoot that occurs nocturnally and is relieved by dependency. At first, these ulcers may have irregular edges, but when chronic, they are more likely to be "punched out." They are commonly located distally over the dorsum of the foot or toes but may occasionally

TABLE 18.4 Differential Diagnosis of Common Leg Ulcers

Type	CHARACTERISTIC					
	Usual Location	Pain	Bleeding With Manipulation	Lesion Characteristics	Surrounding Inflammation	Associated Findings
Ischemic ulcer	Distal, on the dorsum of the foot or toes	Severe, particularly at night; relieved by dependency	Little or none	Irregular edge; poor granulation tissue	Absent	Trophic changes of chronic ischemia; absence of pulses
Neurotrophic ulcer	Under calluses or pressure points (e.g., plantar aspect of the first or fifth metatarsophalangeal joint)	None	May be brisk	Punched out, with a deep sinus	Present	Demonstrable neuropathy
Venous stasis ulcer	Lower third of the leg (gaiter area)	Mild; relieved by elevation	Venous ooze	Shallow, irregular shape; granulating base; rounded edges	Present	Lipodermatofibrosis, pigmentation

TABLE 18.5 Characterization of Areas of Ulceration and Tissue Loss

Ulcer Location	Ulcer Etiology	Clinical Appearance	Treatment
Toes, distal forefoot	Arterial Insufficiency	Dry/Wet Gangrene	Revascularization
Weight bearing surface	Diabetic Neuropathy	Callus, "heaped up"	Offloading
Medial malleolus	Venous insufficiency	Beefy red, brown staining of skin	Compression, venous intervention

be pretibial. The ulcer base usually consists of poorly developed, grayish granulation tissue. The surrounding skin may be pale or mottled, and the previously described signs of chronic ischemia are invariably present. Notably, the usual signs of inflammation that one would expect surrounding such a skin lesion are absent, because it is the lack of adequate circulation to provide the necessary inflammatory response for healing that underlies ischemic ulcers. For the same reason, probing or debriding the ulcer causes little bleeding.

Neurotrophic Ulcers

Neurotrophic ulcers are completely painless but bleed with manipulation. They are deep and indolent and are often surrounded not only by acute but also by chronic inflammatory reaction and callus. Their location is typically over pressure points or calluses (e.g., the plantar surface of the first or fifth metatarsophalangeal joint, the base of the distal phalanx of the great toe, the dorsum of the interphalangeal joints of toes with flexion contractures, or the callused posterior rim of the heel pad). The patient generally has long-standing diabetes with a neuropathy characterized by patchy hypoesthesia and diminution of positional sense, two-point discrimination, and vibratory perception.

Stasis Ulceration

The so-called venous stasis ulcer, actually secondary to ambulatory venous hypertension, is located within the gaiter area, most commonly near the medial malleolus. It is usually larger than the other types of ulcers and irregular in outline, but it is also shallower and has a moist granulating base. The ulcer is almost invariably surrounded by a zone containing some of the hallmarks of chronic venous insufficiency—pigmentation and inflammation ("stasis dermatitis"), lipodermatofibrosis, and cutaneous atrophy.

Other Types of Ulcers

More than 95% of all chronic leg or foot ulcers fit into one of the previously described recognizable types. However, leg ulcers may also be produced by vasculitis and hypertension. Vasculitis frequently produces multiple punched-out ulcers and an inflamed indurated base, which, on biopsy, suggests fat necrosis or chronic panniculitis. Hypertensive ulcers represent focal infarcts and are very painful. They may be located around the malleoli, particularly laterally. Long-standing ulcers that are refractory to treatment may represent underlying osteomyelitis or a secondary malignant lesion. Finally, most patients with ulcers identify trauma as an initiating cause. In diabetics, ulcers may also be related to poorly fitting shoes that result in persistent irritation or trauma, or uneven weight distribution on the plantar surface of the foot.

Ulcer Assessment: What's Next

The presence of an ulcer can be a risk factor for amputation. However, as outlined above, there is significant heterogeneity in ulcer types, and with it, heterogeneity in amputation

risk. Categorizing and assessing ulcers has proven challenging, and several wound assessment mechanisms beyond physical examination have evolved. The testing and validation of these assessment systems, which usually involve digital photography, electronic health records, and a rating system, is an active area of investigation.[23]

INTRODUCTION

Clinical evaluation of the patient with suspected venous or lymphatic disease can be challenging due to common presenting symptoms, varied pathophysiology, and the potential for associated comorbidity. Symptoms can range from mild to severe, impairing quality of life and threatening limb viability.

The vascular surgeon is typically consulted in order to establish a diagnosis in addition to developing and initiating a therapeutic plan. The evaluation begins with a history of the present illness. From the history, it should be possible to determine whether the problem is acute or chronic and whether the patient requires immediate intervention or there is time to complete a more extensive evaluation (Fig. 19.1). After obtaining the history, the next step is a complete physical examination, which should allow the practitioner to identify well over 90% of venous and lymphatic syndromes prior to any confirmatory studies. The emphasis of this chapter is on the use of the history and physical examination to identify the various disease states associated with venous and lymphatic pathology and the varying classification systems commonly used in clinical practice. In general, the lower extremities provide a model for the clinical evaluation and can be used to demonstrate the value of an organized approach to the history and physical examination. When appropriate, correlations with related pathology and presenting symptoms in the upper extremities are discussed. There are few areas in

scoring systems

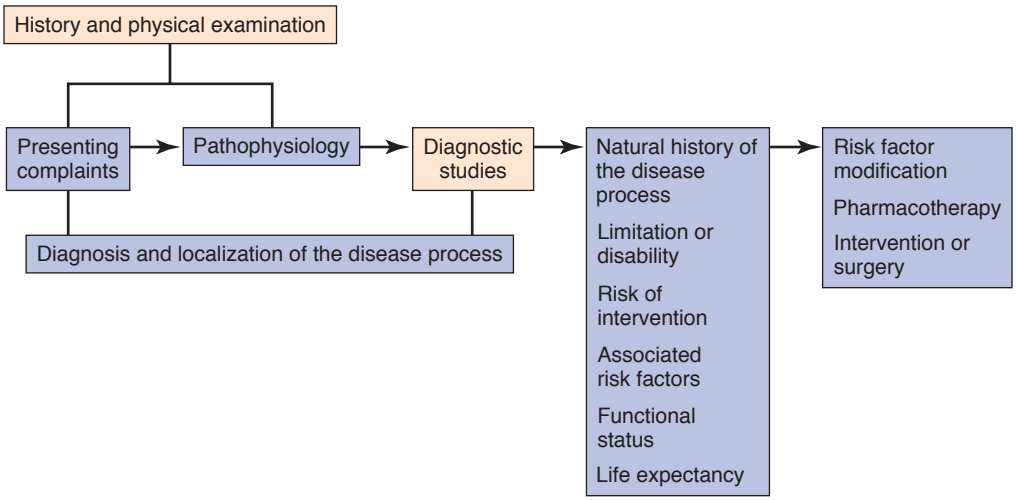

Figure 19.1 This algorithm illustrates the stepwise evaluation and management of patients presenting with arterial, venous, or lymphatic disease. The diagnosis and localization of the disease process involves the history and physical examination and any indicated diagnostic studies. The history and physical examination identify the presenting findings and provide a bridge to potential pathology and pathophysiology. Therapy is dependent upon the natural history of the disease process and its impact on the patient's quality of life as well as the patient's associated risk factors and functional status. (From Rutherford, 7th edition, Fig. 13.1, p. 204.)

medicine where conditions lend themselves so readily to diagnosis solely on the basis of a thoughtful, organized history and a careful physical examination.

Therefore the goal of this chapter is to present in a systematic fashion the classic presentation of the most common venous and lymphatic diseases. By correlating the clinical presentation with an understanding of the anatomy and pathophysiologic alterations, the clinician should be able to make a presumptive diagnosis that can be confirmed with common noninvasive tests and, if necessary, the sparring use of invasive procedures.

ANATOMIC CONSIDERATIONS

The anatomy of the veins and lymphatics provides the basis for understanding the pathophysiology of common disease states. With the primary purpose of the veins to return blood to the heart in a unidirectional fashion and for the lymphatics to carry excess interstitial fluid and particulate matter back to the central circulatory system, any interruption in normal flow patterns forms the basis for venous and lymphatic pathology.

Deep Veins of the Lower Extremity

The deep veins of the leg are bounded within their muscular compartments and enveloping fascia; they run together with the corresponding arterial and lymphatic structures.[1,2] The anterior tibial, posterior tibial, and peroneal veins are paired and coalesce to form the popliteal vein or veins, which may also be paired. The popliteal vein passes superiorly through the adductor canal, becoming the femoral vein (previously referred to as the superficial femoral vein), which then merges with the deep femoral vein to form the common femoral vein. Superior to the inguinal ligament, the common femoral vein becomes the external iliac vein. The external and internal iliac veins merge to form the common iliac vein. The left common iliac vein passes beneath the right common iliac artery and joins the right common iliac vein to become the inferior vena cava.

Superficial Veins of the Lower Extremity

The superficial veins, lying above the muscular fascia, are bounded superficially by the saphenous fascia. The great saphenous vein originates at the level of the ankle and continues medially to the level of the saphenofemoral junction to empty into the common femoral vein. Accessory saphenous tributaries arise from the saphenofemoral junction in variable anteromedial and anterolateral distributions (Fig. 19.2). The small saphenous vein originates over the ankle, lying above the muscular compartment, and is bounded by saphenous fascia superficially. It empties into the popliteal vein at the saphenopopliteal junction (Fig. 19.3). Two anatomically important veins are the intersaphenous vein, connecting the great and the small saphenous veins, and the posterior accessory great saphenous vein, draining the subcutaneous tissue and skin overlying the medial calf.[2,3]

Perforating veins can be found along the length of the lower extremity, with the majority located below the knee.[4,5] These veins traverse the muscular fascia and connect the deep and superficial veins, with flow normally occurring from the superficial veins into the deep venous system. These perforators (Fig. 19.4) are located from the level of the heel to the upper thigh along the medial leg in a narrow band and are often described based on named anatomic location or distance from the proximal medial malleolus.

The remaining veins lying above the muscular fascia and underneath the dermis are best described as communicating veins, which form a variable network that interconnects the named superficial veins.

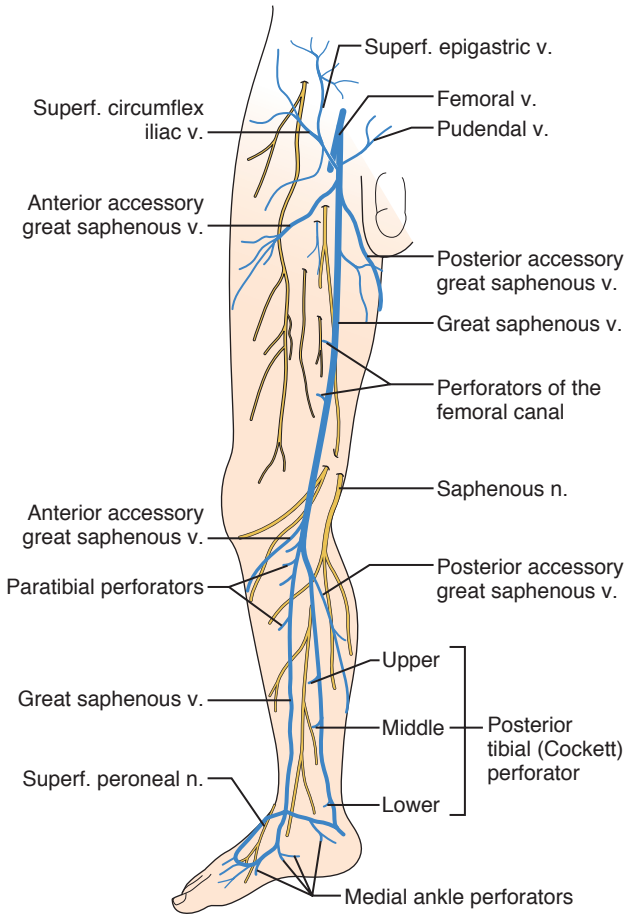

Figure 19.2 Anatomy of medial superficial and perforating veins of the leg. (From Rutherford, 6th edition, Fig. 158–151, p. 2269.)

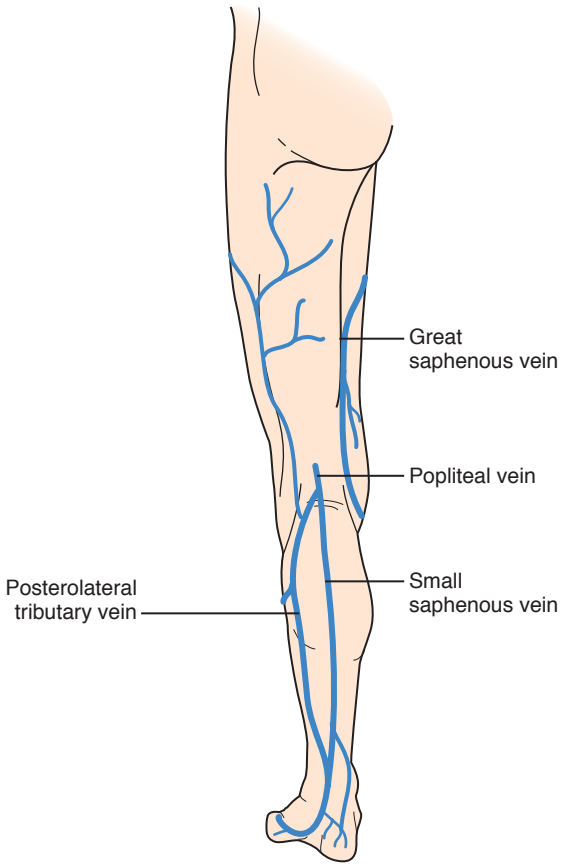

Figure 19.3 The small saphenous vein dominates the posterolateral superficial venous drainage and originates in the dorsal venous arch. At the posterolateral ankle, it is intimately associated with the sural nerve. Note the important posterolateral tributary vein and the posterior thigh vein, which ascend and connect the small saphenous venous system with the great saphenous venous system. (From Mozes G, Carmichael SW, Gloviczki P. Development and anatomy of the venous system. In: Gloviczki P, Yao JST, eds. *Handbook of Venous Disorders*. 2nd ed. London: Arnold; 2001:11–24. (From Rutherford, 6th edition, Fig. 158–152, p. 2269.)

Deep Veins of the Upper Extremity

Similar to those in the lower extremity, the deep veins of the upper extremity run in a paired fashion along with the radial and ulnar arteries, coalescing to form the brachial veins at the level of the antecubital fossa and bounded by the bicipital aponeurosis. Traversing the upper arm, the brachial vein or veins become the axillary vein or veins at the lower margin of the teres major muscle and subsequently the subclavian vein at the lateral edge of the first rib.[6]

Superficial Veins of the Upper Extremity

Superficial veins arising at the wrist include the cephalic and basilic veins, which lie above the muscular fascia underneath the skin and invariably become invested in superficial fascia at the level of the middle forearm. The cephalic vein continues along the lateral aspect of the arm, coursing to the level of the deltopectoral groove and finally emptying into the subclavian vein. Similarly, the basilic vein lies medially at the level of the wrist underneath the skin and courses to the level of the upper arm, where it subsequently pierces the muscular fascia to join the brachial or axillary vein.

Lymphatics of the Lower Extremity

In the lower extremity the lymphatics can be divided into vessels and nodes. There are two sets of lymphatic vessels, which correspond to the deep and superficial veins. The vessels follow the courses of the corresponding veins. There are a significantly increased number of superficial lymphatic vessels as compared with the deep lymphatic vessels. The vessels drain into lymphatic glands or lymph nodes. These are primarily found in the popliteal region, where it is common to see five to seven of them embedded within the popliteal fossa. In the inguinal region 10 to 20 nodes are present and are primarily found in the femoral triangle (Fig. 19.5).[7]

Lymphatics of the Upper Extremity

The lymphatic vessels of the upper extremity also follow the superficial and deep vascular structures. As in the lower extremity, the lymph node numbers increase as one moves proximally, with a significant number at the level of the axillary and supraclavicular region (Fig. 19.6).

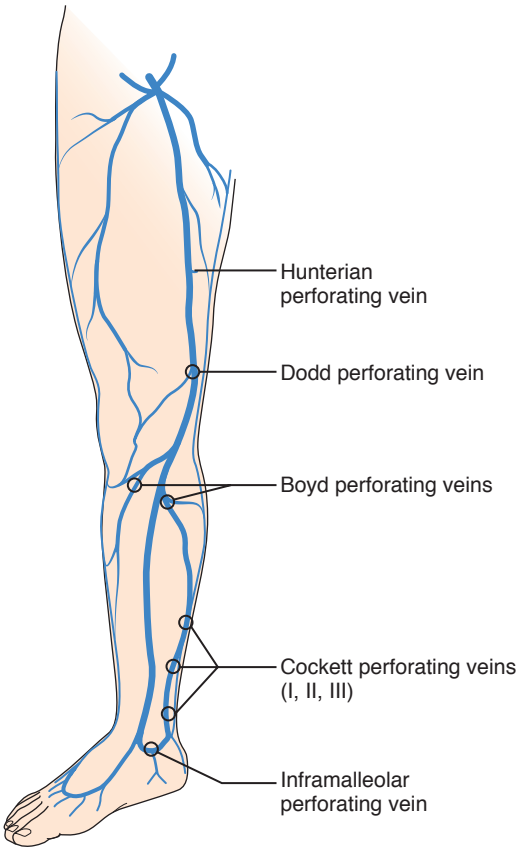

Figure 19.4 The location of the most important perforating veins associated with the great saphenous vein is shown. The Cockett and inframalleolar perforating veins are actually separate from the great saphenous system. The Boyd perforating vein is constantly present, but it may drain the saphenous vein or its tributaries. Perforating veins in the distal third of the thigh are referred to as "Dodd perforators," whereas those in the middle third of the thigh are referred to "Hunterian perforators." (From Rutherford, 6th edition, Fig. 157–152, p. 2252.)

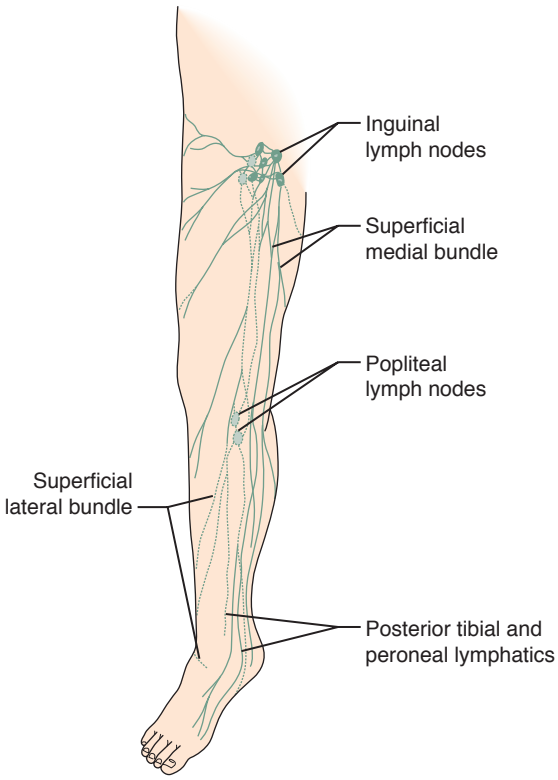

Figure 19.5 The lymphatic system of the lower extremity. (From Rutherford, 6th edition, Fig. 169.4, p. 2434.)

THE CLINICAL EVALUATION

Whether the examiner is familiar with vascular disease or not, most venous and lymphatic problems can be approached in an organized and sequential fashion. First, the presenting complaint should be determined; physical examination should correlate with the presenting history and should also provide a bridge to the pathophysiology of the disease process. When the history and physical examination have been completed, diagnostic studies can be ordered, if necessary, to further localize the disease or quantify the extent of the process. Therapy is ultimately driven by the natural history of the disease process and its impact on the patient's quality of life as well as the patient's risk factors and functional status. A relatively benign natural history, or significant and unmodified patient risk factors, may indicate an initial course of medical management, risk-factor modification, and observation; threat of significant hemodynamic consequences or tissue loss may indicate the need for a more aggressive intervention.

Typically, the presenting symptoms can be broadly classified into the following categories: pain; weakness; neurosensory

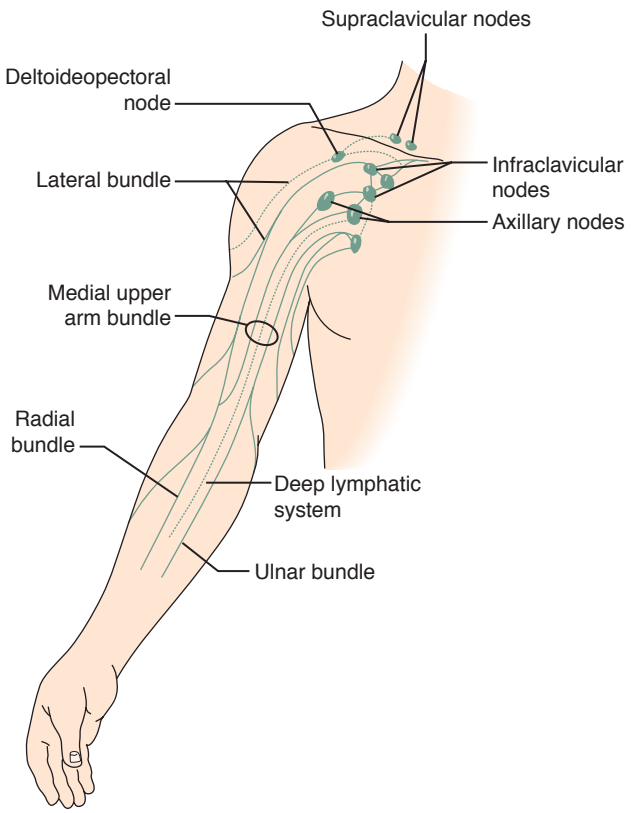

Figure 19.6 The lymphatic system of the upper extremity. (From Rutherford, 6th edition, Fig. 169.6, p. 2434.)

complaints including warmth, coolness, numbness, and hypersensitivity; discoloration; swelling; tissue loss and ulceration; and varicosities. The history should attempt to identify and characterize the location of the symptoms (unilateral, bilateral, proximal, distal); acuity of onset (sudden/gradual); duration; character, including frequency of symptoms and temporal patterns (continuous, intermittent); course or progression (better, worse, unchanged); and factors that aggravate and ameliorate the symptoms, including position, activity, temperature, menses, vibration, and pressure.

The physical examination should progress from observation and inspection to palpation. On observation, the extremity should be assessed for evidence of skin changes, including atrophy, cyanosis or mottling, pallor, and rubor. The presence and location of edema should be identified and quantified by measurement of circumference. Tissue loss and ulceration should be noted and fully described, including the location, size and depth, and presence of associated cellulitis and inflammation. On initial palpation, changes in temperature and sensation should be noted and compared with the contralateral extremity. All accessible pulses should be evaluated. At a minimum, pulses should be classified as absent, decreased, or normal, with use of the Doppler when pulses are nonpalpable, especially in patients with marked edema, to confirm adequate arterial inflow.

The severity of venous diseases can be classified using multiple models that have been shown to be of value for clinical and research purposes. These include anatomic location (Table 19.1; the Clinical, Etiologic, Anatomic, Pathophysiologic (CEAP) classification system (Table 19.2), the Venous Clinical Severity Score (VCSS) (Table 19.3), the Venous Segmental Disease Score (VSDS) (Table 19.4), and the Venous Disability Score (VDS) (Table 19.5).[8-10] Table 19.6 outlines available chronic venous disease–specific and health-related quality-of-life measures.

TABLE 19.1 Segmental Localization of Chronic Venous Disease of the Lower Extremity

Number	Segment		
	Superficial veins (AS1-5)		
1		Great saphenous vein	
2			Above knee
3			Below knee
4		Small saphenous vein	
5	Deep veins (AD6-16)	Nonsaphenous	
6		Inferior vena cava Iliac	
7			Common
8			Internal
9			External
10		Femoral	Pelvic: gonadal, broad ligament
11			Common
12			Deep
13		Superficial	
14			Popliteal
15		Tibial (anterior, posterior, or peroneal)	
16	Perforating veins (AP17-18)	Muscular (gastrocnemius, soleal, other)	
17		Thigh	
18		Calf

Venous Obstruction

Veins are normally patent and competent, with functioning valves. Pathologically, intraluminal thrombus can partially or completely obstruct a vein. Venous obstruction can remain asymptomatic, often associated with isolated tibial vein thrombosis, or can present with a symptomatic painful, swollen extremity. The latter is frequently associated with progression of the obstructing thrombus proximally. Untreated thrombosis, initially with minimal symptoms, can potentially lead to phlegmasia cerulea dolens and limb loss.

Isolated venous obstruction secondary to anatomic compression, such as that associated with May–Thurner syndrome, can result in mild to incapacitating swelling. Symptoms can be associated with compression, acute or chronic venous thrombosis, or postobstructive valvular incompetence and venous reflux.[11]

Deep Venous Thrombosis

Patients with deep venous thrombosis (DVT) can present with varying symptoms and signs, depending on the extent of obstruction, the degree of inflammatory reaction, the location and anatomic extent of the obstruction, and associated comorbidities. DVT most commonly presents with unilateral swelling, discomfort, and a sense of fullness or pressure in the affected extremity. The symptoms are acute in onset and the pain is often characterized as an aching discomfort. There may be a sensation of tightness or heaviness. Patients will note that the symptoms are exacerbated with ambulation or when the legs are kept in a dependent position. Leg elevation, however, will often relieve the discomfort. Hospitalized patients with DVT can be asymptomatic, and approximately half of nonhospitalized

TABLE 19.2 Overall Classification System for Chronic Venous Insufficiency: Clinical, Etiologic, Anatomic, Pathophysiologic (CEAP)

Category	Finding	Classification
Clinical	Asymptomatic	C0
	Telangiectasias, reticular veins, malleolar flare	C1
	Varicose veins	C2
	Edema, no skin changes	C3
	Skin changes (pigmentation, venous eczema, lipodermatosclerosis)	C4
	Skin changes as above with healed ulcer	C5
	Skin changes as above with active ulcer	C6
Etiologic	Congenital: present since birth	EC
	Primary: undetermined cause	EP
	Secondary: known cause (postthrombotic, etc.)	ES
Anatomic	Superficial veins (AS)	
	Telangiectasias/reticular veins	AS1
	Greater saphenous vein	
	Above the knee	AS2
	Below the knee	AS3
	Lesser saphenous vein	AS4
	Nonsaphenous vein	AS5
	Deep veins (AD)	
	Inferior vena cava	AD6
	Iliac veins	
	Common	AD7
	Internal	AD8
	External	AD9
	Pelvic; gonadal, broad ligament	AD10
	Femoral veins	
	Common	AD11
	Deep	AD12
	Superficial	AD13
	Popliteal	AD14
	Tibial; anterior, posterior, or peroneal	AD15
	Muscular; gastrointestinal, soleal	AD16
	Perforating veins (AP)	
	Thigh	AP17
	Calf	AP18
Pathophysiologic	Reflux	PR
	Obstruction	PO
	Reflux and obstruction	PR,O

From Rutherford, 6th edition, Table 6.6, p. 47.

patients presenting with symptoms of DVT will not have venous pathology.[12]

In assessing the patient with suspected DVT, it is most important to determine any predisposing risk factors that may be present. Multiple risk factors can be associated with an increased threat of DVT, including advanced age; prolonged immobility, including hospitalization or recent travel; recent surgery, pregnancy, significant trauma, cancer, a previous history of DVT, or a family history of venous thrombosis and hypercoagulability (see Chapter 38). The presence or absence of risk factors can markedly influence the duration of treatment and the potential need for lifelong anticoagulation.[13,14]

The differential diagnosis can include systemic causes of lower extremity swelling, which generally result in bilateral lower extremity edema. Congestive heart failure and cirrhosis (liver failure) are common systemic etiologies and may also be seen in patients with chronic renal insufficiency. The common denominator among systemic causes of lower extremity swelling is fluid overload or retention. The first manifestation of heart failure is progressive swelling of the legs, but it may also be associated with dyspnea and orthopnea.

Localized trauma or injury is most often associated with unilateral swelling. The differential diagnosis also includes cellulitis, muscle strain or tear, a Baker cyst, hematoma, or dermatitis. Although the diagnosis of DVT can be suspected on the basis of pain, swelling, and associated risk factors, noninvasive imaging remains a necessary adjunct in order to confirm a suspected diagnosis.

In attempts to improve diagnostic accuracy in the case of a patient with suspected DVT, various models for risk stratification have been developed, since the signs and symptoms of DVT are often nonspecific. The most commonly used probability model is that of Wells (Table 19.7) (See Chapter 147). The Wells criteria include both subjective and objective elements, resulting in a score that indicates a low, moderate, or high risk of DVT.[15] The Wells criteria have been prospectively validated and are in use clinically, especially in emergency departments, where routine use of vascular ultrasound is not practical and a low pretest probability is associated with only a 2% to 3% incidence of DVT. Unfortunately the Wells scoring model still incorporates a subjective determination of alternative diagnoses, which, if present, significantly lower the clinical probability of DVT. Similarly, the Caprini Risk Assessment model is specific to surgical patients, factoring in clinical variables based on a point system. This assessment has been validated to be accurate in appropriate populations (Table 19.8).[16,17]

Regardless of the presentation or physical findings, one of the most important factors in the initial assessment of the patient presenting with DVT is the necessity to determine whether there is a proximate cause of the thrombotic event. This allows the provider to classify the event as either a provoked or unprovoked DVT. The duration of anticoagulation is markedly altered in those patients who present with an unprovoked DVT. They are by default considered potentially hypercoagulable, even in the presence of a negative laboratory workup, and consideration for lifelong anticoagulation should be entertained. The American College of Chest Physicians has provided ongoing evidence-based guidelines for the treatment of DVT.[18,19]

DVT may also involve the subclavian and axillary veins in the upper extremity. Onset is typically acute and associated with swelling of the entire arm. There has always been a strong relationship between venous thrombosis and compression of the subclavian vein at the thoracic outlet, and patients will frequently note an association with upper-body exercise and activity (see Chapter 123). More recently, subclavian and axillary

TABLE 19.3 Venous Severity Scoring: The Venous Clinical Severity Score

Attribute	Absent: 0	Mild: 1	Moderate: 2	Severe: 3
Pain	None	Occasional; not restricting activity or requiring analgesics	Daily; moderate activity limitation; occasional analgesics	Daily; severely limiting activities or requiring regular use of analgesics
Varicose veins[a]	None	Few, scattered: branch varicose veins	Multiple: GS varicose veins confined to calf or thigh	Extensive: Thigh and calf or GS and LS distribution
Venous edema[b]	None	Evening ankle edema only	Afternoon edema above ankle	Morning edema above ankle and requiring activity change, elevation
Skin pigmentation[c]	None or focal, low-intensity (tan)	Diffuse, but limited in area and old (brown)	Diffuse over most of gaiter distribution (lower 1/3 of leg) or recent pigmentation (purple)	Wider distribution (above lower 1/3 of leg) and recent pigmentation
Inflammation	None	Mild cellulitis, limited to marginal area around ulcer	Moderate cellulitis, involving most of gaiter area (lower 1/3 of leg)	Severe cellulitis (lower 1/3 of leg and above) or significant venous eczema
Induration	None	Focal, circummalleolar (<5 cm)	Medial or lateral, less than lower	Entire lower 1/3 of leg or more
No. of acute ulcers	0	1	2	>2
Active ulceration;	No	Yes; <3 months	Yes; >3 months, <1 year	Yes; not healed > 1 year duration
Active ulcer, size	No	Yes; <2 cm	Yes; 2-6 cm	Yes; >6 cm (diameter)
Compressive therapy	Not used or not compliant	Intermittent use of stockings	Patient wears elastic stockings most days	Full compliance: stockings and compliant elevation

[a]"Varicose" veins must be >4 mm in diameter to qualify so that differentiation is ensured between C1 and C2 venous disease.
[b]Presumes venous origin from characteristics (e.g., brawny [not pitting or spongy] edema), with significant effect of standing/limb elevation and/or other clinical evidence of venous etiology (i.e., varicose veins, history of deep venous thrombosis). Edema must be regular finding (e.g., daily occurrence). Occasional or mild edema does not qualify.
[c]Focal pigmentation over varicose veins does not qualify.
GS, Greater saphenous; *LS*, lesser saphenous.
From Rutherford, 6th edition, Table 155.3, p. 2235.
Modified from Rutherford RB, Padberg FT, Comerota AJ, et al. Venous severity scoring: an adjunct to venous outcome assessment. *J Vasc Surg.* 2000;31:1307–1312; with permission from Society for Vascular Surgery.

vein thrombosis has been increasingly associated with subclavian vein catheters placed for central access.

Physical Examination

The presence of any swelling or edema should be noted and described. Unilateral or bilateral involvement should be noted, as well as the extent of involvement (i.e., is the entire extremity swollen, or just the calf and foot?). Swelling associated with acute DVT is frequently unilateral. The entire extremity may be swollen in patients with iliofemoral venous thrombosis, while femoropopliteal venous obstruction frequently results in swelling of the distal extremity or calf. The left leg is more commonly affected, as noted in multiple studies of patients presenting with DVT.[20] If there is unilateral swelling, it should also be determined if this results in a measureable discrepancy in the size of the leg relative to the other extremity. In patients with unilateral swelling resulting in a difference in leg circumference of more than 2 cm at the level of the thigh or 3 cm in the calf, the potential for a deep venous thrombotic process is high.[21] In contrast, absence of a significant change in limb circumference is associated with a very low likelihood of a deep venous thrombotic process. Physical examination should also include the joints as well as other skin changes, as joint pain and localized cellulitis are rarely associated with DVT.

The Homans sign describes the association between calf vein thrombus and calf pain with passive dorsiflexion of the foot. Other clinical findings that have been associated with acute DVT include the Bancroft sign, or tenderness on anteroposterior but not lateral compression of the calf, and the Lowenberg sign, which is calf pain associated with inflation of a blood pressure cuff about the calf. Unfortunately these "signs" persist in the literature and within medical documentation despite the fact that none of them are diagnostic of DVT.[12]

Phlegmasia

In the patient with DVT, the extremity may appear cyanotic secondary to venous congestion. Phlegmasia alba dolens, or "milk leg of pregnancy," describes a pale, white extremity, which was frequently seen in the postpartum period. Homans[22,23] attributed the finding to an underlying iliofemoral venous thrombosis. Collateral veins were noted over the upper thigh and abdomen. The swelling was frequently associated with fever as well as pain in the calf, popliteal fossa, or groin. The absence

TABLE 19.4 Venous Severity Scoring: The Venous Segmental Disease Score (Based on Venous Segmental Involvement With Reflux or Obstruction[a])

Reflux[b] Score	Vein(s)	Obstruction[bc] Score	Vein(s)
1/2	Small saphenous	0[d]	
1	Great saphenous	1	Greater saphenous (only if thrombosed from groin to below knee)
1/2	Perforators, thigh	0[d]	
1	Perforator, calf	0[d]	
2	Calf veins, multiple (posterior tibial alone = 1)	1	Calf veins, multiple
2	Popliteal vein	2	Popliteal vein
1	Femoral vein	1	Femoral vein
1	Profunda femoris vein	1	Profunda femoris vein
1	Common femoral vein and above[d] 1 1	2 Iliac vein Inferior vena cava	Common femoral
10	Maximum reflux score	10	Maximum obstruction score[e]

[a]As determined by appropriate venous imaging (phlebography or duplex ultrasonography scan). Although some segments may not be routinely studied in some laboratories (e.g., profunda femoris and tibial veins), points cannot be awarded on the basis of presumption without scanning of the segments for obstruction or reflux.

[b]*Reflux* means that all the valves in that segment are incompetent. *Obstruction* means there is total occlusion at some point in the segment or >50% narrowing of at least half of the segment. Most segments are assigned 1 point, but some segments have been weighted more or less to fit with their perceived significance (e.g., increasing points for common femoral or popliteal obstruction and for popliteal and multiple calf vein reflux and decreasing points for lesser saphenous or thigh perforator reflux). Points can be assigned for both obstruction and reflux in the same segment; this is uncommon but can occur in some postthrombotic states, potentially giving secondary venous insufficiency higher severity scores than primary disease.

[c]The excision, ligation, or traumatic obstruction of deep venous segments counts toward obstruction points just as much as their thrombosis.

[d]Normally there are no valves above the common femoral vein, so no reflux points are assigned to them. In addition, perforator interruption and saphenous ligation/excision do not count in the obstruction score, but as a reduction of the reflux score.

[e]Not all of the 11 segments can be involved in reflux or obstruction; 10 is the maximum score that can be assigned, and the maximum might be achieved by complete reflux at all segmental levels.

From Rutherford, 6th edition, Table 155.4, p. 2236.

TABLE 19.5 Venous Severity Scoring: The Venous Disability Score

0	Asymptomatic
1	Symptomatic but patient is able to carry out usual activities[a] without compressive therapy
2	Patient can carry out usual activities[a] only with compression and/or limb elevation
3	Patient is unable to carry out usual activities[a] even with compression and/or limb elevation

[a]Usual activities = patient's activities before onset of disability from venous disease.

From Rutherford, 6th edition, Table 155.5, p. 2236.

Adapted from Rutherford RB, Padberg FT, Comerota AJ, et al. Venous severity scoring: an adjunct to venous outcome assessment. *J Vasc Surg.* 2000;31:1307–1312; with permission from Society for Vascular Surgery.

of bluish discoloration was attributed to the rapid development of collateral venous flow. Phlegmasia cerulea dolens is associated with extensive proximal venous obstruction and minimal collateralization. The leg is massively swollen and cyanotic in appearance. The affected extremity begins to sequester fluid in the interstitium, and massive swelling ensues. The examiner should perform a bedside Doppler examination to confirm the presence of multiphasic flow in the tibial arteries; the swelling and edema are often so significant that palpation of pulses is rendered useless. As interstitial fluid accumulates within the muscular compartments, findings consistent with compartment syndrome may be present.

A prompt diagnosis of phlegmasia cerulea dolens is critical, as the limb is salvageable with appropriate and aggressive therapy; however, progression to venous gangrene and limb loss in this setting can occur despite maximal medical and surgical therapy.

Superficial Thrombophlebitis

Thrombosis of the superficial veins results in localized inflammation surrounding the affected vein or veins. As opposed to deep venous obstruction, venous hemodynamics in the deep veins of the lower extremity are not usually affected by a superficial thrombophlebitis. Patients who present with superficial thrombophlebitis of the great saphenous vein, however, do have an approximate 10% risk of progression to DVT primarily involving the common femoral vein of the affected extremity.[24]

TABLE 19.6 Quality-of-Life Assessments

Outcome Assessment	Focus on CVD	QoL Score[a]	Construct
SF-36	Generic, applicable to a spectrum of nonvenous and venous diseases	Ascending	36 items Physical and mental health 8 domains
AVVQ—Aberdeen Varicose Vein Questionnaire	Varicose veins, CVD	Descending	13 items Weighted scoring Patient draws varices onto template
CIVIQ—Chronic Venous Insufficiency Questionnaire	General venous	Ascending	20 items Diagnosis based on clinical and subjective symptoms; no objective confirmation of venous etiology
VEINES—Venous Insufficiency Epidemiologic and Economic Study	General venous	Ascending	35 items, 2 categories VEINES-QoL measures the effect on QoL VEINES-Sym measures symptoms
CCVUQ—Charing Cross Venous Ulcer Questionnaire	Venous ulcer	Descending	20 items Venous etiology confirmed with clinical examination and Duplex ultrasonography

[a]Ascending scores indicate that a higher score means a better QoL, whereas a descending score indicates that a lower score has a better QoL.
CVD, chronic venous disease; *QoL*, quality of life; *SF-36*, short form health survey (36 items).

TABLE 19.7 Stratification of Pretest Probability: The Wells Criteria

Clinical Feature	Score
Active cancer (treatment ongoing or within previous 6 months or palliative)	1
Paralysis, paresis, or recent plaster immobilization of the lower extremities	1
Recently bedridden >3 days or major surgery within 4 weeks	1
Localized tenderness along the distribution of the deep venous system	1
Entire leg swollen	1
Calf swelling by more than 3 cm compared with the asymptomatic leg (measured 10 cm below tibial tuberosity)	1
Pitting edema (greater in the symptomatic leg)	1
Collateral superficial veins (nonvaricose)	1
Alternative diagnosis as likely as or more likely than that of deep venous thrombosis	−2

Low probability, ≤0 points; moderate probability, 1–2 points; high probability, 3 points.
From Rutherford, 6th edition, Table 148.3, p. 2151.
Modified from Wells PS, Anderson DR, Bormanis J, et al. Value of assessment of pretest probability of deep-vein thrombosis in clinical management. *Lancet*. 1997;350:1795–1798. Reprinted with permission.

Similar to any thrombotic process, risk factors for superficial thrombophlebitis include advancing age, obesity, history of DVT, previous history of superficial thrombophlebitis, and recent cannulation of the affected vein. The latter is most common in the upper extremity, where it can be associated with a fever of unknown origin.

Physical Examination

Patients presenting with superficial thrombophlebitis will generally complain of pain, tenderness, and warmth over the involved vein with a cord palpable subjacent to the area of the pain. Additionally, erythema with proximal streaking is not uncommon. The presence of erythema is often misconstrued as a cellulitis, and it is not uncommon for patients to be placed on antibiotics because of a presumptive diagnosis of skin infection. If conservative therapy does not produce expected resolution of the thrombotic process in patients with extensive involvement of the extremity along the length of a named superficial vein, consideration should be given to a limited trial of full-dose anticoagulation.

For a discussion of postthrombotic (postphlebitic) syndrome, see Chapter 156.

Pathophysiology and Clinical History

Chronic venous insufficiency (CVI) is generally thought to be secondary to venous valvular dysfunction following an episode of DVT, resulting in apposition of the vein valve to the wall of the vein with subsequent incompetence after recanalization. Unfortunately, although the majority of patients have recanalization of their previously occluded veins, almost half of such patients have residual partial thrombosis, which also contributes.[25] The combination of venous obstruction and valvular incompetence can be associated with worsening symptoms with physical activity to the point of effort discomfort, often referred to "venous claudication." Thrombotic obstruction of the venous outflow and venous insufficiency can also result in ambulatory venous hypertension and edema. Long-standing symptoms of venous hypertension and swelling can ultimately result in the development of venous stasis ulceration (Fig. 19.7).

Initial presenting symptoms include mild swelling and discomfort at the end of the day relieved by rest and limb

TABLE 19.8 Venous Thromboembolism Risk-Factor Assessment

Patient's Name: _____ Age: _____ Sex: _____ Wt, lb:_____ Ht, in: _____

Choose All That Apply

Each Risk Factor Represents 1 Point

- ☐ Age 41-59 years
- ☐ Minor surgery planned
- ☐ History of prior major surgery
- ☐ Varicose veins
- ☐ History of inflammatory bowel disease
- ☐ Swollen legs (current)
- ☐ Obesity (BMI >30)
- ☐ Acute myocardial infarction (<1 month)
- ☐ Congestive heart failure (<1 month)
- ☐ Sepsis (< 1 month)
- ☐ Serious lung disease incl. pneumonia (< 1 month)
- ☐ Abnormal pulmonary function (COPD)
- ☐ Medical patient currently at bed rest
- ☐ Leg plaster cast or brace
- ☐ Central venous access other risk factor_____

For Women Only (Each Represents 1 Point)

- ☐ Oral contraceptives or hormone replacement therapy
- ☐ Pregnancy or postpartum (<1 month)
- ☐ History of unexplained stillborn infant, recurrent spontaneous abortion (≥ 3), premature birth with toxemia or growth-restricted infant

Total Risk Factor Score ☐

Please see following page for prophylaxis suggestions and safety considerations

Each Risk Factor Represents 2 Points

- ☐ Age 60-74 years
- ☐ Major surgery (> 60 min)[a]
- ☐ Arthroscopic surgery (>60 min)[a]
- ☐ Laparoscopic surgery (>60 min)[a]
- ☐ Previous malignancy
- ☐ Morbid obesity (BMI >40)

Each Risk Factor Represents 3 Points

- ☐ Age 75 years or more
- ☐ Major surgery lasting 2-3 h[a]
- ☐ BMI > 50 (venous stasis syndrome)
- ☐ History of SVT, DVT/PE
- ☐ **Family history of DVT/PE**
- ☐ Present cancer or chemotherapy
- ☐ Positive factor V Leiden
- ☐ Positive prothrombin 20210A
- ☐ Elevated serum homocysteine
- ☐ Positive lupus anticoagulant
- ☐ Elevated anticardiolipin antibodies
- ☐ Heparin-induced thrombocytopenia (HIT)
- ☐ Other thrombophilia type _____

Each Risk Factor Represents 5 Points

- ☐ Elective major lower extremity arthroplasty
- ☐ Hip, pelvis or leg fracture (< 1 month)
- ☐ Stroke (< 1 month)
- ☐ Multiple trauma (< 1 month)
- ☐ Acute spinal cord injury (paralysis)(< 1 month)
- ☐ Major surgery lasting over 3 hours[a]

[a]Select only one from the surgery category.

In: A validation study of a retrospective venous thromboembolism risk scoring method. Bahl V, Hu HM, Henke PK, et al. *Ann Surg*. 2010;251(2):344–350.

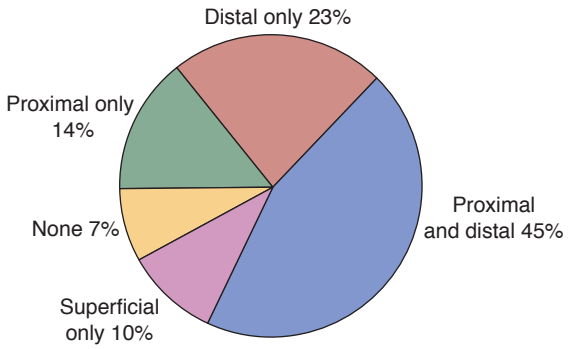

Figure 19.7 Distribution of venous valvular incompetence in limbs with stasis ulcers and pigmentation. (From Rutherford, 6th edition, Fig. 9.51, p. 113.)

elevation. The wearing of compression stockings, in general, will significantly improve the patient's symptoms at this stage. As the duration and severity of deep venous insufficiency increases, mild symptomatology is replaced by late findings, which include brawny edema, venous eczema, lipodermatosclerosis (hemosiderin deposition typically in the gaiter distribution), and eventual progression to venous stasis ulceration, commonly occurring at the level of the medial malleolus.

Physical Examination

Patients presenting with deep venous insufficiency exhibit mild to significant swelling depending on the stage of presentation. Unilateral swelling is more likely to be venous in nature, whereas bilateral swelling may more likely be associated with a central cardiac and hepatic dysfunction. In the late stages edema should be pitting and is often 3 to 4+ in nature, although the presence of brawny edema and chronic fibrosis may impede pitting at the level of the ankle or in the gaiter distribution (Fig. 19.8). The latter term is derived from the gaiter, or spat, which were garments worn over the shoe and the lower leg below the knee. The patient may have associated varicosities, although these are not a requirement and would be secondary to coexistent superficial venous insufficiency. The presence of active or healed ulcerations should be documented with regard to size, depth, and location. Classically ulcers associated with deep venous insufficiency are located primarily over the medial malleolar region, although in long-standing and severe cases these can be multiple and located throughout the gaiter distribution. Determination of ulcer etiology can be complex and should be made in conjunction with pulse assessment and neurologic examination for sensory deficits.

Chronic ulcers can be associated with arterial ischemia, venous stasis, and neuropathy (Table 19.9). A history of arterial insufficiency, including claudication and rest pain, should be sought. Ischemic ulcers and tissue loss represent the far end of the spectrum of arterial disease. Diabetic patients can present with arterial disease and peripheral neuropathy. Neuropathy can predispose such patients to neurotrophic ulcers over the weight-bearing prominences of the plantar foot. Venous stasis disease can result in characteristic ulcerations, but associated arterial disease can affect healing and influence treatment. The history should be accompanied by a complete physical examination, beginning with observation and inspection of the extremity. All areas of ulceration and tissue loss should be fully characterized with respect to location and size, and the status of all pulses should be documented.

Ischemic ulcers are usually quite painful, and there is likely to be typical ischemic rest pain in the distal forefoot that occurs nocturnally and is relieved by dependency. At first, these ulcers may have irregular edges, but when chronic, they are more likely to be "punched out." They are commonly located distally over the dorsum of the foot or toes but may occasionally be pretibial. The ulcer base usually consists of poorly developed grayish granulation tissue. The surrounding skin may be pale or mottled, and the previously described signs of chronic ischemia are invariably present. Notably, the usual signs of inflammation one would expect surrounding such a skin lesion are absent, for it is the lack of adequate circulation to provide the necessary inflammatory response for healing that underlies ischemic ulcers. For the same reason, probing or debriding the ulcer causes little bleeding.

Figure 19.8 The "gaiter" distribution of stasis dermatitis and leg ulcers. (From Rutherford, 6th edition, Fig. 1.3, p. 1.)

Neurotrophic ulcers, however, are completely painless but bleed with manipulation. They are deep and indolent and are often surrounded by both acute and chronic inflammatory reactions and callus. Their location is typically over pressure points or calluses (e.g., the plantar surface of the first or fifth metatarsophalangeal joint, the base of the distal phalanx of the great toe, the dorsum of the interphalangeal joints of toes with flexion contractures, or the callused posterior rim of the heel pad). The patient usually has long-standing diabetes with a neuropathy characterized by patchy hypoesthesia and diminution of positional sense, two-point discrimination, and vibratory perception.

The so-called venous stasis ulcer, actually secondary to ambulatory venous hypertension, is located within the gaiter area, most commonly near the medial malleolus. It is usually larger than the other types of ulcers and irregular in outline but also shallower and with a moist granulating base. The ulcer is almost invariably surrounded by a zone containing some of the hallmarks of chronic venous insufficiency—pigmentation and inflammation ("stasis dermatitis"), lipodermatofibrosis, and cutaneous atrophy, as already described. Ulcerations of long duration should undergo biopsy to rule out malignancy.

May-Thurner Syndrome

May-Thurner syndrome is a specific anatomic diagnosis arising from stenosis or obstruction of the left common iliac vein as it crosses under the right common iliac artery with a concomitant band or web found at the site of obstruction. It is commonly seen in young female patients although also not infrequently

TABLE 19.9 Differential Diagnosis of Common Ulcers

Type	Usual Location	Pain	Bleeding with Manipulation	Lesion Characteristics	Surrounding Inflammation	Associated Findings
Ischemic ulcer	Distal, on the dorsum of the foot or toes	Severe, particularly at night; relieved by dependency	Little or none	Irregular edge; poor granulation tissue	Absent	Trophic changes of chronic ischemia; absence of pulses
Neurotrophic ulcer	Under calluses or pressure points (e.g., plantar aspect of the first or fifth metatarsophalangeal joint)	None	May be brisk	Punched out, with a deep sinus	Present	Demonstrable neuropathy
Venous stasis ulcer	Lower third of the leg (gaiter area)	Mild; relieved by elevation	Venous ooze	Shallow, irregular shape; granulating base; rounded edges	Present	Lipodermatofibrosis, pigmentation

From Rutherford 7th edition, Table 13.5, p. 214.

found in asymptomatic patients.[26] The presentation is usually a unilateral swelling of the left lower extremity that is aggravated by exercise and activity. "Venous claudication" described as an intense pain, or a bursting sensation, is induced by exercise and relieved by rest and elevation of the limb. This is in contrast to arterial claudication, where the cessation of activity and standing rest result in relief.

Physical Examination

The classic presentation is a young female, past puberty, who presents with either provoked or unprovoked DVT of the left leg. Without treatment, limb swelling and venous claudication may develop. Alternatively and less commonly, unilateral swelling of the left leg, varicose veins, and venous ulcers may occur. However, many patients with May-Thurner anatomy remain entirely asymptomatic throughout their adult lives.[26,27]

Superficial Venous Insufficiency

Pathophysiology and Clinical History

Superficial venous insufficiency is classically thought to be caused by incompetent valves at the saphenofemoral and saphenopopliteal junctions, with subsequent loss of valvular function along the length of the great and small saphenous veins, respectively. Findings of superficial venous insufficiency include telangiectasias, reticular varicosities, and large ropey varicose veins. The large varicose veins can generally be traced back to the great or small saphenous veins. The majority of patients with varicose veins are women with a significant hereditary component as well as specific risk factors including multiple pregnancies, with general worsening of the varicosities with each successive pregnancy. Patients with varicose veins usually do not complain of severe pain; typically, the discomfort is described as burning or throbbing in character and is localized to the varicosities. Swelling of the calf, and rarely the proximal foot, can often be associated with varicosities. The symptoms associated with varicose veins are relieved with elevation of the extremity, and patients frequently note an absence of symptoms in the morning.[28] They also observe that symptoms increase during the course of the day, particularly if the patients are ambulatory and active with episodes of standing and sitting for long periods of time. Compression stockings are usually effective and significantly improve the symptoms in patients with superficial venous insufficiency.

Physical Examination

The patient with varicose veins should be examined in the standing position. The location of all varicosities should be noted. The presence of ankle flare or corona phlebectatica should be noted. Additional venous abnormalities may include telangiectasias, which are dilated intradermal venules about 1 mm in size. Reticular veins are nonpalpable subdermal veins measuring 1 to 3 mm in size.

Varicosities along the medial leg are generally related to the great saphenous vein or its perforating branches; varicosities over the posterior calf are in the distribution of the small saphenous vein, which begins on the lateral aspect of the foot and ascends along the posterior midline of the calf. Venous reflux in the great saphenous vein may be associated with incompetence at the saphenofemoral junction or related to incompetent deep and perforating veins. The great saphenous vein can communicate with the Dodd, Boyd, Cockett, Sherman, and Hunterian perforating veins (see Fig. 19.4). Hunterian perforator incompetence can be associated with varicosities in the middle third of the thigh. The Dodd perforator is located in the medial and distal third of the thigh; the Boyd perforators are along the medial aspect of the knee; the Cockett and Sherman perforators are located at the ankle.

In moderate to morbidly obese patients varicosities may not be visible but may be palpable. Physical examination should include an assessment of varicosities throughout the upper and lower extremities. Prominent veins, especially in the upper extremity, can signal the presence of normal but prominent veins in the lower extremities.

The Trendelenburg and Perthes tests are described here for completeness, however, they are used infrequently in clinical practice, given the ubiquitous use of duplex Doppler examination for patients with superficial venous insufficiency; this renders the test useful in only very selected circumstances. During the Trendelenburg test, the patient is initially supine, with the extremity elevated. Manual compression or a tourniquet is used to occlude the proximal great saphenous vein. The patient then stands upright. In the absence of significant deep venous insufficiency and perforator incompetence, the superficial varicosities will fill slowly over approximately 20 seconds. On repeating the maneuver when the patient first stands, release of compression will result in rapid filling of varicosities in the presence of significant proximal incompetence. With the Perthes test, a tourniquet is used to occlude the proximal superficial veins. As the patient ambulates, the varicosities enlarge if there are incompetent perforating veins. Use of a handheld Doppler in conjunction with these tests markedly improves the diagnostic accuracy.[29]

Klippel-Trenaunay Syndrome

Pathophysiology and Clinical History

Klippel-Trenaunay syndrome comprises a constellation of findings including varicose veins, port wine stain, and associated hypertrophy of the bone and soft tissue, resulting in limb-length discrepancy. With associated arteriovenous malformations, the condition is more correctly termed Parkes Weber syndrome or Klippel-Trenaunay-Weber syndrome.

The majority of patients present with unilateral limb involvement, with the lower extremity being the most frequent site. A port wine stain is the most common finding, followed by the presence of varicosities and then by limb hypertrophy. The varicose veins and port wine stain are invariably congenital and present at birth. Venous involvement can be associated with pain or venous ulcerations.[30]

Physical Examination

The patient's extremity should be examined for the presence or absence of other defining arteriovenous malformations or limb abnormalities. In isolated Klippel-Trenaunay syndrome, the port wine stain is most frequently located on the affected limb. The varicosities associated with the condition are classically described

as arising from the foot or the lower leg, extending proximally into the thigh or gluteal area. The varicose veins can be prominent or may only present with ambulation. In some cases varicosities may not be present until the onset of puberty. The veins often spare the saphenous distribution. Prior to treating the varicosities, it is essential to ensure the presence of a patent deep venous system, as often these patients can have atretic deep veins.

Lymphedema (See Chapter 168)

Overview/Pathophysiology

Lymphedema results from obstruction of the lymphatics, with resultant accumulation of protein and fluid in the interstitial tissues of the extremity. Lymphedema may be classified based on underlying etiology, genetic predisposition, morphology, and age of onset. Clinically, lymphedema is grossly classified as primary/intrinsic or secondary to other contributing factors (Table 19.10).[31-33] Primary etiologies are characterized by the age of onset; lymphedema may present as a congenital condition at birth, at puberty through adolescence, or later in life. Genetically, lymphedema may be familial or sporadic. Morphologically, lymphedema is the result of lymphatic aplasia, hypoplasia, hyperplasia, or less commonly the incompetence of the lymphatic system. Genetic predisposition and lymphatic morphology are most useful in predicting clinical severity and guiding potential therapies.

Primary Lymphedema

Primary lymphedema can present at birth as a congenital condition and is more common in males, with the vast majority of patients presenting with involvement of the lower extremity (>80%). Milroy disease is a familial variant.[34] It is more common in women and is associated with a mutation of the *VEGFR-3* or *FLT4* gene. It is frequently bilateral. Males can have an associated hydrocele, and males and females can have papillomas. Primary lymphedema can be associated with other syndromes including Turner syndrome, Noonan syndrome, Klinefelter syndrome, hemangiomas, trisomy 13, trisomy 18, neurofibromatosis type 1, yellow nail syndrome, congenital nail absence, distichiasis, lymphedema syndrome, and xanthomatosis.

Lymphedema praecox (or its familial variant, Meige disease) is the most common form of lymphedema, primarily affecting females between the ages of 10 and 35. It is commonly associated with puberty. It accounts for over 80% of all patients with lymphedema. Lymphedema tarda generally presents in patients over 35 years of age and also occurs more commonly in women.[35]

TABLE 19.10 Etiologic Classification of Lymphedema

I. Primary Lymphedema
A. Congenital (onset before 1 year of age)
1. Nonfamilial
2. Familial (Milroy disease)
B. Praecox (onset at 1-35 years of age)
1. Nonfamilial
2. Familial (Meige disease)
C. Tarda (onset after 35 years of age)
II. Secondary Lymphedema
A. Filariasis
B. Lymph node excision ± radiation
C. Tumor invasion
D. Infection
E. Trauma
F. Other

From Rutherford, 6th edition, Table 167.1, p. 2397.

Secondary Lymphedema

Secondary lymphedema is more common than primary lymphedema and results from any process leading to lymphatic injury, such as infection and filariasis. Patients who present with a sudden onset lymphedema later in life should be questioned about international travel.[36] In developed countries the most common cause of secondary lymphedema is direct injury or surgical dissection of regional lymph nodes and also trauma, cancer (tumor, surgery, or radiation), and infection.[37]

Physical Examination

Lymphedema most commonly involves the lower extremities. In the upper extremity, it can be associated with prior mastectomy and axillary lymph node dissection. It is unilateral, and elevation of the extremity generally does not result in resolution of the edema.[38] In the lower extremity, swelling generally begins distally, involving the area about the ankle; it rarely spares the toes and foot, which differentiates lymphedema from other conditions. At onset, the swelling begins as mild pitting edema, slowly increasing in extent, that is relatively painless in character. The edema may progress to involve the proximal extremity, including the genitalia and trunk. Stemmer sign describes the inability to pinch and lift the dorsal skin of the foot between the first and second toes; if the skin fold cannot be lifted, the test is indicative of lymphedema. Additionally, with lymphedema, the toes can become squared, suggesting the appearance of "boxcars."[39] With progression of the lymphedema, fibrosis develops in the subcutaneous tissues, with subsequent ulcerations, fissures, and lymphorrhea. Not infrequently, patients may present with inflammation secondary to lymphangitis and red streaks in the distribution of the lymphatic channels (Table 19.11).

TABLE 19.11 Clinical Staging of Chronic Lymphedema

Grade I	Early pitting prevalent that reduces with elevation No fibrotic skin thickening
Grade II	Skin thickened and fibrotic pitting only to deep prolonged pressure Often no pitting No reduction with elevation overnight
Grade III	Skin fibrotic and sclerotic in subcutaneous tissues Often secondary hyperkeratosis Verrucal development These changes are permanent

Peripheral arterial occlusive disease (PAD) can usually be diagnosed by a careful history and physical examination. Arterial physiologic testing adds a degree of objectivity to the subjective clinical evaluation. With the advances in direct physiologic testing of specific arterial sites by duplex scanning and noninvasive imaging evaluation (see Chapters 27 and 28), the approximate localization of extent of disease provided by indirect physiologic testing is now less critical.

Nevertheless, physiologic testing is helpful when the diagnosis is uncertain, such as in patients with possible pseudoclaudication. These tests are also useful in determining the extent to which arterial disease limits walking in patients who have concomitant orthopedic or neurologic problems contributing to their disability. Noninvasive testing can be used to detect PAD in otherwise asymptomatic patients, which is significant because PAD is an independent risk factor for cardiac events.[1-3] These tests are uniquely able to identify intermittent arterial obstructions, such as those arising from entrapment syndromes, and to distinguish between fixed arterial obstructions and obstructions caused by vasospasm. In patients with advanced disease, physiologic testing helps to determine the ability of ischemic ulcers to heal or provides guidance for the optimal level of amputation. This chapter reviews the theory, methods, interpretation, and applications of the various indirect physiologic arterial tests available in the vascular laboratory.

DOPPLER ULTRASONOGRAPHY

The development of Doppler ultrasound to detect blood flow and analyze velocity waveforms revolutionized the ability to detect and quantitate peripheral vascular disease noninvasively.[4] This chapter discusses the use of basic continuous wave Doppler and waveform analysis. Pulsed Doppler combined with B-mode imaging in duplex ultrasound machines that allows analysis of velocity waveforms from specific sites along visualized vessels is described in Chapter 21.

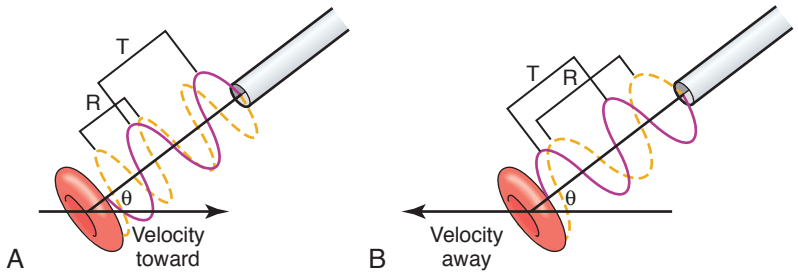

Figure 20.1 The Doppler device compares the frequency of backscattered sound from moving red blood cells with the transmitting frequency to determine the frequency shift, which is proportional to the speed of the flowing blood, the transmitting frequency, and the cosine of the Doppler angle, θ. The drawing shows a Doppler probe transmitting ultrasound at a wavelength *T* to a red blood cell moving in a direction indicated by an *arrow*. The red cell is moving toward the probe in (A) and away from the probe in (B). The angle between the ultrasound beam and the direction of red cell velocity is given by θ. The frequency of the ultrasound that is transmitted is the same in both cases *(red line)*. The ultrasound signal that is received *(yellow line)* has a shorter wavelength *(R)* and thus a higher frequency in (A) and a longer wavelength and lower frequency in (B).

Principles of Doppler Ultrasound

The hand-held continuous wave "pocket Doppler" devices typically have a transmitting frequency between 5 and 10 MHz, suitable for more superficial arteries due to the limited penetration depth of ultrasound waves at this frequency. The tip of the probe has a transmitting piezoelectric crystal that converts electrical energy into ultrasound waves, as well as a receiving piezoelectric crystal that detects reflected ultrasound waves. The probe converts detected frequency shift and sends it to the speakers for an audible signal. A fluid interface, generally an aqueous gel, is required between the probe and the skin to allow penetration of ultrasound waves into the tissue without significant loss of energy from impedance mismatch (difference in density causing significant reflection of ultrasound waves, thus preventing further tissue penetration).

Moving red blood cells act as reflectors that backscatter ultrasound waves. The frequency of the reflected ultrasound wave is shifted from the transmitted frequency in direct proportion to the velocity of the blood flow due to the Doppler effect (Fig. 20.1). The magnitude of the frequency shift (Δf) is given by the following Doppler equation:

$$\Delta f = \frac{2V f_0 \operatorname{Cos}\theta}{C}$$

where V is blood velocity in centimeters per second, f_0 is the transmitted frequency, θ is the angle between the velocity vector and the path of the ultrasound beam (known as the Doppler angle), and C is the velocity of sound through blood (1.54×10^5 cm/s). This equation can be rearranged to solve for V when the Doppler angle is known, or it can be estimated, as it is in duplex scanning.

Aural Interpretation of the Doppler Waveform

The velocity of blood flow is proportional to the frequency shift, which is heard as a change in pitch of the audio signal. Loudness (amplitude) is proportional to the volume of red blood cells moving through the Doppler signal path. Turbulence causes nonuniform velocities and imparts a harsh quality to the audible Doppler signal. An experienced listener can identify increased pitch, which corresponds to luminal narrowing causing increased velocity of flow. The listener can also perform elementary waveform analysis by taking note of the contour of the velocity waveform. Normal peripheral arteries at rest have a triphasic or biphasic quality with a brisk upstroke of forward flow in systole, a brief reverse flow component in diastole caused by the reflection of the flow wave from the high resistance periphery, and finally, in most, but not all peripheral arteries, a small forward component in late diastole (Fig. 20.2A and B). When the peripheral vascular resistance is low, either due to the arterial bed downstream such as the kidneys, brain, or liver, or after exercise, hyperemia, or intraarterial administration of vasodilating drugs, the velocity waveform loses the reverse flow component and becomes monophasic with forward flow throughout the entire cardiac cycle.

Arterial obstruction causes dampening of the waveform, which becomes monophasic (see Fig. 20.2C). The low-amplitude, monophasic Doppler signals that result from extensive occlusive disease may be difficult to distinguish from venous signals. Gentle compression of the foot causes a rush of venous blood from emptying the veins that is easy to appreciate in the Doppler signal. Directional Doppler can also be useful to distinguish arterial from venous signals because it will indicate whether blood is flowing toward or away from the ultrasound probe.

Qualitative and Quantitative Waveform Analysis

The earliest change at the site of stenosis is widening of the waveform (spectral broadening) in early diastole, when flow is decelerating and least stable. More severe stenosis produces a marked increase in systolic velocity in addition to spectral broadening. Critical stenosis limits flow and pressure and generally occurs when the lumen is narrowed by 50% or more. Waveforms at the site of stenosis are associated with a doubling of peak systolic velocity when compared with the adjacent segments (Fig. 20.3). Downstream from significant stenoses, waveforms become blunted and monophasic with widening as a result of turbulence.

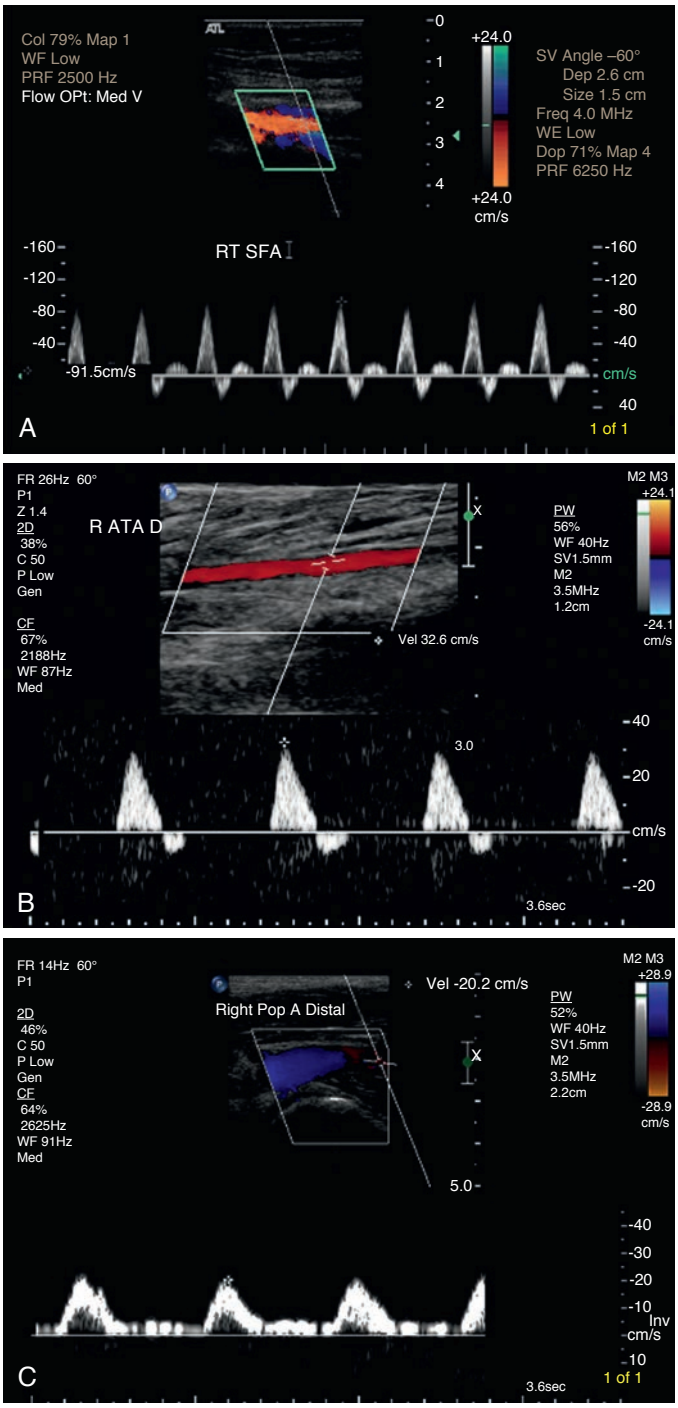

Figure 20.2 Normal and Dampened Velocity Waveforms Obtained With a Duplex Scanner. (A) Normal triphasic velocity waveform. (B) Biphasic velocity waveform. (C) Monophasic velocity waveform.

The result is a noisy, high-pitched Doppler signal at the site of stenosis. This signal can be heard for several vessel diameters downstream from the site of stenosis because of transmission of the high-velocity jet over this distance. A few centimeters upstream from the stenosis, the waveform is affected by the high resistance of the stenosis. This results in less forward flow and a large, reflected wave following the lower frequency systolic peak. It is heard as a "to-and-fro" signal pattern. Extremely low flow may not be detectable by hand-held Doppler instruments because of inadequate signal generation or cutoff of very low frequencies by the filter that is used to eliminate wall motion artifacts.

To overcome the subjective, operator-dependent nature of qualitative waveform analysis, spectrum analyzers can be used. These instruments have a frequency analyzer that uses fast Fourier analysis or similar methods to give a full picture of the entire spectrum of frequencies present in each sampling interval. Frequency shifts are displayed on the vertical axis and time on the horizontal axis. The amplitude of the reflected signal at each frequency is represented by a gray scale (see Fig. 20.2). The intensity of the gray scale is proportional to the number of red blood cells traveling at a particular velocity at each point in time. These devices, which are used in all duplex scanners, permit identification of features, such as uniformity of flow (narrow band of velocities) or nonuniformity (widening of the velocity waveform, known as spectral broadening). When the angle of insonation is known, the output can be displayed as velocity over time and various parameters can be measured, such as peak and end-diastolic velocity and ratios of various velocity components. Duplex scanners also use pulsed Doppler with time-gated reception of the reflected ultrasound to allow the operator to select the depth at which velocity information is obtained. This permits interrogation of Doppler information within a visualized vessel and thereby more precise categorization of the degree and location of stenosis (see Chapter 21). In the absence of Duplex scanning, indirect analysis of waveforms obtained at the common femoral artery level such as peak-to-peak pulsatility index (calculated as $(V_{max} - V_{min})/V_{mean}$ where V stands for velocity, max for maximum, and min for minimum), Laplace transform, power frequency spectral analysis, pulse wave velocity, and pulse transit time have been used to determine whether significant aortoiliac occlusive disease is present. However, these indirect methods are prone to false-negative interpretations because waveforms can return to a normal contour within only a few vessel diameters downstream from a significant stenosis.[5,6]

PRESSURE MEASUREMENTS

Strandness and coworkers developed noninvasive pressure measurement in the 1960s when continuous wave Doppler instruments became available to detect blood flow.[4] Since pressure differentials drive flow, decreased pressure results in decreased flow. In most instances, therefore, pressure is an acceptable surrogate measure for flow and is easier to measure.

The higher-frequency components of the pressure waveform are more sensitive to the dampening effect of stenoses, and therefore decreases in systolic pressure are more sensitive than changes in mean or diastolic pressure for detecting stenosis. The reduction in pressure is caused by viscous losses from flow through narrow channels and by kinetic energy losses secondary to turbulence (which is the dominant source of loss in all but the smallest arteries). Turbulence occurs when kinetic forces are much greater than the viscous forces that produce ordered, laminar flow. The relationship between these forces is estimated by the Reynold number (Re):

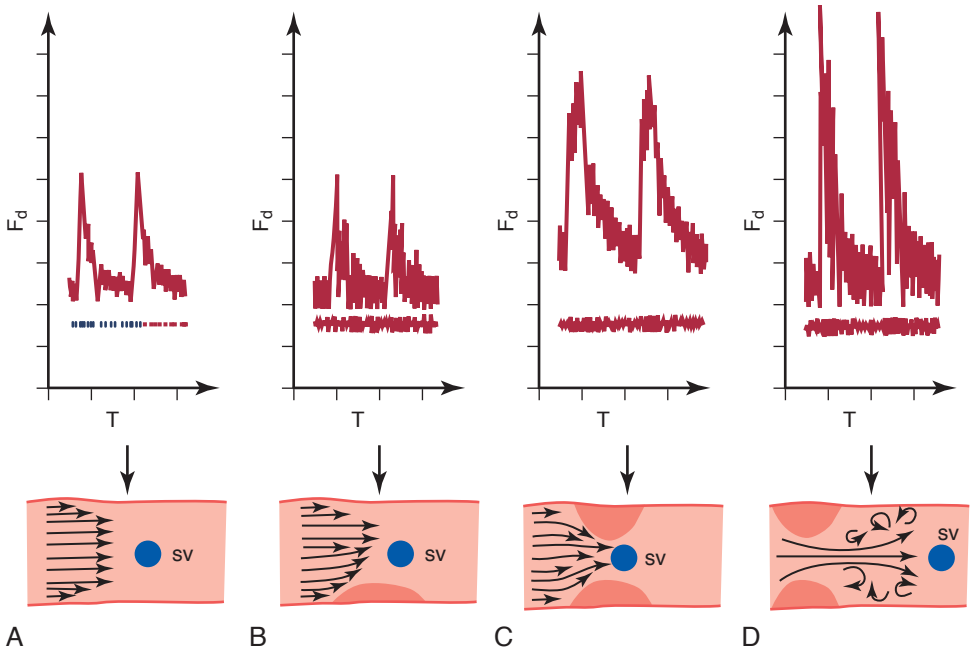

Figure 20.3 Changes in the Velocity Waveform Caused by Arterial Stenosis. (A) Normal waveform with relatively low and uniform velocity (frequency shift). (B) Mild stenosis causes disturbed flow in diastole (broadened waveform) and little increase in velocity. (C) Significant narrowing (>50%) causes at least a doubling of the peak systolic velocity. (D) Beyond a significant narrowing, post-stenotic turbulence causes marked widening of the waveform. F_d, Frequency shift; *SV*, sample volume; *T*, time. (Compliments of Jean Primozich.)

$$Re = Vd/\nu$$

where V is velocity in centimeters per second, d is diameter of the vessel, and ν is viscosity (which varies with velocity; in other words, blood is a non-Newtonian fluid). As flow increases, velocity increases, and flow becomes less stable as both viscous and kinetic losses increase. Greater than Reynold numbers of approximately 2500, turbulence develops (at least in straight tubes with nonpulsatile flow, conditions that are not met in the normal human vasculature) and energy is lost (as imperceptible heat generation). Thus resting flow and velocity may not be associated with a reduction in pressure. However, a pressure gradient may develop when flow increases, resulting in increased turbulence.

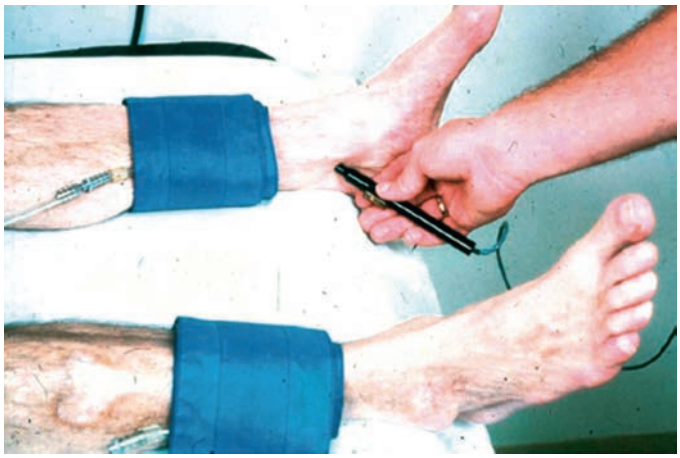
Mild stenoses that do not cause a drop in pressure at rest may become evident when flow is increased. A peak systolic pressure drop across an arterial segment of 10 mm Hg at rest or 15 mm Hg after hyperemia induced by exercise, ischemia, or the administration of vasodilators indicates increased resistance in this segment sufficient to reduce flow by a clinically meaningful amount. Conversely, significant proximal lesions (e.g., in the iliac system) may not be evident even after vasodilation if the outflow vessels (superficial and profunda femoral arteries) are so diseased that outflow is severely restricted. Without flow, there is no pressure drop across a vessel no matter how stenotic.

Ankle-Brachial Index Measurement

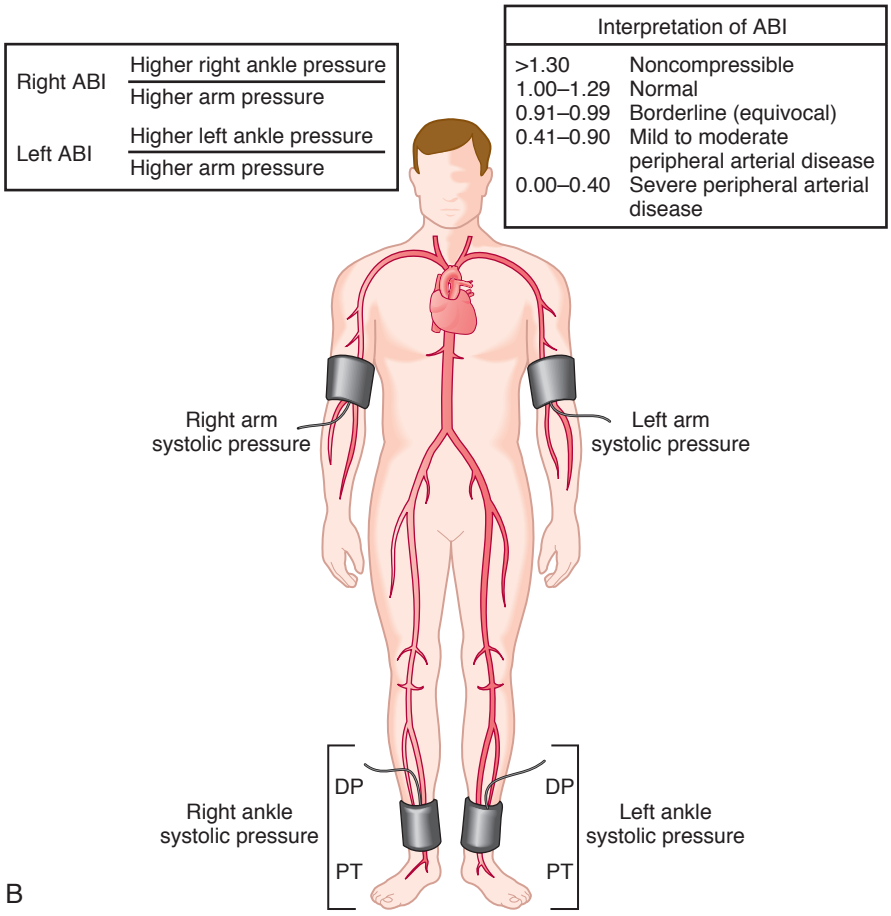
Basic Technique

Significant arterial occlusive disease anywhere between the heart and a blood pressure cuff will cause a decrease in systolic pressure at the cuff level. The simplest noninvasive method for documenting the presence of lower extremity arterial occlusive disease is the ankle-brachial index (ABI).[7] The cuff is placed as low as possible on the leg above the ankle, inflated above systolic pressure, and then slowly deflated while the Doppler probe is held over the posterior tibial artery, just behind the medial malleolus (Fig. 20.4A), or the dorsalis pedis artery, slightly lateral to the extensor hallucis longus tendon approximately a centimeter distal to the ankle joint. The ankle pressure is recorded as the highest pressure at which the Doppler signal returns. If no signal can be obtained over these arteries, the examiner should check for the terminal branch of the peroneal artery (the lateral tarsal artery), which is just anterior and medial to the lateral malleolus. However, pressure in this artery may not be as good a measure of pedal flow as in the other two tibial arteries because it does not connect directly to the pedal arch.

