SELECTED KEY REFERENCES 662

Surgical exposure of the aorta involves three main segments: the ascending aorta and aortic arch, the thoracic aorta, and the abdominal aorta. Depending on the pathology, either one or several of these segments will need exposure simultaneously. This chapter presents the various incisions, techniques, and key elements for exposure of each aortic segment or combinations of segments.

EXPOSURE OF THE ASCENDING AORTA AND AORTIC ARCH

Median Sternotomy

The median sternotomy exposure is an optimal method to access the chambers of the heart, the ascending aorta, and the aortic

Abstract

Aortic hybrid repair involves open surgical bypass and endovascular stent grafting to treat a number of aortic pathologies. Typical debranchings are done for the great vessels off the aortic arch, or the visceral vessels in the abdominal aorta

Keywords

hybrid
debranching
stent graft
thoracoabdominal aortic aneurysm
arch aneurysm

arch. As a result, it is the most common exposure technique for operations involving the ascending aorta and the great vessels.

Position

The patient is placed supine on the operating room table, with arms tucked along the patient's side to relax the musculature and allow opening of the mediastinum and chest space.

Incisions

An incision is made from just below the sternal notch to the tip of the xyphoid process. This incision can be extended for additional exposure of the aortic arch vessels, either along the anterior borders of the sternocleidomastoid muscle for exposure of the left or right common carotid arteries or superiorly along the midline for greater overall exposure. If additional exposure of the right subclavian artery is required, the incision can be carried along the superior border of the clavicle. Although an anterior 3rd or 4th intercostal space thoracotomy is the approach typically used for exposing the left subclavian artery, the very proximal part of the left subclavian artery can also be reached through a median sternotomy. Extension into a left supraclavicular incision may be needed for further distal control. An additional anterior 3rd or 4th intercostal space thoracotomy with creation of a trap door thoracotomy can be added to obtain exposure of the full continuum of the left subclavian artery in extremis patients with challenging traumatic injuries.

Dissection

Electrocautery is used to divide the subcutaneous tissue down to the pectoral fascia, which is also divided. The periosteum is then scored along the midline an equal distance from both sides of the intercostal space. The interclavicular ligament at the top of the sternal notch is divided. The tissues on one side of the xyphoid process are released, though some surgeons prefer to resect the entire process. Using a sternal saw, the sternum is divided along the midline. It is imperative to hold mechanical ventilation at this time to avoid inadvertent pleural tears. Electrocautery is then used to achieve hemostasis along the anterior and posterior edges of the sternum. Manual pressure and a small amount of bone wax can be used to achieve hemostasis of the bone marrow. Once the sternopericardial ligaments are divided and the pericardium is freed from the posterior sternum, the sternal retractor is placed and progressively opened to achieve homogeneous retraction. The vessels arising from the internal thoracic artery and draining into the brachiocephalic vein are identified and ligated. This allows full mobilization of the brachiocephalic vein. The superior portion of the pericardium is then opened vertically to access the ascending aorta and origin of the aortic arch vessels (Fig. 53.1). In certain circumstances, it may be necessary to ligate the left innominate vein, which is often well tolerated. Following these maneuvers, the ascending aorta, the aortic arch, and the innominate and left common carotid arteries can easily be identified and dissected free from surrounding tissues. The right vagus and right recurrent laryngeal nerves must be avoided during dissection of the distal portion of the innominate artery. It should be recognized that the vagus nerve courses anterior to the subclavian artery at its origin, with the recurrent laryngeal nerve originating from the vagus nerve and coursing posterior to the subclavian artery origin, creating a sling where the subclavian artery rests. Exposure of the innominate artery bifurcation can be obtained, often requiring caudal retraction of the left innominate vein. Small vessels draining into the innominate vein should be ligated prior to any manipulation of the innominate vein to avoid tearing of these vessels. Exposure beyond the proximal right common carotid artery and subclavian artery may require extending the incision.

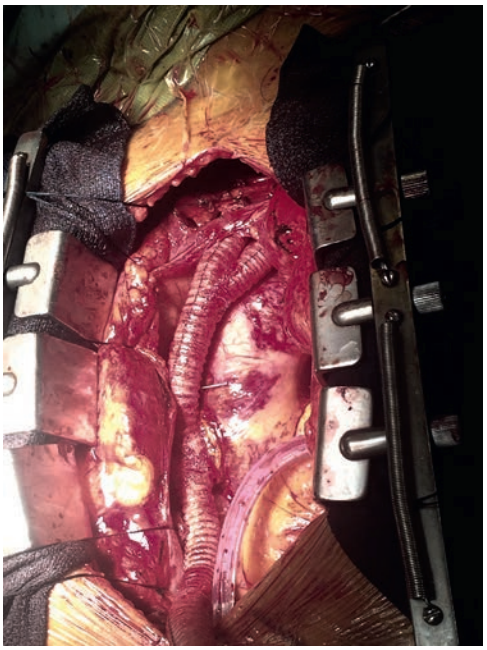

Figure 53.1 Exposure of the ascending aorta. The median sternotomy allows ample exposure of the ascending aorta and the proximal branches. This image shows an aorto-innominate graft with second limb traveling to the left carotid artery. A third limb traveling caudally will be used as a conduit to place an endograft. The two cranial limbs travel posterior to the brachiocephalic vein.

Mini-Sternotomy

The mini-sternotomy was first described in 1949 by Holman and Willett.[1] Today, it is commonly used for valve replacements, aortic root replacements, and ascending aortic aneurysm repairs. Its benefits include reduced trauma and a lower risk of sternal instability. It is also commonly used in re-operative cardiac surgery to reduce the risk of ventricular injury during sternal retraction. The advantages of this technique include decreased post-operative pain, decreased blood loss, and decreased adhesions around the right ventricle, as this region is not dissected during this exposure.[2] A number of studies have been conducted by Svensson and colleagues regarding minimally invasive sternotomy techniques. In one particular study, 54 patients underwent mini-sternotomy, 18 of which were redo sternotomies. Thirty-six patients underwent ascending aortic repair and 18 underwent ascending and aortic arch repair. Mortality and incidence of stroke were 4% and 3.7%, respectively, indicating that this method was safe for use in ascending and aortic arch repairs.[3]

Position

As with a full sternotomy, the patient is placed supine on the operating room table, with arms tucked along the patient's side.

Incision

There are various incisions for this approach, including the upper "T" and upper "J" incisions, which are the most commonly employed incisions to expose the superior mediastinum. Both incisions often provide adequate exposure to the aortic arch and the proximal portions of the innominate artery and vein. Moreover, conversion to a full median sternotomy is always an option when exposure is inadequate using this technique. An upper reversed "T" incision spans from the sternal notch caudally to the level of the 3rd or 4th intercostal space, while the "J" incision begins at the sternal notch and comes across the right 3rd or 4th intercostal space. Transesophageal echocardiography may be used to aid in determining the caudal extent of the incision.[2]

Dissection

The sternum is divided in the midline and then transected transversely taking care to avoid injuring the internal mammary arteries, which lie just lateral to the sternum. For additional exposure the internal mammary arteries can be ligated. A self-retaining retractor is then placed to separate the upper portion of the sternum and the dissection is continued in the same fashion as a full sternotomy.

EXPOSURE OF THE DISTAL AORTIC ARCH AND DESCENDING THORACIC AORTA

Trans-Sternal Bilateral Thoracotomy (Clamshell)

The trans-sternal bilateral thoracotomy incision is used in traumatic situations, lung transplantation, single-stage operations, as well as for repair of aortic arch and proximal descending aortic pathology. This technique is most useful for exposures that require not only arch access, but also access to the descending aorta. As with the mini-sternotomy, the clamshell incision may be used in redo operations. The major disadvantage of this exposure is the need for increased ventilatory support postoperatively as compared to a median sternotomy.

Position

The patient lies in the supine position with the right arm alongside the chest. The left shoulder and hip are slightly raised with bumps.

Incision

An incision is made from the medioclavicular line on the right to the anterior axillary line on the left at the level of the 4th intercostal space.[4]

Dissection

Dissection is carried down through the intercostal muscles in the fourth intercostal space, and both internal mammary arteries are ligated and then divided. The sternum is then divided transversely using a saw in the transverse plane. Using rib spreaders, the thoracic cavity is exposed. The pericardium and pleural reflections are dissected free from the posterior portion of the sternum. The left lung is mobilized and retracted away from the region of interest.

Left Posterolateral Thoracotomy

Exposure of both the distal aortic arch and proximal descending thoracic aorta may be accomplished using a left posterolateral thoracotomy. This incision requires tolerance for single lung ventilation.

Position

The patient is positioned in the right lateral decubitus position with the left arm placed above the head on a padded armrest. The right arm is extended at 90 degrees to the operating room table with the elbow partially flexed to avoid traction of the brachial plexus. Padding is placed between the legs with the right leg flexed at the knee and the left leg extended resting on top of the padding. An axillary roll is placed under the right shoulder to support the shoulder girdle.

Incision

A curvilinear incision is started at a point midway between the medial border of the scapula and the thoracic spine along the 4th intercostal space along the inframammary crease to the tip of the scapula. This can be extended medially for additional exposure of the aortic arch vessels. In cases involving the aortic root, the sternum can be transected but this requires sacrifice of the internal mammary artery.

Following skin incision, flaps are raised and the anterior edge of the latissimus dorsi is incised vertically. The plane between the latissimus and the serratus anterior is developed. Following this, the posterolateral edge of the serratus muscle is incised and the muscle is elevated. The latissimus dorsi is retracted posteriorly, and the serratus retracted anteriorly, thereby exposing the intercostal space.

The 4th intercostal space is identified and entered on the superior portion of the rib to avoid injury to the neurovascular bundle. The pleural sac is appreciated and opened with a fine-tipped scissors. A ratcheted, self-retaining chest wall retractor, such as a Finichetto retractor, is then carefully placed between the ribs at the incision site and slowly opened. If the distal portion of the descending aorta is involved in the operation, the fifth rib may be resected for adequate exposure. The left lung is deflated and retracted to expose the descending aorta. The vagus, recurrent laryngeal, and phrenic nerves are identified just proximal to the origin of the left subclavian artery. The aorta is then mobilized and intercostal arteries are ligated. In patients with thoracoabdominal aneurysms, the incision can be extended through the retroperitoneum, dividing the

costochondral margin that is described in detail later in this chapter.

EXPOSURE OF THE THORACOABDOMINAL AORTA

This approach will allow for exposure of the entire thoracic and abdominal aorta. The incision and dissection will vary depending on the level of exposure required. Due to the location of the aorta, this incision crosses both the thoracic and abdominal cavity, making it difficult to stay within anatomic boundaries. When possible more limited incisions should be utilized; it is important to note that the abdominal part of the aorta can be reached through an extraperitoneal (retroperitoneal) or transperitoneal approach. In the extraperitoneal approach, the aorta is exposed through the retroperitoneum without entering the peritoneal cavity, avoiding bowel manipulation and limiting fluid loss. In the transperitoneal approach, the abdominal cavity is entered and the aorta and its branches are exposed using a left medial visceral rotation. The latter is typically used when access to the distal visceral vessels, right renal artery, or right common iliac bifurcation is needed.

Position

The patient is placed in modified right lateral decubitus position with the shoulders at 60 degrees to the table (Fig. 53.2). The hips are rotated up to 45 degrees and partially flexed with the legs parallel to the bed. This allows access to both groins. The right arm is placed in a sling above the patient's head to enable proper rotation of the upper body, and a shoulder roll is placed under the chest to ensure the right shoulder is free from pressure. The operating table is hyperextended to open the space between iliac crest and costal margin. Once the patient is in the appropriate position, a moldable beanbag that was previously placed to sit between the patient and the operative table is secured by vacuum suction.

Figure 53.2 Positioning for exposure of the thoracoabdominal aorta. The body is placed in a lateral decubitus position with the operating table extended to provide maximum exposure.

Incision

Prepping and draping should allow for access to the left thorax, the abdomen caudal for exposure of the distal right common iliac artery. A gentle curve near the superior portion of the incision reduces the risk of tissue necrosis at the apex of the lower portion of the musculoskeletal tissue flap as the incision crosses the costal margin. The more superior the exposure of the aorta, the more medial and superior the incision travels, with the incision traversing the skin along the 5th, 6th, or 7th intercostal space according to the desired level of exposure (Figs. 53.3 and 53.4). To expose portions of the distal aortic arch, it may be necessary to enter the space between the 3rd and 4th rib through the same skin incision but as a separate thoracotomy incision (double thoracotomy).

Thoracic Dissection

To expose the thoracic aorta, the latissimus dorsi, anterior serratus, and rectus muscles are divided by electrocautery. The pleural space is entered after single right-lung ventilation is initiated. The subcostal margin is cut with either electrocautery or scissors at the lower intercostal space and the incision is linked downward with the abdominal portion of the incision. The entire rib or the posterior section of the rib of the particular interspace can be resected to aid in exposure. Once the pleural space is entered, the inferior pulmonary ligament is divided with cautery, ligating any vessels within it.

The lung can then be gently retracted superiorly and laterally to expose the distal portion of the thoracic aorta. Pulmonary

Figure 53.3 Incision used to repair a type 3 thoracoabdominal aortic aneurysm. Exposure of both the abdominal and thoracic aorta requires an incision that crosses anatomic boundaries.

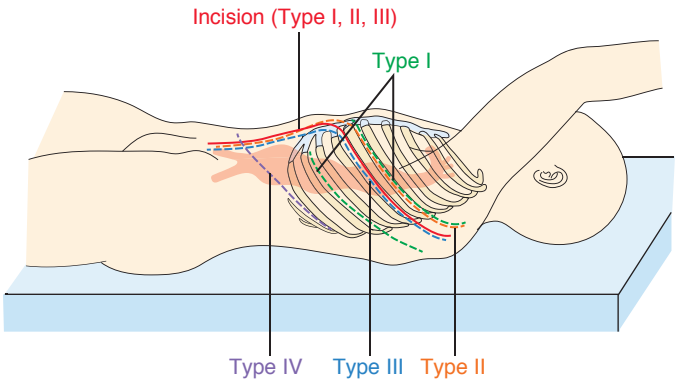

Figure 53.4 Skin incisions and superficial dissection for thoracoabdominal aortic (TAA) exposure. The red line indicates the skin incision for exposure of Type 1 to 3 TAA aneurysms. Manipulation of this skin incision allows for multiple entry points into the thoracic and abdominal cavities based on aneurysm location. The plane used for superficial dissection, including the appropriate rib space to enter the pleural cavity, is shown with the various green, gray, and orange dotted lines for TAA aneurysms 1 to 3. The blue dotted line indicates both the skin incision and the superficial dissection plane for type 4 TAA aneurysms.

manipulation should be kept to a minimum. The proximal descending aorta can be separated from the surrounding mediastinal tissue to expose the origin of the left subclavian artery. The vagus nerve and recurrent laryngeal never are in close proximity to the aorta just proximal to the subclavian artery, and care should be taken not to injure these structures during this portion of the dissection. The thoracic aorta is then circumferentially dissected from the esophagus, which lies just anterior and medial to the aorta. The diaphragm is radially divided to avoid injury to the phrenic nerve for several centimeters near its peripheral attachment to the anterior chest wall for maximal exposure. Some surgeons advocate partial division of the diaphragm in an attempt to decrease postoperative pulmonary complications. This decision is often dictated by the intraoperative anatomy and level of complexity of the exposure.

Abdominal Dissection

The abdominal aortic dissection is initiated by dissecting down to the abdominal wall musculature lateral to the rectus abdominus muscle and fascia.

Medially, the rectus muscle and associated fascia can be divided if additional exposure is required. It is often better to mobilize the rectus from medial to lateral after superior transection to avoid denervation. The anterior and posterior sheaths are divided longitudinally. This will allow two-layer closure of the anterior and posterior rectus sheath at the end of the procedure. Laterally, the dissection is continued by dividing the external oblique, internal oblique, and transversalis muscles to identify the peritoneum (Fig. 53.5). Great care must be taken not to disrupt the peritoneal lining, as it is thin and often difficult to distinguish from the transversalis fascia. Difficulty in separating the "peritoneum" from the abdominal wall is often due to incomplete division of the transversalis fascia. Once the peritoneum is identified, it is separated from the abdominal wall using a combination of manual dissection and gentle traction. The peritoneum and the abdominal visceral are retracted to the right to reveal the retroperitoneal fat. The plane between the retroperitoneal fat and the psoas muscle is then created and traced superiorly to the diaphragm. Gerotas fascia and the contained left kidney are included with the peritoneal contents and lifted anteromedially to expose the infrarenal and visceral segments of the aorta. The parietal peritoneum is dissected free from the periaortic fat and rolled medial to expose the anterior portion of the aorta and identify the proximal portions of the visceral vessels. The right renal artery will not be visible with this exposure unless the infrarenal aorta is either transected or fully mobilized. The left ureter will be on the back of the peritoneal sac and should be identified as it crosses the iliac artery (Fig. 53.6).

The left renal artery is identified to orient the visceral aortic dissection (Fig. 53.7). A relatively constant structure nearby the left renal artery origin is the reno-lumbar vein, which rises from the psoas groove to enter the renal vein, taking a course around the left side of the aorta. This vessel must be identified and ligated to allow the kidney to be retracted further medially. In rare circumstance, a retro-aortic left renal vein prevents this retraction. In that situation, the kidney can be left in its native position (see below) with the renal vein ligated distal to the adrenal and gonadal vein to allow collateral drainage. Ligation with planning of re-anastomosis is extremely difficult due to retraction, which creates tension during repair and should be avoided.

The peritoneal cavity is dissected free from the periaortic fat and rolled medial to expose the anterior portion of the aorta and identify the proximal portions of the visceral vessels.

The diaphragmatic crus is divided, freeing the visceral aorta and allowing greater mobility of the aorta during the operation (Fig. 53.8). Further mobilization is aided by dividing the median arcuate ligament. With these maneuvers, the origins of the left renal artery, the superior mesenteric artery, and the celiac artery can all be identified and circumferentially dissected (Figs. 53.9 and 53.10).

EXPOSURE OF THE DISTAL DESCENDING THORACIC AORTA AND VISCERAL AORTA

Transperitoneal Approach

A transperitoneal approach should be used to access the visceral and infrarenal aorta, both renal arteries, the hepatic artery, as well as the distal portion of the celiac and superior mesenteric artery. The origins of the superior mesenteric artery and celiac artery can also be exposed although extensive mobilization of the spleen and pancreas is needed. The approach requires significant manipulation of the abdominal viscera and thus should be used selectively.

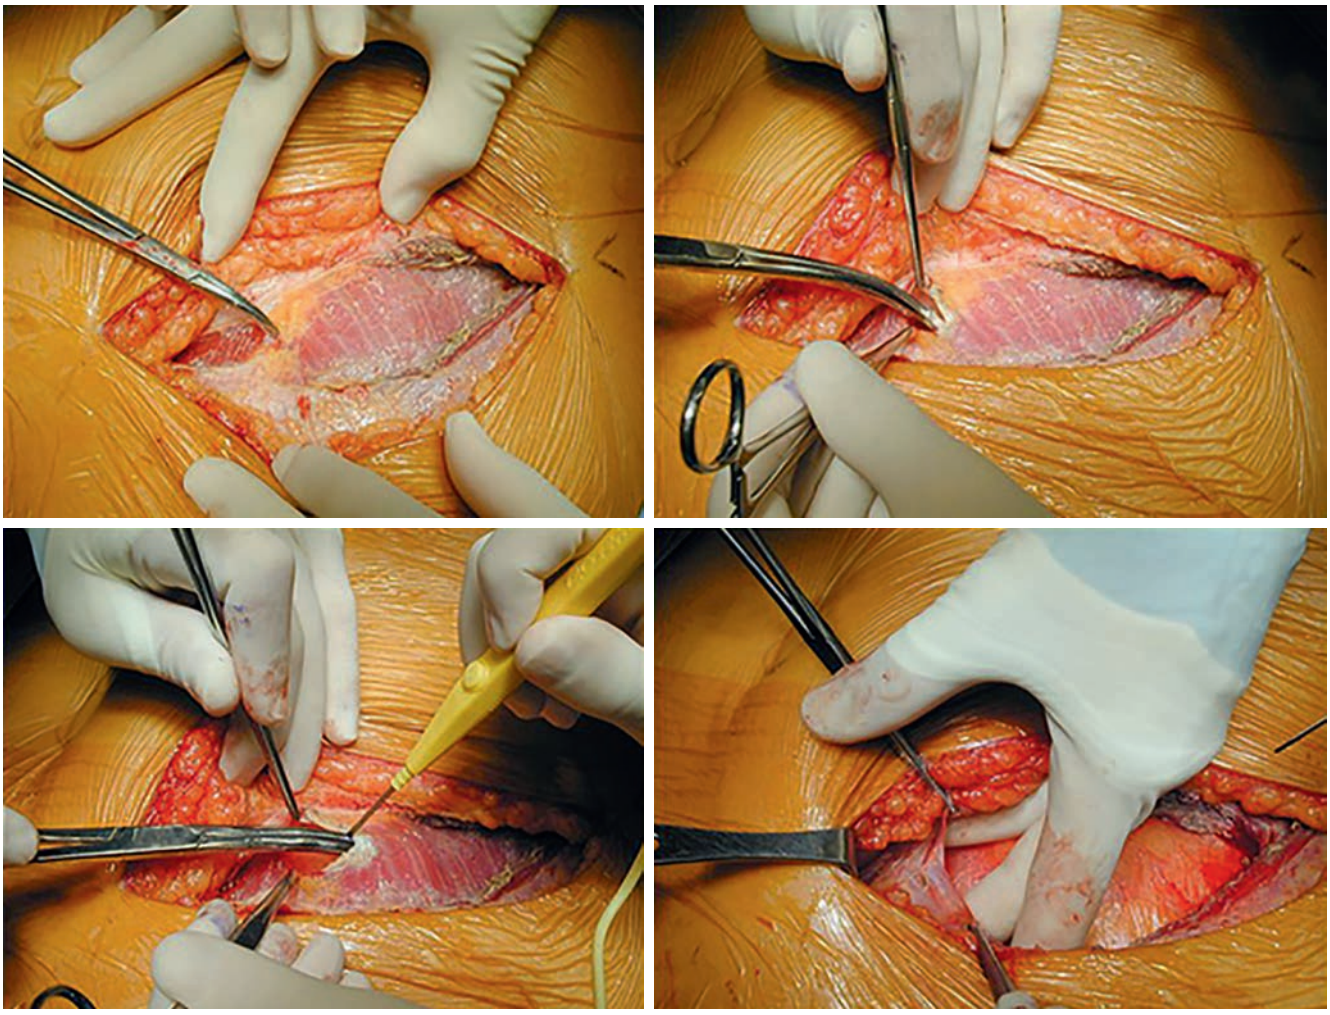

Figure 53.5 Layers of the abdominal wall. This panel shows the identification of the lateral border of the rectus muscle *(top left)*, followed by the dissection of the external oblique, internal oblique, and transversus abdominis musculature (*top right* and *bottom left*). Ultimately, the peritoneal lining is identified *(bottom right)*.