The brachial pressure, measured with a manual blood pressure cuff and continuous wave Doppler at the distal brachial or radial artery, is used as the denominator for the ABI and serves as a surrogate for central aortic pressure, which cannot be measured noninvasively. As upper extremity occlusive disease may lower brachial pressure, the higher of the two arm measurements should be used. Bilateral upper extremity occlusive disease renders the ABI nondiagnostic. The ABI for each lower extremity is the highest of the detectable ankle pressures divided by the higher of the two brachial pressures (see Fig. 20.4B). The ABI is less variable than ankle pressure, with a standard deviation of approximately 0.07, so a measurement greater than two standard deviations is considered significant. Normalizing to the brachial pressure accounts for the normal variation in central pressure and allows a better appreciation of the extent of arterial



A



B

Figure 20.4 (A) Method for measurement of ankle pressure. The cuff is placed just above the ankle, and pressure is measured over the dorsalis pedis and posterior tibial arteries. The higher of the two is used to estimate perfusion pressure at the ankle. (B) Method for measurement of the ankle-brachial index (ABI). The higher of the two brachial pressures and the higher of the two ankle pressures are used for calculation of the index. The patient should be supine and resting for at least 5 minutes before the measurements are made. *DP*, Dorsalis pedis; *PT*, posterior tibial. (From Hiatt WR. Medical treatment of peripheral arterial disease and claudication. *N Engl J Med.* 2001;344:1608–1621.)

occlusive disease in the presence of systemic hypotension or hypertension.

The pressure waveform changes as it moves through the vasculature (Fig. 20.5). Peak systolic pressure is accentuated by the additive effect of reflected pressure waves from the periphery. In addition, the lower extremity vasculature remodels in reaction to increased intraluminal pressure from gravity and upright posture to have increased wall thickening and unchanged inner radius, leading to increased arterial stiffness.[8] Thus, although mean pressure decreases as the pressure wave travels distally, peak systolic pressure increases. As a result, ankle systolic pressure is normally approximately 10% higher than brachial pressure

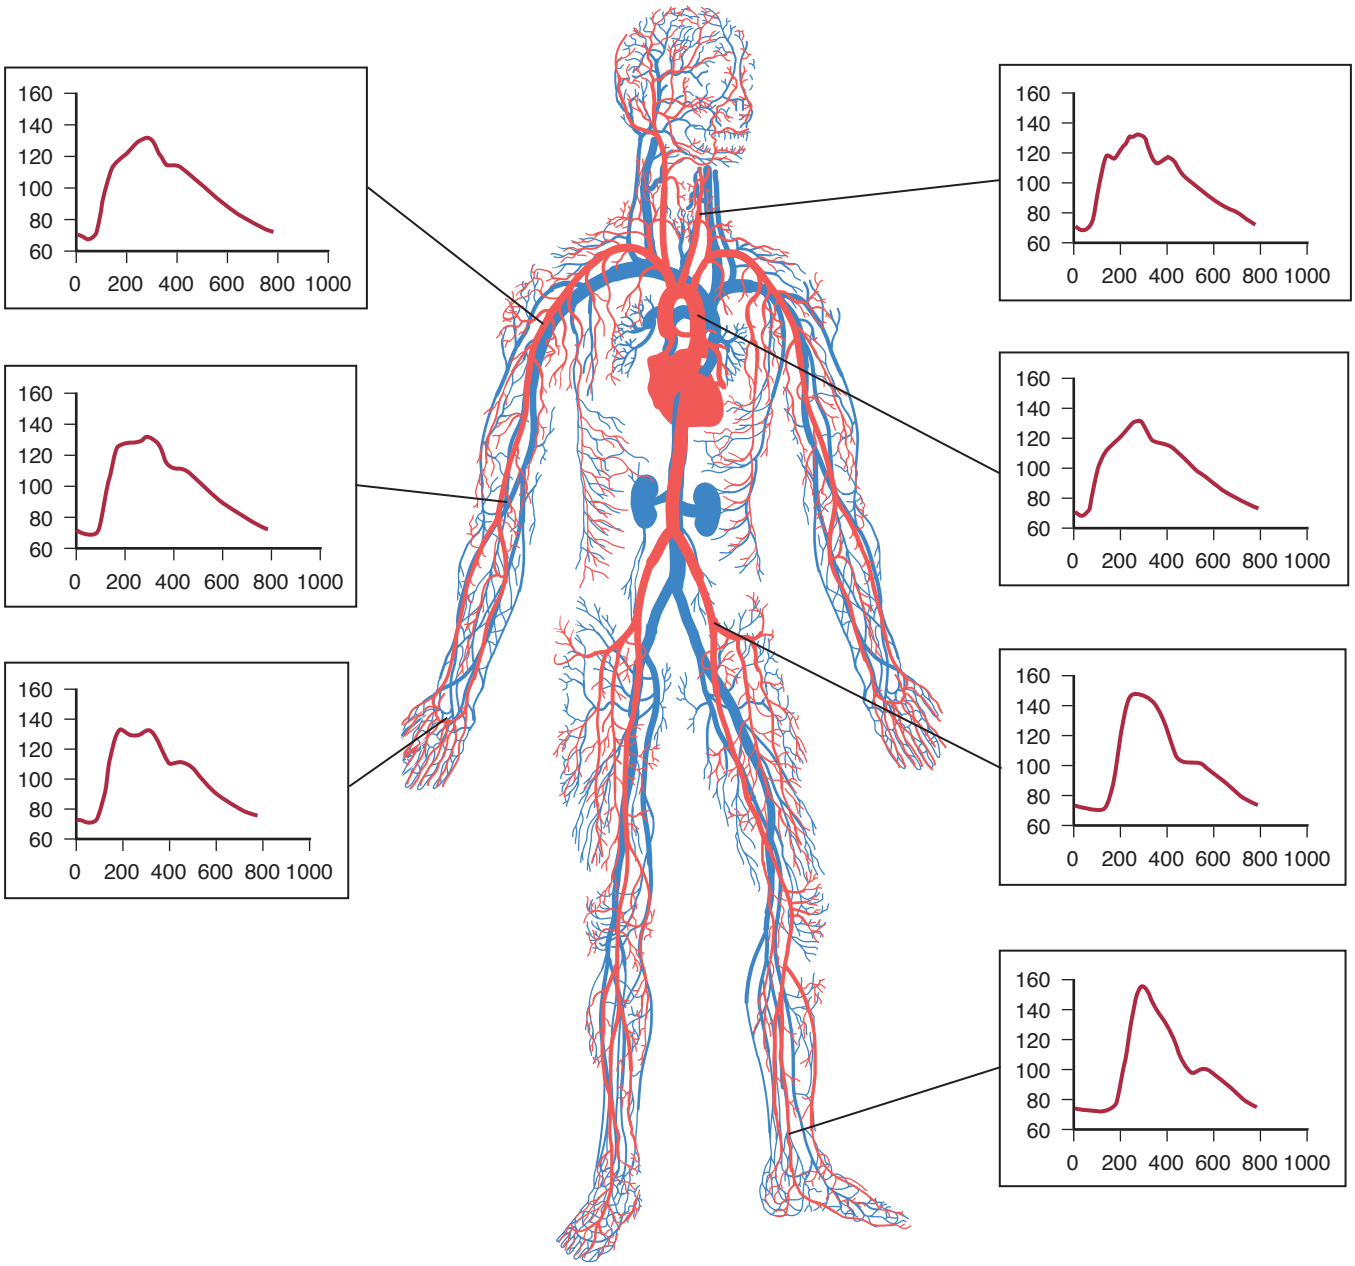


Figure 20.5 The pressure wave changes as it moves distally through the vasculature. Peak systolic pressure is accentuated, and mean arterial pressure decreases.

(ABI of 1.1). Significant PAD decreases this ratio. Because of the known variance of this test, ABIs in the range of 0.9 to 1.29 are considered normal. However, a value of 0.9 to 1 should be considered borderline because these patients have been demonstrated to have increased lower extremity and cardiovascular risk.[9] As the extent and severity of PAD increases, ABI decreases (Fig. 20.6A).

ABI has been well validated against contrast-enhanced angiography for its ability to detect stenosis of greater than 50%.[8,10,11] The sensitivity of this test depends on the lower limit of normal that is chosen, with higher limits detecting more disease, as well as the population being tested, with lower sensitivity in more elderly populations or with a higher percentage of diabetic or chronic kidney disease patients. Using an average of the two measurements has been found to correlate better with walking distance than using either the lower or higher ankle pressure.[12] In general, the sensitivity of ABI in detecting PAD ranges from 80% to 95% and the specificity from 95% to 100%, with positive and negative predictive values in excess of 90%.[10,13]

The automated blood pressure instruments commonly used in hospitals and clinics to determine arm blood pressures may also be used at the ankle level. The machine detects oscillations of pressure, caused by changes in volume in the extremity as a result of influx of blood with each systolic pulse, in the cuff as it deflates. Oscillation begins while the cuff is well above systolic pressure and continues until it is well below diastolic pressure. Maximum oscillation occurs at mean arterial pressure. Each

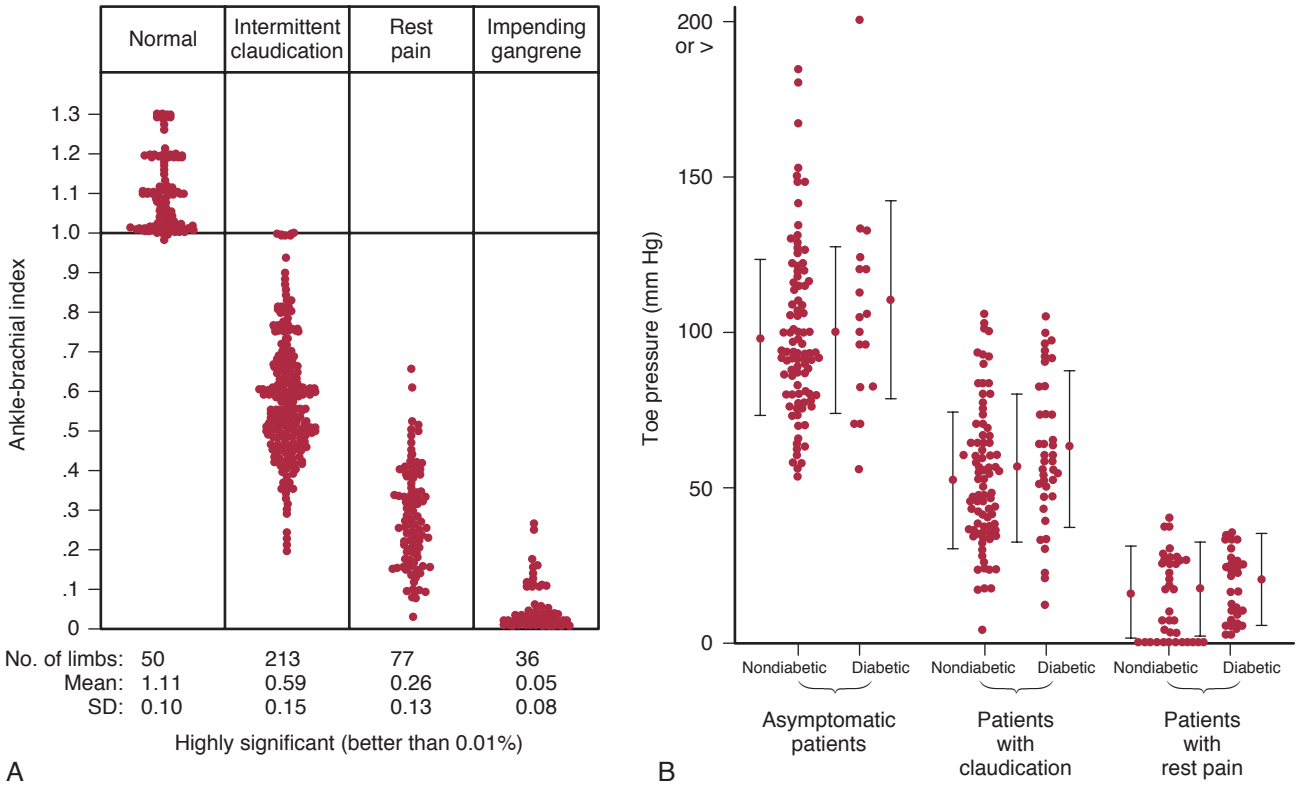

Figure 20.6 (A) Relationship of the ankle-brachial index to functional impairment produced by the occlusive process. *SD*, Standard deviation. (B) Toe blood pressure grouped according to symptoms and the presence of diabetes in patients with arterial disease. Mean and SDs for the nondiabetic and diabetic subgroups and for the two groups combined are indicated by *vertical bars*. ([A] Modified from Yao JST: Hemodynamic studies in peripheral arterial disease. *Br J Surg* 57:761, 1970; [B] Modified from Ramsey DE, Manke DA, Sumner DS. Toe blood pressure: a valuable adjunct to ankle pressure measurement for assessing peripheral arterial disease. *J Cardiovasc Surg.* 1983;24:43–48.)

manufacturer has its own proprietary algorithm, empirically derived, to determine systolic and diastolic pressure from oscillometry. These algorithms were developed for measurement of arm pressure but can also be used for ankle pressure. Like standard Doppler methods, oscillometry has good concordance for normal ankle pressure, but it overestimates pressure when there is moderate disease and is unable to determine pressure in severe disease due to the significantly diminished pulse pressure. Nevertheless, this method may be useful to screen for PAD in primary care clinics because it is rapid and requires no specialized training or equipment.[8,14]

Noninvasive tests can help to make the diagnosis of entrapment syndrome. A change in ankle plethysmography and ABI with stress maneuvers suggests entrapment. The limb is examined with the knee extended and the foot in the neutral, forced plantar-flexed, and forced dorsiflexed positions. The test is considered positive if the ABI drops more than 0.5 or there is flattening of the plethysmographic tracing with forced dorsiflexion or plantar flexion.[15,16]

Prognostic Value of Ankle-Brachial Index

ABI has some predictive value; measurements greater than 0.5 are infrequently associated with progression to critical limb ischemia over the next 6 years.[17] Decreased ABI and the presence of diabetes mellitus were the two factors associated with the development of chronic limb ischemia in a 15-year study of 1244 patients with claudication.[18] Abnormal ABI (either <0.60 or >1.30) has been associated with increased overall mortality, as has decline in ABI over time.[19-22] ABI is useful as an office screening tool for PAD in asymptomatic patients older than 65 years of age, for whom an ABI < 0.90 is associated with a high mortality and vascular event risk.[23] The American Diabetes Association has recommended similar screening with ABI for diabetic patients older than 50 years of age.[24] Although detection of PAD can identify patients at risk for cardiac events, there are no data demonstrating that screening leads to prevention of such events. Nor is there evidence that ABI adds significantly to Framingham Risk Score or other assessments of cardiovascular risk.[25-27] Routine surveillance of ABI is not indicated in untreated patients with PAD unless they develop new or worsening symptoms.[28]

Technical Errors

Although measurement of ABI is straightforward, errors are often made, particularly by those unfamiliar with vascular pathophysiology. A common mistake made by the uninitiated is to use the left brachial pressure for calculation of the left ABI and the right brachial pressure for the right ABI. Once it is understood that brachial pressure is a surrogate for systemic

pressure and that atherosclerosis may lower pressure to an upper extremity, the correct practice of using the higher of the two brachial pressures becomes obvious.

Failure to have the patient supine for long enough to allow stabilization of blood pressure, preferably for ≥5 minutes, is the next most common error, particularly when it is difficult to assist nonambulatory patients from a wheelchair onto an examination table. Because hydrostatic pressure is equal to "ρgh" (where ρ is the density of blood, g is acceleration as a result of gravity, and h the height in centimeters of the blood column measured from the right atrium, also known as the phlebostatic level), ankle pressure will be increased by 0.74 times the height in centimeters from the right atrium to the cuff. If the patient is sitting or standing, this distance is on the order of 100 cm; ankle pressure would be elevated by 74 mm Hg above the supine value—a significant difference.

Accurate measurement requires that the cuff pressure reflect the actual pressure in the tissue underneath it. Use of a cuff that is too small will result in poor conduction of pressure to the extremity and falsely elevated readings. Conversely, a cuff that is too wide may cause an underestimation of pressure. The American Heart Association recommends that the bladder length of the cuff be 80% and the width be 40% of the circumference of the extremity (for a length-to-width ratio of 2:1).[29] It may not be possible to measure upper arm pressure accurately in obese patients because the width of a properly sized cuff exceeds the length of the upper part of the arm. In such cases, forearm pressure may be more accurate.

If the artery wall is stiffened by medial calcinosis, as often occurs in diabetics and patients with chronic kidney disease, increased pressure may be required to collapse the wall and stop the flow of blood. An ABI greater than 1.3 should raise suspicion that the wall is stiffened. In the extreme, blood flow is never occluded even at the highest cuff pressure. Stiff arteries may also reopen when cuff pressures are still well above intraluminal pressure, resulting in falsely elevated ankle pressure. There are several ways to suspect that such is the case. First, the quality of the Doppler waveform, which would be brisk and triphasic in a normal vessel, may be blunted and monophasic as a result of the occlusive disease (see later). Second, the pulse may not be palpable even though the measured pressure is well above the palpable level. Third, the remainder of the clinical picture, such as ischemic ulceration or a clear history of claudication or pain at rest in a patient with known atherosclerosis, may be strongly suggestive of significant PAD. Fourth, the Doppler signal may diminish if the ankle is elevated while the patient is supine. (Using the aforementioned equation, the ankle pressure in millimeter of mercury [mm Hg] may be estimated as 0.74 times the height of the ankle above the bed in centimeters when flow is no longer detectable by Doppler.) Because digital arteries are less commonly involved with calcification, toe pressure measurements can be useful when ankle pressure is falsely elevated.

Segmental Pressures

An estimate of the level of disease in the lower extremity can be made by measuring blood pressure with cuffs placed at the arm, upper thigh, above-knee, below-knee, and ankle levels (Fig. 20.7). A Doppler device is used to detect blood flow at the ankle as each individual cuff is inflated and then slowly deflated. Typical segmental pressures from normal subjects and patients with various levels of occlusive disease are shown in Table 20.1. Upper thigh pressure is normally higher than brachial pressure, particularly when the relatively narrow, 10-cm standard thigh cuff is used. In this case, upper thigh pressure may be as high as or somewhat higher than brachial pressure, even in the presence of significant iliac disease. False negatives may also result from restriction of outflow into the thigh because of occlusion of vessels by the cuff. The resulting limitation of flow across a stenotic iliac segment can prevent a pressure drop across it. A decrease in pressure of 20 mm Hg or more at any one level in comparison to the level above indicates significant disease. Because the most distal cuff is at the ankle, disease below this level is not detected.

Segmental pressure measurements do not detect disease in nonaxial vessels, such as the profunda femoris. Because of the difficulty in detecting stenoses when flow is restricted, multilevel disease can be difficult to identify when a proximal stenosis is causing a significant decrease in distal pressure and flow. Side-to-side comparisons should be made and are meaningful when there is a difference, but they may be misleading in patients with symmetric disease in the two extremities.

Figure 20.7 Segmental pressure is measured with the same technique as ankle pressure, but with cuffs placed at the upper part of the thigh, at the lower part of the thigh, below the knee, and at the ankle.

TABLE 20.1 Typical Segmental Systolic Arterial Pressures (mm Hg)

	ARTERIAL DISEASE				
	Normal	Iliac	Superficial Femoral	Iliac and Superficial Femoral	Below-Knee
Arm	120	120	120	120	120
Upper thigh	160	110	160	110	160
Above knee	150	100	100	70	150
Below knee	140	90	90	60	140
Ankle	130	80	80	50	90

An estimate of the extent of collateralization around the knee in patients with superficial femoral artery occlusion can be made using the profundapopliteal collateral index (PPCI).[30] PPCI is calculated as the difference between the above-knee and below-knee blood pressure divided by the above-knee pressure. A low index indicates good collateral development (little pressure drop across the knee). In general, a PPCI of less than 0.25 predicts a good result from profundaplasty without infrainguinal bypass, whereas a PPCI of greater than 0.50 predicts no improvement with profundaplasty alone.[31]

Use of segmental pressure does not add to simple ABI in improving the accuracy of Doppler waveform analysis in the diagnosis of PAD.[32] Segmental pressure measurement is frequently combined with pulse volume recording (see later) to provide a more accurate method for diagnosing PAD. Disadvantages include lack of exact anatomic detail, patient discomfort, and the potential to damage balloon-expandable peripheral arterial stents.

Digital Pressure Measurement

Pressure in a digit can be measured in much the same way as arm and ankle measurements. An appropriately sized minicuff is placed around the base of the digit and attached to a standard manometer. Any type of flow detector can be used to determine when flow returns as the inflated cuff is slowly deflated. Most commonly used are photoplethysmography (PPG) probes and continuous wave Doppler flow detectors placed on the distal phalanx, but laser Doppler probes have also been used and may be more sensitive to extremely low flow.[33] As digital arteries are less commonly calcified than tibial arteries, toe pressures are most useful in patients prone to arterial calcification, such as diabetics and patients with chronic kidney disease. Toe pressure is also sensitive to disease at the level of the pedal arch and digital vessels, which is not detectable by ankle pressure measurements.[34] However, even digital arteries can be calcified and noncompressible, at which point waveform analysis or transcutaneous oxygen tension ($tcPO_2$) measurements may be helpful.

Normal toe pressure is 20 to 40 mm Hg less than ankle pressure, possibly because of the measurement technique. A toe-brachial index less than 0.7 is considered abnormal.[11] Pressures of 30 mm Hg or lower are associated with ischemic symptoms (see Fig. 20.6B). Foot lesions usually heal when the toe pressure is greater than 50 mm Hg (or slightly higher in diabetics). The correlation between foot wound healing and toe pressure is shown in Fig. 20.8. Unfortunately, toe pressures often cannot be obtained in patients with forefoot and digital gangrene for whom transmetatarsal amputation is contemplated. For more detail on methods to predict amputation healing at various levels, see Chapter 111, Lower Extremity Amputations: Epidemiology, Procedure Selection, and Rehabilitation Outcomes.

Stress Testing

As noted earlier, the pressure reduction across a stenosis depends on the rate of flow through it. This is the basis of exercise testing to detect stenoses that may not cause abnormalities at rest. It is a useful, practical method for quantitating the functional effect of arterial insufficiency.

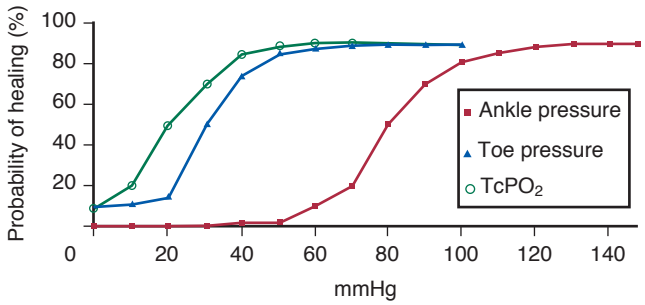

Figure 20.8 A schematic estimate of the probability of healing of foot ulcers and minor amputations in relation to ankle blood pressure, toe blood pressure, and transcutaneous oxygen pressure (tcPO2) based on selected reports. (From Bakker K, Apelqvist J, Schaper NC; International Working Group on the Diabetic Foot Editorial Board. Practical guidelines on the management and prevention of the diabetic foot 2011. *Diabetes Metab Res Rev.* 2012;28:225–231.)

Exercise Testing

Because most patients with claudication and those with ischemic symptoms have decreased ABI at rest, exercise testing is only rarely required to diagnose PAD. This test is most useful when it is difficult to distinguish between true arterial claudication and pseudoclaudication or when patients have both. It also helps to determine the extent to which cardiopulmonary, orthopedic, and vascular disease contributes to the patient's difficulty walking.

For standard exercise testing the patient rests supine for 20 minutes, after which resting ABI is measured. Blood pressure cuffs are left in position at both ankles and the upper extremities, and the patient is asked to walk at 2 miles/h on a treadmill at a 12-degree inclination for 5 minutes or until forced to stop because of symptoms (Fig. 20.9A). Note is taken of the time to initial symptom onset, the nature of the symptoms, and the time until stopping, which may be influenced by many factors, such as shortness of breath, patient motivation, and muscular pain. The patient is then asked to lie down, and ankle and arm pressures are measured immediately and then every 2 minutes for 10 minutes or until the pressure returns to resting levels.

Clinically significant lower extremity PAD can be reliably ruled out in patients who can walk the entire time without symptoms or a decrease in the ABI. The severity of PAD is reflected by the extent of the post-exercise drop and the length of time required to return to baseline levels (see Fig. 20.9B). Patients with mild disease may have normal resting pressure but a mild drop in pressure after exercise that returns within minutes to baseline levels. Those with moderate to severe disease have abnormal resting ABIs with further decreases after exercise that persists throughout the post-exercise observation period of 10 to 15 minutes. Patients who have less than a 20-mm Hg pressure drop at the ankle in comparison with the upper extremity rarely benefit from vascular reconstruction. The exception to this is a patient with a mild or no arterial stenosis at rest and vasoconstriction induced by intense exercise as seen in iliac endofibrosis. A standard walking test does not result in a drop

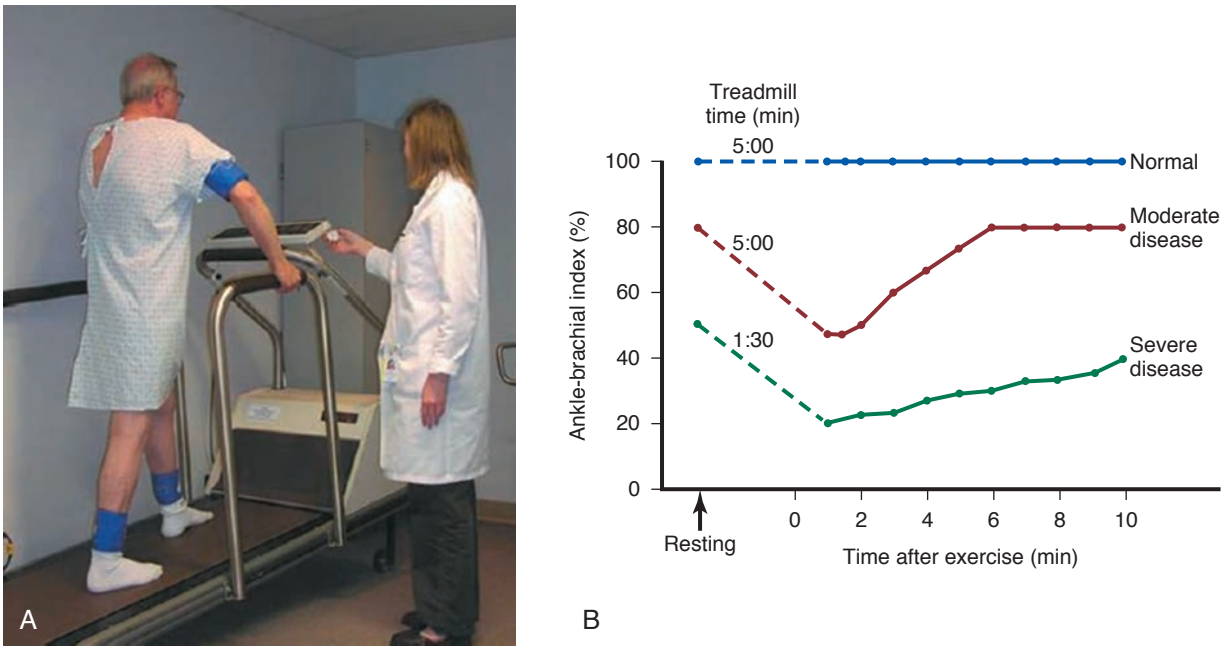

Figure 20.9 (A) Patient undergoing a standard treadmill test. Pressure cuffs are left in position at the arms and ankles to allow immediate measurement on stopping. (B) Examples of exercise test results in patients with various degrees of peripheral arterial occlusive disease. The resting ankle-brachial indices are noted, followed by similar measurements immediately after exercise and for several minutes thereafter.

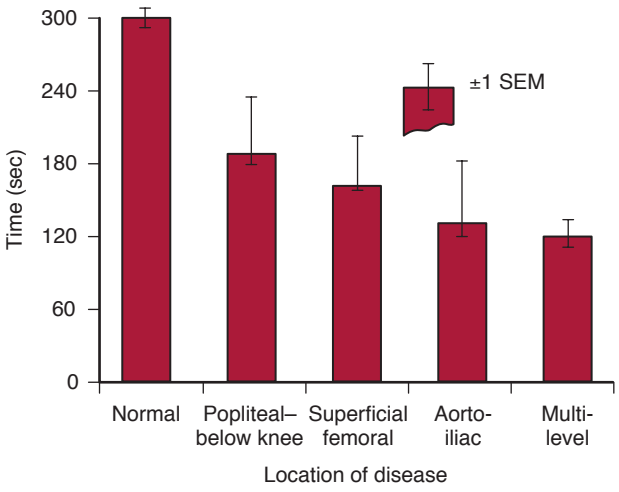

Figure 20.10 Treadmill walking times in patients with occlusive arterial disease. Normal individuals can almost always exceed 5 minutes (300 seconds). (Modified from Strandness DE Jr, Sumner DS. *Hemodynamics for Surgeons.* New York: Grune & Stratton; 1975.)

in ankle pressure in these young athletes; and a more intense exercise protocol may be required to elicit symptoms and a pressure drop.[35]

The treadmill test tends to be more positive with proximal disease than with distal disease (Fig. 20.10). The aortoiliac vessels supply all the musculature of the lower extremity, including the large muscular groups of the buttock and thighs, so the effect of lesions in these vessels is greater than the effect of isolated occlusion of an infrainguinal vessel. Exercise testing is not effective for detection of disease below the level of the popliteal artery because the sural branches to the gastrocnemius muscle come off at or proximal to this level. This is the same reason that revascularization of tibial arteries is not generally indicated for patients whose only complaint is claudication.

Reactive Hyperemia

There are times when exercise testing is not possible because of comorbid conditions or during situations when walking is not possible. In these situations, flow may be increased by reactive hyperemia or vasodilators. Reactive hyperemia is induced by occlusion of blood flow to the extremity by the tourniquet effect of a proximal blood pressure cuff inflated above the systolic pressure level for 3 to 5 minutes. When the cuff is released, peripheral vascular resistance is reduced, and flow is increased. This test is used infrequently because it is uncomfortable and does not produce sustained increases in flow. Reactive hyperemia can also be used to assess endothelial function in the brachial artery reactivity test.[36]

For the standard lower extremity reactive hyperemia test, a cuff placed around the thigh is inflated above systolic pressure for 3 to 7 minutes. After cuff deflation, ankle pressure is monitored two or three times a minute for up to 6 minutes or until measurements return to resting levels. In normal individuals, ankle pressure drops immediately to approximately 80% of resting levels but recovers within minutes to nearly normal levels. In patients with PAD the drop in pressure is approximately the same as that occurring after exercise, but recovery is more rapid, presumably because there is less oxygen debt. The magnitude of the drop in pressure correlates with the severity of disease, as does the length of recovery time, although less closely. This test has advantages over treadmill testing, such as being faster and less cumbersome, not needing a treadmill, not depending on patient motivation, being more easily standardized,

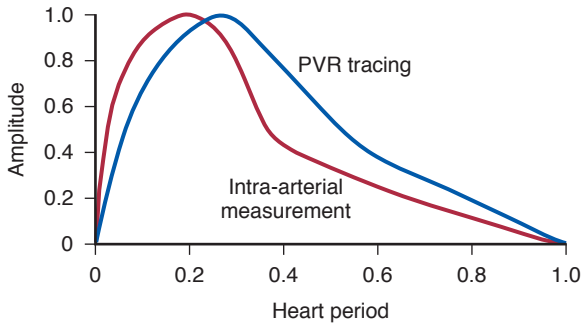

Figure 20.11 Comparison of pressure contours obtained with the pulse volume recorder (PVR) and direct cannulation of the common femoral artery. Axes normalized: y = fraction of maximal amplitude; x = fraction of one cardiac cycle. (Redrawn from Darling RC, Raines JK, Brener BJ, Austen WG. Quantitative segmental pulse volume recorder: a clinical tool. *Surgery.* 1972;72:873–877.)

and not being affected by cardiovascular or orthopedic conditions. Disadvantages include less specificity and sensitivity than exercise testing, patient discomfort, and more operator dependence because of the need for rapid pressure measurements, and it does not directly test the patient's ability to walk. These factors tend to outweigh the advantages of this technique, particularly because duplex scanning provides greater anatomic detail without patient discomfort.

Direct Pressure Measurement

In some cases it is difficult to determine either by imaging or indirect testing whether a segment of artery has clinically significant narrowing. In such cases the most definitive test is direct pressure measurement, which can be done intraoperatively or at the time of percutaneous angiography. Vasodilators can be used when results are equivocal. Measurement of pressure along the course of a bypass can be a useful, rapid means of locating technical problems. The technique is simple. The artery at the level of interest (generally the common femoral artery when the aortoiliac segment is being assessed) is punctured with a 19-gauge needle and connected to a standard strain gauge with stiff tubing. When comparing with a reference pressure, such as the radial artery, the same pressure transducer is used to make it easy to switch between the two pressure lines and to eliminate errors that may be caused by having the two transducers at different heights. Direct pressure measurement is the gold standard to which indirect methods are compared (Fig. 20.11).

Penile Pressure

Of the three paired penile arteries, which all arise from the internal pudendal artery (Fig. 20.12), the cavernosal artery is the most important for erectile function. Proximal occlusive disease can be responsible for vasculogenic impotence. Measurement of penile blood pressure is performed by applying a pneumatic cuff 2.5 cm in width to the base of the penis. Return of blood flow when the cuff is deflated can be detected by a mercury strain-gauge plethysmograph, a PPG probe applied to the anterolateral aspect of the shaft, or a Doppler flow probe.

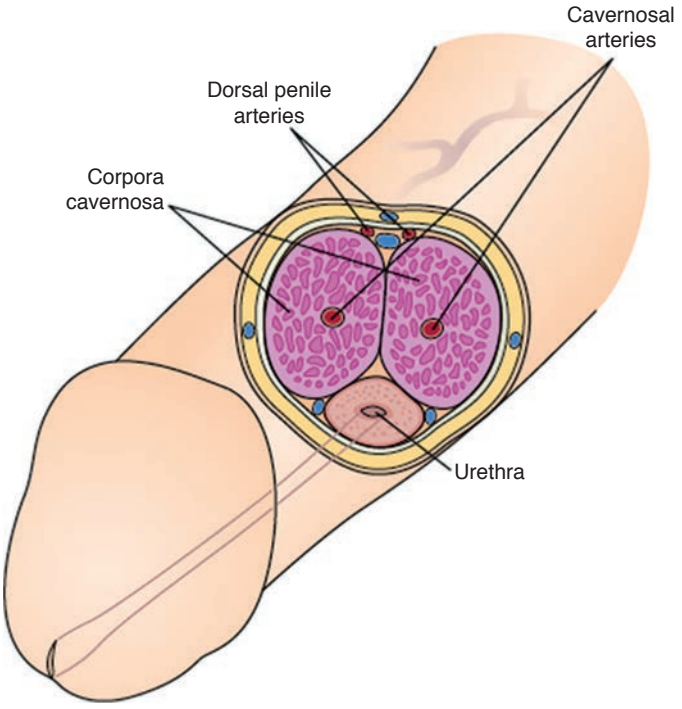

Figure 20.12 The paired penile arteries *(urethral arteries not shown).*

Although some investigators have positioned the probe over the dorsal penile arteries, others have emphasized the importance of detecting flow in the cavernosal artery.[37]

Penile pressure and brachial pressure are normally equivalent, but penile-brachial index declines with age. Penile-brachial indices greater than 0.75 to 0.80 are considered compatible with normal erectile function; an index of less than 0.60 is diagnostic of vasculogenic impotence, especially in patients with peripheral vascular disease. A brachial-penile pressure gradient of less than 20 to 40 mm Hg suggests adequate penile blood flow. Gradients in excess of 60 mm Hg suggest arterial insufficiency. For a more detailed discussion of the assessment of erectile dysfunction, including other diagnostic modalities, see Chapter 192.

PLETHYSMOGRAPHY

Plethysmography is based on measurement of change in volume of the extremity caused by the cyclic nature of arterial inflow. The technique was developed using a mercury strain gauge placed around the extremity. Change in volume causes a change in circumference and therefore in the length and electrical resistance of the strain gauge. The resistance is easily measured and plotted on a strip chart, which results in a waveform that has the same basic contour as the pressure wave (see Fig. 20.11).[38] Impedance plethysmography works on similar principles; it monitors electrical impedance, which is inversely proportional to volume. These devices have largely been replaced by air plethysmography, which monitors pressure in a cuff placed around the extremity and inflated to 65 mm Hg, because the cuffs are more rugged and easier to use. Raines and colleagues, who developed these instruments, called them pulse volume recorders (PVRs).[39,40]

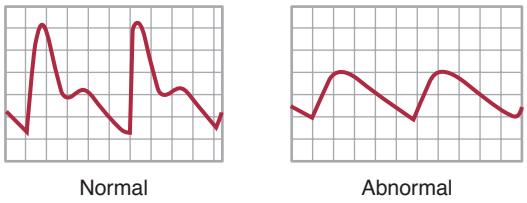

Figure 20.13 Normal and abnormal pulse volume contours recorded at the ankle level. The normal form shows a prominent dicrotic wave on the downslope. Cuff pressure, 65 mm Hg; cuff volume, 75 mL.

TABLE 20.2 Definition of Pulse Volume Recorder Categories

CHART DEFLECTION (mm)			DV (mm^3)		
Category	Thigh and Ankle	Calf	Ankle	Calf	Thigh
1	>15[a]	>200[a]	>160	>213	>715

[b]No reflected wave.
DV, Maximal segmental volume change per heartbeat.

Pulse Volume Recording

Like segmental pressure measurements, PVR waveforms obtained at various levels of the lower extremity can be used to infer the presence and location of arterial occlusive disease. The normal pulse contour has a rapid upslope, a sharp systolic peak, a dicrotic notch, and a downslope that bows toward the baseline (Fig. 20.13). Downstream from stenotic segments, the waveform becomes dampened—the upstroke becomes less steep, the dicrotic notch is lost, and the overall amplitude is decreased. Thus a decrease in pulsatility (either the amplitude or upstroke) from one segment to the next indicates the presence of stenosis upstream. The extent of the changes in the waveform is related to the severity and extent of the proximal disease. Similar waveform changes may be also caused by downstream disease, confounding results.

Although the amplitude of the plethysmographic pulse is reduced by arterial occlusive disease, it alone is not a useful parameter for determining the extent of disease. Amplitude is fairly constant within an individual; however, intersubject variability is large because of differences in body and limb size, blood pressure, peripheral resistance, and cardiac output. A classification scheme has been devised to rate arterial disease from normal (1) to mild (2, 3) to severe (5), based on amplitude and changes in the waveform (Table 20.2). Pulse amplitude increases in normal limbs after exercise. As with pressure measurements, waveform contours that are normal at rest may become abnormal with increased flow. Flow-limiting stenosis causes deterioration of the waveform and reduction of the PVR amplitude at the ankle. PVR tracings from limbs with various combinations of disease are shown in Fig. 20.14.

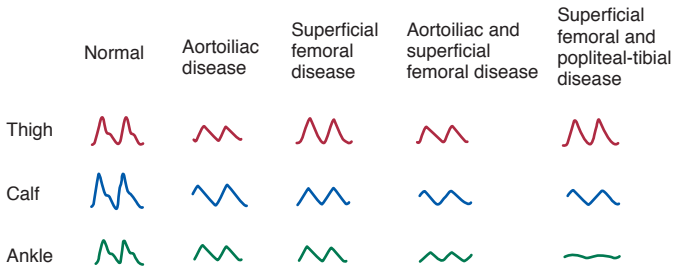

Figure 20.14 Pulse volume recorder tracings from a normal limb and from limbs with various combinations of peripheral vascular disease. (Modified from Rutherford RB, Lowenstein DH, Klein MF. Combining segmental systolic pressures and plethysmography to diagnose arterial occlusive disease of the legs. *Am J Surg.* 1979;138:216.)

PVR is less affected than pressure measurements by arterial calcification. The combination of segmental pressure measurements and PVR is more accurate than either method alone for detecting PAD.[41] There is current debate regarding whether these indirect physiologic tests should be completely replaced with arterial duplex scanning; however, they require less technologist expertise, allow assessment of the adequacy of the collateral circulation, and may be more appropriate for screening purposes.

Digital Plethysmography

As mentioned earlier, digital pressure measurements are useful when calcification of tibial vessels causes false elevations in ankle pressure or when patients have occlusive disease distal to the ankle level. The PPG probe commonly used for this application sends an infrared light into the tissue and has a detector for backscattered light that corresponds to the variation of blood volume over time.[42] The pulse oximeter is a form of PPG probe.

Pulse Contour

Changes in the plethysmographic waveform in the digit reflect any proximal disease. Significant disease documented by digital pressure and abnormal plethysmographic waveforms may be present despite adequate ankle pressure. Digital PVR is also useful for determining the extent of sympathetic activity in patients with cold sensitivity or the presence of significant steal syndrome caused by dialysis access grafts. Comparison of waveforms and digital pressures with and without access flow occlusion demonstrates the hemodynamic effects of the access.

The pulse contour in the digits is similar to that described previously for the lower extremity with the normal waveform having a rapid upslope, a sharp systolic peak, a dicrotic notch, and a downslope that bows toward the baseline. Occlusive disease causes dampening of the waveform with flattening and loss of the dicrotic notch. In extreme cases there may be no detectable waveform. Conversely, the presence of a normal digital waveform indicates that there is no clinically significant arterial disease in the arteries supplying the digit.

Reactive Hyperemia

Because resistance vessels in extremities with significant flow-limiting PAD are already maximally dilated to compensate for reduced flow, there is little additional response to reactive

hyperemia. A cuff is placed at the ankle or above, inflated above systolic pressure for 3 to 5 minute then, and rapidly deflated while the digital PVR is monitored. In normal limbs the pulse returns rapidly, attains half its baseline amplitude within a few seconds, and then rises quickly to twice baseline (Fig. 20.15A). With PAD, reappearance of the waveform and return to half the resting value are markedly delayed in proportion to the severity and extent of the disease (see Fig. 20.15B–D, Table 20.3).

The response to reactive hyperemia requires resting sympathetic tone. Therefore this test is useful for predicting the response to sympathectomy, which increases blood flow by decreasing peripheral resistance. If the increase in PVR amplitude is less than twice the resting level, sympathectomy likely will not improve skin blood flow. However, the response to reactive hyperemia is not dependent on intact sympathetic innervation, so this test cannot be used to determine if the sympathetic nerves are intact. Instead the deep breath test can be used for this purpose. Sympathetic innervation is intact if there is a decrease in pulse volume in response to a deep breath.

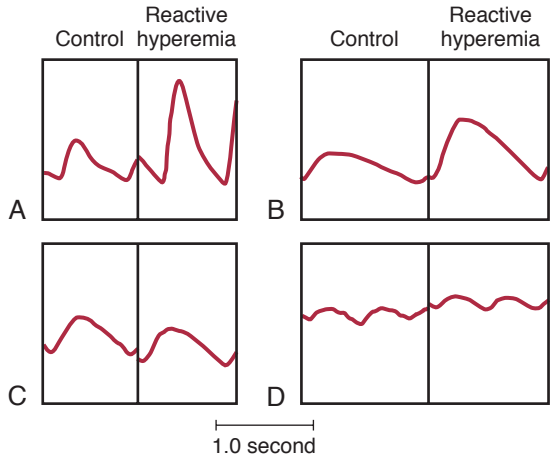

Figure 20.15 Reactive Hyperemia Test; Digit Pulse, Second Toe. Digit pulse volume more than doubles with a normal response *(upper panels)*. Little hyperemic response in pulse volume is evident with an abnormal response *(lower panels)*. (A) Normal circulation. (B) Superficial femoral occlusion. (C) Diabetic for 20 years. (D) Iliac and superficial femoral arterial disease.

TABLE 20.3 Pulse Reappearance Time After Release of Arterial Occlusion

Location of Occlusive Disease	Pulse Reappearance Time (s)	Time Required to Reach Half Control Volume (s)
No occlusion	0.2 ± 0.1	3.4 ± 0.8
Aortoiliac	7.2 ± 4.0	23.9 ± 6.7
Femoropopliteal	3.7 ± 3.7	26.5 ± 12.7
Popliteal trifurcation	15.2 ± 9.3	23.9 ± 9.4
Multilevel	45.3 ± 5.5	71.2 ± 5.5

Modified from Fronek A, Coel M, Bernstein EF. The pulse-reappearance time: an index of over-all blood flow impairment in the ischemic extremity. *Surgery*. 1977;81:376.

OTHER METHODS

Several methods can be used to evaluate the effects of PAD on the microcirculation, including $tcPO_2$, laser Doppler, hyperspectral imaging, cold testing, vasoreactivity, and capillaroscopy. The first two are briefly discussed in this chapter. The others are less commonly performed, and the reader is referred to the literature to learn more about their role in the diagnosis of PAD.[43,44]

Transcutaneous Oxygen Tension

$TcPO_2$ measurements reflect the metabolic state of the target tissues. Electrodes containing a circular silver–silver chloride anode surrounding a central platinum cathode are placed on the skin at the dorsum of the foot, the anteromedial aspect of the calf 10 cm below the patella, and the thigh 10 cm above the patella. The subclavicular region of the chest has been used as a reference site to calculate a regional perfusion index in an effort to control for variation caused by age, cardiac output, and arterial partial pressure of oxygen (PO_2). This index is not widely used. Oxygen diffusing to the surface of the skin is reduced at the cathode to produce a current proportional to the PO_2 within the sensor. The electrode has a heating element that raises the skin temperature to 45° C for optimal blood flow and diffusion of oxygen, from vasodilatation, rise in capillary PO_2, liquefaction of lipids in the stratum corneum, and a right shift in the oxyhemoglobin dissociation curve.[45]

Transcutaneous oxygen measurement is relatively insensitive to mild or moderate degrees of PAD because the oxygen supplied to the skin is far greater than the demand. Furthermore, because the oxyhemoglobin dissociation curve does not change rapidly until oxygen saturation drops to less than 80%, capillary oxygen tension does not decrease until inflow is severely restricted and oxygen demand equals or exceeds supply. When values are low, $tcPO_2$ is not linearly related to flow. A value of zero means all the available oxygen has been consumed rather than the absence of flow. Measurement of $tcPO_2$ must be interpreted cautiously as it is affected by many factors that are difficult to measure or to control and therefore is unreliable (Box 20.1). For this reason and because the method is time consuming, it has not gained wide popularity.

BOX 20.1 Factors Affecting Transcutaneous Oxygen Tension

Skin temperature
Sympathetic tone
Body temperature
Cellulitis
Hyperkeratosis
Obesity
Edema
Metabolic activity
Oxygen diffusion through tissue
Oxyhemoglobin curve
Increased venous pressure
Vertical position of the site of measurement relative to the heart
Age

Measurement of $tcPO_2$ is most helpful for evaluating cases of severe ischemia, particularly when determining the optimal level for amputation. It is especially useful in diabetic patients because it is not affected by arterial calcification. Normal $tcPO_2$ values depend on age (higher for younger patients) and position (higher for more proximal locations). In general, values greater than 55 mm Hg are considered normal. Proximal locations are less sensitive than more distal locations to PAD, with the foot being the most sensitive. Wound healing is not reliable when the local $tcPO_2$ is between 20 and 40 mm Hg (see Fig. 20.8).[46]

Various enhancement procedures have been proposed to improve the discriminative value of $tcPO_2$. Among these are observing the change in $tcPO_2$ with dependency.[47] Advanced disease is associated with a larger increase when the patient moves from the supine position to sitting or standing. This increase in $tcPO_2$ may be related to the increased hydrostatic pressure that dilates capillaries and resistance vessels, thereby increasing flow. This phenomenon may explain why dependency relieves rest pain.[48] Exercise is followed by a decrease in skin $tcPO_2$ because of shunting of blood away from the foot by dilatation of intramuscular vessels. The $tcPO_2$ response to hyperemia is similar to that of ankle pressure; it decreases after inflow obstruction and is much slower to recover in patients with severe PAD. Finally, oxygen inhalation has been used in attempts to improve the accuracy of $tcPO_2$ for determining the amputation level and predicting the effectiveness of hyperbaric oxygen therapy. A greater than 10 mm Hg increase after the inhalation of 100% oxygen is considered normal.[49] Patients with severe PAD have a much smaller increase in $tcPO_2$ than do normal individuals upon oxygen inhalation. None of these enhancement techniques have improved the reliability of the test enough to make transcutaneous oxygen measurement a routine part of most vascular laboratory practices.

Laser Doppler and Skin Perfusion Pressure

The laser Doppler uses monochromatic light to detect motion of red blood cells to a depth of approximately 1.5 mm in the skin.[50] The actual depth depends on the power of the laser beam, the thickness of the epidermis, and skin pigmentation. Cutaneous blood flow includes vessels in a complex, interlacing network. Light is backscattered by the tissues after transmission and again after it is reflected back to the receiving system. As a result the frequency shifts are a composite of multiple vessels with multiple velocities and multiple angles. The output, measured in millivolts, is approximately proportional to the average blood flow in a 1.5-mm^3 volume of skin lying 0.8 to 1.5 mm below the skin surface. The signal tracing has pulse waves that coincide with the cardiac cycle and vasomotor waves at a frequency of four to six times per minute. The instrument cannot be calibrated to give an exact estimate of blood flow because of the multiple factors that affect the signal. It is useful when only qualitative information is needed.

Resting values in the lower extremity vary anatomically and are highest in the great toe and lowest in the proximal part of the leg. PAD causes attenuation of the waveform, a reduction in velocity, and loss of vasomotor waves. Like $tcPO_2$ and ankle pressure, the response to hyperemia is diminished, and the time to recovery is increased. The ability of this test to predict amputation healing is not as good as that of transcutaneous oxygen measurements. Laser Doppler can be used with blood pressure cuffs to measure skin perfusion pressure.[33] The probe can be placed distally as a flow detector for similar results in obtaining segmental pressures, or beneath the cuff, which is then inflated. The pressure at which skin blood flow returns is noted as the cuff is slowly deflated. Normal pressures of 50 to 70 mm Hg are decreased to 10 to 20 mm Hg with significant PAD. Pressures less than 30 mm Hg are predictive of critical limb ischemia.[51] A combination of skin perfusion pressure greater than 40 mm Hg and toe blood pressure greater than 30 mm Hg has been associated with successful lower extremity wound healing.[52]

Duplex ultrasound (DUS) is an integral component of diagnostic testing for the evaluation and management of arterial disease. This technology, which combines the acquisition of blood flow (pulsed Doppler spectral analysis) and anatomic (B-mode and color Doppler imaging) information, was developed under the guidance of D. Eugene Strandness, Jr., at the University of Washington in the 1970s.[1] The initial clinical application of arterial duplex scanning assessed the extracranial carotid artery bifurcation for the presence and extent of atherosclerotic plaque and developed velocity criteria to estimate internal carotid artery (ICA) stenosis on the basis of correlations with angiographic measurements.[2] Commercial duplex scanners became available by the 1980s, and the clinical use of DUS rapidly expanded into peripheral arterial, visceral arterial, and peripheral venous applications. The development of real-time, color-encoded Doppler imaging was an important technologic advance that simplified patient testing, enhanced diagnostic accuracy, and led to additional clinical applications in the areas of screening for arterial disease, intraoperative assessment, and surveillance after arterial intervention.

Modern DUS systems provide high-resolution B-mode ultrasound imaging of tissue and vessel anatomy, including three-dimensional vessel reconstruction and evaluation of atherosclerotic plaque morphology. Detailed assessment of blood flow characteristics can be made in real time by one of several techniques, color Doppler imaging, power Doppler imaging, B-flow imaging, or pulsed Doppler spectral analysis.

Test interpretation is based on both imaging and Doppler findings with classification ranging from normal to clinically relevant disease categories. Duplex testing is noninvasive and cost-effective and thus suitable for serial examination; because it not only permits the identification of disease, but also reveals its natural history, including progression, regression, and response to intervention. In many patients, duplex testing can establish a definitive diagnosis and can allow interventions, such as carotid endarterectomy or peripheral artery angioplasty, to be based solely on the B-mode imaging and velocity spectral changes recorded from diseased arterial segments. In the upper and lower limbs, duplex testing should be performed in conjunction with indirect physiologic testing (measurement of systolic blood

pressure, pulse volume plethysmography) to assess arterial hemodynamics (see Chapter 20). When peripheral arterial disease is identified, DUS can be used to map the site or sites of occlusive or aneurysmal lesions, analogous to contrast-enhanced arteriography. Arterial duplex test interpretation combined with the patient's clinical history and physical examination is often sufficient to counsel the patient on the advisability of intervention and whether it can be performed by an endovascular or conventional open surgical procedure.

The reliability of arterial duplex testing depends on several factors, including the expertise of the examiner (vascular technologist, physician) and the knowledge and experience of the interpreting physician. Testing performed and interpreted in an accredited vascular laboratory has sufficient diagnostic accuracy for clinicians to rely on the final interpretation provided and often avoid performing more invasive, expensive diagnostic testing, such as computed tomography, magnetic resonance imaging, or catheter-based contrast-enhanced angiography, to confirm disease severity.

INSTRUMENTATION AND BASIC CONCEPTS

DUS systems use transducers fabricated from piezoelectric crystals to convert electrical activity to mechanical energy (ultrasound) and vice versa, thereby allowing the same device to transmit and receive ultrasound signals to and from the patient to produce images of tissue anatomy as well as to characterize blood flow. Transducers consist of multiple elements that enable focusing of the ultrasound beam, steering of the beam, and resolution sufficient for detailed tissue imaging at depths of less than 1 cm to more than 20 cm. To perform detailed arterial mapping, DUS instrumentation for carotid and peripheral testing should be equipped with linear array transducers with frequencies ranging from 5 to 12 MHz. For visceral artery or abdominal imaging and transcranial Doppler (TCD) examination, lower frequency transducers are needed because of the higher tissue attenuation; typically, 2.5- or 3.5-MHz curved linear or phased array transducers are appropriate. Newer generation transducers have an ultrawide bandwidth that enables harmonic imaging, with its increased resolution and freedom from artifacts, and dynamic frequency tuning for improving image quality at greater tissue depths. Moreover, the development of two-dimensional transducer arrays enables the beam to be focused at a specific depth and steered, which facilitates the use of three-dimensional imaging.

A duplex B-mode, or brightness mode, ultrasound image is displayed as gray-scale pixels reflecting the amplitude and position of returning ultrasound echoes. By processing up to 200 or more separate ultrasound beam signals retrieved from the transducer array, a scan converter organizes both horizontal and vertical pixels to yield a two-dimensional view of the tissue being scanned. Optimal arterial anatomic imaging is achieved when the transducer scan lines (beam) are directed perpendicular to the vessel wall. A 90-degree imaging angle is best used for measuring vessel diameter, identifying intima-media thickening, and assessing atherosclerotic plaque composition. Transmit power and receiver gain should be adjusted to produce a gray-scale image with the best tissue signal-to-noise ratio so that subtle differences can be perceived by the human eye. The examiner can modify image appearance by adjustment of the instrument's time gain compensation, which is designed to correct for the effects of increasing attenuation with depth. When duplex arterial imaging is performed, the left side of the image should be oriented toward the patient's head.

There are two types of Doppler ultrasound displays. In one form, a color-flow Doppler image shows the flow velocity distribution over a wide area displayed as a color-encoded map superimposed on the gray-scale B-mode tissue image. The second type, often referred to as spectral Doppler, shows the time-varying flow velocity distribution at a selected sample volume. Spectral Doppler provides quantitative information on the peak velocity within the sample volume, whereas color-flow Doppler provides semiquantitative information on the distribution of velocities over an entire region.

To obtain reliable information from spectral Doppler, it is best to use scan line angles (i.e., Doppler angles) of 60 degrees or less relative to the transducer insonation beam and arterial wall (Fig. 21.1). Assignment of the Doppler angle is controlled by the examiner. Because calculation of blood flow velocity is determined by the Doppler equation, which is proportional to the cosine of the Doppler angle, recording velocity spectra at large Doppler angles results in reduced Doppler frequency shift and thereby increases flow velocity error as a result of uncertainty in knowing the true Doppler angle. For example, an error in Doppler angle assignment such as 5 degrees higher than the recommended 60 degrees (i.e., at 65 degrees) will result in a 15% measurement error in flow velocity, whereas if a 55-degree angle was assigned, an 8% error results. The velocity measurement error caused by incorrect or imprecise assignment of the Doppler angle by the examiner is a common duplex testing inaccuracy that can result in overestimation or underestimation of the severity of the stenosis when disease classification is based on

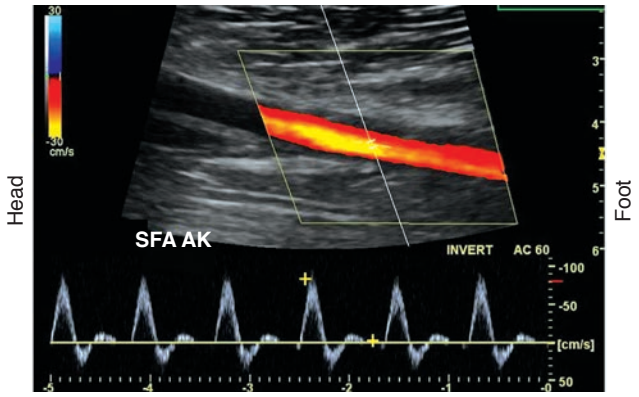

Figure 21.1 Color duplex image with velocity spectra of normal superficial femoral artery (SFA) flow recorded from the above-knee segment (AK) with a 60-degree Doppler beam angle. Note that the pulsed Doppler sample volume is positioned in the center stream of flow, where color-flow pixels indicate the highest flow velocity.

peak systolic velocity (PSV) or end-diastolic velocity (EDV) criteria. When pulsed Doppler flow signals are recorded, the instrument sample volume should be sized to encompass less than a third of the flow lumen and should be positioned in the center stream of flow.

Blood Flow Imaging Techniques

Blood flow detection can be performed with one of three imaging techniques: color Doppler, power Doppler, and B-flow.

Color Doppler Imaging

Color Doppler imaging refers to pixel encoding of blood flow based on a color bar that depicts both flow direction (toward and away from the transducer) and mean velocity (MV). The examiner adjusts the velocity scale, color priority, and saturation of the color bar as well as instrument color gain to show the appearance of normal, laminar arterial flow as homogeneous regions varying in color-coded pixels during the pulse cycle. To set the color gain correctly, the examiner should increase the gain until a noise speckle appears within the flow region and then reduce it slightly. This technique will optimize the display of weak or lower velocity blood flow signals, such as those adjacent to the artery wall. Excessive color gain causes color-coded flow pixels to bleed into or beyond the artery wall, thus making the flow lumen appear larger than reality. Interpretation of real-time color Doppler flow is based on the color bar settings (peak MV, baseline, wall filter, and color assignment of flow toward or away from the transducer). In tortuous vessels, blood flow is color-coded according to its direction relative to the transducer scan lines. When blood flow velocity exceeds the mean peak velocity threshold of the color bar, color aliasing occurs, because the sampling rate as defined by the pulse repetition frequency is no longer sufficient (the Nyquist limit). With aliasing, blood flow is erroneously encoded as the "wrap-around" color shown in the color bar, and the color image display will show flow in the opposite direction. Increasing the pulse repetition frequency and increasing the Doppler angle are two techniques that can be used to reduce the color-flow "aliasing" artifact.

Arterial stenosis is recognized by color Doppler imaging as a reduction in the color-encoded flow lumen, imaging of a high-velocity flow region with color bar aliasing, and development of a mosaic flow pattern in the lumen signifying turbulent flow. At the site of a high-grade (>75% diameter reduction) stenosis, real-time color Doppler flow will appear as a whitened, color-desaturated "flow jet" with mosaic color flow extending for several vessel diameters downstream corresponding to post-stenotic turbulence (Fig. 21.2). A tissue bruit may appear as low-velocity flow signals outside the artery lumen and is caused by vibration of the arterial wall. The presence of persistence of color, color bar aliasing, and changes in flow lumen diameter on color Doppler imaging is indicative of abnormal flow patterns produced by stenosis. The examiner should then carefully interrogate this diseased arterial segment with pulsed Doppler spectral analysis to measure changes in flow velocity, which are then used to estimate the severity of the stenosis.

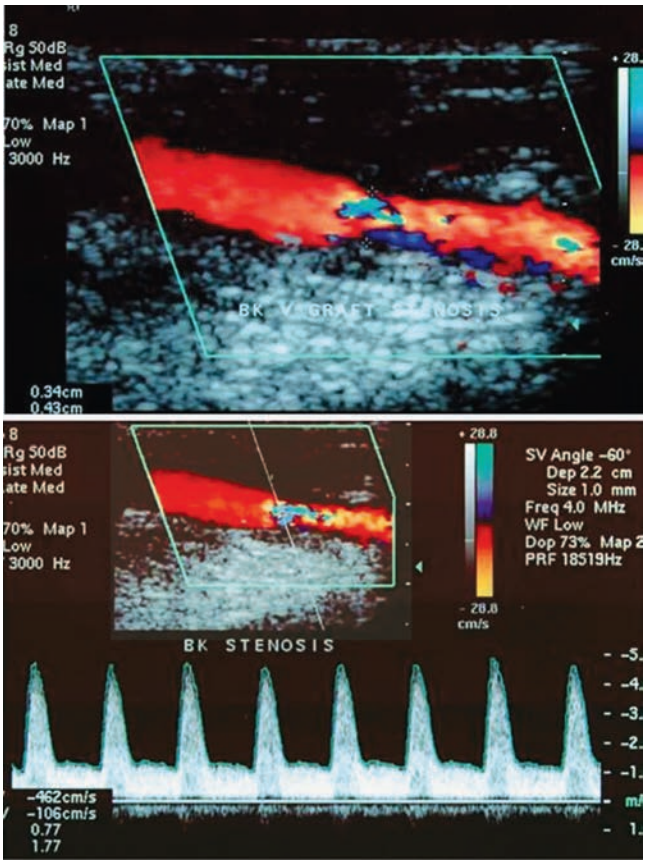

Figure 21.2 Color duplex image and velocity spectra of an arterial vein bypass graft stenosis. *Top image,* Color aliasing occurs at the stenosis when mean velocity is greater than 28 cm/s and extends for several vessel diameters downstream. *Bottom image,* Velocity spectra recording at the stenosis "flow jet" indicates a peak velocity of 426 cm/s and spectral broadening of highly disturbed, turbulent flow.

Power Doppler Imaging

Power Doppler imaging is a technique in which the display of blood flow is based on the amplitude of the backscattered Doppler signal; it increases the sensitivity of flow detection three to five times with respect to color Doppler imaging. This imaging mode is termed "color angio" and is used by the technologist for imaging of small-diameter vessels, detection of slow flow, assessment of residual lumen diameter at a stenosis, and detection of "trickle" flow associated with high-grade stenosis. Flow direction is not evident with the power Doppler imaging option, and the flow signal is less dependent on the Doppler angle.

B-Flow Imaging

B-flow imaging shows blood flow in gray scale; that is, flowing blood and the surrounding structures are depicted in shades of gray. The imaging technique is a visual depiction of flow hemodynamics and should not be confused with color Doppler imaging, because no velocity information is provided. B-flow imaging relies on the amplification of weak echoes from moving red blood cells and is most useful during arterial imaging to show boundary layer flow adjacent to the vessel wall and traversing atherosclerotic plaque. B-flow imaging can demonstrate the

complex flow patterns seen at bypass graft anastomoses and arteriovenous fistulae and within dialysis access conduits where color Doppler artifacts can obscure flow patterns.

Pulsed Doppler Spectral Analysis

Pulsed Doppler velocity spectra recorded from a normal artery have a narrow range of velocities throughout the pulse cycle, which indicates that red blood cells are moving at a similar speed and direction in a nondisturbed, or laminar, flow pattern. If the "sample volume" of the pulsed Doppler is too large relative to the diameter of the artery or positioned adjacent to the arterial wall, low-velocity flow signals will be displayed as "broadening" or increased width of the velocity spectra.

Spectral broadening in the pulsed Doppler signal can also indicate "disturbed" flow or flow turbulence when it is recorded center-stream at bifurcations, regions of abrupt diameter change, and sites of stenosis. The "normal" appearance of arterial duplex flow varies with the artery being studied (peripheral, carotid, renal, or mesenteric) but should demonstrate rapid flow acceleration in systole, narrow spectral width, and varied diastolic flow corresponding to the vascular resistance of the arterial bed.

The velocity spectrum of a normal peripheral (aorta, iliac, extremity, external carotid) artery is triphasic or multiphasic (see Fig. 21.1) and consists of high outflow resistance with a systolic flow component, early diastolic flow reversal, and late diastolic forward flow. Low-resistance arterial flow, such as in the internal carotid, vertebral, renal, celiac, splenic, and hepatic arteries, is characterized by continuous flow throughout the pulse cycle with only a single (systolic) phasic flow component producing a monophasic pulsed Doppler spectral waveform. Changes in flow resistance of the microcirculation are primarily reflected as an increase or decrease in diastolic flow velocity.

Measurements

The pulsed Doppler spectral parameters of acceleration time, pulsatility index (PI), resistive index (RI), and maximum spectral velocity measured at peak systole (PSV) and end-diastole (EDV) constitute the primary criteria used for test interpretation. The PSV measurement is reproducible and thus the most common velocity spectral parameter used for the interpretation of normal arterial flow and critical limb ischemia and for the grading of arterial stenosis. The EDV measurement is used in conjunction with PSV for evaluating high-grade stenosis (>70% diameter reduction; see Table 21.1).

RI is calculated by subtracting EDV from PSV and then dividing by PSV. It is used clinically to assess the renal and cerebral circulations for abnormal peripheral resistance. Normal values are less than 0.7, and levels higher than 0.85 are associated with increased vascular bed resistance and decreased end-organ perfusion.

PI is calculated by dividing the peak-to-peak velocity spectral shift by the average (mean) velocity. The PI of normal peripheral arteries is greater than 4.0 (femoral artery, >6; popliteal artery, >8). PI values lower than 4 may reflect proximal inflow or occlusive disease, and change in PI or spectral waveform damping is diagnostic of multilevel occlusive disease. Division of distal artery PI by proximal artery PI calculates the "damping factor;" a normal value is 0.9 or higher, and a value of less than 0.9 is diagnostic of occlusive disease.

TABLE 21.1 Velocity Spectra Waveform Parameters Used for Interpretation of Duplex Tests

Testing Area	PSV	EDV	RI	AT	PI	Mean Flow Velocity
Carotid duplex	X	X	X	X		
Transcranial Doppler	X		X		X	X
Peripheral duplex	X	X		X	X	
Duplex draft surveillance	X	X	X	X	X	
Renal duplex	X		X		X	
Mesenteric duplex	X	X	X	X	X	

AT, Systolic acceleration time; *EDV*, end-diastolic velocity; *PI*, pulsatility index; *PSV*, peak systolic velocity; *RI*, resistive index.

The systolic acceleration time during systole can also be used to diagnose occlusive disease proximal to the pulsed Doppler recording site. A normal value is less than 133 ms. As systolic acceleration time increases to longer than 200 ms, the spectral waveform develops a rounded upslope configuration, termed tardus-parvus, because of the prolonged time to PSV. Diagnostic accuracy of the systolic acceleration time is influenced by cardiac conditions (cardiomyopathy, aortic valve disease), but downstream occlusive disease has minimal influence on diagnostic sensitivity.

Artifacts and Errors

Artifacts and errors in ultrasound measurement can limit the effectiveness of the evaluation and create inaccurate results. Various artifacts include mirror image artifacts, shadowing from overlying vessel calcification, inaccuracy due to refraction, and aliasing. Most errors can be attributed to the technologist, because studies using flow models have found that adjustment of Doppler angle, sample volume placement, and Doppler gain were the most significant sources of error in PSV measurement.

Spectral Doppler aliasing is the most common artifact and, similar to color Doppler aliasing, is recognized by a "characteristic" signal wraparound in the spectral display. Adjustment of the velocity scale (i.e., pulse repetition frequency) to above the Nyquist limit or a reduction in the baseline level can shift the spectrum downward and eliminate the artifact. Shadowing from overlying calcification impedes adequate visualization of underlying vessel anatomy with B-mode imaging and interferes with accurate velocity measurement. Mirror image artifacts, created when a tissue structure is reproduced at an incorrect location, occur when a strongly reflecting surface is further reflected by other strongly reflecting surfaces.[3] Refraction can cause misregistration of the image and the Doppler sample volume and occurs when an ultrasound beam passes through mediums with different propagation speeds. Crosstalk, found only in Doppler evaluation, creates a mirror image where identical spectra appear above and below the baseline. It is

usually caused by an excessive receiver gain setting or an incident angle near 90 degrees. Ghosting occurs when low-velocity motion from pulsating vessel walls produces small Doppler shifts that can cause color flashing into the surrounding anatomy; it can be fixed with wall filters.

Variability of diagnostic criteria between laboratories stems from methods for defining the percentage of stenosis, different machines, and differences in technique.[3] Factors such as gender and physiologic condition of the patient can also affect the outcomes of DUS evaluations. Studies have found that carotid PSV measurements in women average 10% higher than in men.[4] Congestive heart failure, dysrhythmias, and artificial support measures (ventilators, intraaortic balloon pumps, or pacemakers) can alter cardiac output, which in turn can affect PSV measurements. Regarding technologist error, the largest source is error in accurately aligning the cursor of the sample volume. Even small errors in angle measurement can result in significant errors in velocity measurement and severity of the stenosis.[3] Sample volume assumes that flow is parallel to the walls; however, flow is not usually parallel in tortuous vessels or beyond an asymmetrical stenosis, and these situations can make correct sample volume positioning and true velocity readings difficult. Finally, the most accurate measurement of PSV at a stenosis is within the narrowest portion of the stenosis, and reproducible measurements can be best obtained only if the sample volume is placed at or very near this area.

Duplex Velocity Spectral Classification of Arterial Stenosis

A significant or "critical" arterial stenosis is a lesion that is associated with a resting systolic pressure gradient of more than 15 mm Hg and reduces volume flow. In the peripheral arterial circulation, this correlates with a 50% or larger diameter reduction stenosis or greater than 75% reduction in cross-sectional area. Stenosis produces losses in blood energy primarily as a result of losses in inertial energy caused by the development of turbulent flow; such losses are much greater than the friction energy losses predicted by Poiseuille law.

By measuring changes in velocity proximal to and across an arterial stenosis, duplex testing can noninvasively estimate its hemodynamic significance and predict reductions in diameter within specified ranges (e.g., 0%-49% diameter reduction, ≥50%, 50%-79%, ≥80%). The relationship between the increase in flow velocity and the reduction in diameter by stenosis is nonlinear, especially with stenoses greater than 50% diameter reduction (Fig. 21.3). The DUS characteristics of greater than 50% diameter reduction arterial stenosis include elevated PSV in comparison to adjacent normal segment, a color Doppler mosaic flow pattern, and pulsed Doppler spectral broadening of highly disturbed flow (i.e., post-stenotic turbulence with simultaneous forward and retrograde velocity spectra during systole).

The ratio of PSV (Vr) across a stenosis is a useful parameter for grading the severity of a stenosis; a Vr value higher than 2 indicates a greater than 50% diameter reduction, and a value higher than 4 correlates with greater than 70% diameter reduction. Typically, a pressure-reducing (peak systolic pressure >20 to 30 mm Hg) and flow-reducing arterial stenosis is associated with a Vr above 3.5, a PSV higher than 250 to 300 cm/s, and an elevation in EDV of 40 cm/s or more. Downstream of a "significant" pressure-reducing arterial stenosis, the spectral waveform should appear damped and monophasic with prolongation of the acceleration time and a decrease in PSV to below normal levels.

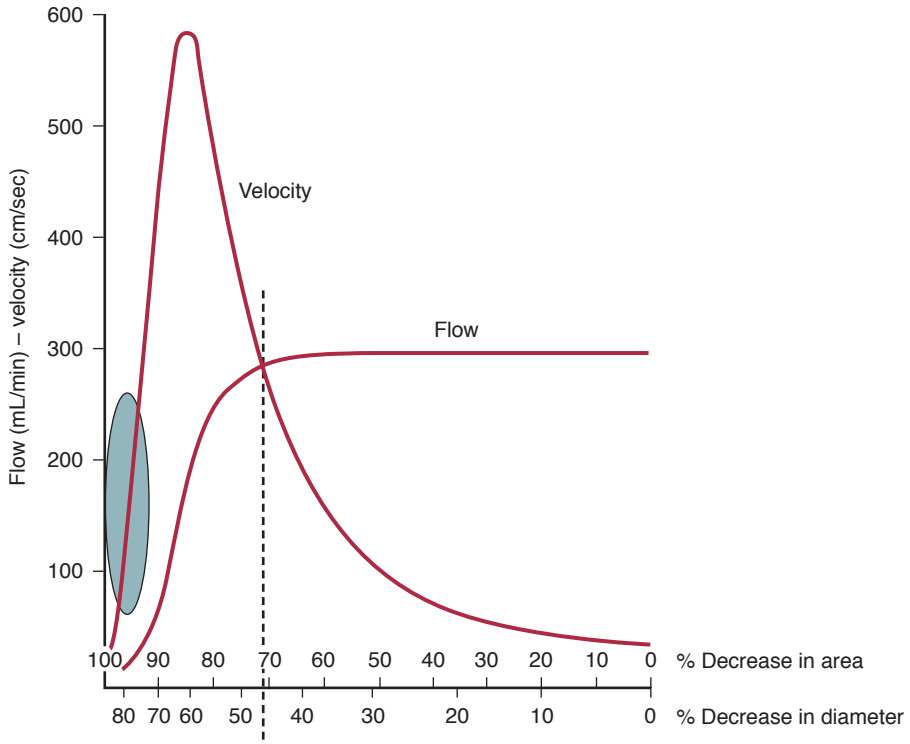

Figure 21.3 Correlation of percent diameter reduction with increases in blood flow velocity (cm/s) and reduction in volume flow (mL/min) in arteries. Note that a high-grade (>95%) diameter-reducing stenosis causes volume flow to decrease toward zero, whereas the velocity within the stenosis may be minimally elevated.

As stenosis severity increases beyond greater than 90% diameter reduction, volume flow through the stenosis tends toward zero, which can produce PSV at the stenosis in a minimally elevated range (100-200 cm/s) and low-velocity (<10 cm/s) trickle flow downstream. The atherosclerotic plaque associated with greater than 50% stenosis is typically irregular and may be calcified, which produces an acoustic shadow on the image and makes measurements of residual artery diameter or reduction in cross-sectional area too inaccurate on transverse imaging to classify the severity of an arterial stenosis. Correlation studies between duplex testing and angiographic measurements have found that PSV and Vr are the best predictors of the severity of stenosis when it is expressed as percentage diameter reduction.

Validation studies comparing duplex interpretation of stenosis severity with angiographic measurements have reported different threshold PSVs for lesions with greater than 50% diameter reduction.[5-19] PSV measurement variation is in the ±15% range, similar to other biologic measurements. This variation is related to the type of ultrasound system used and differences in Doppler angle assessment and sample volume positioning by the examiner. This limitation of duplex scanning can be minimized by reporting stenosis (i.e., diameter reduction) within a specified range (e.g., 0%-49%, 50%-75%, and 76%-99%). In each clinical application, it is recommended that the vascular laboratory conduct ongoing quality assurance studies to confirm that the diagnostic accuracy of stenosis interpretation in their laboratory in comparison to angiographic reports.

Patient Testing

Arterial duplex scanning can be performed as a portable bedside or vascular laboratory examination. Scanning should be conducted on a height-adjustable table or stretcher with the patient in a supine position. The bed and room environment should provide a comfortable, quiet atmosphere for patient examination, a warm room temperature (75-77°F) to avoid vasoconstriction of the extremities, and sufficient space to permit bilateral body access for ultrasound scanning. The typical examination time ranges from 30 to 60 minutes. Patients should refrain from tobacco use for at least 1 hour before the examination, and if abdominal scanning or visceral artery testing is planned, the patient should have fasted for 4 hours, and the examination should be performed in the morning to minimize accumulation of intestinal gas. Assessment of visceral artery flow before and after a test meal may be required for the evaluation of patients with symptoms of mesenteric ischemia.

Peripheral Arteries

Vascular specialists should be familiar with the spectrum of testing available as well as the information provided in conjunction with other hemodynamic tests. The duplex testing performed in the vascular laboratory is an extension of clinical assessment and is used to verify the presence and extent of disease. Numerous studies have analyzed the role of DUS, computed tomography, or MRA for preoperative assessment in efforts to limit the need for digital subtraction arteriography. In contemporary vascular practices, imaging with contrast-based modalities is generally limited to interventional procedures. This is because less invasive alternative imaging techniques can usually determine whether interventional treatment is possible without the performance of diagnostic arteriography. In patients with peripheral arterial disease, duplex imaging can determine disease location and length of lesions and help guide interventions.

Indications

DUS evaluation is beneficial for the following: patients with suspected symptomatic, chronic peripheral arterial disease[5-10]; patients with suspected acute limb ischemia; patients with pedal infection without a palpable pulse; patients with atheroembolic or thromboembolic disease states; and patients who require surveillance after revascularization procedures.

Technique

The extent of duplex arterial mapping should be individualized to the indication for peripheral arterial testing. Screening for aneurysm and imaging to identify tibial artery calcification are appropriate indications for testing in selected patients. Evaluation of patients with symptoms of claudication or other signs of peripheral arterial disease can localize sites of occlusive disease. Arterial scanning proceeds from proximal to distal, with notation of artery diameter, wall morphology, plaque or thrombus accumulation, and velocity spectral waveform; it can include both upper and lower extremities.

Abdominal imaging is optimally performed after fasting to minimize intestinal gas artifact. Lower limb testing should include imaging (3- to 5-MHz phased, curvilinear, or linear array transducer) of the abdominal aorta and iliac arteries for aneurysm and occlusive disease and the common femoral arteries for the presence of normal (i.e., triphasic) velocity spectra. Multiple scan windows are used to image the aorta at the level of the renal arteries, proceeding to the tibial arteries at the ankle. From the inguinal ligament distally, a 5- to 7-MHz linear array transducer is used to map the arterial tree. PSV and EDV should be reported in the arteries evaluated, with ratios of PSV compared with a more proximal segment of designated healthy vessel.

The findings on duplex mapping should be recorded in a schematic of the extremity arterial tree, analogous to an arteriogram, with notation of the site or sites of aneurysm or occlusive disease and measurements of velocity spectra at nondiseased arterial segments (common femoral, superficial femoral, popliteal, and tibial arteries) and at sites of stenosis (Fig. 21.4). Standardized values for arterial diameter and PSV in the lower limb arteries have been reported for healthy subjects under resting conditions (Table 21.2).[5-9] Duplex mapping allows classification of atherosclerotic occlusive disease in the aortoiliac, femoral-popliteal, and popliteal-tibial arterial segments based on Trans-Atlantic Inter-Society Consensus (TASC) guidelines for grading of lesions from A through D according to lesion length and morphology.[10]

Interpretation

Duplex-derived data to estimate severity of stenosis of the lower extremity have not undergone a consensus recommendation

Occlusion is denoted by a filled-in lumen and stenosis by an asterisk at the lesion. *AKP*, Above-knee popliteal; *ATA*, anterior tibial artery; *BKP*, below-knee popliteal; *CFA*, common femoral artery; *DFA*, deep femoral artery; *PER*, peroneal artery; *PTA*, posterior tibial artery; *SFA*, superficial femoral artery; *TPT*, tibioperoneal trunk.

TABLE 21.2 Artery Diameters and Peak Systolic Velocities in Healthy Subjects

Artery	Diameter (cm)*	Velocity (cm/s)*
Infrarenal aorta	2 ± 0.2	55 ± 12
Common iliac	1.5 ± 0.18	70 ± 18
External iliac	0.8 ± 0.13	115 ± 21
Common femoral	0.8 ± 0.14	114 ± 24
Superior femoral	0.6 ± 11	90 ± 14
Popliteal	0.5 ± 0.1	68 ± 14
Tibial arteries	0.3 ± 0.4	55 ± 10

*Values are means ± standard deviation.

process. Velocity-based criteria have been recommended by Cossman et al.[17] since 1989 (Table 21.3).

The PSV/EDV ratio should be calculated from an adjacent segment of a nonstenotic artery. Although the PI can aid in grading severity of stenosis, this number is not routinely independently used.

Fig. 21.5 depicts the classic progression of deterioration of ankle-brachial index (ABI), decreasing PSV, and decreasing PI.

Classification of peripheral arterial stenosis is based on duplex-derived criteria, similar to carotid duplex testing (e.g., PSV, EDV, and PSV ratio across a stenosis identified by color Doppler imaging) (Fig. 21.6; see Table 21.3). A doubling or

TABLE 21.3 Duplex Classification of Peripheral Artery Occlusive Disease

Stenosis Category	Peak Systolic Velocity (cm/s)	Velocity Ratio (Vr)	Distal Artery Spectral Waveform
Normal	<150	<1.5	Triphasic, normal PSV
30%-49%	150-200	1.5-2	Triphasic, normal PSV
50%-75%	200-400	2-4	Monophasic, reduced PSV
>75%	>400	>4	Damped, monophasic, reduced PSV
Occlusion	No flow; length of occlusion estimated by distance from exit and reentry collaterals		Damped, monophasic, reduced PSV

PSV, Peak systolic velocity.

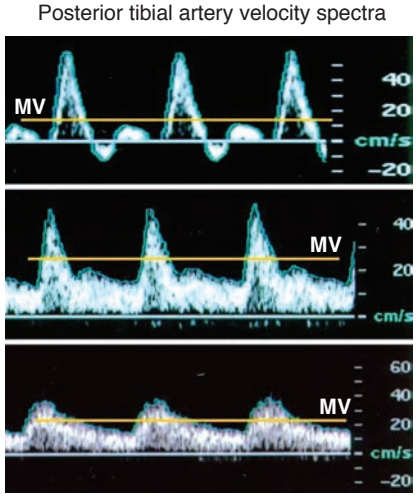

Figure 21.5 Velocity spectra, ankle-brachial index (ABI), and pulsatility index (PI) recorded from the posterior tibial artery of limbs with normal (ABI > 0.9, PI > 4), moderate (ABI = 0.5-0.8), and severe (ABI < 0.5, PI < 1.5) limb ischemia. *MV*, Mean velocity; *PSV*, peak systolic velocity.

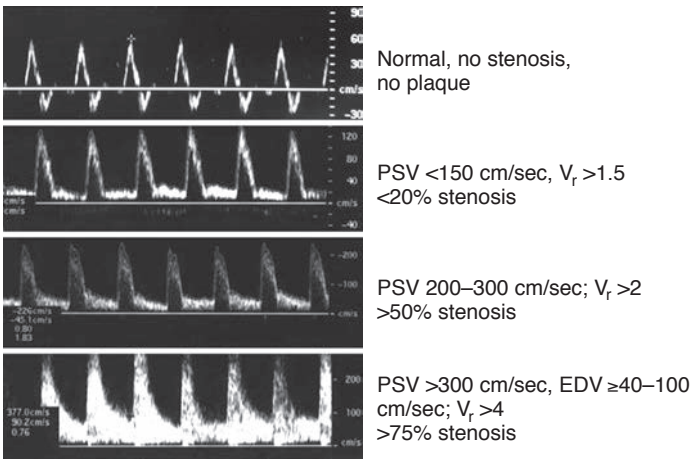

Figure 21.6 Duplex categories of peripheral artery stenosis based on velocity spectral waveform interpretation. *EDV*, End-diastolic velocity; *PSV*, peak systolic velocity.

step-up in PSV to more than 150 cm/s (Vr > 2) indicates 50% or greater diameter reduction stenosis. Duplex criteria for a critical flow-limiting stenosis include loss of the triphasic waveform, spectral broadening with an increase in velocity (PSV > 200 cm/s, EDV > 0 cm/s), and Vr greater than 3 across the stenosis. Higher degrees of stenosis (>75%) are associated with an EDV higher than 100 cm/s and a Vr above 4.[12]

Accuracy

A prospective comparison of DUS to contrast-enhanced MRA was performed with 152 patients, with conventional digital subtraction angiography as the "gold standard." A PSV ratio of more than 2.5 was used to define a significant stenosis. Duplex had sensitivity, specificity, and overall accuracy of 76%, 93%, and 89%, respectively, whereas MRA had a sensitivity of 84%, a specificity of 97%, and an overall accuracy of 94%, with statistically significant improvements in MRA sensitivity ($P = .002$) and specificity ($P = .03$).[13] Collins et al.[14] performed a systematic review of the literature comparing the three different imaging modalities. In detecting a greater than 50% stenosis, contrast-enhanced MRA demonstrated a median sensitivity and specificity of 95% and 97%, respectively; CTA showed a sensitivity and specificity of 91% and 91%, respectively; and DUS showed a sensitivity and specificity of 88% and 96%, respectively. For detection of occlusions, contrast-enhanced MRA was more sensitive and specific than CTA or DUS.

Iliac Arteries

The iliac arteries can be evaluated either by direct assessment via interrogation of the iliac artery or by indirect measures of common femoral artery waveform and velocity assessment. Direct assessment requires lower frequency abdominal probes and is limited by body habitus as well as by other factors (e.g., tortuosity, deep vessels) compared with indirect assessment of the femoral arteries.

Interpretation

Direct Imaging Criteria

Direct imaging criteria for iliac artery stenosis include the following: for greater than 50% stenosis: PSV higher than 200 cm/s or PSV ratio of 2.5 or more; for greater than 75% stenosis: PSV ratio above 5.0 and EDV higher than 40 cm/s. PSV of 400 cm/s or more is suggestive of greater than 75% stenosis.[15]

Indirect Imaging Criteria

Reduced velocities in the common femoral artery (<45 cm/s) with an associated monophasic waveform pattern are nearly 90% accurate in identifying a proximal iliac artery lesion without direct iliac artery evaluation. In addition, Shaalan et al.[16] did not find any statistical difference in velocities of the common femoral artery by gender or in the presence of significant ipsilateral superficial femoral artery or contralateral iliac artery disease.

Accuracy

The accuracy of DUS for detection of iliac artery disease is as follows.

Direct Imaging

For greater than 50% stenosis (PSV > 200 cm/s): 95% sensitivity, 55% specificity, 68% PPV, 91% NPV, and 75% accuracy; for greater than 75% stenosis (EDV > 40 cm/s): 70% sensitivity, 90% specificity, 64% PPV, 92% NPV, and 86% accuracy; for greater than 75% (with Vr > 5.0): 65% sensitivity, 91% specificity, 65% PPV, 91% NPV, and 86% accuracy.[15]

Indirect Imaging

An abnormal common femoral artery waveform contour (monophasic or biphasic) differentiated ipsilateral iliac artery stenosis of less than 50% from stenosis of greater than 50%, with 95% sensitivity, 89% specificity, 89% PPV, 95% NPV, and 92% accuracy. In differentiating between groups with greater than 50% stenosis and occlusion of the ipsilateral iliac artery, the specificity, PPV, and accuracy for PSV lower than 45 cm/s combined with a common femoral artery monophasic waveform are 97%, 92%, and 88%, respectively (Fig. 21.7).[16]

Femoral-Popliteal and Tibial Arteries

Studies, including a prospective blinded comparative study, have shown good agreement in the femoral-popliteal segment between DUS and digital subtraction angiography with use of a Vr of more than 2 for defining a greater than 50% stenosis by DUS. Agreement was better in the supragenicular than in the infragenicular segments.[17] In a comparison of the agreement with digital subtraction angiography, specific areas had poor correlation: profunda femoral artery, tibioperoneal trunk, peroneal artery, and crural arteries. In addition, a report has recommended the combined use of a PSV higher than 200 cm/s and a Vr above 2 to predict a greater than 70% femoropopliteal stenosis.[18]

The sensitivity and specificity of DUS in the femoral-popliteal arteries depend on criteria used to determine the degree of stenosis. With use of a Vr above 2.4 in detecting a greater than 50% stenosis in the femoral artery, the sensitivity, specificity, PPV, and NPV were 81%, 93%, 84%, and 91%.[16] A combined Vr above 2.0 and a PSV higher than 200 cm/s was associated with a sensitivity, specificity, PPV, and NPV of 79%, 99%, 99%, and 85% in detecting a greater than 70% stenosis.[18]

In the tibial arteries, the largest series reporting the accuracy of DUS in detecting 50% stenosis found a sensitivity of 88%, specificity of 75%, PPV of 83%, and NPV of 81% in 1690 infrageniculate segments correlated with conventional angiography (see Table 21.3).[19]

Limitations

For the aortoiliac disease segment, body habitus is the main limitation. For infrainguinal stenosis, the major limitation of

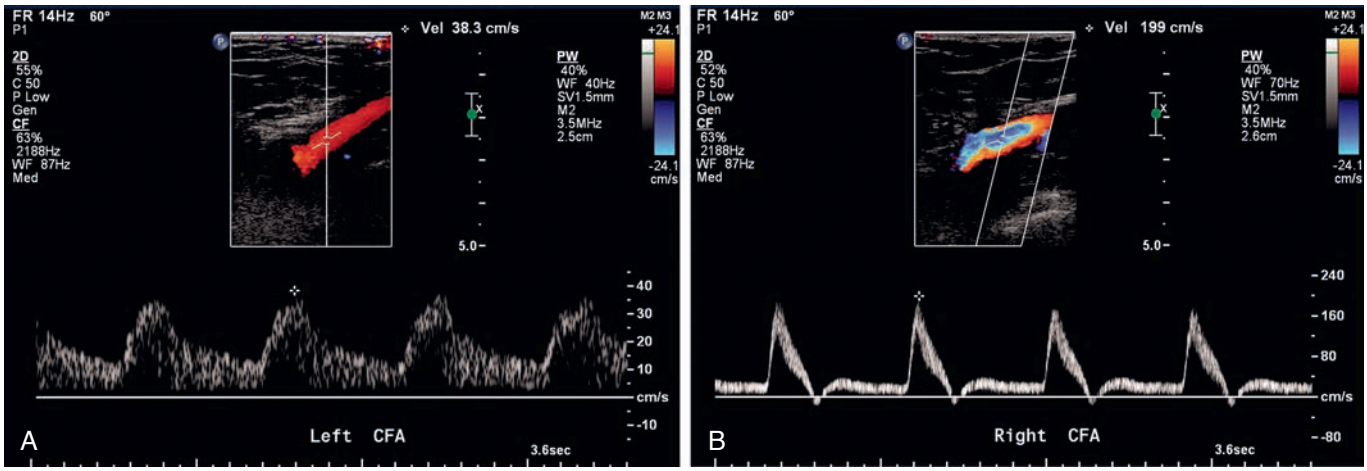

Figure 21.7 Indirect imaging of iliac arteries. **A,** Common femoral artery (CFA) with damped low-velocity waveform. **B,** Common femoral artery triphasic waveform for comparison.

accuracy is the presence of a proximal stenosis, which can falsely decrease distal velocities. Consequently, the velocity ratio may more accurately identify focal areas of stenosis. DUS may signify a high-grade stenosis instead of occlusion if a collateral vessel is visualized therefore falsely demonstrating flow adjacent to an occluded vessel. Incomplete vessel imaging may occur as a result of poor patient cooperation or acoustic shadowing caused by plaque calcification. Arterial segments difficult to image include the proximal external iliac artery, internal iliac origin, and tibioperoneal trunk. Calcific changes in the tibial arteries can decrease the accuracy of velocities.

DUPLEX SURVEILLANCE

Bypass Graft and Intervention Surveillance

Vein Grafts

A surveillance program after lower limb vein bypass grafting is recommended, but the extent of testing, including routine duplex testing, remains controversial.[20] Current recommendations include a baseline examination within 30 days of surgery, if it is not performed intraoperatively, subsequent examinations at 6-month intervals, and then annually after the first year for vein grafts.[21] However, an opposing view by TASC II recommended surveillance with physical examination and ABI only.[10] Duplex surveillance has been strongly advocated by the University of South Florida group. The latest recommendations for duplex surveillance of infrainguinal vein grafting reported improved efficacy of duplex surveillance with rigorous imaging for high-risk bypasses.[20] When it is conducted appropriately, a graft surveillance program should result in a graft failure rate of less than 3%/y. It can be anticipated with DUS surveillance that approximately 20% of infrainguinal vein bypasses will have either a residual operative stenosis or developing graft stenosis within 1 year of reconstruction.

Technique

Similar to native infrainguinal arterial examination, B-mode, color-flow, and pulsed Doppler imaging should be performed of the inflow, conduit, and outflow vessels. B-mode imaging can often identify early technical issues (i.e., retained valves or sclerotic vein segments). Pulsed Doppler with waveform analysis should be mapped of the lower limb with PSV, EDV, and Vr recorded. Specifics of the stenosis should also be recorded: diameter of the vein in transverse imaging above and below the stenosis, including length of stenosis in centimeters and anatomic location.

Interpretation

A combination of ABI, PSV, and Vr has been used to stratify patients into risk of subsequent vein graft failure. A PSV higher than 180 cm/s with associated Vr of 2.0 and no change in ABI correlates well with a 50% stenosis. A critical vein graft stenosis with impending failure has a PSV higher than 300 cm/s, a Vr of more than 3.5, and a decrease in ABI by 0.15 or more. Refer to Table 21.4 for risk stratification of failure.

Vein graft lesions with the duplex-derived velocity spectra of a high-grade stenosis (PSV > 300 cm/s, EDV > 20 cm/s, Vr across the stenosis > 3.5) correlate with a greater than 70% diameter reduction stenosis and should be repaired (see Fig. 21.2). In a prospective study, application of these threshold criteria identified all grafts at risk for thrombosis, and only one lesion with high-velocity criteria regressed. Multiple investigators have observed an approximately 25% incidence of graft thrombosis in stenotic bypasses when a policy of no intervention was followed.[20]

The risk for graft thrombosis is predicted by using the combination of high- and low-velocity duplex criteria and decreases in ABI (see Table 21.4). In the highest risk group (category I), the development of a pressure-reducing stenosis produces low flow in the graft, which will result in thrombosis if it is decreased below the "thrombotic threshold velocity." Prompt repair of category I lesions is recommended, whereas category II lesions can be scheduled for elective repair within 1 to 2 weeks. A category III stenosis (PSV of 180-300 cm/s, Vr < 3.5) does not reduce pressure or flow in the resting limb. Serial scans at 4- to 6-week intervals are recommended to determine hemodynamic progression of these lesions. An

TABLE 21.4 Risk Stratification for Vein Graft Occlusion by Duplex Criteria

Category	High-Velocity Criteria, Peak Systolic Velocity	Velocity Ratio (Vr)	Low-Velocity Criteria, Graft Flow Velocity	Change in ABI
I: Highest risk* (>70% stenosis with low graft flow)	>300 cm/s	>3.5	<45 cm/s or staccato graft flow	>0.15
II: High risk* (>70% stenosis without change or normal graft flow)	>300 cm/s	>3.5	>45 cm/s	<0.15
III: Moderate risk† (50%-70% stenosis with normal graft flow)	180-300 cm/s	>2.0	>45 cm/s	<0.15
IV: Low risk (normal bypass or <50% stenosis with normal graft fl ow)	<180 cm/s	<2.0	>45 cm/s	<0.15

ABI, Ankle-brachial index.
*Likelihood of progression of stenosis or graft thrombosis within 3 to 6 months is 40% to 50%.
†Of early (<3 months) lesions, 20% to 30% regress, 10% to 20% remain stable, and 40% to 50% progress to greater than 70% stenosis.

important feature of a "graft-threatening" stenosis is its propensity to progress in severity, to reduce graft flow, and to form surface thrombus, which are events that can precipitate thrombosis. By use of serial duplex scans, a category III stenosis that does not progress can be distinguished from a progressive lesion that needs to be repaired. The majority (approximately 80%) of bypass grafts will have no stenosis identified (i.e., category I scan). For these patients, surveillance at 6-month intervals is recommended. In patients with category I scans, a graft flow velocity lower than 40 cm/s indicates a "low-flow" bypass that is at increased risk for thrombosis by the concept of the thrombotic threshold velocity, which is lower in autologous vein than in prosthetic bypasses. Prescribing an anticoagulation regimen of warfarin to maintain the prothrombin time at an international normalized ratio of 1.6 to 2 and antiplatelet therapy (aspirin, 81 mg/day, or clopidogrel bisulfate, 75 mg/day) may reduce the incidence of low-flow vein bypasses.[20] Patients who are at high risk for development of vein graft stenosis[20] include those with abnormal results on baseline testing (PSV, 180-300 cm/s; Vr, 2-3.5), multisegment venous conduit, repeated bypass grafting, and need for warfarin therapy (Fig. 21.8).

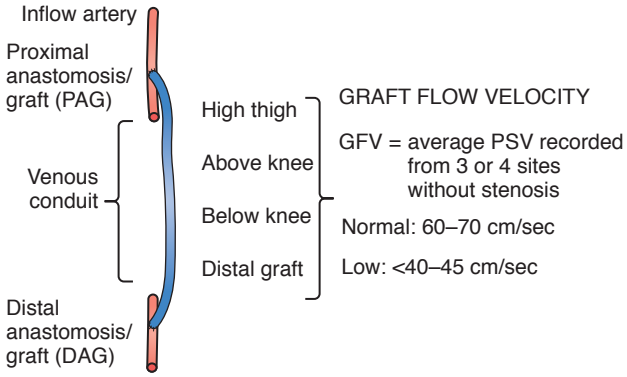

Figure 21.8 Schematic of a lower limb bypass graft indicating the duplex recording site and calculation of mean graft velocity (MGV). *PSV,* Peak systolic velocity.

Prosthetic Grafts

Although it is not supported by the TASC II recommendations, Mohler et al.,[21] in a consensus document, support the surveillance of prosthetic reconstructions at baseline and at 6-month intervals, similar to vein reconstructions. Duplex criteria were recommended by Stone et al.[22] for patients after femoral-femoral bypass grafting, with a PSV higher than 300 cm/s in the inflow iliac artery and midgraft velocity lower than 60 cm/s predictive of graft failure. When duplex-directed intervention was performed, patency at 5 years (assisted patency) was 88%. Patency appeared to be improved in comparison to most reports in the literature of patency without surveillance.

Duplex surveillance of prosthetic grafts does not appear to detect correctable lesions as in vein bypass grafts. Surveillance appears to serve more as a predictor of graft thrombosis by the detection of midgraft velocities below 45 cm/s. It has been shown that prosthetic grafts with low velocity benefit from warfarin to improve patency, which may justify surveillance. Brumberg et al.[23] recommended the use of warfarin if the mean graft velocity was below 60 cm/s to reduce the incidence of polytetrafluoroethylene bypass graft thrombosis.

Peripheral Interventions

Current guidelines recommend routine surveillance of peripheral arteries after percutaneous interventions.[21] However, the role of duplex examination after percutaneous peripheral interventions has been reported sparsely in the literature. Threshold criteria for repeated angiography included a PSV above 300 cm/s and a Vr of 2, which is commonly predicated on a clinical deterioration, an ABI decrease by 0.15, or an abnormal common femoral artery waveform analysis suggesting inflow disease. DUS after iliac artery interventions may serve a limited role. Back et al.[24] evaluated 67 patients with a mean follow-up of 1 year, finding a 4% stent thrombosis and only 20% of patients with potentially failing stents.

Similar to iliac artery percutaneous interventions, data are limited to support the routine use of duplex surveillance of

femoral-popliteal endovascular interventions. Several studies have evaluated DUS in determining recurrent stenosis of the femoral-popliteal segment after catheter-based procedures, with conflicting results.[25]

Chronic venous insufficiency (CVI) of the lower extremity is most often characterized by venous hypertension caused by valvular reflux, obstruction, or a combination of both.[1] Just as in the treatment of arterial disease, appropriate management of venous disease is predicated on accurate assessment of the anatomic abnormality, as well as the physiologic impact of the disease. The development of therapies for patients with CVI was historically hampered by inadequate tools for objective clinical and noninvasive anatomic and hemodynamic evaluation of the venous system.

Currently available clinical and laboratory evaluations address the physical findings, underlying etiology, anatomic distribution, and mechanism of disease. The results of these evaluations provide the essential elements of the clinical, etiologic, anatomic, pathophysiologic (CEAP) classification, detailed in Chapter 156.[2] Introduction of this system has advanced the evaluation of CVI from a subjective clinical impression based on physical examination alone to a more objective process similar to that followed for arterial disease.

As B-mode imaging technology has improved, it has assumed an important role in the anatomic diagnosis of CVI. By using the techniques outlined in Chapter 23, physicians can gain extensive knowledge of the anatomic sites and extent of disease noninvasively with B-mode imaging. Furthermore, the increasing sophistication of Doppler waveform analysis enables assessment of certain local physiologic measurements, such as the extent of segmental reflux. Many physicians base their clinical decisions on this combination of B-mode and Doppler waveform information (duplex ultrasonography) alone. However, duplex ultrasonography cannot define the importance of anatomic abnormalities in the context of global venous function of the limb.[3] Clearly, one patient with gross reflux in the greater saphenous vein may have no resultant symptoms, whereas another may have an active ulcer. An objective measurement of the hemodynamic performance of the lower extremity's venous system would greatly improve our ability to evaluate patients and recommend treatment.

Several noninvasive techniques are available to evaluate the global hemodynamic function of the venous system. However, they have not gained widespread use. The same considerations that exist in arterial disease are important in the diagnosis of CVI and assessment of treatment efficacy.[4,5] Furthermore, for clinical research on the treatment of venous disease, hemodynamic evaluation should and will progressively become an important expectation in reporting standards.

This chapter focuses on methods of evaluating the hemodynamic significance of CVI. It details the instrumentation, techniques, interpretation, accuracy, and limitations of these

tests. It also offers a perspective on appropriate clinical situations in which each test may provide clinically relevant information.

AMBULATORY VENOUS PRESSURE

Venous insufficiency most often results in elevated venous pressure and may be due to the net result of outflow obstruction, valvular incompetence, arteriovenous malformations, or any combination of these conditions. Pollack and Wood first described venous pressure changes in 1949, when they noted that muscle contraction increased the outflow of blood from the lower extremities during exercise, thereby lowering venous pressure.[6] They also documented the gradual return to resting venous pressure when the activity ceased. When Arnoldi and associates demonstrated that variations in venous pressure in the superficial venous system reflected those in the deep venous pathways,[7] it validated the use of a dorsal foot vein for the evaluation of venous hemodynamics.

The sum of the hemodynamic factors involved in venous insufficiency can be quantified by the measurement of ambulatory venous pressure (AVP). AVP is defined as the venous pressure in a dorsal foot vein after the execution of 10 tiptoe maneuvers in a standing position. A direct measurement of AVP is considered the "gold standard" measure of venous hemodynamics.[8,9]

Technique

To measure AVP, a catheter or butterfly needle is placed in a dorsal pedal vein and connected to a pressure transducer, and baseline standing pedal venous pressure is recorded. The patient then performs 10 tiptoe maneuvers at a rate of 1 per second to empty the calf veins and returns to the standing position. The pressure recorded at the end of the tiptoe maneuvers is defined as AVP. Refill time is measured as the time required to return to 90% of baseline venous pressure after cessation of calf muscle contraction.

Interpretation

In normal subjects, standing venous pressure is around 90 mm Hg (depending on the individual's height). During exercise it should fall to around 30 mm Hg, and after exercise it should rise slowly back to standing pressure. Usually 90% of baseline pressure is achieved in about half a minute (Fig. 22.1A). There are a number of possible abnormal results. The pressure may not fall normally during exercise, which indicates that the calf pump is not working effectively (see Fig. 22.1B). AVP may return to the standing pressure too quickly, which would indicate reflux in the deep or superficial veins (see Fig. 22.1B). Pressure may also rise rather than fall during exercise, which indicates that the deep veins are occluded.

A higher AVP is generally indicative of more severe CVI. Nicolaides and associates correlated AVP values to the incidence of limb ulceration and severity of CVI and showed a progressive increase in the incidence of skin ulceration as the mean values of AVP increased.[8] They also reported differences in the AVP based on the anatomic pattern of venous reflux. Patients with deep venous insufficiency had higher AVPs than did those with superficial insufficiency. Perforator incompetence and outflow obstruction also increased AVP, with the highest AVP reported in patients with deep valvular incompetence and proximal obstruction.

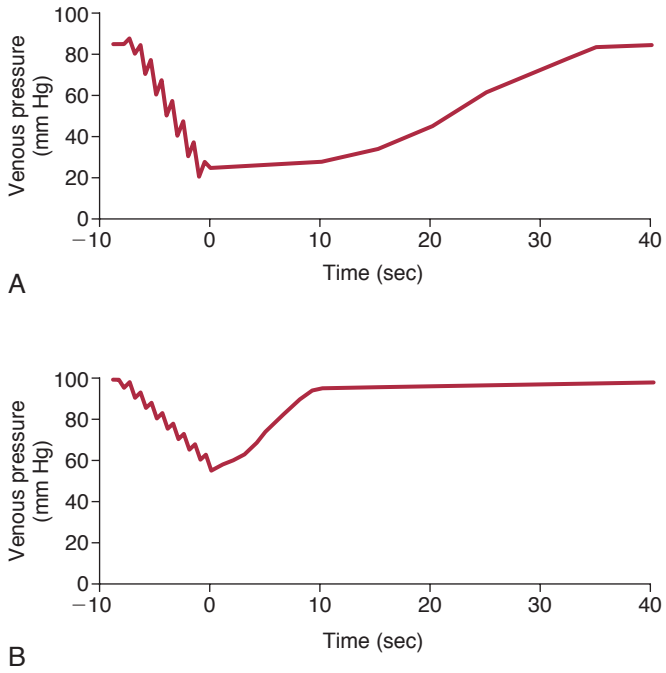

Figure 22.1 (A) Tracing of ambulatory venous pressure (AVP) in a normal subject. Note the rapid fall in pressure during 10 calf contractions, indicative of good venous outflow and calf muscle pump function. Also note the slow rise to baseline pressure on completion of the calf contractions, indicative of absence of venous reflux. (B) Tracing of AVP in a patient with chronic venous insufficiency. Note the higher baseline pressure, slow fall in pressure with tiptoe maneuvers, and high pressure on completion of the contractions, indicative of venous outflow obstruction and poor calf muscle pump function. Also note the rapid rise to baseline on completion of the calf contractions, indicative of severe venous reflux.

Accuracy

Overlap can exist between the AVP values of normal limbs and those with varying clinical categories of CVI. Up to 25% of patients with ulceration can have AVP values within normal limits.[8,10] The use of tourniquets to occlude the superficial venous system during the study may help define the contribution of the superficial and perforator veins to refill time. In theory, a thigh tourniquet should occlude reflux occurring in the superficial system. If AVP and refill time correct after tourniquet application, the superficial system is probably the primary source of abnormal function. A lack of correction implicates the deep venous system. However, this aspect of the test has not proved to be reliable,[11] and AVP should not be routinely used to identify the differential contribution of the deep and superficial systems to global venous hemodynamic dysfunction.

Limitations

Although AVP is generally perceived to be the gold standard measure of venous function, there is concern that pressure at the pedal vein may not accurately reflect changes in venous pressure within the leg, particularly in the deep venous system.[12] Furthermore, it is an invasive and time-consuming procedure that may be difficult to perform in many patients, particularly

those with active ulcers. Severe edema or dermal thickening and inflammation often accompany advanced CVI and may obscure the pedal veins, thus making access difficult. Therefore it has been largely supplanted by techniques that measure venous hemodynamics noninvasively. These techniques also depend on a protocol of calf contraction and rest, much like the one used for measurement of AVP.

PLETHYSMOGRAPHY

Plethysmography is a noninvasive method of estimating changes in volume in an extremity.[13] Because all other tissues maintain constant volume during the short period of testing, any recorded volumetric differences reflect changes in blood volume. Several plethysmographic techniques with different sensors have been used to measure changes in blood volume in a limb, including strain-gauge plethysmography (SGP), impedance plethysmography (IPG), photoplethysmography (PPG), and air plethysmography (APG).

These tests rely on the fact that the lower extremity veins are not filled to maximum capacity when the patient is in the supine position. With positional changes or when outflow is occluded by a pressure cuff, the venous system can accommodate increased volume before reaching maximal venous capacitance. With subsequent rapid positional changes or release of an externally inflated pressure cuff, patients with normal outflow exhibit rapid emptying of their lower extremity veins. These tests now routinely use an occlusion cuff, which has increased standardization by avoiding active patient movement and positional changes.

Positioning of the patient is critical in these tests. The patient is placed supine with the leg elevated 20 to 30 degrees on a soft heel support to enable venous drainage. The knee is flexed 10 to 20 degrees to prevent obstruction of popliteal vein outflow. The plethysmographic sensor is applied and a thigh occlusion cuff is inflated to above venous pressure (50 to 60 mm Hg) and maintained until limb volume increases to a stable level. The cuff is then released rapidly to allow the tracing to return to baseline readings (Fig. 22.2A). The rise in the recording to the plateau during cuff inflation measures calf venous volume (VV), whereas the fall in the recording after rapid deflation measures venous outflow (VO). The rate at which this outflow occurs is inversely proportional to the resistance to VO. In the presence of VO obstruction or venous insufficiency, VV and VO are reduced (see Fig. 22.2B).

Strain-Gauge Plethysmography

SGP is designed to detect changes in calf volume after inflation and then rapid deflation of a thigh occlusion cuff. A change in calf volume stretches a mercury-filled Silastic conductor tube with a proportional change in its resistance, which results in a corresponding change in voltage output signal. SGP provides an estimate of VO obstruction and has primarily been used in the past for the diagnosis of deep venous thrombosis (DVT). Although estimates of VV have not proved to be reliable diagnostic indicators of DVT, an estimate of VO in the form of MVO provides improved sensitivity.[14] Barnes and coauthors reported that MVO had a sensitivity of 90% for above-knee DVT but only 66% for below-knee DVT, whereas its overall specificity was 81%.[15] Successful recordings from SGP require full cooperation from the patient. It cannot be performed on patients who are unable to lie flat. Prolonged recumbency, muscle wasting, and cardiac failure may result in measurement errors. Patients with limb injuries, bandages, casts, or severe edema are unsuitable candidates for SPG. Today its use has been largely supplanted by duplex sonography.

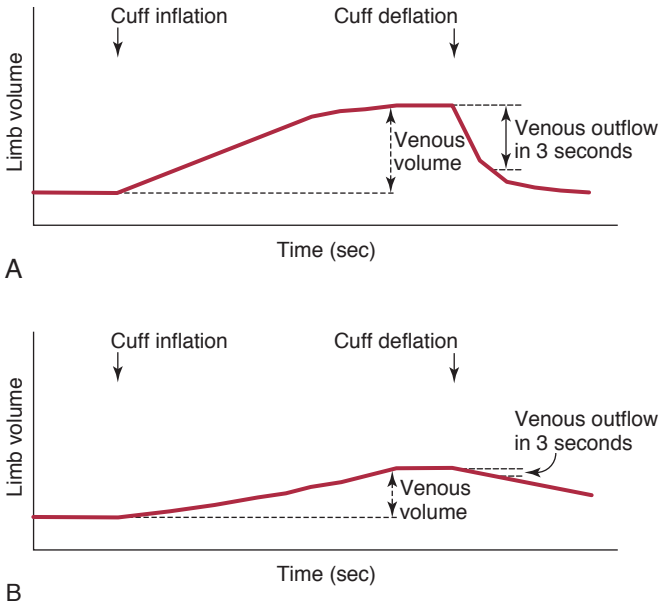

Figure 22.2 (A) Representative plethysmographic tracing in a normal subject during inflation and deflation of proximal thigh occlusive cuff. (B) Representative plethysmographic tracing in a patient with chronic venous insufficiency. Note the significantly reduced venous outflow recorded during the 3 seconds after cuff deflation (3-second venous outflow), indicative of severe venous outflow obstruction. The slope of the outflow curve (maximum venous outflow) is also reduced in comparison with the normal tracing in A.

Impedance Plethysmography

IPG is a technique that measures changes in electrical resistance in tissues of the extremity in response to changes in volume. Two electrodes are placed on the calf and the voltage output is used to derive the resistance. A thigh occlusion cuff is inflated and then rapidly deflated to provide an estimate of VO. IPG has primarily been used for the diagnosis of acute DVT. The sensitivity of IPG in diagnosing DVT ranges from 33% to 96%, with accuracy reduced in asymptomatic patients or those with DVT below the knee.[16] For these reasons, given the reliability of duplex ultrasound techniques, IPG is now rarely used to diagnose DVT. Neither SPG nor IPG has been well characterized as a diagnostic technique in the hemodynamic evaluation of CVI.

Photoplethysmography

PPG uses light absorbance by hemoglobin as a reflection of blood volume in the venous and capillary networks of the skin to estimate the degree of venous stasis.

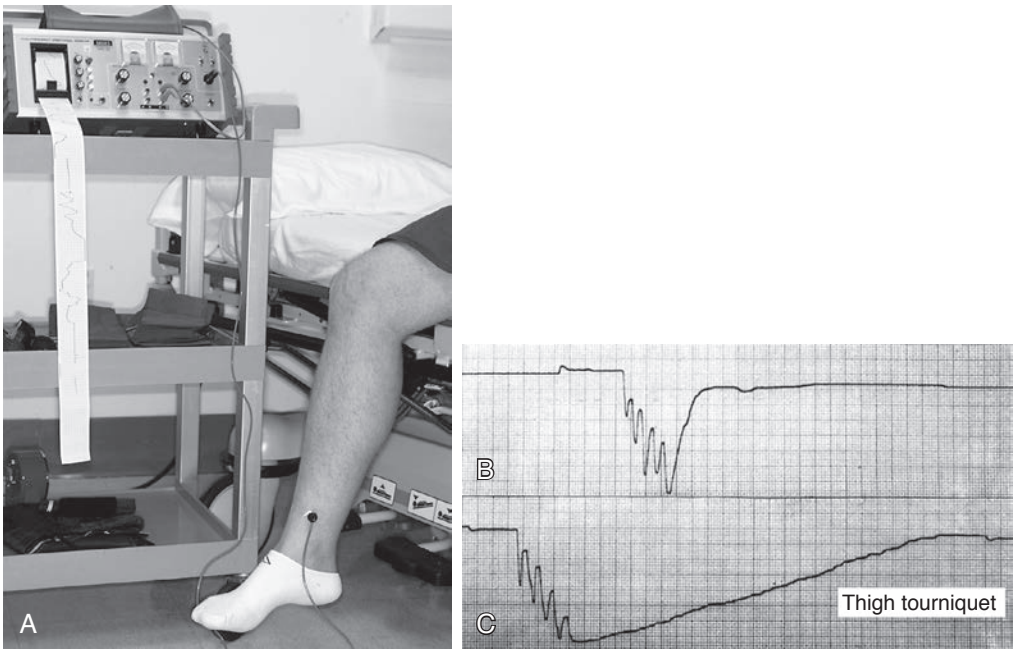

Figure 22.3 (A) Standard position for photoplethysmography (PPG), with the phototransducer located above the medial malleolus. (B) Tracing of PPG refill time in a patient with chronic venous insufficiency. Note the rapid refill time, indicating severe venous reflux. (C) Repeat test with a thigh tourniquet in place indicating correction of refill time to normal. This suggests that venous reflux is limited to the superficial system.

Technique

PPG uses a transducer that emits infrared light from a light-emitting diode into the dermis. Hemoglobin absorbs light and is the most abundant chromophore in the skin. The amount of light absorbed from the transducer is therefore a good estimation of blood volume in the venous and capillary networks of the skin.[17] The backscattered light is measured by an adjacent photodetector, and net absorption is displayed as a line tracing. Absorption of light is high when skin venous and capillary blood is increased during sitting or standing; conversely, it is decreased during exertion when venous blood is expelled from the limb by the action of the calf muscles.

The patient is asked to sit comfortably with the legs hanging freely. The transducer is applied to the leg (Fig. 22.3A) and a baseline recording is obtained. The patient is then asked to perform five consecutive ankle flexion/extension maneuvers. The tracing drops as the calf muscles empty the veins. The time taken to recover to 90% of the original baseline tracing after the exertion is completed is recorded as the venous refill time (VRT) (see Fig. 22.3B).

Interpretation

In normal individuals, VRT tends be longer than 20 seconds and can extend to as long as 60 seconds. Significant venous reflux results in a VRT of less than 20 seconds,[18] and reducing times generally reflect increasing severity of reflux (see Fig. 22.3C).[19] In the presence of abnormal findings, the test can be repeated with a tourniquet inflated (50 mm Hg) alternately above and below the knee to identify the source of reflux.

Accuracy

Although PPG can provide an assessment of the overall physiologic function of the venous system, it is most useful as a relatively simple measure to detect the presence of venous reflux. Duplex ultrasonography provides detailed information on segmental reflux, and PPG provides an estimate of the global effect of reflux on the limb. Quantitative measurements are not obtained, so each laboratory should define its own standard for a normal refill time based on the equipment used. PPG measurements have not been proved to be a strong discriminator of the severity of CVI. Nicolaides' group has reported that abnormal limbs demonstrated refill times of less than 18 seconds with their protocol.[20] However, within this group, VRT could not differentiate between degrees of CVI, with similar times obtained in patients with AVP measurements ranging from 45 to 100 mm Hg.

Limitations

In addition to being inversely proportional to the degree of reflux, refill time is also affected by arterial inflow. In the presence of occlusive arterial disease, VRT may be reduced despite an absence of venous reflux. This test also requires full patient cooperation, and inability to perform the contraction maneuvers or inability to access the calf for proper placement of the transducer will preclude accurate results. VRT can vary depending on the site of photosensor placement, the size of the sample area obtained, and the type and amount of exercise performed during the recording.[21] Placement near the site of a varicose or perforating vein may also affect the results. The test has limited reliability in

differentiating deep from superficial reflux despite the addition of tourniquet testing. Because of its inability to reliably grade the severity of CVI, PPG has limited utility for assessing the results of corrective venous surgical procedures. Therefore PPG is a reasonable measure of the presence or absence of CVI that is best used when no further information concerning the venous hemodynamic situation is desired. If information on the severity of CVI or evaluation of improvement after venous surgery is required, a quantitative test will be more useful.

Air Plethysmography

APG is a technique that measures changes in size in a large sample area of the lower part of the leg by using an air-filled cuff snugly applied to the extremity.

Technique

APG can potentially measure each individual component of clinical venous hemodynamics—namely reflux, calf muscle pump function, and outflow obstruction.[22-24] It uses a technique to improve on the shortcomings of PPG and other types of plethysmography that have limited sampling areas. A low-pressure air-filled cuff measuring 30 to 40 cm in length is applied to the lower part of the leg from the knee to the ankle. It is connected to a plethysmograph and serves as the sensor for changes in volume. This approach enables precise quantitation of the changes in volume of the entire lower leg region from the knee to the ankle. The test is performed with the patient resting supine with the leg elevated and supported in the same fashion as for SGP or IPG (Fig. 22.4A). The cuff is inflated to a pressure of 6 mm Hg to provide snug apposition to the limb without compressing the superficial veins. A baseline volume is obtained with the patient resting. A proximal occluding thigh cuff is inflated to 80 mm Hg to assess outflow obstruction.[19] Subsequent testing focuses on detection of reflux and calf muscle pump function. The patient moves to a standing position supported by a walker to remove weight from the tested limb (see Fig. 22.4B). The volume tracing gradually increases until a plateau is reached, which is recorded as VV. The time required to achieve 90% VV is described as the 90% venous filling time. The patient then performs one calf contraction with a tiptoe maneuver, followed by rest. The extent to which the volume reduces is defined as the ejected volume. The volume is then allowed to return to baseline, at which time a subsequent series of 10 tiptoe maneuvers completes the test procedure. The volume drops as venous blood is expelled from the leg. The amount of volume remaining in the limb after the tiptoe maneuvers is defined as the residual volume. Fig. 22.5A describes the measurements obtained during cuff inflation/deflation; Fig. 22.5B describes the recordings and indices obtained from the standing/tiptoe testing.

Three important indices can be derived from these APG measurements. The venous filling index (VFI) defines the rate of increase in volume on standing. Expressed in milliliters per second, VFI measures the mean filling rate of the dependent leg and is slow in normal limbs. The ejection fraction (EF) is the percentage of volume removed from the leg with one calf contraction. Finally, the residual volume fraction (RVF) is the residual volume expressed as a percentage of the baseline volume of the leg. The test protocol may be repeated with the use of a thigh tourniquet to isolate the deep venous system from the superficial system.

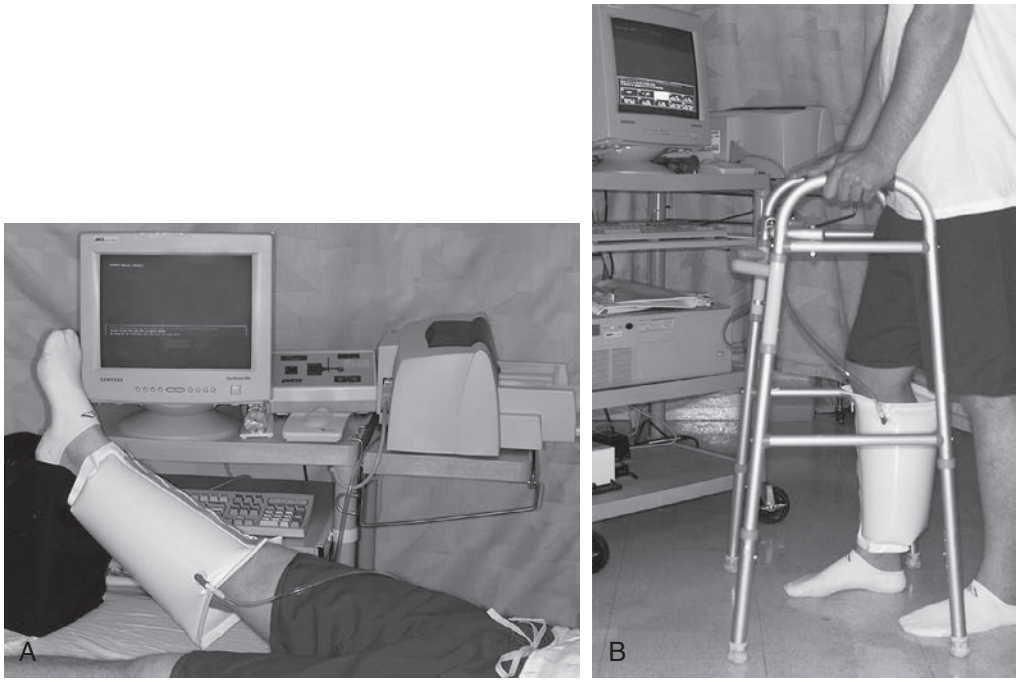

Figure 22.4 (A) Recording of baseline leg volume at the onset of air plethysmography (APG) testing with the patient supine and the leg elevated to minimize venous volume. Note the APG cuff over the leg. (B) Patient demonstrating a tiptoe maneuver during APG and the use of a walker to allow the limb under examination to remain relaxed.

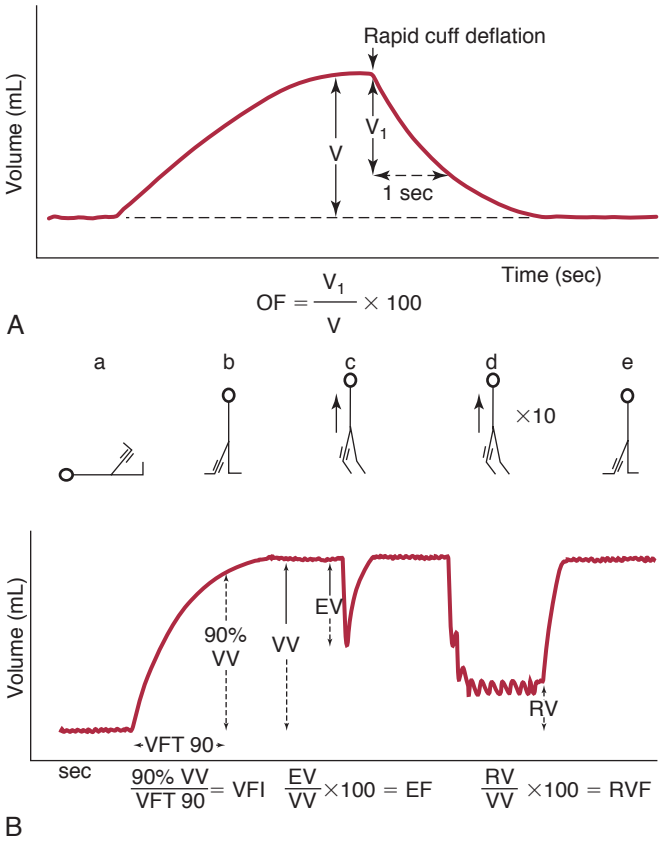

Figure 22.5 (A) Typical outflow fraction tracing obtained with air plethysmography (APG). After venous congestion is created with a thigh occlusion cuff, rapid deflation allows venous emptying. The outflow fraction (OF) is obtained by dividing the amount of venous volume emptied in 1 second (V_1) by the venous volume (V) and multiplying by 100. (B) APG data obtained from tracings. The figures along the top indicate the patient's position and maneuvers performed during the recording. *EF*, Ejection fraction; *EV*, ejected volume; *RV*, residual volume; *RVF*, residual volume fraction; *VFI*, venous filling index; *VFT*, venous filling time; *VV*, venous volume. TABLE 22.1 Prevalence of the Sequelae of Venous Disease in Relation to Venous Filling Index in 134 Limbs With Venous Disease Studied With Air Plethysmography

	SEQUELAE OF VENOUS DISEASE		
VFI (mL/s)	Swelling (%)	Skin Changes (%)	Ulceration (%)
<3	0	0	0
3-5	12	19	0
5-10	46	61	46
>10	76	76	58

VFI, Venous filling index.

Interpretation

The VFI provides a reasonable estimate of the global function of the lower extremity venous system and venous reflux. A VFI of less than 2 mL/s is associated with clinically normal limbs. The VFI may be increased to 30 mL/s in severe reflux, and increasing VFI values indicate more severe reflux, more symptoms, and higher grades of CVI (Table 22.1).[23]

EF and RVF provide measures of the efficacy of the calf muscle to pump blood out of the leg. RVF correlates closely with AVP throughout the range of AVP measurements (Fig. 22.6), with lower RVF values representing better calf pump function (normal RVF is defined as <35%).[25]

Like other plethysmographic measurements, APG can also provide estimates of VO obstruction. A cuff is placed around the proximal part of the thigh and inflated to 80 mm Hg. VV in the limb is measured until a plateau is reached. The cuff is rapidly deflated, and an outflow curve is recorded as limb volume decreases (see Fig. 22.5A). The recordings are similar to those obtained with SGP or IPG. The increase in volume recording above baseline is the VV, whereas the volume expelled after cuff deflation in 1 second is the 1-second VO. Using these measurements, Nicolaides and Sumner have calculated the outflow fraction by dividing the 1-second VO by VV.[26] Nicolaides has reported that the outflow fraction is higher than 38% in limbs with normal VO, 30% to 38% in patients with partial VO obstruction, and less than 30% in limbs with severe obstruction.[27]

Accuracy

Indices derived from APG measurements are useful in predicting the clinical severity of CVI. The VFI provides a particularly

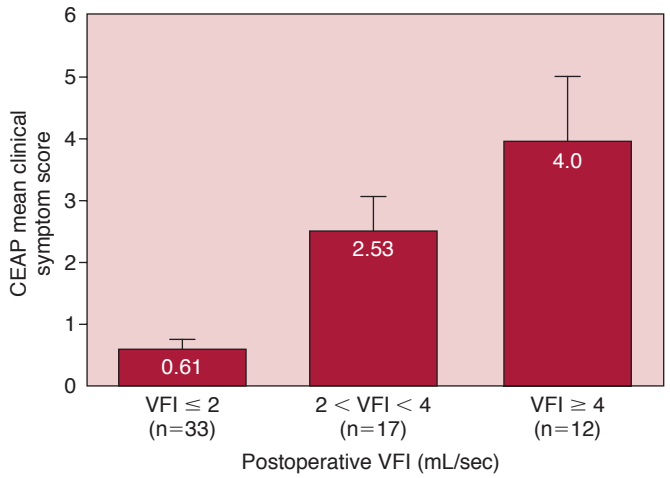

Figure 22.7 Correlation of the venous filling index (VFI) obtained by air plethysmography at early postoperative follow-up to symptom score at late follow-up. Mean values and numbers in each group are shown. *CEAP*, Clinical, etiologic, anatomic, pathophysiologic. (Redrawn from Owens LV, Farber MA, Young ML. The value of air plethysmography in predicting clinical outcome after surgical treatment of chronic venous insufficiency. *J Vasc Surg.* 2000;32:961–968.)

good estimate of disease severity and can assist in the selection of patients for venous surgery. Criado and colleagues showed that 93% of limbs with a VFI of less than 2 mL/s were CEAP class 0, and only 9% of patients with a VFI higher than 5 mL/s were CEAP class 0.[23] VFI was found to have 80% sensitivity and a 99% positive predictive value for detecting abnormal reflux.

The VFI also predicts recurrence of venous ulcers. In patients with healed leg ulcers, a VFI higher than 4 mL/s was associated with an increased risk of recurrence as compared with those with a VFI lower than 4 mL/s. For each 1 mL/s greater than 4 mL/s, the risk of ulcer recurrence increased 17%.[5] Based on this information, APG parameters can be used to assist in the selection of patients at higher risk for recurrent ulceration who may wish to consider corrective venous surgery.

The VFI is also useful for monitoring improvement in venous function and in predicting long-term outcome after venous surgical procedures.[28] In a review of 71 patients undergoing venous surgery, Owens and associates reported that 94% of patients in whom the VFI corrected to less than 2 mL/s after venous surgery were asymptomatic after a mean follow-up of 44 months (Fig. 22.7).[29]

APG, by sampling a large portion of the calf area, provides a better measure of the global venous function of the limb than PPG does.[27] Bays and coworkers reported that APG accurately separated normal limbs from those with CVI, and the parameters that significantly differentiated the two groups were VFI, VV, EF, and RVF.[4] PPG refill times had a sensitivity of 100% in identifying reflux; however, the specificity was only 60%. Furthermore, the κ coefficient between duplex and APG was 0.83, whereas it was 0.47 between duplex and PPG.

Limitations

The accuracy of APG depends on the ability of patients to stand unassisted and perform vigorous tiptoe maneuvers. Furthermore, in patients with advanced CVI, particularly CEAP classes 5 and 6, ankle range of motion is frequently limited. It is possible that some of the changes in EF and RVF seen in these groups are related to intrinsic dysfunction of the calf muscle pump or the patient's inability to activate the pump because of reduced ankle range of motion. APG is also limited in obese patients as a result of cuff size limitations; PPG may be the only option in such patients. Despite the use of a thigh tourniquet, APG is less reliable in differentiating superficial from deep reflux.

SELECTIVE USE OF VENOUS PHYSIOLOGIC TESTING

Several factors must be considered in determining the use of physiologic testing in the vascular laboratory.[30] The clinical manifestations (acute versus chronic) of the patient, the questions being asked of each individual patient, the ability of the patient to comply with the requested study, the use of vascular laboratory resources, and the examiner's facility with the testing procedures are all important considerations.

If the only question asked is whether venous disease is present and no details concerning anatomy or the severity of CVI are necessary, PPG is relatively rapid to perform and a reasonable choice. If the primary question concerns the anatomic site of reflux to plan intervention, duplex ultrasound evaluation should be performed. If the primary question concerns the severity of CVI or whether improvement has occurred after intervention, APG measurements should be performed.

Physiologic assessment with PPG or APG can provide evidence of global venous dysfunction, thereby separating CEAP class 2 patients with a primarily cosmetic problem from class 3 and 4 patients with more significant venous dysfunction. Once that determination has been made, duplex examination will be required to identify the sites of reflux, evaluate the deep and perforator systems, and guide intervention. In these patients, APG can also serve to document improvement and predict long-term outcome after intervention. CEAP class 5 and 6 patients should also undergo duplex evaluation to determine their candidacy for surgical or endovascular intervention. APG measurements are helpful in identifying patients at high risk for recurrent ulceration after intervention.

The use of Doppler ultrasound for the evaluation of lower extremity veins was pioneered in 1960s.[1,2] In 1968, David Sumner, Dennis Baker, and D. Eugene Strandness described use of an ultrasonic flow detect to assess venous flow patterns.[3] In 1972, Strandness and Sumner published their observations on the use of Doppler ultrasound for the diagnosis of venous thrombosis.[4] Steven Talbot, a vascular technologist, published his description of the use of B-mode (2-D gray-scale) imaging for the diagnosis of deep vein thrombosis (DVT) in 1982.[5,6]

Early validation studies that compared venous ultrasonography with venography identified limitations of B-mode imaging when it was used as a sole modality. Imaging of deeper structures was limited. Moderate probe compression did not collapse some normal vein segments (e.g., femoral vein at the level of the adductor hiatus) and vein compressibility could also be limited by obesity, edema, or tenderness. It was soon recognized that the accuracy of the examination was improved by combining imaging *and* Doppler-derived information about the presence and nature of venous flow in the interrogated segments.[7,8] Within a few years, venous duplex scanning had been accepted as a primary diagnostic modality, not just a screening method.

Duplex scanning is now readily available, noninvasive, and relatively inexpensive. It is the primary means for diagnosis of DVT and venous insufficiency.[8a,8b,9-12] There are limitations, however. The accuracy and reliability of venous duplex scanning still depend on the thoroughness of the examination, the skill of the vascular technologist performing the study, and the competence of the interpreting physician.

Variation is reduced by exam standardization and by the use of appropriate study procedures and interpretation criteria.[12a] Accreditation recognizes facilities that provide quality vascular testing services by compliance with relevant standards. It also serves as an educational tool to improve overall quality. The Intersocietal Accreditation Commission (IAC) accredits imaging facilities specific to vascular testing. The IAC publishes accreditation standards that are regularly updated, and they represent a consensus on what constitutes an appropriate vascular laboratory examination.[13] These standards include appropriate training and credentials of technologists and interpreting physicians, and the use of established, consistent examination protocols (Tables 23.1 and 23.2).

Abstract

Venous duplex scanning is readily available, inexpensive, safe, and reliable for most clinical situations. Duplex ultrasound is the primary diagnostic method for evaluation of suspected deep vein thrombosis, chronic venous insufficiency, and other disorders of the venous system.

Keywords

Ultrasonography, Doppler, color
Ultrasonography, Doppler, duplex
Veins/diagnostic imaging
Venous insufficiency/diagnosis
Venous thrombosis/diagnostic imaging

TABLE 23.1 Vascular Laboratory Standards for Peripheral Venous Testing

INDICATIONS: Peripheral venous testing must be performed for appropriate clinical indications
- Testing indication must be documented

Equipment: Equipment must provide accurate data.
- Imaging equipment: duplex ultrasound with color flow Doppler, with
  - imaging frequencies appropriate for the structures evaluated
  - Doppler frequencies appropriate for the vessels evaluated
  - range-gated spectral Doppler with ability to adjust the depth and position of the range gate in the area of interest
  - Doppler angle which is measurable and adjustable
  - visual display and permanent recording of images
  - visual display, audible output, and permanent recording of Doppler waveforms and corresponding images
- Equipment quality control: equipment used for diagnostic testing must be maintained in good operating condition

PROTOCOLS: There must be a written protocol for each examination, including:
- Equipment to be used
- Proper technique
- Anatomic extent of a complete examination, generally includes entire course of the accessible portion of each vessel
- Variations in technique following vascular interventions, including dialysis access
- Variations in technique and documentation for limited exams
- Routine documentation and additional documentation that must be acquired to describe abnormalities
- Description of how color Doppler or other flow imaging modes (e.g., power Doppler) are used to supplement grayscale imaging and spectral Doppler measurements

TECHNIQUES: Appropriate techniques to document their severity, location, extent and (whenever possible) etiology. Elements of proper technique include:
- Performance of an examination according to a specific written protocol
- Proper patient positioning
  - limb must be in dependent position when examined for valvular function
  - standing preferred, if not constrained by the patient's physical condition
  - sitting or reverse Trendelenburg may be used if the patient cannot stand
  - patient position should be noted in the final report
- Patient preparation
  - appropriate equipment and transducer selection
  - appropriate transducer positioning and orientation
  - proper Doppler sample volume size and positioning
  - optimization of equipment gain and display settings
- Proper vein diameter measurements:
  - acquired with the limb in a dependent position
  - measured anterior wall to posterior wall
  - no external pressure is applied to the vein during measurement
  - identification of vessels by imaging and Doppler, using appropriate terminology for vessel nomenclature and anatomic level
  - transverse grayscale imaging without and with transducer compressions

DOCUMENTATION
- Grayscale images
- Color Doppler images
- Doppler spectral waveforms
- Velocity measurements
- Valve closure time, reflux duration
- Abnormalities will require additional images and waveforms that demonstrate the severity, location, extent, and etiology
  - trace superficial reflux to source
  - areas of suspected obstruction must include representative Doppler waveforms recorded at and distal to the obstruction

Vascular laboratory standards for peripheral venous testing (modified from: Intersocietal Accreditation Commission—Vascular Testing. IAC Standards and Guidelines for Vascular Testing Accreditation. *Section 4B: Peripheral Venous Testing*, revised January 15, 2018. (https://www.intersocietal.org/vascular/standards/IACVascularTestingStandards2018.pdf)

NORMAL B-MODE IMAGING FINDINGS

Venous duplex scanning may be performed with most ultrasound systems. Transducer selection depends on the depth of the veins to be scanned. A 5 to 10 MHz linear array transducer is sufficient for most extremity venous examinations, but a 3 to 5 MHz curved linear transducer may be needed to evaluate deeply located vessels, such as the inferior vena cava (IVC) and iliac veins, or to evaluate obese or edematous extremities. High-frequency transducers may be used for mapping or guiding access to superficial veins.

Blood is not an effective reflector of ultrasound. Thus with conventional B-mode imaging the lumen of normal vein is typically anechoic (black). The interface between blood and

TABLE 23.2 Components of Venous Duplex Scans: Peripheral Venous Documentation

LOWER EXTREMITY VENOUS DUPLEX FOR THROMBOSIS AND PATENCY

- Transverse grayscale images without and with transducer compression, including:
  - common femoral vein
  - saphenofemoral junction
  - proximal femoral vein
  - mid femoral vein
  - distal femoral vein
  - popliteal vein
  - posterior tibial veins
  - peroneal veins
  - additional images to document areas of suspected thrombus (including superficial veins and muscular calf veins)
- Spectral Doppler waveforms demonstrating spontaneous venous flow, phasicity and/or flow augmentation, including:
  - right and left common femoral veins
  - popliteal vein
  - additional waveforms, as appropriate
  - abnormalities require additional images, waveforms and velocity measurements

LOWER EXTREMITY VENOUS DUPLEX FOR REFLUX

- Transverse grayscale images of diameter measurement, including:
  - common femoral vein
  - saphenofemoral junction
  - mid femoral vein
  - great saphenous vein
  - popliteal vein
  - small saphenous vein
- Spectral Doppler waveforms with the leg in a dependent position, demonstrating baseline flow and response to distal augmentation; if reflux is present, duration of retrograde flow is measured with calipers:
  - common femoral vein
  - saphenofemoral junction
  - great saphenous vein
  - femoral vein, mid thigh
  - popliteal vein
  - saphenopopliteal junction
  - small saphenous vein
- Transverse grayscale images without and with transducer compression, including:
  - saphenofemoral junction
  - great saphenous vein at proximal thigh
  - great saphenous vein at knee
  - small saphenous vein (at saphenopopliteal junction)

UPPER EXTREMITY VENOUS DUPLEX FOR THROMBOSIS AND PATENCY

- Transverse grayscale images without and with transducer compression, including:
  - internal jugular vein
  - subclavian vein
  - axillary vein
  - brachial vein(s)
  - basilic vein
  - cephalic vein
  - additional images to document areas of suspected thrombus
  - brachiocephalic vein should be imaged, if possible, but compression maneuvers are not used for intrathoracic veins
- Spectral Doppler waveforms demonstrating spontaneous venous flow, phasicity and/or flow augmentation, including:
  - internal jugular vein
  - right and left subclavian veins
  - axillary vein
  - additional waveforms (e.g. brachiocephalic veins), as appropriate

VEIN MAPPING

- Assessment of the veins (distended with use of superficial tourniquet)
- Vein patency and diameter

VENOUS STENTS

- Spectral Doppler waveforms with color Doppler images, including:
  - proximal stent
  - mid stent
  - distal stent
  - native vessel adjacent to the proximal end of the stent
  - native vessel adjacent to distal end of the stent

Components of venous duplex scans: Peripheral venous documentation (modified from: Intersocietal Accreditation Commission—Vascular Testing. IAC Standards and Guidelines for Vascular Testing Accreditation. *Section 4B: Peripheral Venous Testing*, revised January 15, 2018. (https://www.intersocietal.org/vascular/standards/IACVascularTestingStandards2018.pdf)

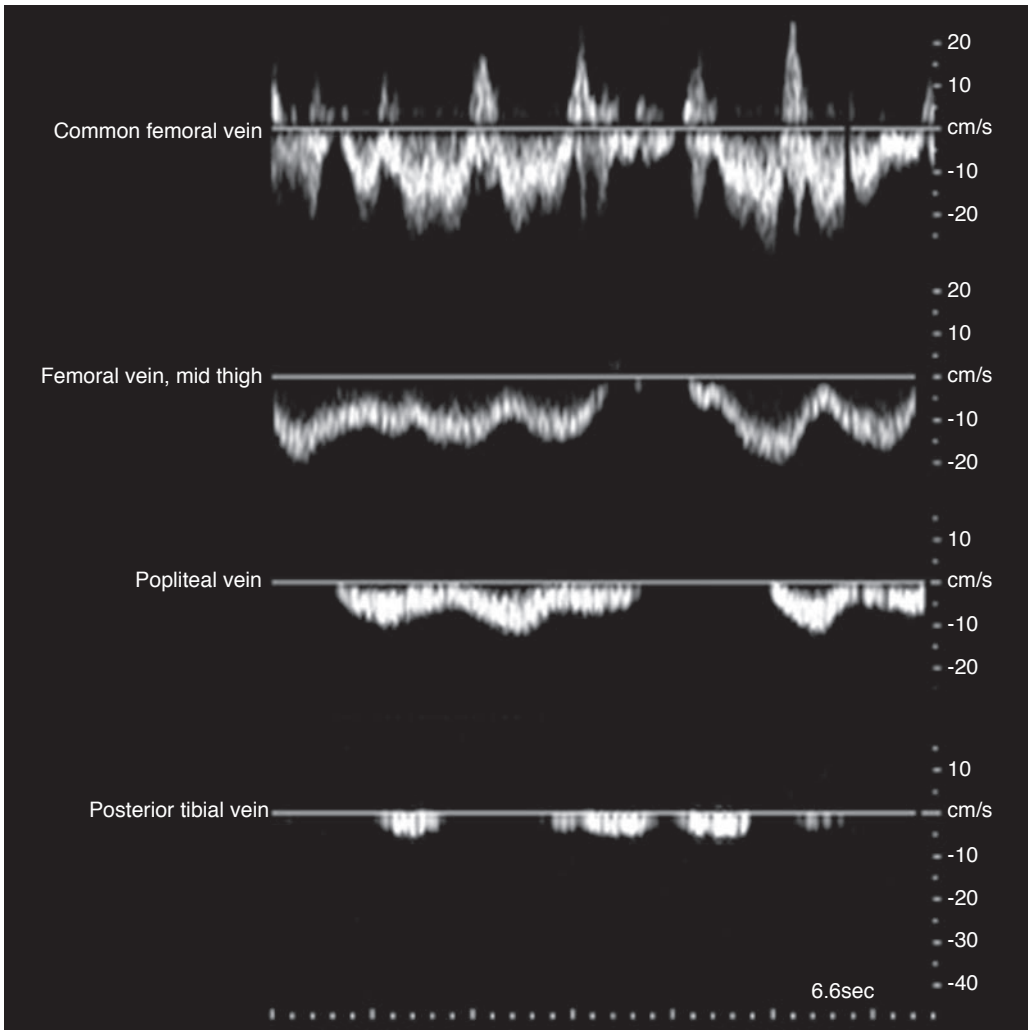

Figure 23.1 Normal flow in the lower extremity veins is spontaneous (occurring without calf pump function or other augmentation maneuvers) and phasic with respiration. Flow patterns differ at proximal and distal locations, with less spontaneous flow observed in the smaller veins in the distal limb. The presence or absence of thrombus within an imaged vein can be confirmed with probe compression. (Image from Dawson DL, Gray HM. Acute lower extremity deep vein thrombosis. In: Zierler RE and Dawson DL, editors: *Strandness's Duplex Scanning in Vascular Disorders*. 5th ed. Philadelphia: Wolters Kluwer; 2016: 235 [Chapter 19, Fig. 19.8].)

the vein wall is echogenic (bright), especially when specular reflections are created when the ultrasound angle of incidence is close to 90 degrees. The wall of a vein appears thinner than the wall of the adjacent artery. Flowing blood may sometimes be seen within veins, especially when a high-frequency transducer is used to examine a vein that is close to the skin surface. This may be most apparent when slow flow conditions result in red blood cell aggregation with rouleaux formation, creating greater echogenicity.[14]

Extremity veins may vary in size and profile. With hypovolemia, veins may appear ovoid or collapsed. Because of the normally low pressure in veins, they are easily collapsed with extrinsic compression. (Of note, normal arteries may also be compressible if sufficient probe pressure is applied.) When venous pressure is high (heart failure, more central obstruction, etc.), veins may be distended. Extremity veins may appear collapsed when the limb is elevated above the phlebostatic axis (level of the right atrium), and they will be full and dilated when the limb is dependent. Lower extremity examinations are typically done with some reverse-Trendelenburg (foot down) positioning to make the veins easier to identify.

NORMAL FLOW PATTERNS IN VEINS

Color flow Doppler and pulsed Doppler spectral waveform analysis are used to evaluate venous flow characteristics (Fig. 23.1).

In the arterial system, the pumping action of the heart is the primary driving force for blood flow, but in the low-pressure venous system, the antegrade movement of venous blood flow is substantially affected by other factors. Normal venous flow is **phasic** with respiratory movements. During inspiration, the diaphragm moves downward and intraabdominal pressure is increased. This decreases venous return from the lower extremities. Flow increases during expiration. In the upper extremity veins, respiratory phasicity has a different pattern. Intrathoracic pressure is decreased during inspiration; antegrade flow in upper extremity veins is increased. The cardiac cycle has greater effects on venous flow patterns in more central veins.

Spontaneous antegrade venous flow is seen under resting conditions, but flow velocity is dramatically augmented with voluntary muscle contraction or by manual compression by the examiner. Muscle contraction transiently increases compartment

pressures, compresses deep veins and venous sinuses within the muscles, and thereby functions as a peripheral pumping mechanism in the circulation. Venous obstruction interferes with the flow **augmentation** produced by compression or other provocative maneuvers.

DIAGNOSIS OF DEEP VEIN THROMBOSIS

Direct ultrasound visualization of thrombus within a vein is the most obvious finding associated with DVT (see Chapter 147). Deep veins that are acutely occluded by thrombosis are often distended, appearing round and larger than the adjacent artery. Thrombus echogenicity increases as the clot organizes, making it easier to detect with B-mode imaging over time. Acute thrombus may be adherent to the vein wall, or it may be loosely attached and mobile, a "free floating thrombus" or "thrombus tail."

B-mode imaging alone has limited sensitivity. Fresh thrombus may be hypoechoic. It can also be difficult to recognize intraluminal thrombus if the imaging quality is suboptimal, as can be the case with an uncooperative patient, greater imaging depth (obesity), failure to optimize imaging settings, or other technical factors.

For better detection of thrombus in the lumen, venous scanning is done with compression maneuvers (Fig. 23.2). Pressure is manually applied with the imaging probe. Normal vein walls are coapted with modest compression. Vein walls will not collapse when there is thrombus in the lumen, though soft thrombus may deform with firm pressure. Partial compressibility may be seen with non-obstructive acute thrombosis or as recanalization of an occluded segment occurs over time.

B-mode imaging is not a stand-alone modality for DVT diagnosis. Imaging of deeper structures can be limited, and some normal venous segments may not collapse with probe pressure (e.g., femoral vein at the level of the adductor hiatus). Venous compressibility can also be limited by obesity, edema, or tenderness. Calf veins may be difficult to visualize.

Duplex scanning, the combination of imaging *and* Doppler-derived information about the presence and nature of venous flow, improves the accuracy of the examination (Fig. 23.3).[7] The addition of flow information makes it possible to identify veins that are not well demonstrated with B-mode alone and to determine patency. Color flow Doppler helps confirm the patency of venous segments that were incompletely evaluated with B-mode imaging. It can help to distinguish between occluding and non-occluding thrombus and identify anechoic thrombus by visualization of the flow around it. The color velocity scale (pulse repetition frequency or PRF) should be at a low setting to detect low velocity venous flow.

The diagnostic accuracy of duplex ultrasound scanning is good enough that it has replaced contrast venography as the definitive diagnostic test for DVT, except in limited situations. A systematic review found 100 publications from 1966 to 2004 that compared ultrasound with venography in patients with suspected DVT. Meta-analyses of data from these studies confirmed that the best results were obtained with examinations that combined B-mode, pulsed Doppler, and color Doppler imaging.[15] The pooled sensitivity was 96% for proximal limb DVT, 75% for distal DVT, and a pooled specificity of 94%. Sensitivity was found to be higher in the more recently published studies, in cohorts with higher pretest probability of DVT and more proximal DVT, and was lower in cohorts that reported interpretation by a radiologist. Specificity was higher in cohorts that excluded patients with known prior DVT.

Imaging techniques and provocative maneuvers need to be used in combination to correctly distinguish normal flow variations from DVT (Fig. 23.4). The presence of intraluminal echoes from rouleaux formation can be distinguished from thrombus by the disruption of the echogenic erythrocyte aggregates by flow augmentation and by vein wall collapse with compression. The absence of spontaneous flow (pulsed Doppler or color Doppler) may be normal in the distal limb, or it may be the result of more central obstruction. Augmentation maneuvers (calf pump, manual distal compression) will demonstrate flow.

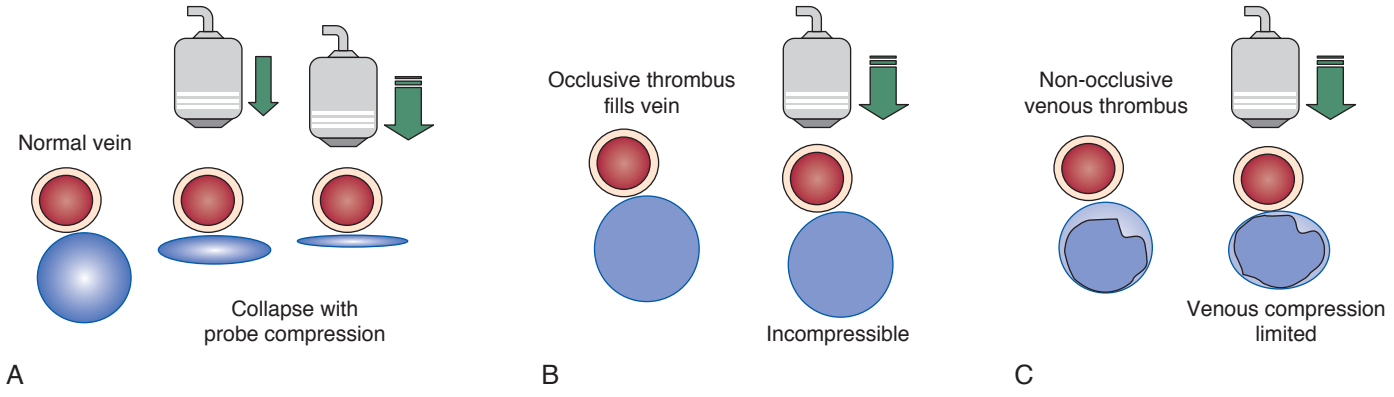

Figure 23.2 The presence or absence of thrombus within an imaged vein can be confirmed with probe compression. (A) Normal vein collapses with probe pressure. (B) Thrombosed vein does not compress. (C) Partial vein compressibility with non-occlusive venous thrombosis. (Modified from Dawson DL, Gray HM. Acute lower extremity deep vein thrombosis. In: Zierler RE and Dawson DL, eds. *Strandness's Duplex Scanning in Vascular Disorders*. 5th ed. Philadelphia: Wolters Kluwer; 2016:233 [Chapter 19, Fig. 19.2].)

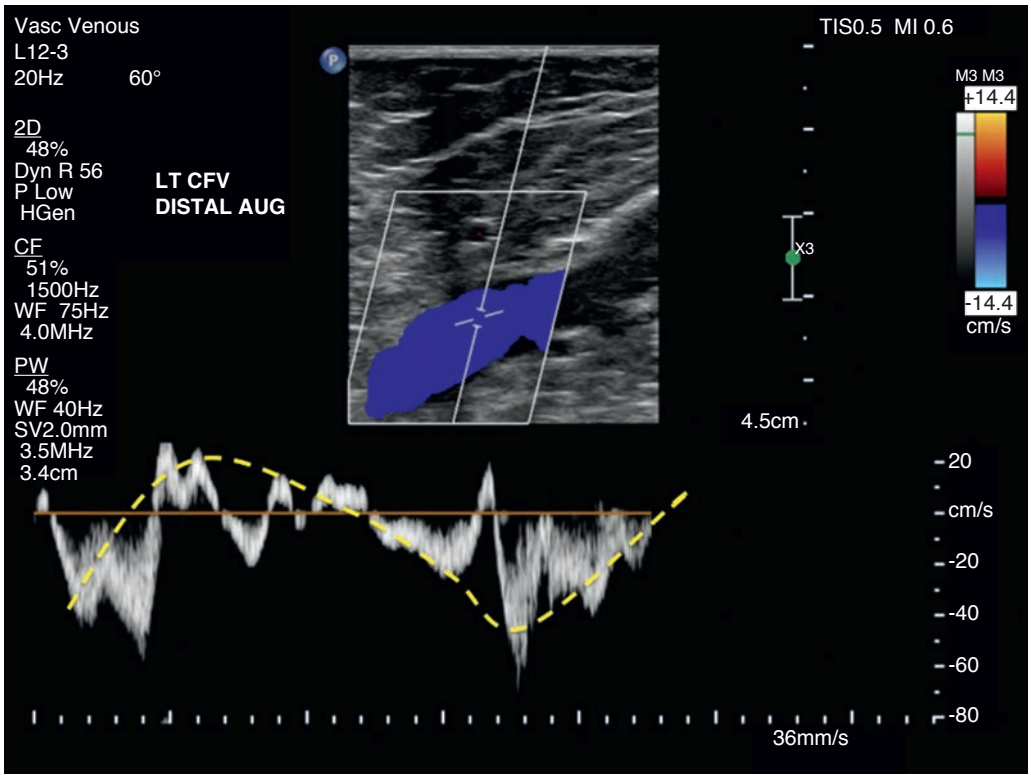

Figure 23.3 Color Doppler Image of a Normal Common Femoral Vein. There is complete color filling of the vein lumen. The flow velocity waveform demonstrates spontaneous flow that is phasic with respiration (highlighted by *dashed yellow line*). Cardiac effects are also seen in the waveform.

CALF VEIN THROMBOSIS

All lower extremity deep veins should be examined as part of a complete DVT examination, including infrapopliteal veins: peroneal, posterior tibial, soleal, and gastrocnemius veins. Calf vein thrombosis is common in patients with acute DVT and often occurs as an isolated finding.[16] The peroneal and posterior tibial veins are involved in the majority of cases. Anterior tibial vein thrombi are less common.

Duplex scanning can reliably evaluate for calf vein DVT, but there are some differences in examination technique and interpretation. Spontaneous flow is not always detected, but there will be Doppler-detectable flow with augmentation by distal manual compression. Calf veins may be difficult to visualize with B-mode imaging, especially in the obese or those with significant edema. Detection of venous flow with color Doppler, with or without augmentation maneuvers, can confirm calf vein patency (Fig. 23.5).