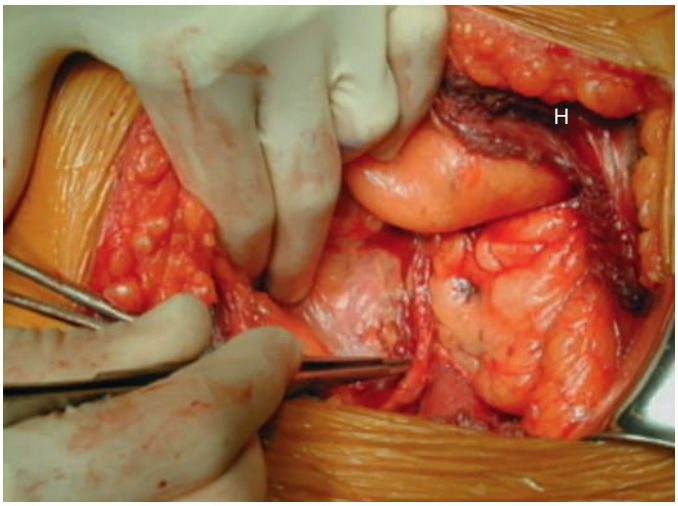

Figure 53.6 Ureter lying within the retroperitoneal fat. In this image, it is identified and reflected posteriorly to allow the left kidney to remain in its anatomic position.

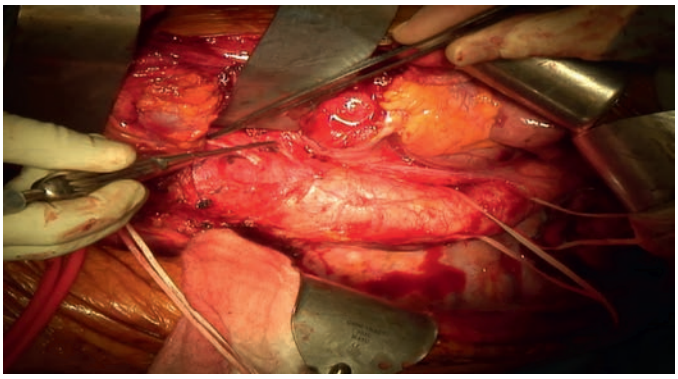

Figure 53.7 Exposure of the thoracoabdominal aorta. The left renal artery is identified at the tip of the surgeon's forceps as it courses posterior to a metal suction device. Identification of the left renal artery helps orient the surgeon to the remaining visceral vessels.

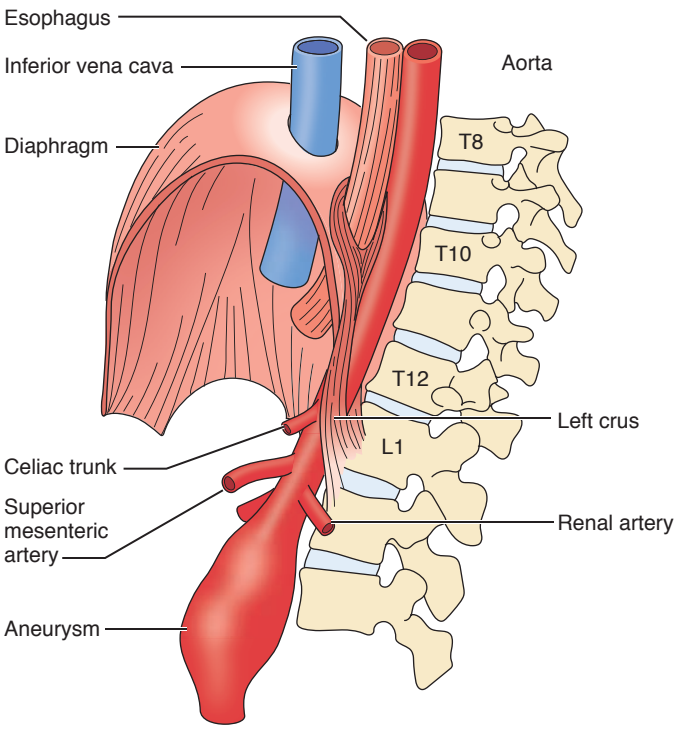

Figure 53.8 Sagittal view of the aorta and adjacent structures. The left crus of the diaphragm overlies the aorta proximal to the renal artery at the same level as the first lumbar vertebrae. Division of this structure allows access the paravisceral aorta and descending aorta from within the abdominal cavity.

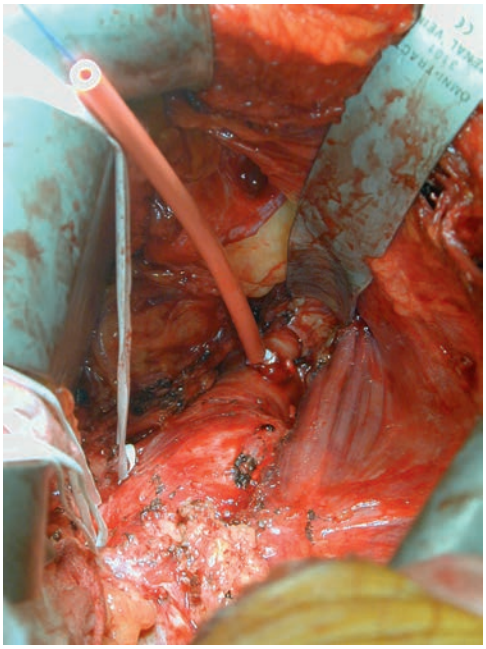

Figure 53.9 Exposure of the visceral aorta after dividing the diaphragmatic crus. A Rommel tourniquet is around the descending thoracic aorta.

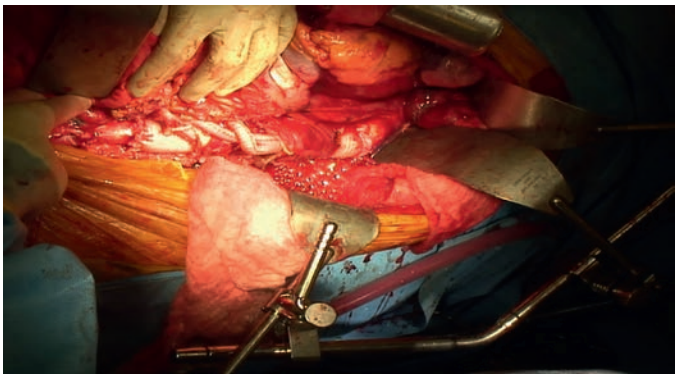

Figure 53.10 Complete replacement of the thoracoabdominal aorta. Note the three smaller caliber grafts anastomose with the left renal, superior mesenteric, and celiac arteries.

Position

The patient is placed supine with the arms extended laterally.

Incision

A midline laparotomy incision is made extending from the xiphoid process to the symphysis pubis. Alternatively, a transverse reversed "smile" incision can be used. The latter, however, divides the abdominal musculature and causes significant denervation of the abdominal wall muscles. Some surgeons, however, believe it is better tolerated by patients with pulmonary insufficiency.

Dissection

Once the midline fascia is incised the peritoneal cavity is entered and the abdominal contents can be inspected. The visceral aorta is exposed using a left medial visceral rotation. The splenic attachments to the abdominal wall are released and the spleen is mobilized superiorly and medially. This dissection is carried posteriorly along the space between the spleen and the left kidney by ligating the spleno-colic and spleno-renal ligaments. A plane is then developed following the lateral curvature of the spleen into the space posterior to the pancreas. The spleen and pancreas are then separated from the retroperitoneum and rotated medially until the suprarenal aorta is exposed. Dissection of the retroperitoneal and periaortic fat along with division of the left crus of the diaphragm provides additional proximal exposure of the suprarenal aorta. As with the retroperitoneal exposure, division of the medial arcuate ligament allows for identification of the celiac artery origin. The left kidney can be kept in the renal fossa or mobilized medially.

Retroperitoneal Approach

The retroperitoneal approach is used to expose the distal descending and abdominal portion of the aorta including the paravisceral segment. This allows for excellent exposure of the proximal abdominal aorta while not violating the peritoneal cavity, making it ideal for treating paravisceral aortic pathology and type 4 thoracoabdominal aneurysms.

Figure 53.11 Incision used for a retroperitoneal exposure of the aorta. Note the groin incisions used to expose the femoral arteries. When positioning a patient for a retroperitoneal exposure, both groins should be accessible.

Several studies have demonstrated reduced time in the intensive care unit and reduced time until return of bowel function using a retroperitoneal approach compared to a transperitoneal approach.[5,6]

Position

The patient is placed in modified right lateral decubitus position similar to the positioning for a thoracoabdominal exposure. However, in this case, the hips are rotated only 20 to 30 degrees and the right leg is partially flexed.

Incision

A curvilinear incision begins in the midline between the umbilicus and pubic symphysis and is carried laterally to the 10th or 11th intercostal space (Fig. 53.11). For exposure that focuses on the cranial portion of the abdominal aorta, the incision can be further extended along the intercostal space recognizing that the more cranial the incision, the more likely the pleural cavity will be entered. To avoid postoperative bulging, it is best to keep the incision within a single dermatome.

Dissection

The dissection is performed in a similar fashion to the abdominal portion of a thoracoabdominal exposure with the following exceptions. The anterior layer of the rectus sheath is divided

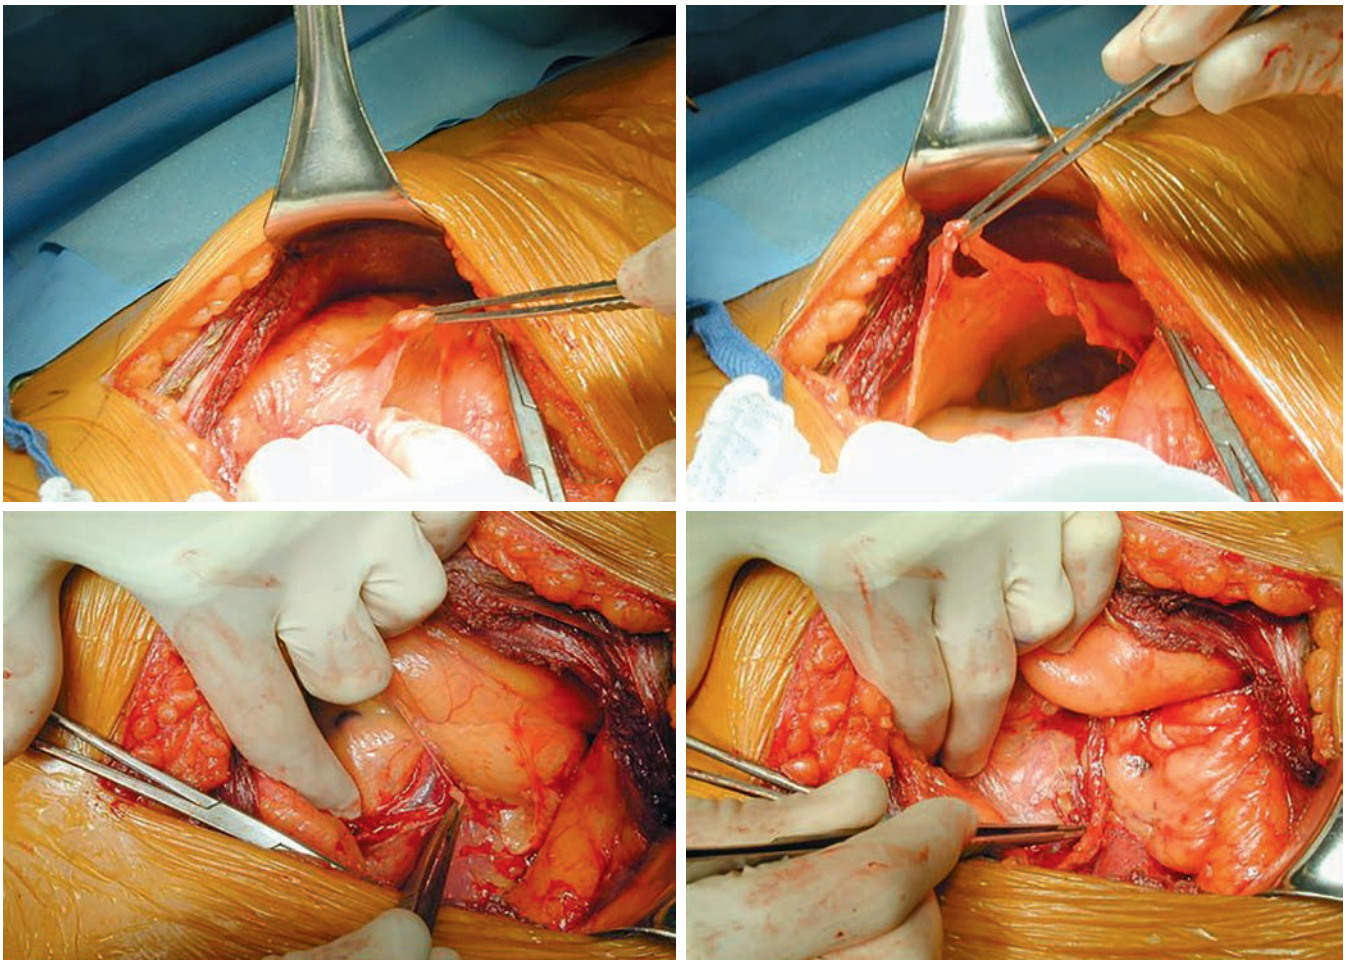

Figure 53.12 Dissection of the retroperitoneal space. The *top panels* demonstrate the plane between the pre-peritoneal fat and pro-peritoneal fat. Developing this plane will guide the surgeon down the aorta. The gonadal vessels and ureter can then be reflected posteriorly *(bottom panels)* while the peritoneal contents are retracted anteromedially. This allows the left kidney to remain in its anatomic position while still exposing the abdominal aorta.

after dissecting through the subcutaneous tissue; however, care should be taken not to divide the rectus muscle fiber, as this reduces hernia formation.[7] If exposure of the right common iliac artery is needed, division of the posterior rectus sheath can be performed, leaving the muscle fibers of the rectus intact. The lateral musculature is again divided down to the peritoneal cavity, keeping this division within a single dermatome.

Once the retroperitoneal space is created, the surgeon can continue the dissection in the pre-peritoneal space, the plane used in a thoracoabdominal incision, ultimately sweeping the contents off of the psoas muscle. Care should be taken to stay in the plane anterior to the psoas muscle. There is a tendency to go behind the psoas muscle, which leads to increased bleeding and injury to the ilioinguinal and genitofemoral nerves.

Alternatively, the plane between the pre-peritoneal fat and pro-peritoneal fat can be developed (Figs. 53.12 and 53.13). Developing this space allows the surgeon to sweep the pre-peritoneal fat and the peritoneal contents medially while leaving the pro-peritoneal contents in place, ultimately leaving Gerotas fascia and the left kidney undisturbed in its anatomic location. This approach reduces manipulation of the left kidney but limits the amount of cranial exposure that can be achieved. In both scenarios, the abdominal aorta is encountered, and the para-aortic fat is dissected free. When the pro-peritoneal fat is left in place, the gonadal vein and ureter should be identified to ensure it is not lifted medially with the peritoneal contents but rather left in their anatomic location. In cases where the kidney is left in its anatomic location, the gonadal vein can be ligated at its junction with the left renal vein to allow complete retraction

Once the aorta is encountered, the dissection of the infrarenal and paravisceral segments of the aorta can be completed as described in the thoracoabdominal section.

ANATOMIC CONSIDERATIONS

The aorta enters the abdomen through the aortic hiatus in the diaphragm at the level of T12 vertebra.[1] It is surrounded at this level by the right and left crura of the diaphragm and runs anterior to the spine. The first two branches off the aorta are the two phrenic arteries, which arise anterolaterally. The celiac axis refers to a short arterial trunk originating from the anterior surface of the proximal abdominal aorta as it passes between the diaphragmatic crura. The celiac trunk and its proximal branches are surrounded by tough, fibrous splanchnic ganglionic tissue, making dissection challenging. The celiac trunk splits 1 cm beyond its origin, most often (in 75% of patients) into three branches: the splenic, the common hepatic, and the left gastric artery.[2,3] The common hepatic arises from the celiac and runs on the posterior wall of the lesser sac, forming the lower boundary of the foramen of Winslow. It follows the upper border of the pancreas before it divides into the gastroduodenal and proper hepatic arteries. The proper hepatic lies anterior to the portal vein and gives rise to the right gastric before it divides into the left and right hepatics. In approximately 18% of cases the right hepatic artery is "replaced" and originates from the superior mesenteric artery (SMA). A "replaced" left hepatic artery originates from the left gastric artery in approximately 12% of cases. The SMA arises from the anterior aorta at the level of mid-L1, then courses inferiorly behind the pancreas and anterior to the third and fourth portions of the duodenum, to enter the root of the mesentery. Similar to the celiac trunk,

Abstract

This chapter explores the various approaches for exposure of the abdominal vasculature. It is an important reference for the vascular surgeon planning an open operation on vessels within the abdomen. It depicts the operative anatomy of the major abdominal arteries and veins and their relationship to surrounding structures and then walks the surgeon through the ideal exposure technique in an easy step-by-step fashion. The different approaches described along with advantages and pitfalls will help to guide surgical decision-making. The chapter starts with an anatomic overview, followed by a description of the variety of incisions available to expose the abdominal vasculature, and concludes by detailing the different approaches to each major vessel within the abdomen.

its origin is usually associated with some ganglionic neural tissue and large lymphatics which can make exposure tedious. The main branches of the SMA are the inferior pancreaticoduodenal artery (which forms an arcade with the superior pancreaticoduodenal artery from the proper hepatic), the first jejunal branch (which is usually spared in embolic occlusions of the SMA[4]), the middle colic artery, and the ileocolic artery. There are extensive collateral networks between the celiac trunk, SMA, inferior mesenteric artery (IMA), and internal iliac arteries. The celiac axis and SMA collateralize through the superior and inferior pancreaticoduodenal arteries. The SMA and IMA collateralize through the meandering mesenteric artery and the marginal artery of Drummond.[1] The meandering mesenteric artery is a collateral vessel that develops in the presence of SMA stenosis. It lies at the base of the mesentery and is at risk of being ligated along with the inferior mesenteric vein during exposure of the infrarenal aorta.[1] The renal arteries usually arise at the level of first lumbar vertebra, but there is considerable variability.[5] For example, multiple renal arteries occur in up to 30% of patients.[6] The left renal artery runs posterior to the left renal vein (LRV), whereas the right renal artery courses posterior to the vena cava. The juxtarenal aorta is the segment of aorta between 1 cm above and 1 cm below the renal arteries and frequently overlaps the visceral segment. The aortic bifurcation is usually at the level of L4-L5, with the IMA arising 2 to 3 cm above this juncture. The IMA gives rise to the superior rectal artery, the sigmoid artery, and the left colic artery. The right common iliac artery runs anterior to the inferior vena cava (IVC) and the origin of the left common iliac vein. At the level of the iliac bifurcation each artery is crossed by the ureter. The cisterna chyli lies to the right of the aorta and passes beneath the right crus of the diaphragm.

Abdominal Incisions

Vascular surgeons need to be familiar with a variety of approaches for exposing the abdominal vasculature (Figs. 54.1 and 54.2). Transperitoneal exposure through a midline celiotomy incision is the most versatile and therefore remains the standard approach. Virtually every major artery and vein can be exposed through this incision. Disadvantages compared with transverse or oblique incisions are a greater degree of postoperative pain and a higher incidence of incisional hernia, which can reach as high as 20% to 35% when used for aortic aneurysm repair.[15a] Transverse and oblique incisions are less painful (helpful in patients with pulmonary compromise) and less prone to hernias but lack the versatility of a midline incision.[7-10] The following is a more detailed description of the various abdominal incisions used by vascular surgeons.

Midline Incision

As mentioned previously, this is considered the most versatile approach, allowing unrestricted exposure of the infrarenal aorta and its branches (see Fig. 54.1). It can also provide exposure to the suprarenal aorta when combined with medial visceral rotation. The patient is positioned supine, with one arm abducted to 90 degrees and accessible to the anesthesia team. Skin preparation should extend from the nipples to include both groins down to mid thighs for access to the femoral arteries, and saphenous veins if needed. The incision starts at the level

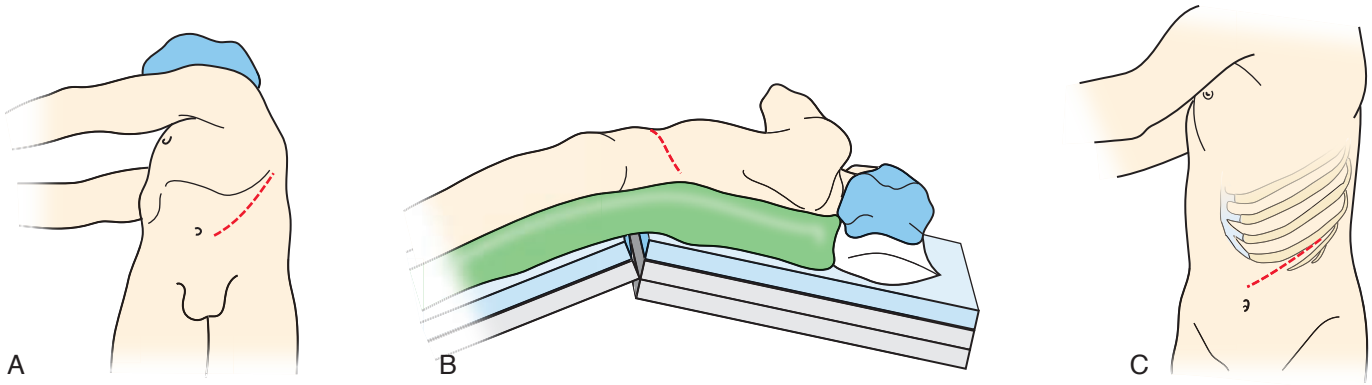

Figure 54.2 Patient Positioning for Left Flank Approach to Abdominal Aorta. (A) The shoulders are positioned at 50 to 70 degrees to the operating table and the pelvis rotated posteriorly as far as possible (corkscrew position). **(B)** The table can be jackknifed to widen the space between the left iliac crest and costal margin. **(C)** The incision can be carried into the 10th interspace for more proximal aortic exposure.

of the xiphoid in the upper abdomen and is carried down around the umbilicus. It can be extended to just above the pubic bone if the iliac vessels need to be exposed. The peritoneal cavity is entered through the linea alba, and the viscera are packed into the lower abdomen if one is working on the upper abdominal vessels, or in the right side of the abdomen if one is working on the infrarenal aorta. If the small bowel is eviscerated, it is placed in a bowel bag to keep the heat in and collect the transudate; a moist towel may also be used. A large mechanical retraction system (i.e., Omni Tract or Thompson) is useful to retract the bowel and help with exposure.