Isolated calf vein thrombi rarely cause clinically relevant pulmonary emboli (PE), but patients with calf vein DVT are at risk for progression to involve the femoropopliteal veins (see Chapter 147). Symptomatic calf-vein DVT is associated with progression or recurrent thrombosis in 15% to 20% of patients within 3 months.[17,18] Calf vein DVT is a marker for increased thromboembolic risk, for which anticoagulation may be indicated.[19] Few patients with calf vein DVT are at high risk for progression or PE.[20] Risk is higher when thrombus is isolated to calf veins,[21-23] if the DVT was a second or subsequent venous thromboembolism (VTE) episode, in patients with recent orthopedic procedures, in patients with malignancy, and in those who are immobile.[24-26]

When anticoagulation is not used to treat acute, isolated calf vein thrombi, follow-up duplex scanning over at least 2 weeks is recommended to evaluate for progression.[27]

Thrombosis of intramuscular veins, those within the gastrocnemius or soleus muscles, can be associated with localized calf tenderness. In rare cases, there can be propagation and subsequent pulmonary embolism, but isolated muscular calf vein thrombosis has a low risk of extension. If extension is not observed within 2 weeks, it is very unlikely.[27-30] Patients with muscular calf vein thrombosis, with only transient risk factors, do not require anticoagulation, but they should be re-evaluated with duplex scanning 1 week after diagnosis to confirm thrombus resolution or the absence of progression.[31]

ILIAC VEIN AND INFERIOR VENA CAVA

The IVC and iliac veins, like other intraabdominal and retroperitoneal vessels, can be difficult to evaluate due to overlying abdominal bowel gas and the decreased resolution of ultrasound when evaluating deeper structures. When possible, patients should fast for 6 hours prior to the examination to help reduce bowel gas. B-mode imaging and transverse probe compression maneuvers are seldom effective when evaluating abdominal or

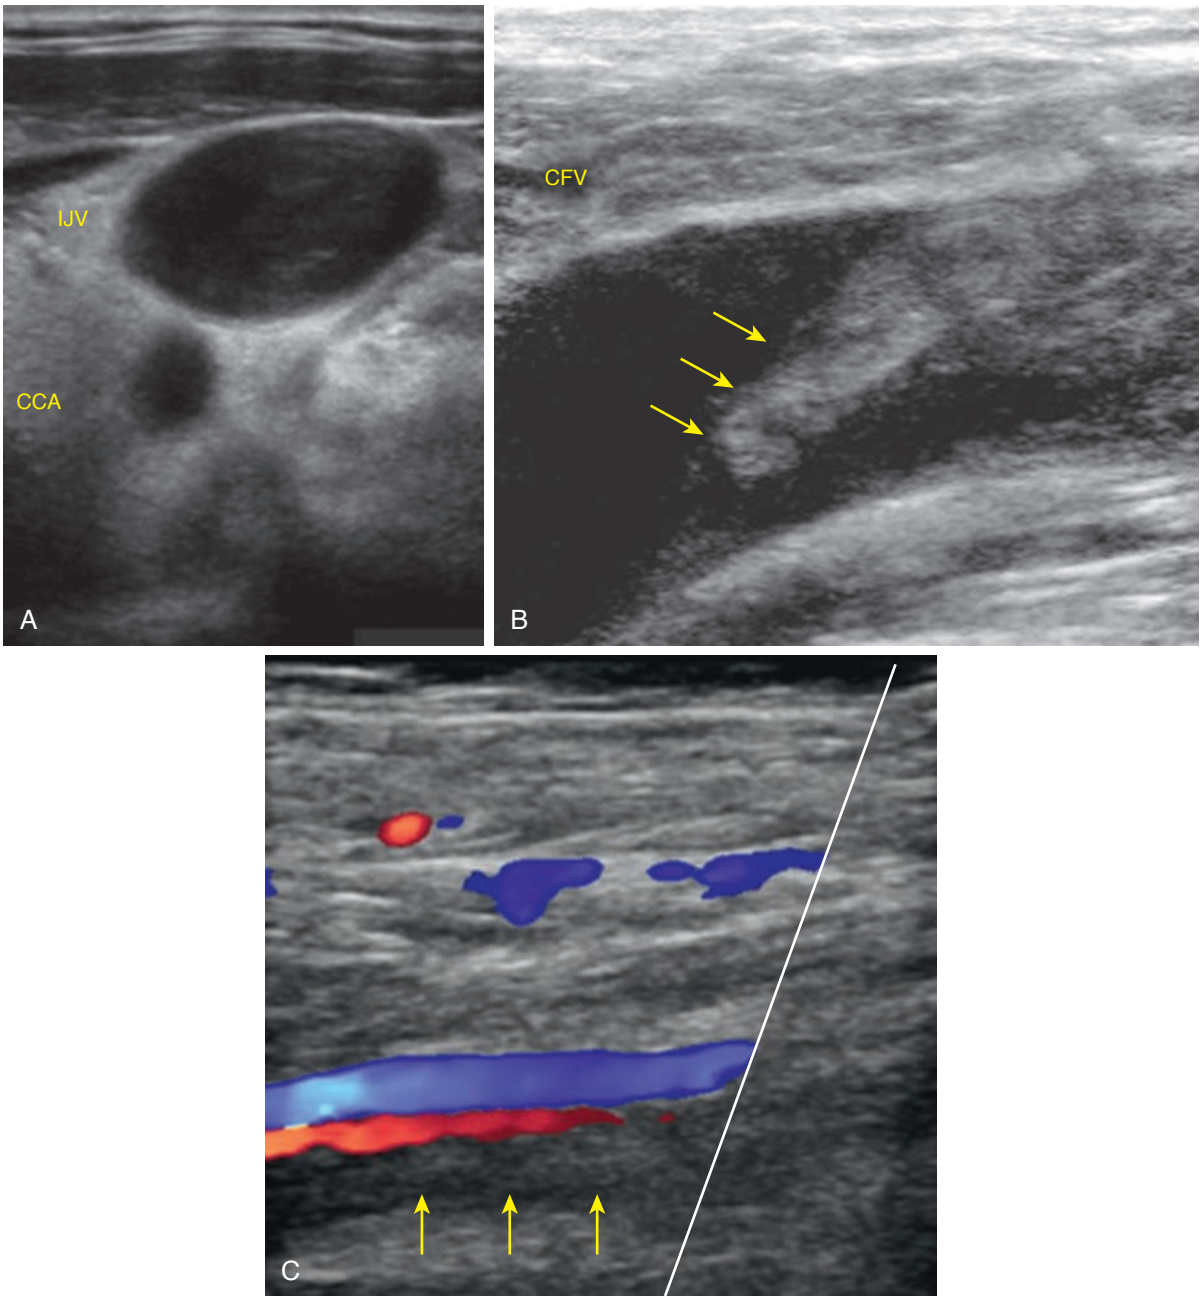

Figure 23.4 Examples of Acute Deep Vein Thrombosis. (A) Dilated internal jugular vein with hypoechoic lumen. (B) Intraluminal thrombus in the common femoral vein with a "free floating tail" *(yellow arrows)* extending cephalad. (C) Absence of color filling in one of two peroneal veins, with the presence of intraluminal echogenic thrombus *(yellow arrows)*.

pelvic veins. Therefore color flow and Doppler spectral waveforms are the primary modalities for evaluation of the IVC and iliac veins. Color scale and gain settings are adjusted for depth.

IVC flow should be spontaneous and phasic throughout. Greater pulsatility is seen in the IVC due to its proximity to the heart. Absence of detectable flow by pulsed Doppler and color Doppler imaging suggests IVC occlusion or thrombosis.

External iliac and common iliac veins can be evaluated from the inguinal ligament to the level of the IVC. Augmentation of flow is produced with thigh compressions. Internal iliac veins are identified at their confluence with the external iliac veins. Complete or partial absence of color flow within the iliac veins may indicate intraluminal thrombus. Absence of spontaneous flow or lack of respiratory phasicity (continuous flow) may indicate a more central venous obstruction. Comparison of venous flow characteristics to the contralateral side may show indirect findings that indicate common iliac vein obstruction or compression (Fig. 23.6). Continuous venous waveforms with elevated flow velocities may be seen with venous stenosis.

Abnormal flow patterns in lower extremity veins may reflect abnormal (central) cardiovascular abnormalities. Heart failure

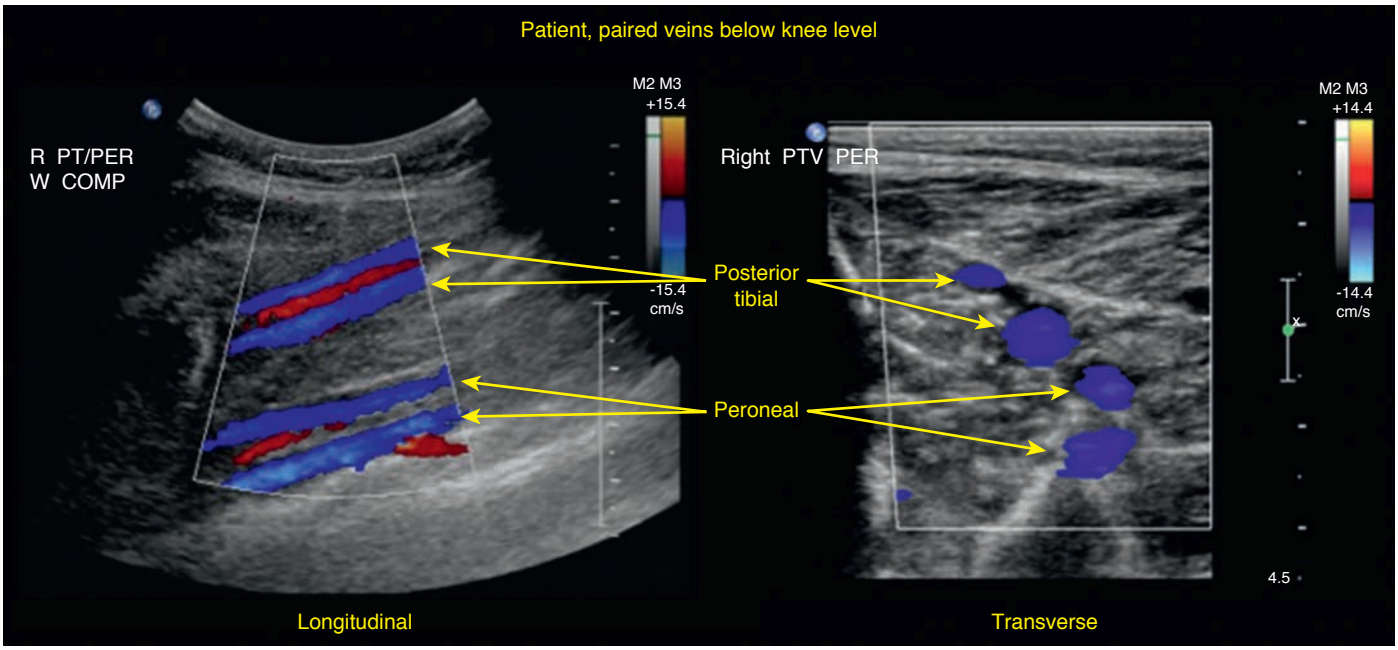

Figure 23.5 **Imaging of the Posterior Tibial and Peroneal Veins.** *Left,* longitudinal view; *right,* transverse view. Color flow imaging can confirm patency of the posterior tibial and peroneal veins. This can help to rule out calf deep vein thrombosis when vein wall coaptation with compression maneuvers is difficult to demonstrate. (Image from Dawson DL, Gray HM. Acute lower extremity deep vein thrombosis. In: Zierler RE and Dawson DL, eds. *Strandness's Duplex Scanning in Vascular Disorders.* 5th ed. Philadelphia: Wolters Kluwer; 2016:240 [Chapter 19, Fig. 19.17].)

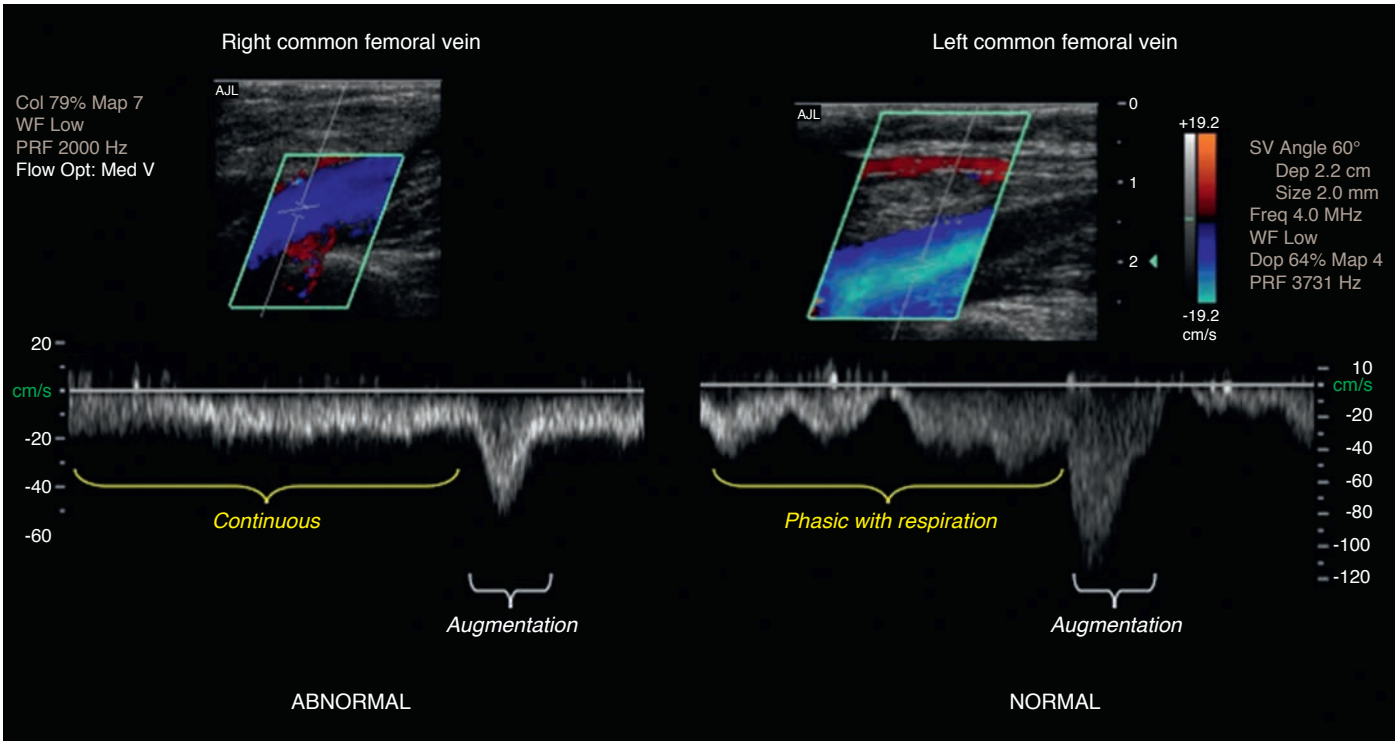

Figure 23.6 Continuous venous flow (loss of normal respiratory phasic variation) indicates venous outflow obstruction. This indirect finding does not distinguish occlusion, non-occlusive thrombosis, chronic narrowing, or extrinsic compression. When seen in one common femoral vein, as shown, it indicates iliac vein obstruction. (Image from Dawson DL, Gray HM. Acute lower extremity deep vein thrombosis. In: Zierler RE and Dawson DL, eds. *Strandness's Duplex Scanning in Vascular Disorders.* 5th ed. Philadelphia: Wolters Kluwer; 2016:233 [Chapter 19, Fig. 19.2].)

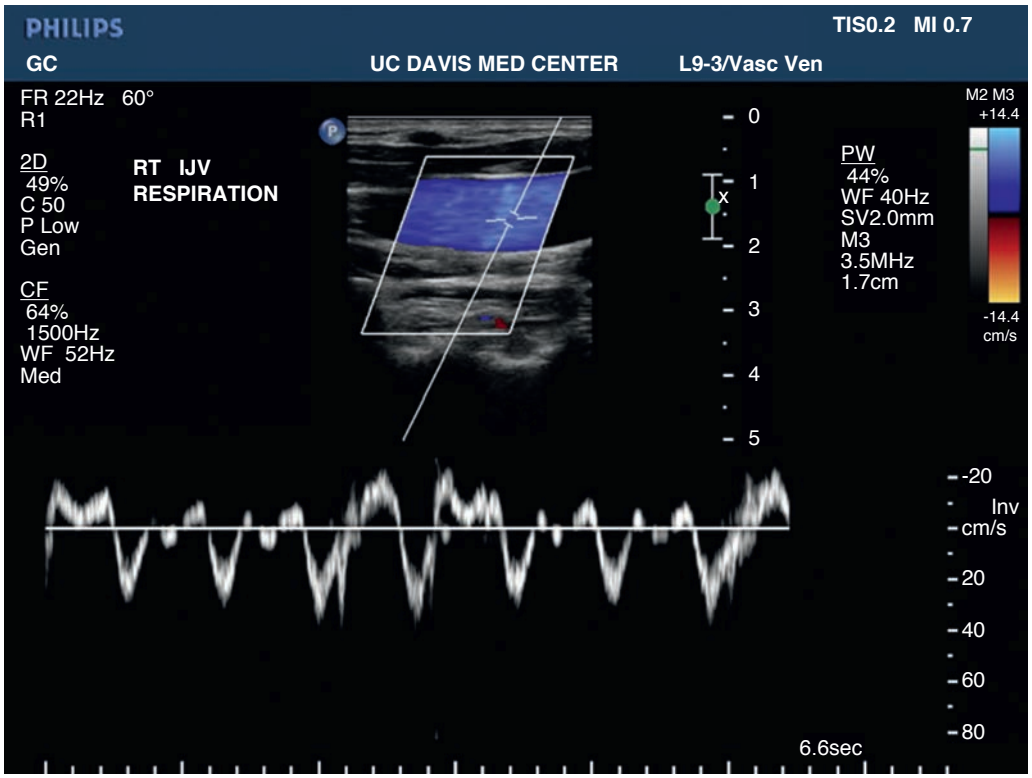

Figure 23.7 The normal flow pattern in the internal jugular vein (IJV), like other veins close to the heart, is more affected by the cardiac cycle than phasic respiratory variation.

or tricuspid valve regurgitation can increase venous flow variations with each cardiac cycle.

DIAGNOSIS OF UPPER EXTREMITY DEEP VEIN THROMBOSIS

Compared with the lower extremities, the upper extremities are less frequently affected by deep venous thrombosis.[32-34] Upper extremity DVT usually develops secondary to an identified inciting factor, such as the presence of central venous catheters (Fig. 23.7), pacemaker wires, or malignancy (see Chapter 149).[34,35] Primary upper extremity venous thrombosis, when it does occur, is most commonly due to extrinsic compression at the level of the thoracic outlet (Paget-von Schrötter syndrome; see Chapter 123).[34-40]

Catheter venography may be performed for diagnosis or as part of an intervention to treat upper extremity or central venous thrombosis or stenosis, but duplex scanning is the primary diagnostic modality in clinical practice.

Upper extremity venous duplex scanning, compared with lower extremity studies, has both similarities and differences. Venous incompressibility is similarly used in upper extremity examinations as a sign of vein thrombosis, but compression techniques are not practical for evaluation of veins under the clavicle or more centrally. The presence or absence of Doppler detectable flow can be used to assess for patency, but anatomic features

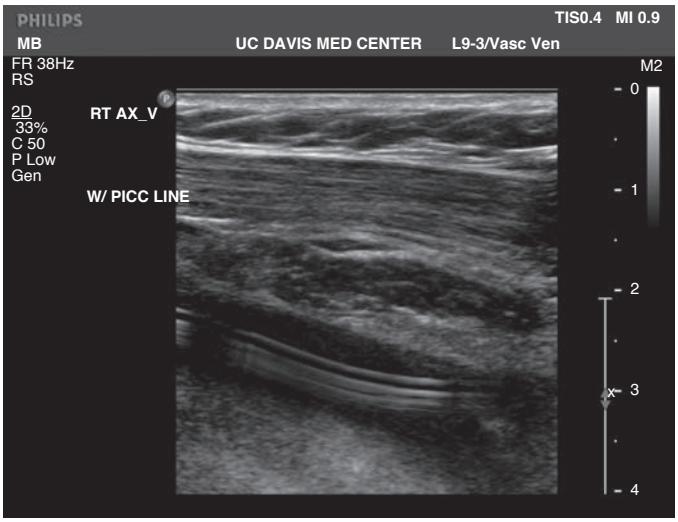

Figure 23.8 Intraluminal foreign bodies can be visualized with B-mode gray-scale ultrasound imaging. In this example, the echogenic walls of a catheter are seen within the anechoic lumen of the axillary vein. The echogenicity of the catheter produces the reverberation artifact, seen here. Upper extremity venous thrombosis is often associated with the presence of an indwelling catheter.

limit direct B-mode imaging of the central venous outflow from the upper extremities (brachiocephalic veins and superior vena cava). Greater pulsatility is a normal finding in central veins or proximal upper extremity veins (Fig. 23.8). Indirect findings, such as asymmetry of venous flow velocity waveforms,

may suggest the presence of central venous obstruction, but robust collateral formation may develop around chronically occluded segments, limiting the reliability of indirect findings. In some cases, occluded axillo-subclavian venous segments may be incorrectly identified as patent due to the prominence of adjacent collateral veins.

A systematic review of diagnostic tests for clinically suspected upper extremity DVT found 84% to 97% sensitivity and 93% to 96% specificity for venous ultrasound techniques, including compression ultrasonography, Doppler ultrasonography, or combinations of techniques.[41] Methodologic limitations, differences between studies, and small sample sizes limited the strength of the evidence.

LIMITED OR POINT-OF-CARE ULTRASOUND EXAMINATIONS

Point-of-care ultrasound (POCUS) examinations have become more common as ultrasound imaging systems become smaller, less expensive, and more user-friendly. POCUS examinations can be used to evaluate for DVT in outpatient clinics or offices, emergency rooms, or inpatient settings.[42] It is anticipated that venous POCUS applications will have increasing importance in clinical practice.

With appropriate training and testing procedures, it appears that the diagnosis of femoropopliteal DVT by providers at the point of care may approach the accuracy of vascular laboratory professionals.[43] While some have suggested the use of an abbreviated "two-point" compression ultrasound examination that only evaluates the common femoral and popliteal veins, this approach does not identify thrombus limited to the femoral vein in the thigh or thrombosis of calf veins, reducing exam sensitivity.[44] While this shortcoming may not be a major problem in ambulatory patients with low suspicion for DVT who have appropriate follow-up,[45] it is clinically relevant in high-risk patients (e.g., severely ill hospitalized patients).[44,46]

A systematic review that included meta-analysis of 16 studies with 2379 patients compared emergency department POCUS examinations with a reference examination (a color flow duplex scan performed by a radiology department or vascular laboratory, or angiography) for the diagnosis of DVT. The prevalence of DVT was high in these studies: 23% (498 in 2379 patients). The weighted mean sensitivity of emergency department POCUS, compared with the reference imaging test, was 96% with a weighted mean specificity of 97%, suggesting that with appropriate patient selection and testing procedures, POCUS can be a useful tool for DVT diagnosis.[47] The differences in the clinical characteristics of patients in various settings will substantially affect the pretest probability of DVT; and the training and experience of the clinicians performing the examinations will affect the accuracy of the results.

In vascular laboratories, routine bilateral evaluation is not standard in the absence of bilateral symptoms or other indications.[48,49] Unilateral studies are a common and accepted practice, except when a prothrombotic state is suspected, there are systemic symptoms, or there is a suspicion of pulmonary embolism.[50,51] The incidence of unilateral thrombus in an asymptomatic extremity in an otherwise healthy individual approximates 1%.[52]

DETERMINATION OF THROMBUS AGE

The manifestations and clinical significance of venous thrombus change over time. Acute thrombus in the deep veins is associated with the highest risk of thromboembolism. As the thrombus ages, it becomes less friable, increasingly fibrotic, and more firmly attached to the vein wall. Embolic risk declines over time. The age and characteristics of venous thrombus also affect the potential for success with thrombolysis or thrombus extraction procedures. Thrombus age may also affect the clinical manifestations of DVT. Thus diagnostic assessments need to consider whether identified abnormalities reflect acute or chronic disease. The vascular laboratory needs to have diagnostic criteria for the interpretation and evaluation of thrombus and its age.

Typical features of acute DVT and its late sequelae are summarized in Table 23.3. The sonographic appearance of fresh thrombus is relatively hypoechoic. Acute thrombus may have some deformability that can be demonstrated with probe compression. The vein may be occluded or there may be some residual flow around the thrombus, which may not be firmly attached to the vessel wall. In some cases, there may be a cephalad tail of free-floating thrombus that may be visualized moving in the lumen. As time passes, soft acute thrombus becomes firmer and more echogenic. Fibrin cross-links are formed, and thrombus becomes more organized and adherent to the vessel wall. Subsequently, there may be thrombolysis and vein recanalization, or inflammatory changes in the thrombus and vessel wall may lead to fibrosis (Figs. 23.9 and 23.10).[53,54]

TABLE 23.3 Ultrasound Features That May Determine Venous Thrombus Age

Feature	Early (Acute Deep Vein Thrombosis)	Late
Thrombus appearance	Hypoechoic, may be mobile or loosely attached to vein wall	Echogenic
Vein lumen size	Larger, distended	Smaller than adjacent artery, irregular
Vein wall	Thin, smooth luminal surface	Thickened, hyperechoic
Compressibility	Slightly deformable, "spongy" (may or may not occlude lumen)	Rigid, incompressible (may be partially recanalized)
Flow	Absent, or abnormal on color Doppler, with filling defects	Varying degree of recanalization
Collateral veins	Absent	Present
Valvular function	Competent (usually)	Incompetent (reflux)

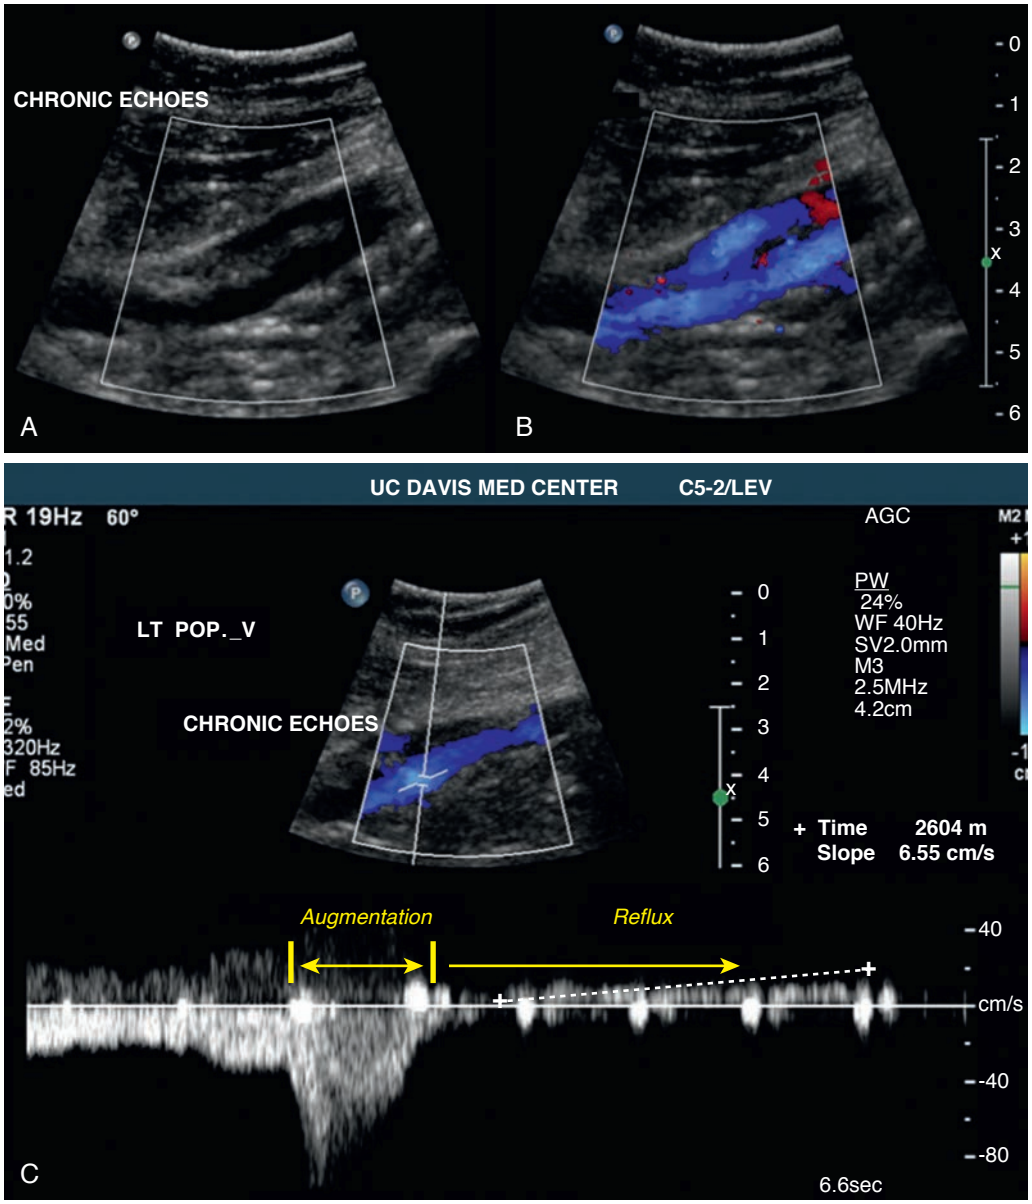

Figure 23.9 Chronic Postthrombotic Changes in the Popliteal Vein. (A) Echogenic material is seen in the lumen. (B) Color flow Doppler shows partial recanalization. (C) Venous reflux indicates valvular incompetence (though retrograde flow is slow in this example from a supine patient).

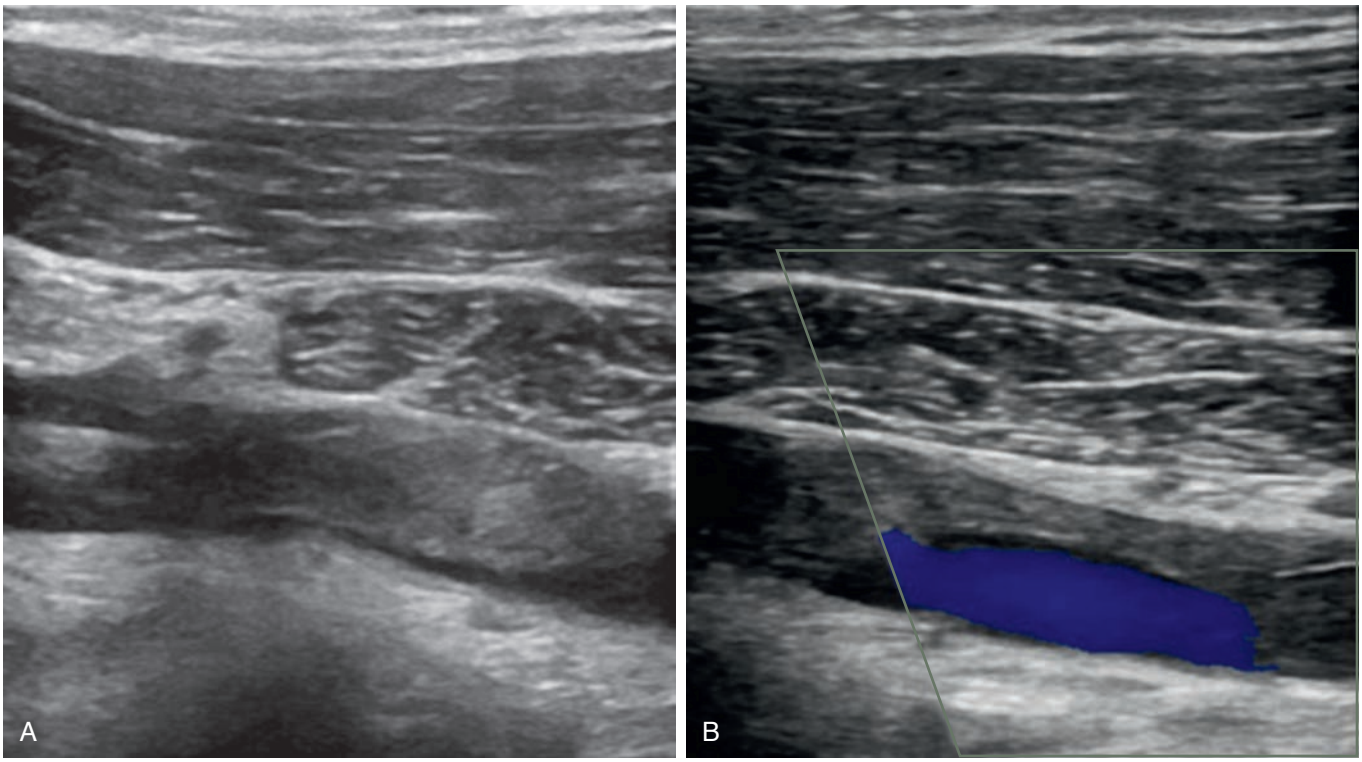

Figure 23.10 Chronic Postthrombotic Changes in the Right Axillary Vein. (A) Echogenic material is seen in the lumen. (B) Color flow Doppler shows partial recanalization.

Thrombus extent in deep veins generally regresses over time after acute DVT, but the rate and extent of thrombus resolution is variable.[55]

Venous thrombosis is appropriately described as "acute" when it first occurs. Chronic venous thrombosis has been used to describe the appearance of late intraluminal obstruction after acute DVT, but the term may be inaccurate and confusing. Fibrotic tissue, not thrombus, may be the principal content of residual intraluminal material. Abnormal findings may be seen with ultrasound months or years after DVT.[56] Some providers mistakenly assume that anticoagulation needs to be prescribed when these findings are reported as "chronic DVT." In the absence of recurrent thrombosis, there is generally no need for anticoagulation. Therefore **chronic postthrombotic change** has become the preferred term to describe what is seen months after an acute DVT. This nomenclature emphasizes the pathophysiology and may reduce misunderstandings about the implications of the diagnosis. Postthrombotic changes may be associated with a variety of manifestations of chronic venous disease, including swelling, pain, skin change, and secondary varicosities.

The term "subacute venous thrombosis" is nonspecific, and its use is no longer recommended. There is no standard definition for the duration of the acute period. There are no verified ultrasound criteria that can be used to determine the age of thrombus in the weeks or months after acute venous thrombosis. Further, the term does not have clinical significance. For the purposes of ultrasound diagnosis, when the findings are not clearly acute or chronic, the preferred terminology for reporting is **venous thrombosis, indeterminate age**. Therapeutic decisions consider individual circumstances and risk factors. If DVT is found in an asymptomatic patient in the absence of clinical history to help establish when the thrombosis occurred, it may be reasonable to consider anticoagulation, though no randomized trials have evaluated the value of anticoagulation for incidentally found VTE. The benefit of anticoagulation may be less than for patients with symptomatic DVT, as the extent of the thrombosis may be less. Clinical assessment of DVT risk is especially important in this setting.

NOVEL ULTRASOUND TECHNIQUES: ELASTOGRAPHY

Ultrasonic elastography uses ultrasound imaging to measure soft tissue strain to objectively assess the mechanical properties of tissues, such as hardness or stiffness.[57,58] This may be considered a correlate to the palpation of tissue to determine its characteristics. Several ultrasonic elastography methods have been used to characterize tissues in research and clinical applications (liver, breast masses, etc.), and elastography has been studied as an additional diagnostic modality for the characterization of venous thrombus.[57-63]

Elasticity is the tendency of a material to resume its original size and shape after deformation by a force. Fluids possess only volume elasticity, resisting changes in volume, but not shape. Solids resist changes in shape and volume, as they have both shear elasticity (rigidity) and volume elasticity. **Strain** is term

that describes changes in size or shape. Deformational forces produce strain. It is the ratio of the change in length per unit length. Force acting on an area is **stress**. When a material is stressed, thickness may decrease as length extends.

For a homogeneous isotropic (uniform) solid, the ratio of stress/strain is a constant, the modulus of elasticity. There are three moduli that describe elasticity: the Young modulus (longitudinal elasticity), the ratio of stress to strain; shear or torsion modulus (rigidity); and bulk or volume modulus (volume elasticity).

Compression elastography (quasistatic elastography or strain imaging) uses ultrasound imaging with and without external probe compression. Ultrasound images are recorded with and without compression. Areas of interest are compared—evaluated to determine relative deformation. Less deformation is seen in tissues or thrombi that are more rigid.[57,64,65] Tissue strain is determined by relative distortion.

Acoustic Radiation Force Impulse (ARFI) imaging uses energy of the insonated ultrasound to move tissues at the microscopic level. A focused ultrasound beam passing though soft tissues is primarily attenuated through absorption, but some of the acoustic pressure of the beam creates tissue movements that cause deformational stress, with greater effects on softer tissues. This is the basis of ARFI mapping of tissue stiffness. AFRI provides a qualitative stiffness value along the axis of the beam. The magnitude, location, spatial extent, and duration of acoustic radiation force can be manipulated for the evaluation of different tissues. This technique is most widely used for the evaluation of hepatic fibrosis, but studies of venous thrombus have used variations of this modality.[63]

In addition to the compression waves that propagate acoustic energy through tissue, there are also shear waves (transverse waves) created by oscillations at right angles to the direction of the ultrasound beam. The compressional wave speed through tissue is related to the bulk modulus, while the shear wave speed is related to the shear modulus. Because variations in tissue characteristics have a greater effect on the shear modulus than the bulk modulus, changes in the shear wave speed indicate structural differences in tissues. Because of this, several advanced imaging modalities use shear waves for tissue characterization. Feasibility studies with shear wave elasticity imaging (SWEI), or shear wave induced resonance elastography (SWIRE), have shown that thrombus elasticity can be quantitatively assessed.[63,66,67]

To date, however, elastography for thrombus characterization has not been standardized or sufficiently validated for their practical use in the vascular laboratory.

DETERMINING THE DURATION OF THERAPY FOR ACUTE DEEP VEIN THROMBOSIS

Benefits and risks of anticoagulant therapy should be considered when choosing the duration of anticoagulation for a first episode of unprovoked VTE.[27] Isolated calf vein DVT has half the risk of recurrence compared with proximal DVT and PE. One the other hand, a second or subsequent episode of VTE is estimated to have a 50% higher of recurrence risk compared with a first-time VTE.[27]

Venous ultrasound findings may have some value in predicting recurrence risk. Residual vein thrombosis (RVT) may indicate a continuing prothrombotic state.[68] The Duration of Anticoagulation based on Compression UltraSonography (DACUS) study found residual thrombus in the proximal veins was associated with an increased risk of recurrent thrombosis after a first episode of DVT. Conversely, the absence of RVT identified patients at very low risk for recurrence. A subsequent study similarly found that in the absence of RVT, a short period of DVT treatment may be sufficient. For those with persistent RVT, treatment extended to 2 years substantially reduced, but did not eliminate, the risk of recurrent thrombosis.[69] Among 409 patients with unprovoked DVT, 33% did not have RVT, and anticoagulation was stopped after 3 months, with a recurrent DVT rate of only 1.4%. Patients found to have residual thrombus (n = 273) received anticoagulants for an additional 21 months. Anticoagulation was stopped after a total of 24 months, and the subjects were again evaluated for residual thrombus. The rate of recurrent thrombotic events in the following year was 1.4% in those with no RVT after extended therapy, but 10.4% in those with persistent RVT.

The Cancer-DACUS study evaluated the association of RVT with recurrent VTE in patients with lower extremity DVT and cancer.[70] In cancer patients with a first DVT, treated for 6 months, the overall risk of thrombosis after cessation of anticoagulation was 15% at 1 year. The absence of RVT identified a subgroup at low risk for recurrent thrombosis, but this study's findings were not considered compelling enough to warrant a change in the guideline for long-term anticoagulation treatment for VTE in patients with cancer.[27]

The D-dimer level is another predictor of recurrent thrombosis in patients after an unprovoked first episode of VTE. Recurrence rates were found to be higher for patients with positive D-dimer results compared with those with a normal D-dimer level (3.5% vs. 8.9%).[71] The PROLONG study looked at residual venous obstruction, alone and in combination with D-dimer, to predict risk for recurrence after anticoagulation withdrawal following a first episode of DVT. An elevated D-dimer at 1 month after anticoagulation withdrawal appeared to be a risk factor for recurrence, while residual venous obstruction at the time of anticoagulation withdrawal was not.[72,73]

DIAGNOSIS OF RECURRENT THROMBOSIS

The diagnosis of recurrent venous thrombosis can be challenging.[74,75] Previous DVT is a known predictor of risk for venous thrombosis, particularly when the predisposing factor was a nonsurgical condition or if no clinical risk factor was identified.[76] Previous DVT is also a cause for symptoms occurring months or years after the acute event.

Patients with prior DVT may undergo venous duplex ultrasound to evaluate newly recognized (or chronic) leg pain

or swelling; however, abnormal findings may not be indicative of acute thrombosis. Visualized abnormalities may be residua of prior DVT (chronic postthrombotic changes). Residual vein incompressibility or other postthrombotic abnormalities can be found in approximately 80% of DVT patients at 3 months[77,78] and up to 50% at 1 year.[77,79,80]

Distinguishing acute from chronic findings is important, as postthrombotic syndrome is not treated with anticoagulation (in the absence of recurrent thrombosis or another indication). If venous reflux is demonstrated, postthrombotic syndrome may fully explain chronic or persistent symptoms.

There can be recurrent acute thrombosis in an abnormal segment ("acute on chronic" DVT), or there may be new acute DVT in a previously normal venous segment. Imaging findings typical of acute thrombosis, in combination with other chronic postthrombotic changes, suggest the recurrent, acute DVT.

Findings from a single ultrasound imaging study may be insufficient to make the diagnosis of recurrent DVT. Comparison with a prior venous duplex scan is the most reliable means to distinguish new from chronic abnormalities.[81] A study performed after completion of a course of anticoagulation establishes a new baseline for future comparison.[82] This examination can determine the posttreatment status of venous segments previously shown to have acute thrombus, including whether there is persistent occlusive thrombus, partial recanalization or postthrombotic change, or if there has been complete recanalization of the segment. If a subsequent examination is abnormal, comparison with the posttreatment baseline study allows the interpreting physician to distinguish persistent abnormalities from new ones. Late recanalization (9-12 months) after DVT may occur, so imaging findings after DVT should not be assumed to be static over time.[83,84]

When a posttreatment study is unavailable for comparison, the clinical, laboratory, and imaging findings should be considered together.[85] Recurrent DVT is more likely when there are new or persistent risk factors (including malignancy, acute illness, injury, recent surgery, etc.). A normal D-dimer level is a strong indicator that abnormal venous imaging findings are due to chronic postthrombotic changes. An elevated D-dimer level is not diagnostically useful, though.[73] D-dimer testing frequently yields false positive results associated with other conditions (cancer, chronic diseases, advanced age, inflammatory status, infections, etc.).

SUPERFICIAL VEINS

Patients may be referred to the vascular laboratory when symptoms prompt concern for DVT, but other venous problems, including superficial vein disorders, may also need to be considered.[86,87] Examination of the great saphenous vein at the level of the saphenofemoral junction is a routine part of a lower extremity veins evaluation for DVT, but a more thorough evaluation of the superficial veins is needed when patients report symptoms of localized pain, swelling, erythema, palpable venous cord, or painful varicosities. Imaging of superficial veins is also used to determine the suitability of venous segments as conduits for vascular reconstruction.

"Superficial venous thrombosis" (SVT) is the most broadly applicable term to describe thrombotic occlusion of a superficial vein. The term "superficial thrombophlebitis" may be used clinical findings of inflammation are present (pain, tender venous cord, erythema; see Chapter 150).

Inflammation is more common with superficial vein thrombosis than with DVT. The term "suppurative thrombophlebitis" is used when there is bacterial infection of a thrombosed vein.

Thrombosis of lower extremity superficial veins is commonly associated with varicose veins, but 5% to 10% of patients with SVT may have nonvaricose veins. In this setting, phlebitis may be a marker for hypercoagulable conditions, malignancy, vasculitis, or other systemic disease.[73] The Trousseau sign of malignancy, characterized by recurrent, migratory thrombosis in superficial veins, including uncommon sites, such as the torso and upper extremities, is associated with adenocarcinoma, especially of pancreas or lung origin.[88] Inherited (Factor V Leiden, prothrombin G20210A mutation, and MTHFR C677T mutation) and acquired thrombophilias are associated with an increased risk of superficial vein phlebitis and thrombosis, as well as an increased risk of thrombus progression to involve the deep veins.[89] Thrombophlebitis of upper extremity superficial veins most commonly occurs as a complication of venipuncture and intravenous catheter use.[90]

The ultrasound findings used to diagnose SVT are similar to those for DVT: venous distension, incompressibility, intraluminal echogenic material, and the absence of Doppler flow. With inflammation, there can also be vein wall thickening, perivascular edema, and tenderness with examination.

It is important to determine the extent of superficial vein thrombus, as progression of thrombosis on serial examinations, or the proximity of the thrombus to the confluence with the deep system (i.e., saphenofemoral junction), may help guide therapy. Anticoagulation for SVT reduces the incidence of thrombus extension or recurrence in high-risk cases.[89,91] In a single center series of patients with SVT who were not anticoagulated, progression to involve the deep veins was seen in 11%, most commonly though the saphenofemoral junction.[92] Based on observations like these, it has been recommended that great saphenous vein thrombosis in the proximal thigh should be treated with anticoagulation or at least followed by serial duplex ultrasound evaluation.

In a cross-sectional, prospective epidemiologic cohort study of consecutive patients with symptomatic lower extremity SVT, 10% developed thromboembolic complications at 3 months (pulmonary embolism, 0.5%; DVT, 2.8%; extension of SVT, 3.3%; and recurrent SVT, 1.9%), despite therapeutic anticoagulation of more than 60%.[93] Risk factors for complications at 3 months were male sex, history of DVT or pulmonary embolism, previous cancer, and absence of varicose veins.

Evaluation of lower extremity superficial veins is an integral component of examinations of patient with chronic venous insufficiency (CVI). Varicose axial veins (great saphenous and short saphenous veins) and varicose tributaries are assessed for patency, diameter, and their course. As superficial vein anatomy and patterns of varicose vein development are variable, a worksheet with a diagram to illustrate the sonographer's findings

TABLE 23.4 Characteristic of Superficial Vein Segments to Consider Prior Use as Bypass Conduit (Great Saphenous, Short Saphenous, Cephalic, and Basilic Veins)

	Compressibility	Diameter	Other Factors to Be Considered
Findings considered **suitable** for use as bypass conduit	• Fully compressible at all levels • No intraluminal echoes	≥0.25 cm	Vein should be of uniform caliber, without tortuosity
Findings considered **unsuitable** for use as bypass conduit	• Intraluminal echoes • Incompressible • Thickened walls	<0.20 cm	Tortuosity; varicose segments, multiple branches, location superficial to fascia

is particularly useful. Prior to procedures to treat varicose veins, duplex scanning to define the venous segments with reflux and to demonstrate the relationships of varicosities or symptomatic sites to the sources of reflux is needed.

Preoperative imaging helps determine suitability of superficial veins that might be used for creation of an arteriovenous fistula (AVF). Routine preoperative vascular ultrasound improves AVF outcomes in terms of patency and use for dialysis.[94] It can guide the selection of which vein segment to use and which type of procedure to perform. In a randomized, prospective study, the addition of ultrasound imaging to the preoperative assessment was found better than physical examination alone, with a significantly lower rate of immediate technical failure and better rates of fistula maturation to usability. Assisted primary patency at 1 year was significantly better for the ultrasound group (80% vs. 65%, $P = .012$).[95] Upper extremities veins 2.5 mm or greater in diameter are sought for AVF creation,[96,97] although there is no consensus about an absolute threshold. A 2 mm vein may be usable. A larger vein is better.

Ultrasound vein mapping prior to revascularization procedures can assess superficial veins for potential suitability as bypass conduits (Table 23.4).[98] Preoperative vein mapping reduces costs and improves outcomes for patients undergoing infrainguinal bypass surgery.[99,100] Vein mapping in the vascular laboratory or a POCUS examination prior to arteriography provides practical information that can help select between an endovascular intervention or an open surgical approach.

Guidelines for lower extremity vein mapping recommend examinations be performed with the patient in reverse Trendelenburg position using a high frequency transducer.[101] For standard vein mapping, the entire length of the great saphenous and small saphenous vein (if indicated) are evaluated with diameter measurements in transverse views. The vein is evaluated for anomalies or anatomic variants, and large branches are noted. In addition to measuring diameter, the vein is assessed for evidence of prior thrombosis or phlebitis, checking for compressibility, wall thickening, intraluminal echoes, and sclerotic valve leaflets (Fig. 23.11). It may be helpful to mark the course of the superficial veins facilitate positioning of skin incisions.

A venous tourniquet is used to dilate the veins for upper extremity vein mapping.[102] An elastic tourniquet is placed at the axilla for upper arm vein mapping and at the antecubital fossa for the forearm. The diameters of the brachial, cephalic, and basilic veins are measured in transverse view, throughout their course.

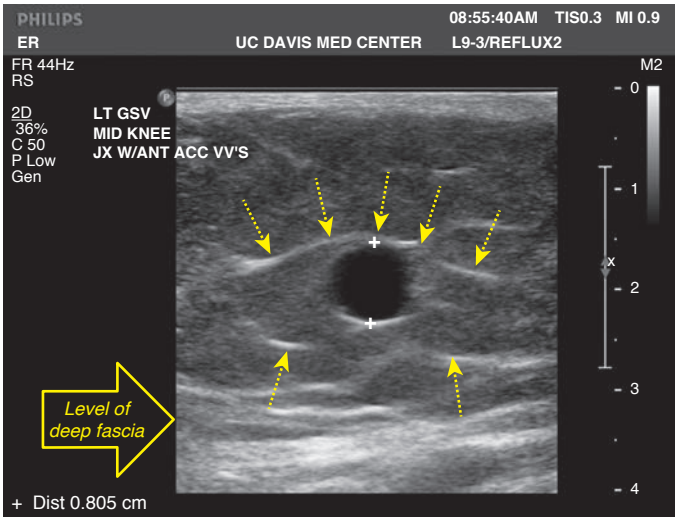

Figure 23.11 Lower extremity superficial veins are measured with electronic calipers. Measurements are performed with the leg in a dependent position. Superficial veins are distinguished from deep veins by their location between the skin and muscular fascia. A layer of subcutaneous fascia envelops the great saphenous vein *(dashed arrows)*.

EVALUATION FOR CHRONIC VENOUS DISEASE: VENOUS INSUFFICIENCY

The vascular laboratory has an integral role in the evaluation of patients with CVI (see Chapter 156).[102a,102b,103-107]

The CEAP system (Clinical-Etiology-Anatomy-Pathophysiology) is a descriptive classification that standardizes reporting and clinical documentation of chronic venous disease.[108] The diagnostic assessments for chronic venous disorders are organized into levels of testing, which may be included in the reporting of CEAP classification:

Level I: office visit, with history and clinical examination, which may include use of a handheld Doppler

Level II: noninvasive vascular laboratory testing, including duplex color scanning and plethysmographic methods

Level III: invasive investigations or more complex imaging studies, including ascending and descending venography, venous pressure measurements, computed tomography venous scanning (CTV), or magnetic resonance imaging (MRV).

The Level II assessment with duplex ultrasound scanning allows for objective evaluation of the affected anatomic levels and locations (A), as well as the pathophysiology (P) involved.

The scanning techniques for venous insufficiency testing evolved from the techniques developed for DVT diagnosis, with increased emphasis on the Doppler evaluation of flow patterns.[50,104,109] The limb swelling and pain associated with acute DVT are due to venous obstruction. CVI is the result of abnormally elevated venous pressure due to outflow obstruction (similar to acute DVT), pathologic reflux, or a combination of the two. Chronic venous stenosis or occlusion can be the cause of continued symptoms. Venous hypertension due to outflow obstruction worsens when limb blood flow is increased. This is the pathophysiologic mechanism of venous claudication.[110,111]

Incompetence of venous valves is the most common etiology of CVI.[112] Valvular incompetence can be primary (without an underlying or antecedent disorder) or secondary, where valvular dysfunction is the result prior venous thrombosis or injury.[113] Competent venous valves and muscular pumping of venous blood are needed to move blood from the lower extremities to the central circulation when upright.[114] When valves are incompetent, the musculovenous pump becomes ineffective. Distal limb pressure is not decreased with walking as it should, and ambulatory venous hypertension results.

A duplex scan for CVI directly evaluates for obstruction by examining the appearance and compressibility of the vein, as well as flow patterns, including assessment with provocative maneuvers to augment antegrade flow or to cause retrograde flow. Indirect findings that may indicate more central venous obstruction include asymmetry in flow velocity, lack of respiratory flow variation, or lack of spontaneous flow.

A 4- to 7-MHz linear array transducer is commonly used, though a lower frequency curved array probe may be useful for large or obese patients. A higher-frequency probe is best for scanning superficial veins. Testing for deep and superficial vein reflux is properly performed with the patient upright, with the lower extremity externally rotated (Fig. 23.12). The heel may be on the ground, with weight bearing on the opposite limb, or a step may be used to offload examined side.[105]

Though some venous valves may be visualized with high-resolution B-mode imaging, the functioning of the bicuspid venous valves is determined observing the direction of blood flow. Normally, in the supine position, venous flow is phasic with respiration. Retrograde flow may be physiologic, as valve closure may not occur if the velocity of the retrograde flow is less than 30 cm/s, too slow to close the valve leaflets. In the upright position, vein valves open to allow antegrade flow, and then snap shut as forward flow ceases and flow reversal commences.

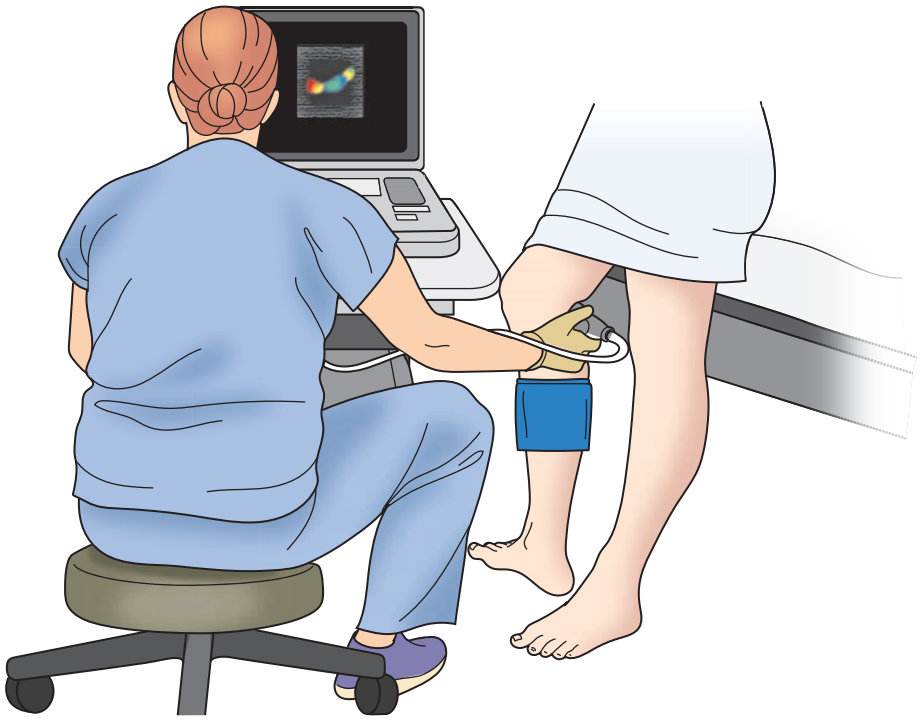

Figure 23.12 Examinations to evaluate for reflux (valvular incompetence) in lower extremity veins should be performed with the patient standing. Reflux is elicited with release of a pneumatic cuff, while imaging the vein approximately 5 cm above the cuff.

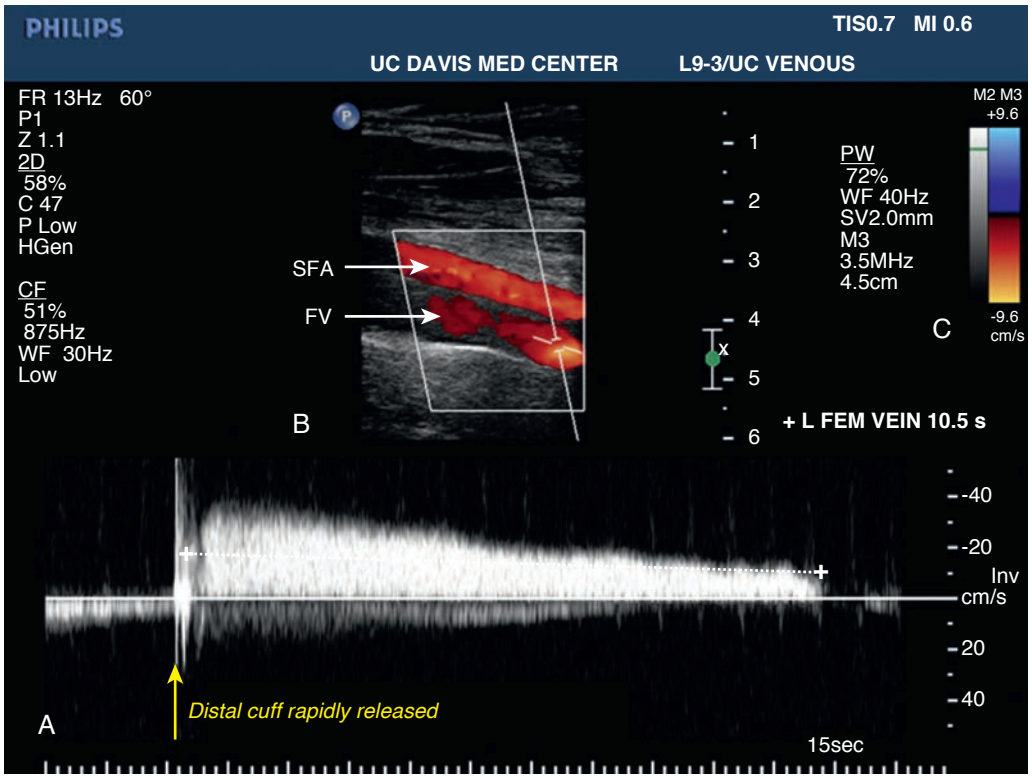

Figure 23.13 Deep Vein Reflux With Standing Examination. (A) Slow antegrade flow is demonstrated with pulsed Doppler waveform. Rapid reversal of flow (negative values shown above baseline) immediately after release of pneumatic cuff on distal thigh. (B) Color flow image shows the same direction of flow in the superficial femoral artery *(SFA)* and the adjacent femoral vein *(FV)*. (C) The color map with red colors below the baseline indicates red color Doppler display indicates flow vector away from the transducer (cephalad to caudal direction in this example).

Venous reflux is defined as retrograde flow of abnormal duration (Fig. 23.13). Venous reflux can be characterized as axial if there is uninterrupted retrograde flow from the groin to the calf. Segmental reflux involves only some segments of the venous system, while other segments retain competent functioning valves.[115]

Techniques to elicit reflux include increasing intraabdominal pressure using a Valsalva maneuver (for the common femoral vein or the saphenofemoral junctions) or by manual compression and release of the limb distal to the point of examination. The preferred method, however, is to use a standardized technique with calibrated inflation and rapid (less than 0.3 seconds) deflation of a pneumatic cuff applied distally on the limb.[116] The advantage of the distal cuff deflation technique was emphasized by van Bemmelen et al.[117] This technique, when performed in the standing position, ensures sufficient retrograde flow to achieve the closure of normal valves. The supine position should not be used for reflux testing, as both false-positives and false-negatives result.[116,118]

A prospective study to establish the upper limits of normal for the duration of retrograde flow in lower extremity veins suggested that the cutoff value should be 1.0 seconds for identifying deep vein reflux in the femoral and popliteal veins; the cutoff value to define reflux should be greater than 0.5 seconds in the superficial veins and the deep veins of the calf; and outward flow in perforating veins should be considered abnormal if greater than 350 ms.[119] A different multicenter study suggested a 0.5 second threshold for defining reversed venous flow as abnormal could be used for all veins.[120] Use of this standard value may provide diagnostic sensitivity. Diagnostic reports should include the measured reflux time in each examined vein, the patient's position (if not standing, the reason), and the provoking maneuver used.

PERFORATING VEINS

Perforating veins in the lower extremities connect the superficial veins to the deep veins.[120a] They pass through the fascia that separates the muscular compartments from the subcutaneous tissue. Normal venous flow is from superficial to deep, but valves are only present in larger perforators. Perforating veins less than 1 mm in size do not have valves.

Scanning of perforators is best done with imaging in the transverse plane, focusing on boundary between the deep and superficial compartments, looking for the interruptions in the fascia through which the perforating veins pass. Flow in perforating veins may be bidirectional, but reflux is diagnosed when there is net outward (deep to superficial) flow (Fig. 23.14).

Perforating veins may be evaluated selectively, for example, for patients with advanced disease or when evaluating recurrent varicose veins.[109] The finding of a perforating vein greater than 3.5 mm is associated with demonstrable perforator reflux in 90% of patients.[121]

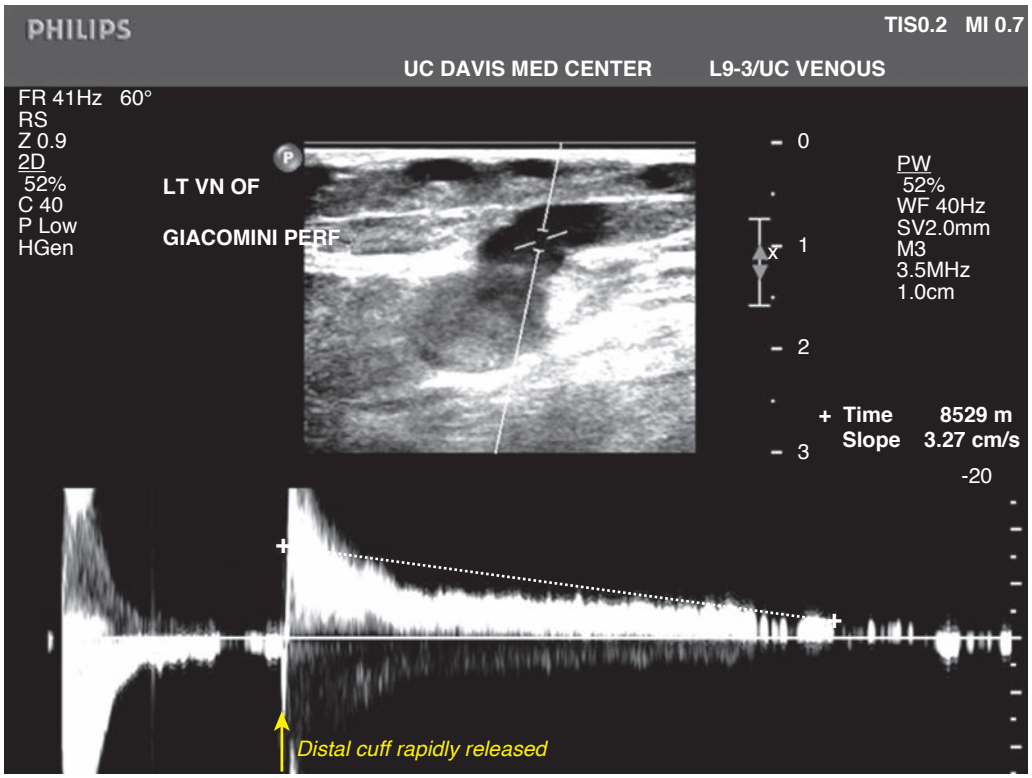

Figure 23.14 Reflux in an Incompetent Perforating Vein. Rapid reversal of flow (negative values shown above baseline) immediately after release of pneumatic cuff on proximal calf. Though the lumen of the vein deep to the fascia appears echogenic, this is an artifact from high gray-scale gain setting. The fascial gap measured 0.52 cm. Large perforators often have incompetent valves.

Textbooks

Liem TK. Duplex ultrasound for acute venous disease. In: Gloviczki P, ed. *Handbook of Venous and Lymphatic Disorders: Guidelines of the American Venous Forum*. 4th ed. Boca Raton, FL: CRC Press, Taylor & Francis Group; 2017:141–150, [chapter 12].

The American Venous Forum (AVF) is a multidisciplinary, international medical society that promotes research, education, and clinical care for all aspects of venous disease, including diagnosis, pathophysiology, and treatment. The fourth edition of the AVF Handbook of Venous and Lymphatic Disorders *serves as an up-to-date reference for vascular surgeons and specialists in vascular medicine. Chapter 12 addresses the diagnosis of deep vein thrombosis.*

Malgor RD, Labropoulos N. Duplex ultrasound scanning for chronic venous obstruction and valvular incompetence. In: Gloviczki P, ed. *Handbook of Venous and Lymphatic Disorders: Guidelines of the American Venous Forum*. 4th ed. Boca Raton, FL: CRC Press, Taylor & Francis Group; 2017:151–164, [chapter 13].

Chapter 13 of the AVF Handbook of Venous and Lymphatic Disorders *addresses duplex scanning for venous insufficiency.*

Section V. Peripheral Venous. In: Zierler RE, Dawson DL, eds. *Strandness's Duplex Scanning in Vascular Disorders*. 5th ed. Philadelphia: Wolters Kluwer; 2016:223–283.

Dr. D. Eugene Strandness, Jr., first published his textbook on duplex scanning and its applications in 1990. Dr. Strandness died in 2002, just as the third edition was published. Subsequent editions by his former trainees and colleagues expanded and updated the content. The Strandness textbook now includes clinical perspectives, techniques of scanning, and discussions of applications and pitfalls of vascular laboratory tests. The book is intended as a comprehensive text for residents, fellows, and vascular laboratory professionals. Section V includes chapters on acute lower extremity DVT, upper extremity venous thrombosis, and chronic venous disorders.

Clinical Practice Guidelines

American Institute of Ultrasound in Medicine; American College of Radiology; Society of Radiologists in Ultrasound: Practice guideline for the performance of peripheral venous ultrasound examinations. *J Ultrasound Med*. 2011;30(1):143-150.

Guidelines for venous duplex scanning developed by ultrasonographers and radiologists, with representation from several organizations, including the American Institute of Ultrasound in Medicine (AIUM). The AIUM was established in 1952 as a multidisciplinary organization when uses of ultrasound for medical diagnosis were first being explored.

Barleben A, Bandyk DF. Interpretation of peripheral venous duplex testing. *Semin Vasc Surg*. 2013;26(2–3):111–119. doi:10.1053/j.semvascsurg.2014.01.001.

Review of vascular laboratory standards for venous physiologic testing and duplex scanning.

Coleridge-Smith P, Labropoulos N, Partsch H, et al. Duplex ultrasound investigation of the veins in chronic venous disease of the lower limbs—UIP consensus document. Part I. Basic principles. *Eur J Vasc Endovasc Surg*. 2006;31(1):83–92.

This paper reports on an initiative of the Union Internationale de Phlébologie (UIP) to establish a consensus on the methods to be used for duplex

ultrasound examination, the interpretation and reporting of images and measurements obtained, and recommendations on training vascular laboratory personnel.

Cavezzi A, Labropoulos N, Partsch H, et al. Duplex ultrasound investigation of the veins in chronic venous disease of the lower limbs—UIP consensus document. Part II. Anatomy. *Eur J Vasc Endovasc Surg*. 2006;31(3):288–299.

This paper reports on an initiative of the Union Internationale de Phlébologie (UIP) to establish consensus on the methodology for assessment of anatomy of superficial, deep, and perforating veins in the lower limb by ultrasound imaging. The document provides a detailed description for complete ultrasound assessment of the anatomy of the lower extremity veins.

Gloviczki P, Comerota AJ, Dalsing MC, et al. The care of patients with varicose veins and associated chronic venous diseases: clinical practice guidelines of the Society for Vascular Surgery and the American Venous Forum. *J Vasc Surg*. 2011;53(5 suppl):2S–48S. doi:10.1016/j.jvs.2011.01.079.

Evidence-based practice guidelines for evaluation and treatment of varicose veins and chronic venous diseases, jointly written by representatives of the Society for Vascular Surgery and the American Venous Forum.

Intersocietal Accreditation Commission—Vascular Testing. IAC Standards and Guidelines for Vascular Testing Accreditation. *Section 4B: Peripheral Venous Testing* 2018; http://intersocietal.org/vascular/standards/IACVascularTestingStandards2018.pdf.

The Intersocietal Accreditation Commission—Vascular Testing (previously the Intersocietal Commission for the Accreditation of Vascular Laboratories) has been the primary organization for vascular laboratory accreditation since 1991. IAC standards, developed by subject matter experts in vascular surgery and other specialties, represent standards of practice in noninvasive vascular testing, including venous duplex scanning.

Lee BB, Nicolaides AN, Myers K, et al. Venous hemodynamic changes in lower limb venous disease: the UIP consensus according to scientific evidence. *Int Angiol*. 2016;35(3):236–352.

The Union Internationale de Phlébologie (UIP) commissioned a large group from member societies, including the European Venous Forum (EVF), American Venous Forum (AVF), American College of Phlebology (ACP), and Cardiovascular Disease Educational and Research Trust (CDERT), to provide a comprehensive review of venous hemodynamic concepts underlying the pathophysiology of lower limb venous disorders. Chapters include basic hemodynamic concepts and normal venous physiology; the mechanism and magnitude of hemodynamic changes in acute deep vein thrombosis; hemodynamic changes that occur with chronic venous disease; and hemodynamic changes resulting from treatment by compression, drugs, and surgical or endovenous ablation, as well as other topics.

Advances in radiation have led to a significant increase in its use for diagnostic, interventional, and therapeutic purposes. With the ever-increasing utilization of endovascular techniques, concern has grown regarding the potential harmful effects of radiation delivered to both the patient and the operator. Although radiation exposure from diagnostic procedures is generally low and comparable to natural background doses, therapeutic use of radiation involves a higher level of exposure, which can be harmful if not controlled.[1] Surgeon education on appropriate use of fluoroscopic equipment has been shown to be beneficial in decreasing radiation exposure.[2]

Radiation poses risk to workers and patients alike. Many medical specialists operate medical x-ray equipment frequently. Operating room assistants are often not properly educated regarding the potential damaging effects of radiation and are not trained to minimize exposure to themselves or to the patient. Patients may undergo procedures without being properly informed of the risks. These deficiencies may result in unnecessary exposure to both patients and staff.

The concern about radiation exposure is particularly pressing in the field of vascular surgery, where endovascular procedures have evolved to be the mainstays of clinical practice. Percutaneous angioplasty and stenting of peripheral and carotid arteries, as well as endovascular stent-grafts for treating abdominal and thoracic aortic diseases are now first-line treatment options. Advanced techniques such as fenestrated and branched endografts for complex thoracoabdominal aneurysms may carry significant radiation exposure to surgeons and the patient. Computed tomography angiography (CTA) as a primary modality of investigation and follow-up has become widely accepted in vascular surgery and is emerging in cardiology with the advent of coronary CT scanning. Given the incidence of coronary disease in a vascular surgery patient population, the potential exists for significant radiation exposure over the patient's lifetime.

Abstract

Vascular surgeons are performing an increasing number of endovascular treatments for their patients. These procedures vary from straightforward peripheral interventions to complex branched aortic endovascular aneurysm repair. As the complexity increases, concern grows with regard to radiation exposure for both patient and physician. Surgeon education is paramount in reducing radiation exposure and decreasing possible radiation-induced injuries.

deterministic injury
skin injury

The principles of radiation safety have been well addressed by a number of national bodies—for instance, the International Commission on Radiological Protection (ICRP) and the National Council on Radiation Protection and Measurements (NCRP). These organizations provide valuable resources and publications that disseminate information and recommendations about radiation exposure and protection. This chapter serves to familiarize vascular surgeons with terminology, metrics regarding dose, radiation-induced injury, and techniques to lower radiation dose.

TYPES OF RADIATION

Radiation is a form of energy emitted as electromagnetic waves or particles. It can be classified as nonionizing (ultrasound, magnetic resonance, laser, microwaves) or ionizing (x-rays, gamma rays). Nonionizing radiation does not possess the energy to ionize atoms of the absorbing matter. Ionizing radiation consists of alpha and beta particles, neutrons, and energetic photons (ultraviolet and above), which contain sufficiently high energy to interact with atoms and produce biologic injury. The most common forms of ionizing radiation used in medicine are x-rays, gamma rays, beta rays, and electrons.

MEASUREMENT

The amount of ionization that radiation produces in air, measured in roentgens (R), does not accurately reflect its potential to cause biologic injury. More important, the actual damage or biologic effect of radiation depends on the total energy of radiation absorbed per unit mass, the sensitivity of the organ, and the actual strength of the radiation. To quantify radiation for the purposes of risk assessment and setting standards and limits, the terms *absorbed dose*, *equivalent dose*, and *effective dose* are commonly used (Table 24.1).

Absorbed Dose

The absorbed dose is a measure of the amount of energy deposited in a medium by ionizing radiation per unit mass of matter and is equal to the amount of heat generated by the radiation per tissue weight in a specified material. The International System (SI) unit for absorbed dose is the gray (Gy), named after Louis Harold Gray, a British physicist. One gray equals 1 joule (J) of energy absorbed per kilogram (J/kg). Previously, the unit most commonly used was the "radiation absorbed dose (rad)" (1 Gy = 100 rad). The absorbed dose is not a good indicator of biologic effect because different ionizing radiation produces different degrees of damage.

TABLE 24.1 Units of Radiation

Measurement	Unit	Measures	
Radioactivity	Curie	Number of particles/sec from 1 g of radium	
Ionizing radiation	Roentgen (R)	Charge/unit mass	1 R = 2.58 × 10^{-4} C/kg
Absorbed dose	Rad	1 rad = 0.01 J/kg	1 rad = 0.01 Gy
	Gray (Gy)	1 Gy = 1 J/kg	1 Gy = 100 rad
Equivalent dose/ effective dose	Rem	Rem = rad × W	1 rem = 0.01 Sv
	Sievert (Sv)	Sv = Gy × W	1 Sv = 100 rem

W, Weighting factor.

Equivalent Dose

The equivalent dose is a measure of the radiation dose to tissue and takes into account the different degrees of damage by different types of radiation by introducing a radiation weighting factor (W_R). The SI unit of equivalent dose is the sievert (Sv), named after Rolf Sievert, a Swedish physicist. Thus equivalent dose = absorbed dose × W_R. (Another unit, the roentgen equivalent man, or rem, is still sometimes used; 1 Sv = 100 rem.)

W_R is calculated by the type of radiation (1 for x-rays and gamma rays and 3-10 for protons and neutrons). The sievert better describes the biologic effect of radiation and is commonly used when risk from ionizing radiation is assessed. It also allows quantification of risk and comparison to other commonly encountered modes of exposure. For fluoroscopic interventions in vascular surgery, the sievert and gray are roughly equal (absorbed dose = equivalent dose).

Effective Dose

Because different tissues and organs have different sensitivity to radiation, the concept of effective dose is introduced to take into account the part of the body irradiated and the volume and time over which the dose is applied. The effective dose is formed by weighting the equivalent dose by another tissue weighting factor (W_T), according to the distribution of radiation and the radiosensitivity of various organs. To avoid confusion, W_R and W_T are sometimes grouped together into one single weighting factor (W). The effective dose is also measured in sieverts.

Effective dose in radiation protection can be used prospectively for planning and optimization of radiation protection, as well as retrospectively for assessment of risk. It is mainly used as a protective and regulatory quantity and not for epidemiologic study of populations. It does not give a precise indicator of an individual patient's risk; there is no consideration of patient age, gender, or other confounding factors.

Because grays and sieverts quantify relatively large amounts of radiation, in medical use radiation is typically described in milligrays (mGy) or millisieverts (mSv).

BIOLOGIC EFFECTS OF RADIATION

Ionizing radiation damages living cells, which can repair themselves, die, or undergo a mutation. The effects of radiation on biologic tissue are generally classified as two types: deterministic effects and stochastic effects.

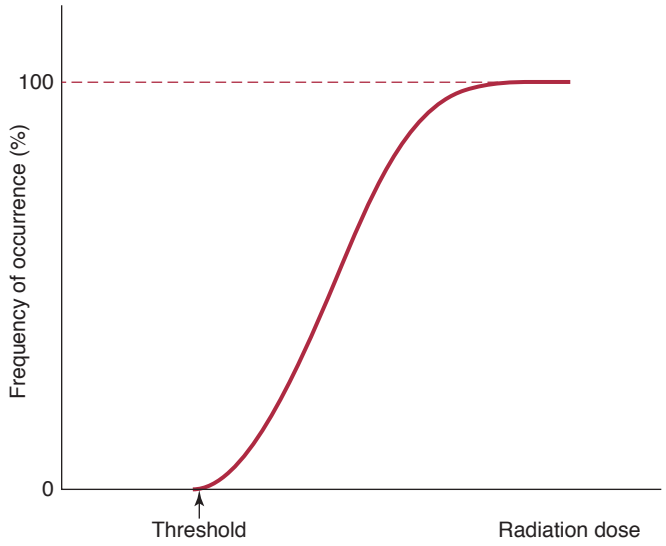

Figure 24.1 General dose-response curve for the deterministic effects of radiation.

TABLE 24.2 Deterministic Effects and Threshold Doses of Radiation

Organ	Effects	THRESHOLD EFFECTIVE DOSE (Sv)	
		Single Dose	Multiple Yearly Doses
Gonads	Temporary sterility	0.1	0.4
	Permanent sterility	3-6	2
Eye	Cataracts	0.5	0.2
Bone marrow	Marrow depression	0.5	0.5
Skin	Transient erythema	2	—
	Desquamation	2-10	—
	Temporary hair loss	4	—
	Dermal necrosis	25	—
	Skin atrophy	10	1
Whole body	Acute radiation sickness	1	—

Modified from the International Commission on Radiological Protection guidelines.

Deterministic Effects

Deterministic effects are dose dependent and result in cell death, impacting hair follicles, skin, subcutaneous tissues, and the lens of the eye. These are acute events when a threshold level of radiation has been exceeded, and the higher the dose, the greater the injury (Fig. 24.1). The threshold is not absolute and can vary among individuals. Table 24.2 shows some threshold levels of human organs with corresponding deterministic effects. Doses required to produce deterministic effects are often large and exceed 1 to 2 Sv. Symptoms arise when a significant proportion of cells are killed by radiation, and subsequent inflammation or fibrosis may produce additional damage to the organ. Examples of deterministic effects include radiation dermatitis, cataracts, infertility, and organ atrophy or fibrosis (Figs. 24.2 and 24.3). Recently, concerns have increased about the late manifestation of cataracts from low doses of ionizing radiation, and the recommended threshold of the lens has been lowered to 0.5 Sv.

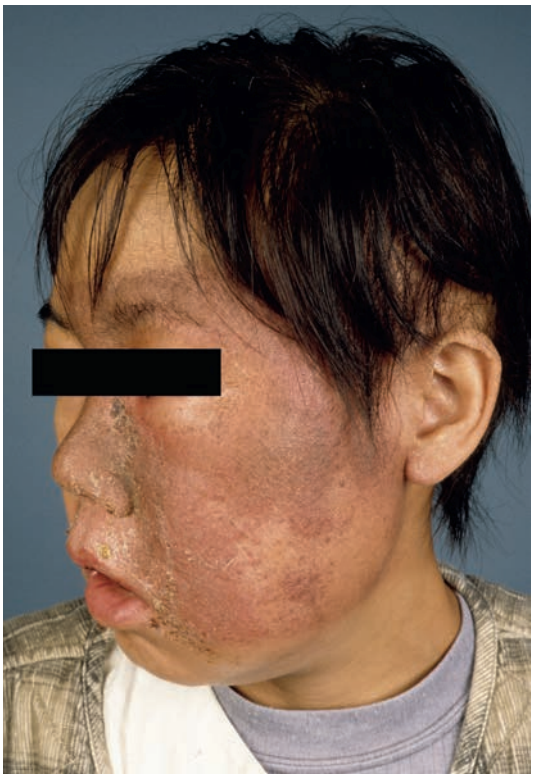

Figure 24.2 Radiation dermatitis of the face.

Whole-body exposure to 10- to 20-Gy high-energy radiation, delivered at one time, can be fatal to humans. For acute whole-body equivalent doses, 0.5 to 1 Sv may produce light radiation sickness; 1 Sv causes slight blood changes; and 2 to 3 Sv causes nausea, hair loss, and hemorrhage. An acute dose of 3 Sv causes death in 50% of individuals within 30 days, and with doses higher than 6 Sv, survival is unlikely.

Stochastic Effects

Stochastic (or probabilistic) effects cause DNA damage to single cells, which results in mutation. This is an all-or-none phenomenon, with the probability of occurrence increasing as the cumulative radiation exposure increases without an established threshold level (Fig. 24.4). The severity of the effect of mutation is unrelated to the dose. Mutations lead to cancer and heritable genetic defects. Theoretically, stochastic effects can occur even at low doses, but it is assumed that with radiation doses of less than 100 mSv/yr, the probability of stochastic effects is very low. At such low doses, it is assumed that the probability of incurring cancer or heritable effects will be directly proportional to the equivalent dose. This is known as the linear-nonthreshold model of incremental risk.

Leukemia and other cancers have been shown to be associated with radiation exposure. It is estimated that the probability of

Figure 24.3 Radiation-induced skin necrosis.

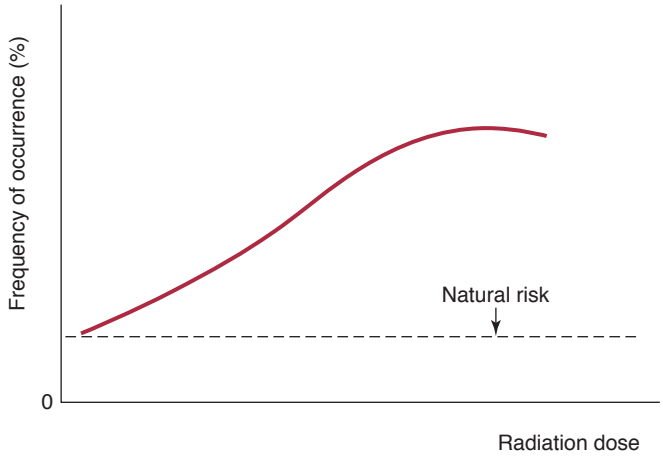

Figure 24.4 General dose-response curve for the stochastic effects of radiation.

fatal cancer developing as a result of radiation exposure is 4% per 1 Sv of lifetime dose equivalent (or 0.004% per mSv). The background risk of spontaneous fatal cancer is around 20%. The nominal nonfatal cancer risk has been estimated at 0.8% per sievert. Radiation-induced cancer risks from relatively low-dose exposure are difficult to interpret. A statistically significant increase in cancer risk has not been demonstrated in populations exposed to doses of less than 100 mSv. Studies of atomic bomb survivors showed an increased incidence of leukemia and other tumors of the lungs, thyroid, breast, skin, and gastrointestinal tract. There is usually a latent period of 2 to 5 years for leukemia, about 5 years for thyroid cancer, and 10 or more years for other cancers to become manifested. The risk with antenatal exposure and for children and adolescents is slightly higher by a factor of 2 to 3, whereas for older adult patients, the relative risk of malignancy is lower. Fetal effects are discussed in the "Radiation and Pregnancy" section later in this chapter.

Hereditary effects from radiation exposure have not been observed in humans from studies of the offspring of atomic bomb survivors. Based on extrapolation from animal studies, the ICRP proposed a nominal risk of heritable effects of 0.1% per sievert.

TABLE 24.3 Background and Occupational Exposure

Occupation	Effective Dose (mSv/Yr)
Natural background radiation	3
Aircrew (1000 h)	5
Frequent flyer (75,000 miles/200 h)	1
Catheterization laboratory physician	2-60
Catheterization laboratory nurse	8-16

EXPOSURE AND RECOMMENDED LIMITS

Background Radiation

We are constantly exposed to radiation through naturally occurring radioactive materials, as well as by cosmic radiation and human activities. The average annual natural background radiation, which varies depending on the geographic location, is around 3 mSv/yr in the continental United States. Living at higher altitude is associated with a higher dose. The greatest source of domestic radiation is radon gas (about 2 mSv/yr). Radon arises from the decay of radium; it seeps out of the soil and may concentrate in poorly ventilated concrete homes because of its high density. Radon is the second most frequent cause of lung cancer after cigarette smoking. Other manmade radiation sources include building materials, fuel, televisions, smoke detectors, and various fluorescent devices.

Occupational and Medical Exposure

For the general public, about 80% of lifetime exposure to radiation comes from natural sources and the rest from manmade sources such as medical radiographs and CT scans. The total average exposure for Americans is about 3.6 mSv/yr. In the United Kingdom, the average yearly dose is about 2.2 mSv. Some of the common occupation-related radiation dosages are addressed in Table 24.3. Pilots, who are exposed to solar radiation, are at a higher risk. On average, the amount of cosmic radiation doubles with every 2000-mile increase in altitude; cosmic radiation is strongest at the poles. Taking a long-haul commercial flight results in about 0.1 mSv of radiation.

The typical doses of common diagnostic radiology examinations are given in Table 24.4. These values vary, depending on the machine and manufacturer, the study technique, and patient's build.

TABLE 24.4 Typical Effective Dose in Common Diagnostic Procedures

Examination	Effective Dose (mSv)
Chest radiograph (PA)	0.02
Chest radiograph (lateral)	0.04
Skull radiograph	0.03
Pelvic radiograph	0.7
Abdominal radiograph	1.0
Thoracic spine (AP)	0.4
Lumbar spine (AP)	0.7
Mammogram	0.1
Barium swallow	1.5
Barium enema	7.0
CT of the head	2
CT of the thorax	8
CT of the abdomen	10
CT of the pelvis	10
Cardiac CT (calcium score)	2
Coronary angiogram	5-15

AP, Anteroposterior; *CT*, computed tomography; *PA*, posteroanterior.

TABLE 24.5 International Commission on Radiological Protection Safety Dose Limits

	Occupational	Public (mSv/yr)
Whole-body effective dose	20 mSv/yr averaged over 5 years	1
Ocular lens	20 mSv/yr	15
Skin	500 mSv/yr	50
Extremities	500 mSv/yr	—
Pregnant women	1 mSv to the fetus	—

Recommended Dose Limits

The ICRP recommends a dose limit of 1 mSv/yr to the general public. For radiation workers, an effective dose limit is 20 mSv/yr, averaged over 5 years and not exceeding 50 mSv in any single year. Additional exposure limits for the ocular lens and extremities of workers are defined separately (Table 24.5). It is generally believed that for occupational exposure, the risk of health effects is too small to be observed at doses below 50 to 100 mSv/yr.

PRINCIPLES OF RADIATION PROTECTION

The ICRP system of protection in medical practice stresses the fundamental principles of justification, optimization of protection, and dose and risk limits. The use of radiation in medicine must be justified—that is, the diagnostic information or therapeutic use should produce more benefit than harm. It is the responsibility of the hospital and medical personnel to ensure that the radiation equipment is properly maintained to deliver the lowest possible dose of radiation and to ensure that safety instructions and protective measures are available and adopted. All procedures involving ionizing radiation should be monitored and the risk limits determined for patients and staff beforehand. A system of reporting and remedial measures should be in place whenever the recommended limit is exceeded. In addition, special operating procedures should be available for high-risk individuals, such as pediatric patients and pregnant workers.

RADIATION SAFETY: DIAGNOSTIC PROCEDURES

For diagnostic procedures, an alternative imaging modality that does not involve radiation, such as magnetic resonance imaging or ultrasound scans, should be considered whenever possible. Certain routine radiographs and screening tests, such as chest radiographs on hospital admission and skull radiographs for minor head injuries, are shown to be nonbeneficial and should be avoided.

CT has become one of the most commonly used diagnostic tools, largely because of the availability of faster, more powerful machines with multislice capabilities, thus reducing examination time and increasing accuracy. Contrary to common belief, the effective dose of spiral CT and multislice detector CT can be 10% to 30% higher than that for older CT scanners, depending on the protocol and machine. In less essential situations, the physician should request lower-dose examinations, wider pitch, and partial rotation instead of large numbers of overlapping scans of extensive body regions. A number of techniques such as automated tube current modulation or attenuation-based kilovoltage selection algorithm can be used to reduce radiation exposure for CT angiograms after endovascular aneurysm repair (EVAR).

Many patients receive CT angiography and also serial CT scans for follow-up of endovascular aortic procedures. The effective dose of a CT scan of the chest is about 8 mSv, and for the abdomen and pelvis it is about 10 to 20 mSv (see Table 24.4). Repeated examinations of large areas may deliver an effective dose that can approach harmful levels. The excess relative risk of a patient acquiring solid organ malignancy from postoperative CT scans in EVAR surveillance is higher in young patients, women, and multiple examinations. A policy of switching to standard or contrast-enhanced ultrasound scans for postoperative EVAR surveillance has been shown to be equally effective even for fenestrated grafts; this will further reduce exposure to radiation.[3]

Three-dimensional rotational angiography (DynaCT) has recently found a role in preoperative planning, especially under emergency situations, and also in postoperative identification of endoleaks. The mean dose area product for a DynaCT is in the region of 3500 to 4000 μGy m^2, which is seven to eight times less than the radiation from a standard multidetector CT.[4]

Consideration should be given to the patient as a whole during imaging. Sometimes higher-risk organs may be exposed to unnecessarily high doses even if they are not the targets of the examination. For example, the lens, thyroid, and breast in CT examinations of the head and thorax often receive doses as high as 30 to 40 mSv. The gonads are also at risk during CT scans of the pelvis. This is particularly important for younger patients and females of childbearing age. Every effort should be made to shield radiosensitive organs whenever possible—in particular when they are adjacent to but not part of the actual radiographic examination.

RADIATION SAFETY: ENDOVASCULAR PROCEDURES

Modern coronary interventional procedures incur an average dose of 0.05 mSv per procedure. Radiation exposure for an operator in modern catheterization laboratories can amount to 5 to 60 mSv/yr. The hands are at particular risk. One minute of unprotected screening time leads to 20 mSv of skin dose, and transient skin erythema can result from doses of 2 Sv. Higher doses of radiation can lead to eye damage characterized by cataract formation in the posterior pole of the lens. Chronic exposure will increase the risk of cancer, in particular in the thyroid, brain, and skin.

Although most endovascular procedures are usually performed on older patients, in whom the perceived stochastic risks are relatively small, one must always be conscious of the radiation dosage to reduce the probability of deterministic effects to skin, soft tissue, and the eyes. The typical exposure of a patient in a catheterization laboratory with 10 minutes of fluoroscopic time is estimated to be equivalent to 200 to 400 chest radiographs.

The operator in an interventional suite is responsible for the amount of radiation exposure to the patient and coworkers. Fluoroscopy should be intermittent and never used unless the operator is looking at the monitor. Only essential personnel should be in the room, and ample warning signs should be displayed at all entrances. All staff not essential to the procedure should leave the room during serial exposure sequences or stand behind a barrier shield. Good practice in minimizing patient exposure will also cut down exposure to the operator and assistant staff.

Radiation equipment should be regularly serviced and inspected by a medical physicist and calibrated at proper intervals. Standard radiation checklists should be used regularly for self-inspection. The radiation dose varies among different machines and room setups. In general, newer machines and fixed systems generate lower energy because of a better image intensifier. They also incorporate more dose-reducing features such as pulse fluoroscopy and provide better-quality images, thus further reducing imaging time. Operators should try to familiarize themselves with these safety features to maximize radiation protection.

High dosages during interventional procedures are often due to inappropriate use of equipment or poor technique. The following are essential practice guidelines to reduce radiation exposure.

Emission Control

The voltage of the fluoroscopic tube controls the penetration of the beam and contrast, whereas the current determines the number of photons produced by the tube. Most machines have an automatic exposure control based on the feedback from the image receptor. Using higher tube voltage (kVp) and less current (mA) will reduce radiation and will not usually affect image quality. Lower frame rates should be adopted, and pulsed fluoroscopy instead of continuous fluoroscopy should be used for less critical maneuvers. In pulsed fluoro the x-ray generator emits short bursts of energy, which decreases the exposure time compared with continuous fluoroscopy. Higher dose fluoroscopy modes often increase the pulse rate, thereby further increasing dose. A large image intensifier requires less radiation than does a small one. The use of magnification should be limited because magnified views incur two to three times the radiation of a normal view. The use of high-level fluoroscopy should be kept to a bare minimum. X-ray field collimation and filters should be used whenever possible. This helps in focusing the beam of radiation by decreasing the field of view, thereby allowing for a clearer image. A large patient will expose the operator to more radiation because of an automatic increase in voltage and current from the machine to obtain a satisfactory image.

Time

Every effort should be made to minimize fluoroscopy and screening time. A conscientious operator will refrain from continuous activation of the beam-on switch and instead perform intermittent short exposures only when necessary. When the table position must be changed, it should be done before confirming with fluoroscopy. Liberal use of fluoroscopy often accounts for the largest radiation exposure during a procedure. Safety features are built into modern equipment to alert the operator to excessive use. A timer usually produces an audible warning at the end of a 5-minute interval. Making a habit of noting the total fluoroscopy time and patient absorbed dose at the end of the procedure may increase awareness and motivate improvement in practice.

Digital subtraction angiography is used to acquire images and generate a permanent record, and it requires high-dose rapid-sequence screening. This procedure can result in 10 times more radiation than fluoroscopy and accounts for 60% of total personnel doses. The use of cinefluoroscopic acquisition should be limited and an attempt made by operators to maintain a distance (or leave the room) when activating this function.

Distance

Personnel should always maintain a distance from the x-ray tube and keep the image intensifier as close to the patient (and the tube as far away) as possible to reduce patient skin dosage.

The amount of scatter radiation decreases with the square of the distance from the tube (exposure = $1/d^2$); thus the radiation dose will diminish fourfold if the distance from the operator doubles. Transfemoral procedures will therefore incur less exposure than transbrachial procedures will.

Radiation exposure varies according to the angulation of the tube. The left anterior oblique view exposes the operator (on the right of the patient) and the anesthetist to the greatest amount of radiation because the tube is closest to the operator. This view can account for three to five times more radiation than a right anterior oblique view. Steep gantry angulations also increase exposure by increasing the length of the radiation path and the thickness of tissue penetration. Changing the beam angulation during prolonged procedures can help spread out the radiation and reduce the skin dose to a particular area.

Maximizing the source (radiation) to the patient distance decreases as a function of the inverse square law. Raising the fluoroscopic table as high as possible from the source decreases the radiation. Once the table is raised to a comfortable height as high as possible away from the source, the image intensifier should be lowered as close as possible to the patient. A recent study on scatter radiation levels using cadavers showed that operator radiation exposure is lowest with a detector-to-patient distance of <5 cm, a source-to-image distance of <15 cm, and a 10-cm vertical collimation. The assistant's exposure is 23% to 46% of the operator's.[5]

Barriers

Radiation scatter is not uniform but propagates in isodose curves and decreases exponentially with the distance from the table. The highest scatter exposure is at the table level. A modern interventional suite should be equipped with tableside lead shields and additional mobile shields to reduce scatter. Ceiling-mounted mobile acrylic shields are very effective and will reduce doses to the brain and eye by a factor of 20. The first operator should always try to stand behind a barrier for the entire procedure.

Properly worn personal protective equipment is essential. Staff members should wear protective aprons with at least a 0.25-mm lead equivalent; many modern lightweight models provide wraparound designs to maximize frontal protection. A 0.25-mm lead apron will attenuate approximately 96% of the dose, and a 0.5-mm apron, 99%. The front of the apron should be kept toward the x-ray tube at all times. Lead glasses and thyroid shields should always be worn. Protective gloves should be at least a 0.35-mm lead equivalent but are less widely used because of reduced tactile sensitivity. All protective gear should be inspected at least yearly and replaced if defective.

Technique

The primary operator should possess the necessary endovascular skills to perform the procedure. Even a straightforward procedure can result in significant radiation exposure if the operator's technique and protection practice are poor.

Monitoring Exposure

In a work environment, radiation dosage should be monitored by dosimeters—one worn at waist level under the apron and, ideally, a second one worn on the thyroid shield. These are usually film-badge–based, thermoluminescent dosimeters that measure an absolute dose received over a specific period of time. An investigation is necessary when the cumulative total dose during a year reaches recommended ICRP limits, and temporary withdrawal from radiation work should be enforced.

Informed consent and proper recording of patient exposure should be ensured if the anticipated dose of a complicated procedure is high. Discussion should be undertaken with the patient and family immediately after a complicated procedure to inform them of the high use of radiation and possible development of skin reactions or changes on the back or side. If a patient is exposed to a higher dose (>3 to 5 Gy), follow-up should be arranged within 1 to 2 weeks to determine whether any harmful effects have developed.

RADIATION AND THE ENDOVASCULAR SURGEON

Endovascular therapy has become more complex, and many hospitals have modern hybrid suites installed to replace mobile C-arms. Although these fixed units provide much better image quality and have no overheating issues, operators may become oblivious to fluoroscopy time and the use of image acquisition and magnification during a more complex case.

Few studies have been completed on the radiation exposure of vascular surgeons undertaking endovascular procedures. Ho and colleagues conducted a prospective study on an active endovascular practice in an academic unit over a 12-month period.[6] All endovascular procedures were performed with mobile fluoroscopic units in an operating room setting, using tableside barriers, standard 0.5-mm lead aprons, thyroid shields, and protective eyewear. The workload consisted of an average of 150 endovascular procedures, including 30 endovascular aneurysm repairs, 60 diagnostic angiograms, and 60 peripheral angioplasty and stenting procedures. With an average of 500 to 700 minutes of annual fluoroscopy time, the median yearly effective doses that the surgeons received were 0.2, 0.2, and 1 mSv for the body, eye, and hand, respectively—these amounts are significantly below ICRP recommended dose limits. It was extrapolated that a vascular surgeon has to perform 2600 endovascular aneurysm repairs or 6500 peripheral procedures annually to reach the dose limit.

Provided that a stringent protection policy is used, the amount of radiation absorbed by vascular surgeons appears to be lower than that absorbed by cardiologists and interventional radiologists, who reportedly receive up to 60 and 10 mSv annually. However, the study also revealed significant individual variations in dosage, probably related to technique and habit. This difference was most marked for doses to the hand, in which case less experienced surgeons accumulated up to 3.3 times the dosage per minute for the same procedure used by more experienced

surgeons. Regular use of eye protection also reduced eye doses by a factor of 3.

Recently, a number of studies focused on the radiation exposure of patients during EVAR, using indirect dose area product (DAP) measurement.[7-11] An estimated average effective dose of 12.4 mSv was reported based on DAP estimation in 111 EVAR cases, and average peak skin dose was 0.69 Gy, with 99% of patients having a peak skin dose of <2 Gy.[7] Significantly higher exposure was reported in patients with a high body mass index (>30),[8] those with complex anatomy,[8] and for those undergoing fenestrated and branched procedures.[10] For a standard EVAR, the average fluoroscopy time is about 20 minutes, with approximately 50% in a magnified view. The incurred entrance skin dose is 0.85 Gy, with a DAP of 60 to 150 Gy cm^2 and a patient effective dose of 8 to 27 mSv. Skin injury is still possible, but it is unlikely at these levels. These dosages can be further decreased by the usage of low-dose and pulse mode, especially for fenestrated and branched grafts, procedures in which mean DAP values of 860 and 1890 Gy cm^2 are to be expected.[8]

Modern imaging systems, which provide multiple high-resolution video screens and give the operator full motorized control of the C-arm, patient position, and imaging mode, have been shown to reduce radiation exposure, operation and screening time, and contrast volume.[12] State-of-the-art equipment now allows for off-table planning, precision of cannulation, and remote control. The use of three-dimensional (3D) navigation software by fusion of preoperative CT with DynaCT images obtained on table will allow a 3D real-time visualization of catheter position with respect to the target vessels. In complex endograft procedures this would reduce radiation exposure and the use of contrast media by facilitating branch cannulation. Also in development is a robotic system for peripheral vascular interventions, allowing distal 3D catheter tip control by a surgeon from a remote workstation, thus protecting him or her from radiation exposure.

RADIATION AND PREGNANCY

With the increasing use of medical radiation, many women who are pregnant or potentially pregnant will be exposed to ionizing radiation. In most instances, the radiation risk to the fetus is small in comparison to the risk of spontaneous abortion (15%), genetic abnormalities (4%-10%), and malformations (2%-4%) in the general population. However, undue anxiety and termination of pregnancy may result if the patient and staff are not properly educated.

Declaration of Pregnancy

Under federal law a pregnant woman can choose to continue to incur occupational radiation exposure at the level allowed for adult workers. However, it is recommended that an occupationally exposed pregnant woman declare pregnancy for the purpose of reducing the risk to the unborn child. Once pregnancy is declared, additional precautions should be adopted to protect the fetus and limit the radiation exposure to recommended levels.

Fetal Risk From Radiation

Risks to the fetus from radiation depend on the dosage and the stage of pregnancy, the risk being highest during organogenesis in the first trimester and least in the third trimester. Whenever possible, diagnostic tests or procedures that involve radiation should be deferred or replaced with safer options. In all cases, the patient should be adequately informed of any chances of radiation exposure. Estimated fetal radiation doses for diagnostic tests vary based on the type of procedure and the stages of the pregnancy; doses are generally highest in the later trimesters. A plain anteroposterior radiograph of the pelvis carries a dose of about 1.5 mSv. A lumbar spine anteroposterior radiograph at 3 months of gestation results in about 2 mSv of exposure; this increases to 9 mSv when performed near term. A CT scan of the head of the mother delivers less than 0.005 mSv, but an abdominal CT scan can lead to 8 mSv of fetal exposure.

The major adverse effects on the fetus include abortion, teratogenicity, mental retardation, intrauterine growth retardation, and the induction of cancer. Normal diagnostic procedures would seldom involve sufficient dosage to induce malformations, fetal death, or central nervous system defects, but the threshold may be exceeded with complicated interventional procedures.

Malformations and Mental Retardation

Based on animal studies, malformations after in utero exposure to doses below 100 mSv are not expected. Central nervous system malformations may appear if a dose threshold of 100 mSv has been exceeded (Table 24.6). Fetal doses of 100 mSv or higher, especially if incurred between 8 and 16 weeks of pregnancy, can be associated with reduction of intelligence and microcephaly. As an example, in victims exposed to in utero radiation during the 1945 atomic bombing of Hiroshima, the risk of mental retardation has been estimated to be about 0.04% per mSv of exposure, with an estimated loss of 2 to 3 IQ points/mSv.

Cancer Risk

The main issue with prenatal exposure at lower levels is cancer. Radiation has been shown to increase the risk of leukemia and cancer in children and the fetus. The threshold of childhood

TABLE 24.6 Probability of Fetal Risk as a Function of Radiation Dose

Fetal Dose (mSv)	Probability of Malformation (%)	Probability of Development of Cancer (%)
1	3	0.3
5	3	0.3
10	3	0.4
50	3	0.6
100	3	0.9

Modified from the International Commission on Radiological Protection guidelines.

cancer induction is not clear. For in utero exposure of 10 mSv, a 1.4-fold increase in leukemia and cancer and 1 excess cancer death per 1700 have been reported.

From studies of atomic bomb survivors and patients receiving radiotherapy, preconception exposure of the gonads to radiation has not been shown to result in a significant increase in the risk of cancer or malformations in children. The risk of serious birth defects was estimated at 2^{-6} per 1-mSv gonadal dose.

Recommendations for Pregnant Workers

Pregnant healthcare workers may work in a radiation environment as long as it is determined that the fetal dose can be kept below 1 mSv during the course of pregnancy. With such doses, radiation should have negligible effects on the fetus. Properly sized protection should be worn at all times, although lead aprons may present other health hazards, such as back strain, in pregnant women. Fetal doses approaching 100 mSv pose a small risk of radiation-induced cancer or leukemia, but the risk is minimal in the third trimester. The National Nuclear Commission guideline calls for no more than 5 mSv of equivalent dose exposure during the entire pregnancy, or less than 0.5 mSv/mo. If a worker has declared pregnancy while having been exposed to radiation, it should be ensured that any additional dose to the fetus would not exceed 1 mSv during the remainder of the pregnancy.

A unique concern to female vascular surgeons and trainees is radiation exposure during pregnancy. The author was involved in a multiinstitutional study in 2013 aimed to evaluate the dosages recorded on fetal dosimeter badges and compare them to the external badges worn by the same cohort of 81 women.[13] The average fetal dosimeter recording during the pregnancy rounded to zero. Only two women had positive fetal dosimeter recordings; one had a single reading of 3 mrem and the other had a single recording of 7 mrem. No significant difference between maternal exposure prior to, during, and postpregnancy was noted. This documentation of negligible radiation exposure on fetal monitoring suggests that with appropriate safety precautions, heightened concerns during pregnancy may be unfounded.

Despite many advances in the quality and availability of less invasive arterial imaging modalities, arteriography remains the "gold standard." Alternative modalities, such as duplex arterial mapping, computed tomographic angiography (CTA), and magnetic resonance angiography (MRA), are being used with increasing frequency because of improved image quality and minimal risk.[1-6] For some clinical scenarios, such as duplex surveillance of lower extremity vein bypass grafts, these imaging techniques have supplanted arteriography as the preferred test.[7-9] However, arteriography remains an indispensable tool for the vascular surgeon. A comprehensive understanding of basic to advanced techniques permits a wide array of arteriographic imaging studies to be performed optimally. In addition, a wide breadth of knowledge about arterial anatomy, equipment and materials, potential complications, and sources of interpretation error are required for becoming an expert in performing arteriography.

The goal of this chapter is to impart a broad overview of modern arteriography. Clinical acumen about vascular disease and operative experience also play important roles in determining how to optimize arteriographic imaging. This chapter provides evidence-based guidance, as well as practical experience, for safe performance of high-quality arteriography.

EQUIPMENT

The task to determine what equipment is needed to perform high-quality arteriography can seem overwhelming. The necessary components can be divided into venue, imaging hardware, catheters, contrast agents, devices for delivery of contrast agents, and digital software used to assist in the processing of arteriographic images. Image processing closely relates to techniques of arteriography and is discussed later in the chapter.

Abstract

Arteriography is an indispensable tool of the vascular surgeon. Despite the proliferation and advancement of enodovascular procedures, exposure to basic principles and techniques of arteriography is somewhat variable during vascular surgical training. This chapter describes the various options available to the vascular surgeon with regards to equipment, venue and acquisition techniques. Recent advances in equipment are highlighted as are potential pitfalls and complications associated with various arteriography agents and techniques.

Operating Room Versus Imaging Suite

Depending on facility-specific logistics, angiography can be performed with a portable fluoroscopy unit or in a designated interventional radiology suite with a fixed imaging unit. In addition, many centers now contain "hybrid operating rooms," featuring a fixed-mount imaging unit combined with all the features of an operating room, a fully equipped endovascular stock (catheters, guide wires, and devices), and a trained staff that is comfortable with endovascular and open vascular surgery.

The advantages of an operative-endovascular or hybrid suite are clear. Combined endovascular and open procedures are commonplace. Aortic endograft procedures, common femoral endarterectomy with concomitant retrograde or antegrade stenting and hybrid approaches to acute limb ischemia are evolving into the "standard of care." Lastly, complications that arise during any endovascular procedure, albeit rarely, can be managed by immediate and seamless conversion to open surgery, as opposed to the need for emergency transport from an angiography suite to the operating room.

Fixed-Mount Versus Portable Equipment

The two principal types of radiographic imaging units that can provide state-of-the-art arteriography are the fixed-mount unit physically attached to one suite (Fig. 25.1) and the portable fluoroscopy unit equipped with wheels so that it can be moved from room to room (Fig. 25.2). Each type has the basic components, including a power generator for fluoroscopy, a C-arm with image intensifier, screens for viewing real-time and reference images, and digital image processing software. In experienced hands, both types of imaging units have their advantages and disadvantages.

In general, fixed-mount units have more powerful generators that allow more detailed imaging. More power allows greater depth of fluoroscopic penetration and thus the ability to discern finer detail. Depending on the types of imaging units compared, fixed-mount units can provide upward of 10 times the resolution of portable units. Although this greater resolution may not be needed in persons of ideal body weight, increased power for improved penetration is important when arteriography is performed on obese patients. Another distinct advantage of a fixed-mount unit is a larger field of view. Modern fixed-mount units now have flat detector image intensifiers as large as 22 inches (57-cm image projection). This increased size translates into the ability to cover more imaging area during arteriography with less radiation exposure and less total volume of contrast material. In addition, fixed-mount units have tableside controls that allow precise and easily directed movement of the C-arm and table. This feature is useful during visceral and cerebrovascular arteriography inasmuch as subtle manipulations in C-arm angulation can result in significantly improved arterial visualization.

A portable fluoroscopy unit designed for high-quality arteriography is advantageous by the mere ability to move the equipment from room to room. This may be important in trying to fulfill the needs of different types of vascular surgical practices, operating rooms, specialty procedure rooms, and intensive care units. Typically, portable fluoroscopy units require only one technician in addition to the vascular surgeon for arteriography to be adequately performed. Fixed-mount units require, in addition to the angiographer, three or four specially trained staff, including a technician who is gowned and gloved with the vascular surgeon, a circulator attending to material needs, a technician coordinating image acquisition and processing, and a certified nurse who is responsible for monitoring the patient and administering medications. Finally, portable

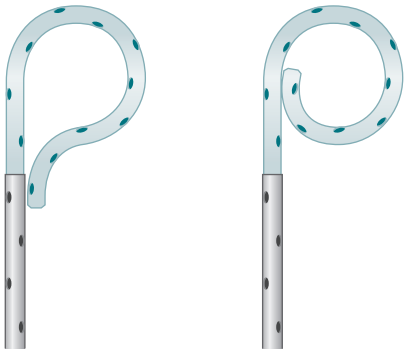

Figure 25.3 Flush catheters in various shapes with multiple side holes, as opposed to end-hole catheters (not pictured), are ideal for power injections.

units are much less costly than fixed-mount units. Not only are fixed-mount units expensive (ranging from $1.5 to $5 million), but construction of such a suite may require major structural modifications to an existing room, which can be a significant additional cost.

Catheters

The type of catheter used also plays an important role in optimizing the arteriographic image and avoiding injury to the vessel. Intraarterial catheters come in virtually all shapes, sizes, and lengths. Given this variety, attention should be paid to whether the catheter has just an end hole or multiple side holes in addition to the end hole (Fig. 25.3). The latter, known as a flush catheter, is designed for safe, quick, and even dispersion of contrast material at high injection pressures to image large arteries with high flow. End-hole catheters, with their greater variety of shapes, are often all that can be used after remote arterial access is achieved. Care should be taken whenever a power injection is performed with an end-hole catheter in a medium-sized muscular artery. Problems may include loss of a tenuous catheter crossing because of pressure forcing the catheter out of the arterial lumen, creation of intimal flaps, and arterial rupture. Direct power injection into very small arteries, such as the vertebral or tibial arteries, should be avoided with any type of catheter. Hand injection with a manifold should also be performed gently to avoid injury to these vessels.

Contrast Agents

The concept of angiographic imaging relies on the presence of an intravascular contrast agent. To maximize vascular anatomic detail, this agent needs to have a radiodensity that is distinct from that of the tissue being imaged. Typical contrast agents have greater radiodensity than surrounding tissue and therefore appear markedly darker on imaging. However, an agent significantly less radiodense than surrounding tissue, such as carbon dioxide (CO_2) gas, can also provide adequate contrast to image intravascular anatomic detail,[10,11] albeit with less quality in some cases. The underlying concept is to provide adequate visual contrast between the intravascular space and the extravascular space. Selecting the appropriate contrast agent and adjusting the imaging equipment and technique accordingly are essential for patient safety and imaging quality.

Iodinated Contrast Agents

Conventional contrast agents are composed of molecular compounds containing iodine. These iodinated agents can be categorized as ionic or nonionic.

Ionic contrast agents dissociate into anions and cations when they are placed in solution, which includes flowing blood. The anion is a benzene ring fully substituted with three iodine atoms. Iodine atoms absorb the x-ray photons and are responsible for contrast visualization, or radiopacity, of the artery visualized. The cation can be sodium, methylglucamine, or a combination thereof. When iodinated contrast agents dissolve, their osmolality doubles because of the presence of two ions. The osmolality of these agents ranges from 1500 to 1700 mOsm, thus making them significantly more hyperosmolar than plasma (285 mOsm).

Nonionic contrast agents have considerably less osmolality. Because dissolution of the benzene compound into two ions is prevented, the osmolality remains half that of ionic contrast agents. However, because the number of iodine atoms remains the same, radiopacity remains comparable to that of conventional ionic agents but with much less ionic charge. Osmolality can be further reduced by a compounding method that creates a *dimeric* ionic contrast agent, whereby two benzene rings are attached to each cation. With this formulation, twice the number of iodine atoms are present with the same level of osmolality (ranging from 320 to 880 mOsm). Doubling of the iodine atoms leads to a greater amount of x-ray photon absorption, and thus comparable arteriographic images are achieved with less volume of contrast material (Table 25.1).

Carbon Dioxide Arteriography

Another contrast agent with novel properties and applications is CO_2.[10,11] Injection of this gas with its decreased radiodensity creates radiographic contrast by transiently displacing blood from the artery being imaged. Improvements in equipment, technology, and image-processing software, coupled with the significant number of vascular patients who have compromised renal function, have led to increased use of CO_2 arteriography.[11-13] Digital subtraction technology has greatly enhanced anatomic definition and visualization with this contrast agent. However, despite improved techniques, image quality still remains inferior to that of conventional contrast agents.

Many techniques can enhance the quality of CO_2 arteriography. Because of the image settings developed to enhance visualization of intravascular CO_2, the presence of bowel gas can especially degrade image quality in this acquisition mode. Because CO_2 rapidly displaces blood and then dissolves quickly, frame rates are increased during image acquisition (four to eight frames per second). Modern arteriographic imaging systems now feature prescribed settings that depend on the type of contrast agent and area of the body to be imaged. Further image enhancement can be achieved by selective catheterization and magnified views of smaller-caliber vessels (Fig. 25.4). Contrast injections may be performed rapidly by hand or with an automatic pump system. They should be spaced 3 to 5

Modified from *Drug Topics Red Book 2008,* Montvale, NJ, 2008, Thompson Healthcare.

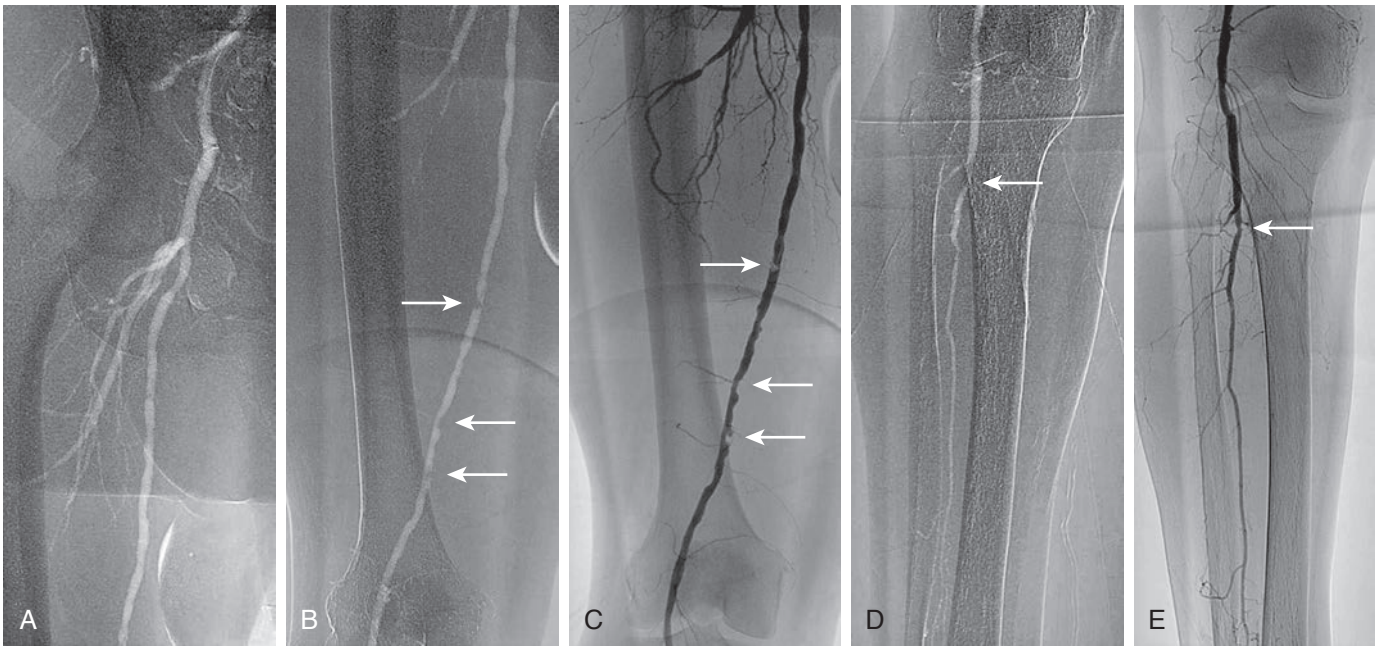

Figure 25.4 (A) Angiogram of the femoral bifurcation visualized with CO_2 contrast and selective placement of the catheter in the common femoral artery. (B) Opacification of the superficial femoral artery reveals multiple stenoses *(arrows)*. (C) Comparison of the same vessel opacified with iodinated contrast material shows much better characterization of each stenosis *(arrows)*. (D) Distal views show relatively well-visualized popliteal and single-vessel peroneal runoff with CO_2; significant disease is evident at the proximal peroneal artery *(arrow)*. (E) Again, better characterization with iodinated contrast material reveals only a mild stenosis at the proximal peroneal artery *(arrow)*.

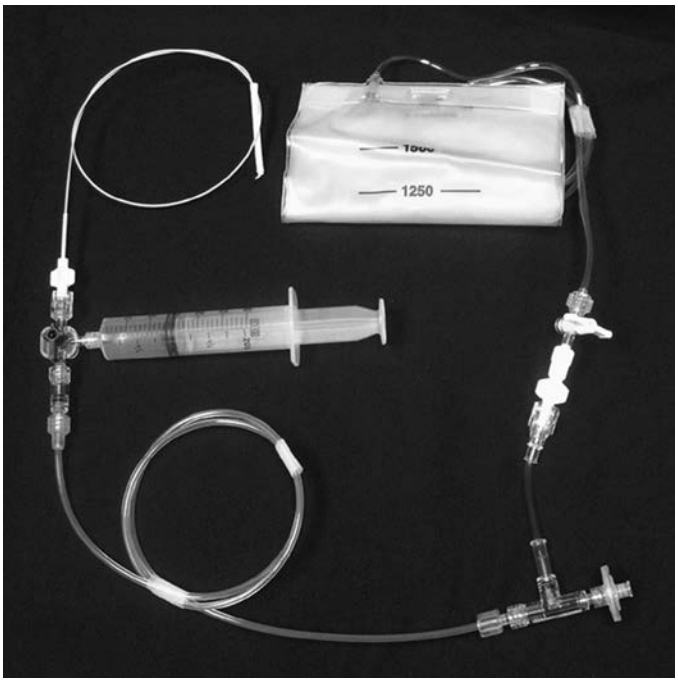

Figure 25.5 CO_2 System Connected to a Diagnostic Catheter. The delivery system uses a three-way stopcock, check valve, and filter port connected to the gas tank (not shown). A 1500-mL bag is attached to the delivery system with low-pressure tubing and a two-way stopcock. A large Luer-Lok syringe is required for hand injection.

minutes apart to allow complete dissolution before the next injection. Overestimation of the degree of stenosis can occur when one is unable to completely fill the diameter of the artery with CO_2.[14] For lower extremity arteriography, Trendelenburg positioning or elevation of the extremity to approximately 20 to 30 degrees will slow distal blood flow and promote concentration of the CO_2, thus slowing the dispersion rate as CO_2 exits the catheter and travels distally.

The CO_2 delivery system includes a 30- to 60-mL Luer-Lok syringe, tubing with a two-way distal stopcock and two one-way check valves, a 1500-mL fixed-volume gas bag, and the CO_2 tank (Fig. 25.5). After assembly of the system, purging of the tubing with three syringe volumes (90 to 180 mL) of gas prevents the possibility of accidental injection of air. Nitrogen gas in ambient air is not soluble and can lead to gas embolization. Once the gas bag is filled with CO_2 directly from the gas tank, the syringe is pulled back to be filled with gas from the gas bag. Because of a one-way valve distal to the syringe, only gas from the bag can be withdrawn. Another reversed one-way valve proximal to the syringe forces gas to travel only to the patient on injection.

Devices for Injection of Contrast Agents

Injection of liquid contrast material can be performed with a power injector or manually. For optimal arteriography, the ability to perform both methods is preferable because both have distinct advantages, depending on which arteries are being imaged.

Power Injection

Power injectors allow rapid high-pressure injection of contrast material into the catheter. Precise control exists with regard to the pressure setting (psi), amount of contrast material used during a set period, timing of injection in relation to fluoroscopic imaging and catheter position, and rate of rise of the injection. Typically, use of a power injector allows rapid filling of large arteries at high flow rates. This produces equal distribution of contrast material and hence a higher-quality image. Power injectors can also be used for prolonged injections, generally ranging from 3 to 6 seconds, when the catheter can be placed only in a very proximal position and the target artery is remote. Imaging of the dorsal pedal artery with the catheter placed in the ipsilateral common femoral artery is one such example. When a power injector is used, settings must be adjusted to manipulate pressure and the rate of rise of the injection, depending on the vessels being imaged. Large high-flow arteries require high pressure (800 psi) and rapid rise of the injectate to quickly disperse the contrast agent for a proper image. Smaller arteries, such as the superficial femoral artery, can be traumatized by such settings and require a lower pressure setting (300 to 600 psi) and reduced rate of rise of the injectate. For every power injection, the vascular surgeon will determine what volume of contrast material is to be given during what time. For example, typical aortic arch arteriography may require 20 mL of contrast material per second for a total of 2 seconds. Common jargon in the endovascular suite before such an injection would be "20 for 40," or 20 mL of contrast material injected per second for a total volume of 40 mL.

Manual Injection

Manual injection of contrast material can be performed by use of a simple syringe with full-strength contrast agent or a manifold device that allows more precise and rapid loading of contrast material (Fig. 25.6). Manifolds are also equipped with the ability to dilute contrast material with saline, to evacuate air and liquid waste, and to perform real-time intraarterial pressure measurements. The ability to perform high-quality arteriography with the use of dilute contrast material should not be underestimated. Contrast agents, many of which are nephrotoxic, should always be used conservatively regardless of renal function. Establishing this habit helps to prevent injury to patients with mild renal disease not yet manifested by abnormal laboratory values. In smaller arteries (e.g., the common carotid artery or tibial arteries), 3 to 4 mL of diluted contrast material (1 : 1 mixture of contrast material and saline) should be sufficient to give a high-quality arteriographic image. The learning curve for maximizing proper use of a manifold is not very steep, and after it is mastered, optimal arteriographic images can be obtained rapidly with minimal volume of contrast material. Typical injection methods, rates, and volumes of contrast agent are detailed in Table 25.2.

TECHNIQUES

Arteriographic imaging in the modern era is synonymous with digital subtraction angiography (DSA). The basic concept behind

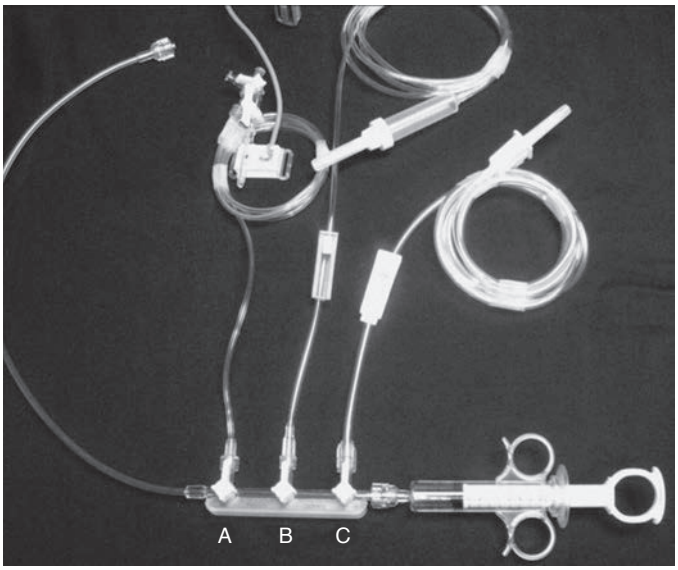

Figure 25.6 Rapid, Convenient Device for Mixing and Delivery of Contrast Material. The control syringe and manifold allow quick reloading after each injection of contrast agent, with one hand operating the syringe and the other regulating the proportions of contrast material *(C)* and saline *(B)* being drawn up via the stopcocks on the manifold. Between injections, the saline line can be left on flush to keep the catheter irrigated. The third stopcock *(A)* allows continuous monitoring of pressure when it is connected to a transducer.

TABLE 25.2 Typical Injection Method, Rate, and Volume of Contrast Agent for Various Vascular Regions

Location	Suggested Method	Injection Rate (mL/s)	Total Volume (mL)
Aortic arch	Power injection	20	40
Selective carotid	Hand or power injection	3-5	5-10
Selective vertebral	Hand injection	2-4	2-4
Selective subclavian or brachial	Hand or power injection	5-10	10
Abdominal aorta	Power injection	20	40
Renal or mesenteric	Hand injection	3-5	5-10
Iliac artery	Hand or power injection	10	10
Infrainguinal segments	Hand or power injection	5-10	10
Aorta to pedals, stepped run	Power injection	20	90[a]

[a]Full-strength contrast agent; all others typically performed with a half-strength contrast agent when digital subtraction angiography is used.

DSA involves a recording technique by which the captured fluoroscopic image is amplified and digitized. With advanced computer data processing capability, multiple manipulations of the stored data can be performed to optimize image quality.

Image Processing

Some of the commonly used postprocessing capabilities are subtraction, masking, pixel shifting, and view tracing. Other tools, such as roadmapping and unsubtracted image referencing, can assist in guiding wires and catheters during the actual procedure.

Subtraction Tool and Masking

The subtraction tool is the single most effective characteristic of this technology that enhances and improves image quality. This technique subtracts all visible radiodensities on the current image to create a mask image, represented as a blank screen. Once the mask has been established, any motion in the field during the fluoroscopic run will be highlighted as a dynamic image on this blank background. All radiodense tissues subtracted on the mask image will remain subtracted as long as they remain in the same position and alignment as in the mask image. After subtraction is achieved and the mask image is created, the contrast agent is injected and visualized because it is radiodense and moves with blood flow through the vessels of concern. By subtraction of the surrounding tissue and vessel wall from the contrast images, the quality of visualization of intraluminal contrast is greatly enhanced. In an ideal image capture, there is no movement between creation of the mask and injection of contrast material. This would produce the purest image derived solely from flow of the contrast agent. However, such is often not the case, and unintended motion can greatly compromise imaging. If the mask has been created and the patient then changes position, breathes, or even has bowel peristalsis, this skeletal or visceral motion will be seen on the contrast images because it was not part of the original mask image. Therefore it is essential for the patient to remain very still during image capture.

Masking can be used beyond the original subtraction maneuver to improve image quality. If a patient moves during an injection, any image prior to contrast appearance or after contrast washout can be used as the mask image to improve image quality and minimize motion artifact. A trial of different mask images is often an effective way of finding the best possible result.

Pixel Shifting

Pixel shifting provides a valuable tool when movement occurs after contrast material has already entered the field of view. Instead of creating a new mask, one can take the existing mask and slide it in a bidirectional plane (vertical, horizontal, or both) to realign the surrounding tissue (Fig. 25.7). This realignment of the existing mask to the patient's current position on the contrast image erases the discrepancy and minimizes the motion artifact. Software programs allow automatic or manual pixel shifting. In the automatic mode the computer will try to

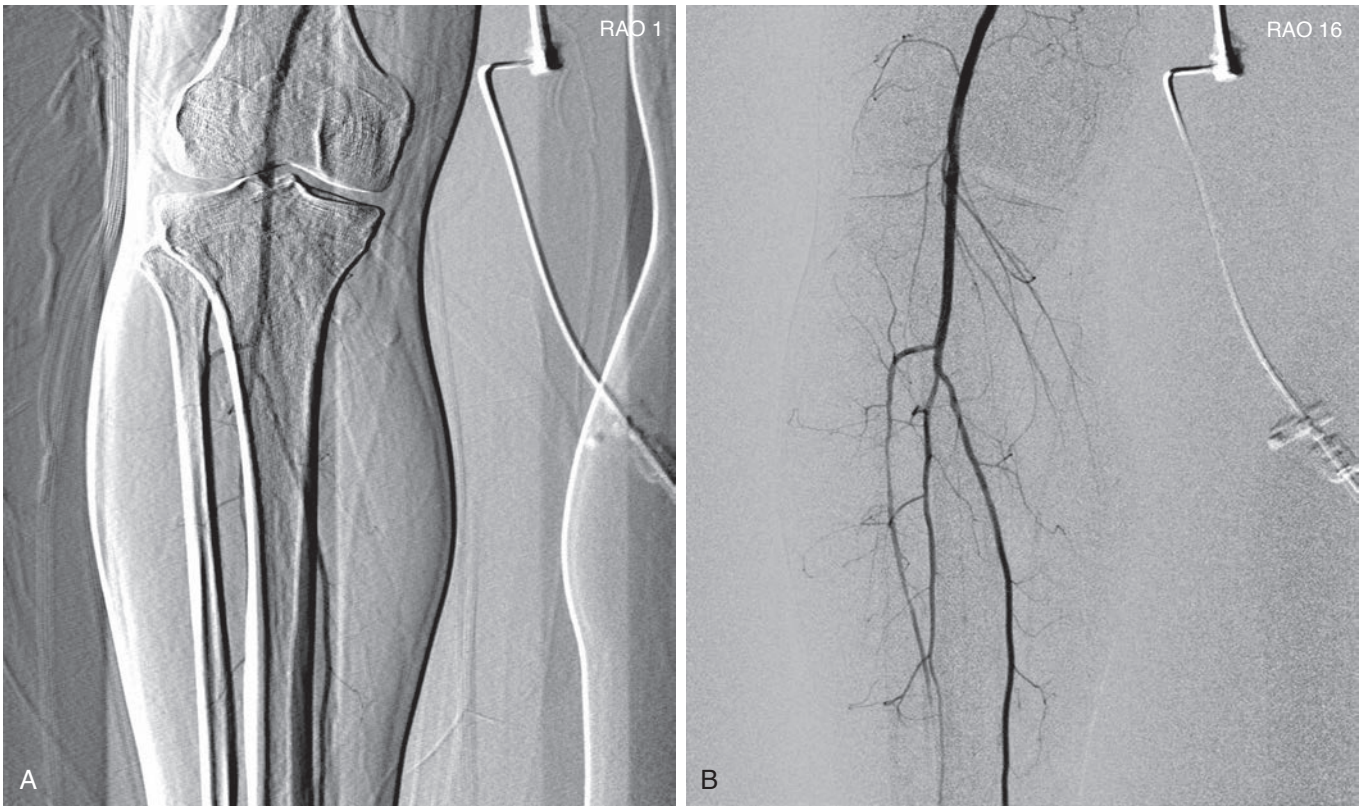

Figure 25.7 (A) Patient motion during contrast opacification significantly degrading image quality. (B) Pixel shifting during postprocessing realigns the mask image with the contrast image and thereby results in optimal visualization of the artery. If the motion occurs before contrast injection as opposed to during it, reassigning the mask image can accomplish a similar result. *RAO,* Right anterior oblique.

realign the mask image to create the best subtracted result for that particular region of the field. In manual mode, the pixel shifting can be done freehand in real time by sliding the cursor vertically, horizontally, or both until the optimal image is achieved.

View Tracing

Because arteriography is a dynamic imaging modality, obtaining one static image from a series during injection of contrast material will often fail to provide complete visualization of the target vessel. As the contrast agent opacifies one segment of the blood vessel, a previous segment may already have washed out and a distal segment may not yet have filled with the contrast agent. This property can be ameliorated using view tracing.

View tracing, sometimes referred to as opacification, allows consolidation or "stacking" of different time points by overlaying consecutive static images in a series to provide one cumulative arteriographic image. The first image in which contrast appears may be designated the first image in a view-traced series. Each subsequent image that is stacked over the previous one will show further progression of contrast and further visualization of the vessel distally (Fig. 25.8). However, with each additional view-traced image, any motion artifact will also be superimposed, thereby degrading the image more and more with sequential stacking. To circumvent this problem, each individual static image can first be optimized by pixel shifting to minimize artifact in the final cumulative image.

After broad manipulations with the techniques just discussed, images can be further enhanced by finer adjustments. Image contrast, brightness, edge enhancement, sharpness, and even color of the contrast agent (image invert) can be modified to create a final optimized image. These finalized images can then be stored in the patient database along with the dynamic DSA runs.

Roadmapping and Measuring

Other useful techniques involving DSA can help with guidance during the actual procedure. Roadmapping allows a previously constructed image of a contrast-filled vessel to be displayed on the working monitor. Real-time fluoroscopic imaging can then be superimposed on the monitor so that the contrast image can be used as a "roadmap" to direct guide wires and catheters. This technique is effective as long as table and patient positions do not change. The roadmap mask is extremely sensitive to motion, and image quality will degrade during use. Another valuable guiding tool during arteriography is the simple use of unsubtracted image referencing. Disabling subtraction from a contrast image allows identification of native tissue reference points, most often bone landmarks, near vessel bifurcations (Fig. 25.9). This image can then be displayed on a reference

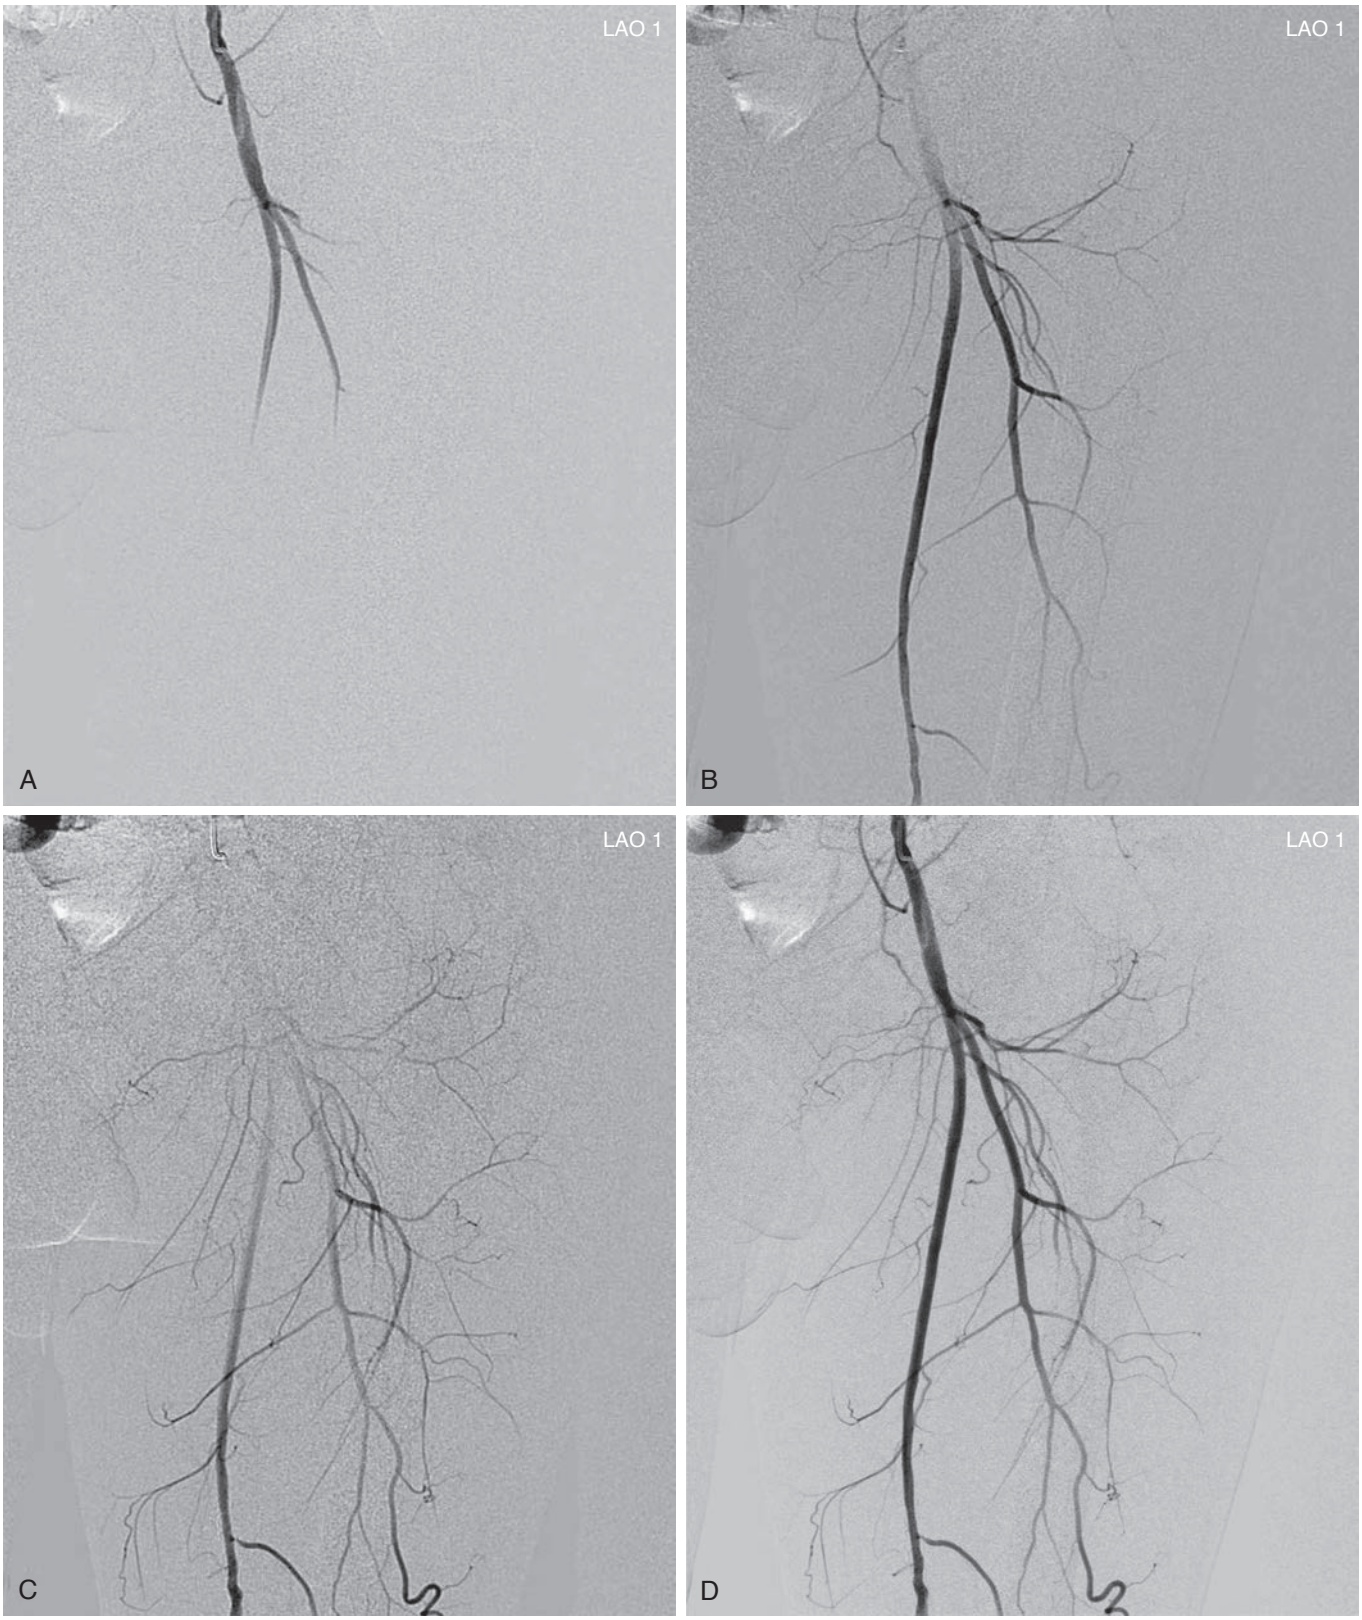

Figure 25.8 (A) Femoral arteriogram early after injection of contrast material illustrating only proximal opacification of the vessels. (B and C) Progress of contrast opacification through the femoral vessels with improved distal but poor proximal visualization. (D) View tracing allows stacking of sequential images to give a comprehensive view of the vessels with all areas opacified during the different time points of the contrast run. *LAO,* Left anterior oblique.

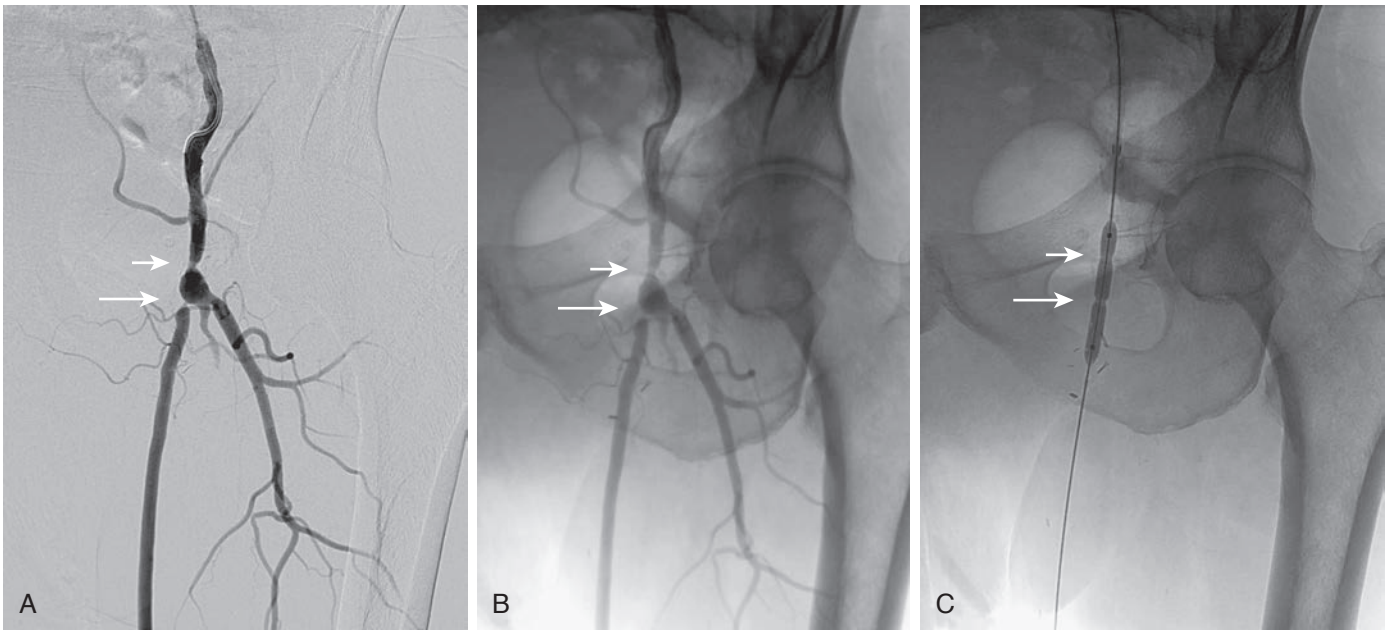

Figure 25.9 (A) A femoral arteriogram to evaluate a lower extremity bypass graft shows a stenosis at the proximal anastomosis *(short arrow)* and a second stenosis in the proximal graft *(long arrow)*. (B) Viewing of the same image in an unsubtracted mode allows the use of bone structures, such as the pubic rami and obturator foramen, to serve as reference landmarks. (C) On the unsubtracted reference image, localization and treatment of the target lesions can be performed accurately with guidance from these bone landmarks.

monitor alongside the working monitor so that the angiographer can manipulate catheters or wires on the basis of these reference points.

Finally, imaging units' software includes measurement tools. These tools can be autocalibrated on the basis of estimated distances from the image intensifier to the center of the patient's body, or they can be manually calibrated by measuring an object with known dimensions, such a known distance between radiopaque markers on catheters. This allows more accurate interpretation of stenoses and vessel dimensions than is possible with mere visual estimation or "eyeballing."[15]

Single-Injection Multiple–Linear Field Arteriography

The technique, which allows imaging of both lower extremities with a single injection of contrast agent, is referred to as single-injection multiple–linear field or bolus chase arteriography. With this method, contrast material is injected into the abdominal aorta and imaging proceeds sequentially down the entire length of both lower extremities. Image intensifiers larger than 15 inches are required to view both extremities in one field with this technique. After a single bolus injection of contrast agent, imaging must follow the progression of contrast in a dynamic manner.

Stage Technique

In the stage technique the operator sets the image intensifier at a certain number of sequential positions, or stages, from the lower part of the abdomen to the feet. Four or five stages with some overlap between stages is usually required, depending on the size of the image intensifier. When the imaging process is initiated, the image intensifier starts at the feet and travels proximally from stage to stage to acquire a mask image for each particular position. Once the final mask is obtained in the lower part of the abdomen, a bolus of contrast material is injected and continuous imaging proceeds in a staged manner from the abdominal aorta back down to the feet. In essence, the image intensifier "chases" the bolus of contrast material as it travels distally. On completion, the images can then be viewed at each stage individually and processed in the standard manner (Fig. 25.10). Because the mask images are obtained before the run, the contrast imaging is viewed in subtracted mode, which enhances visualization during the actual run.

Stepping Technique

In the second technique, referred to as stepping, the image intensifier remains stationary while the fluoroscopic table moves for proper imaging. This method uses a large number of small incremental advancements in position, or steps, as opposed to the smaller number of large position changes in the stage method. The process begins with injection of contrast material into the abdominal aorta as the table is stepped sequentially from the abdomen to the feet. Because the incremental changes in position are smaller than with staging, fluoroscopic imaging can more precisely follow the progression of contrast material down the extremities. Stepping can be slowed or even stopped by the operator, depending on the rate of travel of the contrast agent. Once the contrast run is completed, the table returns to the

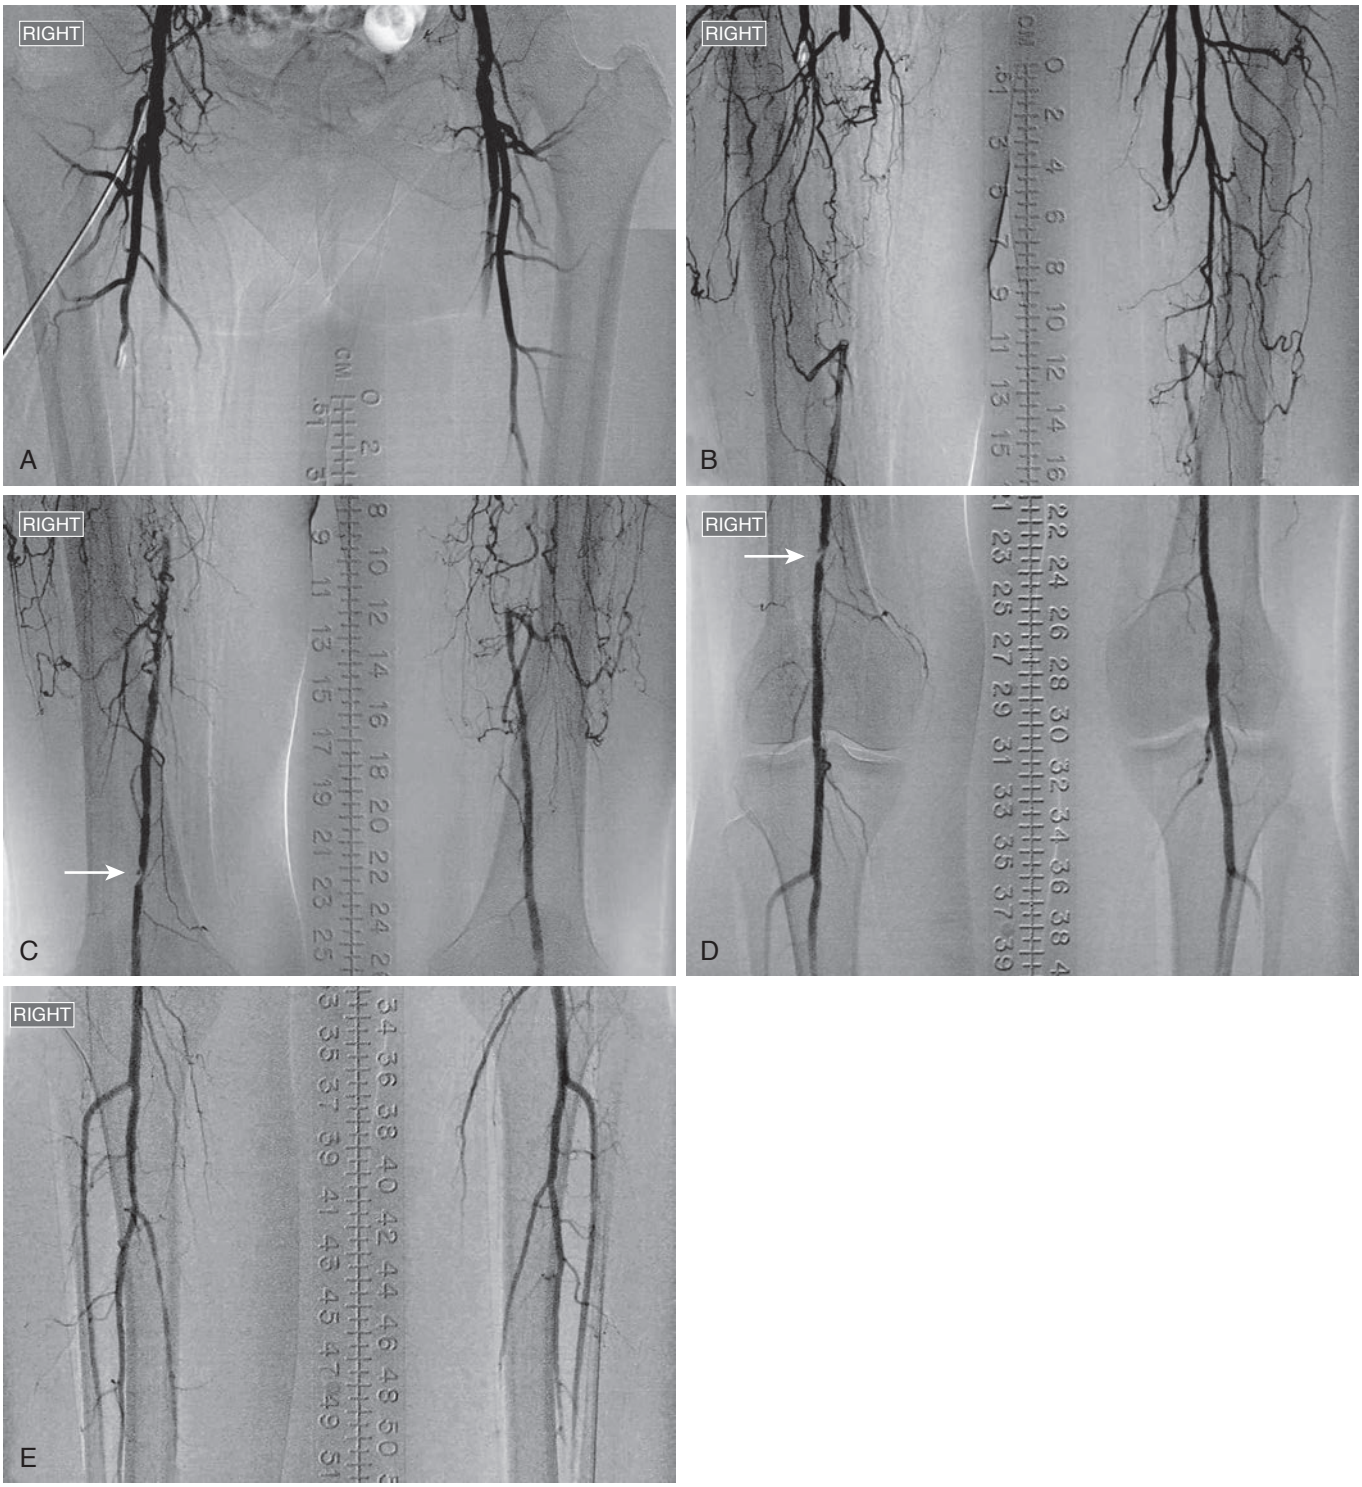

Figure 25.10 Single-injection multiple–linear field (bolus chase) arteriogram of both lower extremities showing bilateral mid-superficial femoral artery segmental occlusion (A and B), right popliteal artery stenosis *(arrow)* (C and D), and bilateral patent tibioperoneal trunks and three-vessel runoff with posterior tibial artery disease on the right (E). Because disease severity appears similar in both lower extremities, there is no discrepancy in contrast transit time between the two; hence imaging appears to have adequate and equal bilateral vessel opacification at each level.

original position and automatically proceeds through the same step sequence used to acquire the mask images.

Limitations of Single-Injection Multiple-Field Arteriography

There are two significant limitations of single-injection multiple-field arteriography. First, as with any DSA imaging, patient movement can significantly compromise image quality. Because the time required to complete this type of study is considerably longer (often lasting 2 minutes) than a standard single-field run, the possibility of motion artifact is significantly increased. A second limitation occurs in patients with a discrepancy in the severity of arterial occlusive disease between the two extremities. More severe occlusive disease on one side will cause delayed contrast transit time and decreased visualization on that side because the image follows the progression of contrast in the more rapidly filling extremity. In this case, it will be necessary to obtain unilateral images separately. Although this technique of arteriography can be performed for each leg individually, the amount of contrast agent needed to do so must be considered. Typical bolus chase arteriography requires 80 to 100 mL of full-strength contrast material, whereas selective single-field imaging of each extremity can be performed in sequential fashion with a manifold and a diluted contrast agent to provide quality images with significantly less volume of contrast material. In the presence of severe unilateral disease, this is the preferred injection technique.

Rotational Arteriography

Rotational arteriography involves rotational image capture and incorporates specific computer software to record the fluoroscopic image series in multiple planes. Preset algorithms are then used to convert the data acquisition into a comprehensive three-dimensional (3D) image. The final reconstructed image can be rotated and manipulated to fully visualize the vessel from any angle, thereby addressing the limitations of single-plane arteriography. Figs. 25.11 and 25.12 illustrate examples of single-plane and rotational arteriography.

Rotational arteriography is similar to the bolus chase technique in that a single injection of contrast material is administered as images are captured from a series of varying positions. The target vessel is first centered on the fluoroscopic image. As contrast material is injected, the image intensifier rotates between two predetermined points (usually 90 to 213 degrees, depending on the system) and captures a broad spectrum of imaging angles with each frame of acquisition during the rotation. The final reconstructed image can be viewed with or without subtraction, and further "cutting" of surrounding tissue artifact can be performed with postprocessing tools (see Fig. 25.12). More recent software even allows roadmapping with 3D imaging for catheter guidance, which may prove especially useful in the cerebral vasculature.

Three-Dimensional Fusion Computed Tomography

With the advent of complex aortic endograft procedures, the need to minimize contrast loads and radiation exposure is more critical than ever. Three-dimensional fusion computed tomography (CT) imaging allows for the patient's preoperative CTA to be used as an overlay roadmap image during the procedure. Briefly, the areas of interest, such as the visceral artery origins, are manually marked on the preoperative CTA. Next an intraoperative "CT scan" is obtained by performing a rotational imaging spin of the patient. Available commercial software packages align the bony landmarks and aortic calcifications of the preoperative CTA and the intraoperative rotational image, allowing the preoperative image to overlay the intraoperative image as a roadmap to guide endograft orientation and target vessel cannulation (Fig. 25.13A and B). Use of this imaging technique does require additional training of the surgeon and hybrid room staff but has been shown to reduce procedure times, radiation exposure, and contrast use in fenestrated aortic endograft procedures and coronary angiography.[16,17]

Maximizing Image Quality During Arteriography

Limiting patient movement is essential to maximize the quality of an arteriographic image. To effectively do so, the angiographer must pay special attention to the patient's comfort and anxiety. Pain and anxiety can cause a patient to make even subtle position changes that can translate to deleterious artifact on imaging. Explaining each step of the procedure ahead of time can help to alleviate anxiety during imaging. Administration of anxiolytic and narcotic medications before and during the procedure is the most effective tool to minimize patient motion. Midazolam (Versed), 1 to 2 mg, and fentanyl, 25 to 50 μg, intravenously can be used before the start of most arteriography procedures. Depending on the patient's condition and tolerance and the length of the procedure, additional small doses can be given as needed. Use of conscious sedation usually requires certification in advanced cardiac life support and also necessitates adequate patient monitoring and the presence of nursing staff during the procedure.

Breathing maneuvers are also important to ensure quality imaging because motion of surrounding tissue secondary to breathing can result in significant image degradation, especially on imaging of the chest, abdomen, or pelvis. Patients should be asked to hold the breath as imaging is initiated, because vessel position can be significantly altered with deep inspiration or expiration. Alternatively, patients can be asked to hold the breath at the midbreath cycle to minimize significant vessel displacement, compared with a deep inspiration, which can cause downward displacement of visceral vessels. When the neck is being imaged, such as the extracranial carotid and vertebral vessels, asking patients to avoid swallowing will likewise prevent significant motion artifact in this area.

Proper positioning of the patient and the imaging equipment is also necessary to maximize information during a study. For example, the legs can be placed closer together during bolus chase angiography to include both of them in the field of view (see Fig. 25.10). Some tables may offer tilt features to increase the capability of patient positioning. However, the majority of positioning relies on adjustment of the image intensifier,

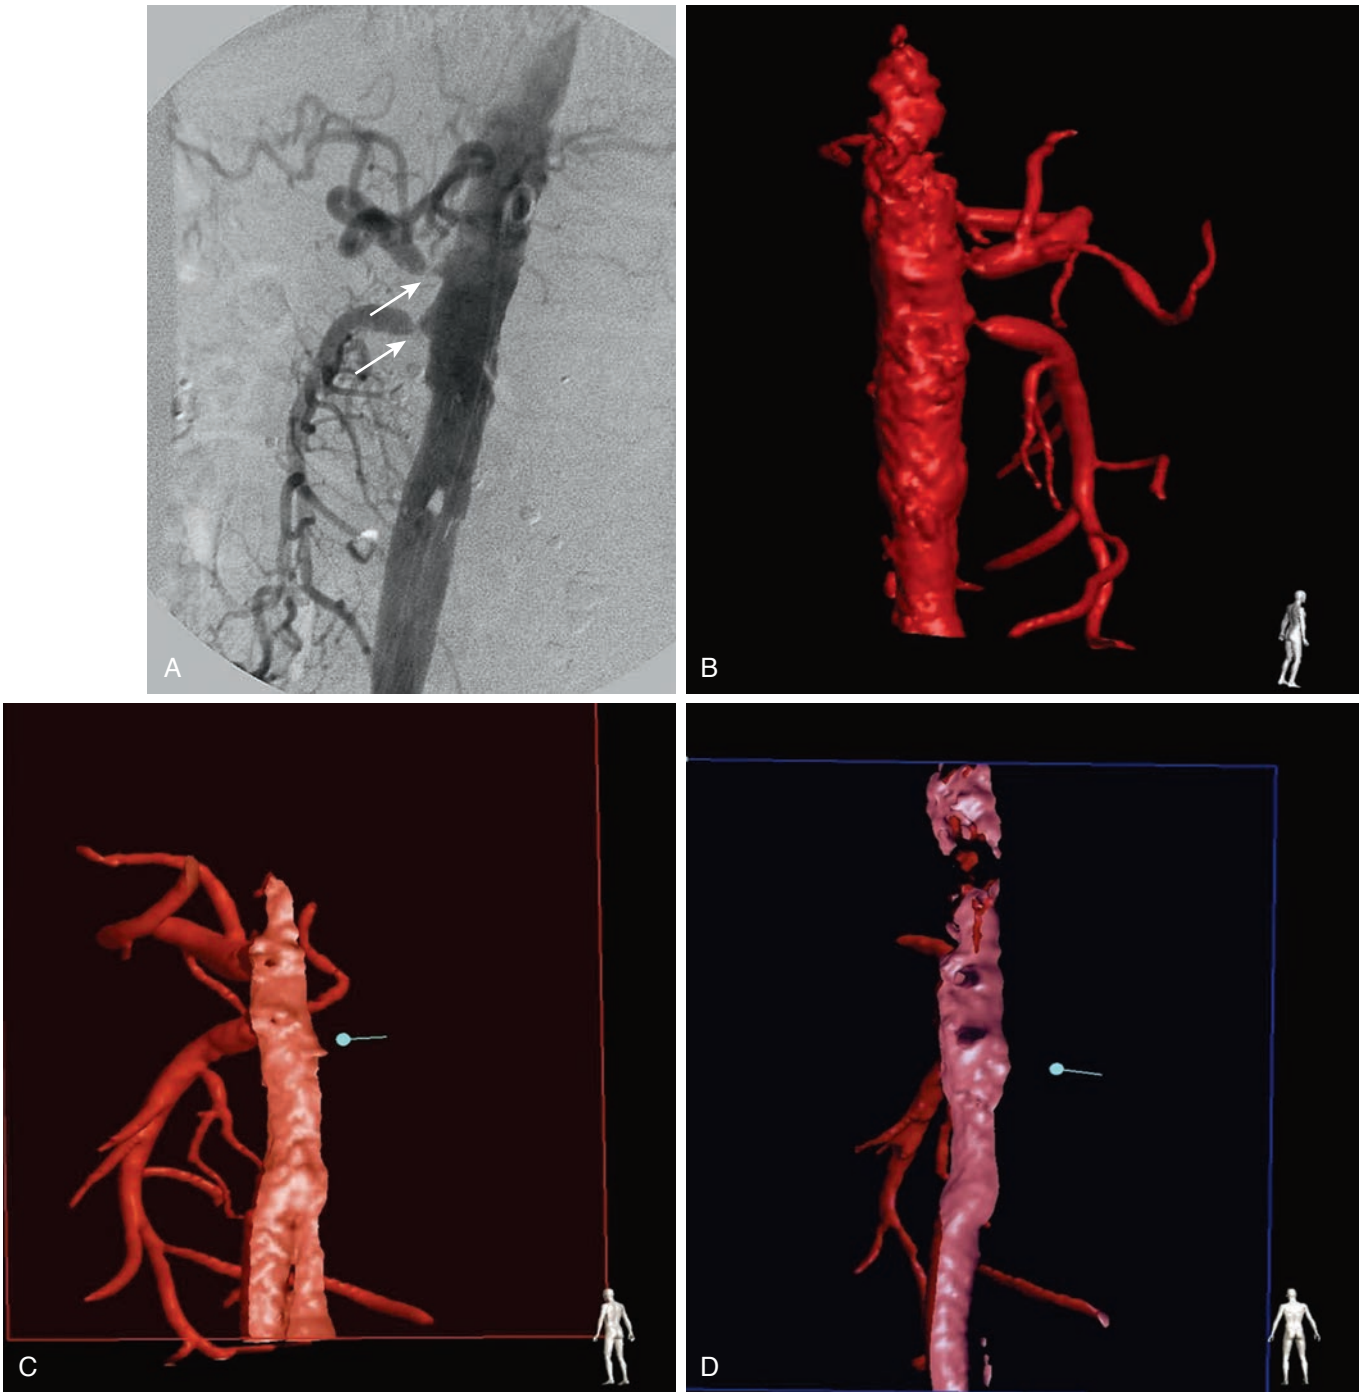

Figure 25.11 (A) Lateral view arteriogram of the aorta showing proximal celiac and superior mesenteric artery stenoses *(arrows)*. (B) Rotational arteriography with three-dimensional reconstruction allows improved characterization of the lesions and rotating views of the image. The images can also be manipulated to view an intraluminal perspective of the aorta, which reveals significant orificial narrowing of both mesenteric vessels before stenting (C) and improved orificial diameter after stenting (D).

including both lateral angular rotation (anteroposterior versus oblique versus lateral views) and craniocaudal angulation. General recommended filming projections for viewing of some commonly imaged arteries are listed in Table 25.3. Depending on the particular vessels being imaged and the patient's individual anatomy, varying degrees of rotation are preferred for optimal visualization (Figs. 25.14 and 25.15).