Transverse and Subcostal Incisions

The transverse and subcostal incisions are transperitoneal incisions (see Fig. 54.1). The transverse incision is carried across both rectus muscles from the contralateral anterior/mid-axillary line to the ipsilateral anterior/mid-axillary line (depending on the amount of exposure needed), midway between the costal margins and the iliac crests. When unilateral flank exposure is contemplated, the incision can be limited to one side and end at the contralateral midclavicular line. Transverse incisions can be supraumbilical ("frown") or infraumbilical ("smile"). The apex of the supraumbilical incision is centered halfway between the umbilicus and the xiphoid, and the center of the infraumbilical incision is 3 to 4 cm below the umbilicus. A supraumbilical transverse incision is good for infrarenal aortic exposure, particularly when concomitant distal renal artery exposure is necessary.[11] An infraumbilical incision provides excellent pelvic exposure (e.g., for large iliac/hypogastric aneurysms) but offers poor access to the pararenal aorta. When compared with a midline incision, some studies show a significant decrease in postoperative pain, pneumonia, and hernias,[12] whereas some show no difference in outcomes or complications.[10,13-15]

Subcostal incisions are transverse incisions infrequently used by vascular surgeons, which run parallel to the costal margins and two fingerbreadths below them. The most common variety is an extended right or left incision which begins at the lateral edge of the contralateral rectus sheath and is carried across the midline as far laterally on the ipsilateral side as necessary (usually the anterior axillary line). The subcostal incision is helpful in exposing the hepatic, splenic, and renal arteries, as well as upper abdominal venous structures.

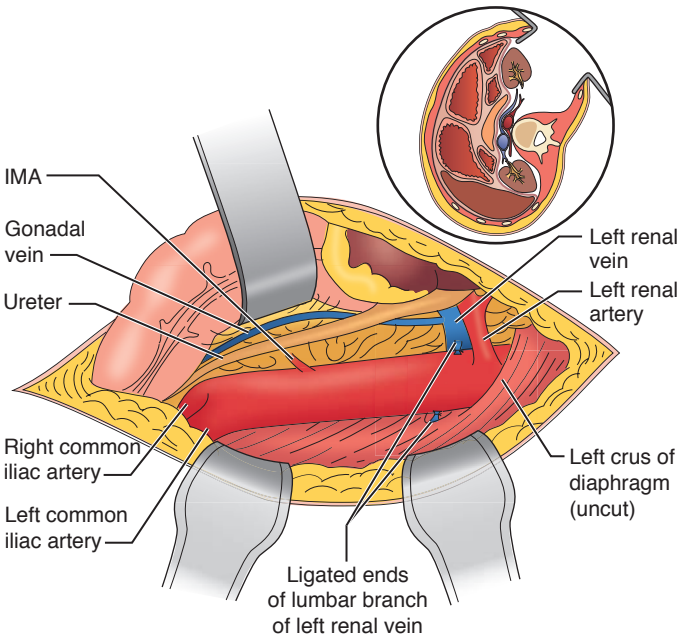

Figure 54.3 Left Flank Incision Retroperitoneal Dissection. The abdominal contents are retracted anteriorly and to the right. The left kidney is mobilized anteriorly, and the lumbar branch of the left renal vein is divided; inset is a cross sectional view demonstrating a retrorenal dissection plane. *IMA*, Inferior mesenteric artery.

Oblique Flank Incision

These incisions are retroperitoneal and helpful for exposing the aorta and its branches through the left flank, and the IVC through the right flank (see Figs. 54.1-54.3).

A left retroperitoneal flank incision (see Figs. 54.2-54.4) is excellent for patients with complex aortic anatomy.[15a] Different

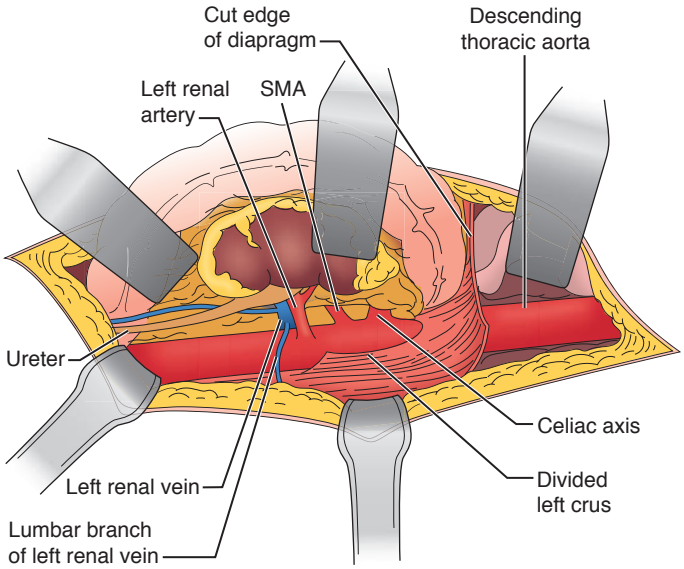

Figure 54.4 Left flank thoracoretroperitoneal approach with exposure of aorta from distal descending thoracic segment to aortic bifurcation. *SMA*, Superior mesenteric artery.

sections of the aorta from hiatus to bifurcation can be exposed based on which intercostal space is used. The restrictions of this incision are limited exposure of the right iliac system and poor visualization of nonostial right renal artery lesions. This approach is extremely helpful in redo-aortic operations, suprarenal aortic pathology, horseshoe kidney with multiple renal arteries, morbid obesity, inflammatory aneurysms, diastasis of the abdominal wall, and in patients with respiratory compromise (because the incision generates less pain). The patient is placed in a modified right lateral decubitus position, with the left shoulder at 30 to 70 degrees to the operating table, and the pelvis rotated posteriorly as far as possible (corkscrew position). A vacuum "bean bag" helps to maintain this position. The left arm is supported on an over-arm board. The table may be broken at the level of the umbilicus to open up the space between the left costal margin and iliac crest. An oblique incision is made from the lateral edge of the left rectus sheath, a centimeter or so above the midpoint between the umbilicus and pubis and extended a few centimeters into the 11th intercostal space. This incision is particularly good for infrarenal aortic exposure. Extension across the rectus to the midline aids in more distal right iliac exposure. For more proximal aortic exposure, the incision can be extended posteriorly or taken into a more proximal intercostal space (10th or 9th), which requires entry into the chest (a thoracoretroperitoneal approach; see Figs. 54.2 and 54.4). The external and internal oblique and transversus muscles are divided to the margin of the left rectus sheath medially, which is partially split. Posteriorly the intercostal muscles are divided on the superior aspect of the 12th (or 11th or 10th) rib, making no attempt to stay out of the chest. The retroperitoneal space is entered at the tip of the chosen rib, and the peritoneum stripped away from the musculature anteriorly (with or without the transversalis fascia). Dorsally, the peritoneum is stripped off the lumbodorsal fascia to the level of the psoas, and using blunt dissection, a retroperitoneal plane is developed by retracting the spleen, tail of pancreas, and left colon to the patient's right. This plane is developed either anterior or posterior to the left kidney depending on the nature of the procedure. A right flank incision can be performed in a similar fashion to expose the IVC. Shorter oblique incisions (extending from the lateral edge of the rectus just to the tip of the 12th rib) can also be used, but these provide very limited exposure.

Thoracoabdominal Incision (see Chapter 53)

This incision is used to expose the upper abdominal and lower thoracic aorta (see Figs. 54.2 and 54.4). It should be considered as an extended version of the retroperitoneal approach for exposure of the thoracic aorta. A double-lumen endobronchial tube is helpful when collapse of the left lung is needed during extensive work on the thoracic aorta; otherwise when only limited exposure is required the lung may be retracted out of the way. After intubation, the patient is rolled into a right lateral decubitus position and the scapula set between 60 and 90 degrees to the table, depending on the exposure needed. The hips are rotated as far posteriorly as 30 degrees to the table if access to the femoral arteries is necessary. A vacuum bean bag aids in maintaining the patient's torso in the ideal position. Other safety measures to minimize nerve injury include an axillary roll, and positioning of the lower extremities, with the bottom leg (the right) bent at the knee, the top leg (left) straight, and a pillow placed between the legs. The incision starts 2 cm below the tip of the scapula and extends to the midline. It is then deepened, preserving the latissimus dorsi if possible, and incising the serratus anterior muscle. Depending on the extent of the aneurysm, the thorax may be entered through any appropriate intercostal space (from the fifth interspace for an extent II thoracoabdominal aneurysm (TAAA), to the ninth interspace for an extent IV aneurysm). After entering the chest, the inferior pulmonary ligament is divided and the lung is mobilized and retracted. Distally, the incision may extend to the upper abdomen if the aneurysm involves only the upper visceral aorta (extent I and V TAAA), or it may extend down the midline to just above the pubis if it involves the iliac arteries. The abdomen can be entered through a retroperitoneal plane or transperitoneally, with left medial visceral rotation. The diaphragm is partially divided peripherally (50% of the circumference), 2 to 3 cm away from its attachments to the chest wall.[16,17] This avoids injury to the phrenic nerve. Leaving the diaphragm intact may result in earlier ventilator weaning.[17] A portion of the costochondral cartilage is excised to prevent postoperative costochondritis. Excising a 1.5 to 2 cm posterior segment of rib assists with the exposure and reduces pain postoperatively.

Lower Quadrant Incisions

Lower quadrant incisions are useful for exposure of the iliac arteries (see Fig. 54.1). The patient is placed supine, with a roll under his flank on the side of the incision. The classic transplant incision is a curvilinear ("hockey stick") incision, beginning one or two fingerbreadths above the symphysis pubis and lateral to the midline. This incision curves up laterally to the edge of

the rectus sheath and is then extended superiorly along the lateral edge of the rectus for a distance determined by how much of the iliac system needs to be exposed. The fascia at the edge of the rectus is divided along with the transversalis fascia to expose the peritoneum. The crossing inferior epigastric vessels caudally are ligated and divided. The spermatic cord should be preserved in male patients (freed up laterally and retracted medially), but the round ligament in females can be sacrificed if deemed necessary. A retroperitoneal plane is gently created laterally and the peritoneal sac and contents retracted medially to expose the iliac vessels from just below the aortic bifurcation to the inguinal ligament. Shorter suprainguinal incisions, running parallel to, and one or two fingerbreadths above, the inguinal ligament, provide excellent exposure for control of the distal external iliac artery, when femoral artery exposure is deemed hazardous (e.g., in the presence of a large femoral artery pseudoaneurysm).

Exposure of Infrarenal Abdominal Aorta and Iliac Arteries

Transperitoneal Approach

Inframesocolic exposure of the infrarenal aorta (Figs. 54.5-54.7) is the most common approach practiced by vascular surgeons.[5,14] It can be performed through a midline or transverse incision and is the preferred approach when access to the right renal artery, distal right iliac system, or intraabdominal organs is necessary. After entering the peritoneal cavity, the transverse colon is reflected superiorly out of the abdomen and the small bowel retracted to the right and protected with a moist towel, or placed in a plastic bag (see Fig. 54.5). Maintaining the small bowel within the abdominal cavity, as opposed to retracting it on to the abdominal wall, helps to reduce bowel wall edema. The peritoneal attachments of the third and fourth portions of the duodenum are divided and the mobilized duodenum reflected to the right. The retroperitoneum overlying the aorta, along with the paraaortic tissue, is incised. The inferior mesenteric

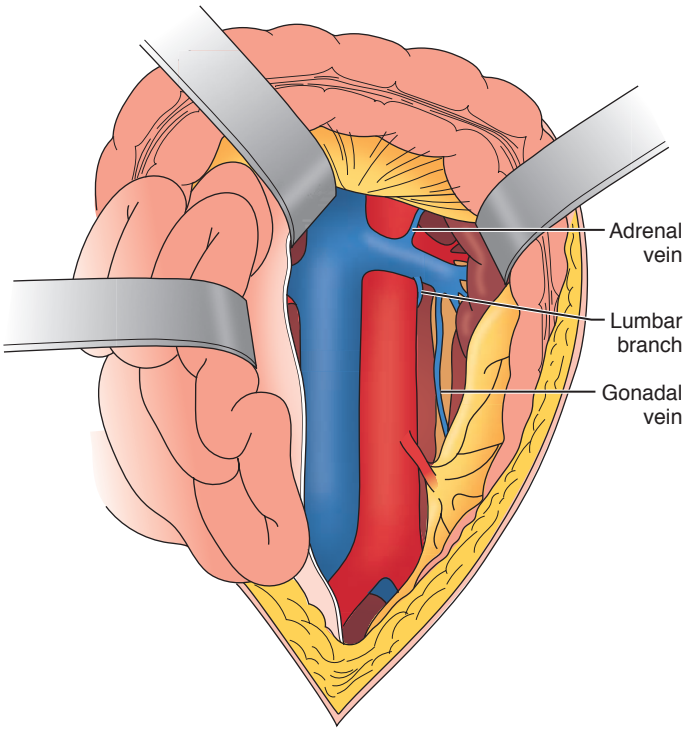

Figure 54.6 Inframesocolic approach to infrarenal aorta (II): Infrarenal aorta exposed from left renal vein to just below aortic bifurcation showing origin of the inferior mesenteric artery.

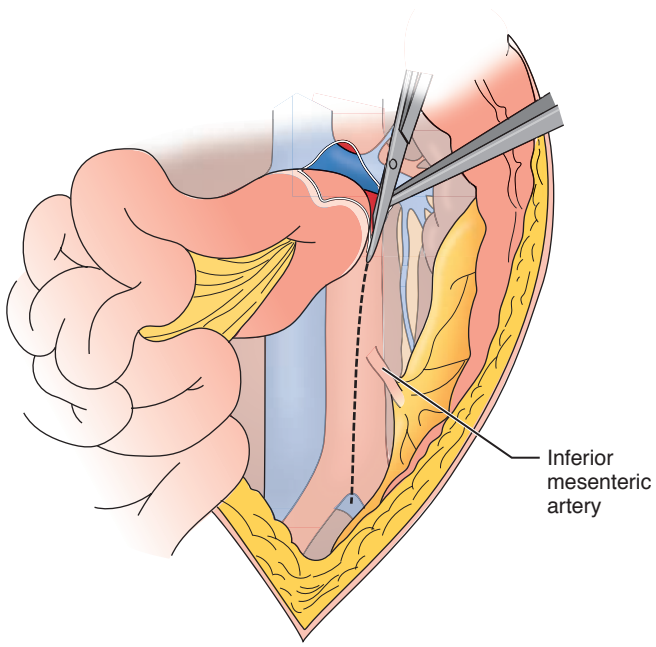

Figure 54.5 Inframesocolic approach to infrarenal aorta (I): Reflection of transverse colon superiorly, retraction of small bowel and duodenum to right after division of the ligament of Treitz.

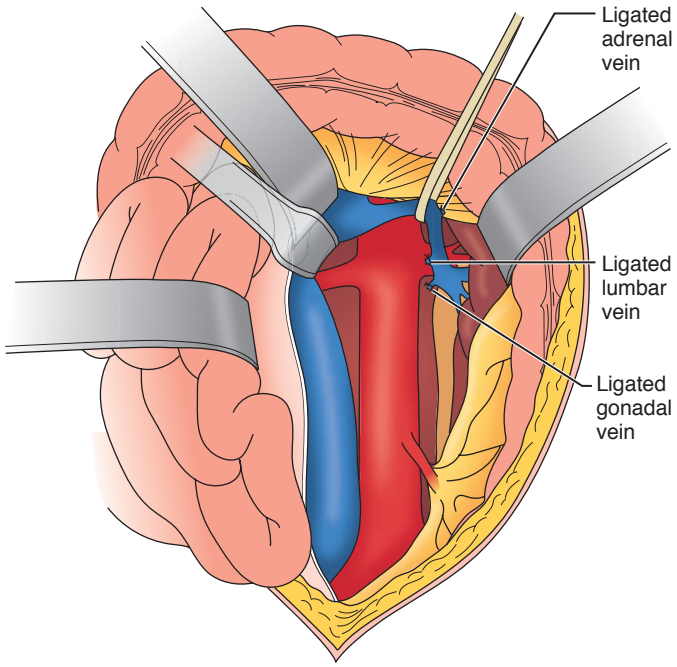

Figure 54.7 Inframesocolic exposure of the pararenal aorta with mobilization of left renal vein (following division of venous branches and retraction) to show renal artery origins.

vein is the most superficial venous structure encountered in the retroperitoneum superiorly and can be ligated and divided if necessary. The aorta is palpated and dissected out. The superior extent of the dissection is the LRV (see Figs. 54.6 and 54.7), where draining lymphatic channels are particularly abundant and should be ligated or divided with an ultrasonic scalpel, rather than cauterized, to avoid troublesome chyle leaks postoperatively. The anterior surface of the aorta can be cleared off distally to the level of the bifurcation, with the only structure at risk being the IMA. This vessel is surrounded by a plexus of nerves which should be avoided if possible. During mobilization of the duodenum and exposure of the retroperitoneal aorta, care must be taken to identify and protect any large visceral collaterals (e.g., the meandering mesenteric artery) that can sometimes course at this level.

Exposure of the pararenal aorta (see Fig. 54.7) more superiorly requires full mobilization of the LRV, again taking care to ligate adjacent lymphatics. The vein is freed up from its junction to the IVC to a point past its major branches, which include the left adrenal vein superiorly, the left gonadal vein inferiorly, and a lumbar branch posteroinferiorly. Ligating and dividing these branches allows the LRV to be retracted superiorly or inferiorly with an encircling Penrose drain, as needed. The LRV can be divided to improve exposure, but in this case, its branches (gonadal, adrenal, and lumbar branches) must be preserved to provide venous outflow for the left kidney. Division of the LRV should be performed close to the IVC to help preserve these collaterals. Whether LRV ligation is associated with an increased risk of renal dysfunction is controversial.[18,19] Exposure of the proximal left renal artery is accomplished by dissecting posterior to the mobilized LRV. The right renal artery courses posterior to the IVC, and its origin is visualized by freeing up the LRV-IVC junction. Crural fibers extending down from the diaphragm posterior to the renal arteries can be released to improve exposure. Aortic dissection can be carried superiorly to the origin of the SMA which is the cranial extent of this exposure. Again, large crossing lymphatics at this level should be ligated to avoid a chyle leak.

The origins of the iliac arteries (Figs. 54.8 and 54.9) can be exposed by slight distal extension of the retroperitoneal incision used for the infrarenal aorta. This extension can be continued over the course of the right iliac beyond the iliac bifurcation to expose the entire right iliac system. Exposure of the right bifurcation and hypogastric artery requires retraction of the cecum and small bowel laterally and superiorly. At the level of the iliac artery bifurcation, caution is taken to identify and protect the overlying ureter. Exposure of the external iliac artery is achieved by incising the peritoneum over it distal to the ureter.

Only a few centimeters of the left common iliac artery can be exposed as an extension of aortic exposure, because of the overlying sigmoid colon. The tissue crossing over the origin of the left common iliac artery contains parasympathetic nerve fibers (nervi erigentes), which should be carefully preserved and retracted rather than incised in sexually active male patients to avoid postoperative erectile dysfunction.[20] Circumferential dissection of the aortic bifurcation and most proximal common iliac arteries should be avoided unless absolutely necessary,

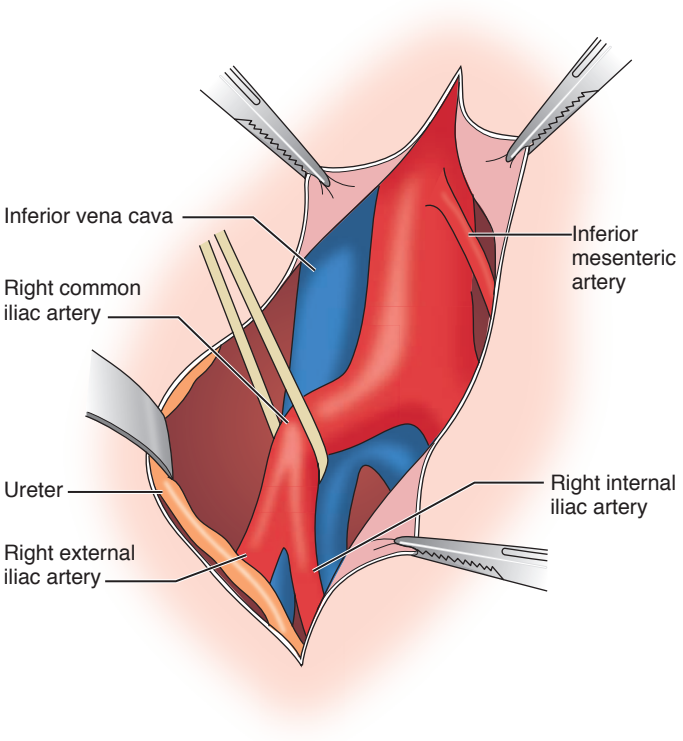

Figure 54.8 Exposure of right iliac artery bifurcation with ureter retracted distally.

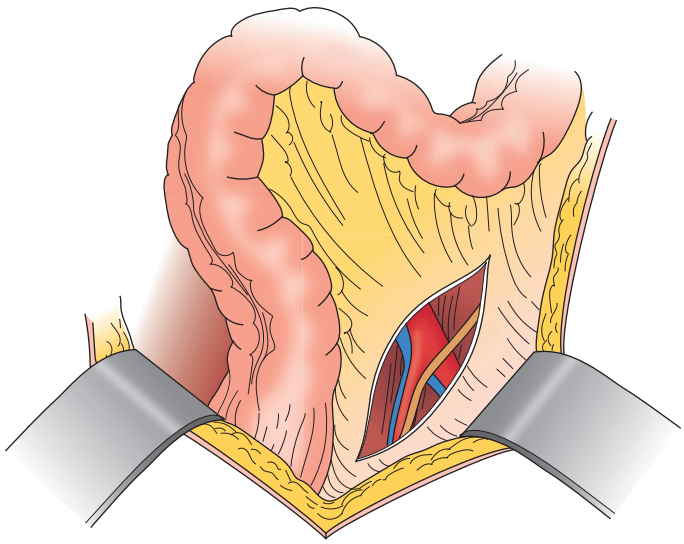

Figure 54.9 Exposure of left iliac artery bifurcation with crossing ureter after incising peritoneal reflection lateral to sigmoid colon.

because of the risk of injuring the underlying caval confluence, which can be quite adherent to diseased or aneurysmal arteries. Controlling the common iliac arteries just a few centimeters distally is usually safer. To access the left external and hypogastric arteries, the sigmoid colon is reflected medially after incising

its lateral peritoneal reflection. The external iliac artery is visually confirmed as traversing laterally and superiorly over the psoas muscles to form the common femoral artery beneath the inguinal ligament. The dissection is carried cephalad to identify the iliac bifurcation and crossing ureter. The hypogastric artery is confirmed as the branch coming off at right angles and coursing medially and inferiorly. Careful and meticulous dissection is performed to separate the internal iliac artery from the underlying vein.

Retroperitoneal Approach

As outlined previously, surgical exposure through a left flank retroperitoneal approach (see Figs. 54.2 and 54.3) offers a number of advantages.[7,8] Oftentimes the impediment to choose this approach is lack of surgeon's experience. An oblique left flank incision is made as described previously. After entering the retroperitoneal space, the surgeon must decide whether to expose the aorta anterior or posterior to the left kidney. A retrorenal plane is the one most commonly chosen, and the left kidney and ureter are reflected anteriorly along with the peritoneal sac and contents. When developing this plane, it is important to stay anterior to the lumbodorsal fascia covering the psoas and flank musculature, because of increased bleeding when this fascia is stripped off. As the viscera are retracted to the patient's right, the aorta should become palpable in the base of the wound. Initial efforts are focused on identification of the left renal artery because this is the only major structure that can be injured while clearing off the aorta from this approach. Identification does not necessarily require dissection of all the tissue around the pararenal aorta. A guide to this artery is provided by a large vein (the lumbar branch of the LRV) that crosses the left lateral wall of the aorta at this level; this vein usually requires division for exposure of the juxtarenal aorta. If this vein is quite large, the surgeon needs to be concerned that it may represent a retroaortic LRV, a possibility which can be confirmed by a review of preoperative imaging studies. In this instance the retrorenal approach should be abandoned in favor of an exposure plane anterior to the kidney, which will leave this vein undisturbed. Following division of the lumbar branch, dissection of the left lateral wall of the aorta is carried distally to the aortic bifurcation, watching for the origin of the IMA. During exposure of the aortic bifurcation, care should be taken to ensure that the left ureter has been mobilized and retracted out of harm's way. The entire left common iliac artery and its bifurcation are easily visualized through this approach, but only the proximal right common iliac artery is accessible. Division of the IMA can improve right iliac exposure, as can extension of the incision across the rectus to the midline, but exposure beyond the iliac bifurcation is rarely possible through this approach.

Exposing the aorta anterior to the left kidney is more tedious because a plane between the kidney and mesocolon must be developed with more sharp than blunt dissection. As the left colon and viscera are retracted anteriorly, the left kidney and ureter are left in their normal anatomic position posteriorly; the ureter must be carefully protected during subsequent left iliac dissection as it courses medially over the iliac bifurcation. Besides a retroaortic LRV, the only other indication for this approach is the need to expose a long segment of the SMA which is obscured by the crossing left renal artery when approached retrorenally.

As previously outlined, disadvantages of this approach include limited exposure of the distal right iliac system and right renal artery, as well as an inability to perform a complete abdominal exploration. However, a limited abdominal exploration is still possible by making a rent in the peritoneal sac.

Exposure of the Proximal Abdominal Aorta (Hiatus to Renals)

Transperitoneal Approach Through the Lesser Sac

Use of this approach is limited because the exposure provided is confined to 4 to 5 cm of supraceliac aorta, the celiac axis, and proximal SMA (Fig. 54.10). Indications include visceral bypasses and exposure for supraceliac aortic clamping. The segment of aorta proximal to the celiac artery is usually devoid of plaque and is used for aortic control when the lower aorta is not favorable for clamping (e.g., excessive thrombus, or plaque). Either a midline or supraumbilical transverse incision is used. The triangular ligament of the left lobe of the liver is divided, and the distal end of the left lobe retracted to the right. Care is taken not to injure the left hepatic vein while dividing the triangular ligament. The lesser sac is entered through a longitudinal incision in the gastrohepatic ligament. Identification of the esophagus is greatly aided by the presence of a nasogastric tube, particularly in hypotensive ruptured aneurysm patients, when the aorta is flaccid. During division of the gastrohepatic ligament, care is taken not to divide an aberrant (replaced) left hepatic artery, present in 10% to 15% of patients. When present, it usually runs in the cephalad portion of the ligament, coming off the left gastric artery. After retracting the esophagus and stomach to the left, the right crus of the diaphragm can be exposed, lifted off the aorta with a right-angle clamp and divided with electrocautery. The operator's index finger can then be inserted between the aorta and the median arcuate ligament, which is divided if necessary to expose the distal descending thoracic aorta. The pleural cavity is occasionally entered, which makes a chest radiograph in the immediate postoperative period necessary. Circumferential isolation of the aorta at this level is usually unnecessary and may injure posterior intercostal branches.

In an emergency requiring urgent proximal aortic control, a more rapid supraceliac aortic dissection is performed after entering the lesser sac (Fig. 54.11). The avascular portion of the gastrohepatic ligament is incised, and the esophagus is retracted to the left, guided by the nasogastric tube. The aorta is palpated and compressed against the spine. Blunt index finger dissection is used to separate the aorta from the crura of the diaphragm and from surrounding tissues. Once reasonable dissection is completed, the aorta is pinched between the index and middle fingers, while a long vascular clamp is applied.

The celiac axis is exposed by dissecting away the enveloping celiac plexus; this nerve tissue is thick and can be quite adherent

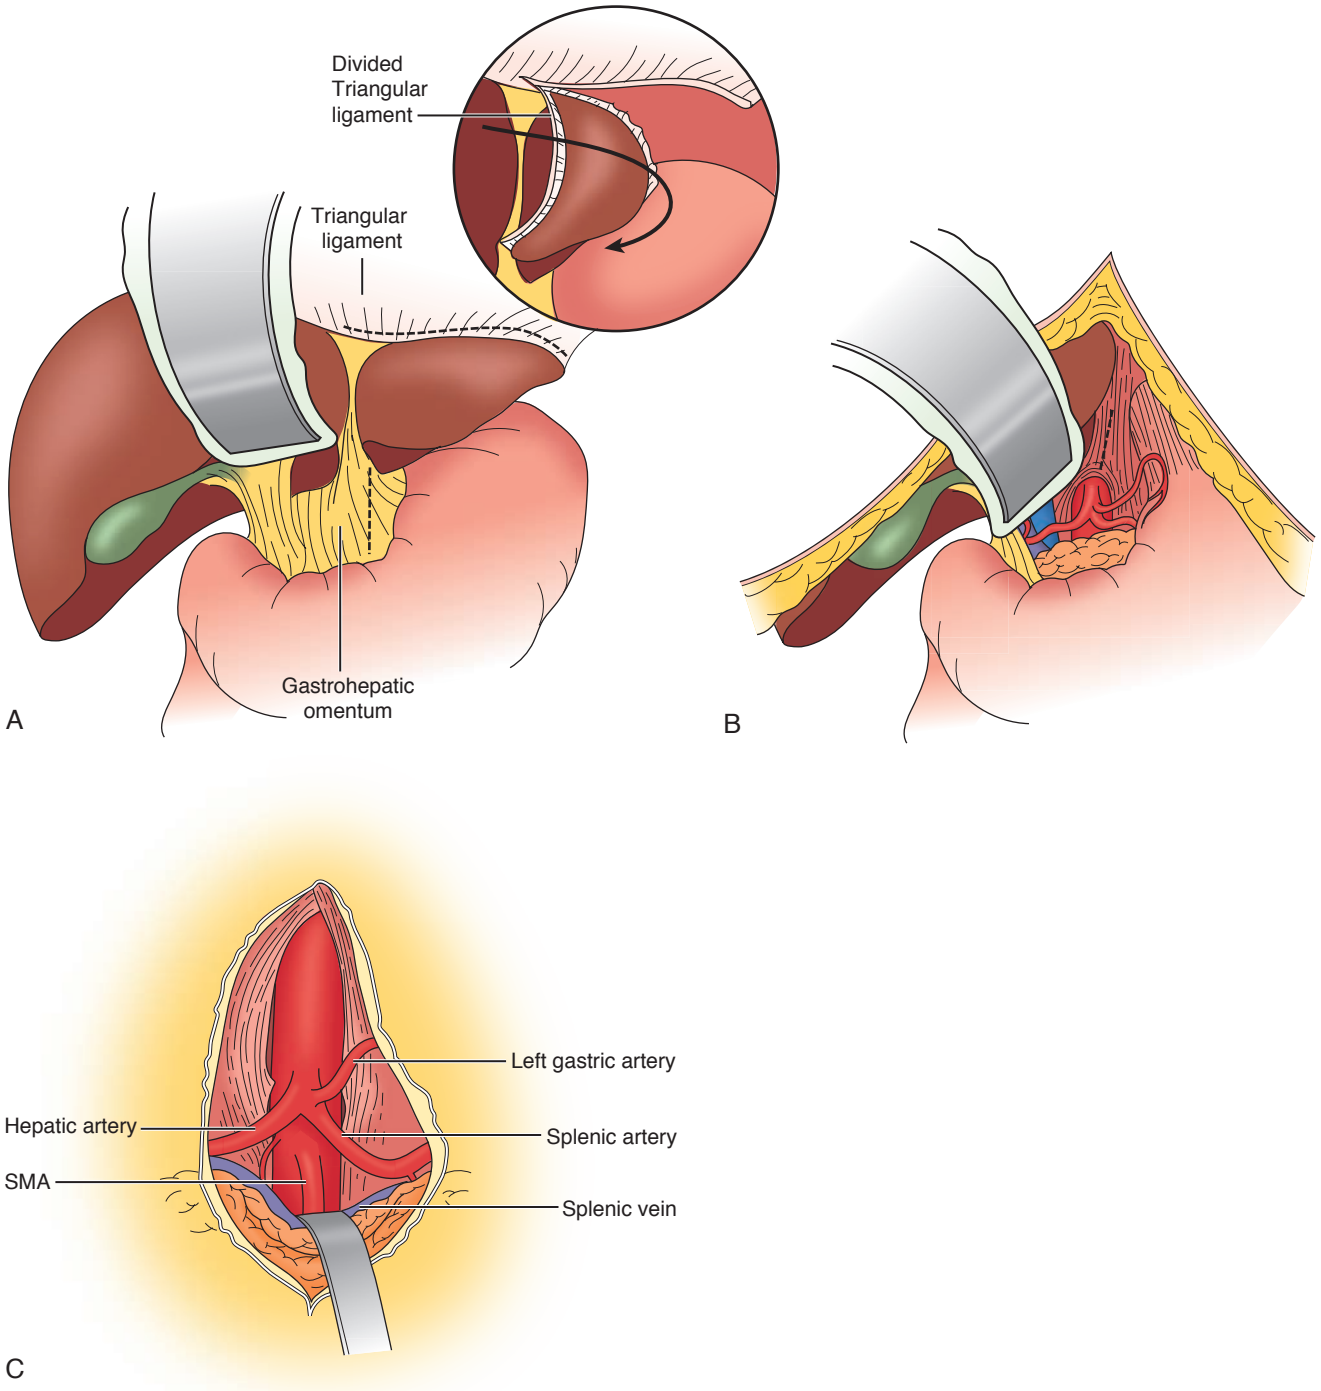

Figure 54.10 Exposure of the Celiac Trunk/Branches and the Superior Mesenteric Artery. (A) Division of gastrohepatic omentum and triangular ligament of left lobe of liver; inset shows lateral edge of left hepatic lobe folded back on itself to expose aortic hiatus. **(B)** Lateral segment of left hepatic lobe retracted to the right; dotted line shows division of median arcuate ligament and diaphragmatic crura over anterior surface of aorta; celiac artery and branches are typically covered by a thickened rind of neural/lymphatic tissue (not shown). **(C)** Exposure of celiac artery and proximal branches after division of crura, and resection of neural/lymphatic tissue; superior mesenteric artery is exposed by retracting the superior border of the pancreas distally. *SMA*, Superior mesenteric artery.

(A) Retraction of lateral segment of left hepatic lobe and division of gastrohepatic omentum (along *dotted line*). **(B)** Division of overlying diaphragmatic crural fibers and blunt index finger mobilization of supraceliac aorta; palpation of nasogastric tube and retraction of stomach to left reduces risk of inadvertent injury to stomach/esophagus during this maneuver. **(C)** Placement of large, vertically oriented clamp across supraceliac aorta.

to the aorta and celiac artery. As the dissection proceeds distally, the three branches of the celiac artery are encountered and should be treated with care because they are much thinner walled than the main trunk and can easily be damaged. The SMA can be identified just below the celiac; caudal retraction on the mid body of the pancreas provides exposure to up to 3 to 5 cm of this vessel. Surrounding lymphatics require careful attention to prevent postoperative chyle leaks.

Transperitoneal Approach With Medial Visceral Rotation

The entire proximal abdominal aorta can be exposed through a transabdominal approach by performing a medial visceral rotation (the so-called Mattox maneuver; Fig. 54.12).[21,22] This approach is challenging in obese patients and those with a narrow costal angle, but it does avoid a thoracic incision. The

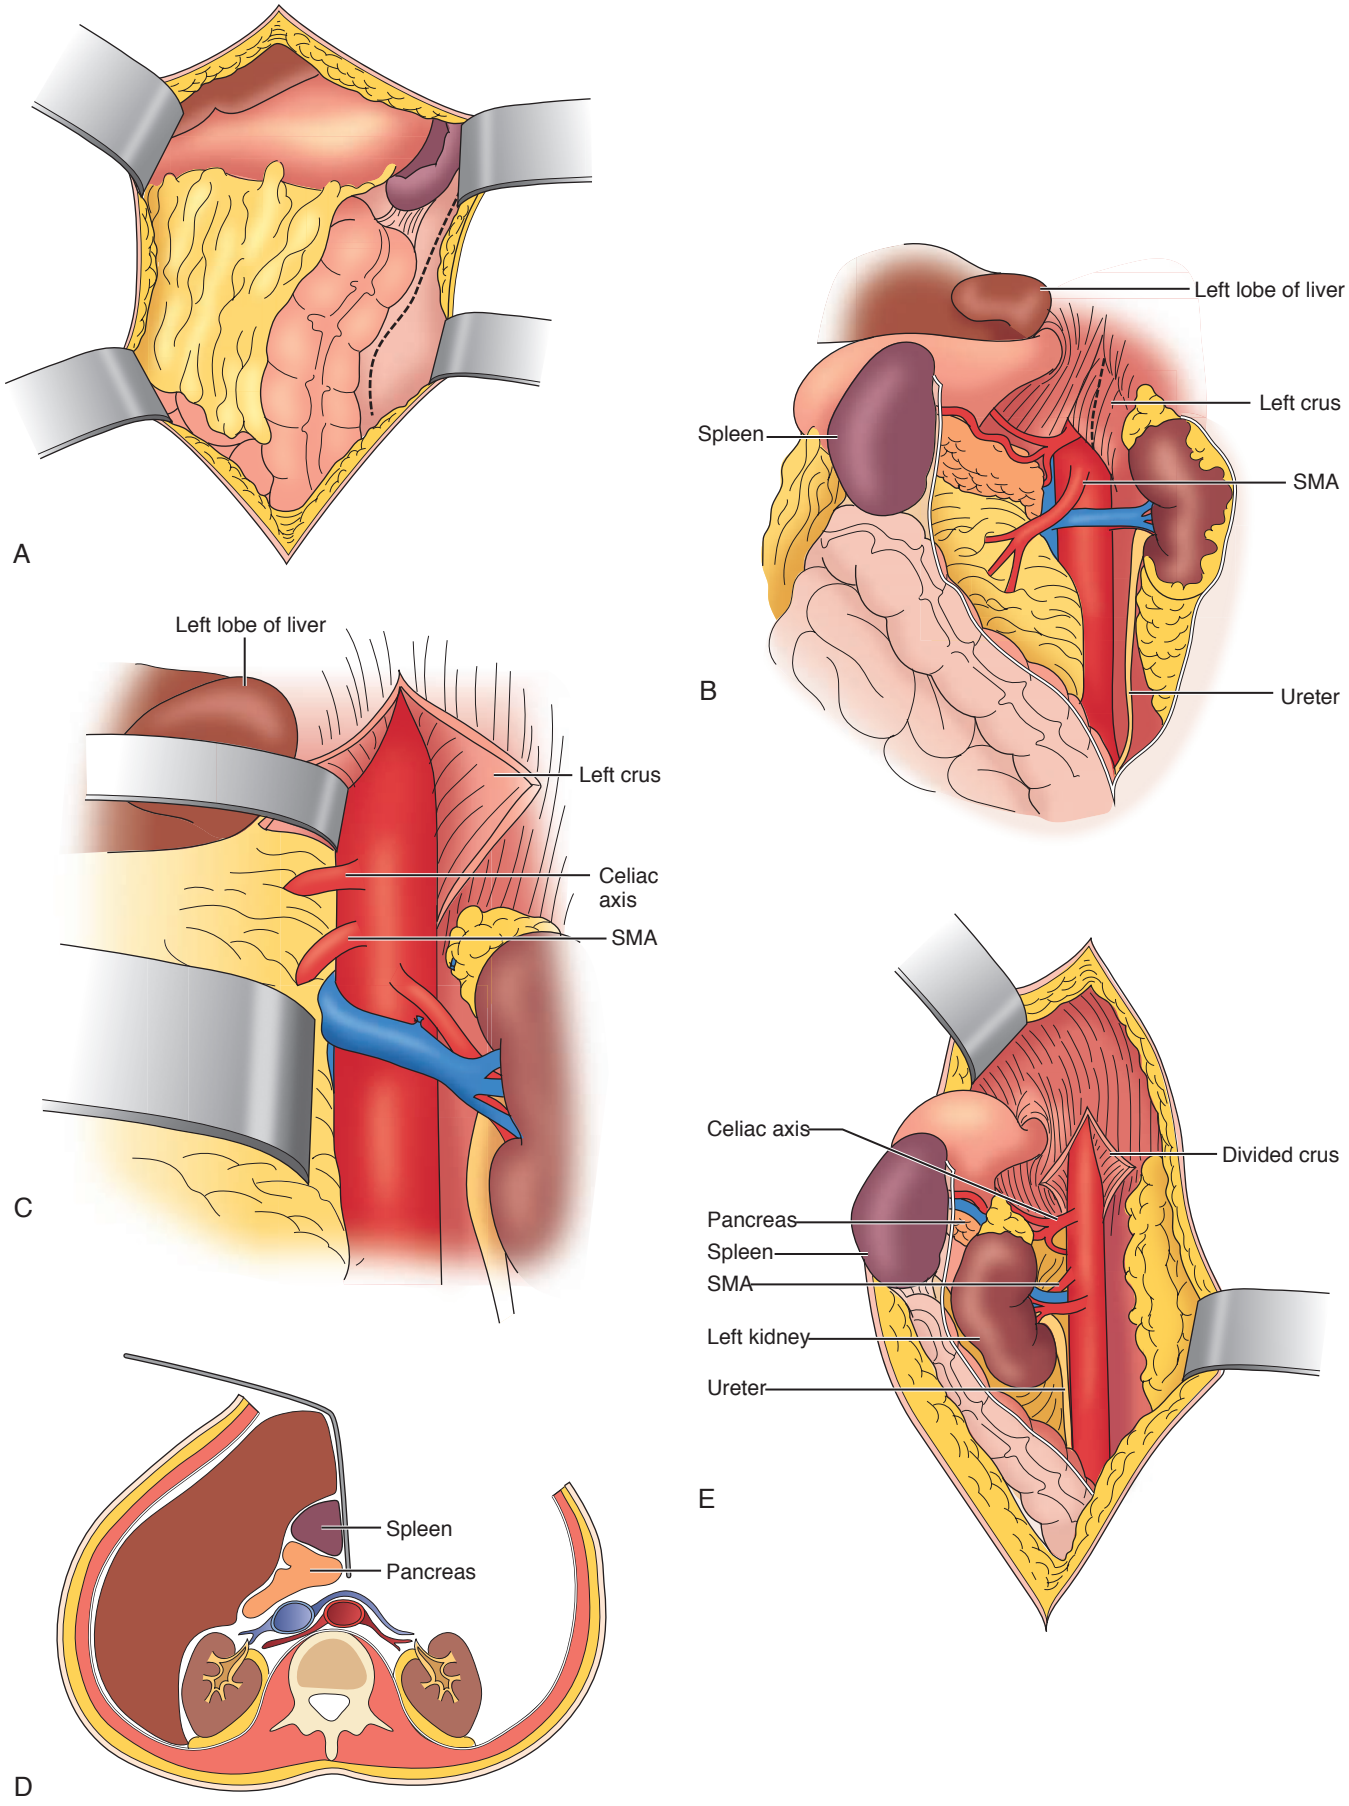

Figure 54.12 Left Medial Visceral Rotation. **(A)** Peritoneal incision lateral to descending colon and spleen. **(B)** Reflection/rotation of abdominal viscera from left to right (medially) in a plane anterior to left kidney leaving kidney in normal anatomic location with exposure of proximal abdominal aorta in base of wound. *Dotted line* is intended division line of left diaphragmatic crus. **(C)** Same exposure following division of left diaphragmatic crus and mobilization of left renal vein. **(D)** Cross-sectional view showing potential retraction injury of spleen and pancreas with this approach. **(E)** Same exposure but dissection plane is carried posterior to left kidney elevating it out of its bed and retracting it medially. *SMA*, Superior mesenteric artery.

lateral peritoneal reflection adjacent to the descending/sigmoid colon and spleen is incised cephalad, curving toward the aortic hiatus. Using largely blunt dissection, a retroperitoneal plane is developed, and the spleen, tail of pancreas, and left colon are retracted anteriorly and to the patient's right. The left kidney is usually elevated with these structures, and the avascular plane posterior to the left kidney is entered anterior to the psoas and flank musculature, taking care not to strip off the lumbodorsal fascia. When the left kidney is reflected upward, the origins of the celiac trunk, SMA, and the entire left renal artery can be visualized. However, exposure of the SMA beyond its first 2-3 cm is limited by the crossing left renal artery. In the case of a retroaortic LRV, or when exposure of a longer segment of proximal SMA is necessary, a plane anterior to the kidney may be developed. When the kidney is left down, a much longer segment of SMA (up to 10 cm) is accessible, but exposure of the left renal artery then requires wide mobilization of the LRV. Developing an anterior plane is more tedious than a posterior one, and care must be taken to avoid injury to the left adrenal gland.