The maximum size of available image intensifiers has increased significantly in recent years, and current equipment may allow a broad field of view on imaging at maximum projection. This feature is especially useful in performing abdominal and lower extremity angiography because it allows complete evaluation with less contrast agent and shorter radiation exposure times. However, smaller vessels and subtle lesions may be difficult to

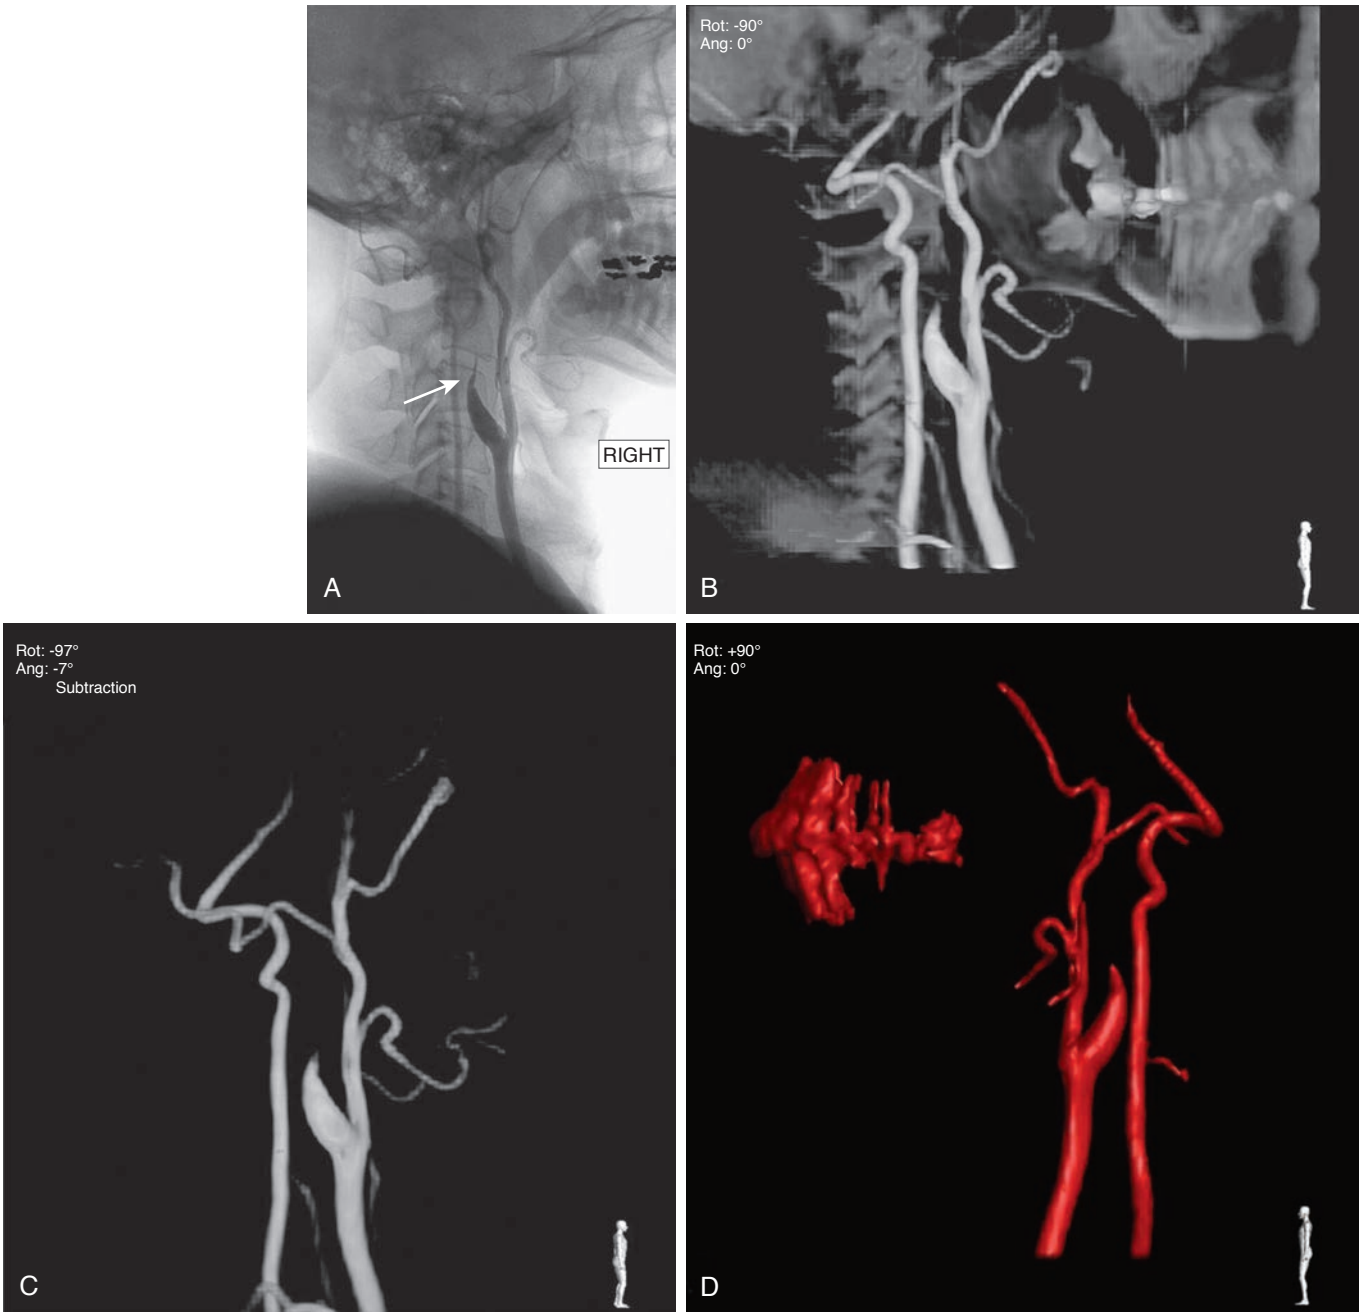

Figure 25.12 (A) Selective carotid arteriogram showing the typical "tapering" appearance of an internal carotid artery dissection *(arrow)*. (B) Preliminary three-dimensional (3D) reconstructed image from a rotational arteriogram showing the same lesion. (C and D) After color manipulation and "cutting" of surrounding bony tissue, the final 3D image can be rotated for different viewing angles.

characterize at such a wide view. By reduction of the projected image dimension, a magnified view focused on the vessel of interest can be obtained (Fig. 25.16).

CLINICAL APPLICATIONS

The quality of MRA and CTA has improved immensely during the past 10 years, and in many clinical scenarios, MRA or CTA can become the preferred choice for planning of either endovascular or operative procedures. Nevertheless, arteriography still has a major role as the primary modality to provide a first diagnostic vascular image. Although arteriography remains the criterion standard, variability exists among all three modalities with respect to quality of imaging and useful information that is gained. CTA and MRA continue to improve in ease of use, accuracy, and speed, but they are still dependent on the physicians and technicians who oversee the production of those images. Therefore variability exists from center to center, which can influence the path that a vascular surgeon will take in obtaining the best vascular images for treatment decisions. Possible

TABLE 25.3 Recommended Radiographic Filming Projections for Optimal Branch Separation

Location	Recommended Filming Projection
Aortic arch	30-degree left anterior oblique
Cervical carotids	AP, lateral, and 45-degree ipsilateral anterior oblique
Intracranial carotids	AP and lateral
Vertebrobasilar system	AP and lateral
Right subclavian	Right anterior oblique
Renal artery origins	AP ± 10 degrees
Celiac artery and SMA origins	Lateral
Iliac bifurcation	20- to 30-degree contralateral anterior oblique
Femoral bifurcation	20- to 30-degree ipsilateral anterior oblique
Trifurcation and tibial arteries	Anatomic AP (or 20-degree ipsilateral anterior oblique with feet in the neutral supine position)

AP, Anteroposterior; *SMA*, superior mesenteric artery.

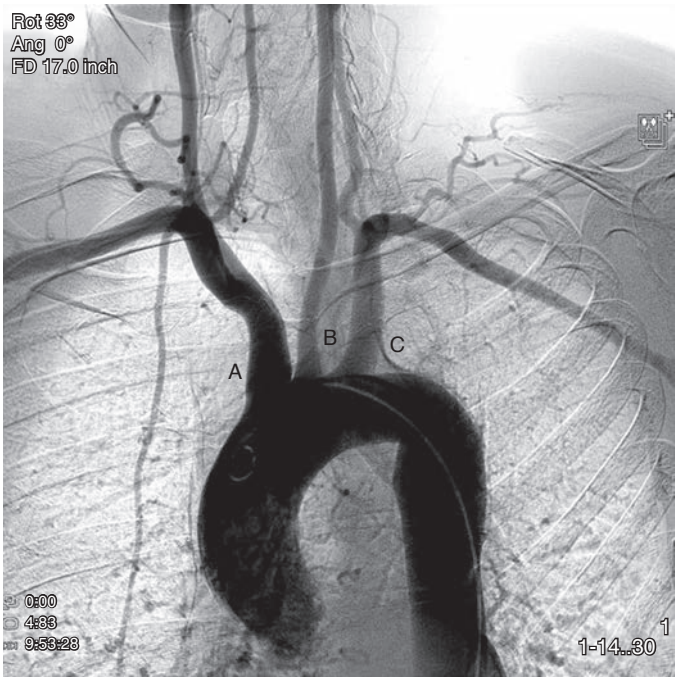

Figure 25.14 Viewing the aortic arch from an approximately 30-degree left anterior oblique angle splays out the arch anatomy with good visualization of the origins of the innominate *(A)*, left common carotid *(B)*, and left subclavian *(C)* arteries.

variability of MRA and CTA make it all the more important that vascular surgeons be highly adept at performing high-quality arteriography to include such small vascular beds as the foot, hand, viscera, pelvis, and brain.

A thorough history and physical examination have become even more important in an era surrounded by cost consciousness and minimization of risks to the patient from unnecessary radiologic evaluation. From a vascular examination perspective, the history and the physical examination in association with routine noninvasive vascular laboratory testing may guide the vascular surgeon directly to primary diagnostic arteriography, particularly if endovascular treatment is anticipated at the time of the diagnostic. There are several clinical scenarios in which CTA or MRA is necessary before arteriography: when diagnosis of a vascular problem is in question and CTA or MRA can provide a diagnosis that will avoid arteriography; in the diagnosis and treatment of aneurysmal disease; when the route of optimal percutaneous access is uncertain; and when other juxtaposition body imaging information is necessary in addition to vascular imaging. Other advantages of arteriography that may affect clinical decision-making include the ability to obtain physiologic testing of differing blood pressures proximal

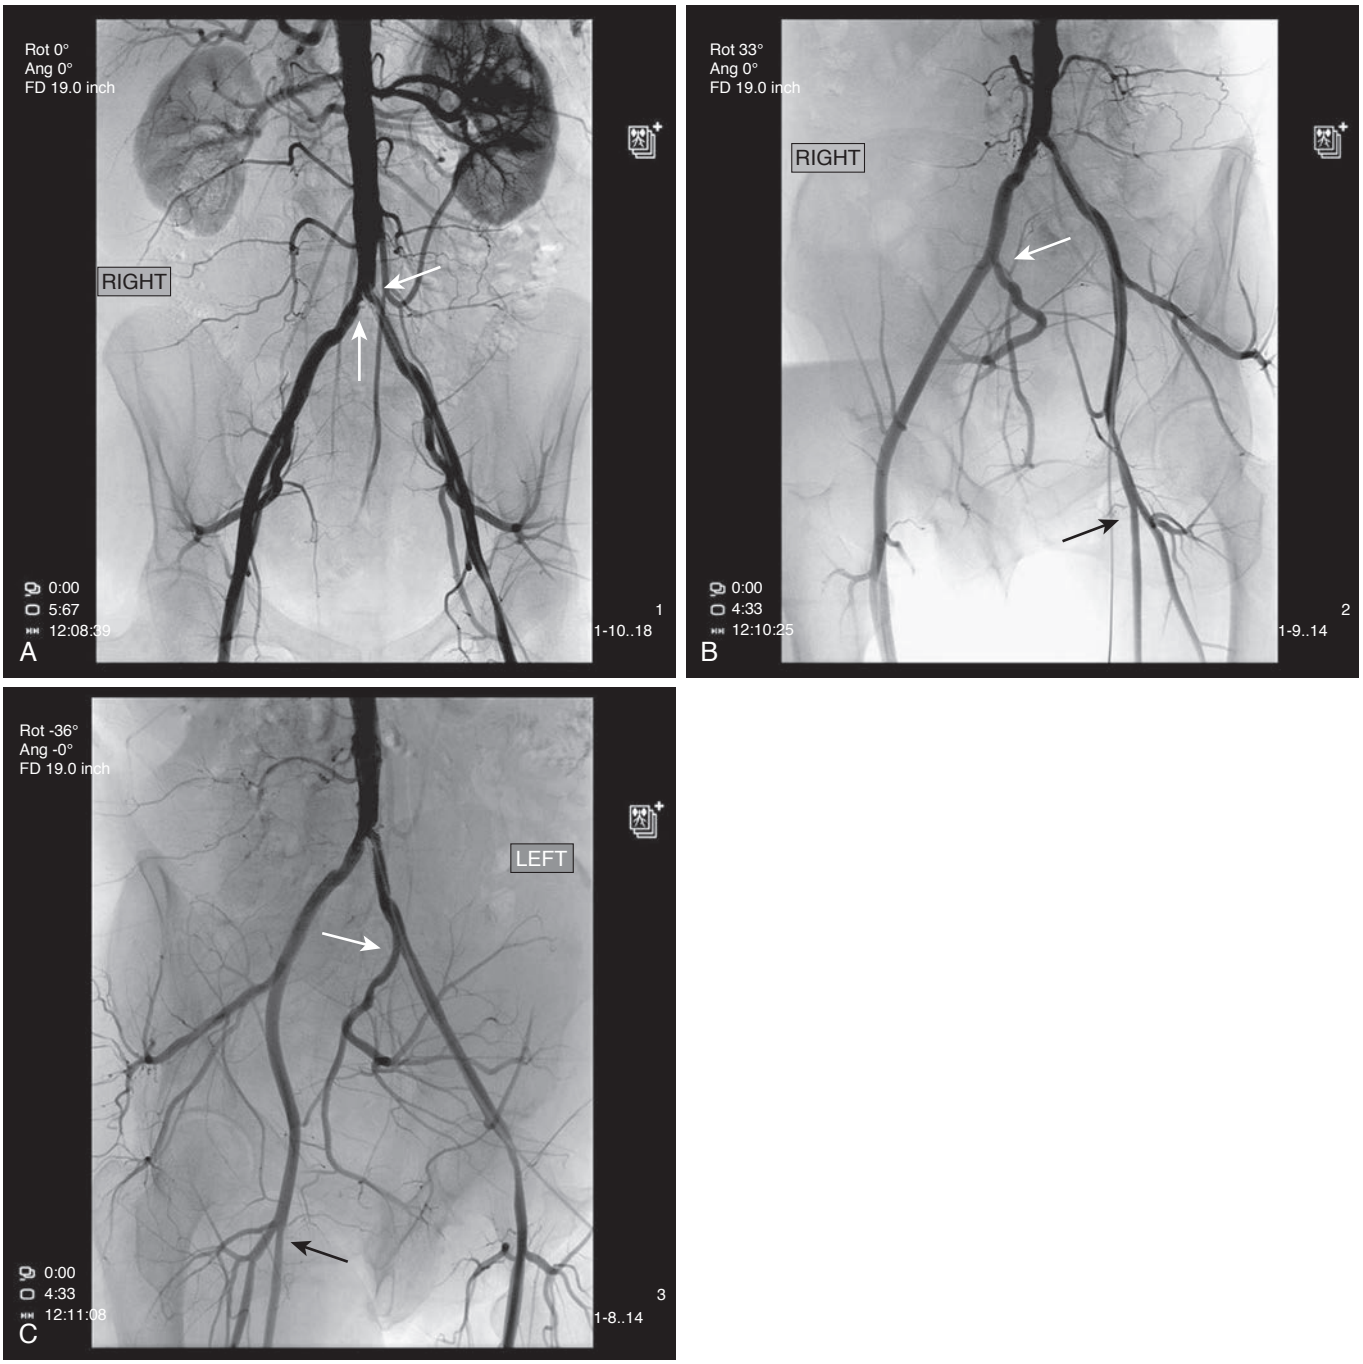

Figure 25.15 (A) An anteroposterior view of an aorta-iliac-femoral arteriogram is the ideal orientation to visualize the aortic bifurcation and bilateral common iliac arteries. Mild stenosis is present in the proximal right common iliac artery, and moderate in-stent restenosis is present in the proximal left common iliac artery *(arrows)*. (B) A 30-degree left anterior oblique view splays out both the right iliac bifurcation *(white arrow)* and the left femoral bifurcation *(black arrow)*. (C) Alternatively, a right anterior oblique view is ideal for visualizing the left iliac bifurcation *(white arrow)* and the right femoral bifurcation *(black arrow)*.

and distal to stenoses, the ability to directly affect a specific vascular bed with a vasodilator drug, and the ability to take blood samples from certain vascular beds for a certain diagnosis to be made.

Studies comparing arteriography with CTA and MRA conflict as to whether the two are equivalent to the criterion standard.[18-27] More important, in making clinical decisions, some studies have shown benefit of CTA or MRA, whereas others have not. Hingorani et al.[19,21] compared CTA and MRA with contrast arteriography in patients with chronic lower extremity ischemia requiring revascularization. Accuracy of CTA and MRA were poor in femoropopliteal and tibial segments compared with contrast arteriography. In these studies, CTA and MRA could not provide equivalent imaging to ensure the optimal clinical

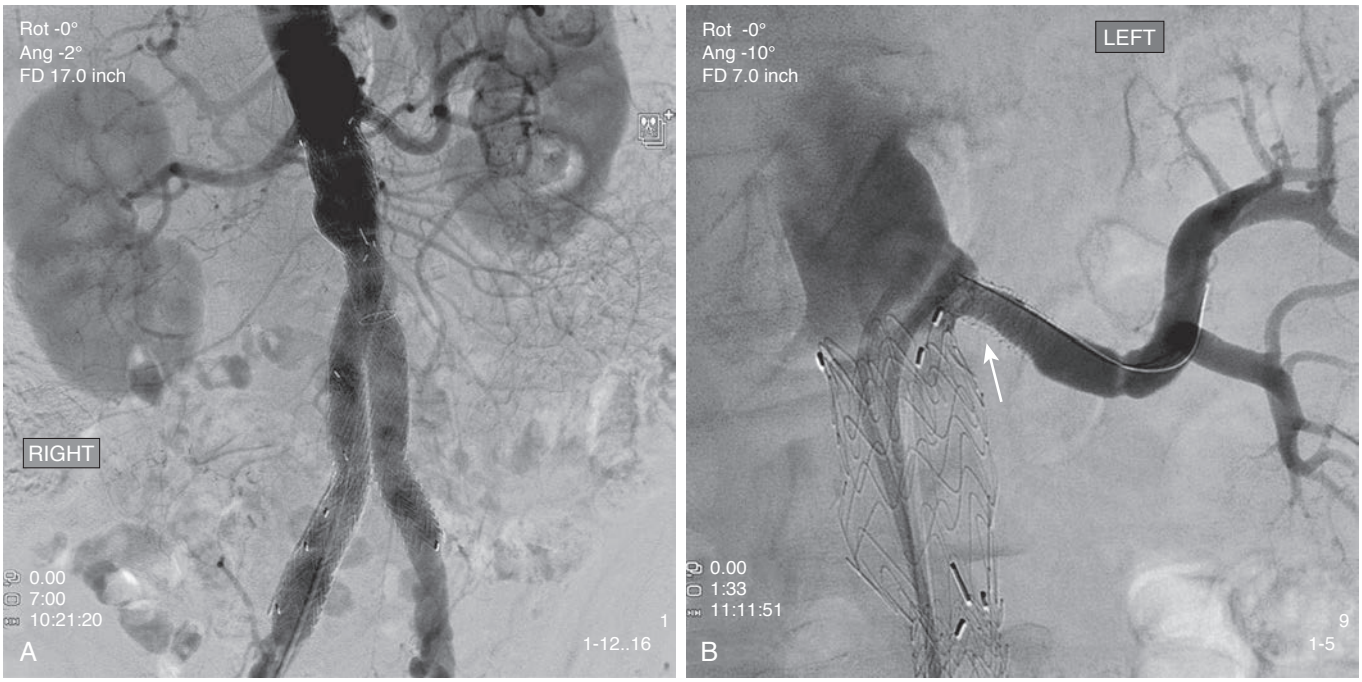

Figure 25.16 (A) Flush aortic arteriogram showing an adequately sealed aortic endograft and patent left renal artery stent. (B) Adjustment of the image intensifier, or flat detector, from a 17-inch to a 7-inch projection gives a much clearer magnified view of the left renal artery and reveals mild in-stent restenosis *(arrow)*.

decision for lower extremity revascularization. In contrast, MRA may have a role in identifying patent tibial target vessels for lower extremity bypass that are not seen on DSA due to very low flows (Owen et al., 1993).[24,25] All studies comparing CTA and MRA with DSA for lower extremity arterial occlusive disease are fraught with small numbers of patients and differing methodologies of stenosis criteria and techniques, and the selection of optimal imaging remains somewhat case-, center-, and surgeon-specific.

LIMITATIONS AND RISKS

Sources of Error With Arteriography

Motion artifact is the most common source of degradation of image quality and can be devastating to accurate visual interpretation. However, other potential sources of image compromise involve the patient's anatomy. Bone, bowel gas, surgical clips, implanted devices, shrapnel or other foreign bodies, and any other surrounding tissue densities can obscure true anatomic detail of a vessel. This problem is addressed by obtaining images from multiple angles and thereby separating the target vessel from the interfering tissue density. Vital interpretations and interventions are almost never based on a single-plane image. Superimposed contrast columns in overlying arteries can also obscure anatomic detail. This often occurs at vessel bifurcations and in vessels that are angulated in a plane parallel to the angle of view. Because significant occlusive lesions commonly occur at vessel bifurcations, this scenario can seriously adversely affect accurate disease diagnosis and proper management decisions. Recognizing subtle differences in the density of contrast in areas of artery overlap will help to prevent misinterpretation. Again, emphasis should be on changing the angle of view to splay out such a bifurcation and better visualize each individual vessel (Fig. 25.17).

An extremely important concept in angiography is the limitation of expecting a two-dimensional image to accurately represent a 3D structure. Relying solely on single-plane imaging, in an anteroposterior-only view, for example, may lead to underestimation of significant arterial disease in some instances. This is highlighted by some of the aforementioned scenarios. Posterior plaques are another notorious example of this potential source of error (Fig. 25.18). In one view, a vessel may appear to have uniform diameter and no evidence of stenosis; but in an oblique or lateral view, hidden ulceration or a profound stenosis may be evident, a so-called pancake lesion as opposed to a circumferential lesion. This underscores the importance of multiplanar arteriography to truly highlight its accuracy over other imaging modalities.

Risks From Contrast Agents

Systemic Toxicity

The toxic side effects of iodinated contrast agents are primarily thought to be due to hyperosmolality. The most common adverse symptoms are nausea, vomiting, and pain in the distribution of the specific arterial bed that is injected. The discomfort seems to become more significant as the osmolality increases,[28] especially when it is greater than 400 to 500 mOsm. Furthermore, nonionic agents tend to cause fewer adverse symptoms than ionic agents

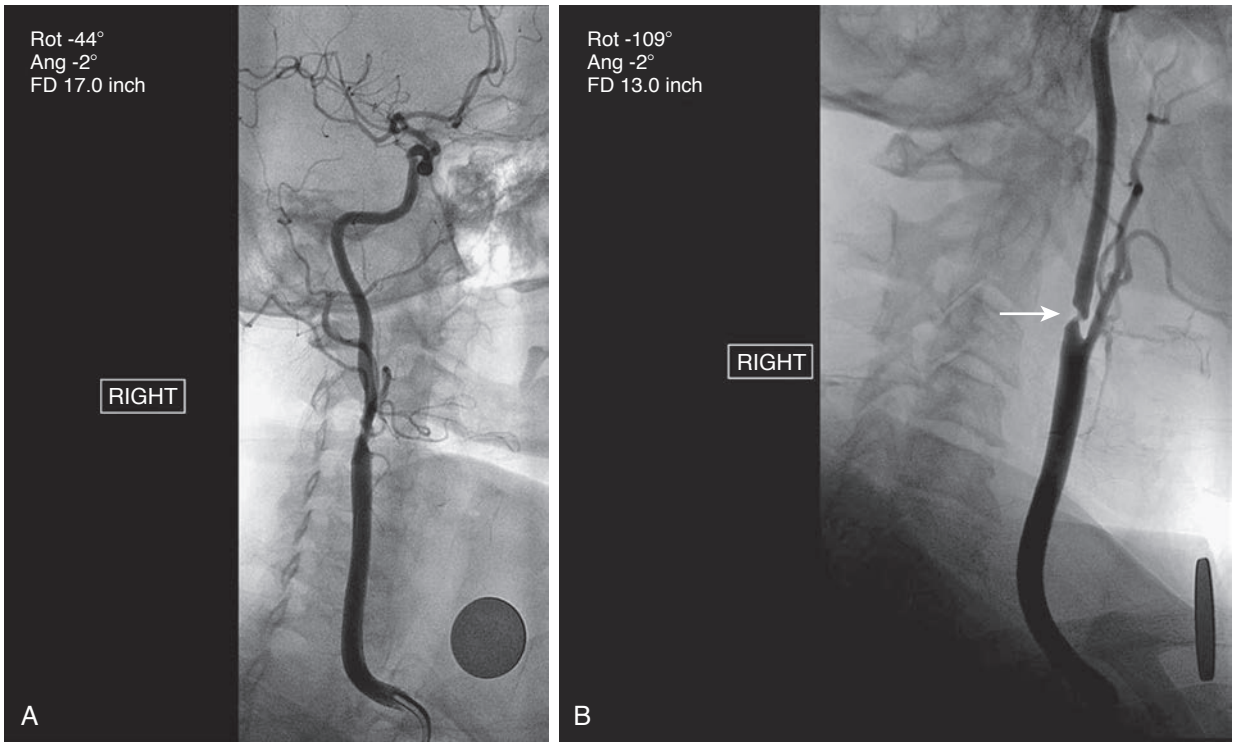

Figure 25.17 (A) Selective carotid arteriogram showing poor characterization of the carotid bifurcation on an oblique view because of superimposed vessels. (B) Adjustment of the angle of projection opens the bifurcation to clearly visualize the internal and external carotid arteries, revealing a significant proximal internal carotid stenosis *(arrow)* that previously was not apparent.

Figure 25.18 Selective Carotid Arteriogram Highlighting the Importance of Multiplane Imaging to Unmask Suspicious Posterior Vessel Lesions. (A) An oblique view seems to demonstrate good visualization of the carotid bifurcation with some mild irregularity of the internal carotid artery *(arrow)*. (B) Repeated imaging with a lateral projection, however, unveils a high-grade stenosis of the internal carotid artery with an ulcerated posterior plaque *(arrow)*.

do, which is why there has been a significant trend toward formulating lower osmolality, nonionic agents.

Other adverse systemic effects of contrast administration are related to nonspecific reactions involving histamine release. Such reactions are usually treated with antihistamines alone in minor cases, such as urticaria. For more severe reactions, such as laryngeal edema or bronchospasm, treatment starts with inhaled adrenergic medications such as albuterol and, if that is ineffective, intravenous administration of epinephrine. Finally, cardiopulmonary arrest may require full hemodynamic support with vasopressors in addition to mechanical ventilation for respiratory support. It is important to distinguish hemodynamic instability caused by cardiopulmonary collapse from the more common vagally mediated hypotension, which may be due to such causes as anxiety or catheter manipulation and is best treated with intravenous fluid and close observation. In cases of severe bradycardia and hemodynamic instability, atropine (0.5 to 1.0 mg intravenously) should also be administered. Patients with a history of asthma, other allergies, reactions to contrast media in the past, or anxiety are predisposed to the aforementioned side effects.[29,30]

After a patient has suffered an adverse reaction from exposure to an iodinated contrast agent, it is imperative to minimize this risk in the event of subsequent exposure. Multiple studies have shown corticosteroids to be effective for prophylaxis in these patients.[31-37] Lasser and colleagues demonstrated a significant reduction in reactions related to hyperosmolar agents with the administration of 32 mg of methylprednisolone 12 and 2 hours before injection of the contrast agent. In a similar regimen, these investigators also found that use of a nonionic contrast agent with lower osmolality reduced adverse events from 4.9% in the untreated group to 1.7% in the pretreated group.[32,33] Other studies have shown that premedication with 50 mg of prednisone given at 13, 7, and 1 hour prior to contrast administration, often in conjunction with diphenhydramine, is an effective method of preventing contrast-induced allergic reactions, with breakthrough reactions occurring only 2.1% of the time.[38,39] Katayama and associates found a reduction in adverse reactions from 12.6% to 3.1% with use of ionic, high-osmolality contrast agents, as opposed to nonionic, low-osmolality agents.[40] Steroid premedication should be administered to all patients who have a history of reaction to contrast media or who are otherwise at high risk for such. Some authors assert that despite prophylaxis, albeit at lower doses than described previously, and the use of low-osmolality contrast agents, as many as 10% of patients may still suffer a breakthrough reaction.[41]

Cardiac Toxicity

Contrast agents can adversely affect cardiac function, particularly during coronary angiography and ventriculography. These physiologic disturbances are spurred by electrolyte imbalances of sodium and calcium in the coronary system caused by passive washout after the injection of contrast material. Even in noncoronary arteriography, some older contrast agents were able to bind calcium and induce arrhythmias by reducing levels of free ionized calcium.[42] The most common hemodynamic effect is a decrease in heart rate and blood pressure, usually temporary and self-limited. However, this can be much more pronounced in patients with severe underlying cardiac dysfunction, aortic stenosis, or direct exposure of the heart to the contrast agent. Use of low-osmolality agents has been shown to reduce the incidence of such adverse hemodynamic effects.[43]

Hematologic Toxicity

Conventional iodinated contrast agents have been shown to inhibit multiple coagulation factors and antithrombin activity, as well as to exhibit antifibrinolytic properties.[44] The clinical significance of these findings is unclear within circulating blood. However, red blood cells do aggregate when in contact with contrast media.[45] This can present a compromising situation with stasis of blood and contrast material within the catheters and sheaths used for injection. To prevent the possible introduction of fresh thrombus into the circulation, it is strongly advised that one remain vigilant about frequent flushing of catheters and sheaths with saline. Anticoagulation (heparin, 2500 to 5000 units) during endovascular procedures should be considered on a case-by-case basis. In cases in which heparin is used, measuring activating clotting times and possibly reversing heparin effects with protamine administration may be necessary before sheath removal. There is some evidence that use of nonionic contrast agents may reduce these adverse hematologic effects.[46]

Nephrotoxicity

Contrast-induced nephropathy is perhaps the most commonly cited and studied adverse reaction to iodinated contrast agents and carries with it significant morbidity and mortality. It continues to be the third leading cause of acute renal failure in hospitalized patients.[47,48] The severity of clinical manifestations in these patients ranges from a mild reversible rise in serum creatinine concentration to end-stage renal failure and death. Multiple clinical trials have shown the deleterious effect of iodinated contrast agents on renal function.[49-51] Many risk factors for the development of contrast-induced nephropathy have been identified, of which preexisting renal dysfunction remains the most important.[52] Other risk factors include advanced age,[53] congestive heart failure, dehydration, hyperosmolar states (e.g., multiple myeloma), and severe proteinuria. In such patients the volume of contrast material should be minimized and adequate hydration should be administered. Interestingly, neither the type of contrast agent used nor the total volume infused seems to play a significant role in the development of this complication in patients with normal renal function.[52,54-56] Although administration of contrast agents to patients already suffering from complete renal failure may be done without fear of inducing further nephropathy, these patients are at risk for hyperosmolar volume overload and should be scheduled for dialysis after the angiography procedure.

All iodinated contrast agents are primarily excreted by the kidneys. It was originally thought that the high osmolality and ionization of conventional contrast agents were responsible for contrast-induced nephropathy. However, there is no difference in such occurrence with ionic and nonionic contrast agents.[57] However, there does appear to be reduced risk with the use of low-osmolality contrast agents as opposed to those with high

osmolality.[57-59] After infusion, contrast material is filtered by the glomerulus with little or no evidence of tubular reabsorption. The principal site of contrast-induced nephropathy is the renal tubule secondary to transient local ischemia.[60] Because contrast material is filtered without reabsorption, an osmotic gradient is created that results in increased intratubular pressure, afferent arteriolar vasoconstriction, and decreased glomerular filtration rate. This decrease in glomerular filtration rate results in regional tubular ischemia.

The incidence of contrast-induced nephropathy in patients with normal renal function is only 1% to 2%.[52] This risk increases to 10% in patients with creatinine levels of 1.3 to 1.9 mg/dL (115 µmol/L to 168 µmol/L) and to as much as 62% in patients with levels higher than 2 mg/dL (177 µmol/L). The incidence of contrast-induced nephropathy is high in the diabetic population, although diabetes is not considered an independent risk factor. It is probably an unmasking effect of subclinical renal insufficiency, which is common in these patients. Patients with type 1 diabetes are more prone to the development of contrast-induced nephropathy than are patients with type 2 diabetes.[61,62] Moreover, diabetics with renal insufficiency in whom acute contrast-induced renal failure develops are less likely to recover than are nondiabetics with baseline renal insufficiency, and they are at greater risk of permanently requiring dialysis.[61-63]

Metformin

Diabetic patients taking metformin (dimethylbiguanide), an oral hypoglycemic agent, require special consideration when receiving iodinated contrast material. Metformin is excreted by the kidneys, and continuing to take this drug in the setting of renal dysfunction can result in lactic acidosis. This is a rare complication resulting from impaired drug clearance in patients in whom nephropathy develops as a result of iodinated contrast material. There have been published guidelines pertaining to the use of contrast material in these patients.[64] Only low-osmolality contrast agents should be used, and creatinine levels should be checked before and after the procedure. Patients with normal preprocedure and postprocedure renal function should refrain from taking metformin for a period of 48 hours after the procedure. Patients with baseline renal insufficiency that remains stable should refrain from taking the drug for 48 hours before and 48 hours after the procedure. In an emergency setting, patients with renal insufficiency should be well hydrated for 24 hours after the procedure while being monitored for the development of lactic acidosis. Findings can include nausea, vomiting, somnolence, epigastric pain, anorexia, lethargy, diarrhea, thirst, pH less than 7.25, lactic acid level greater than 45 mg/dL (5 mmol/L), anion gap greater than 15 mEq/L (15 mmol/L), and increase in the lactate-to-pyruvate ratio.

Prevention of Contrast-Induced Nephropathy

Prevention of contrast-induced nephropathy has been the subject of many research trials and studies. Intravenous hydration appears to be the most effective tool,[65,66] with 0.9% normal saline offering better protection than 0.45% normal saline.[67] Intravenous sodium bicarbonate administered before exposure to contrast material may also significantly reduce renal dysfunction.[68] Another agent that may offer protection against contrast-induced nephropathy in patients with renal dysfunction is the antioxidant *N*-acetylcysteine[69-73] given at a dose of 600 mg for 2 days before and after the procedure. Tepel and colleagues found that the incidence of contrast-induced nephropathy was reduced from 22% to 2% in patients receiving *N*-acetylcysteine with hydration versus those receiving hydration alone.[70] Other trials have failed to show a clear benefit, and therefore the recommendation for routine use remains controversial.[74-77] Many other agents have been studied for possible protective effects against contrast-induced nephropathy through the actions of increasing vasodilation, renal perfusion, or diuresis (or any combination of these mechanisms). Such agents include fenoldopam, theophylline, prostaglandin E_1, endothelin antagonists, calcium channel blockers, dopamine, and diuretics. However, none of these agents can be recommended for the prevention of contrast-induced nephropathy on the basis of current scientific evidence.[50,51,65,78-96] The development of strict protocols with adherence to low dosing of contrast agents has also been shown to further improve results in the prevention of contrast-induced nephropathy. Although many of these protocols have been developed for CT, they are equally applicable to arteriography.[97-99]

Limitations and Risks of CO_2 Contrast

Because CO_2 gas tends to rise, visualization of vessels with posterior origins may sometimes be difficult in the supine position. A typical example is the left renal artery, which often has a posterolateral takeoff from the aorta. To address this issue, patients can be positioned with the left flank slightly elevated, either by placing a roll under the left side or by tilting the table in that direction if such a feature is available. This will raise the left renal artery above the plane of the catheter and allow better filling with CO_2.

Complications from CO_2 injection for angiography are extremely uncommon, with only a handful of serious adverse events reported in the literature.[100-104] Most of them were related to mesenteric ischemia secondary to gas trapping. CO_2 dissipates rapidly in the bloodstream, but gas trapping can occur in any vessel and lead to ischemia. The most important consideration when CO_2 is used for intraarterial injection is the potential risk of neurotoxicity. An animal study involving direct injection of CO_2 into the carotid vessels resulted in multiple ischemic infarcts and subsequent neurologic deficits.[105] However, other animal studies found no adverse reactions when CO_2 was injected into the thoracic aorta or carotid vessels.[106,107] Although there is no strong evidence in humans, this potential risk demonstrated in animals has led to the general recommendation to avoid use of CO_2 as a contrast agent when injection is above the diaphragm.

FUTURE ADVANCES

Arteriography is an essential tool in the practice of vascular surgery, and the outlook of future advances is promising. Arteriography will be integrated with other modalities to create improved images, provide physiologic information, and deliver novel therapies in a targeted manner. The possibilities will

continue to grow as scientists and vascular surgeons alike move to treat standard problems in ways previously thought not possible. A sound education and training in arteriography, with the commitment to modernize as standards of care change, is necessary as vascular surgery continues to evolve.

GENERAL LIMITATIONS AND RISKS OF VENOGRAPHY 311
FUTURE ADVANCES 311
SELECTED KEY REFERENCES 311

Since the early 1970s contrast-enhanced venography has been the "gold standard" for the diagnosis of deep venous thrombosis (DVT). Early leg venography required venous cut-down for access to the deep venous system, but this technique has evolved such that contrast material is injected percutaneously into a superficial vein in the foot, with a tourniquet applied above the ankle to prevent filling of the superficial veins that often obscure the deep system. As equipment and contrast agents have improved, so has the safety and efficacy of venography in evaluating DVT. However, in recent decades, duplex ultrasonography has emerged and become readily available as a noninvasive means of accurately diagnosing DVT. This modality has largely supplanted venography for the diagnosis of extremity venous disease; however, venography remains important in evaluating the proximal iliofemoral or axillosubclavian veins and integral in the endovascular treatment of DVT. It also remains an effective imaging tool for evaluating venous structures within the thoracic and abdominal cavities.

obstruction
thrombosis

BASIC PRINCIPLES

The two primary techniques of venography that we currently use are ascending and descending venography. Ascending venography is more common and is used to elucidate the presence of DVT in the lower extremity. Descending venography predominantly evaluates incompetent valves in patients with chronic venous insufficiency. This requires direct access to the deep venous system. The techniques of ascending and descending venography are described in the next section on clinical applications.

CLINICAL APPLICATIONS

The current indications for venography are detailed in Box 26.1. Despite the availability of less invasive techniques, venography is still considered the gold standard against which all examination modalities are compared to determine the presence of DVT. This is particularly true in instances in which duplex ultrasound is inconclusive or unavailable. Venography also continues to have a higher sensitivity and specificity in detection of infrapopliteal thrombotic disease. Venography is indicated in evaluation of valvular insufficiency and venous malformations, and it has been shown to be helpful in planning adjunctive techniques in the operating room. Relative contraindications to venography are also listed in Box 20.1. Other common modalities used in detection of thrombosis and reflux are compared in Table 26.1.

BOX 26.1 Current Indications for and Relative Contraindications to Venography

Current Indications for Venography

1. Diagnosis of DVT in a patient
   a. With a nondiagnostic duplex ultrasound examination or for whom a duplex examination is not technically feasible
   b. With a high clinical suspicion for DVT but with a negative duplex examination
   c. When duplex ultrasound is not available
2. As an adjunct during venous intervention (thrombolysis, thrombectomy, angioplasty, and stenting)
3. Evaluation of valvular insufficiency prior to stripping or ligation of superficial varicose veins
4. Venous mapping prior to or following a surgical interventional procedure
5. Evaluation for venous stenosis or venous hypertension
6. Evaluation for venous malformations
7. Preoperative evaluation for tumor involvement or encasement

Relative Contraindications (Included But Not Limited to)

1. Evidence of active cellulitis of the extremity to be imaged
2. Iodinated contrast allergy
3. Renal insufficiency in patients who are not on dialysis, particularly those with diabetes or congestive heart failure

Ascending Venography

Ascending venography has been used for many indications, including DVT, incompetent perforating veins, and venous aneurysms and malformations.

Deep Venous Thrombosis

DVT cannot be reliably diagnosed by clinical examination. Indications for ascending leg venography include a nondiagnostic ultrasound study and a need for better imaging of calf veins in the setting of high clinical suspicion of DVT.[1] Because of its high diagnostic accuracy, a leg venogram is immediately useful for evaluation of the presence of deep venous disease in these circumstances. Another indication is delineation of DVT during endovascular intervention, such as thrombolysis, thrombectomy, or angioplasty.

Technique

Diagnostic ascending venography requires a 22-gauge catheter, three 25-mL syringes, two tourniquets, a tilting fluoroscopic table with footrest, C-arm fluoroscopy, contrast agent, and normal saline. In addition, a 4F micropuncture sheath should be available for direct access to the venous system through the popliteal vein if needed. It begins with placement of a catheter in a peripheral vein. The access device is usually a 22-gauge intravenous catheter inserted into a superficial vein on the dorsum of the foot. When the affected extremity has significant edema, percutaneous catheterization of peripheral veins becomes difficult. In such cases, we use ultrasound to guide vascular access. It is important that access for ascending venography not be through the saphenous vein adjacent to the medial malleolus at the ankle because contrast material may preferentially fill the superficial system without demonstrating the deep venous systems adequately. The likelihood of this problem can be decreased by placing a tourniquet at the ankle and one at the knee, which will drive the contrast material into the deep venous system. However, these tourniquets should be released just before image acquisition to relieve extrinsic compression and to avoid occlusion of the deep veins.

The patient is placed on a tilting fluoroscopic table and a footrest to enable near-upright positioning. With the patient initially in a reverse Trendelenburg position, the table is tilted to recumbency as the bolus is tracked. This approach enhances visualization of the large-capacity lower extremity venous anatomy as gravity delays the outflow of contrast material. The contralateral leg is supported with a small platform so that no weight is borne on the leg to be examined. Side grip handles can be placed on the table as needed, depending on the patient's comfort and security in the semiupright position.

The examination is begun with the patient in a 40- to 60-degree semiupright position. The bolus is followed by radiographic imaging as the material flows to the central veins. As the contrast agent ascends, additional filming of the deep and superficial femoral veins is performed. At least two projections are needed in the tibial and popliteal locations. Approximately 50 to 100 mL of contrast material is needed to fill the deep venous system adequately from ankle to groin.

TABLE 26.1 Comparison of Various Modalities for the Detection of Venous Disease

Technique	Pros	Cons
Venography	Good confirmatory test with diagnostic uncertainty and in detection of asymptomatic DVT Good diagnostic ability below the knee Descending venography demonstrates the location of the valve as well as valvular competence or incompetence	Invasive Not as readily available Expensive Potential for patient discomfort Risk of phlebitis Intravenous administration of contrast material Risk of nephrotoxicity Allergic reactions Increased cost Need for adequate intravenous access
Duplex ultrasound	Noninvasive Portable Readily available Absence of ionizing radiation High sensitivity and specificity above the elbow and above the knee	Operator dependent Detection of calf DVT is variable Greater accuracy in detecting DVT in symptomatic versus asymptomatic patients Does not permit accurate localization of the levels of valve stations and specific identification of incompetent segments Difficult to ascertain in those with massive edema, wounds, or obesity
Computed tomography venography	Noninvasive Technically simple Time requirement to ascertain the examination is low High sensitivity and specificity	Contrast agent required Risk of nephrotoxicity Radiation exposure Requires patient participation with breathing techniques Flow artifacts may complicate results
Magnetic resonance venography	Noninvasive Improved image quality	Expensive Long examination requirements Radiation exposure Caution in renal disease Inability to be used in patients with metal-based implanted devices

DVT, Deep venous thrombosis.

Additional contrast material can be injected, as needed, to visualize problem areas.

Even with appropriate venous access and the use of tourniquets, adequate opacification of the deep veins of the lower extremities may be difficult because of dilution of the contrast agent and preferential flow from deep to superficial regions, which allows contrast material to escape to the superficial system. In such cases, we place the patient in the prone position, access the popliteal vein under ultrasound guidance, insert a 4F micropuncture sheath, and inject contrast material into the deep venous system. At completion of the examination, the veins are flushed with 50 mL of normal saline to minimize contact of the contrast agent with the venous endothelium and the chance for development of thrombophlebitis.

Interpretation

The classic venographic sign of venous thrombosis is a luminal filling defect with a surrounding rim of contrast (Figs. 26.1-26.6). This appearance of parallel lines of contrast material around the thrombus is referred to as the "tram-track" sign. Other indicators of thromboembolism are an abrupt termination of intravascular contrast or the formation of a meniscus. However, correct and consistent interpretation of lower extremity venography to rule out DVT may be difficult. Intraobserver disagreement about the probable presence or absence of thrombus has been shown to occur in up to 10% of venographic cases.[2] The invasive nature of the technique, the exposure to radiation, and the upsurge of ultrasound technology have made venography a secondary technique for the detection of acute and chronic venous thrombosis. However, venography does play a primary role in the treatment of DVT, allowing for localization and use of mechanical thrombectomy devices for acute venous clot and placement of stents in the setting of chronic venous scarring.

Incompetent Perforating Veins

The normal outflow from veins of the lower extremity includes pathways from the superficial system to the deep system through perforating veins. Perforating veins possess unidirectional valves, which, when competent, prevent reflux of blood from the deep into the superficial veins of the leg. Perforating veins with incompetent valves contribute to the development of venous hypertension in the superficial system, which results in the formation of varicose veins and venous ulceration.

Normal perforating veins are small, thin, and smooth. However, incompetent veins are dilated, irregular, and valveless. Historically, ascending venography has been a reliable technique for identifying incompetent perforating veins. This invasive technique, although useful, has largely been replaced by color-flow duplex examination of the lower extremity.

Figure 26.1 Normal right leg venogram. (A) Lateral calf projection. (B) Anteroposterior projection of the knee. The anterior tibial veins *(small arrow),* peroneal veins *(short arrow),* posterior tibial veins *(arrowhead),* gastrocnemius veins *(open arrow),* great saphenous vein *(curved arrow),* and popliteal vein *(long arrow)* are indicated.

Technique

Ascending venography for incompetent perforating veins involves the injection of contrast material into a foot vein with a tight tourniquet around the ankle to occlude the superficial veins such that reverse flow from the deep veins into the superficial veins through the incompetent perforating veins can be seen. A translucent ruler is then used to measure the location of the incompetent perforating vein from the tip of the medial or lateral malleolus. The table is next moved through the horizontal position and then into Trendelenburg position, and flow of contrast material is followed under fluoroscopy. Lateral views are especially important in the thigh for accurate localization of a midthigh perforating vein. After a perforating vein is identified, a tourniquet can be used above that level to direct the contrast agent into any incompetent perforating vein.

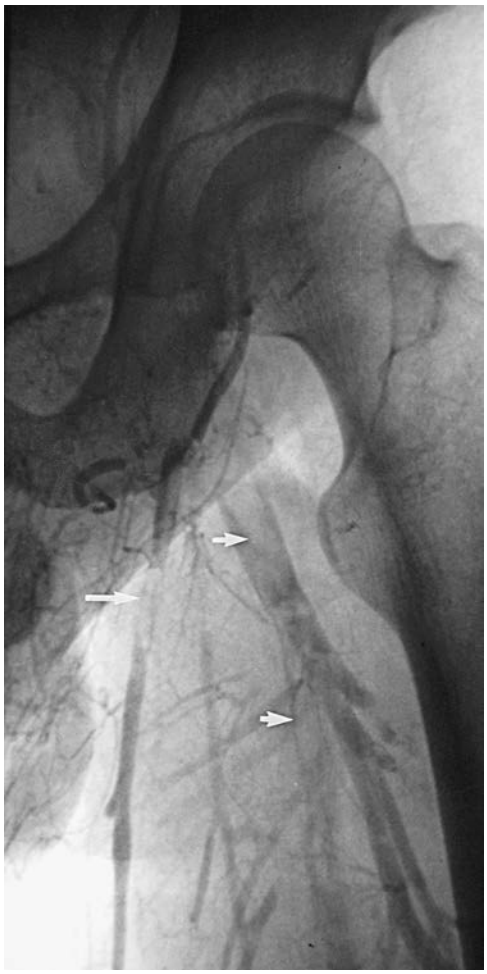

Figure 26.2 Acute thrombus in the deep femoral and great saphenous veins. The deep femoral vein *(short arrows)* and the great saphenous vein *(long arrow)* are shown. The femoral vein is occluded.

Interpretation

Thomas and Bowles compared ascending venography with varicography for identification of incompetent perforating veins.[3] Sixty-one legs of 50 patients were examined with both methods. Incompetent perforating veins of the gastrocnemius muscle and midthigh were more accurately shown with varicography than with ascending venography (Fig. 26.7).

Venous Aneurysms and Malformations

The most serious complication associated with lower extremity venous aneurysms is the development of thrombus within the aneurysm and subsequent embolization. Pulmonary embolization has been reported to occur frequently in extremity venous aneurysms, most notably in those involving the popliteal vein (Fig. 26.8). Aldridge and coauthors in 1993 reported 24 cases of popliteal venous aneurysm in which all patients had experienced thromboembolic events.[4] Aggressive treatment with immediate anticoagulation and preoperative planning has become the standard of care for this reason. Venography is a useful method for preoperative planning before resection and interposition grafting or lateral suture repair of these aneurysms.

Figure 26.3 Acute thrombosis of the soleal veins. *Arrows* indicate fresh thrombus filling the soleal veins.

Figure 26.4 Subacute thrombus in the popliteal vein. *Arrows* denote retracted thrombus, indicative of subacute thrombosis.

Venous malformations may take the form of isolated venous lakes or diffuse venous aneurysm formation, such as Klippel-Trénaunay syndrome (Fig. 26.9). Patients often become symptomatic from mass effect, reflux, or venous thromboembolism. Operative or interventional management may be indicated in symptomatic patients. Most patients do well without treatment or with elastic compression only. Surgical treatment of the vascular malformation in Klippel-Trénaunay syndrome is rarely needed and continues to be controversial.[5] Preoperative venous imaging with ascending venography or direct stick varicography is useful for planning treatment.

Technique

The technique used is the same as when ascending venography is performed. Direct stick varicography is most useful for the evaluation of venous malformations (see Figs. 26.8 and 26.9). Ultrasound-guided access provides the ability to perform direct stick venography. In patients being treated for venous malformations, access can be difficult and painful. In such cases, either general or regional anesthesia may be useful.

Interpretation

Focal dilation of the deep or superficial venous system is diagnostic of venous aneurysms and malformations (see Figs. 26.8 and 26.9). Because of the small number of venous aneurysms included in most individual series, no single diagnostic method has been reported to be superior to another. However, most series do report color-flow duplex examination to be extremely valuable in the diagnosis of popliteal venous aneurysms and to provide information on the presence of mural thrombus.[6] Gillespie and associates found in their series that venous aneurysms were correctly diagnosed in 85% of patients with imaging techniques: phlebography (60%), color-flow duplex scanning (27%), and magnetic resonance imaging (10%).[7]

Passive filling of the vascular tree after compressive exsanguination of an extremity, extrinsic occlusion of its arterial supply, and venous drainage has been shown to be a useful technique for evaluation of venous malformations.[8] Closed-system venography was performed in 17 patients, and it correctly identified 11 of 12 surgically confirmed vascular abnormalities. There were no false-positive findings.

Descending Venography

As with ascending venography, lower extremity descending venography is no longer used as a screening study. It has largely been replaced by color-flow duplex study, which has shown good agreement with descending venography in the grading of deep and superficial vein reflux.[9] However, duplex examination is limited in that it does not permit accurate localization of the levels of valve stations and specific identification of incompetent segments. For this reason, descending venography remains the definitive test for identifying incompetent valves in patients

Figure 26.5 Chronic popliteal venous thrombosis. Note the extensive recanalization of the popliteal vein *(open arrows)* and relatively large caliber of the great saphenous vein *(solid arrow)*.

Figure 26.6 Chronic deep venous thrombosis. Note the extensive collateral channels and no visualization of normal deep venous structures.

with chronic venous insufficiency who are candidates for venous valve repair or valve transplantation.

Descending venography is used for evaluation of the anatomy and function of the venous valves in the lower extremities. It shows the location of the valves in the veins and also demonstrates the competence or incompetence of these valves. Kistner[10] and Herman[11] and colleagues developed a classification system used commonly to categorize the severity of deep venous reflux and the functional integrity of the venous valves (Table 26.2).

Technique

Descending venography requires a tilt radiographic table, C-arm fluoroscopy, a short 4F or 5F straight catheter with distal side holes, syringes, and contrast agent. It is performed on a tilt radiographic table to allow examination in the 40- to 60-degree upright position. Descending venography always requires direct catheter access into the deep veins. In most cases the venous access site is the common femoral vein contralateral to the side of interest. The catheter is advanced to the inferior vena cava (IVC) and then to the iliac vein and common femoral vein of

Figure 26.7 Incompetent medial calf perforating veins. A single-frame image of a videotape shows free flow of contrast material from the posterior tibial vein through the incompetent perforating veins *(arrows)* into the superficial varicose veins.

TABLE 26.2 Grades of Venous Reflux

Grade	Description
0	Normal valvular function with no reflux
1	Minimal reflux confined to the upper part of the thigh
2	More extensive reflux, which may reach the lower part of the thigh; a competent valve is present in the popliteal vein, and there is no reflux to the calf level
3	Reflux as above but associated with popliteal valvular incompetence and leakage of contrast material into the calf veins
4	Virtually no valvular competence with immediate and dramatic reflux distally into the calf; this type of reflux often opacifies incompetent calf perforating veins

From Kistner RL, Ferris EB, Randhawa G, Kamida C. A method of performing descending venography. *J Vasc Surg*. 1986;4:464–468; and Herman RJ, Neiman HL, Yao JS, et al. Descending venography: a method of evaluating lower extremity venous valvular function. *Radiology*. 1980;137:63–69.

the symptomatic lower extremity. A short 4F or 5F straight catheter with distal side holes is positioned at the junction of the external iliac vein and common femoral vein (Fig. 26.10). For unilateral examination the catheter is placed from the ipsilateral femoral vein, and for bilateral examination a single femoral vein puncture is used. A transjugular approach may be used to direct the retrograde catheter into both lower extremities from a single access site. The contralateral leg is supported with a small platform, as with ascending venography, so that the leg being examined will be relaxed and bear no weight.

With the catheter tip in the common femoral vein, the table tilted to a 60-degree semiupright position, and the patient bearing weight on a block placed under the nonexamined leg, contrast material is injected and tracked by fluoroscopy as it flows caudad through the incompetent venous valves. A total of 10 mL of contrast material is slowly injected by hand at a rate of 5 mL/s. As the contrast material is injected, the patient breathes normally, after which the patient is instructed to bear down and perform a Valsalva maneuver to enhance evidence of valvular incompetence. Specific areas of interest can be further studied by sequential injections of contrast material to optimize image capture of valve location and function and the extent of reflux.

Interpretation

Although superficial varicosities are frequently present, they are rarely a prominent feature of symptomatic advanced chronic venous disease.[12] Most patients with symptoms of chronic venous insufficiency who undergo venography have reflux into the deep venous system. The two main abnormalities that cause venous valve reflux are postphlebitic valvular incompetence and primary valvular incompetence, with primary valvular incompetence being responsible more frequently.[13] Although venous duplex evaluation is a widely used screening modality for venous reflux, the use of descending venography provides the degree of detail and specificity that allows selection of candidates for deep venous valve repair or transplantation. These procedures are offered to patients with grade 3 or grade 4 reflux who have

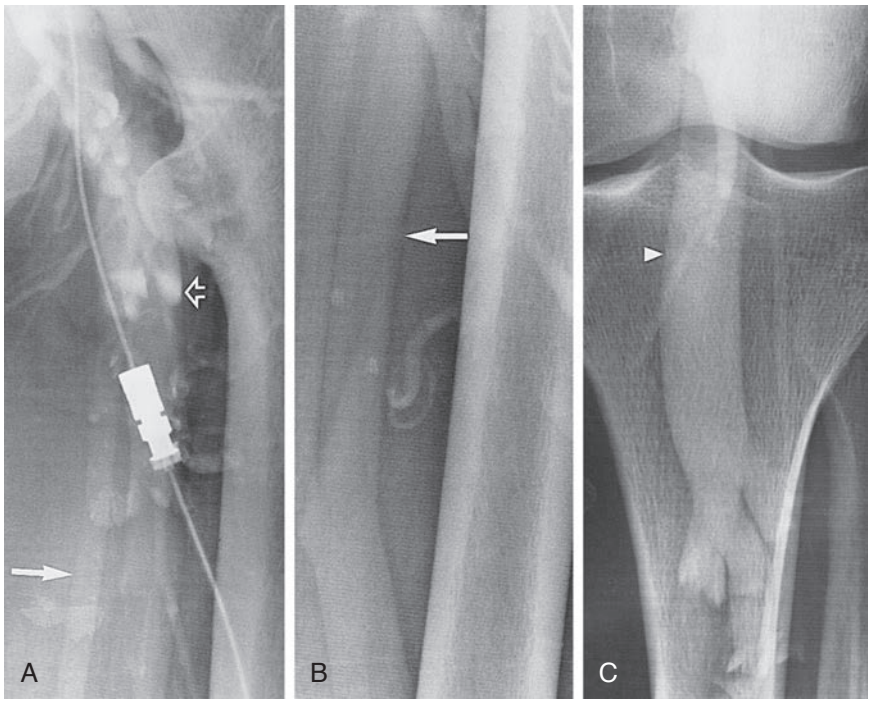

Figure 26.10 (A-C) Descending left leg venogram showing grade 4 reflux. Note the lack of valves in the femoral vein *(solid arrow)* and the large caliber of the popliteal vein *(arrowhead)*. The deep femoral vein *(open arrow)* is shown.

recurrent symptoms of venous insufficiency after treatment of superficial varicosities and perforating vein incompetence (see Fig. 26.10 and Table 26.2).

ILIAC VEIN ASSESSMENT AND INFERIOR VENACAVOGRAPHY

IVC anatomy and patency are routinely assessed as part of IVC filter placement. Phlebography allows assessment of caval anatomy and evaluation for the presence of caval thrombus. In addition, there are several anomalies of the IVC, as outlined in previous chapters. Duplicated cavae, megacavae, and left-sided venae cavae are but a few of these anomalies. Although these anomalies are uncommon, it is important to routinely assess the vena cava with venography before placement of IVC filters to avoid complications caused by either filter misplacement or leaving the patient vulnerable to pulmonary embolism through alternative pathways.

Technique

Access to the venous system is achieved through the internal jugular or common femoral vein. Puncture of just a single wall is facilitated by ultrasound guidance, and a micropuncture kit is used to minimize access size. After access is achieved, a 4 or 5F sheath is placed and proper placement confirmed by free flow of venous blood from the sheath and during femoral access, confirmation that there is no iliac vein thrombus prior to inserting a larger sheath in the vena cava.

From the groin, a 0.035-inch J wire is passed into the common iliac vein. A 5F pigtail catheter is advanced over this wire into the common iliac vein, and cavography is performed.

An alternative method of cavography is to proceed with placement of the IVC filter kit, which consists of a sheath, usually 6.5F to 8F. The insertion track is serially dilated to the appropriate French size. The IVC filter sheath is advanced over the wire to the level of the common iliac vein, and a cavogram is performed.

From the neck a 0.035-inch J wire is passed through the right atrium to the common iliac vein. Passing the J wire through the right atrium into the IVC can sometimes be a challenge. If simple manipulation fails, an angled glidewire and angled glide catheter can be useful. After the J wire is in position, an iliocavogram is performed using a protocol of 10 mL/s for a total of 20 mL of nonionic contrast agent.

Interpretation

The iliocavogram is reviewed for the diameter of the vena cava, the anatomic level of the bifurcation, the level of the renal veins, and any other anomalies (Figs. 26.11 and 26.12). Typically, the renal veins will not fill with contrast material and instead will be identified by a characteristic flow pattern of the mixing of blood filled with contrast material and unopacified blood. The confluence of the common iliac veins is usually identified by the spilling over of contrast material into the contralateral side. The IVC filter can then be placed at a level between the lowest renal vein and the common iliac vein junction.

Some centers advocate first-order selective venography instead of or as a supplement to nonselective venography. Danetz and coworkers found that when selective venography was used in conjunction with nonselective venography, 23% of patients had either an abnormal finding or aberrant anatomy, and most of these patients required a major change in vena cava filter position.[14]

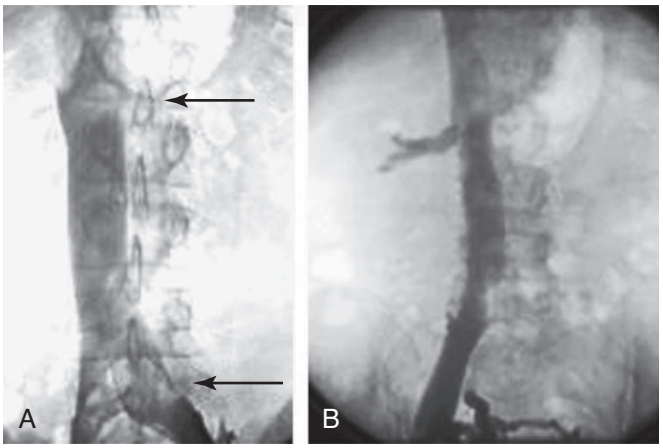

Figure 26.11 (A) Inferior venacavogram demonstrating confluence of the common iliac veins and a normal flow pattern formed by mixing of unopacified renal vein blood with contrast material in the inferior vena cava *(arrows)*. (B) Inferior venacavogram demonstrating filling of the renal veins.

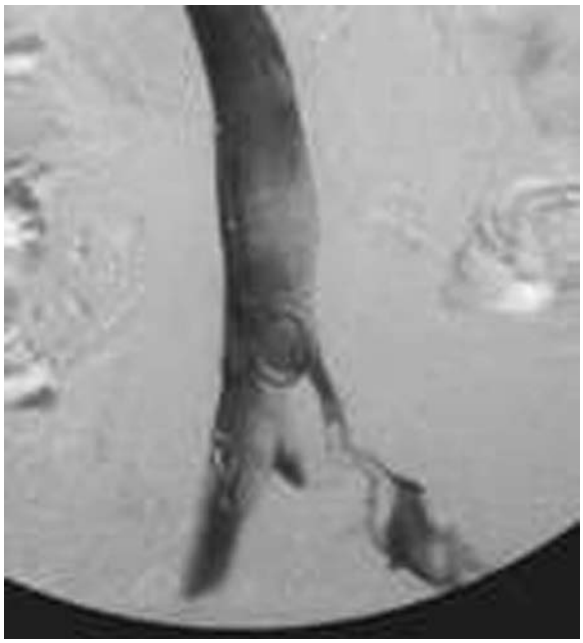

Figure 26.12 Inferior venacavogram demonstrating left common iliac vein deep venous thrombosis (unknown source).

In terms of IVC filter retrieval the surgeon should examine whether the filter has retained thrombus, penetrated the IVC, migrated, or angulated (Fig. 26.13). Severely angulated temporary filters with more than 20 degrees of tilt are more likely to make removal unsuccessful, and filters with retained thrombus should not be percutaneously retrieved unless the operator can lyse the thrombus prior to retrieval.[15]

VENOGRAPHY DURING TREATMENT OF ILIOCAVAL STENOSIS

Advances in angioplasty and stent technology have led to percutaneous treatment of acute and chronic iliocaval occlusion due to thrombosis or external compression (May-Thurner

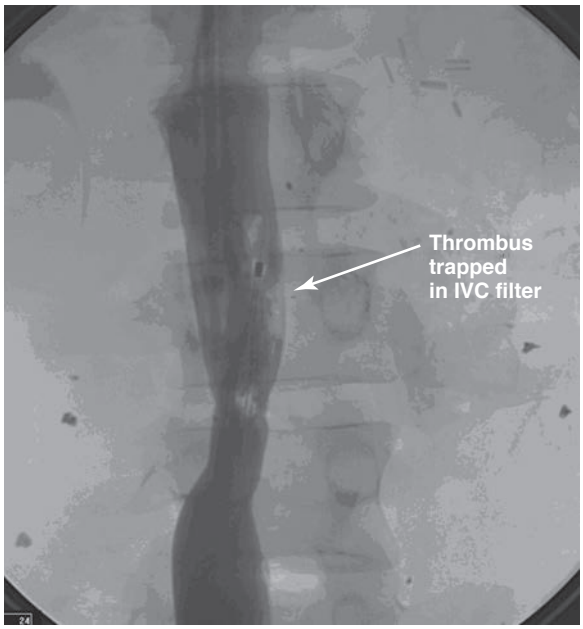

Figure 26.13 Venogram of the inferior vena cava *(IVC)* before attempted retrieval of a prophylactic IVC filter with trapped thrombus *(arrow)*. (Courtesy Eric Adams, MD.)

syndrome). Many authors have written on the efficacy of this method of treating lower extremity venous outflow obstruction.[16-39] Investigation of the safety and efficacy of this treatment has led to refinements of the technique. Neglen and Raju have shown that ensuring adequate inflow into the common femoral vein segment is critical to long-term patency.[27-30,40-44]

Technique

To facilitate visualization of the confluence of the profunda femoral vein and the superficial femoral vein, it is recommended that access be obtained at the midthigh or popliteal level.[45] Ultrasound guidance facilitates placement of a 5F sheath into either of these deep veins. Access to the superficial femoral vein is best achieved in the supine position. However, to obtain popliteal venous access, the patient is placed in the prone position. Once venous access has been achieved, a J wire is advanced to the level of the common femoral vein. A catheter is then advanced over this wire, and iliocavography is performed in the usual fashion. The surgeon can use either a hand injection technique or power injection.

Interpretation

Accurate hemodynamic tests for detecting and grading venous outflow stenosis are currently unavailable. Diagnosis and treatment must be based on morphologic findings. Single-plane transfemoral venography is often used as a standard investigation (Fig. 26.14). These studies may show definite obstruction and the development of collaterals. However, findings are often subtle and only suggestive of an underlying obstruction. Subtle findings of significant venous stenosis include widening of the iliac vein, pancaking, "thinning" of the contrast dye, partial

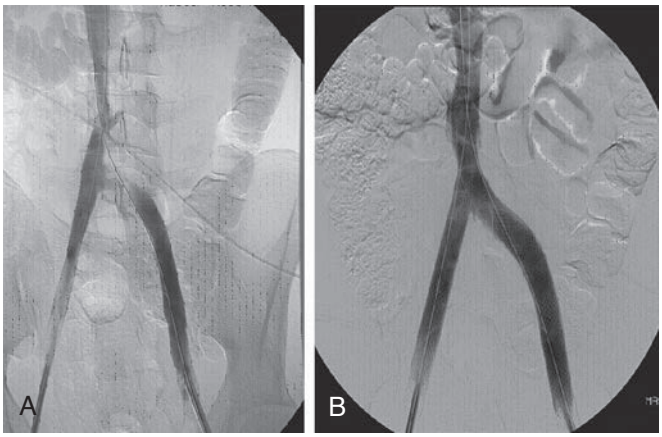

Figure 26.14 Venacavogram revealing left common iliac vein stenosis before (A) and after (B) stenting.

intraluminal defects, septa, and transpelvic collateral formation.[28] To increase the overall accuracy of detecting iliac vein stenosis, the use of intravascular ultrasound can complement venography in these circumstances by providing a cross-sectional view of the area of interest.

DIAGNOSTIC VENOGRAPHY OF PELVIC CONGESTION SYNDROME

Pelvic venous congestion syndrome is characterized by symptoms of pelvic pain, dysmenorrhea, dysuria, dyspareunia, vulvar and pelvic varices in women, and varicoceles in men.[46] Sources of pelvic venous plexus congestion include ovarian vein reflux, pelvic varices, and hypogastric venous insufficiency.

The ovarian veins provide drainage of the parametrium, cervix, mesosalpinx, and pampiniform plexus. Two or three trunks form a single vein at L4, with the right ovarian vein draining directly into the IVC and the left into the left renal vein. These veins have an average diameter of 3.1 mm and possess two or three valves.

In addition to primary valvular incompetence of the ovarian vein valves, pelvic congestion syndrome may also result from obstruction of ovarian vein outflow. This obstruction is most often caused by compression of the left renal vein between the superior mesenteric artery (SMA) and the aorta, also known as the nutcracker syndrome, and it can also occur with a renal vein that travels posterior to the aorta with compression of the vein between the aorta and spine. Distal obstruction leads to increased venous pressure and subsequent venodilation, valvular incompetence, and tortuosity of the ovarian vein. The development of numerous pelvic collateral pathways concurrently allows venous drainage around the point of obstruction. Distal obstruction of ovarian vein outflow leads to the development of an elevated gradient between the left renal vein and the vena cava. Normally, there is minimal or no gradient between the left renal vein and the vena cava, so the presence of an elevated gradient is diagnostic of nutcracker syndrome.[47]

Vulvar varices may arise from the lower extremity veins, the pelvic veins, or both. Varicose veins of the lower extremities are a frequent source of venous hypertension resulting in pelvic congestion. Almost half of vulvar varices arise from an incompetent great saphenous vein through the superficial external pudendal or posteromedial tributaries. Less often, they arise from a tributary communicating directly with the common or deep femoral vein. The remaining varices arise from the pelvic veins through branches of the internal iliac, including the internal pudendal vein, the obturator vein, and the inferior gluteal vein. The internal pudendal tributaries communicate with the ovarian vein. Rarely, the veins arise from the round ligament.[48]

Technique

Diagnostic venography of the ovarian vein is achieved with standard catheter-based techniques. After access to the venous system has been achieved, a 4F angled glide catheter is advanced into the vena cava. The right ovarian vein drains into the IVC just inferior to the renal veins. The left ovarian vein drains into the left renal vein. Selective catheterization of each ovarian vein is then achieved with an angled glide wire and catheter system. After the catheter is placed in the ovarian vein, the angiographic table is tilted into reverse Trendelenburg. Then, after hand injection, the patient is asked to perform a Valsalva maneuver as images are obtained. Venography can be performed through either the jugular or femoral approach.

The diagnosis of nutcracker syndrome is made by determining the retrograde renocaval gradient. To do so, a glide catheter is placed in the distal left renal vein and the pressure transduced. This pressure is compared with the pressure in the vena cava. An elevated renocaval gradient is one clue in making the diagnosis. In addition, contrast-enhanced visualization of the gonadal system and its pelvic and extrapelvic connections should be performed to look for ovarian vein reflux. Intravascular ultrasound can be a useful adjunct in providing a cross-sectional view of the area of extrinsic compression. Patients with the clinical and radiologic diagnosis of nutcracker syndrome can be studied in both the supine and prone positions. Placing the patient in the prone position theoretically decreases the renocaval gradient and displaces the SMA forward with the intestinal mass.

Interpretation

The venographic criteria for pelvic congestion syndrome were established by Beard and colleagues in 1984.[49] The criteria for pelvic congestion syndrome include (1) an ovarian vein diameter of 6 mm or greater, (2) retention of contrast material for longer than 20 seconds, (3) congestion of the pelvic venous plexus or opacification of the ipsilateral or contralateral internal iliac vein (or both veins), and (4) filling of vulvovaginal and thigh varicosities (Fig. 26.15). Each variable is assigned a value of 1 to 3, depending on the degree of abnormality, and scores higher than 5 indicate pelvic congestion syndrome.[49]

Diagnostic criteria for ovarian vein reflux include a left ovarian vein diameter of 6 mm or greater and retrograde left ovarian vein flow (Fig. 26.16). Valvular incompetence exists in up to 47% of all women. In a study of preoperative aortography in

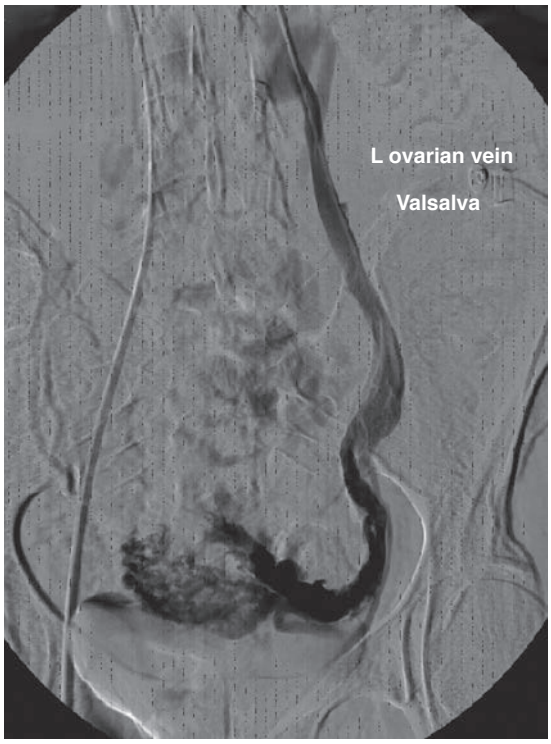

Figure 26.15 Pelvic congestion syndrome resulting from common iliac vein reflux. (Courtesy Mark Meissner, MD.)

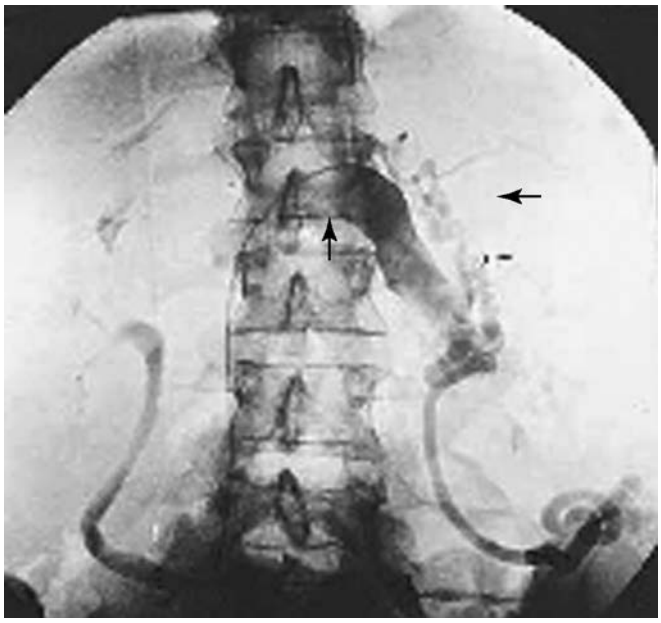

Figure 26.17 Nutcracker syndrome. Retrograde catheterization of the left renal vein shows mesoaortic compression *(vertical arrow)* of the left renal vein and perirenal varicosities *(horizontal arrow)*. Obstruction of gonadal outflow is evident. Kinking and curls of the gonadal vein are the radiographic manifestations of obstruction. This patient had left flank pain and hematuria. (From Scultetus AH, Villavicencio JL, Gillespie DL. The nutcracker syndrome: its role in the pelvic venous disorders. *J Vasc Surg*. 2001;34:812–819.)

273 female kidney donors, Belenky and coworkers found incompetent left ovarian veins in 27 (9.9%).[50] Fifty-nine percent of these patients had pelvic symptoms. A secondary cause arising from iliac artery or left renal vein compression of the left ovarian vein was noted in 20% of these patients.

Venographic evidence of SMA compression of the renal vein may be seen on an anteroposterior view of midstream venacavography (Fig. 26.17). Further delineation is aided by selective catheterization of the left renal vein and looking for proximal compression or pancaking. However, definitive documentation requires measurement of the retrograde renocaval gradient and contrast visualization of the gonadal system, as well as of its pelvic and extrapelvic connections. A renocaval gradient greater than 1 mm Hg is consistent with the presence of nutcracker syndrome.[51]

VENOGRAPHY FOR VARICOCELES

Abnormal distention of the pampiniform venous plexus, the venous drainage from the testicle, results in varicocele formation. Varicocele can be due to absence of testicular vein valves; however, it is generally due to retrograde flow in or impaired drainage of the testicular vein. Veins of the testes, along with tributaries from the epididymis, converge to form the pampiniform plexus. This plexus begins in the scrotum and extends into the spermatic cord and ascends along the cord in front of the ductus deferens. Below the inguinal ring, the pampiniform plexus unites to form three or four veins that enter the abdomen through the inguinal ring and further coalesces to form two gonadal veins. Intraabdominally, on the right side, the gonadal vein drains

directly into the infrarenal IVC; on the left side, the gonadal vein drains into the left renal vein. The left renal vein then drains into the IVC. Collateral pathways for venous drainage of the testis include perirenal, retroperitoneal, and lumbar veins.

Varicocele predominantly occurs on the left side. It is suspected that this is related to the indirect drainage of the testicular vein to the IVC through the left renal vein. Bilateral and right-sided varicoceles account for approximately 10% to 15% of varicoceles.[52] An isolated right-sided varicocele is less frequent, and its presence should prompt an evaluation for obstructive disease like renal tumors or adenopathy.

Patients presenting with varicocele will often report pain and reduced sperm count. Varicoceles have been associated with a time-dependent decrease in size and function of the testes, and this is assumed to contribute to male infertility. The physical examination is the cornerstone in diagnosis of this entity. The patient should be examined in the standing position after he has been upright for at least 5 minutes. Visual inspection of the scrotum should occur first, and obvious distention of the spermatic cord is noted. Next, the patient is palpated before and after a Valsalva maneuver. Previous descriptions of varicocele have described a "bag of worms" or a thickened cord on palpation. Although the physical examination is key in diagnosis, it is subjective. Therefore imaging should be obtained to assist in diagnosis. A duplex ultrasound study can be performed to confirm the physical examination findings. On ultrasound, the presence of two prominent tortuous veins in the pampiniform plexus that measure at least 2 mm in diameter and that increase with the Valsalva maneuver is diagnostic. Other potential imaging modalities include computed tomography and magnetic resonance imaging. However, venography remains the gold standard in diagnosis of varicocele, and reflux of more than 2 seconds is determined to diagnose it.[52]

Indications for treatment include an infertile man with a palpable varicocele and an abnormal sperm count, prophylactic repair in adolescent men with a reduction in testicular size, bilateral varicoceles, and impaired spermatogenesis in patients older than 18 years.[52]

Technique

Access may occur through the femoral or jugular approach. Access through the femoral vein generally requires a sheath or guiding catheter to stabilize the renal vein access and to allow passage of a catheter into the testicular vein. We obtain a venogram from the midpoint of the renal vein to determine renal vein patency and testicular vein incompetence. Venography with a Valsalva maneuver or preferably a tilt table with the patient placed in the reverse Trendelenburg position is performed of the testicular vein, and retrograde flow and collaterals can be visualized. Visualizing the entire anatomy of the testicular vein and pampiniform plexus is necessary to evaluate retrograde and collateral flow, as well as aberrant blood supply to the varicocele. At times during instrumentation, the gonadal vein may spasm, and nitroglycerin is used. If reflux is not demonstrated with this technique, renal venography with a Valsalva maneuver may be used, or an internal iliac study with an occlusion balloon may be warranted. This technique, described before, is used to determine a right- or left-sided varicocele.

Treatment

The goal of treatment is to stop the retrograde flow from the gonadal vein or collateral veins to the pampiniform plexus. Occlusion of the testicular vein should extend from just above the inguinal ligament to 5 cm below the convergence of the testicular vein with the left renal vein on the left side. This technique eliminates all collateral and aberrant vessels. Several techniques for occlusion are available: coil embolization, sclerosing agents, and open surgical repair. Coil embolization is commonly used, owing to its painless ease of use. Coils must be sized correctly to at least 10% larger than the diameter of the spermatic vein at the level of deployment. If the coils are undersized, there is a risk of embolization to the pulmonary artery. Other groups, particularly those in Europe, use sclerosants exclusively. In general, if the right side does not evidence reflux, it is not routinely treated. Open surgical options for repair involve retroperitoneal or inguinal access to the testicular vein for ligation. The traditional open approach usually requires general anesthesia and a 2- to 3-day hospitalization.

Complications associated with treatment of varicocele include spasm, dissection, and perforation. Venous puncture–associated complications such as false aneurysms or hematomas are generally rare. Phlebothrombosis and phlebitis are the most common complications of embolization specific to embolization of the spermatic vein. Patients may present with fever, pain, and scrotal swelling within 24 to 48 hours of intervention. Patients with this complication should undergo an immediate duplex ultrasound examination followed by a repeated study 6 weeks later for evaluation of signs of testicular necrosis, which rarely occurs. Patients may also be treated with a short course of steroids and nonsteroidal antiinflammatory drugs. Antibiotics may also be prescribed if there is difficulty in differentiating phlebitis from infection.

RENAL VENOGRAPHY

The renal veins may be evaluated for anatomic verification or assessment of congenital anomalies or tumor invasion before resection. Renal venography is also useful for the evaluation of suspected renal vein thrombosis in both native and transplanted kidneys. Patients typically have generalized malaise, flank pain, hematuria, and hypertension. Renal vein thrombosis affects men more than women and most often involves the left renal vein.[53] Renal vein thrombosis may arise from four separate causes: (1) thrombus propagating from below to obstruct the IVC and renal veins; (2) caval obstruction or invasion from malignant neoplasms with compromise of the renal veins; (3) primary renal vein thrombosis, which usually occurs in infants; and (4) renal vein thrombosis secondary to nephritis.[54] Catheter venography may be especially useful in patients with acute renal vein thrombosis because it may be followed by therapeutic intervention consisting of catheter-directed thrombolysis.

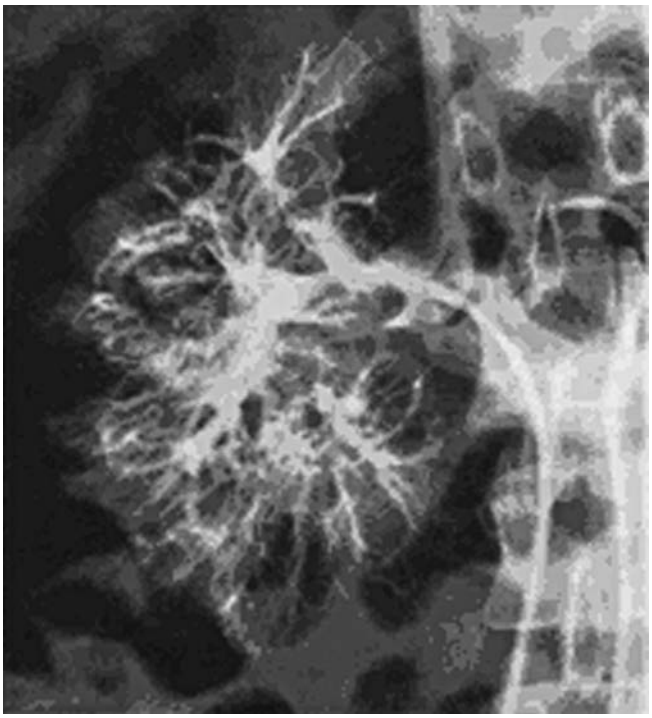

Figure 26.18 Epinephrine renal venogram. The thrombus in the intrarenal veins and the main renal vein is well seen. (From Martin EC, Gordon DH. Selective renal venography in patients with primary renal disease and the nephrotic syndrome. *Cardiovasc Intervent Radiol.* 1980;3:175–179.)

Technique

Midstream venacavography results in characteristic flow voids seen at the L2-3 level as a result of mixing of unopacified renal vein blood with contrast material in the vena cava. However, detailed evaluation of the renal veins is best achieved by selective catheterization. Renal vein selection is easily achieved with standard glide wires and angled catheters. After access to the renal veins has been attained, venography is usually accomplished by hand injections of 5 to 10 mL of dilute contrast material. Improved visualization of the renal veins has been reported with the injection of 10 μg of epinephrine into the renal artery or balloon occlusion of the renal artery (Fig. 26.18).[54]

Interpretation

Although renal venography is a useful technique for demonstrating renal vein anomalies such as a retroaortic left renal vein or circumaortic venous collar, computed tomography and magnetic resonance imaging are currently more commonly used. Venographic diagnosis of renal vein thrombosis depends on the demonstration of a persistent filling defect within the renal vein. Acute renal vein thrombosis may be partial or complete. Detection of intraluminal defects showing partial occlusion and no collateral formation is consistent with acute thrombosis. Chronic renal vein thrombosis would appear as main renal vein obstruction with numerous collaterals around the obstruction. The risk for pulmonary embolism during renal venography and treatment has been reported to be low.[53,55]

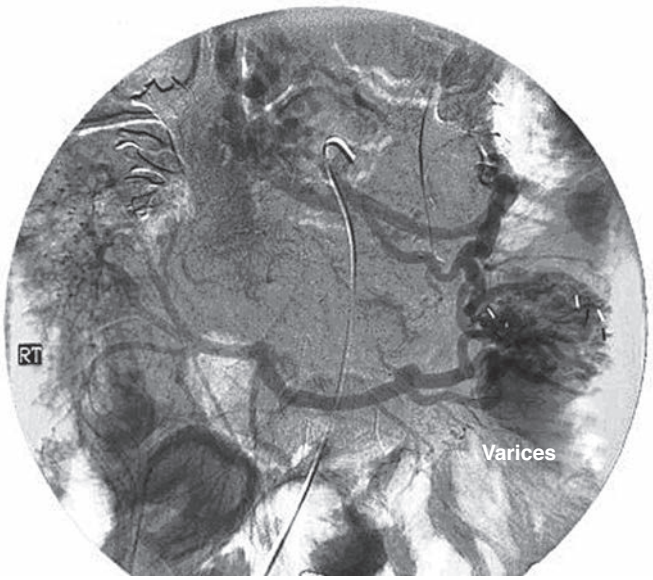

Figure 26.19 Venous phase of a superior mesenteric arteriogram showing occlusion of the superior mesenteric vein. *RT*, Right. (From Ozkan U, Tang SJ, Jutabha R, Jensen DM. Push enteroscopy for recurrent gastrointestinal hemorrhage due to jejunal anastomotic varices: a case report and review of the literature. *Endoscopy*. 2002;34:735.)

Definitive exclusion of renal vein thrombosis requires selective catheterization of the renal veins if an initial midstream venacavogram is normal. Martin and Gordon found that only 6 of 15 (40%) patients with documented renal vein thrombosis had caval thrombus, whereas the cava was completely normal in 46%. The authors suggest that inferior venacavography lacks specificity in the diagnosis of renal vein thrombosis when it is associated with primary renal disease and nephrotic syndrome.[54]

DIAGNOSTIC ANGIOGRAPHY OF MESENTERIC OR PORTAL VENOUS THROMBOSIS

The signs and symptoms of acute mesenteric or portal venous thrombosis are varied and include vague abdominal pain, nausea, vomiting, melena, bloody diarrhea, and ultimately circulatory collapse.[56] The diagnosis is usually accomplished with computed tomography or magnetic resonance imaging but can be made with angiography. High clinical suspicion plus early diagnosis may be lifesaving because it allows systemic anticoagulation or thrombolysis (or both) to be performed.[57]

Technique

Visualization of the superior mesenteric veins may be accomplished either indirectly by review of the venous phase of a superior mesenteric arteriogram (Fig. 26.19) or by direct access (Figs. 26.20 and 26.21). Direct access to the superior mesenteric veins can be accomplished through a transjugular-intrahepatic or transhepatic approach and allows percutaneous intervention.

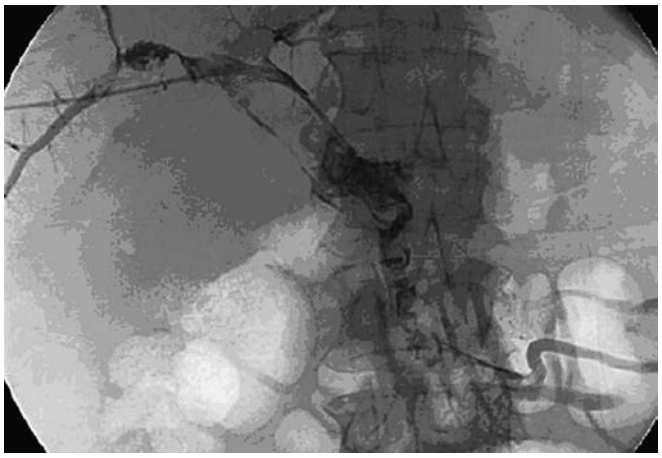

Figure 26.20 Transhepatic venogram showing filling defects attributable to thrombus in the small mesenteric vein, main pulmonary vein, right pulmonary vein, and left pulmonary vein. (From Ozkan U, Oguzkurt L, Tercan F, Tokmak N: Percutaneous transhepatic thrombolysis in the treatment of acute portal venous thrombosis. *Diagn Interv Radiol.* 2006;12:105–107.)

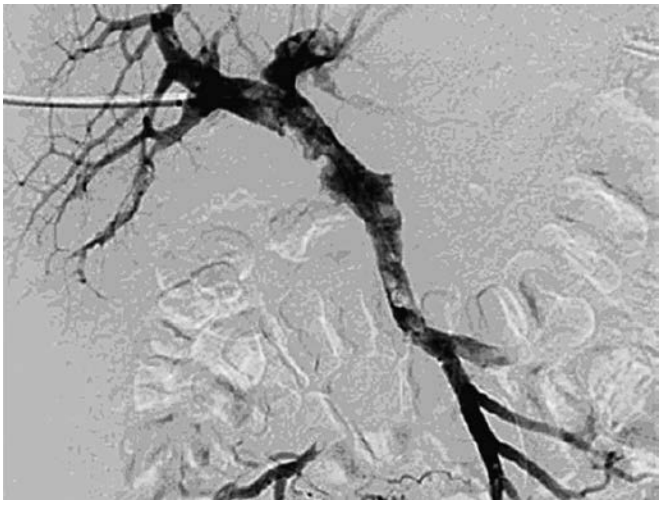

Figure 26.21 Control venography after balloon angioplasty and infusion of recombinant tissue plasminogen activator shows 90% reduction of the thrombus in the superior mesenteric vein and main portal vein, although prominent thrombus is still present in the left pulmonary vein branch. (From Ozkan U, Oguzkurt L, Tercan F, Tokmak N. Percutaneous transhepatic thrombolysis in the treatment of acute portal venous thrombosis. *Diagn Interv Radiol.* 2006;12:105–107.)

The venous phase of an SMA injection provides visualization of superior mesenteric drainage into the portal venous system. After arterial access is achieved, a 5F Simmons 1 catheter is advanced into the aorta. Once the tip is shaped so that it is aimed caudad, the catheter is manipulated into the orifice of the SMA. Hand-injected half-strength contrast dye is helpful in confirming placement of the catheter. Injection of contrast material with a power injector is useful for improving imaging. An injection protocol of 5 mL/s for a total of 10 mL is appropriate. Imaging of the venous phase is accomplished either by delaying acquisition until after injection or by continuing to image after the arterial phase has been completed.

The transcutaneous transhepatic approach is a useful direct technique for access to the portal venous system. Under sonographic guidance, the skin is marked at the point where the right portal vein and the right hepatic vein are aligned in one plane with the portal vein closer to the sonography probe. By use of aseptic technique, the right portal vein is punctured with an 18-gauge needle. After imaging, the superior mesenteric vein has been shown to allow thrombolysis, angioplasty, and stenting in a highly select group of patients.[58]

The transjugular intrahepatic approach to portal venography was popularized in the 1960s by Rösch, who modified the technique of liver biopsy and developed the technique of transjugular intrahepatic portosystemic shunting.[59-62] Transjugular intrahepatic portosystemic shunting is best performed under general anesthesia or heavy intravenous sedation. A 10F introducer sheath is placed through the right internal jugular vein into the IVC. A curved angiographic catheter is used to select a hepatic vein, and the tip of the sheath is then introduced into the hepatic vein. A 16-gauge, 55-cm Colapinto transjugular needle is passed from the hepatic vein through the liver parenchyma into a portal vein branch. A 0.035-inch Amplatz extrastiff guide wire is placed into the superior mesenteric vein and the needle exchanged for a 5F angiography catheter. Portal venography is then performed through a multihole diagnostic catheter placed in the portal vein.[63] Postdiagnostic angiographic embolization of the track formed has routinely been performed, although this is changing.

Interpretation

The superior mesenteric vein joins with the splenic vein to form the portal vein. In general, noninvasive methods of imaging are used as the initial diagnostic modality in the case of portal or mesenteric vein disease. Indirect visualization of the portomesenteric system can be achieved during mesenteric arteriography by prolonged imaging of the venous phase. However, this method does not provide great detail or access for treatment. Advances in percutaneous technology have led to increased use of the transjugular and transhepatic approaches.[57,58,64] These methods carry increased risk for subcapsular or intraabdominal bleeding complications, especially if they are combined with thrombolytic therapy.

DIAGNOSTIC VENOGRAPHY OF BUDD-CHIARI SYNDROME

Normal hepatic venous outflow occurs from the right and left hepatic veins into the retrohepatic vena cava and then into the right atrium (Fig. 26.22). Budd-Chiari syndrome results from thrombosis of hepatic venous outflow, which gives rise to portal hypertension and its sequelae. The liver becomes congested and enlarged, and as the hepatic congestion progresses, hepatic function deteriorates and failure results. For unclear reasons, some patients have mild initial symptoms, whereas others exhibit fulminant hepatic failure and massive hepatic necrosis.[65] Budd-Chiari syndrome can result from various causes, including membranous obstruction of the IVC, pregnancy, oral contraceptive use, tumors, infections, and blood dyscrasias, or it can be

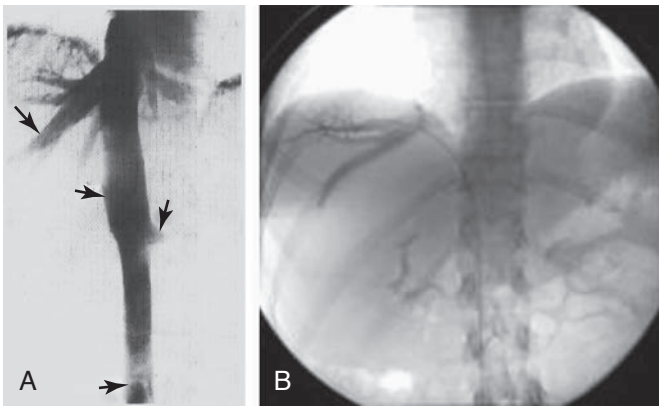

Figure 26.22 (A and B) Normal hepatic venous outflow *(arrows)* demonstrated by cavography and selective catheterization of the hepatic veins. (B courtesy Charles Fox, MD.)

idiopathic. The most useful initial test is a color-flow duplex scan of the portal vein, which will establish the diagnosis. This scan should then be followed by venacavography and portal vein venography with portal venous and vena cava pressure measurements, as well as liver biopsy, to help determine further management.[66]

Technique

The diagnosis of Budd-Chiari syndrome may be confirmed by demonstrating obstruction of hepatic venous outflow, most often by selective catheterization of the right or left hepatic vein. This can easily be accomplished through a transfemoral or transjugular approach. From the groin, a curved catheter, such as a Simmons 1, is manipulated into the suprahepatic cava and then used to select the hepatic vein. From the jugular vein, a straight or angled catheter is easily manipulated into the hepatic outflow tract. Hand injection of 5 to 10 mL of contrast material should reveal a characteristic spiderlike appearance of the occluded hepatic venous system.

In some cases, such as membranous obstruction of the vena cava, imaging is best accomplished with venacavography. A pigtail catheter is placed at the level of the distal IVC. Power injection at 15 mL/s for a total volume of 30 mL would be used. The surgeon should look for filling defects in the distal IVC.

Interpretation

Thrombosis of the hepatic venous outflow tract may be detected by direct catheterization of the hepatic veins. A characteristic spiderlike appearance of the occluded or recanalized hepatic veins is seen (see Fig. 26.22). Distal obstruction of the IVC may take the appearance of a weblike band or stenosis (Figs. 26.23 and 26.24).

UPPER EXTREMITY VENOGRAPHY

Upper extremity venography is the procedure of choice for most clinicians in the evaluation of central thoracic veins and

Figure 26.23 Wedged hepatic venogram showing a fine-meshed spiderweb pattern resulting from an intrahepatic network. (Available at www.emedicine.com.)

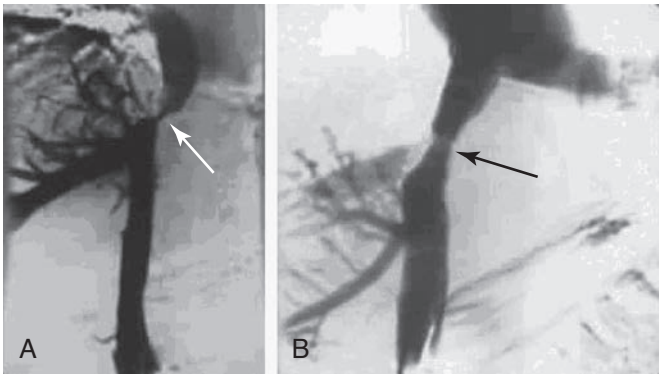

Figure 26.24 (A and B) Inferior venacavogram showing upper inferior vena cava stenosis with reflux of contrast material *(arrow)* into the vena cava. (Available at www.emedicine.com.)

for investigation of upper extremity edema. Upper extremity edema can be caused by acute or chronic venous thrombosis, external venous compression by a tumor of the lymph nodes, venous obstruction secondary to fibrosis after radiation therapy or surgery, superior vena cava (SVC) obstruction, and lymphatic obstruction. Although primary axillary-subclavian vein thrombosis is relatively uncommon (<2% of all cases of DVT), the incidence of central venous occlusion is still rising because of the increasing long-term use of central venous catheters and transvenous cardiac pacers (Fig. 26.25).[67,68]

Upper extremity venography is most commonly used in the investigation of arm edema in patients with primary axillary-subclavian venous thrombosis who are candidates for thrombolytic therapy. The examination is performed to show the extent of thrombosis and to guide placement of infusion catheters for the administration of lytic agents. Other common indications are to evaluate patients with suspected central venous occlusion who are not candidates for magnetic resonance angiography (e.g., because of a cardiac pacemaker or claustrophobia) and to rule out venous injuries from trauma.

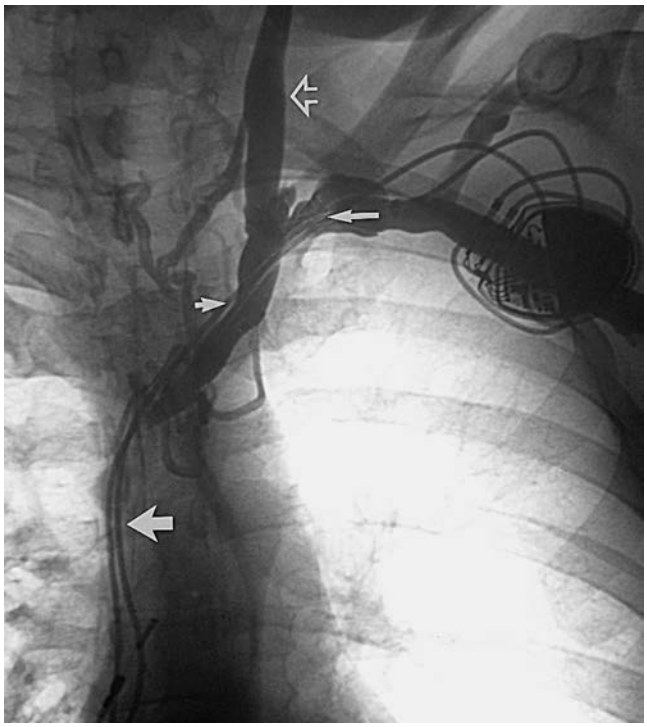

Figure 26.25 Chronic thrombosis of the superior vena cava, the innominate veins, and the subclavian veins caused by cardiac pacer wires. Chronic subclavian venous thrombosis *(long arrow),* the innominate vein *(short arrow),* and the expected location of the superior vena cava *(wide arrow)* are shown. Note the reflux of contrast material up the left internal jugular vein *(open arrow)*.

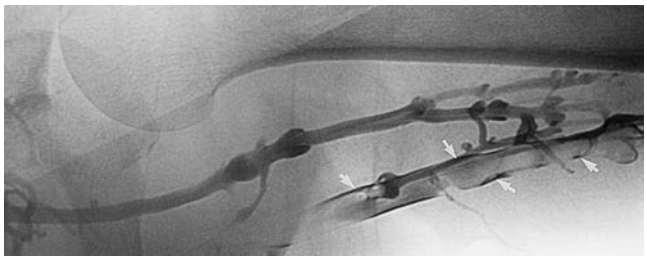

Figure 26.26 Acute thrombosis of the left brachial vein. *Arrows* denote fresh thrombus in the brachial vein.

Technique

Arm venography techniques were initially described in 1971 by Thomas and Andress.[69] The most common method involved accessing the median antecubital vein or a peripheral hand vein and positioning the upper extremity by the side of the patient in 5 to 10 degrees of abduction without the use of tourniquets (Fig. 26.26). Natu and associates modified this technique by abducting the arm 90 degrees, introducing the catheter into a hand vein or forearm vein, and injecting 50 mL of contrast material (Renografin-60) in 5 seconds.[70] If a simultaneous intervention, such as thrombolysis or percutaneous mechanical thrombectomy is contemplated, ultrasound-guided access of the basilic vein in the upper arm is preferred. This site allows for larger sheath placement, as well as a short distance between sheath access site and area of stenosis for improved catheter pushability and control. The arm may be imaged in an adducted position or with less than 90-degree abduction. This can be done with either a hand injection or small volume power injection. The venous system is then reimaged with the arm fully abducted and extended. That position should narrow the thoracic outlet to help diagnose venous thoracic outlet syndrome in patients without axillosubclavian thrombosis.

Interpretation

Significant findings in subclavian venous thrombosis include nonopacification of the vein with filling of collaterals and visualization of the thrombus within the vein. Stenosis or occlusion of the subclavian vein associated with thoracic outlet syndrome typically occurs as the vein enters the chest at the sternoclavicular junction. This point of impingement is often due to hypertrophy of the subclavius muscle. The stenosis is usually more pronounced with the arm in a provocative maneuver (arm abduction and extension). Large collateral vein formation is seen and allows venous outflow from the arm around the point of obstruction. In patients with pacemaker wires, subclavian vein stenosis will typically occur more distally. Patients with central venous catheters will have stenosis or occlusion from the midclavicle, centrally.

CENTRAL THORACIC VENOGRAPHY

Contrast-enhanced venography is considered the diagnostic method of choice for evaluation of SVC obstruction.[71] SVC evaluation is necessary in patients with clinical suspicion of SVC or innominate vein obstruction (or both), many times associated with malignancy.[72,73]

Technique

Sharma and colleagues described their technique for evaluation of the SVC, which involves access in a peripheral vein of each upper extremity and injection of 20 mL of contrast material at a rate of 5 mL/s and a pressure of 150 psi.[74] We perform central thoracic venography similarly by injecting through an intravenous site in the antecubital fossa or forearm with the arm in a neutral position at the patient's side. For each projection needed, 20 to 30 mL of contrast material is injected by hand. Digital images of the mediastinum are obtained at one frame per second until contrast material is seen within the veins, and the frame rate is then increased to three per second. The imaged field should include the upper mediastinum and shoulders for careful evaluation of the site of venous obstruction, collateral channels, and reconstitution of the SVC distal to the obstruction. If central veins are not well opacified with a peripheral IV, then similar to peripheral venography sheath placement can be accomplished percutaneously into the basilic vein with ultrasound guidance. A catheter can then be introduced into the proximal axillary vein, and venography can be performed through a catheter hand injection in closer proximity to the central vein of interest.

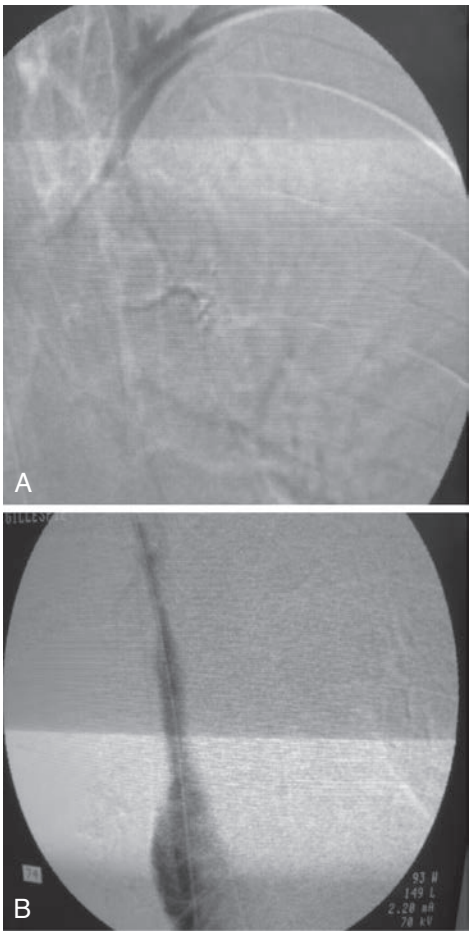

Figure 26.27 High-grade superior vena cava stenosis diagnosed by left (A) and right (B) internal jugular vein catheterization.

In general, contrast material is injected unilaterally for suspected subclavian vein obstruction and bilaterally for suspected SVC obstruction (Fig. 26.27). This helps to compensate for washout of contrast material in the SVC by unopacified blood from the opposite innominate vein. Images are acquired at one frame per second, and the duration of injection and acquisition is determined by opacification of the SVC, brachiocephalic veins, and medial third of the subclavian veins. These structures are commonly obscured within the mediastinal shadows on conventional venography.

Interpretation

Obstruction of the central veins may be associated with either benign or malignant processes. Benign processes are most often related to indwelling catheters for hemodialysis or other infusions. Malignant tumors of the chest may also cause SVC syndrome through external compression or tumor invasion. The existence of large collateral veins arising from the innominate veins and reconstituting in the SVC is indicative of significant obstruction. One may also see less degree of obstruction from extraluminal compression or intraluminal thrombus. Options for treatment of central venous obstruction include operative reconstruction with spiral vein grafts, angioplasty and stenting in select patients, or both (Fig. 26.28).

Figure 26.28 Widely patent superior vena cava after percutaneous transluminal angioplasty and stenting of both the innominate veins and superior vena cava.

PULMONARY ARTERIOGRAPHY

In situations in which there is a strong clinical suspicion of pulmonary embolus and computed tomographic angiography or magnetic resonance angiography is nondiagnostic or the patient has a contraindication to these imaging modalities, pulmonary arteriography should be performed. Pulmonary arteriography is superior to computed tomographic angiography or magnetic resonance angiography for identification of small or subtle peripheral or chronic emboli and has the advantage of being able to measure pulmonary arterial pressure.[75] Another indication for pulmonary arteriography is imaging with intent to treat patient with massive pulmonary embolism through thrombus fragmentation and thrombolysis.

Technique

Selective catheter pulmonary arteriography is performed by advancing a pigtail catheter through the right atrium and ventricle. Angulated pigtail catheters such as the Grollman catheter are preshaped to facilitate advancement from the right ventricle into the pulmonary outflow tract with the guidance of an angled glidewire. Caution should be exercised when the catheter is advanced through the right ventricle because this maneuver can produce transient right bundle branch block. In patients with left bundle branch block, it may cause complete heart block. One should consider the use of a temporary pacemaker in this subset of patients when pulmonary angiography is performed. After the target artery has been selectively catheterized, baseline pulmonary arterial pressure measurements are obtained. The right and left pulmonary artery trunks are

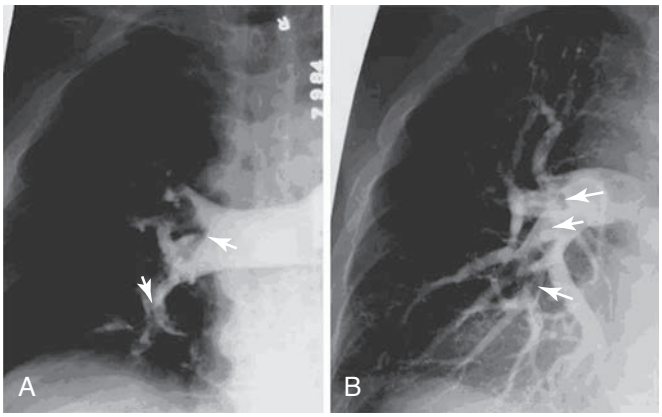

Figure 26.29 (A and B) Pulmonary artery arteriograms showing multiple pulmonary emboli *(arrows)*. (From Santilli JG. Venous thromboembolism in trauma. *Semin Intervent Radiol.* 2003;20:111–124.)

normally evaluated separately. Contrast material is injected at 15 to 25 mL/s for a volume of 30 to 50 mL per injection. Fluoroscopy should be set at high frame rates (4-15 frames per second), and patients should be holding their breath during image acquisition. For complete evaluation, frontal and oblique views of each pulmonary artery should be obtained.

In patients with pulmonary hypertension, injection of large volumes of contrast material into the pulmonary artery is contraindicated. However, patients with chronic compensated pulmonary hypertension can tolerate pulmonary arteriography without difficulty. A right ventricular end-diastolic pressure of greater than 20 mm Hg is considered a relative contraindication to high-volume injection of contrast material, and only small amounts should be injected by hand in such cases.

Interpretation

The classic angiographic sign of acute pulmonary embolism is an intraluminal defect with diminished distal contrast enhancement (Fig. 26.29). Main and segmental pulmonary artery emboli should be easily detectable. Smaller subsegmental pulmonary emboli may be missed with this technique unless digital spot films are obtained. This is often time consuming and less successful. As treatment for massive and submassive pulmonary embolus shifts to percutaneous catheter–directed thrombolysis and mechanical thrombectomy, the use of simultaneous pulmonary angiography will rise despite the widespread use of CT angiogram for its initial diagnosis. Chronic pulmonary emboli are more difficult to detect than acute occlusion and are typically identified as stenosis, webs, or mural thickening consistent with organized thrombus.

GENERAL LIMITATIONS AND RISKS OF VENOGRAPHY

Although venography is still considered the gold standard in diagnosis of DVT and reflux disease, several limitations and risk accompany its use.

Limitations include the invasive nature of the technique, radiation exposure, differences in intraobserver interpretation of the presence or absence of thrombus, and inability to cannulate the appropriate vein in the setting of extremity edema. Several technical issues, such as incomplete filling of the vein, may lead to a 5% to 15% inadequacy of this study. In instances in which the external or common iliac veins are not well visualized, access through the common femoral or iliac vein for venography may need to be accomplished.

Risks of venography can range from minor to major and include pain at the site of injection, local infection at the injection site, extravasation of contrast material, contrast-induced allergic reaction, thrombophlebitis, intraabdominal bleeding complications with the transhepatic approach to evaluate mesenteric or portal vein thrombosis, DVT, and pulmonary embolism. Risks specifically associated with pulmonary angiography include transient right bundle branch block. In those with an already present left bundle branch block, complete heart block may ensue.

FUTURE ADVANCES

It is difficult to ascertain what future role venography will play in the diagnosis of thrombosis or reflux disease. Vascular surgery is a rapidly evolving field, and improvements in less invasive methodologies for diagnosis of disease are evolving. Currently, venography is still the reference by which diagnostic imaging modalities are compared, and its use is preferred in particular instances described earlier in the chapter. As the demand for less invasive diagnostic technology continues, the use of more invasive diagnostic techniques like venography may become more limited. However, the treatment of venous disease is likewise becoming less invasive, shifting from open venous procedures to endovascular techniques. The introduction of intravascular ultrasonography and its utility in venous management had increased the sensitivity and specificity of venography in imaging the venous system, offsetting some of its limitations and yielding more accurate diagnosis and intervention. Venography plays a paramount role in these minimally invasive treatment options, and therefore the knowledge and skill in venography becomes an even greater asset in the vascular surgeons' armamentarium.

Conventional contrast-enhanced arteriography is no longer considered the standard imaging modality for vascular disease.[1-6] As with many technologic advances, however, the process of image creation continues to become more difficult for the average end user to understand. Although the typical vascular surgeon can perform clinical evaluation and can make decisions without an understanding of the basic principles behind computed tomography (CT), these concepts remain important. A better understanding of the imaging process and terminology also aids collaboration between radiologists, radiographers, and the surgeons who use the images to plan interventions. Finally, an understanding of the basic concepts enhances the ability of the surgeon to understand technologic advances as they become the new standard of care.

BASIC PRINCIPLES

In the early 1930s, the Dutch radiologist Ziedses des Plantes first devised a technique that reduced the problem of superimposition of structures in basic radiography (x-ray tube and plain film). Physically connecting the x-ray tube and film opposite each other and rotating the combination around a body segment sharpens the image created by the points on the focal plane, whereas the images of points outside the focal plane are blurred, thereby creating less superimposition artifact. This technique was called "planigraphy" or "tomography," derived from the Greek words *tomos*, which means "a section" or "a cutting," and *graphein,* meaning "to write." Tomography played an important role in diagnostic radiology until the 1970s, when invention of the transverse axial scanning method together with the availability of minicomputers, which allowed computational reconstruction of images, led to the development of so-called computed axial tomography (CAT scan, or later, CT scan).

Two similar methods for transverse axial scanning and image reconstruction were independently invented by Sir Godfrey Newbold Hounsfield in Hayes, United Kingdom, at Elector-Musical Instruments (EMI) Limited Central Research Laboratories, and Allan McLeod Cormack of Tufts University in Massachusetts. A combination of hardware, mathematical algorithms, and computer software resulted in the cross-sectional images. The first so-called EMI scanner was installed in Atkinson Morley's Hospital, Wimbledon, England, in 1971.[7] In the United States, the first installation was at the Mayo Clinic in Rochester, Minnesota. These machines would acquire two adjacent brain tomographic sections in about 4 minutes and needed about 7 minutes of computation time per picture. This was such a leap forward in imaging technology that Hounsfield and Cormack shared the Nobel Prize in 1980.

Many of the principles used in this first-generation CT scanner are still in use today and provide a framework for understanding the technology. The fundamental unit for this scanning method consists of an emitter and a detector. The emitter produces a thin x-ray beam. The beam is transmitted through the tissue and detected on the other side. The attenuation (the rate of reduction of x-ray energy recorded at the detector) of multiple x-ray beams traversing the same point in the matrix from different angles is collected and an ingenious method applied to calculate backward to the density or CT number that must be present at each location in the matrix.

The resulting CT number is expressed in Hounsfield units (HU). CT numbers range from the extremes of air (−1000 HU) to dense bone (>1000 HU), but fat (−20 to −100 HU), water (0 HU), and muscle and blood (40 to 60 HU) tend to lie in a much narrower range. Differences in factors such as the energy level of the beam and tissue thickness prevent the density in HU from being absolutely uniform from one CT scan to another, but the ranges are similar. When the range of CT numbers for a scan is determined, it can be broken up into smaller ranges for graphic display by a set of gray-scale values. Each gray-scale data point in the matrix is known as a pixel because it represents a "picture element." When displayed as a whole, this matrix of gray squares becomes an interpretable image.

Types of Scanners

Single-Slice Sequential Computed Tomography

A first-generation CT scanner is capable of producing a cross-sectional image with a 160 × 160 matrix. These CT scans were applicable only to parts of the body with limited motion (e.g., the head). To obtain useful scans in areas such as the chest and abdomen, subsequent generations of CT scanners were designed to decrease the time required to obtain a complete cross-sectional image.

Spiral (Helical) Computed Tomography

With development of a so-called slip-ring gantry, the emitter and detector array can rotate continuously in the same direction, and at the same time, the computer can acquire data continuously. If the table moves in a continuous linear motion through the gantry while the x-ray emitter and detector rotate continuously over 360 degrees, data can be acquired in a single sweep over the entire volume of interest. In this technique the emitter traces out a spiral relative to the patient, which is referred to as a spiral CT or helical CT scan.

Spiral or helical CT technology has several important ramifications beyond a simple decrease in scan time. A spiral CT scan collects data over a continuous volume rather than discontinuous slices (Fig. 27.1). The most obvious advantage of acquiring data

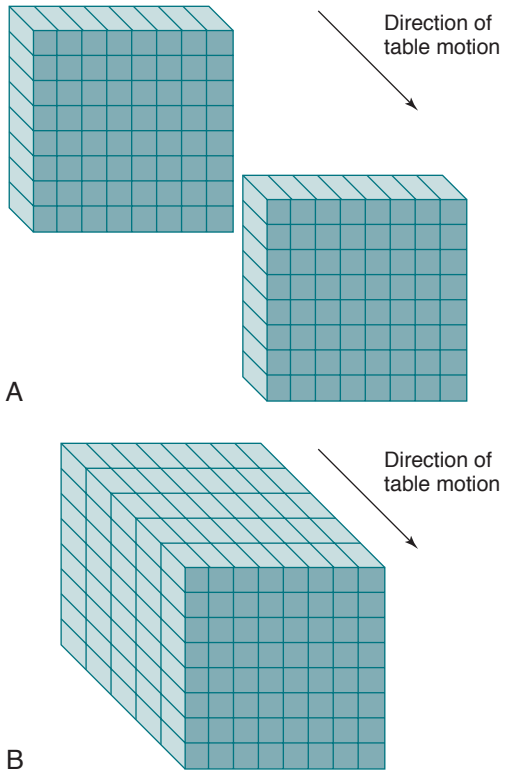

Figure 27.1 Discontinuous data collection (A) versus continuous data collection (B) for conventional and spiral computed tomography.

over a continuous volume is that thin axial slices can be reconstructed from the digital data set at arbitrarily small intervals without additional radiation exposure. Single-slice sequential CT can produce similar overlapping or adjacent axial slices, but the tradeoff is increased scan time and additional radiation exposure. The advantage of sequential scanning, however, is a lower level of reconstruction artifacts because table movement along the z-axis during scanning does not need to be corrected in the acquired data sets. This is the main reason why sequential scanning is often used for brain imaging.

Multislice (Multidetector) Computed Tomography

Multidetector scanners have multiple rows of detectors in craniocaudal direction (z-direction), so that the volume to be scanned can be covered more quickly. Whereas a single-slice detector acquires one slice per rotation, multidetector CT scanners are capable of acquiring multiple separate slices or 1 big volume per rotation. Each slice can be acquired at 1-mm or even smaller with rotation times in the range of 0.2 to 0.3 seconds. Complete imaging of the abdominal vasculature can be accomplished in a fraction of the time required with previous-generation scanners. This diminishes or eliminates many artifacts or compromises that must be dealt with in single-row detector scanners, as discussed subsequently. For this reason, multidetector or multirow scanners have almost completely replaced the earlier-generation single-row scanners.

Advances in hardware and computer software technology have also greatly improved the graphic image display despite the reduction in scan times. A first-generation CT scanner produced a cross-sectional image with a 160 × 160 matrix, but current scanners typically generate a 512 × 512 matrix. Each data point in the matrix is mapped to a gray scale for display, so the size of the matrix and the field of view (FOV) have a direct impact on spatial resolution of the display (the smallest distinguishable element). Data points are displayed as a two-dimensional (2D) picture, and each point in the display matrix is a pixel (picture element). Data points are acquired in three dimensions, however, and each data point in the matrix actually represents a voxel (volume element). The size of the voxel is determined by multiple factors, including FOV (x, y direction) and detector design (x, y, z direction).

Computed Tomography Angiography

Visualization of vessels on CT is limited by the similar densities of blood and soft tissue. Administration of iodine intravenous contrast material highly overcomes this problem, However, optimal visualization of the vessels (computed tomographic angiography [CTA]) was not possible until the availability of fast spiral CT: faster scan times and increased numbers of detectors will allow a larger part of the body to be imaged as the contrast bolus passes.

Timing of the initiation of image acquisition relative to injection of the contrast agent is crucial for maximizing opacification of vessels in the scanned volume. Various dedicated bolus tracking algorithms have been developed by the CT scanner manufacturers to detect contrast arrival in the vessel of interest in order to start the scan on an appropriate time. These algorithms are all based on a stationary, continuous scan of a single slice in which contrast density is measured in an area of interest (usually a large vessel) marked by the operator. Only after a sufficient increase in density is measured is the spiral CT run initiated.

The iodine concentration, injection rate, and the length of the contrast bolus are important parameters. Bolus length should be balanced against the length of the volume to be imaged. Because large distances must often be covered, CTA generally previously required a significant infusion of contrast material. In the past, a typical CTA study from the celiac axis down to the external iliac arteries would require 120 to 180 mL of 300 mg/mL nonionic contrast.[8,9] For optimal arterial enhancement, fast injection rates are important.

Optimization of scanning and power injector protocols, faster scanning times, and the use of saline push bolus techniques reduced this volume significantly, and often volumes do not exceed 100 mL and can only be several milliliters.

Split-bolus techniques are alternative ways of administering intravenous contrast. These techniques employ multiple phases—for instance, enhancement of venous and arterial structures—in one single scan. This is achieved by splitting the contrast bolus volume into one early bolus of contrast and one late bolus of contrast administration before obtaining the CT scan. This technique decreases ionizing radiation dose since fewer scanning phases are needed per patient.

Another factor that increases contrast enhancement is lowering of beam energy (kvpeak) which increases iodine density on scans.[10]

Acquisition Parameters

A scan protocol consists of a series of settings of acquisition and contrast parameters, reconstruction parameters, technician and patient instructions, and maneuvers to generate a set of images that is optimal for the specific anatomy and indication for the CT scan. The protocol includes the setting of x-ray emitter parameters (i.e., beam energy expressed in kilovolts peak [kVp] and tube current expressed in milliampere-second [mAs]), rotation time, length of helical exposure, pitch, collimation, patient instructions (i.e., breath-hold), dosage of contrast material, delay, volume and infusion rates, reconstruction interval and reconstruction algorithm, parameters of radiation dose optimization tools, and FOV.

Prescan and postscan parameter settings should be distinguished from each other. Various postscan settings, such as the reconstruction algorithm or interval, can be applied to the raw image data. This is not true for the prescan settings. Obviously, an improper prescan setting cannot be corrected after the images have been acquired. Particularly in multislice scanners, proper prescan settings are important and have a direct impact on the diagnostic value of the scan.

Scan parameter settings are also important for optimization of the scan protocol in relation to the clinical question because this may be the only way to limit the radiation dose delivered by the scan.

Prescan Parameters

kVp and mAs

Tube voltage, measured in kVp, is the value that determines the energy level of the x-ray tube. Higher tube voltage renders better tissue penetration but leads to decreasing relative contrast differences between the various tissues. High kVp settings (120 kV) are recommended to allow sufficient photons to reach the detector elements in obese patients. In children or slim patients, low kVp settings (80 kV, or even lower) should suffice and also produce increased contrast differences.

mAs values describe the tube current time product. The mAs value is linearly related to the duration and amount of radiation. Higher mAs represents more radiation delivered by the x-ray tube and leads to a decrease in image noise because more photons will reach the detector. However, this decreased noise is achieved at the expense of an increased radiation dose to the patient. kVp and mAs settings are closely linked, and a change in one may dictate a change in the other.

Collimation

Collimation is a method of reducing the thickness of the x-ray beam. Collimation has a direct impact on spatial resolution in the z-axis and determines the smallest possible slice thickness.

Table Feed and Pitch

Pitch (P) is defined as the ratio of table feed (the speed at which the table moves during tube rotation) and collimation. Values above 2 will result in undersampling of the region of interest and might result in artifacts. Values below 1 will result in overlapping scans, which might be beneficial for three-dimensional (3D) reconstructions but will also increase the dose significantly if other scanning parameters are kept constant. For multislice CT scanners, pitch calculations are different, depending on whether single collimation of one detector ring or total collimation of the whole detector array is chosen. An asterisk indicates that total collimation of the detector array is being described; for a four-slice scanner, a pitch of 2 corresponds to a P* of 8.

$$P = TF/SC$$

$$P^* = TF/(N \times SC)$$

where P = pitch, TF = table feed, N = number of detectors, and SC = single-section collimation.

To give an example for a 64-slice scanner, if pitch is set at 2 and collimation is set at 1 mm, the resulting TF—according to the formula P* = TF/(N × SC)—will be 64 mm/s.

Scanning time is the maximum duration of a scan that a certain tube allows while not exceeding the maximum permissible heat capacity. Older scanners are limited to approximately 20 seconds, whereas newer scanners allow scan times of up to 100 seconds.

Patient Positioning

Proper, central positioning of the patient in the gantry can significantly improve image quality and decrease radiation dose.

Figure 27.2 Beam-hardening artifacts caused by the humerus as a consequence of scanning with the patient's arms alongside the upper part of the chest.

A clear example is raising the arms of the patient when scanning the upper part of the chest (Fig. 27.2).

Contrast Protocols

With the newer scanner types, good timing of the administration of contrast material has become an essential part of the examination. Depending on the indication and parameter settings (pitch), optimization of total volume of contrast, contrast iodine density, volume, and speed of injection is required.

Dual Energy/Source Computed Tomography

Dual energy/source CT was introduced as a novel new technique in 2006. Instead of one x-ray tube, the system was equipped with two x-ray tubes each working at a different kVp. The application of dual-energy computed tomography offers two advantages. The simultaneous availability of high and low peak kilo voltage gives improved visualization of the aorta due to an improved conspicuity of contrast media at lower kVp CT imaging. This, in turn, permits an improved aortic visualization or allows for a reduction in volume or rate of the contrast administration. The inherent increased image noise at low kVp is compensated by the simultaneously acquired high kVp images. The second advantage is the potential to calculate material-specific densities from the simultaneous availability of attenuation measurements at 2 distinct energies. Improved visualization of bone, contrast, or even soft tissue might improve visualization and might decrease the need for multiphasic imaging and allows for the application of bone subtraction resulting in subtracted angiographic like images.[11]

It is still uncertain whether dual energy/source CT will become the gold standard. The use of two different x-ray tubes does have inherent hardware design issues. Also, the inherent advantages of dual energy might also be acquired by smart software algorithms with a single source CT.

Postscan Parameters

Increment

The increment or reconstruction index defines the spacing of the reconstructed images from the raw data set. One could, for instance, decide to reconstruct only a 1-mm slice every 3 mm. The main advantage would be the fewer number of reconstructed slices than if a 1-mm slice had been reconstructed for every position. If the raw data are saved, it is possible to obtain reconstructed images at different positions retrospectively.

Slice Width

Slice width or section collimation defines the thickness of the slice. Slices of various thickness ranging from 0.5 to 10 mm can be calculated from the raw data. The minimum slice thickness, however, is defined by the prescan collimation setting. The main advantage of a thicker slice is a lower noise level and a significant reduction in the data load.

Field of View

As mentioned previously, the size of the display matrix and FOV have a direct impact on axial resolution of the display. By keeping FOV to the minimum necessary, pixel size is decreased. If FOV is 30 cm and the matrix size is 512 × 512, each pixel in the display of axial slices is 0.6 mm. If FOV is reduced to 20 cm, pixel size is improved to 0.4 mm, but the tradeoff is that a higher radiation dose is required because of an increase in detector noise.

In general, a small FOV is important only when detailed measurements are necessary (e.g., in endovascular surgery, calculation of carotid artery stenosis or intracerebral aneurysms). In addition, factors such as contrast density, timing of administration of contrast material, window level (WL), and window width (WW) more strongly affect the ability to distinguish different structures and the edges of these structures.

Windowing

WW sets the number of gray scales displayed, and WL defines the middle gray-scale value of the width. Windowing sets the contrast and the brightness of the image.

Reconstruction Algorithms: Filtered Back Projection and Iterative Reconstruction

Reconstruction algorithms are used to reconstruct the raw data. Basically during a rotation of the tube, obtained one-dimensional (1D) data sets (raw data) are reconstructed in a 2D data set (back projection). Obtained images in this way are very fuzzy and additional filters need to be applied in order to improve image quality (filtered back projection). Initially, filtered back projection was the algorithm of choice. The algorithm determines the relation between spatial resolution and noise and thus contrast resolution. Changing of parameter settings allows optimization of the images. For instance, if a high spatial resolution (bone or lung pathology) is needed, high-resolution convolution kernels (HR kernels) are applied. This will result in a significant increase in spatial resolution and improved imaging for bone or lung, but at the expense of a significant increase in image noise.

With the increasing computational power of current systems, iterative reconstruction has became the major reconstruction algorithm for clinical practice.

With iterative reconstructions mathematical calculations of the cone shape of the x-ray beam, the shape of the voxels, focal spot, nature of the x-ray beam, and detectors are all taken into account. By doing this, image noise can be reduced significantly compared to the filter back projection algorithm (70% to 90%).

The initial iterative reconstruction algorithms were in part based on filtered back projection, but the most recently introduced iterative reconstruction algorithms are fully model based, which means that no filtered back projection is necessary. The major advantage of these algorithms is a substantial decrease in noise and therefore lower radiation doses with an inherent higher noise level can be used, and this will be compensated by the algorithm. The major disadvantage, however, is the high demand on computational power, which, with the ever increasing improvements in computational power, is becoming less of a problem.

Dynamic Computed Tomography Scanning

With the increased number of detector rings in the new multislice scanners, dynamic CT scanning has become an option.[12] The basic concept is that of obtaining CT images at a fixed location (in other words, without moving the table) during the injection of contrast material. After injection of a contrast agent, imaging at a fixed position with continuous rotation of the CT gantry will provide insight into passage of contrast material through the arterial, capillary, and venous phases, representing tissue perfusion. The maximum anatomic area covered by this type of imaging is determined by the z length of the detector area. The 256 and 320 scanners are better suited for this technique and are currently used predominantly for brain and cardiac perfusion studies.

Electrocardiogram Triggered and Gated Scanning

Techniques that couple the electrocardiogram (ECG) signal to scan acquisition can be used to obtain images without cardiac pulsation artifacts at the level of the heart, coronaries, and the ascending aorta. Retrospective ECG-gated CT acquisition is a scanning technique in which the ECG is registered during the scan and coupled to the raw data obtained.[13] By partial reconstruction of the images, it is possible to obtain an image at, for instance, 10 different phases of the ECG. The technique is now available on almost all 64-slice scanners and is most often used for coronary imaging.[14] Because partial reconstructions are used, a major drawback of this technique is that the resulting images are substantially noisier than the full reconstructions. In prospective ECG-gated CT acquisition, the x-ray beams are turned on during preselected phases of the cardiac cycle. The main benefit of this way of sampling is the far lower radiation dose, which, in comparison with retrospective gating, proved to be reduced by 52% to 85%. The main disadvantage is that only preselected phases can be reconstructed.

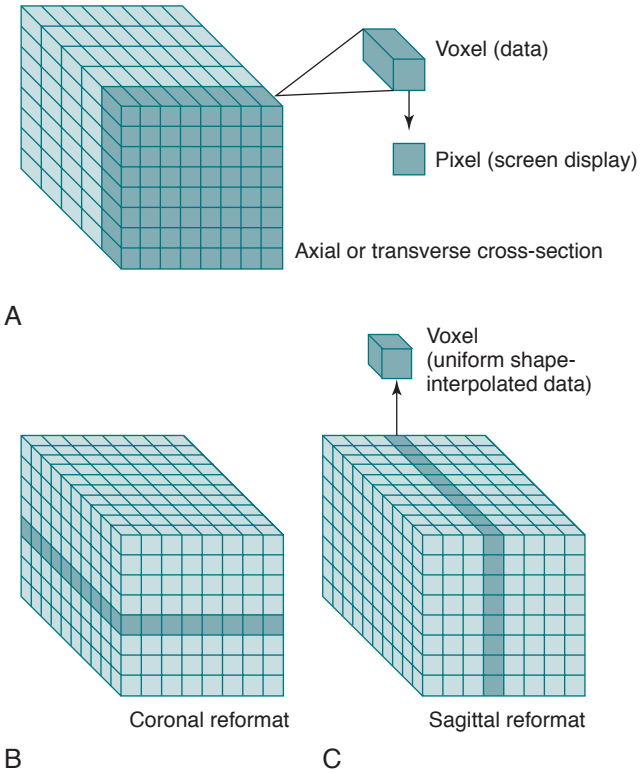

Figure 27.3 (A to C) Because spiral computed tomography (CT) data are acquired and stored over a continuous volume, they can be used to create axial (A), coronal (B), and sagittal (C) sections. For display purposes, the nonuniform voxel can be interpolated into a cube, but the quality of the data still depends on the length of the original voxel (which is determined by the collimation). Reformatting CT data into coronal, sagittal, or other nonaxial planes is often referred to as multiplanar reformatting.

Postprocessing

Multiplanar Reformatting

Reformatting CT data into coronal, sagittal, or other nonaxial planes is often referred to as multiplanar reformatting or multiplanar reconstruction (MPR). A schematic representation of this process is shown in Fig. 27.3. The ability of spiral CT to view the data in coronal, sagittal, or arbitrarily defined planes often gives more insight into vascular anatomy than possible with axial views alone.[15]

Measurements

Simple axial CT slices often do not cut through planes perpendicular to the vessel, which results in elliptical cross-sections that can make measurements of diameter difficult (Fig. 27.4). Generally, the narrowest diameter of the elliptical cross-section is the "true" arterial diameter, but this is not always the case because the aorta does not always have a simple cylindrical or conical shape.[16] Conventional CT may lead to a slight overestimation of diameter on axial slices, whereas spiral CT slices reconstructed perpendicular to the vessel tend to be more accurate.[3,20] Simply using sagittal or coronal reconstruction is not always adequate because these sections may not be perpendicular to the vessel or may not cut through the center of the vessel over an adequate length. Curvilinear reformats continue to improve, but they make measurements of length difficult and straighten out angles, which may affect an endovascular repair. Spiral CT with 3D reconstruction and CT reformats perpendicular to the vessel lumen eliminate the diameter measurement problems associated with the other techniques (see Fig. 20.4).[3,17-20] CTA with 3D reconstruction offers several other important benefits that are key for imaging before endovascular surgery. In conjunction with spiral CTA and MPR, 3D reconstruction speeds assimilation of the CT data and makes the extent of an aneurysm rapidly apparent.[3,18,19] More important, specialized measurement software and unique aspects of the 3D reconstruction can eliminate most of the measurement problems associated with conventional techniques.[3,17-20] Software algorithms can be used to display the centerline of the blood flow channel in the infrarenal aorta and iliac arteries and allow measurements of length along the vessel centerline in tortuous aortic or iliac segments.[17] In some systems, graft paths along a line other than the centerline can also be defined by the user, which is necessary because an endovascular graft may not follow the centerline of the blood flow channel throughout its entire course.

3D reconstructions can be used to calculate the volume of any structure in the 3D model, and data on imaging of tumors and other 3D structures indicate that volume measurements are much more sensitive to changes in size than measurements of maximal diameter.[21-23] Multiple institutions have confirmed that volume measurements are much more sensitive than maximum diameter measurements for the detection of changes in size of abdominal aortic aneurysms (AAAs) after endovascular AAA repair, and it seems that volume is the "gold standard" for early detection and accuracy regarding aneurysm growth or shrinkage.[24-29] Early detection of aneurysm enlargement can be crucial in follow-up of endovascular repair because it indicates that the aneurysm is still at risk for rupture and usually precedes evidence of endoleak or overt rupture.[26,30-32] CT volume measurements may become a standard postoperative test for aneurysm exclusion or risk of rupture either routinely or if the aneurysm is not clearly shrinking.[24-29] These same studies indicate that there may also be a role for early volume measurements within the first 6 months to more clearly identify decreasing aneurysms that may need less frequent imaging or may be able to avoid secondary interventions.

Several systems providing all of the aforementioned display and measurement tools (and more) are commercially available or in development.

Three-Dimensional Reconstruction

The combination of rapid scanning over the volume of interest, new software algorithms, and advances in computer technology has made it possible to create 3D-like reconstructions from spiral CT data. The reconstruction can be limited to individual structures that meet certain parameters, such as density or location within the scan volume. If bony structures are of primary interest, the computer algorithm can select only the elements of the CT (voxels) that are of bone density (i.e., CT numbers representing bone). For vascular structures, CTA produces

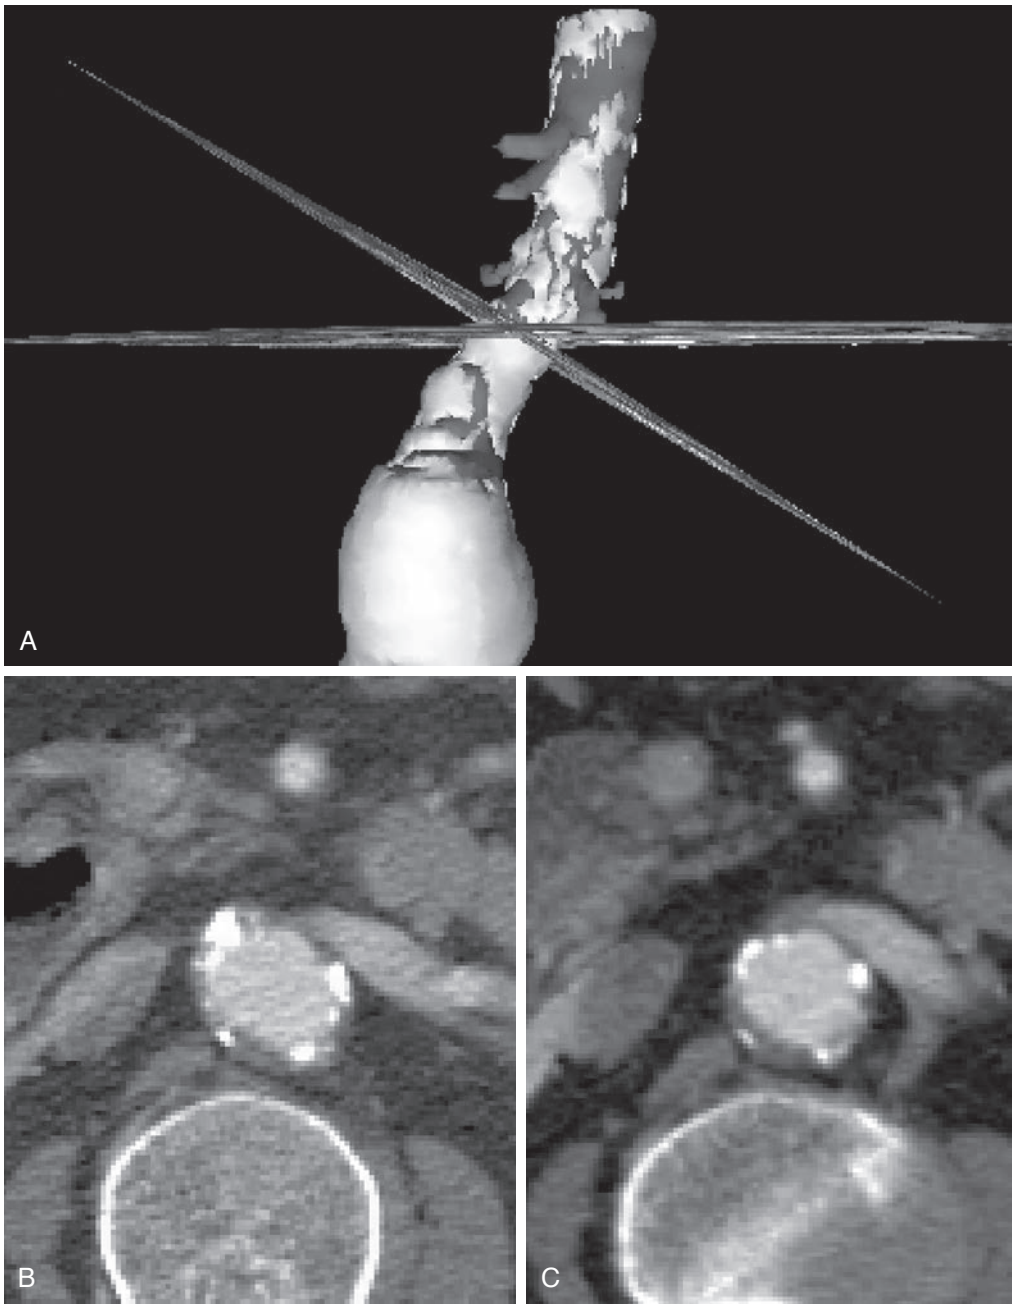

Figure 27.4 Diameter measurement issues and solutions using computed tomography (CT). (A) Three-dimensional (3D) reconstruction with simultaneous display of CT slices in 3D space. The CT slices shown here are a standard axial reformat and a reformat perpendicular to the aorta. The 3D model was rotated to show the intersection of the two CT slices at the same location on the aorta. (B) The same axial CT slice as shown in (A). The axial slice does not intersect the aortic neck perpendicular to its axis, thereby creating an elliptical cross-section. Although the smaller diameter (minor axis of the ellipse) is usually similar to the true diameter, elliptical cross-sections also occur in noncylindrical vessels and at the margins of aneurysms. Viewing multiple cross-sections in sequence can help with this problem, but evaluation is still difficult. (C) The CT slice reformatted perpendicular to the aorta (shown in A) accurately depicts the essentially circular lumen and provides a diameter measurement without ambiguity. This cross-section of the aorta also provides a more correct impression of thrombus thickness, which is artifactually enhanced on an elliptical cross-section. The renal vein and vertebrae help verify the magnification, location, and orientation of the slices.

contrast density within the vessel lumen so that 3D reconstruction of the vessel lumen can be performed. When this type of 3D reconstruction (or 3D model) is created, the density (CT numbers) of vascular contrast and bone may overlap. Bone structures are either included in the model or "cut away" manually. Calcium within the vessel wall cannot be cut away easily, however, and is usually included in a reconstruction of the contrast-enhanced vessel lumen. This produces the typical computer-generated 3D reconstruction, which most often is displayed as a shaded surface display (SSD). In an SSD, the

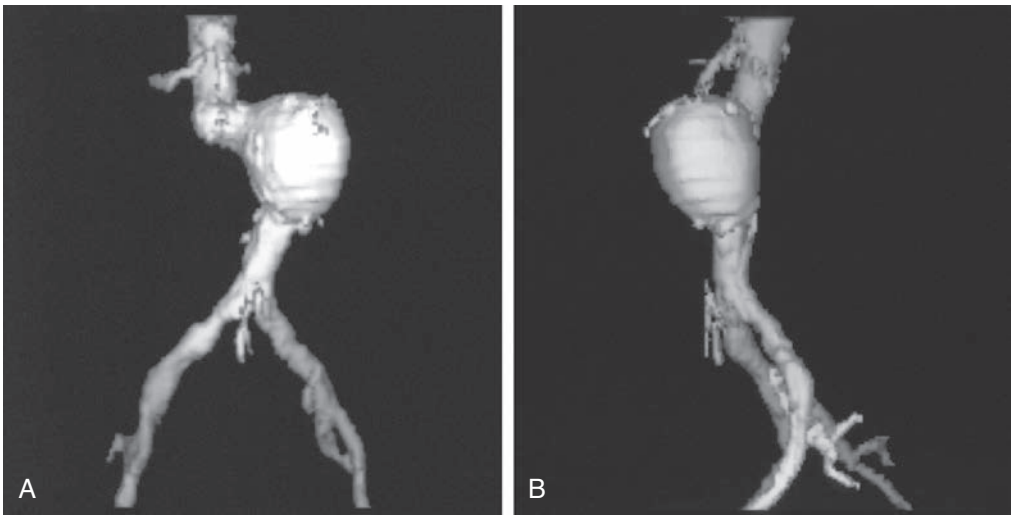

Figure 27.5 Computer-generated shaded surface display (SSD) of computed tomography data. The three-dimensional (3D) relationships of the aneurysm and surrounding structures are immediately apparent in these anteroposterior (A) and left lateral (B) views. In this typical single-object 3D SSD, the threshold for reconstruction is the density of contrast-enhanced blood. Because calcified plaque is denser than contrast-enhanced blood, it is included in the reconstruction. The spine was removed electronically before making the 3D reconstruction. An infinite number of views are possible on the workstation used to create the views, but a limited number of views are printed as hard copy to show the anatomy.

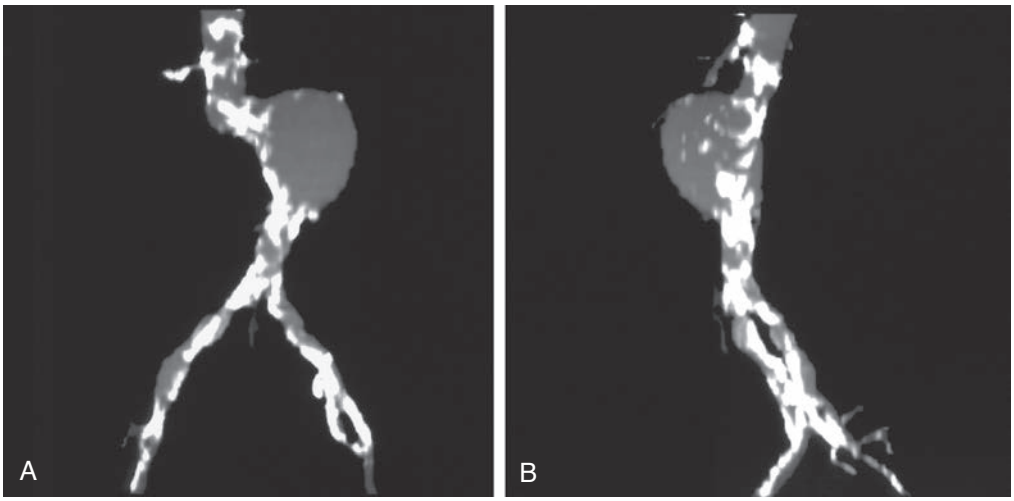

Figure 27.6 Maximum intensity projection (MIP) images of the same abdominal aortic aneurysm shown in Fig. 27.5, anteroposterior (A) and left lateral (B) views. Because this reconstruction represents a two-dimensional projection of the structure along a line defined in three-dimensional space, the MIP appears to be similar to an arteriogram. Only the structure with maximum intensity is projected, so calcified plaque is displayed prominently. MIP images display calcified plaque well, but this same feature can obscure the residual lumen in locations where the vessel is heavily calcified (note the iliac arteries in particular).

exterior of the structure is opaque and shaded to provide an appreciation of depth (Fig. 27.5). The 3D reconstruction can greatly aid in the interpretation of difficult anatomy. Although it lacks the detail of CT scans, morphology within the 3D image is easily recognizable in far less time than it takes to review the CT data. This depiction of 3D relationships is probably most helpful in surgical planning for complicated open procedures or endovascular procedures.[18,19,33,34]

One problem with the SSD of 3D models is that the bulk of structures, such as calcified plaque, cannot be fully appreciated because all CT numbers (physical densities) included in the model are given the same opaque color in the display. One method that better displays different physical densities is called the maximum intensity projection (MIP). MIP images display the 2D projection that would result if one could see only the densest structures (structures that project the maximum intensity). Although an MIP image is created from 3D volume data, it is a projection—similar to an angiogram—and must be defined from a particular point of view (Fig. 27.6). MIP images are relatively familiar to surgeons and interventional radiologists,

and they display calcified plaque well. Adequate evaluation of the structure requires many views, however, and even then a heavily calcified vessel may obscure important details regarding the vessel lumen and degree of stenosis.

Another method developed to improve the display of structures with different physical densities involves the SSD of multiple objects simultaneously. In vascular surgery, the most clinically relevant structures are the contrast-enhanced vessel lumen, calcified plaque, noncalcified plaque, and thrombus. Noncalcified atherosclerotic plaque and thrombus have essentially identical CT numbers and cannot be distinguished as separate objects. The latter two structures are distinct from contrast-enhanced blood flow, however, and blood flow can be distinguished from calcified plaque to a reasonable degree. With proper CT protocols and software algorithms, these structures can be displayed separately on the basis of density. The resulting 3D reconstructions display information that is not available in any other imaging modality (Fig. 27.7). Because the separate elements can be viewed in combination or separately, this type of reconstruction has the advantages of single-object SSD and MIP without most of their disadvantages. This 3D method can display best the extent of an aneurysm (because thrombus is visible), degree of calcification, and lumen narrowing secondary to plaque (especially if structures of differing density can be made invisible or transparent) (Fig. 27.8).

It is important to realize that a 3D SSD is a representation of a real 3D data set, unlike the "fake" 3D created in pictures (or movies) whereby a pair of 2D photographs, each taken from the same point but at a slightly different angle, emulate

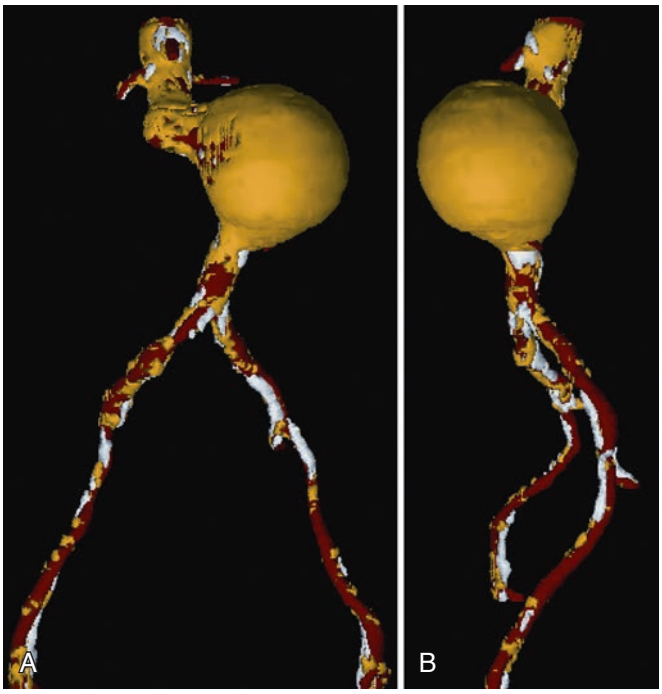

Figure 27.7 Multiple-object shaded surface display, anteroposterior (A) and left lateral (B) views of the same abdominal aortic aneurysm seen in Figs. 27.5 and 27.6. Contrast-enhanced blood flow is displayed in *red*, thrombus and noncalcified plaque in *yellow*, and calcified plaque in *white*. In this type of three-dimensional reconstruction, all the components of the aneurysm are seen. Multiple views are helpful, and it is preferable if the display can be rotated and viewed at will on a computer screen. This type of display is most helpful in determining the true extent of an aneurysm because thrombus is clearly visible.

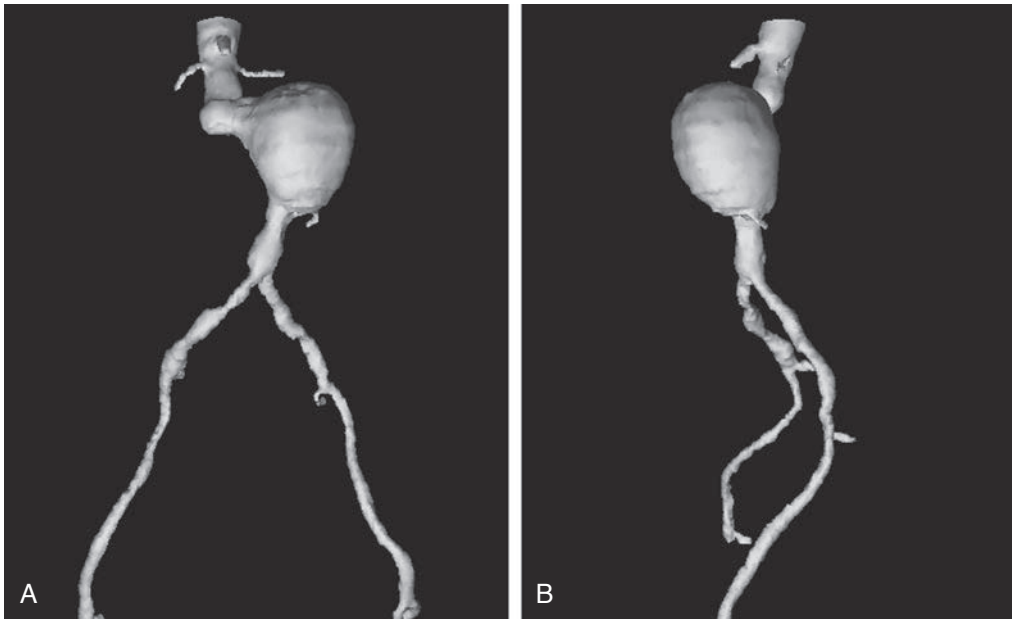

Figure 27.8 Multiple-object shaded surface display (SSD) from Fig. 27.7 with the same anteroposterior (A) and left lateral (B) views and all structures made invisible except blood flow. With calcified plaque made invisible, the degree of occlusive disease becomes apparent in the iliac arteries. A key point is that calcified plaque was modeled separately and has been made invisible so that this three-dimensional reconstruction does not have the same appearance as the typical single-object SSD shown in Fig. 27.5. For surgical planning, it is preferable if the objects can be made visible or invisible at will on a computer screen. An alternative is to print hard-copy images in multiple views with the various components sequentially highlighted, transparent, or invisible.

the physiologic parallax of binocular real 3D vision. Still, this 3D SSD model is displayed in 2D, and real visual depth information is therefore missing. To add the value of depth, several solutions have been proposed. One is the use of sophisticated software programs that add perspective to the 3D CT data (Dextroscope, Bracco AMT, Princeton, California). The main limitation of this technology is that the observer is required to wear dedicated polarizing glasses to see this effect. With the development of 3D monitors, however, this problem seems to be solved. The end result will be real 3D data sets that can be manipulated, viewed, and analyzed with perspective and that will give the observer an optimal feel for the depth information in the 3D model.

CLINICAL APPLICATION

The most common noncardiac, nonbrain vascular imaging indications for CTA are aortic disease (aneurysm, dissection, trauma), peripheral arterial occlusive disease, renovascular disease, venous disease, and, rarely, vascular malformations.

Aortic Disease

In general, CTA has become the primary imaging modality for aortic disease. The excellent spatial resolution and the potential of 3D image reconstruction allow for highly accurate measurements of aortic aneurysms in the preoperative planning of endovascular repair, as well as postoperative follow-up. CTA also allows for imaging of small branches such as the intercostal arteries (important for prevention of spinal cord infarction during thoracic aortic repair) and for tiny contrast enhancements in thrombus (important for identification of endoleak). The CTA acquisition speed of the entire aorta (currently, within 1 minute; in newer scanners, within a few seconds) allows accurate imaging of the aorta in acute cases such as ruptured aneurysm, aortic dissection, and trauma. Endovascular repair of these acute diseases currently relies on acute CTA (Fig. 27.9A and B). ECG gated or triggered CTA aids in detecting and exclusion of pathology of the ascending aorta.

Apart from the acquisition speed, an important advantage of CTA over MRA in both the acute and elective setting is the ability of CTA to image calcium, for instance, in aortic landing zones of endovascular devices that depend on penetrating hooks and barbs or access arteries that may render endovascular repair difficult or impossible (Fig. 27.10). CTA is preferred over MRA when endovascular devices are in place because metal artifacts are rarely a problem.

Figure 27.10 Example of heavily calcified iliac access arteries, coronal reconstruction.

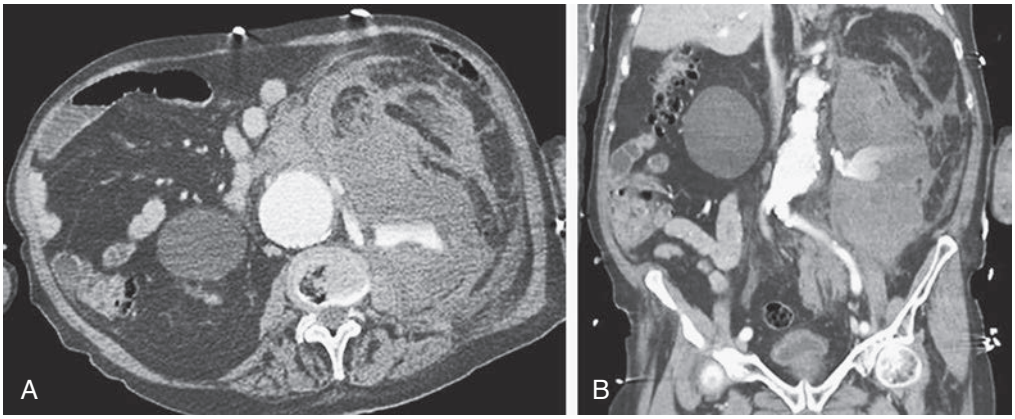

Figure 27.9 Computed tomographic angiography of ruptured abdominal aortic aneurysm. (A) Axial view. (B) Coronal reconstruction.

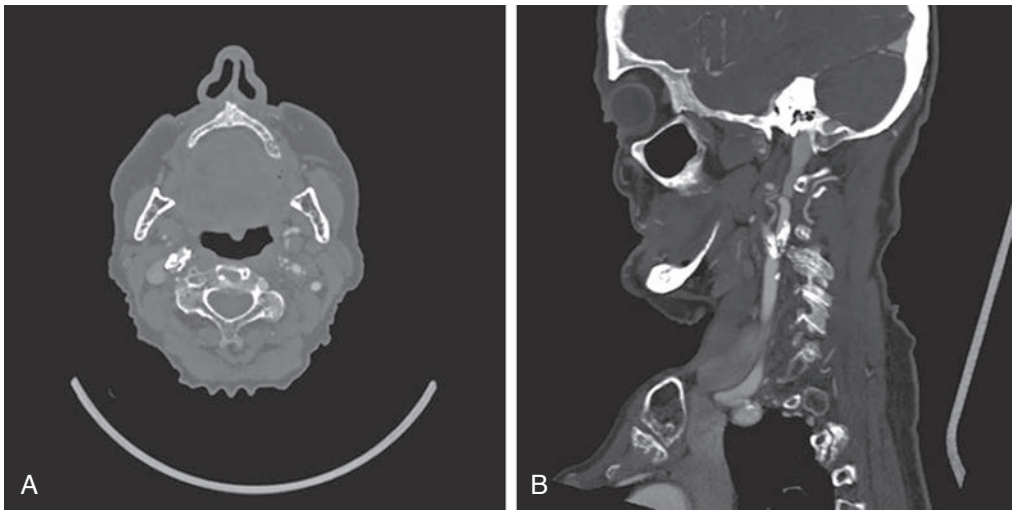

Figure 27.11 Example of carotid artery computed tomographic angiography imaging. (A) Axial view. (B) Sagittal reconstruction.

Peripheral Arterial Occlusive Disease

CTA can be used to image the arterial tree from the aorta through the pedal vessels in a single contrast-enhanced acquisition run. However, accurate timing of contrast injections is essential. The high resolution of CTA allows for accurate delineation of stenotic segments and planning for open and endovascular intervention. It has been shown to be highly accurate in imaging tibial artery runoff.[35] On the downside, interpretation of CTA images and reconstructions of small arteries (tibial vessels) can be very tedious, particularly the distinction between calcium and contrast. Overestimation of the severity of a calcified stenosis is common.[35] Carotid artery stenosis can be accurately defined by CTA. Although duplex-ultrasound imaging can be impeded by calcified plaques, the accuracy of CTA imaging of the carotid artery is hardly affected by calcium (Fig. 27.11A and B). In addition, it can help differentiate occlusion from high-grade stenosis, and it provides better anatomic reference than duplex. CTA also provides the option of adjacent imaging of the aortic arch and intracranial arteries, which may be of help in the diagnosis and treatment of neurovascular disease.[36] CTA can also often be used for diagnosis of mesenteric artery stenosis and aneurysms and for preinterventional planning.

Renovascular Disease

CTA and MRA are comparable in sensitivity for the detection of proximal renal artery stenosis. However, if evaluation of more peripheral abnormalities is needed, MRA suffers significantly from respiratory movement of the kidney.