Exposure of the supraceliac aorta is limited to just a few centimeters with this approach and requires division of the left diaphragmatic crus along the left lateral wall of the aorta. Besides the lack of access to the distal descending thoracic aorta, other disadvantages of this approach include a high incidence of splenic injury (up to 20%), and complications of excessive visceral retraction (e.g., bowel ischemia and pancreatitis; see Fig. 54.12D).[21] Nevertheless, when combined with standard transperitoneal exposure techniques, this approach provides the greatest versatility for exposing the entire abdominal aorta and all its branches.

Left Flank Retroperitoneal/Thoracoretroperitoneal Approach

The proximal abdominal aorta can also be exposed through a left flank incision in the 10th or 9th interspace, depending on how much proximal exposure is necessary (see Figs. 54.2-54.4). The 10th interspace is adequate for supraceliac clamping. However, pararenal exposure and paravisceral procedures are best accomplished through a ninth interspace incision. When going through a 10th or 9th interspace incision the left chest is entered, and it is necessary to divide the diaphragm to prevent tearing it when the ribs are retracted apart. A circumferential division 2 to 3 cm away from the chest wall avoids the risk of phrenic nerve injury, which may contribute to postoperative pulmonary dysfunction. The same remarks outlined earlier apply to exposure anterior or posterior to the left kidney, with a retrorenal plane preferred. Longitudinal division of the left diaphragmatic crus improves exposure of the left renal artery and is essential for revealing the celiac trunk and SMA origins. As previously mentioned, circumferential isolation of the aorta is not necessary.

Exposure of Visceral Arteries

Celiac Axis

Exposure of the proximal celiac through the lesser sac has been described previously (see Fig. 54.10).

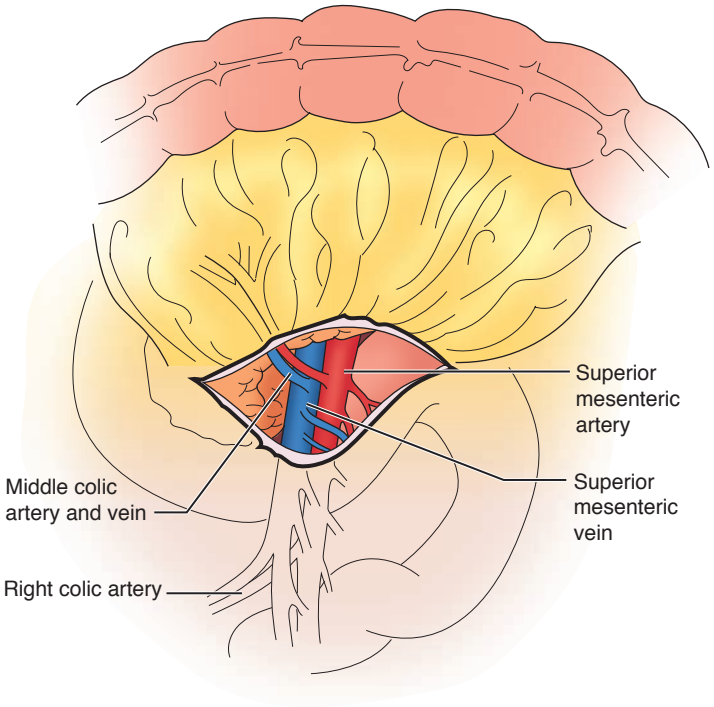

Figure 54.13 Superior mesenteric artery (and vein) exposure at base of mesentery.

Superior Mesenteric Artery

Exposure of the proximal SMA can be accomplished transperitoneally through the lesser sac (allowing for 3-5 cm of exposure; see Fig. 54.10), via medial visceral rotation, or through a left flank retroperitoneal approach (providing 8-10 cm of exposure; see Figs. 54.3, 54.4 and 54.12). Distal SMA exposure requires an inframesocolic approach (Fig. 54.13). Through a transperitoneal incision, the transverse colon is reflected superiorly and the small bowel retracted to the right and inferiorly. The SMA is dissected out to the right of the ligament of Treitz in the root of the mesentery, as it emerges from underneath the pancreas. In SMA embolism a proximal pulse is frequently present and serves as a guide to the artery; if not, an occluded SMA can usually be palpated as a firm tubular structure 5 to 6 mm in diameter. The superior mesenteric vein (SMV) lies immediately to the right of it. With this approach the surgeon can usually dissect out the SMA from just proximal to the middle colic artery to its distal ileocolic branches.

Hepatic Artery

A transperitoneal upper midline or an extended right subcostal incision is usually used (see Fig. 54.10). Elevation of the right flank on a rolled sheet may be helpful. The liver is retracted superiorly and the right transverse colon and small bowel inferiorly. The gastrohepatic ligament is incised transversely, and the lesser sac is entered. The common hepatic artery and proximal portion of the proper hepatic artery are easily palpated within the hepatoduodenal ligament. The common hepatic artery is dissected out as it passes over the pancreatic head and followed distally until the gastroduodenal artery is found. Gentle traction on the

common hepatic artery will facilitate exposure of its branches, the gastroduodenal and proper hepatic. The proper hepatic artery is located more distally within the porta hepatis, anterior to the portal vein and medial to the common bile duct.[2,3]

Splenic Artery

A transperitoneal upper midline or extended left subcostal incision is appropriate, with a rolled sheet placed under the left flank (see Figs. 54.10 and 54.12). The proximal third of the splenic artery is best approached through the lesser sac, which is entered either by dividing the gastrohepatic omentum above the lesser curvature of the stomach or dividing the gastrocolic ligament, after reflecting the greater omentum superiorly and the transverse colon inferiorly. The posterior gastric wall is then separated from the underlying pancreas, and the superior edge of the pancreas is exposed. The splenic artery is located along the superior surface of the body and tail of the pancreas. For distal splenic artery exposure, a partial medial visceral rotation is performed by incising the lateral peritoneal reflection of the descending colon and retracting the left colon medially. The pancreas and spleen are mobilized anteriorly and medially away from the left kidney, which is left in its normal anatomic location. The splenic artery is palpable and dissected out along the superior border of the pancreas.

Exposure of Renal Arteries

The origins (and first 2-3 cm) of the renal arteries can be exposed through an inframesocolic approach, as detailed in the section on infra/pararenal aortic exposure (see Fig. 54.7). The peritoneum over the aorta is incised, and the duodenum is reflected to the right. The avascular plane under the pancreas is entered. The LRV is mobilized, and the lumbar, gonadal, and adrenal branches are ligated and divided. This allows for cephalad or caudal retraction of the vein, depending on the exposure required. The left renal artery is typically posterior to the LRV. The left crus of the diaphragm may be divided to help with exposure. The proximal right renal artery is exposed by mobilizing the IVC-LRV junction. Usually a couple of lumbar veins need to be ligated to retract the vena cava to the right. The LRV is retracted superiorly, exposing the origin of the right renal artery. Overlying lymphatic vessels may need to be ligated and divided to enhance the exposure of the right renal artery origin. Again, dividing the right crus of the diaphragm helps with this exposure. More of the left renal artery (5-6 cm) than the right renal artery can be exposed from the inframesocolic approach with the IVC on the right.[14]

As previously described, the entire length of the left renal artery can be exposed with a full medial visceral rotation (see Fig. 54.12)[22] or through a left flank retroperitoneal approach (see Figs. 54.3 and 54.4). It should be noted that the left renal artery is put on considerable "stretch" when approached posteriorly; this should be kept in mind when retracting the left kidney anteromedially. Therefore bypasses to the left renal artery in this position should always be performed under some tension; otherwise, there is a risk of kinking when the kidney is returned to its normal anatomic position.

The right renal artery (in particular its mid to distal portion) requires a right medial visceral rotation (Cattell-Brasch maneuver), either through a midline or transverse transperitoneal incision (Fig. 54.14).[23,24] The lateral peritoneal reflection of the ascending colon from cecum to hepatic flexure is incised and the colon reflected medially and anteriorly. The underlying second portion of the duodenum and head of the pancreas are mobilized medially with a Kocher maneuver to expose the right kidney and the right renal vein is mobilized circumferentially from its caval junction as far distally as necessary, with the attendant ligation of the small proximal tributaries. This vein may then be easily retracted during dissection of the underlying renal artery. The right renal artery travels under the IVC to its origin off the aorta, and more proximal exposure requires mobilizing the IVC from the midline (see Fig. 54.7). Any lumbar veins encountered in this process should be divided with stitch ligatures on the caval side to avoid tie dislodgement during retraction.

EXPOSURE OF MAJOR ABDOMINAL VEINS

Inferior Vena Cava

Anatomic Considerations

The internal and external iliac veins converge at the sacroiliac joint to form the common iliac veins. The ureter, spermatic cord (male) and round ligament and ovarian vessels (female) cross the external iliac veins at this level. At the bifurcation of the aorta and vena cava, the iliac veins are closely related to the dorsal surface of the arteries. This makes them prone to injury during hasty exposure of these arteries, especially in trauma cases. The IVC starts at the level of L5 to the right of the midline, with the confluence of the common iliac veins. The aortic bifurcation is slightly more cephalad and anterior than the caval confluence, which results in the IVC bifurcation and left iliac vein being crossed anteriorly by the right common iliac artery. There can be significant "adhesions" between the back wall of the aortic bifurcation and the front wall of the caval bifurcation and proximal iliac veins in this overlap zone, which can make dissection in this area quite hazardous. The infrarenal IVC has several pairs of lumbar veins that arise, posteriorly tethering it to the psoas muscles. The renal veins enter the vena cava at the level of L1-L2 and are usually single. The retrohepatic IVC receives three large hepatic veins at the level of the dome of the liver and several small caudate lobe branches. The IVC then enters the chest at the level of T8 and drains into the right atrium.

Infrarenal/Suprarenal Inferior Vena Cava

A variety of incisions are available to expose the infrahepatic IVC, with the choice depending on the amount of exposure desired (Figs. 54.14 and 54.15). A midline, transperitoneal incision is standard in trauma cases and is the most frequent approach used. A right transverse transperitoneal or right flank retroperitoneal approach is also useful but is slightly more limited in visualizing branches beyond the caval bifurcation. A subcostal

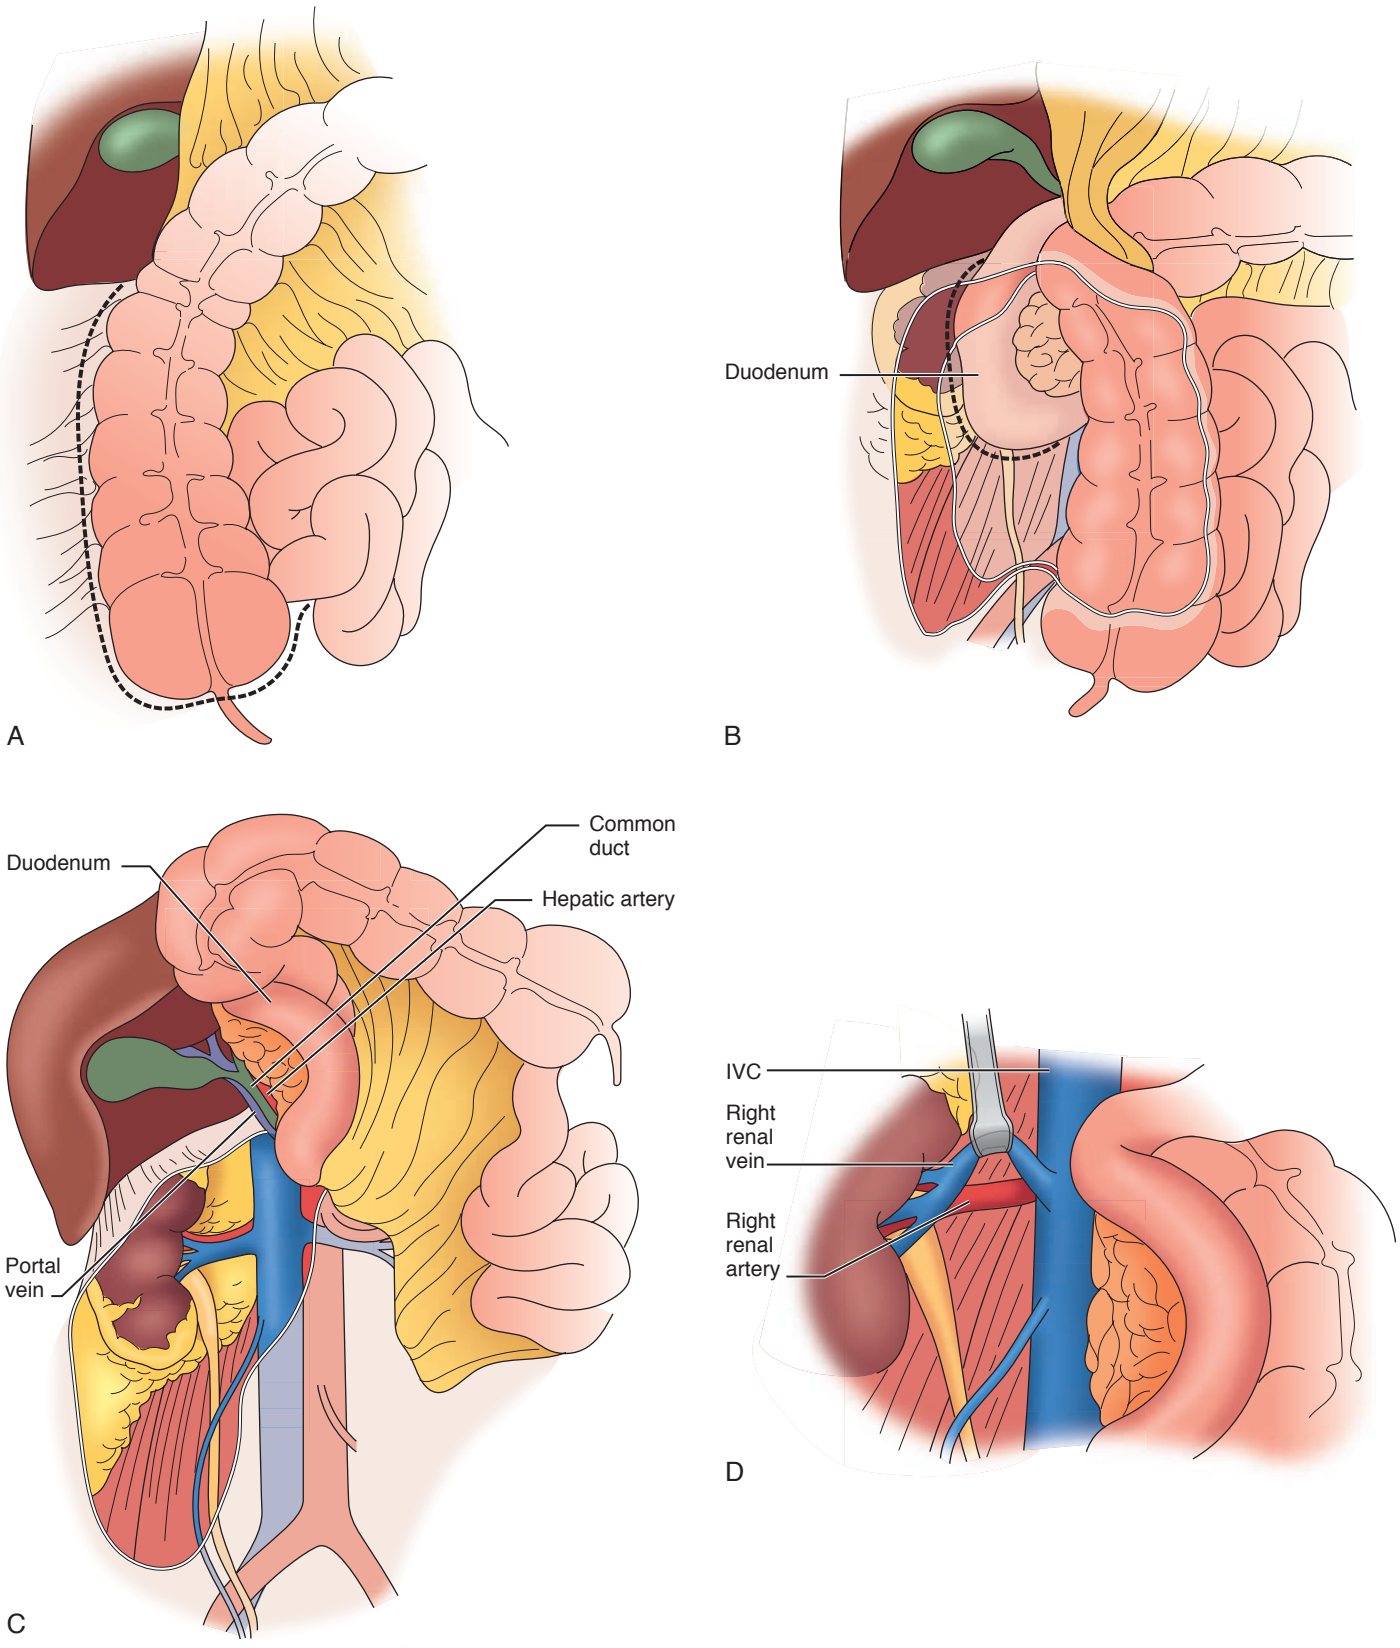

Figure 54.14 **Exposure of Subhepatic Inferior Vena Cava and Right Renal Artery Through Right Medial Visceral Rotation (Cattell-Brasch Maneuver).** **(A)** The lateral peritoneal reflection of the ascending colon is incised (from cecum to hepatic flexure). **(B)** The right colon is reflected medially and anteriorly. **(C)** The underlying second portion of the duodenum and the head of the pancreas are mobilized with a Kocher maneuver and reflected medially to expose the right kidney and inferior vena cava. The cecum can be reflected superiorly to expose the entire infrarenal vena cava to its bifurcation. **(D)** Mobilization of the right renal vein exposes the underlying right renal artery. *IVC*, Inferior vena cava.

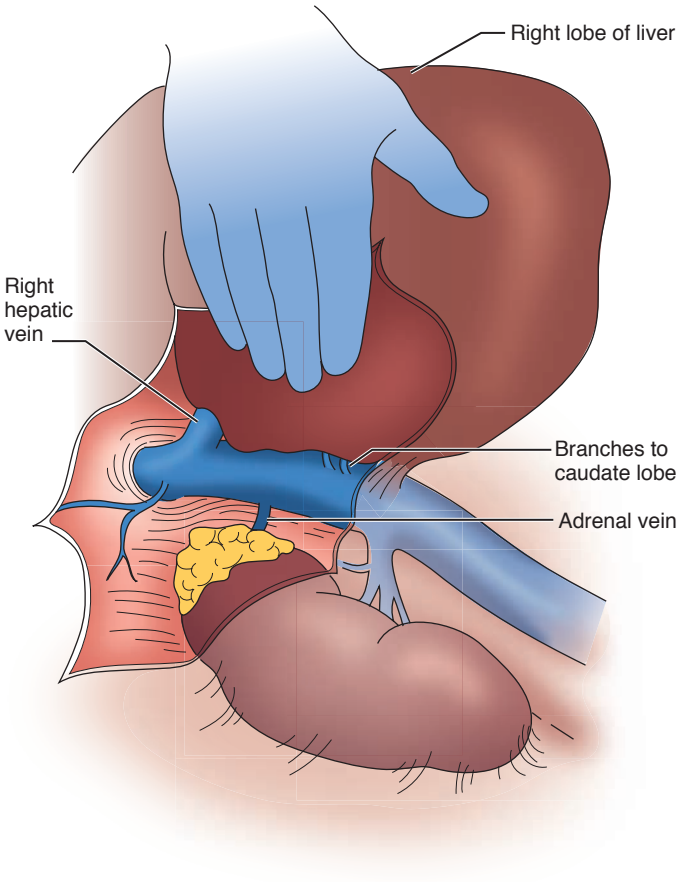

Figure 54.15 Exposure of retrohepatic inferior vena cava and right hepatic vein by mobilizing and retracting the right lobe of the liver to the left.

incision may also be used for limited exposure. With transperitoneal approaches, the small bowel is retracted to the left and a right medial visceral rotation is performed by incising the lateral peritoneal reflection of the ascending colon, as described previously. Following a Kocher maneuver, the pancreatic head and second and third portions of the duodenum are retracted to the left, exposing the IVC and renal veins. This also allows the porta hepatis and distal SMV to be dissected out behind the pancreas.[24] This dissection can be carried cephalad, exposing the retrohepatic vena cava. Some surgeons report that extending the incision into the ninth intercostal space of the right chest improves exposure of the retrohepatic IVC. Dividing the diaphragm can expose the juxtaatrial IVC, along with the major hepatic branches. For more distal exposure (caval confluence and both iliac veins), the peritoneal reflection of the cecum is incised to the level of the ileocecal junction, and the entire right colon is retracted leftward (Cattell-Brasch maneuver).[23,24] The IVC from the common iliac veins to the level of the caudate lobe can be visualized with this approach. Ligation/division of tethering lumbar veins permits mobilization of the IVC, but it is advisable to place suture ligatures on the caval side of these branches to prevent accidental dislodgement. One method to provide rapid exposure to the IVC bifurcation and proximal iliac veins in a trauma situation is to divide the overlying right iliac artery to expose the underlying injury. After venous repair, the artery is reanastomosed and distal blood flow reestablished (see Fig. 54.16)[25,26]

Retrohepatic and Suprahepatic Inferior Vena Cava

A midline approach with superior extension into a sternotomy is the most widely used incision to expose these IVC segments,

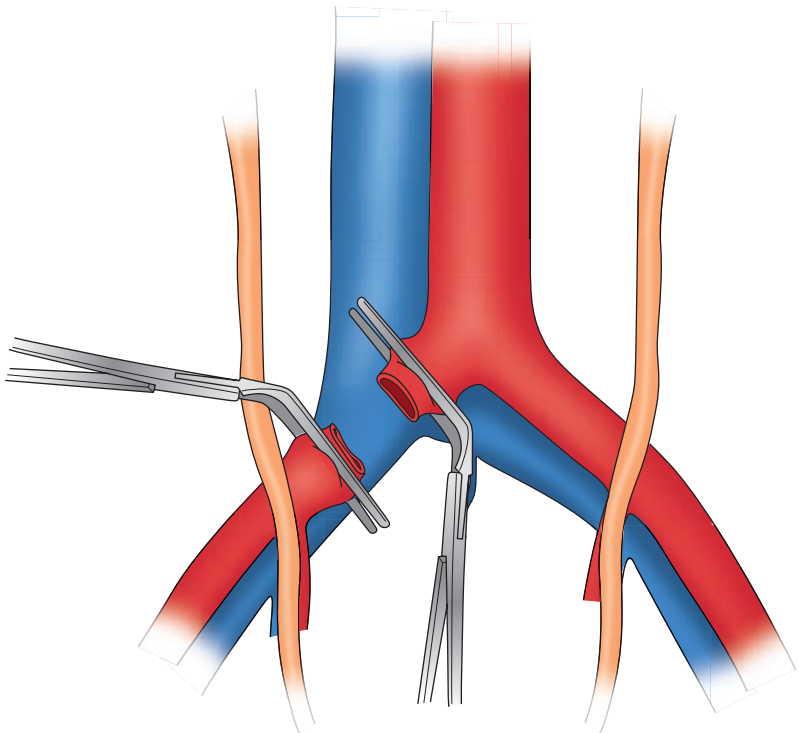

Figure 54.16 Exposure of the inferior vena cava–iliac vein confluence by dividing the right common iliac artery.

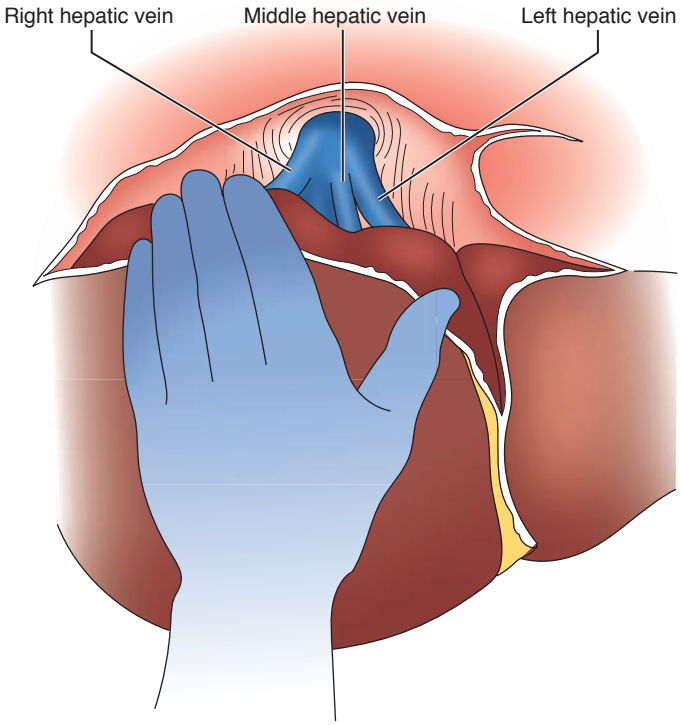

Figure 54.17 Exposure of suprahepatic inferior vena cava and hepatic veins after incising the coronary ligaments and retracting the liver caudally.

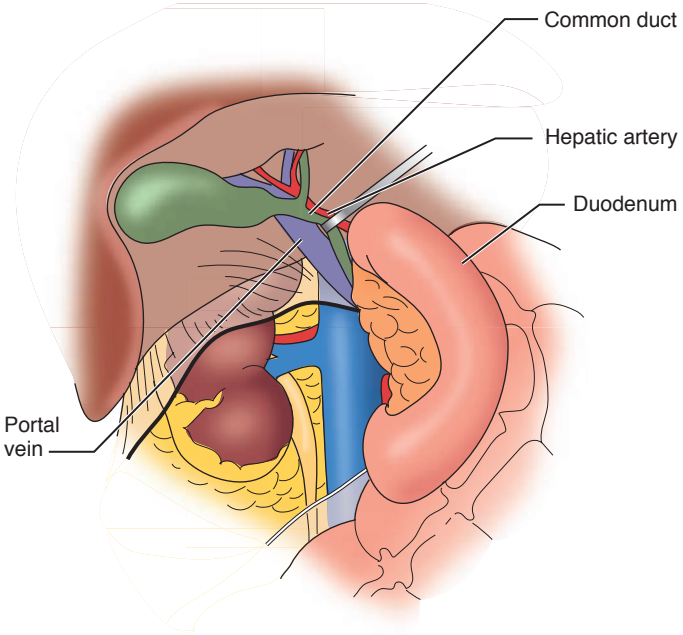

Figure 54.18 Portal vein exposure after mobilizing the hepatic flexure of the right colon and performing a Kocher maneuver on the duodenum. Small retractor is displacing common bile duct to patient's left.

particularly in trauma situations (see Figs. 54.15 and 54.17). A chevron incision ± sternotomy, or an eighth or ninth interspace right thoracoabdominal incision can provide excellent exposure in elective cases. A transperitoneal approach is greatly facilitated by upward and lateral retraction of the costal margins. After entering the peritoneum, the right triangular ligament is divided, along with the peritoneal attachments to the right lobe of the liver, and the right lobe is mobilized and retracted medially and anteriorly. This exposes the retrohepatic IVC. A number of small venous tributaries draining the caudate lobe and sometimes the posterior right lobe are encountered during this mobilization and should be carefully ligated and divided to prevent avulsion. Of the three hepatic veins, only the right can be reliably visualized from this approach. Exposure of the other hepatic veins and the suprahepatic IVC requires wider mobilization. The round and falciform ligaments have to be divided and all the superior peritoneal reflections of the liver (coronary ligaments) incised, to expose the "bare area" of the liver. The liver is then retracted caudally to visualize the suprahepatic IVC and hepatic veins. If control of the IVC between the hepatic veins and diaphragm proves difficult, intrapericardial control of the IVC can be accomplished after performing a sternotomy.

Portal Vein and Branches

Anatomic Considerations

The SMV lies to the right of the SMA in the root of the mesentery. It tracks over the third portion of the duodenum and uncinate process of the pancreas and dives under the neck of the pancreas to join the splenic vein, which runs in a groove along the back of the pancreas. The inferior mesenteric vein lies to the immediate left of the infrarenal aorta and crosses over it to drain into the splenic vein. The portal vein is formed by the confluence of the splenic and SMV at the level of L2 and courses toward the liver within the gastrohepatic ligament, posterior to the medially located hepatic artery and the laterally located common bile duct.

Portal Vein

A subcostal incision extending into the right flank or a midline incision is appropriate. After dividing the falciform ligament, the right lobe of the liver is retracted cephalad and the hepatic flexure of the colon caudally. After a partial Kocher maneuver, the first and second portions of duodenum are mobilized and retracted downward and slightly to the left, to expose the porta hepatis structures (Fig. 54.18). The portal vein is the most posterior structure of the hepatoduodenal ligament and is best isolated by longitudinally dividing the peritoneum along the right posterior aspect of the ligament to avoid injury to the common bile duct. After the lateral wall of the vein has been dissected free proximally and distally, the common bile duct can be gently retracted superiorly and to the left, enhancing exposure. A replaced right hepatic artery, if present, runs parallel and to the right of the vein and should be carefully preserved. Mobilization of the portal vein from the pancreas to its hepatic bifurcation can be accomplished by carefully isolating and dividing tributaries, which usually enter the vein medially and posteriorly. Mobilizing the right lobe of the liver by dividing the triangular ligament and pushing the liver down and forward with laparotomy pads packed behind it greatly improves exposure of the porta hepatis. Uncontrollable bleeding from the porta hepatis or liver

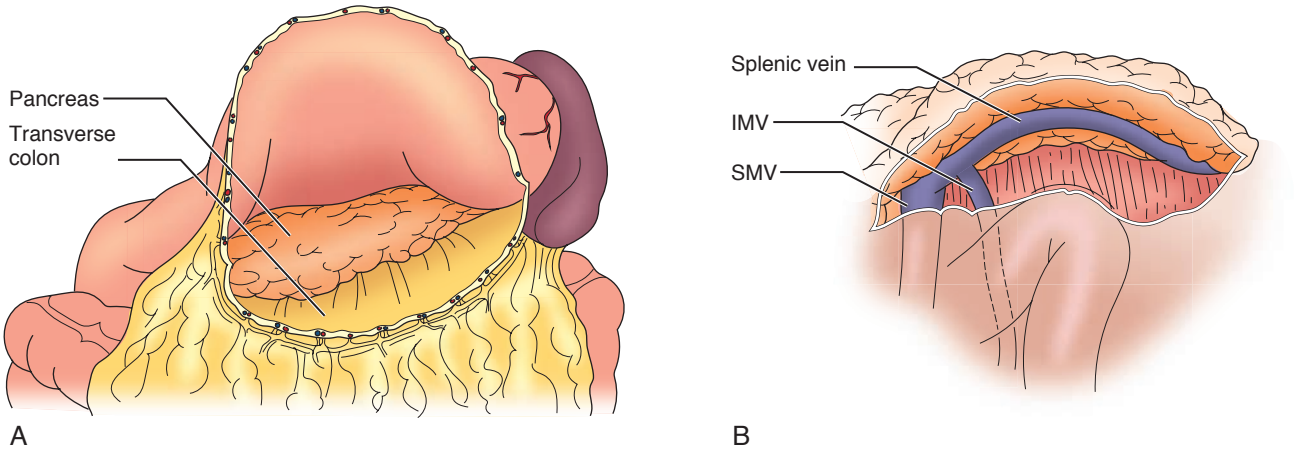

Figure 54.19 Exposure of Splenic Vein. **(A)** Lesser sac is entered by dividing the gastrocolic ligament. **(B)** Pancreas elevated superiorly with splenic vein under it; the splenic veins joins the superior mesenteric vein *(SMV)* to form the portal vein. The inferior mesenteric vein *(IMV)* drains into the splenic vein.

can be managed by inserting an index finger through the foramen of Winslow and pinching the entire porta hepatis between the thumb (on the anterior surface of the porta) and the index finger (Pringle maneuver[27]).

Superior Mesenteric Vein

Exposure of the SMV is similar to that of the SMA (see Fig. 54.13). After elevating the transverse mesocolon to expose the root of the mesocolon, the small bowel is retracted inferiorly, and the SMA is palpated. The SMV lies just to the right of the SMA.

Splenic Vein

The most direct approach to the splenic vein is through the lesser sac (Fig. 54.19). A subcostal incision extending to the left or a midline incision is used. After entering the peritoneum, the lesser sac is reached by dividing the gastrocolic ligament. The greater curvature of the stomach is elevated, and the inferior border of the pancreas is exposed. The splenic vein is dissected out under the inferior border of the pancreas. Multiple small branches drain into it, making the dissection tedious. This approach is useful for distal splenorenal shunts.

The splenic vein can also be approached below the transverse mesocolon. As discussed previously in exposure of the left renal artery through an inframesocolic approach, the transverse colon is elevated and the small bowel retracted to the patient's right. The ligament of Treitz is divided, mobilizing the third and fourth portions of the duodenum to the right. The LRV is identified as a landmark. The inferior border of the pancreas is identified and the inferior mesenteric vein running along the left side of the aorta traced cephalad to its junction with the splenic vein. The inferior border of the pancreas is rotated superiorly to expose the splenic vein running along its posterior surface.

GENERAL

Carotid interventions are among the most frequently performed vascular procedures (see Chapter 91). For revascularization involving cervical vessels, the patient should be positioned supine, with the head averted from the operative side and slightly extended. Extension is typically obtained by placing a small roll behind the shoulder blades transversely. Care should be taken not to hyperextend the neck or over rotate. The bed should also be placed slightly in a reverse Trendelenburg position to decompress the surrounding venous structures. Both arms can be tucked to allow for the surgeon and assistant to stand across from each other or with one at the head of the bed and one at the side of the involved vessel, depending on surgeon preference. The area to be prepped should include the jawline and the inferior aspect of the ear to below the clavicle, with more extensive prep if consideration is given to extending the incision for access to the origins of the great vessels. If regional anesthesia is being performed, this is done prior to prepping and draping. It is also advantageous to place a small squeeze toy in the contralateral hand to allow for neurologic assessment throughout the procedure. This allows the patient to demonstrate function of that limb when regional blocks are being utilized. If regional anesthesia is utilized, the skin should always be tested prior to making the incision to ensure adequate anesthesia. If high exposure is necessary, general anesthesia with nasotrachial intubation is performed to facilitate ear/nose/throat (ENT) assistance with subluxation of the mandible if needed.

EXPOSURE OF THE CAROTID ARTERY FOR ENDARTERECTOMY

Standard Approach

The standard skin incision for carotid exposure is approximately 12 to 15 cm long and is made parallel to the anterior edge of the sternocleidomastoid muscle (SCM) from the end of the

Abstract

This chapter provides descriptions of traditional and newer approaches to the cervical vessels, including the carotid artery, vertebral artery, and subclavian artery. Descriptions include high exposures of the carotid artery, access to various segments of the vertebral artery, and exposures for the resection of carotid body tumors. Mini-incisions as well as retrojugular and posterior approaches are some of the newer technical approaches described for carotid access.

mastoid process to the medial end of the clavicle (Fig. 55.1). In recent years the much shorter incision over the carotid bifurcation as well as the transverse incision in the skin crease have become more popular, as both provide an adequate access to the bifurcation and to the internal and external carotid arteries.

1. Skin incision is made obliquely along the edge of the sternocleidomastoid, with both the standard and retrojugular approaches. At the level of the angle of the jaw, the incision is extended slightly more laterally to prevent injury to the parotid gland. Preoperative duplex can be utilized to identify the level of the carotid bulb and to decrease the length of incision needed.
2. Dissection is continued through platysma, typically with electrocautery. The external jugular frequently has to be divided. Several small nerves of the superficial cervical plexus may have to be divided, which may lead to areas of hypesthesia around the incision. The great auricular nerve may be visualized when the incision is high. The nerve should be protected if possible; if divided, it results in numbness to the ear lobe, which usually regresses within a few months. Care should be taken at the angle of the mandible to remain lateral to avoid dissection into the parotid gland. The dissection is continued through the tissues along the medial border of the sternocleidomastoid until the carotid sheath is encountered. During the dissection, a small sternomastoid branch of the superior thyroid artery usually has to be ligated; other small perforating vessels supplying the SCM can be divided with cautery. At this point one must avoid injury to the accessory nerve, which can be found at the superior aspect of the incision. Once the sternocleidomastoid has been retracted laterally, a Weitlaner or Henle retractor should be utilized to hold the tissues in place. If regional block is utilized, it is occasionally necessary to supplement with additional lidocaine at the carotid sheath.
3. The internal jugular vein is dissected along the medial border and retracted posteriorly. This maneuver requires division of the anterior facial vein (Fig. 55.2). Since the anatomy of the venous structures is quite variable, there may be a single vein or, alternately, two or three veins separately joining the internal jugular vein, in which case they must be separately ligated and divided. Usually the jugular vein is further dissected cephalad as far as the posterior belly of the digastric muscle. The connective tissue between the facial vein and the digastric muscle is rich in lymph nodes, which can be dissected from the vein and, if necessary, divided with cautery.
4. Next, after the vagus nerve in the space between the jugular vein and carotid artery is identified, dissection of the common carotid artery and its branches is performed. This often requires division of the ansa hypoglossi nerve. The common carotid is isolated first, using sharp dissection with attention given to protecting the vagus nerve as it encircles the vessel. Next, the internal carotid artery (ICA) is mobilized along the medial border of the internal jugular vein up to the

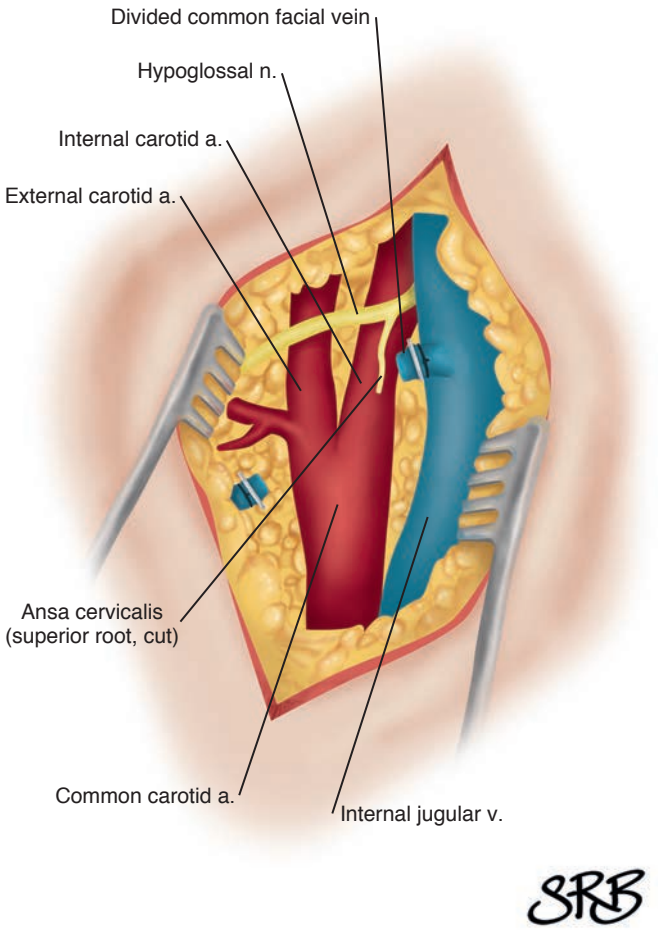

Figure 55.2 Traditional carotid exposure with division of facial vein and ansa cervicalis.

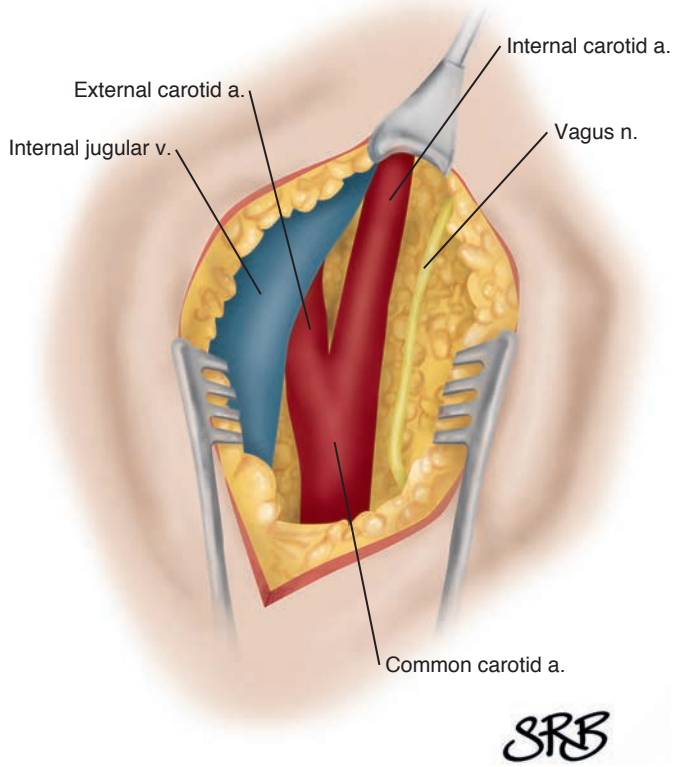

Figure 55.3 Retrojugular approach to carotid artery with medial rotation of internal jugular vein to expose internal carotid artery.

point where the vessel is completely normal. Usually small venous branches and the sternocleidomastoid branch of the occipital artery cross the ICA; once these vessels have been ligated and divided, the hypoglossal nerve can be mobilized cephalad. Finally, the external carotid artery is isolated at the bifurcation. It is important to encircle the artery close to the bifurcation to avoid injury to the superior laryngeal nerve, which runs behind the external carotid artery. The superior thyroid artery also requires dissection, particularly if it branches directly from the common carotid artery.

RETROJUGULAR APPROACH

With the standard approach, when bleeding occurs postoperatively, it is frequently venous, specifically related to the facial vein. The ICA is located more posteriorly with this approach, and it may be difficult to access more distal disease. The vagus nerve is also not well visualized during the standard approach, which can lead to clamp injuries. With the retrojugular approach, the ICA is anterior. Visualization of the external carotid artery (ECA) is slightly more limited, but the origin and superior thyroidal arteries are easily identified and controlled, with markedly better visualization of the ICA. There is no need for ligation or division of major venous structures, thus decreasing the potential for postoperative bleeding, and the ansa hypoglossi is also not divided.

1. Skin incision and initial approach are identical to the standard exposure. Once the sternocleidomastoid has been retracted and the carotid sheath exposed, the dissection diverges from the standard approach.
2. The sheath overlying the vessels is divided at the *lateral* border of the internal jugular vein. Once fully dissected, the vein is then retracted medially, using a blunt Weitlaner. Occasionally there may be small venous branches posteriorly that require ligation and division. The vagus nerve is visualized and left lateral to the carotid artery. This approach avoids division of the facial vein, ansa cervicalis, and the vascular bundle associated with the hypoglossal nerve, as all of these structures are retracted medially with the jugular vein. This approach allows greater visualization of the internal carotid artery (Fig. 55.3).
3. At this point, the dissection is the same as for the standard carotid approach, with mobilization of the ICA, ECA, and common carotid artery (CCA) for clamping as well as the superior thyroid artery. However, the vagus nerve has already been identified laterally and does not fall into the area of concern when encircling the CCA.
4. Carotid endarterectomy (CEA) is then performed in either standard fashion or with the eversion technique.
5. At completion of the procedure, after hemostasis has been verified, the jugular vein is allowed to return to its normal location, lateral to the artery, and the wound is closed in

the standard fashion with reapproximation of the platysma and subcuticular skin closure.

POSTERIOR APPROACH FOR CAROTID ENDARTERECTOMY

This technique has been described by Berguer. It allows exposure of the ICA, medial to the sternocleidomastoid, between the hypoglossal and vagus nerves.