The main benefit of MR for renal artery imaging is the fact that contrast-induced renal nephropathy is avoided, although a limiting factor is the rare occurrence of interstitial fibrosis due to gadolinium in patients with renal failure. Valid alternatives include time of flight or comparable MR techniques that allow for flow imaging without the use of gadolinium; however, these techniques provide less optimal imaging quality.

Venous Disease

Provided that a proper injection protocol with sufficient delay and contrast volume is chosen, CT is able to evaluate a variety of venous pathologies, including mesenteric venous thrombosis. For the evaluation and detection of pulmonary emboli, CT has replaced lung perfusion and ventilation studies. However, for peripheral evaluation of venous disease (in legs, iliac veins, subclavian veins), the optimal imaging modality is still duplex ultrasound because this also provides essential flow information. If cross-sectional imaging is required MRV is an excellent alternative to CT.

Vascular Malformations

The role of CTA in the evaluation of vascular malformations is limited. Only in cases of high-flow malformations (AVM, AVF) can CTA support a proper diagnosis; the extent and composition of the nidus cannot be adequately evaluated without the use of four-dimensional (4D) imaging. For low-flow malformations there is virtually no role for CT imaging. The limited soft tissue contrast and the extremely low-flow situation make a venous malformation very difficult to characterize with CT. Instead, ultrasound and MRI are the modalities of choice.

LIMITATIONS AND RISKS

Radiation Dose

The radiation dose of CT has attracted attention in the recent decade because of the increased frequency of use and recognition of cancer risks.[37] With the development of the new CT technology (spiral and multidetector), the initial hope was that the radiation dose to the patient could be decreased relative to the old single-slice sequential technique. It soon became apparent, however, that this would be true only if the less optimal image quality of the older technique (often 10-mm slices) were still

acceptable. However, the advent of CTA, 3D reconstructions, and MPR has led to optimal use of the new technology, often with imaging at the smallest collimation possible to allow use of the advanced postprocessing techniques. Furthermore, as image quality improved and the diagnostic value of CT became more apparent, an exponential growth in the *number* of CT examinations occurred. As CT rapidly became a major diagnostic instrument, not all physicians ordering CT scans were aware of the long-term carcinogenic potential, particularly in the pediatric group. Additionally, large-scale screening programs for asymptomatic patients based on CT have emerged. The most well known are CT colonography, coronary calcification screening, CT lung screening, and whole-body screening.[37]

Although it is difficult to validate the calculated radiation risk data because they rely heavily on assumptions based on follow-up data from atomic bomb survivors, it is estimated that between 1991 and 1996, 0.4% of all cancers in the United States were attributable to CT studies. As a result of the increased use of CT in the last decade, this figure has increased to 1.5% to 2%.[37] Awareness of the potentially harmful side effects of radiation is important and should play an important role in the clinical decision of whether to order a CT scan, particularly in children. In addition, radiation risk should influence the choice of parameter settings and scan protocol.

Contrast-Induced Nephropathy

Contrast nephropathy has long been considered as an important cause of iatrogenic acute renal failure.[38] This has led to large-scale programs to prevent this entity. During the last years, the debate on less strict criteria for CIN prevention has emerged.[39] However, final conclusions have not yet been drawn. Nephrotoxicity of contrast agents, contrast-induced nephropathy, associated risk factors, prevention, and alternative imaging options are described in detail in Chapter 25.

COMMON ARTIFACTS

Partial-Volume Effects

Partial volume refers to a situation in which objects are only partly included within the scan plane. The resulting image simulates a lesion where none exists. A good example of this effect is, for instance, the appearance of a "nonexistent" lung nodule adjacent to the anterior attachment of the first rib (Fig. 27.12).

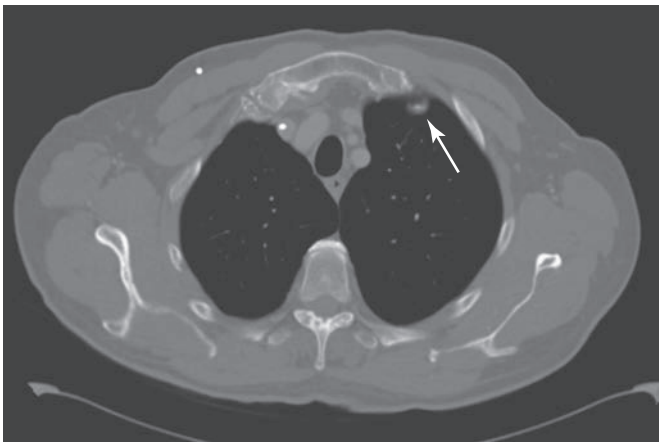

Figure 27.12 Example of a partial-volume effect, here responsible for the appearance of a nonexistent "lung nodule" adjacent to the anterior attachment of the first rib *(arrow)*.

Beam-Hardening Artifacts

Streak artifact or scatter artifact arises from interfaces between materials with large differences in density from the surrounding structures. This artifact is commonly seen with dense materials such as prosthetic hips or metallic stents in endografts. Different materials cause varying levels of artifact. Tantalum and gold stents cause significant beamlike artifacts, whereas platinum has almost no influence on the image. Steel lies in the middle of the spectrum. These artifacts can result in the erroneous interpretation of vessel lumen narrowing—sometimes by 25% to 50%. Tantalum and gold cause few effects on MRI images. Knowledge of the type of stent helps determine the preferable imaging modality.[40,41] Scatter also can occur as a result of dense intravenous contrast material in the subclavian or brachiocephalic veins because dense contrast is often infused rapidly into these veins during the scan. If the aortic arch vessels are the focus of the CT scan, the contrast agent should be infused into the arm opposite the vessel of interest or into the inferior vena cava.

Beam-hardening artifacts can also be seen if both arms are left alongside the body while scanning the chest. To avoid these artifacts, the patient should be positioned with at least one arm, preferably both arms, above the head (see Fig. 27.2), or iterative reconstruction should be used. Another way to reduce this type of artifact is by using metal reducing reconstruction algorithms.

Motion Artifacts

Different types of motion artifact exist, but the most pronounced is due to movement of the patient during the scan. Other well-known motion artifacts are respiratory and pulsation artifacts. The degree of degradation of the resulting image depends on the degree of movement and ranges from a double contour to double visibility of the body. To avoid respiratory artifacts in dyspneic patients, the general recommendation is to ask these patients to *not* hold their breath during scanning, because this will often result in a sudden deep inhalation during the scan and subsequent severe motion artifacts and less contrast enhancement. Instead, the patient should be requested to maintain shallow respiration.

Other Common Artifacts

Averaging artifact has already been mentioned with regard to "missing" a small vessel because of surrounding soft tissue, but it can also work in the opposite fashion. In this type of artifact, comparable to partial volume artifacts, the large attenuation from a small piece of calcified plaque within a CT slice "averages" with thrombus-density material to produce a display with an

intermediate density—similar to intraluminal contrast. This artifact often occurs within aortic aneurysms and should be suspected when contrast-density material appears with no apparent inflow or outflow vessel and when a piece of calcium or metal is nearby. This type of artifact is reduced by using a small reconstruction interval.

Stair-step artifact occurs when the reconstruction interval on a spiral CT scan is too large and a stepped appearance in the vessels is created. This artifact is most likely to occur in vessels oriented away from the z-direction of the scan (e.g., renal or iliac arteries). If such an appearance is noted in a multiplanar reformat, it is difficult to evaluate potential occlusive disease. Some of these artifacts are shown in Fig. 27.13.

A number of scanner-related artifacts are also possible. Most are related to scanner malfunction, improper calibration (ring artifacts), tube malfunction, or detector malfunction.

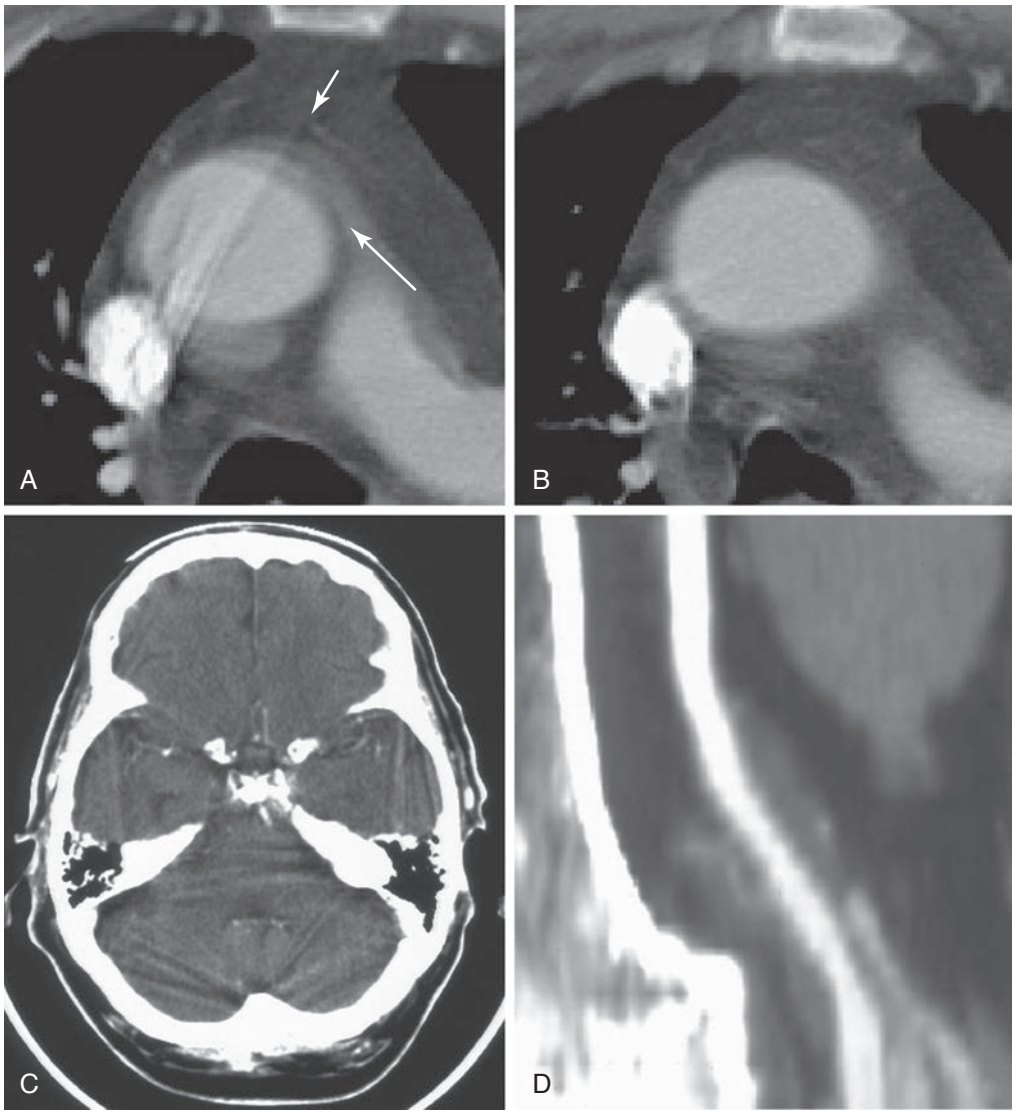

Figure 27.13 Computed tomography (CT) artifacts. (A) Motion artifact in the thoracic aorta creating the impression of an intimal flap or dissection *(long arrow)*. The position of these artifacts is usually due to aortic motion from the left anterior to the right posterior position. Streak artifact is also seen arising from dense contrast within the superior vena cava. The longer streak is clearly artifact because it extends beyond the vessel wall *(short arrow)*, but the shorter streak could be misinterpreted as an intimal flap. One clue is the appearance of an obvious streak artifact in the same vessel. Another clue is the interface between structures with large differences in density. Other clues to the true nature of the aorta come from the benign patient history and the immediately adjacent CT slice. (B) The apparent pathology (artifacts) shown in A is not present in this immediately adjacent CT slice. (C) An intracranial streak artifact can make it difficult to detect infarcts in locations surrounded by dense bone. Beam-hardening artifact is also common on head CT and occurs when low-energy portions of the x-ray beam are absorbed by thick, dense structures, such as the skull. The residual beam that proceeds through the dense bone has higher energy and may cause a small area of adjacent tissue to appear less dense (darker) than it should be. This can create an artifact resembling an ischemic infarct immediately adjacent to the skull. (D) A stair-step artifact creates a stepped appearance in the vessel (see text). This artifact is unique to spiral or helical CT.

Finally, window and level setting errors affect the ability to visualize contrasting objects. A window setting too narrow will result in a significant increase in visible noise that will degrade the visualization of fine structural details, whereas a window too wide will abolish small differences in contrast.

SPECIAL PEDIATRIC CONSIDERATIONS

CT scanning should be avoided in the pediatric age group, if at all possible, to avoid the radiation exposure. Alternative imaging techniques, such as ultrasound and MR, can often replace CT. If CT is necessary, strict adherence to the As Low As Reasonable Achievable (ALARA) principle must guide selection of the scan parameters that determine the radiation dose relative to the image quality. A lower image quality can and should be accepted if this is sufficient for a proper diagnosis.

FUTURE ADVANCES

4D imaging will be incorporated further into clinical practice, and diffusion and perfusion imaging could become an integral part in the evaluation of many organs (e.g., renal transplants). Improved detector designs (with higher-detection quantum efficiency and lower noise levels) combined with noise-reduction iterative algorithms will lower the radiation dose significantly.

Computer-aided diagnostic programs will further expand and be used to assist the clinician in evaluating the huge data sets currently being produced by the 256 and 320 scanners.

Computed Tomography Versus Duplex Ultrasound and Magnetic Resonance

Duplex ultrasound is a noninvasive technique and an excellent screening modality in patients with PAOD. However, duplex ultrasound is hampered by the fact that it is operator-dependent and of limited value in patients with heavily calcified arteries or extensive, multilevel disease. Also, evaluation of the abdominal and pelvic vessels can be quite challenging in the obese patient. In the era of progressive application of endovascular techniques, detailed pretreatment information is essential, and duplex ultrasound alone frequently fails in that respect because of the previously described limitations. CTA and MRA each have their own pros and cons. CTA is an excellent modality for the evaluation of the aorta in case of endovascular treatment and provides detailed and often essential information on calcification in the access arteries and in the wall at the level of landing zones for endografts. MRA is, in this respect, less useful because of its limited ability to visualize calcium. On the other hand, if information about tibial arteries is required, MRA is preferable over CTA because the presence of heavy calcifications in small vessel walls hampers the evaluation of the CTA.

Although the quality of periprocedural imaging in the operating theater is rapidly improving, detailed preprocedural imaging is essential and cannot be replaced by periprocedural imaging without lengthy procedures and high radiation doses.

Positron Emission Tomography With Computed Tomography

Use of positron emission tomography (PET) in concert with CT combines valuable physiologic information from the PET scanner with anatomic information from CT. In oncology imaging, PET/CT is one of the major evaluation tools for detection of malignancy and inflammation. PET/CT might play a role in vascular imaging for the detection of infected grafts. Furthermore, growing evidence indicates that PET/CT may have additional value in identifying inflammatory responses in atherosclerotic plaque, which may allow noninvasive assessment of disease activity.[42,43] In Chapter 29, vascular nuclear imaging is described in detail.

Mobile Computed Tomography and C-Arm Computed Tomography

The new angiographic C-arms, equipped with flat-panel detectors, also offer the possibility of C-arm CT. At present, the quality of acquired CT images is comparable to that of the first- and second-generation CT scanners. Further improvements are to be expected because the technique offers interesting options for incorporating interactive CT models into fluoroscopic images in real time.[44,45] This form of image fusion may be used to improve endovascular therapy and other invasive procedures.

Abstract

Magnetic resonance angiography (MRA) allows evaluation of the vascular system without ionizing radiation and if needed without contrast in patients with contraindications. Recent advances in MRA are discussed in this chapter for evaluation of vascular diseases, including technical developments, applications, artifacts, and novel contrast and noncontrast methods.

Keywords

Magnetic Resonance Angiography
Magnetic Resonance Venography
Aortic Vascular Disease
MRI artifacts
MR contrast agents

BASIC PRINCIPLES

Magnetic resonance imaging (MRI) is performed by using a large external magnetic field, magnetic field gradients, and an applied oscillating magnetic field known as the radiofrequency field (RF). The combination of these three types of applied magnetic fields allows the user to produce signals from inside patients, which in turn can be used to create MR images.

The details of the external magnetic field, magnetic field gradients, and RF determine many of the characteristics of MR images. The goal of the external magnetic field is to magnetize the subject by making the protons within the subject align parallel with the external field. The physical characteristics of the protons and the size of the external magnetic field define the resonance frequency of the proton. If the external magnetic field is uniform, all the protons will resonate at the same frequency. Most MRI machines operate at an external field strength of 1.5 or 3 tesla (T); the potential advantages of 3-T magnetic resonance angiography (MRA) are discussed later in the chapter. Lower field systems, those less than 1.0 T, tend to produce images at a slower rate or at a lower resolution than is typically desirable for MRA examinations.

Magnetic field gradients are used to alter the otherwise uniform external magnetic field in a linear fashion in any of three directions. The gradients ramping on and off produce the noise heard when an MR image is being made. When the gradient fields are applied, the protons resonate at a frequency that is a function of the magnetic field gradient's position. This is analogous to a radio station's frequency corresponding to a specific position on the dial. The speed and strength of the gradients determine the size of the images and may be a rate-limiting step in imaging speed.

Resonant coils placed adjacent to the region of interest produce the RF. These fields are tuned to match the resonant frequency of the protons inside the patient. The applied RF in combination with the gradients is used to manipulate the protons inside the patient to produce a signal. This signal is detected with a receiver RF coil, also tuned to the resonant frequency of the protons. Once detected, the signal is sent to an amplifier and receiver, where it is digitized and processed with a mathematical algorithm known as a Fourier transform to produce the MR image.

Characteristics of Magnetic Resonance Images

The contrast in MR images depends on the characteristics of the object being imaged and on the specifics of the sequence itself. Images are typically referred to as either T1 weighted or T2 weighted. T2-weighted images display simple fluids such as urine, bile, or cerebrospinal fluid as bright and other tissues as lower signal. T2-weighted imaging is one of the basic sequences for imaging of tumors but is not used for angiographic imaging. MRA and magnetic resonance venography (MRV) are performed with T1-weighted image sequences. Objects that are bright on T1-weighted images, including fat, methemoglobin, flow effects, and MRI contrast, will often also be seen on MRA.

Magnetic Resonance Pulse Sequences

The MR pulse sequence is a label that refers to the particular combination of RF and gradients that are used to create the image. There is a large variety of MR pulse sequences, but almost all are variations of spin-echo or gradient-echo sequences. Spin-echo pulse sequence methods use RF alone to produce the MR signal, whereas gradient-echo pulse sequences use RF and applied gradients to produce the signal. As a rough generalization, spin-echo pulse sequences are used to produce T2-weighted images and gradient-echo sequences are used to create T1-weighted images.

Pulse Sequence Parameters

The characteristics of a tissue that determine its appearance on MR images are the T1 and T2 parameters of the tissue. Some tissues are bright on T1-weighted images and others bright on T2-weighted images. How then do we create a T1- or T2-weighted image? All pulse sequences have fundamental parameters known as echo time (TE) and repetition time (TR) that determine image contrast. T2-weighted images have a longer TE, in the range of 80 ms or greater, and a longer TR, in the range of several seconds. Because of the long TE and TR, these sequences are slower and not appropriate for contrast-enhanced MRA. However, T1-weighted images have a very short TR and TE, with a TE of 1 ms or less and a TR ranging from hundreds of milliseconds to less than 10 ms for MRA sequences. These fast T1-weighted gradient-echo sequences are used for most angiographic examinations.

Other parameters used in all MR image sequences include the field of view (FOV) and image matrix. FOV is the size of the imaged region. In a two-dimensional (2D) image, FOV may be 40 × 30 cm with a slice thickness of 5 mm. The resolution of the image in that 5-mm slice will depend on the number of pixels within the 30 × 40-cm region. However, most MRA is performed with a three-dimensional (3D) image sequence. In this case, FOV is specified with three dimensions, such as 40 × 30 × 30 cm. If we have an image matrix of 256 × 192 × 64, we have a voxel (or 3D pixel) size of 1.56 × 3.26 × 4.7 mm. Image postprocessing is usually performed on 3D data to make the last dimension twice as small as specified by the pulse sequence. In this case, such processing would yield a voxel size of 1.56 × 3.26 × 2.35 mm.

Magnetic Resonance Angiography and Venography

Non–Contrast-Enhanced Magnetic Resonance Angiography

Non–contrast-enhanced MRA methods, most notably time-of-flight (TOF) imaging, have largely been supplanted by superior contrast-enhanced methods.[1-5] However, the description of nephrogenic systemic fibrosis (NSF) in patients with poor renal function who have received gadolinium-diethylenetriamine pentaacetic acid (Gd-DTPA)[6,7] (see section "Contrast-Enhanced

Magnetic Resonance Angiography" for further details) has led to renewed interest in non–contrast-enhanced techniques.

TOF angiography uses a rapid T1-weighted pulse sequence in either sequentially acquired 2D slices or a 3D imaging slab. In a single-slice image when data are gathered rapidly, the protons within the slice lose much of their magnetization. Thus there is much less signal from these protons, and the corresponding tissues are not well seen. However, the rapid imaging does not degrade any protons outside the slice. When fully magnetized protons in a vessel flow into the slice of interest, they produce much greater signal than the surrounding tissue. This results in an image in which the blood flowing into the slice is much brighter than surrounding tissue.

For example, if the image were obtained in an axial slice through the mid abdomen, the aorta and inferior vena cava (IVC), as well as some of the mesenteric arteries and veins, would be bright. To remove either the arteries or veins, a special RF pulse is applied to the tissue either above or below the slice to eliminate magnetization from that tissue. If an inferior saturation pulse were used in our example, only the protons flowing into the slab from above (the aorta and mesenteric arteries) would be bright. A series of such images obtained sequentially would produce a 2D TOF abdominal angiogram.

Additional noncontrast MRA techniques such as ECG-gated steady-state free precession (SSFP),[8] ECG-gated arterial spin labeling (ASL),[9] Navigator-gated SSFP, and half-Fourier fast spin-echo imaging (HASTE) with flow-spoiled gradients[10] are used. These techniques use combinations of several different methods that accentuate the signal of flowing blood and attenuate the signal from nonmoving structures and tissue with signal characteristics different from blood. For example, the SSFP technique provides rapid imaging of both large and small vessels, such as the aorta,[11] carotids,[12] and renal arteries,[13] without the need for administration of a contrast agent. Examples of thoracic aorta, noncontrast SSFP MRA and renal arteries, noncontrast MRA using newer methods are shown on Figs. 28.1 and 28.2A and B. In SSFP imaging the signal of a particular tissue is related to the T2/T1 ratio for that tissue, and flowing blood appears bright.

Figure 28.1 Oblique sagittal non–contrast-enhanced steady-state free precession magnetic resonance angiogram of the thoracic aorta. The signal from flowing blood appears bright.

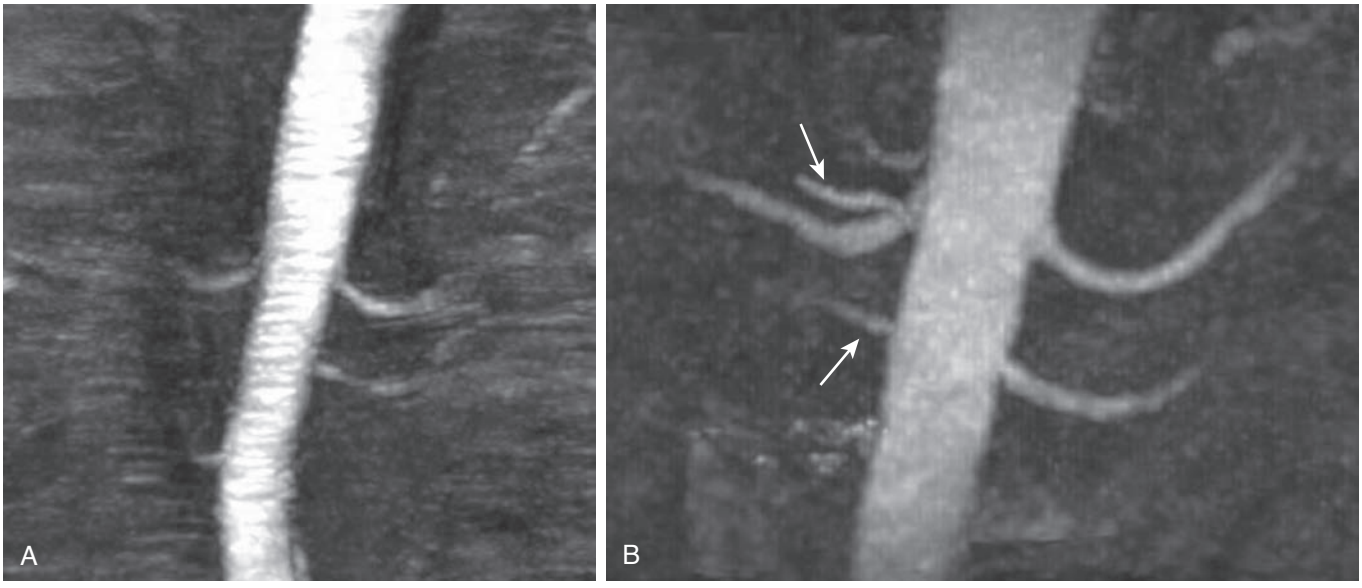

Figure 28.2 (A) Coronal maximum intensity projection (MIP) of time-of-flight (TOF) magnetic resonance angiography (MRA) of the renal arteries. (B) Coronal MIP of noncontrast MRA acquired with a newer method that uses ECG gating to subtract diastolic from systolic images, leaving only arterial systolic flow. Note markedly improved visualization of accessory right renal arteries compared to TOF technique *(arrows)*.

Newer techniques for non–contrast-enhanced MRA include fresh blood imaging (FBI): ECG -gated 3D half Fourier FSE, which relies on the signal difference between systolic and diastolic triggered acquisitions. The arterial signal in systole is dark due to spin-dephasing effects of fast arterial flow. In contrast, venous blood is bright throughout the cardiac cycle because of constant slow flow. By applying flow-spoiling pulses to this technique, arteries can be separated from veins in the peripheral runoff region.[13] Two alternative approaches using the SSFP approach include Flow-sensitive dephasing (FSD) and Quiescent-interval single-shot (QISS). QISS MRA is performed using 2D ECG-gated single-shot SSFP acquisition. Initial saturation pulses suppress in-plane background tissues and venous inflow from below the imaged segment of the body. Advantages of QISS are short acquisition times and ease of use, allowing imaging of fast flowing vessels such as the aorta, and renal arteries; however, this technique requires good magnetic field homogeneity.[13]

Fig. 28.1 shows a non–contrast-enhanced SSFP MR angiogram of the thoracic aorta.

Fig. 28.2A and B shows a noncontrast MRA study of the renal arteries, comparing TOF MRA with images obtained with a technique that uses ECG gating and subtracts diastolic from systolic images, leaving signal only in arteries. Evaluation of these techniques is ongoing[14]; however, they have the potential to replace contrast-enhanced MRA in many circumstances.

Contrast-Enhanced Magnetic Resonance Angiography

Currently, MR contrast agents approved by the US Food and Drug Administration (FDA) include several in which the rare earth element gadolinium is chelated with another substance to avoid release of toxic free gadolinium into the body. These agents are designed to shorten the T1 of the protons in the vicinity, thereby making them more conspicuous on T1-weighted imaging sequences.

There are several important differences between MR contrast and the iodinated contrast used for computed tomographic angiography (CTA) or catheter angiography. First, as suggested, MRI is designed not to image the agent itself but to image its effect on protons in the surrounding water. This has a subtle implication that is important in certain circumstances. That is, a very small amount of MR contrast material may be detected by its effect on multiple water molecules, whereas an equivalently small amount of iodinated contrast is simply not detectable directly by CTA or catheter angiography. This is one reason that the volume of MR contrast can be much less than the volume of iodinated contrast used for CTA or diagnostic angiography. Other advantages of gadolinium-based contrast include decreased nephrotoxicity and a lower incidence of contrast reactions.[15-19]

Step-Table Magnetic Resonance Angiography

For applications involving imaging of a large volume, such as the entire aorta or a peripheral runoff study, acquisition of data from the entire volume of interest is impractical and may lead to decreased image quality. The spatial resolution of the acquired images is inversely proportional to the image matrix size, and the image matrix size has a direct impact on the duration of the acquisition, so a higher resolution image requires longer to acquire. If the FOV is very large, a long acquisition time may be required to achieve the necessary spatial resolution for visualization of the vessels of interest, which may be beyond breath-holding capacity of the patient and lead to respiratory motion artifact. In addition, intravenously administered contrast will flow from the aortic root to distal vessels in a time dependent on the rate and volume of injection, the patient's cardiac output, and the presence of any proximal occlusive disease; thus not all portions of the arterial system will be enhancing optimally at the same time. For these reasons, it is desirable to use a step-table acquisition in which portions of the anatomy of interest are imaged sequentially, with the scanner table moving between stations to place the specific anatomy of interest near the isocenter of the magnet.

A peripheral runoff study may include four step-table stations—abdomen/pelvis, thighs, calves, and feet—each imaged with a coil, FOV, spatial resolution, and orientation optimized to the particular vascular anatomy in that station. For example, whereas the abdominal and pelvic vessels may best be imaged in the coronal plane with a larger FOV and a large array coil, the smaller pedal vessels would optimally be acquired in an oblique plane oriented along the foot, with a small FOV, high spatial resolution, and smaller coils for an improved signal-to-noise ratio (SNR). Although step-table examinations are generally performed in a proximal-to-distal direction, there may be circumstances in which a "reverse step-table" protocol is preferable (e.g., when imaging a patient with known abdominal aortic pathology in whom there is less suspicion of thoracic aortic disease). In this case the abdominal aorta could be imaged first, in the coronal plane, followed by the thoracic aorta, imaged in a more advantageous oblique sagittal plane. This would provide higher resolution imaging of both regions of the aorta, in two shorter breath-holds, than possible with a single large FOV acquisition with imaging of the area of greatest interest in a pure arterial phase and perhaps some venous filling for the less critical thoracic portion.

Step-table MRA requires additional hardware, including a set of MRI coils for optimal imaging of each anatomic segment and (usually) optional software to control the automated table motion. As mentioned before, a disadvantage of the step-table technique may be a longer total acquisition time, which can lead to venous contamination in the later stations. Techniques for minimizing venous contamination are discussed later under section "Continuous Moving Table and Time-Resolved Magnetic Resonance Angiography."

Three-Dimensional Image Processing

Contrast-enhanced MRA is performed as a 3D imaging sequence. Three-dimensional imaging sequences are typically faster and of higher resolution than non–contrast-enhanced angiograms and provide the same coverage. A 3D image can be viewed as a stack of 2D images, but the higher resolution of 3D methods allows the use of multiplanar reformatting (MPR). MPR involves manipulation of the data to create images from multiple views

that optimize visualization of the anatomy or pathology. Images can be processed with many types of algorithms to display the 3D data to best advantage. Because contrast within is designed to have the highest intensity, an algorithm that displays the maximum intensity of the voxels, known as maximum intensity projection[20] (MIP), is the most commonly used for reformatting 3D MR angiograms. Volume rendering (VR) has become a popular evaluation and display method and has been demonstrated to be equivalent or superior to MIP for both MRA and CTA of several vascular territories.[21,22]

Hardware and Software for Magnetic Resonance Angiography

MRA is performed optimally on a 1.5- or 3-T MR system with the fastest and strongest gradients available. This will result in shorter acquisition times with higher spatial resolution and improved SNR. Dedicated coils for specific vascular beds are also useful and include at least a neurovascular coil for head and neck MRA and a peripheral angiography coil covering the pelvis to the ankles or toes for runoff studies. MRA of the thoracic, abdominal, and pelvic vessels is performed with multiple flexible phased-array coils that can be placed over the anatomy of interest; multichannel coils and RF receivers allow parallel imaging (described later under section "Parallel Imaging") for faster acquisitions. Digital and pedal vessels can be imaged either with small local extremity coils or by placing both extremities in a dedicated head coil that is designed for high-resolution and SNR imaging.

An MR-compatible dual-chamber power injector is needed for rapid administration of contrast, followed by a saline chaser (which can decrease the amount of contrast used). MR-compatible patient monitoring equipment is also useful, especially when imaging hospitalized patients or when sedation is needed. Additional software may be needed for step-table and parallel imaging, as well as newer non–contrast-enhanced and contrast-enhanced MRA techniques, so it is important when purchasing MR systems to investigate which sequences are included in the base MR system package and which are optional. MR-compatible blood pressure cuffs can be useful for reducing venous contamination in extremity MRA. For example, placing cuffs around both thighs while inflating to half to two-thirds systemic arterial pressure effectively delays venous return and allows improved visualization of calf arteries.[23]

A postprocessing workstation with MPR, MIP, and VR capability is the minimum necessary for visualization and interpretation of MRA studies. Additional software, such as automated vessel analysis with curved planar reformatting, vessel centerline extraction, automated segmentation, and bone removal, may also be useful for specific applications but is more relevant for CTA than for MRA.

CLINICAL APPLICATIONS OF MAGNETIC RESONANCE ANGIOGRAPHY

Aortic Vascular Disease

Contrast-enhanced 3D MRA has been used to assess the aorta[24-27] in patients with many different types of disease. Assessment of the aortic arch by contrast-enhanced MRA may be superior to any other technique.[28] Several examples are shown in Fig. 28.3. Other diseases that are routinely evaluated by MRA at some centers include aortic dissection,[24,29-31] as shown in Fig. 28.4, and aneurysms.[24,32] MRA is also used to evaluate patients with other vascular diseases, as shown in Figs. 28.5 and 28.6, such as connective tissue disorder—Ehlers Danlos syndrome,[33] and for vascular stent-graft placement,[34,35] as well as for endoleak in those with a nitinol-based stent-graft.[36,37]

Carotid Vascular Disease

MRA is becoming an increasingly used method for evaluating carotid artery atherosclerosis. It has proven to be a very sensitive

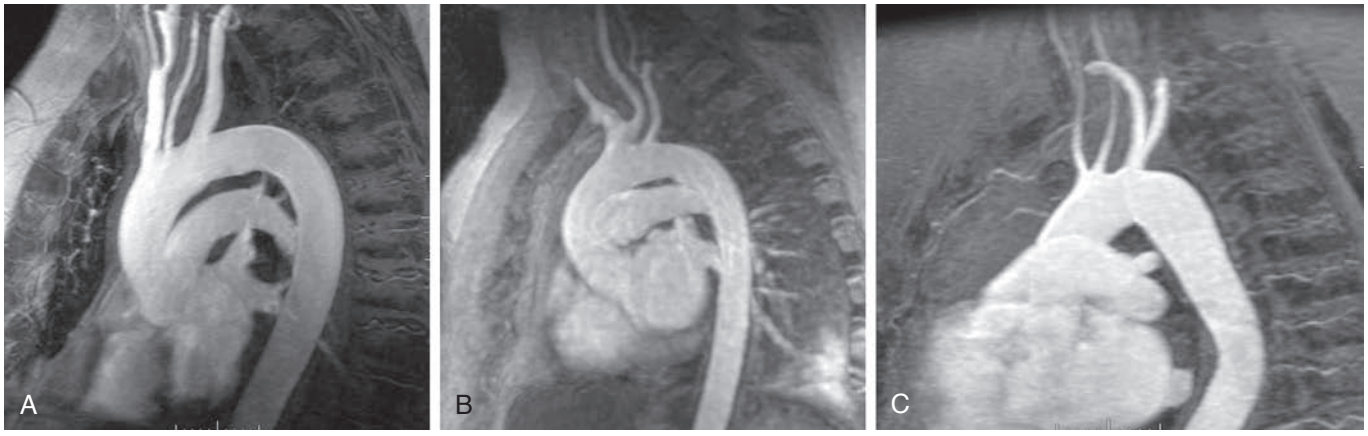

Figure 28.3 (A) Sagittal oblique reformatted magnetic resonance (MR) angiogram of a normal aortic arch. (B) Sagittal oblique reformatted MR angiogram of a bovine arch. (C) Sagittal oblique reformatted image of a rare arch anomaly, bicarotid truncus. All four vessels arise separately from the arch. The carotids arise anteriorly and the subclavians posteriorly.

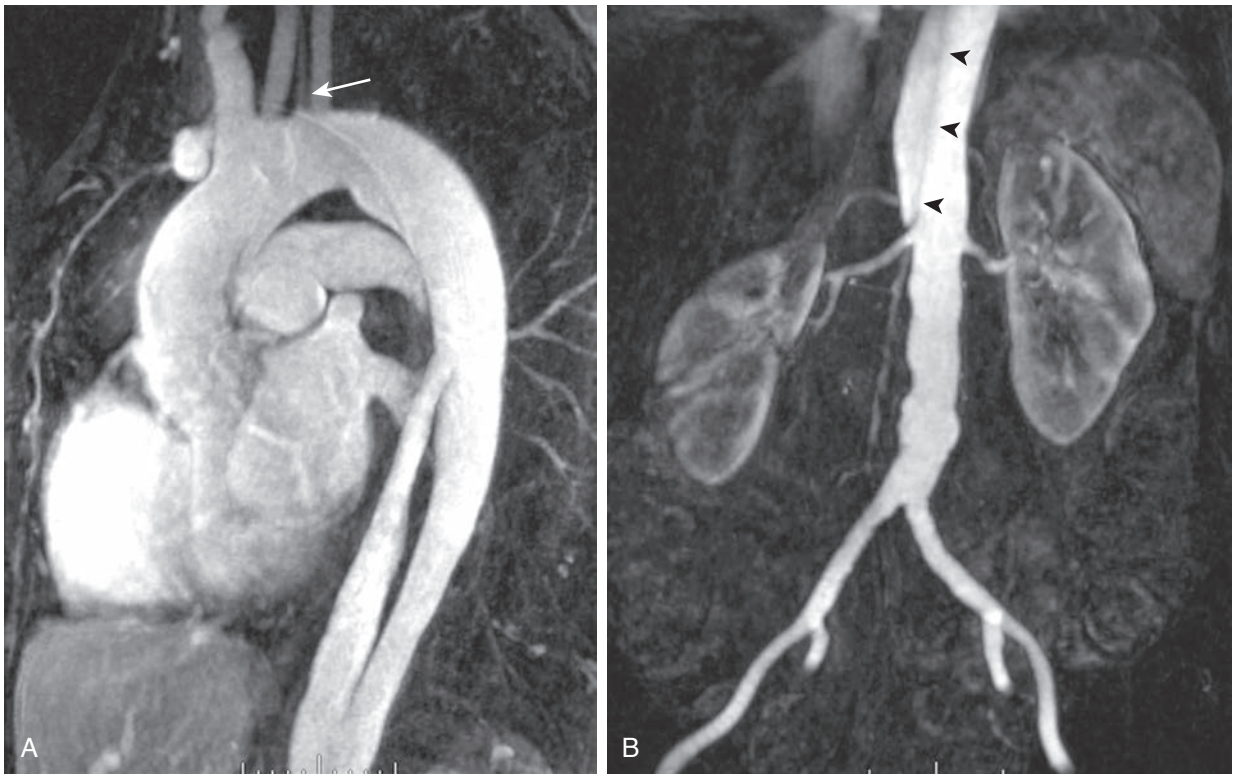

Figure 28.4 (A) Sagittal oblique reformatted magnetic resonance (MR) angiogram showing a type B dissection. The origin of the flap and filling of the proximal false lumen are seen. A separate origin of the left vertebral artery is seen from the aortic arch *(arrow)*. (B) Coronal three-dimensional MR angiogram obtained during the same examination as the chest-station image by using the step-table technique. The dissection flap *(arrowheads)* terminates just above the origin of the right renal artery.

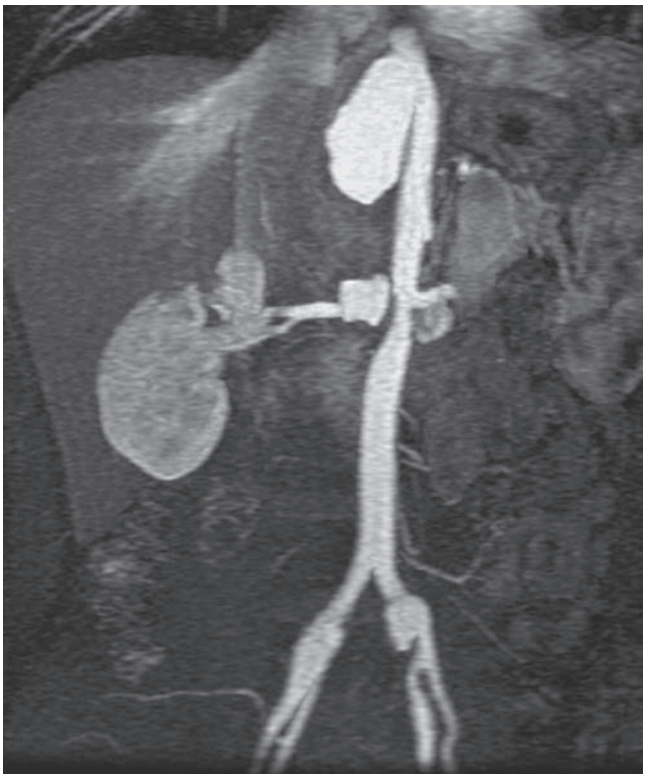

Figure 28.5 Coronal three-dimensional magnetic resonance angiogram in a patient with suspected Ehlers-Danlos syndrome. Saccular aneurysms are seen from the upper abdominal aorta and both renal arteries. An irregular fusiform aneurysm of the left common iliac is also present.

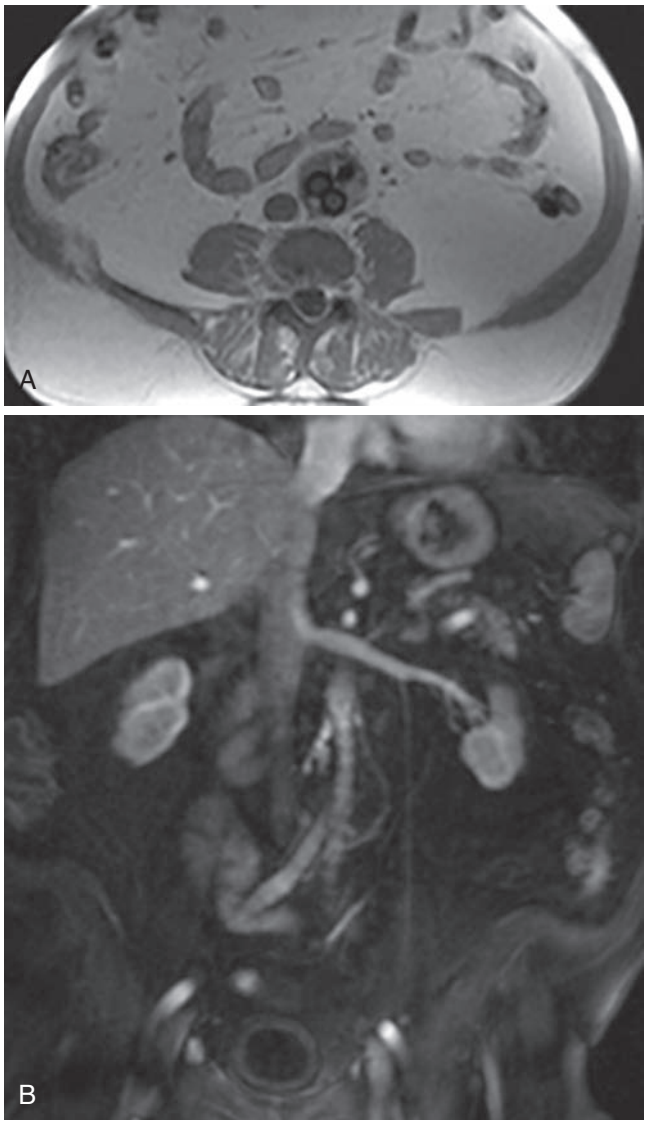

Figure 28.6 Axial (A) and coronal magnetic resonance angiogram (B) images show stented infrarenal abdominal aortic aneurysm with type 1a endoleak.

method of detecting significant stenoses. For stenosis of between 70% and 99% narrowing, MRA has a reported sensitivity of 95% and a specificity of 90%.[38] For all stenoses, MRA has a reported sensitivity of 98% and a specificity of 86%.[39] Several authors conclude that the performance of MRA warrants its use as a tool to plan operative or interventional revascularization.[40,41] A 3D MR angiogram of the carotid and vertebral arteries is shown in Fig. 28.7.

Peripheral Vascular Disease

MRA has become a standard method for evaluation of peripheral vascular disease.[42] Peripheral vascular disease is extremely common in the middle-aged and elderly population. Its prevalence is approximately 3% in those older than 55 years but increases to 11% in those older than 65 and is as high as 20% in individuals older than 70 years.[42] MRA has been demonstrated to be effective in the preoperative assessment of patients[43-45] with peripheral vascular disease, including imaging of inflow vessels[46] and evaluation of stenoses,[46] as shown in Fig. 28.8. Its sensitivity for detecting hemodynamically significant stenoses is 99.5% with a specificity of 98.8% compared with digital subtraction angiography (DSA).[46] In addition, MRA is effective in imaging suitable target vessels, including vessels not seen by catheter angiography.[45,46] MRA is also a cost-effective method for evaluation of patients with peripheral vascular disease.[43]

With the continued advancement in MR technology, MRA evaluation of peripheral vascular disease continues to improve.[3,4,47-49] Improvements in step-table examination have increased the speed and resolution of the examination. This has allowed improved visualization of smaller distal vessels and permitted arterial-phase dedicated imaging of the feet, as shown in Fig. 28.9. As mentioned previously, MRA has been shown to be superior to DSA for the evaluation of distal vessels in some cases.[40] In a study of 37 patients, MRA depicted significantly more vascular segments in the foot than DSA did ($P \approx .0001$).[49]

In addition to the value of MRA for diagnosis and pretreatment planning, it may be used for the evaluation of patients after therapy.[50-52] MRA can be used to assess graft patency and stenosis. Fig. 28.10 demonstrates narrowing at the distal end of a femoral-to-popliteal bypass graft. MRA is also a useful technique for demonstrating complications of graft placement such as pseudoaneurysm formation, as shown in Fig. 28.11.

Renovascular Disease

For the evaluation of renovascular disease, 3D gadolinium-enhanced MRA has become a clinical standard.[53] The most common such disease is atherosclerotic renal artery stenosis. However, MRA has also demonstrated that it is a powerful technique for evaluating more subtle renal vascular conditions such as fibromuscular dysplasia, renal artery aneurysms, and accessory renal arteries.[1] Detection of accessory arteries is particularly important for assessment of potential living renal donors.[54-55]

Approximately 25% of the middle-aged white and African-American population in the United States has high blood pressure.[55] Renal artery stenosis is the most common cause of secondary hypertension, and approximately 1% of people with hypertension will have renal artery stenosis.[56] Because renal artery stenosis is so common and potentially curable,[57-59] it is critical that appropriate screening tests exist for those at risk. 3D contrast-enhanced MRA has a sensitivity of 94% and a specificity of 93%.[1] In addition, it has been shown that when MRA is used to plan a renal artery intervention, both the number of pretreatment angiograms and the total amount of contrast are reduced.[58]

As shown in Fig. 28.12, the majority of renal artery stenoses are located in the ostial or proximal[60,61] segments. As methods for 3D contrast-enhanced MRA have improved, diseases that are not typically near the renal artery origin have more commonly been diagnosed by MRA. Such diseases include another curable

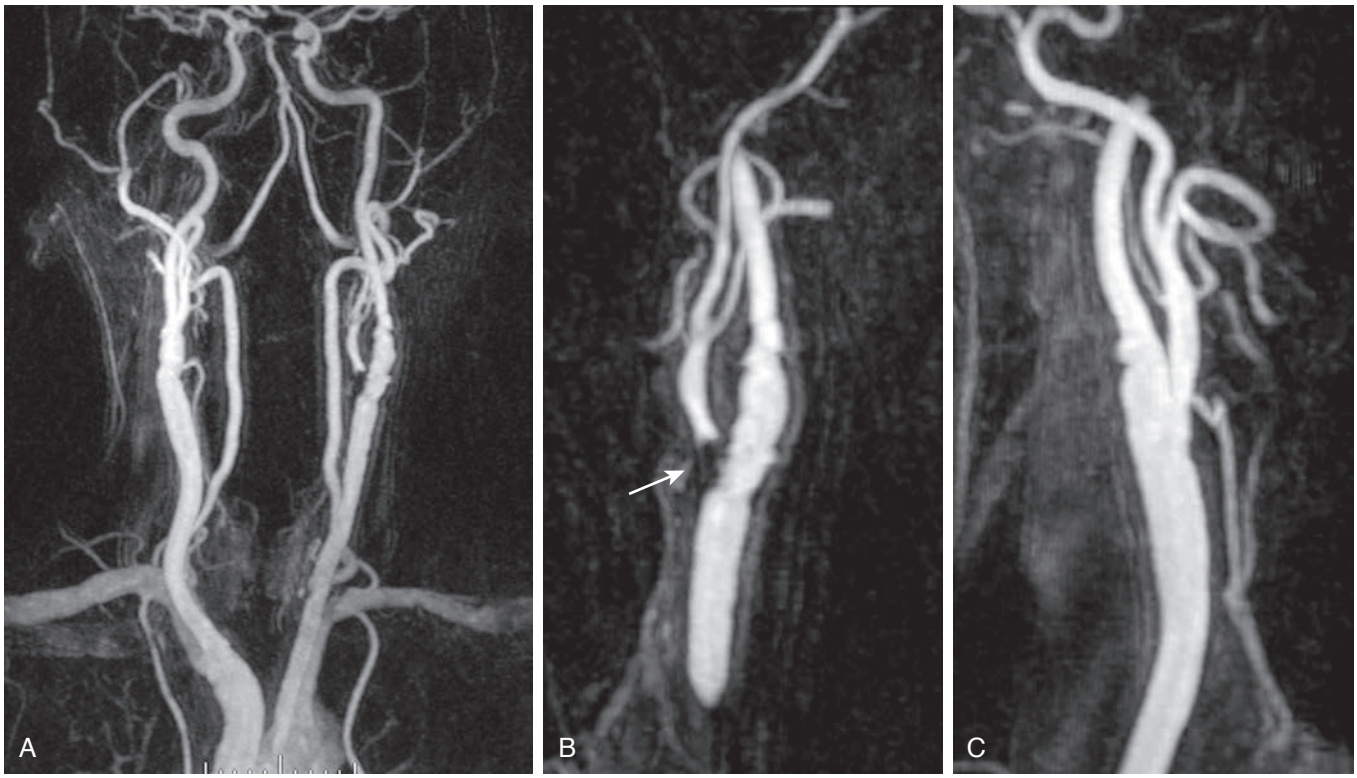

Figure 28.7 (A) Coronal three-dimensional magnetic resonance (MR) angiogram of the carotid and vertebral arteries. (B) Oblique sagittal reformatted MR angiogram showing high-grade narrowing at the origin of the left external carotid artery *(arrow)* and mild disease of the left internal carotid artery. (C) Oblique sagittal reformatted MR angiogram showing the right carotid bifurcation with only mild disease in the proximal right internal carotid.

cause of hypertension, fibromuscular dysplasia,[62] shown in Fig. 28.13.

Accessory renal arteries occur in nearly 45% of patients,[63] and their diagnosis can be important in screening candidates for renal donation.[54,55] MRI and MRA have been shown to be cost-effective methods for evaluating potential renal donors.[62] Fig. 28.14 demonstrates an individual with six total renal arteries.

Mesenteric Vascular Disease

The most common use of MRA in patients with mesenteric vascular disease is to evaluate those with suspected intestinal angina or chronic mesenteric ischemia.[64,65] MRA is between 95% and 97% accurate for characterizing proximal disease of the superior mesenteric artery[66] in cases of chronic mesenteric ischemia.

MRA is also useful to evaluate more complex diseases of the mesenteric vasculature. The median arcuate ligament passes anterior to the descending aorta near the T12 level. During end-expiration the ligament can compress the proximal portion of the celiac axis, which can lead to a false impression of proximal celiac stenosis. MRA can be helpful in demonstrating the effect of the arcuate ligament during a single examination,[67] as shown in Fig. 28.15.

In cases of suspected mesenteric venous thrombosis, MRV can be an extremely useful tool and has been suggested to be superior to mesenteric catheter angiography.[68] MRV is particularly successful because of the ease of detecting small amounts of MR contrast. Central injection of MR contrast will be easily visualized in the veins, even after several cycles of circulation. An example of postcontrast 2D MRI is shown in Fig. 28.16; the portal vein, splenic vein, superior mesenteric vein, and even inferior mesenteric venous branches occluded with thrombus are clearly depicted.

Venous Vascular Disease

MRV is a useful technique for evaluating both central[69,70] and deep[71-73] venous structures. Central venous structures, in particular the superior vena cava, can be evaluated with 3D methods, with 100% sensitivity for the detection of thrombus when compared with DSA.[70] For pelvic and deep venous structures, it is more common to use 2D TOF angiography.[71,72] In cases of suspected deep venous thrombosis (DVT), this method showed that 20% of patients had pelvic DVT that could not be diagnosed by ultrasound.[73] This same study also demonstrated that in cases of known pulmonary embolism and negative lower

extremity Doppler ultrasound, 29% of patients had residual pelvic DVT.

An example of 2D TOF imaging of an IVC thrombus is shown in Fig. 28.17 with corresponding 2D postcontrast MR images. Both types of imaging are useful for detecting DVT in the abdomen, pelvis, and lower extremities.

Other Applications

A large variety of vascular conditions may be evaluated by MRA. The capability of performing the evaluation may depend on the experience of the physicians and technologists performing the study. For example, MRA may be performed to assess patients with suspected thoracic outlet syndrome if the appropriate image sequences can be combined with maneuvers to elicit the symptoms.[74] A case of thoracic outlet syndrome is shown in Fig. 28.18, where compression of the subclavian vein is clearly seen when the ipsilateral upper extremity is raised above the head.

In centers in where transplants are performed, MRA is useful for assessment of potential renal donors,[54,55,62] as mentioned earlier. In addition, MRA can be useful in the assessment of suspected failure of the arterial or venous anastomoses of the transplant graft.[5,75] Fig. 28.19 demonstrates evaluation of a pancreas transplant graft in the postoperative phase and in a later phase in which graft rejection was occurring.

MRA is also useful to assess less common diseases (e.g., to diagnose and assess the response to therapy in cases of large-vessel and medium-vessel vasculitis).[76,77] An example of Takayasu arteritis is shown in Fig. 28.20. Example of Takayasu arteritis involving subclavian artery is shown in Fig. 28.21. Another example of more esoteric disease that has easily been assessed by MRA is pulmonary arteriovenous malformations,[78,79] as shown in Fig. 28.22. In such cases, MRA has 100% sensitivity for imaging pulmonary arteriovenous malformations greater than 5 mm in size, and all feeding arteries and draining veins are also characterized.[79]

LIMITATIONS AND RISKS

Scan Artifacts

Several common artifacts and pitfalls are associated with MRA. Knowledge of these limitations will allow the user to approach diagnostic MRA with increased confidence that any abnormal findings do represent actual pathology.

Fat Saturation in Chest Magnetic Resonance Angiography

Suppressing the signal from fat may be advantageous in that fat will have high signal on the T1-weighted images used for MRA. The so-called fat sat method is an RF suppression pulse that takes advantage of the small difference in resonance frequency between water protons and the protons that are part of long-chain hydrocarbon fat groups. Within the chest there are intravascular water protons in blood vessels directly adjacent to the lungs. When such geometry exists, the resonance frequency of the water protons may be shifted to the precise range at which the fat protons normally resonate. In this case the selective method of fat suppression will result in suppression of the water signal instead.[80] Thus a vessel that is entirely patent may appear entirely occluded, or a vessel that is occluded may not be accurately assessed, as shown in Fig. 28.23.

Susceptibility Artifact From Concentrated Gadolinium

MRA contrast contains a chelated form of the rare earth element gadolinium. The chelate serves several different purposes in the contrast agent. First, it isolates the gadolinium, which is necessary because in its unbound form gadolinium is toxic. Second, the chelate provides multiple binding sites at which surrounding water molecules may remagnetize. Hence the chelate potentiates the T1 relaxation effects of the gadolinium. However, unbound gadolinium would not only shorten the T1 of water but would also shorten the T2 of the surrounding water. The chelate prevents close contact between water and gadolinium, thus minimizing the T2-shortening effects of the gadolinium. However, when the contrast is at high enough concentrations, there is still a T2-shortening effect that reduces the MR signal. In effect, at high concentrations, MR contrast behaves like a small piece of metal and produces a susceptibility artifact on the surrounding tissues. These concentrations occur only during the injection of pure contrast and are typically seen in the area of the origin of the great vessels[81] or in the subclavian artery during initial passage of injected contrast through the adjacent vein,[82] as shown in Fig. 28.24. If this artifact is suspected to be the cause of an apparent stenosis, repeating the sequence immediately should demonstrate resolution because contrast in the adjacent vein becomes more dilute.

Susceptibility Metal Artifacts

Metal produces large signal void and extensive distortion around the implant in MR imaging. Presence of metal also degrades CT studies by metal streaky artifact. Metal artifact reduction sequence (MARS) optimizes in reduction of metal artifact by using selection-selection gradient and increased radiofrequency bandwidth, by increasing read gradient and by applying view angle tilt. These parameter changes can be used in any spin-echo sequence without any increase in imaging time.[83]

Multiacquistion with variable resonance image combination (MAVRIC) and slice-encoding metal artifact correction (SEMAC) are two recently developed metal artifact reduction techniques that significantly reduce susceptibility artifacts near metallic hardware.[84] In CT imaging modality, dual energy CT removes metal artifacts along with use of iterative reconstruction algorithm.[85]

High Intravascular Signal From Thrombus Containing Methemoglobin

Clotted blood has a widely varying appearance on MR images, depending on both the redox state of the hemoglobin molecule and the integrity of the red blood cell wall. At a certain state

in its evolution, clotted blood will pass through a state of either intracellular or extracellular methemoglobin. This state typically occurs in the subacute phase (1-14 days) of a blood clot.[86] When the clot contains large amounts of methemoglobin, particularly extracellular methemoglobin, the signal may be high on the T1-weighted images used in MRA. This signal can be high enough to mimic intravascular contrast, as shown in Fig. 28.25. The use of precontrast T1-weighted imaging can identify the thrombus, as shown.

Contraindications to Magnetic Resonance Imaging

Impaired Renal Function and Nephrogenic Systemic Fibrosis

As noted earlier, gadolinium-containing contrast agent had long been thought to be safer for patients with impaired renal function because they are associated with a much lower incidence of contrast-induced nephropathy than iodinated contrast material is at the dose used for clinical imaging.[16,18] Because the radiodensity of Gd-DTPA is one-half to one-third that of the same dose of iodinated contrast material at the energies used for fluoroscopy, a large dose of contrast material may be necessary to obtain diagnostic images, which may engender higher risk for contrast-induced nephropathy than a dose of iodinated contrast material of equivalent radiodensity.[87]

NSF, previously known as nephrogenic fibrosing dermopathy, is a disease with primarily dermatologic manifestations, although findings in other organs have now been elucidated.[6] NSF is characterized by skin thickening and hyperpigmentation of the extremities and trunk; patients with more severe involvement may have contractures and organ fibrosis, in some cases leading to death. All reported cases to this point have occurred in patients with renal insufficiency, primarily in those with very poor kidney function in the setting of chronic renal failure, although cases have been described with milder renal dysfunction in acute renal failure. Whereas concomitant liver failure was previously thought to be an additional risk factor, longer-term studies have not supported this finding. There is no specific treatment of NSF other than improving renal function, such as through kidney transplantation; steroids and other antiinflammatory treatments have been used, along with hemodialysis and photopheresis.[88]

Although the first cases of NSF were described in 2000,[6] a possible association between NSF and exposure of patients with

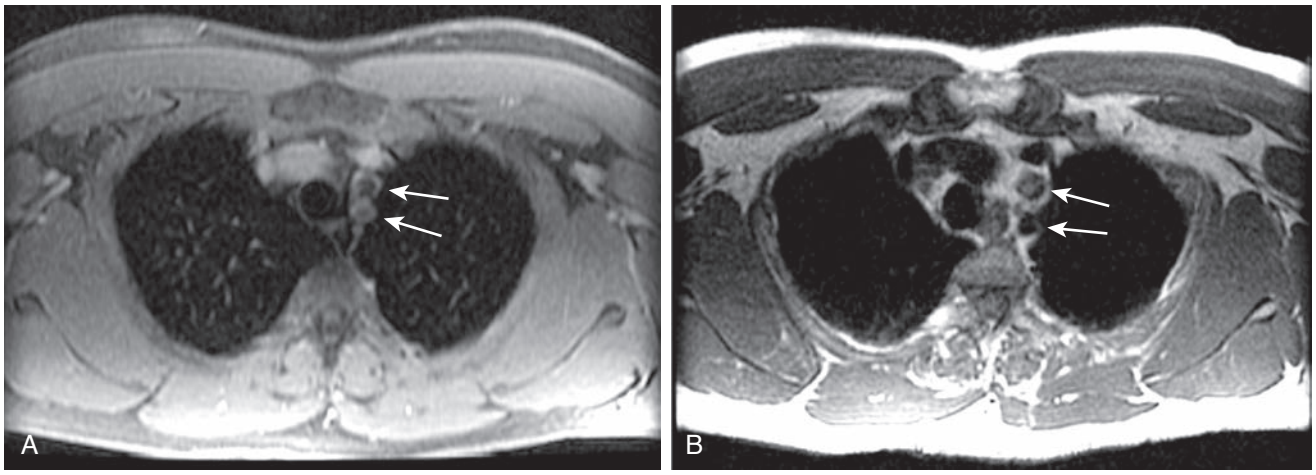

Figure 28.23 (A), Axial two-dimensional postcontrast fat-saturated T1-weighted image showing no contrast within the left subclavian and left common carotid arteries *(arrows)* in a patient with a type A dissection. (B) Axial T2-weighted dark blood imaging showing flow void within the left subclavian but signal within the left common carotid arteries *(arrows)*, findings indicative of thrombosis.

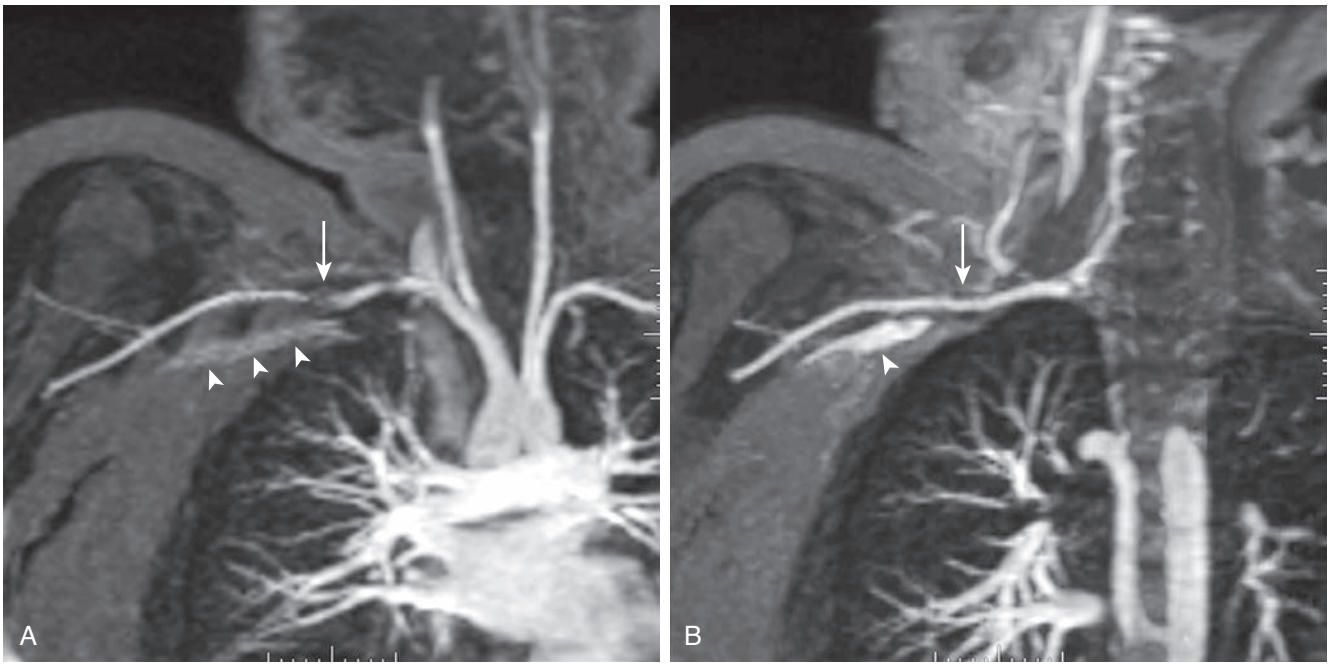

Figure 28.24 (A) Arterial-phase coronal three-dimensional (3D) magnetic resonance (MR) angiogram showing apparent stenosis *(arrow)* in the right subclavian artery. Note that the signal from the pure contrast in the left subclavian vein *(arrowheads)* is not as high as the signal from the dilute contrast in the adjacent artery. (B) Delayed-phase 3D MR angiogram showing no stenosis in the subclavian artery *(arrow)*. Note that the signal from the dilute venous contrast is now much higher than that from pure contrast *(arrowhead)*.

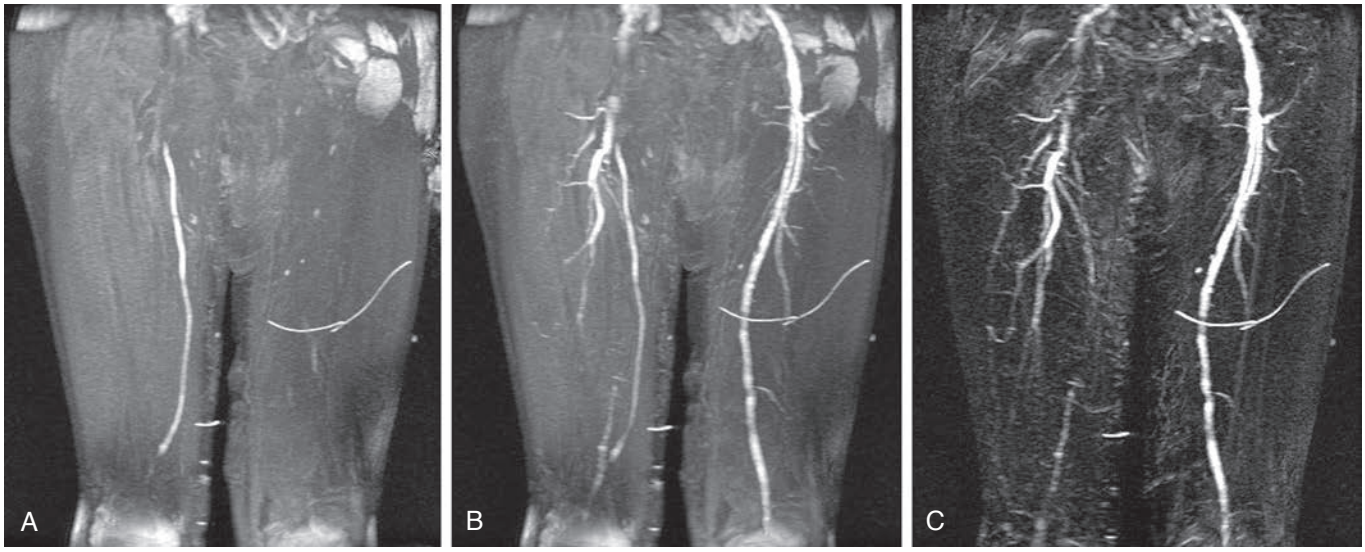

Figure 28.25 (A) Precontrast coronal T1-weighted image showing high intravascular signal from a thrombosed femoral bypass graft. The high signal is from methemoglobin in the thrombus. (B) Coronal three-dimensional magnetic resonance angiogram showing that the signal from the thrombus is as high as the signal in the contralateral superficial femoral artery. There are signal voids at the origin and touchdown of the graft, suggesting stenosis, when in fact the entire graft is occluded. (C) Subtraction image of the arterial-phase image minus the precontrast image showing only the contrast-enhancing arteries.

renal insufficiency to gadolinium-containing contrast agents was not proposed until 2006, when five cases were reported in a cohort of dialysis patients who had undergone MRA.[7] Since that time, approximately 1600 cases have been reported in dialysis and nondialysis patients,[89] and several predisposing factors have come to light, including metabolic acidosis, administration of a larger dose of gadolinium contrast agent, repeated contrast-enhanced studies (i.e., the effect may be cumulative), proinflammatory conditions, and recent vascular procedures, including surgery. All but five documented cases of NSF have occurred in patients exposed to gadolinium contrast agents, and thus far, there have been no documented cases of NSF in patients with normal renal function.[88] Although gadolinium agents are cleared rapidly by the kidneys in those with normal renal function, residence time may be increased 100-fold in those with markedly impaired renal function. It is currently unknown whether repeated exposure to gadolinium agents could induce NSF even in those with normal renal function.

Several new gadolinium-containing contrast agents have become available, and both the FDA and European Society of Uroradiology (ESUR) changed their policies and guidelines with respect to administration in patients with renal failure.[89,90] The FDA requires a boxed warning on all gadolinium-containing contrast agents, stating that the use of these agents should be avoided in patients with impaired elimination of drugs, that patients should be screened for acute kidney injury and other conditions that may reduce renal function (age > 60 years, hypertension, or diabetes), and to estimate glomerular filtration rate (GFR) with laboratory testing. The vast majority of NSF cases have been reported in association with gadodiamide, with small numbers associated with gadopentetate dimeglumine and gadoversetamide, and the use of these agents in patients with severe chronic kidney disease or acute kidney injury is contraindicated by the FDA. There was a single case after exposure to gadobenate dimeglumine, although this patient had also previously received gadodiamide[89]; this and other agents are not contraindicated, although caution is advised as described previously. Of all of these compounds, gadodiamide has the weakest binding of gadolinium ions to the chelating agent, which is consistent with a current theory for the pathogenesis of NSF, that it is caused by a reaction to free gadolinium ions. The histologic finding of gadolinium in affected tissues supports this mechanism, as does the association with proinflammatory states.

For permanently dialysis-dependent patients, CTA should almost always be the examination of choice for vascular imaging. If contrast-enhanced MRI is a clinical necessity, such as for postoperative imaging of brain tumors, repeated hemodialysis within 24 hours of the study has been proposed. In patients with poor renal function who are not dialysis dependent, a temporary dialysis catheter can be placed to allow immediate hemodialysis.[87]

Pacemakers and Other Implanted Devices

Although MRI is extremely safe, the degree of safety is ensured only by maintaining the appropriate environment around the magnet and by careful screening of patients.[91,92] There are a number of implanted metallic devices that are not safe in or near an MRI magnet. The more common include implanted pumps or neurostimulators, some cochlear implants, and some intracranial aneurysm clips. Because of the large variety of implanted devices, sources of information regarding which are safe have been developed. Such sources include books,[93] published articles,[94] and websites,[95] and consultation of these resources is highly suggested before considering MRI in a patient with an implanted device.

Implanted pacemakers and defibrillators had long been considered absolute contraindications to MRI; however, several studies have demonstrated that some patients with pacemakers and defibrillators can be imaged safely under carefully controlled conditions.[96-100] The risks in imaging patients with pacemakers or defibrillators include patient- and device-related complications, although the factor of greatest concern is whether the patient's underlying cardiac rhythm would be able to tolerate the pacemaker's ceasing to function while in the magnet, where immediate treatment may be more difficult. In general, factors that entail greater risk include a pacemaker-dependent patient, pacemaker generator implanted before 2000 (some older models appear to be more susceptible to an electrical reset to default parameters while in the magnet),[98] presence of an implantable cardioverter-defibrillator (ICD), and inclusion of the pacemaker/ICD generator or leads in the RF field. At our institution, we follow a protocol in which the device is interrogated before MRI and pacing parameters altered so that they are less susceptible to interference from the RF and gradient,[98] and an electrophysiologist physician is present throughout the MRI examination. The ICD's antitachycardia therapy capabilities are turned off during the examination, and thus the device would be unable to respond to episodes of tachycardia that would benefit from shocks.[100] We will perform MRI on patients with pacemakers or defibrillators that are not FDA approved as MRI conditional under the following circumstances:

1. There is a compelling clinical need for the scan, and the information to be gained from the examination has a high likelihood of altering patient management or prognosis.
2. There is no other acceptable imaging alternative.
3. An electrophysiologist concurs that the patient will not be harmed by the temporary modifications to pacemaker/ICD programming just noted.

Given the availability and utility of high-quality CTA, there are very few situations in which these conditions would be met in vascular imaging, and the majority of cases reported in the literature involve neurologic, musculoskeletal, and abdominopelvic imaging. However, the recent availability of devices that are approved by the FDA as MRI conditional may mean that MRA of the patients with implanted pacemakers and ICDs will become more routine.

Vascular Stents, Filters, and Coils

The majority of implantable vascular stents, filters, and coils have been shown to be "MRI safe" or, using newer terminology developed by the American Society for Testing and Materials

International, "MRI conditional"[101,102]; that is, they are not subject to significant force when placed inside the magnet and have been demonstrated to pose no known hazards. One exception was the Zenith AAA stent graft system (Cook Inc, Bloomington, Indiana), which is made of stainless steel and was shown to be subject to significant forces in in vitro testing, and was therefore previously characterized as MR unsafe.[103] This stent has not been systematically studied in vivo; however, retrospective results have been reported for a small cohort of 11 patients with Zenith stent grafts who underwent a total of 20 MR exams (including 10 of the abdomen, pelvis, or spine) and suffered no ill effects,[104] and nonclinical testing at field strengths of up to 3 T demonstrated no significant heating or torqueing. Therefore it is now classified as MR conditional at up to 3 T, beginning immediately after placement.[103]

IVC filters and vascular embolization coils are composed of either nonferromagnetic alloys such as nitinol or weakly ferromagnetic stainless steel. Neither of these materials is subject to significant force when exposed to MRI, and all IVC filters tested are classified as MRI safe or conditional. As with stents, many manufacturers recommend waiting up to 8 weeks after placement of the device before performing MRI because this period is thought to be the amount of time needed for stable incorporation into the vessel wall; however, there are no specific data to justify this policy. Stents, filters, and coils composed of nonferromagnetic material may be safely imaged immediately after placement. For weakly ferromagnetic devices, the decision to perform MRI within 6 to 8 weeks after placement should be accompanied by consideration of the potential risks versus the benefits of the information that the studies will provide.[102]

Although it may be safe to perform MRI on patients with stents, IVC filters, or coils, the presence of such devices may cause severe image artifacts related to distortion of the magnetic field by the metal, thus rendering portions or the entire MR study uninterpretable. Stainless steel devices in particular, as well as platinum and some other materials, will cause large areas of signal void on gradient-echo imaging sequences, the primary type of imaging used for MRA. These artifacts extend beyond the region of the device, and thus, for example, MRI of the right kidney may not be the appropriate examination for someone with a stainless steel IVC filter. Nitinol and other alloys will produce less degrees of artifact, and the vessel lumen may be evaluable even inside a stent[35] or adjacent to an IVC filter. Although vessel patency can usually be evaluated, some artifact will still be present, and therefore these images may not reliably demonstrate vessel diameter or the degree of stenosis.

RECENT ADVANCES

3-Tesla Magnetic Resonance Angiography

As noted earlier, MR systems with magnets up to 3 T have now been approved by the FDA. Because the degree of magnetization produced is linearly related to the magnetic field strength, use of a 3-T magnet can result in an improvement of up to a factor of 2 in image signal greater than 1.5 T. This increased signal can then be traded for decreased imaging time or increased spatial resolution. Although the first applications demonstrated to benefit from 3-T imaging were imaging of the brain and spine and musculoskeletal imaging, the entire range of MRI is now being performed at 3 T, including breast, body, and cardiac MRI, as well as MRA.[105-108]

MRA at 3 T has several other advantages over 1.5 T. T1 relaxation times are longer at 3 T than at 1.5 T, which results in an increased degree of enhancement from the same amount of gadolinium contrast or the ability to use less contrast to obtain the same degree of enhancement, which may be relevant for those with impaired renal function. Preliminary studies have shown improved image quality and accuracy of 3-T MRA over 1.5-T MRA for imaging of the renal, carotid, and infrapopliteal arteries.[109-111]

The principal disadvantage of 3-T imaging is a fourfold increase in deposition of RF energy into the patient, known as the specific absorption rate (SAR). There are FDA-mandated limits on SAR, which are encountered more commonly at 3 T than at 1.5 T. Although this is not an important problem for contrast-enhanced MRA because of the types of pulse sequences used, it can be an issue when using non–contrast-enhanced SSFP techniques and in applications such as cardiac MRI. Additional concerns include higher cost for 3-T MR systems than for 1.5-T systems and an increase in certain types of image artifacts related to inhomogeneity of the magnetic field, which requires careful shimming (adjustment) of the gradient magnetic fields to maintain even signal across the image.[112] Despite these difficulties, more MRA studies will be performed at 3 T as radiology practices switch to this new technology because of its advantages for general MRI.[113]

Parallel Imaging

Parallel imaging refers to a collection of MR acquisition and processing techniques that use multiple coils and RF receiver channels to accelerate the acquisition of image data.[114,115] In parallel imaging, multiple receiver coils are placed around the object, and RF signals may be read independently from each coil. Because the different coils are at different positions relative to the object being imaged, analysis of the subtle differences in signal acquired by each coil can provide spatial information about the object. This type of spatial information can be used to reduce the number of different gradient settings (called phase-encoding steps) at which RF signal must be acquired to obtain an image, thus reducing acquisition time. The amount by which the acquisition time is reduced is referred to as the "acceleration factor" and is theoretically proportional to the number of independent coil signals that are acquired. However, in practice, acceleration factors are currently limited to 2 or 3 because the SNR of the resultant images is decreased by the square root of the acceleration factor. As such, the use of parallel imaging is usually confined to high-SNR applications, including MRA, and most contrast-enhanced MRA examinations done on newer scanners are now performed with parallel imaging.[116]

Advantages of parallel imaging include

1. Faster imaging—which may lead to fewer motion artifacts and shorter breath-holding time.
2. Higher resolution imaging in the same acquisition time.
3. Lower SAR—especially important for 3-T imaging.
4. Improved image homogeneity and slightly better SNR because multiple smaller coils are more evenly distributed around the body part being imaged than a larger single coil would be.

Disadvantages of parallel imaging include

1. Need for more expensive multielement coils and multiple–receiver channel MR systems. Newer MR systems may have to 32 receiver channels, which allow the acquisition of 32 simultaneous signals from up to 76 separate coil elements. Although all MR systems are capable of performing parallel imaging, some are limited in the number of coils that may be connected simultaneously, which can have implications when performing step-table examinations.
2. Increase in image noise as a result of acquisition of less information.
3. Image artifacts related to parallel data processing may occur.

Compressed sensing[117-119] is a mathematical framework that provides reconstruction of data from highly undersampled measurements to gain acceleration of acquisition time. The k-space is undersampled to allow reconstruction of an image from less data. This method is useful in pediatric imaging and where shorter breath-hold sequences are required. Compressed sensing approaches are now available from several manufactures and will be incorporated into routine MRA protocols in the coming years.

Continuous Moving Table and Time-Resolved Magnetic Resonance Angiography

One limitation of 3D contrast-enhanced MRA is that signal from the entire volume of data is acquired simultaneously, so respiratory or other motion at any point during the acquisition may result in artifacts throughout the imaged volume. A solution to this difficulty is continuous moving table MRA, in which, as occurs in helical computed tomography (CT), the table moves throughout the acquisition in a proximal-to-distal direction. As in helical CT, data from only a small volume of tissue are being acquired at any moment, and motion artifacts will affect only the region being acquired at the time of the motion. In addition, continuous moving table techniques may truly permit "bolus chasing" because the speed of table motion can be adjusted to match the transit time of contrast in the arteries.[120] This technique has shown promising results for peripheral vascular imaging, particularly when combined with parallel imaging techniques to allow decreased scan time and increased resolution, without venous contamination.[121] Fig. 28.26 demonstrates a continuous table motion MRA runoff obtained at 3 T with parallel imaging.