1. The patient is placed prone/lateral with the contralateral arm placed under the head.
2. The incision is initially transverse, beginning at the occipital protuberance and extending to the mastoid process, where it is curved downward along the posterior border of the SCM for 2 to 3 cm.
3. The fibers of the trapezius, splenius capitis, semispinalis capitis, and longissimus capitis muscles are divided.
4. The greater occipital nerve, which is a dorsal ramus of C2 and courses over the semispinalis capitis muscle, may have to be divided.
5. At this point the internal jugular vein, carotid artery, and the accessory nerve are exposed.

PROXIMAL EXPOSURE FOR CAROTID ENDARTERECTOMY

More proximal control can be obtained of the CCA by division of the omohyoid muscle, and ligation of the associated vessels.

High Exposure

More distal exposure is also possible from the retrojugular or standard approach. This may be necessary for high lesions or reoperative surgery. The retrojugular approach will provide access to the artery to the level of the digastric belly without additional dissection of structures.

1. With the standard approach, more distal exposure may be obtained by mobilizing the hypoglossal nerve. This requires division of the sternomastoid artery and vein, which form a sling around the structure. This allows mobilization of the vessel up to the level where the vagus sheath joins the hypoglossal. Further dissection can also be performed above the level of the nerve, which can be gently retracted with a vein retractor or vessel loop.
2. For more distal exposure, the accessory spinal nerve should be identified as it enters the sternocleidomastoid; it can be followed proximally to the digastric, with care taken not to injure the nerve. To facilitate exposure, both the internal jugular (IJ) and the vagus nerve should be retracted medially, over the top of the carotid artery. The superior laryngeal nerve arises in this area and passes posterior to the ICA. Just above this level, the superior cervical sympathetic ganglion will be seen. Depending on the extent of exposure needed, the posterior belly of the digastric can be retracted or divided (Fig. 55.4). Such division should be done sharply to avoid thermal injury to the glossopharyngeal nerve, which would result in difficulty swallowing. Retraction can also result in nerve injury and should be performed cautiously. The nerve runs on top of the ICA and under the ECA and may present with either a single or double trunk. The muscle should be divided close to the attachment with the mastoid. If high access to the ICA is anticipated, this should prompt consideration for general anesthesia with nasotracheal intubation and preoperative consultation with ENT to allow for subluxation of the mandible if division of the digastric is insufficient (Fig. 55.5; see Chapter 91).

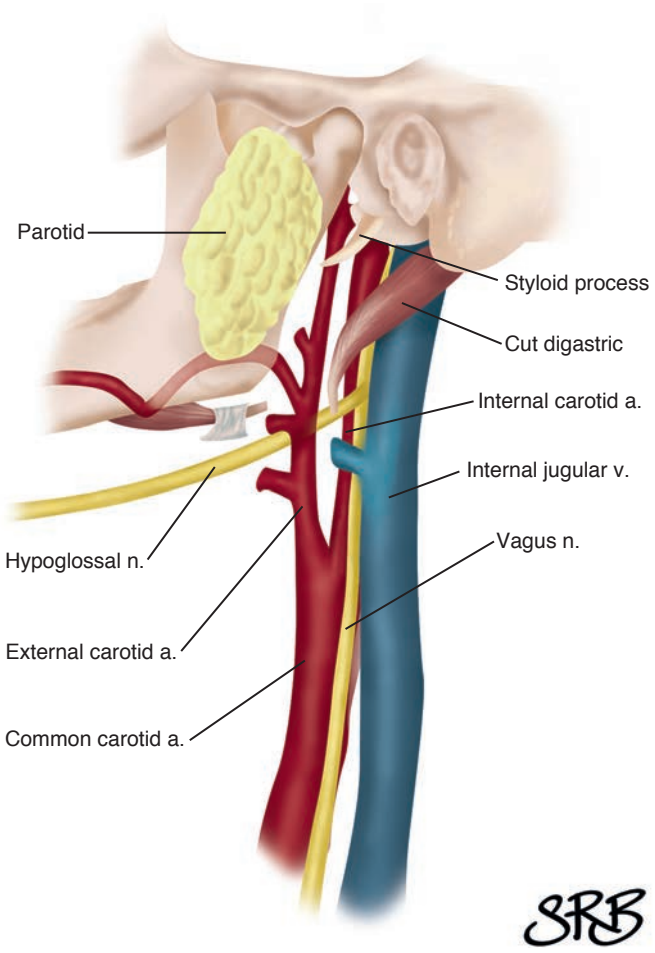

Figure 55.4 High exposure of internal carotid artery with division of digastric muscle.

Mini-Incisions for Carotid Endarterectomy

Short transverse and longitudinal incisions for eversion and standard patch endarterectomy have been popularized in the recent years. The outcome and operative time is generally the same as for standard, long incision.

Short Transverse Incision

Positioning is the same as for standard incision.

1. Duplex is recommended to identify and mark the skin at the carotid bifurcation before draping. If duplex is not used,

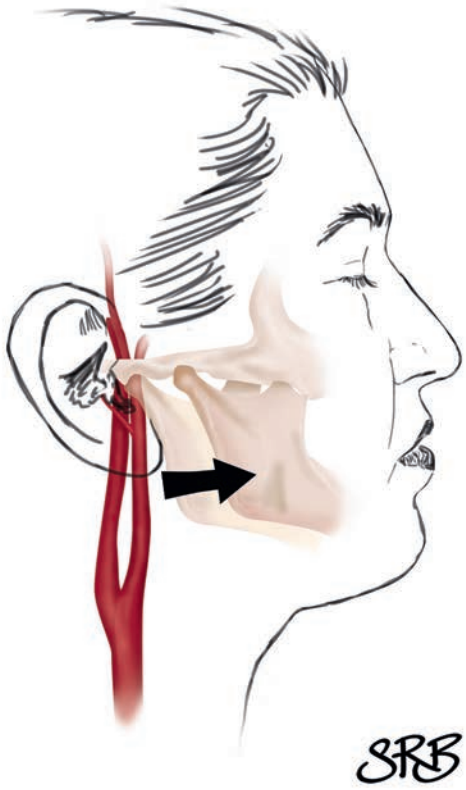

Figure 55.5 Subluxation of mandible for high carotid exposure.

the incision is made in the skin crease at the level of the upper margin of the cricoid medial to the sternomastoid muscle. The length of the incision is approximately 4 cm; it can be extended if exposure is inadequate.

2. After division of the platysma transversely, two self-retaining retractors are placed at 90-degree angles to each other and dissection is carried out in the same fashion as for the standard carotid exposure. Use of the self-retaining retractors allows exposure of up to 1.5 to 2 cm on each side of the carotid bifurcation.
3. Small bulldog clamps, which can be placed deep in the wound, allow the length of the exposed carotid arteries to be longer than the length of the skin incision both in the transverse and longitudinal mini-incision.

Longitudinal Mini-Incision of Skin

1. After appropriate positioning of the patient on the operating table and prior to prepping and draping, duplex is used to identify and mark on the skin the carotid bifurcation and the anticipated skin incision. Length of the incision depends on the depth and extent of the lesion and varies from 2.5 to 5 cm.
2. The dissection and approach to the carotid bifurcation is essentially the same as for the standard longitudinal incision. Use of two self-retaining retractors and skin laxity allow for traction and exposure of a longer segment of carotid arteries than the length of skin incision itself (see Fig. 55.1).

REOPERATIVE EXPOSURE FOR CAROTID STENOSIS

For intimal hyperplastic lesions occurring within the first 2 years of surgery, intervention is not indicated until the lesion is at least 80% or the patient is symptomatic. Lesions occurring late are treated in the same fashion as de novo atherosclerosis of the carotid artery. Morbidity of reoperative procedures is increased due to risk of cranial nerve (CN) injury from scarring, making the identification of critical structures more difficult. The surgeon must also be prepared to resect the involved segment and replace it with an interposition graft. Either autologous vein grafts, using the proximal great saphenous vein (GSV), or prosthetic grafts may be used.

The retrojugular approach may be preferred for reoperative procedures to decrease nerve mobilization and dissection and the ability to work in a field that has not previously been dissected. The surgeon should anticipate the need for more distal and more proximal exposures to an area of healthy artery.

EXPOSURE FOR SUBCLAVIAN CAROTID INTERVENTIONS

These interventions initially declined markedly in the era of endovascular intervention, with stenting of the subclavian or innominate arteries, but then there was a resurgence with the advent of TEVAR and the need for coverage of the left subclavian artery or additional great vessels with debranching procedures.

Transposition

1. The patient is placed supine, with a roll under the scapula transversely and the head averted toward the contralateral side, with care taken not to hyperextend the neck. A slight reverse Trendelenburg position is preferred. Both arms should be tucked.
2. A transverse incision is made one fingerbreadth above the clavicle, extending from medial to the lateral head of the SCM for about 6 cm (see Fig. 55.1). Superficial dissection includes division of the platysma and superficial cervical aponeurosis. The external jugular vein should be ligated and divided. The clavicular head of the SCM is usually divided but sometimes it can be retracted. The omohyoid is next divided. It is helpful to mobilize the internal jugular vein to facilitate both medial and lateral mobilization and exposure of various regions of the subclavian artery. The vein should be mobilized laterally to allow for visualization for transposition and access of the artery prior to the takeoff of the vertebral branch. On the left side, it is important to identify the thoracic duct, which can be ligated and divided if necessary. This structure passes over the subclavian artery and joins the internal jugular vein on the left. There may be one main duct or several smaller ducts. Right-sided thoracic ducts have been reported in patients with aberrant right subclavian arteries; care should be taken in patients with this anatomic

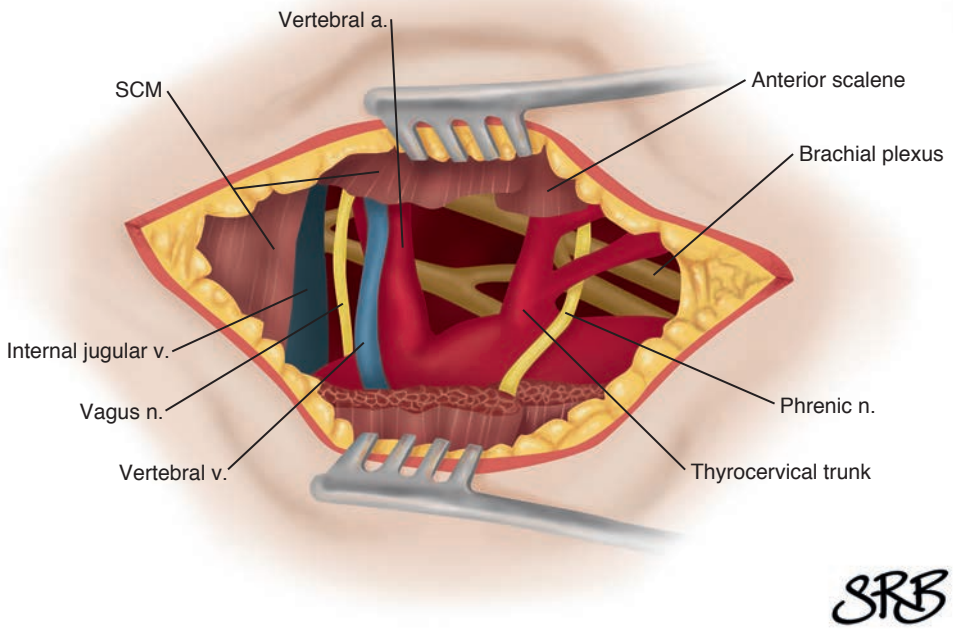

Figure 55.6 Traditional exposure of subclavian artery after division of anterior scalene muscle for carotid subclavian bypass. *SCM,* Sternocleidomastoid muscle.

variant to avoid injury. Inadvertent injury to the duct can lead to lymphatic leak, requiring reoperation. The sternal head of the SCM and subhyoid are retracted medially, as is the common carotid artery. The vertebral vein should be identified, ligated, and divided. The sympathetic ganglion or chain typically has fibers around the subclavian artery at this level just medial to the vertebral vein. Injury should be avoided if possible to prevent Horner syndrome. The vertebral artery superiorly and the internal mammary artery inferiorly should be controlled with vessel loops. At the more proximal aspect of the subclavian artery, the vagus, which crosses anteriorly, and the recurrent laryngeal nerve, which passes posteriorly to the subclavian, should be identified and preserved. The left subclavian artery is deeper than the right and can be slightly more difficult to access proximal to the vertebral artery. After adequate mobilization of the subclavian artery, the common carotid artery, which is in the medial portion of the field, is dissected to allow for a tension-free anastomosis and for adequate vascular control at the level of the subclavian artery. Care should be taken to avoid kinking the vertebral artery during transposition. It is also important to ensure complete hemostatic control of the subclavian stump prior to losing control of this segment as it retracts into the chest.

3. More proximal exposure of the subclavian artery can be gained by division and resection of the medial head of the clavicle. This facilitates exposure up to the junction with the carotid on the right. This is infrequently necessary today and is typically reserved for situations with hemorrhage, when endovascular maneuvers are insufficient or not available to control proximal bleeding. For right-sided proximal exposure of the subclavian artery, the incision can be extended to include a median sternotomy. This may require division of the innominate vein to facilitate full exposure of the more proximal subclavian and carotid arteries and the brachiocephalic trunk. On the left side, anterolateral thoracotomy can be performed to gain access to the origin of the left subclavian.

Subclavian Bypass

1. This dissection is similar to the supraclavicular approach for thoracic outlet syndrome (TOS). The incision is extended about 8 cm from the medial border of the clavicular head of the SCM one fingerbreadth above the clavicle. Superficial dissection is similar to transposition. The clavicular head of the SCM is divided. The scalene fat pad is mobilized inferiorly and medially and retracted superolaterally with a self-retaining retractor. The anterior scalene is next divided sharply after the phrenic nerve is first dissected; it is protected with a vessel loop. Electrocautery should be avoided to prevent thermal injury to the brachial plexus and surrounding nerves. The muscle should be divided as close to the insertion on the first rib as possible. The subclavian artery lies immediately beneath the anterior scalene. The thyrocervical trunk is typically visible and can be divided if necessary or controlled with vessel loops (Fig. 55.6). This exposure provides an adequate length of vessel for bypass with proximal control distal to the vertebral and mammary arteries.

VERTEBRAL ARTERY EXPOSURE

Traditionally, the vertebral artery has been exposed in four segments, a classification proposed by Berguer. The proximal

V1 segment involves vertebral artery from its origin at the subclavian artery to the point where it enters C6 transverse process. The V2 segment lies in the transverse process of C6 to C2 and is seldom exposed primarily for control of hemorrhage. V3 segment is between C2 and the base of the skull before the artery enters foramen magnum. The V4 segment is intracranial and begins at the atlanto-occipital membrane and terminates at the level where the vertebral arteries merge to form the basilar artery.

Exposure of the V1 Segment of the Vertebral Artery

Two approaches to exposure of V1 segment have been described. The more common supraclavicular approach is frequently used for transposition of the vertebral artery into the CCA. This approach allows the exposure of the origin of the vertebral artery but requires transection of the SCM and limits exposure of the distal V1 segment. In contrast, the anterior cervical approach does not require muscle transection and allows access to more distal V1 segment.

Supraclavicular Approach

1. The patient is placed supine, with the head turned away from the surgery site.
2. A transverse incision is made a fingerbreath above the clavicle, beginning at its head and extending laterally for 6 to 8 cm.
3. The platysma muscle, superficial fascia, and external jugular vein are divided.
4. Dissection is carried out between the two bellies of the SCM.
5. Alternatively, the clavicular head of the SCM may be divided, followed by division of the omohyoid muscle.
6. The internal jugular vein is then identified, dissected free on the medial aspect, and retracted laterally.
7. Subsequently the vagus nerve is identified and retracted either medially with the common carotid artery or laterally with the JV. The dissection is carried upward and downward between the JV, the subclavian vein, and the carotid artery.
8. On the left side, the thoracic duct is identified and divided between two ligatures. The dissection is medial to the prescalene fat pad that covers the phrenic nerve. On the right side large lymphatic channels may be identified; this is not uncommon. In such cases these channels should be ligated to avoid lymph leakage.
9. The inferior thyroid artery, which runs transversely, is ligated and divided. Subsequently the vertebral vein is identified. It often has some small branches that have to be controlled. The vertebral vein should be ligated and divided in its proximal aspect (Fig. 55.7).
10. At this point, the vertebral artery and sympathetic ganglion are easily identified in the center of the angle formed by the anterior scalene and longus colli muscles. The ganglion should be dealt with carefully to avoid a Horner syndrome. The vertebral artery should be dissected free from

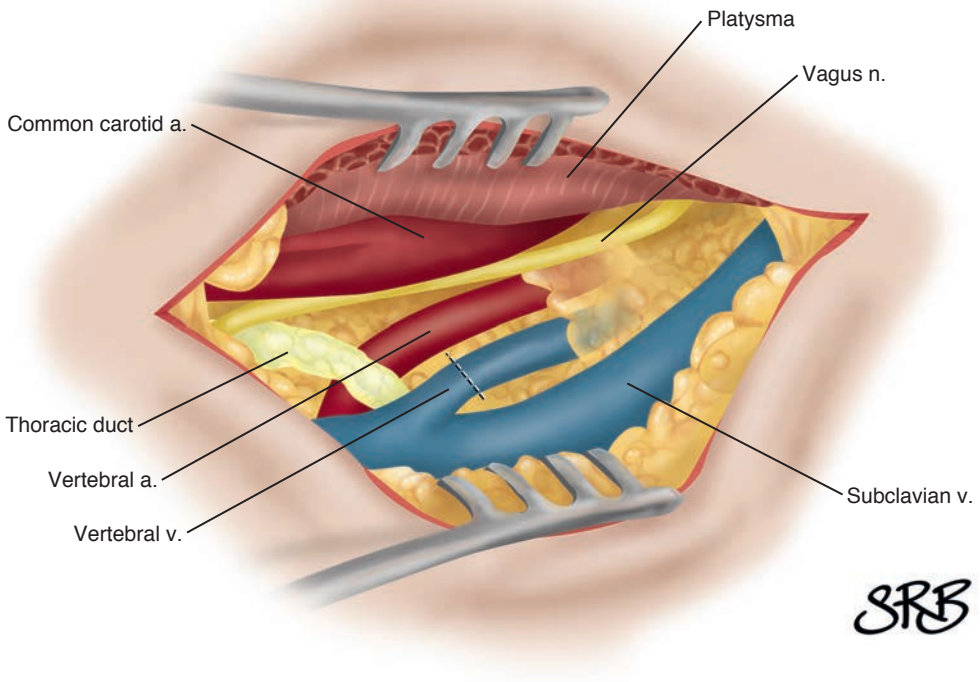

Figure 55.7 Supraclavicular approach to V1 segment of vertebral artery demonstrating overlying vertebral vein and thoracic duct.

sympathetic fibers and encircled with a vessel loop. This then allows for intervention on the V1 segment.

Anterior Cervical Approach

1. The positioning is the same as for the supraclavicular approach.
2. A vertical incision is made from the clavicular head up to the retromandibular area, on the anterior border of the SCM; the dissection is similar to that of standard carotid artery exposure.
3. The superior belly of the omohyoid muscle is often divided. The vagus nerve as well as sympathetic chain should be identified and protected.
4. In the lower aspect of the incision, the scalene fat pad is identified and retracted laterally, exposing the anterior scalene muscle and phrenic nerve.
5. The inferior thyroid artery should be ligated and divided, exposing the vertebral artery. The entire extraosseous vertebral artery (V1 segment) can be easily exposed to the level where it enters the transverse process of C6.

EXPOSURE OF THE V2 SEGMENT OF THE VERTEBRAL ARTERY

Exposure of the V2 segment is usually performed for bleeding control and has become less common in the endovascular area. Since the V2 segment runs through the forearm tranversaria, direct access is possible only by unroofing the transverse process. The exposed vertebral artery in the V2 segment is surrounded by a network of veins referred to as the vertebral transverse sinus. Injury to this vein system adherent to the adventitia and periosteum may lead to significant blood loss.

1. The incision is the same as that used for the anterior cervical approach to the V1 segment and extends from the clavicular head to the mastoid process.
2. The platysma muscle is divided and the SCM is retracted laterally to expose the carotid sheath.
3. Larynx, pharynx, and carotid sheath are dissected free from the prevertebral fascia and retracted medially, exposing the sympathetic ganglia and the anterior longitudinal ligament.
4. The ganglia are preserved and the ligament is incised vertically for the entire length of the incision.
5. The ligament is retracted laterally exposing the prevertebral fascia, longus colli, and longus capitis muscles, which are removed with a periosteal elevator from the transverse processes. In order to prevent cervical nerve injury, it is important to not extend the dissection beyond the lateral border of the transverse processes.
6. Access to the vertebral artery in the bony canal is obtained by carefully removing the anterior arch of the transverse process with a rongeur.

Exposure of the Atlantoaxial (V3) Segment of the Vertebral Artery

Access to V3 segment has been used for bleeding control resulting from traumatic injuries to the distal vertebral artery as well as to create the distal anastomosis in vertebral bypasses. Today exposure of V3 is rarely used since many of vertebral artery pathologies are treated with transcatheter techniques. At this level, the vertebral artery is fragile and susceptible to traumatic injury. In addition, the artery is encircled by the periarterial venous plexus. Thus it is recommended to dissect the artery at the subadventitial level.

1. The positioning of the patient is similar to that for carotid exposure, although some authors recommend a semiseated position to reduce venous pressure in the neck.
2. The vertical incision is carried on along the anterior aspect of the SCM from the level of the cricoid and curved posteriorly beneath the earlobe to cross over the mastoid. The platysma muscle is divided and the dissected carotid sheath is retracted medially and SCM laterally.
3. Partial or complete transection of the SCM at its origin significantly improves the exposure.
4. It is imperative to identify and preserve the spinal accessory nerve, which enters the sternocleidomastoid approximately 2 to 3 cm below the mastoid tip. The nerve should be retracted anteriorly and the transverse process of the first cervical vertebra identified by palpation. The C1 transverse process serves as the point of attachment for the levator scapulae, splenius cervicalis, and inferior oblique muscle, covering the interspace between C1 and C2, where an approximately 2-cm segment of the vertebral artery is readily accessible.
5. These three muscles are carefully divided, paying attention to avoid injury to the anterior ramus of the C2 nerve root, which lies on the anterior border of the levator scapulae muscle. In order to avoid nerve injury, the muscle division is performed over a right-angled clamp or small retractor, which is inserted between the C2 nerve and the muscles.
6. To increase exposure of the intertransverse space and vertebral artery, the cephalad muscle fibers are resected and the lower end of the divided muscle is either resected or retracted inferiorly.

POSTERIOR EXPOSURE OF THE SUBOCCIPITAL VERTEBRAL ARTERY (V4) SEGMENT

This technique, as described earlier for posterior carotid exposure, can also be used to treat dissections or aneurysms involving the most distal segment of the extracranial vertebral artery.

1. The patient is placed in the prone/lateral position with the contralateral arm placed under the head, with the incision as previously described for the posterior approach to the carotid.
2. Once the internal jugular vein and the accessory nerve are exposed, further dissection requires ligation and division of the condyloid emissary vein.
3. This is followed by partial division of the rectus capitis posterior muscle, allowing exposure of the vertebral artery, which is covered by a large venous plexus.

The overlying veins must be dissected away from the artery, which requires meticulous technique. Eventually the vertebral

artery can be dissected to the level of the atlanto-occipital membrane.

Exposure for Carotid Body Tumors

The major risk of intervention for carotid body tumors is injury to CNs (see Chapter 95).

Preoperatively, the diagnosis is made by duplex, CTA, or magnetic resonance angiography (MRA) assessment. Typical imaging demonstrates splaying of the carotid arteries with a highly vascularized tumor. The blood supply is primarily from the external carotid artery. For patients with very large tumors, preoperative embolization can be performed the day prior to decrease the size and potentially the bleeding from the tumor.

1. As with all cerebrovascular approaches, a roll is placed under the shoulders to allow for neck extension. The head is turned away from the operative side. The area is widely prepped, including the ear.
2. There are two possible incisions, depending on surgeon preference: The typical transverse incision or the C-shaped incision, which is more cosmetically appealing.
3. The platysma is raised as a flap.
4. After identifying the SCM and reflecting laterally, lymph nodes should be examined and sent for pathologic evaluation if any concern exists for metastatic disease.
5. The vagus nerve should be identified and protected.
6. Vascular control should be obtained of the common carotid, the external carotid above the tumor, and the internal carotid artery with vessel loops. Proximal ECA branches should be identified and controlled and may require ligation.

Size of the Tumor Determines Further Dissection

In the case of small tumors, such as Shamblin I, the ansa cervicalis is divided, as in a typical anterior approach to the carotid bulb. The tumor is dissected with bipolar electrocautery. The dissection is best started at the external carotid level. This allows one to devascularize the tumor from the external carotid artery branches supplying it. Any vessels identified as directly feeding the tumor are ligated and divided. Typically there is a major feeding vessel at the base of the bifurcation. Gentle tension on the tumor typically allows for better visualization of the plane between tumor and vessels. Care should be taken not to injure the hypoglossal nerve, which can be mobilized by division of the vascular bundle, and the superior laryngeal nerve, which is typically posterior to the tumor and close to the superior thyroid artery.

For Shamblin II tumors—which is defined as partially encompasing the vessels , and Shamblin III tumors—defined as encasement and vessel adherence, the approach is described below. Preoperative embolization can be helpful in decreasing bleeding for these patients. Patients should also be prepped with consideration of an interposition vein bypass. The great saphenous vein is typically utilized if of adequate size and should be mapped prior to surgery. Consideration should be given to ligation and even division of the ECA if needed to facilitate dissection. Only the periadventitial plane should be dissected if bypass is to be avoided. If the tumor invades the media, resection with bypass will be required. Cranial nerve transection may be necessary for larger tumors and should be discussed with the patient prior to surgery. The hypoglossal is typically tented over the tumor. The tumor can then be shaved off the bifurcation using bipolar electrocautery for the vast majority of lesions. With larger tumors, division of the digastric muscle is frequently necessary and should be approached as described previously.

Knowledge of the location and function of the CNs is critical to the exposure and surgery of a carotid body tumor (CBT) (see Chapter 91). The hypoglossal (CN XII) exits the skull from the hypoglossal canal, and runs between the internal jugular and the internal carotid arteries. It then runs medially over the ECA and ICA. Typically it is seen crossing about 2 cm above the carotid bifurcation.

The vagus nerve, CN (X) is posterolateral to the ICA, between the carotid and internal jugular vein. It joins the hypoglossal when followed cranially.

The superior laryngeal nerve lies posterior to the carotid arteries, frequently in direct communication with the tumor and adjacent to the superior thyroid artery.

The spinal accessory nerve (CN XI) and glossopharyngeal nerve (CN IX) run close to the base of the skull and are at risk for injury when division of the digastric is required. The spinal accessory runs over the distal ICA but behind the stylohyoid and then enters the SCM. The glossopharyngeal also crosses anterior to the ICA and to the jugular vein.

The marginal mandibular branch of the facial nerve (CN VII) runs along the masseter and can be injured with retraction.

TIPS

Awareness of CN location will decrease CN injury.

Bipolar electrocautery minimizes risk of thermal nerve injury and decreases blood loss.

Preoperative embolization should be considered for larger tumors but should be done in close proximity to the surgery, typically 1 day prior, to prevent development of new collateral vascularity to the tumor.

INTRODUCTION

Operations involving the arteries and veins of the lower extremity are among the most frequently performed open vascular surgical procedures in clinical practice. Having good familiarity with both the usual and alternative surgical exposures used in the lower extremity should be part of every vascular surgeon's repertoire. Typically, exposure is made through linear, vertical incisions placed directly over the arterial or venous segments in question (Fig. 56.1). In bypass procedures done for treatment of intermittent claudication, femoral endarterectomy, profundaplasty, and when embolectomy or thrombectomy is done for acute limb ischemia, exposure is usually confined to the femoral artery in the groin and the medial approach to the popliteal artery above or below the knee. Not surprisingly, these are by far the most commonly employed exposures, familiar to all vascular surgeons. However, in procedures done for critical limb ischemia and in reoperative surgery, exposure of the more distal crural and pedal

Abstract

Operations involving the arteries and veins of the lower extremity are among the most frequently performed open vascular surgical procedures in clinical practice. Having good familiarity with both the usual and alternative surgical exposures used in the lower extremity should be part of every vascular surgeon's repertoire. This chapter describes the common and infrequently used exposures used in the lower extremity.

Keywords

Exposure
vascular surgical
lower extremity

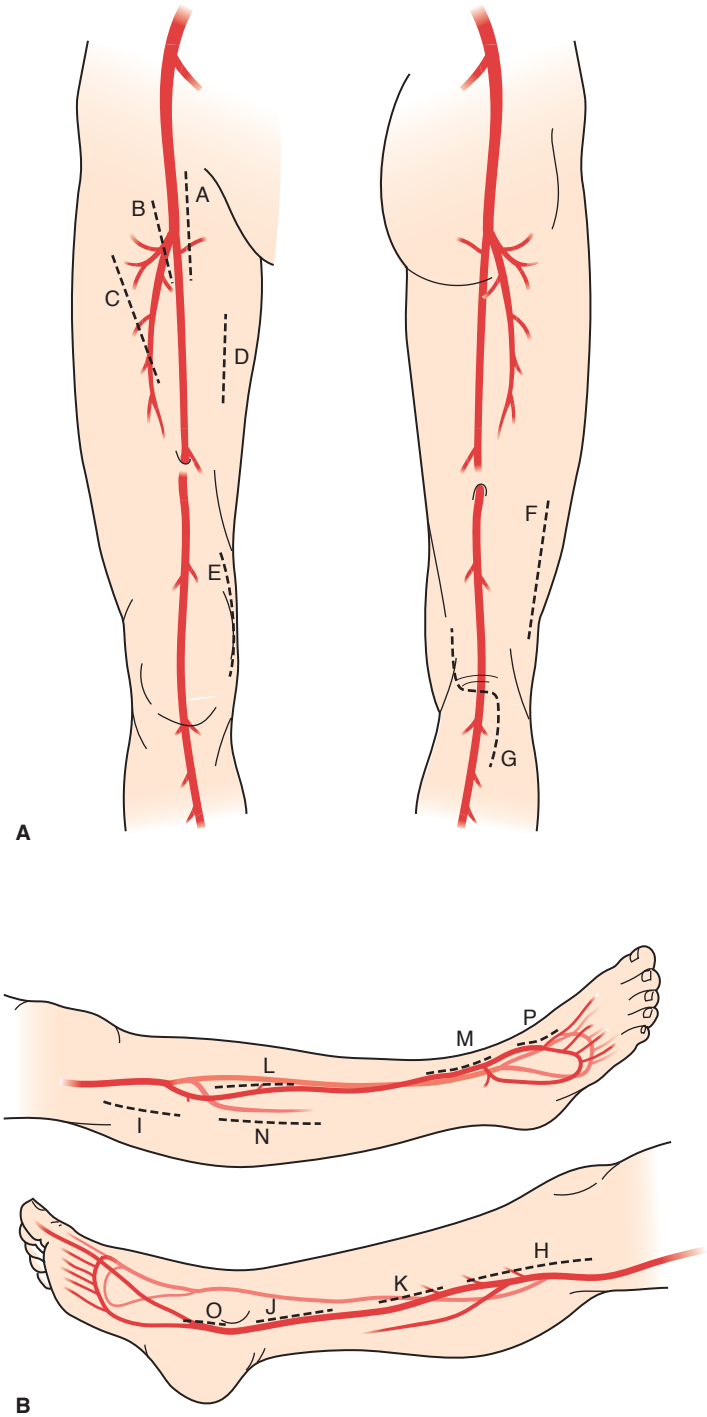

Figure 56.1 (A) Location of the vertical incisions to expose the arteries in the thigh: common femoral, deep femoral, superficial femoral, and popliteal arteries (B) and in the calf: popliteal, tibioperoneal trunk, anterior tibial, posterior tibial, and dorsalis pedis arteries. (Figures 67 and 68 from Rutherford RB. *Atlas of Vascular Surgery: Basic Techniques and Exposure*. Philadelphia: WB Saunders; 1993:114 and 115.)

vessels is frequently required. Moreover, in procedures done for or in the presence of infection, in obese patients, in many redo operations, and those performed for traumatic injury, it may be necessary to use incisions or exposure techniques not frequently employed in everyday practice.

Regardless of the exposure employed, we have found the following general principles to be critical:

Make an incision of adequate length—do not compromise exposure

Use self-retaining retractors whenever possible

Have a sterile continuous-wave Doppler probe available

Make liberal use of the cautery for dissection except in close proximity to adjacent nerves

Ligate all transected lymphatics

Ensure meticulous hemostasis

Adhere to the basic principles of traction/countertraction, bloodless field, meticulous blunt and sharp dissection as close to the artery as possible, obtain proximal and distal control with enough space to perform an anastomosis comfortably, avoid clamping or crushing of heavily calcified segments whenever possible.

Vein conduits should be handled gently and carefully; poorly prepared veins result in inferior outcomes.

Ensure good lighting and make use of magnification when anastomoses are being constructed.

FEMORAL ARTERY EXPOSURE

The common femoral artery (CFA) is located deep to the inguinal skin fold as a continuation of the external iliac artery as it passes beneath the inguinal ligament. It lies medial to the femoral nerve and lateral to the common femoral vein. The femoral neurovascular bundle is contained within the femoral sheath, which is formed by elements of the iliac, pectineus, and transversalis fascia in the femoral triangle.[1] The femoral triangle is covered by the tensor fascia lata and bound by the adductor longus muscle medially and the sartorius muscle laterally. The CFA bifurcates into the superficial femoral artery (SFA) and profunda femoris or deep femoral artery (DFA).

Common Femoral Artery—Longitudinal Approach

The CFA is usually exposed through a longitudinal incision over the femoral pulse just distal to the inguinal ligament. If no pulse is present, the artery is usually still palpable as a firm, cylindrical mass slightly medial to the midpoint of the inguinal ligament. The incision should be extended proximally to expose the inguinal ligament. The length of the incision varies based on the patient's body habitus and the extent of atherosclerotic disease, but typically about one-quarter to one-third of the incision should extend proximal to the ligament and the remainder distally. In very obese patients with a large overhanging pannus, it is important to identify the exact location of the inguinal ligament prior to making an incision. Often it is much more proximal than it may appear, making it possible to keep the distal end incision proximal to the fold in the pannus, which avoids the troublesome wound separation that invariably occurs when a vertical incision needlessly crosses this point. The subcutaneous tissue should be divided directly over the artery to avoid the creation of a medial or lateral flap, which can also lead to troublesome and occasionally

disastrous problems with wound healing. Any small venous or arterial branches of the superficial epigastric and superficial circumflex artery encountered should be ligated and divided. The authors also routinely ligate any divided lymphatics to minimize lymphatic leaks. The saphenous vein typically lies medial to the artery but is often encountered. Care should be taken to extend the dissection lateral to its course to prevent its injury.

The fascia lata lies deep to the subcutaneous tissue and is divided medial to the medial edge of the sartorius muscle over the artery to enter the femoral sheath. Most commonly, exposure will extend to the inguinal ligament. If more proximal exposure is needed, the inguinal ligament can be mobilized and retracted superiorly to increase visibility. Additional exposure can be obtained by dividing the ligament, which must always be repaired at the time of closure. If extended exposure of the proximal SFA is needed, the sartorius muscle can be mobilized and retracted laterally. The DFA typically arises somewhat lateral and posterior to the CFA (see further on). Care must be taken to avoid straying too far posterior and lateral to the CFA, which would risk injury to the femoral nerve. Medially, the common femoral vein is in very close proximity and not uncommonly adherent to the CFA. Careful sharp dissection is required to avoid its injury, especially in redo dissections.

Common Femoral Artery—Transverse Approach

The transverse approach is useful provided that only limited arterial exposure is needed, as for femoral embolectomy or a cutdown for endovascular aneurysm repair (EVAR). It begins with a horizontal skin incision 2 fingers' breadth above to the groin crease, parallel to the inguinal ligament. Once the incision has been made, it is deepened through subcutaneous tissue and Scarpa's fascia until the inguinal ligament is encountered. The ligament should be freed and mobilized to allow retraction superiorly. The dissection is deepened directly over the femoral pulsation until the femoral sheath is encountered, which is then incised longitudinally to expose the CFA. Self-retaining retractors are essential for adequate exposure. Although most of the CFA can usually be exposed through this approach, it provides only limited access to the superficial and deep femoral arteries.

Deep Femoral Artery—Conventional (Proximal) Approach

The DFA originates approximately 2 to 5 cm distal to the inguinal ligament and has a lateral course relative to the CFA in most patients. Exposure of the DFA begins with longitudinal exposure of the CFA, as previously described. As the CFA is exposed distal to the inguinal ligament, the origin of the DFA is usually encountered on the lateral or posterior lateral side of the CFA at the point where the CFA caliber becomes noticeably smaller as it bifurcates into the DFA and SFA. In most cases a few centimeters of the DFA can be exposed before the lateral femoral circumflex vein is encountered (Fig. 56.2); it crosses over its anterior surface and must be carefully divided and suture-ligated for additional exposure. Further dissection may require division of other crossing veins and lateral retraction of the sartorius muscle. Lymphatics are often encountered in extended exposure of the PFA and should be ligated. The femoral nerve is in close proximity and care should be taken to avoid its injury. The length of the proximal profunda varies in length from a few to as many as 8 cm. Branch points and bifurcations increase in frequency with more distal exposure. Both the medial and lateral circumflex arteries most commonly originate from the DFA, although either or both can originate from the CFA, usually near the DFA origin; they may be injured during careless posterior dissection of the CFA or DFA.

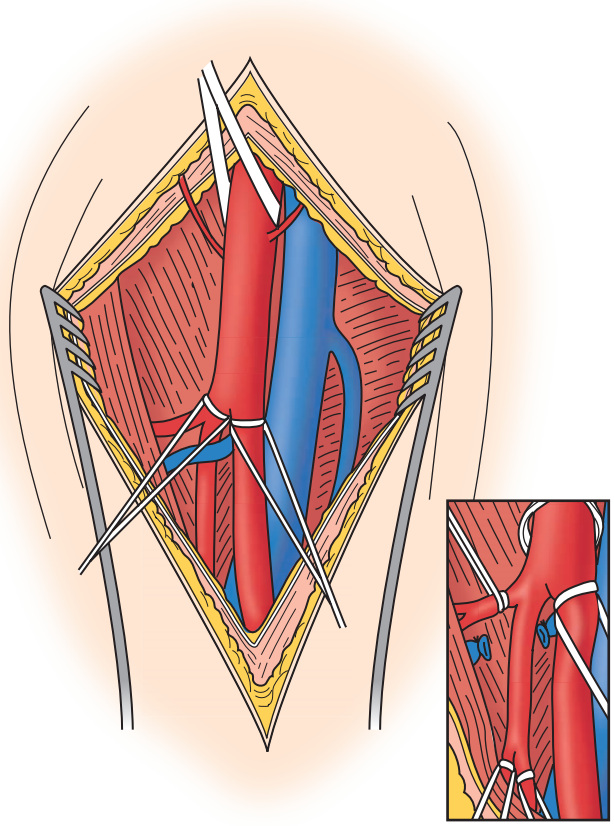

Figure 56.2 The proximal deep femoral artery origin is typically identified as a posterolateral branch of the common femoral bifurcation. Additional exposure is obtained by extending the vertical incision to expose the lateral femoral circumflex vein, which is divided where it crosses over the deep femoral artery. (Figure 71 from Rutherford RB. *Atlas of Vascular Surgery: Basic Techniques and Exposure*. Philadelphia: WB Saunders; 1993:123.)

Deep Femoral Artery—Lateral (Distal) Approach

The lateral approach to the DFA is useful in reoperative surgery as an alternative source of either inflow or outflow when the more proximal femoral vessels are encased in dense scar and/or infection or when a more distal inflow site is needed in the case of limited venous conduit.[2,3] The incision is made parallel to the course of the sartorius muscle usually 6 or 7 cm distal to the femoral pulsation or just distal to the end of a previous femoral

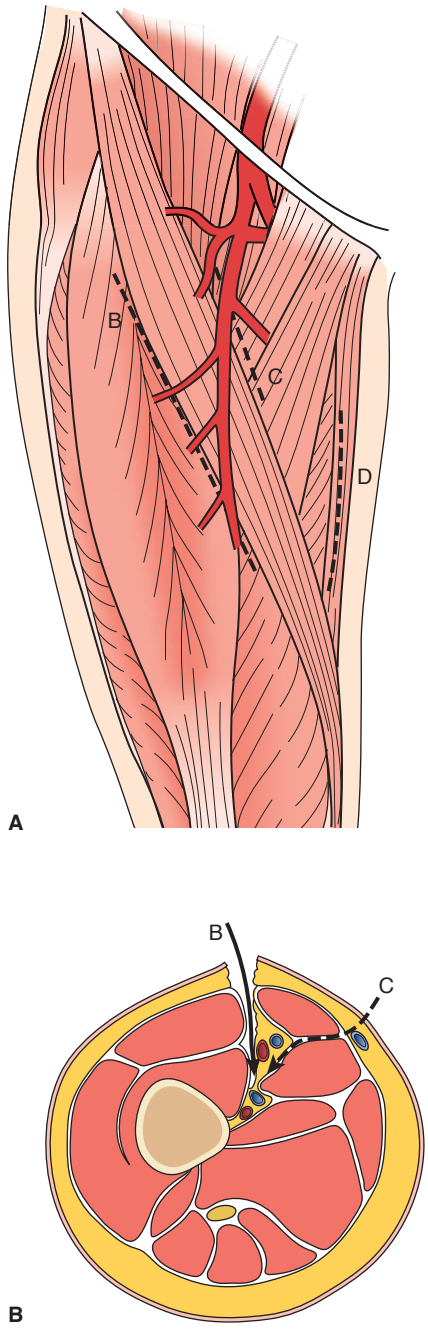

Figure 56.3 (A) The distal deep femoral artery can be approached from either medial or lateral to the sartorius muscle, depending on the course of the bypass. (B) In both cases, the dissection is performed lateral to the superficial femoral vessels. (Figure 73A and B from Rutherford RB. *Atlas of Vascular Surgery: Basic Techniques and Exposure*. Philadelphia: WB Saunders; 1993:128-129.)

incision. It can be placed on either the medial or lateral side of the sartorius depending on the situation and the likely course of the bypass graft; for example, lateral for a profunda-anterior tibial or axillary-profunda graft or medial for a femoral-profunda or profunda-popliteal graft (Fig. 56.3). Regardless of the chosen incision, approaching the distal PFA requires dissection lateral to the superficial femoral vessels and adjacent nerves, which can be easily injured with retraction, especially when Gelpi or sharp-toothed Weintlander retractors are being used. The dissection continues deep to the superficial femoral vessels in a plane between the vastus medialis and adductor longus muscles (Fig. 56.4). Usually a raphe created by the intersecting fibers of the fascia of these muscles is encountered, which, when opened, exposes the underlying deep femoral vein. The artery is usually found deep to the vein. In difficult cases, a handheld Doppler probe is useful for identifying the location of the artery.

Superficial Femoral Artery Exposure—Proximal Approach

The SFA is lies in a plane deep to the sartorius muscle, crossing over the adductor longus muscle. The proximal SFA is easily exposed by distal extension of the longitudinal incision made for exposure of the CFA. The SFA is located under the proximal sartorius muscle, which can be mobilized and retracted laterally. It can also be exposed in this fashion without exposing the CFA or DFA with a more distal incision placed along the anterior edge of the sartorius muscle (see later).

Superficial Femoral Artery Exposure—Mid-/Distal

The SFA follows a course between the anterior and medial compartments of the thigh in an aponeurotic tunnel, the adductor (Hunter) canal, created by components of the investing fascia of the vastus medialis, sartorius, and the adductor longus muscles.[1,4] In addition to the SFA, the Hunter canal contains the superficial femoral vein deep to the artery and two branches of the femoral nerve: the sensory saphenous nerve and the motor nerve to the vastus medialis muscle. To approach the SFA, the patient is placed with the leg externally rotated and the knee flexed to 30 degrees. A longitudinal incision is then made parallel to the anterior border of the sartorius to avoid disrupting the blood supply to the muscle, which enters on its inferomedial edge. The incision is carried down to the fascia lata, which is incised to expose the sartorius muscle. The muscle is then reflected in a posterior direction to reveal the roof of the Hunter canal. The fascia is opened to expose the SFA and vein. The vessels are often densely adhered to one another requiring careful dissection to separate them. Typically several large branches of the vein are encountered crossing over the artery, which should be divided. The SFA, even when widely patent on imaging, usually has some degree of atherosclerosis and is often calcified. In the authors' experience, the surgeon should be prepared to extend the initial exposure either proximally or distally to find the most suitable area for clamping and/or placing an anastomosis.

POPLITEAL ARTERY EXPOSURE

Anatomy

The popliteal artery is the extension of the SFA across the knee. It courses from the adductor hiatus at its superior border to

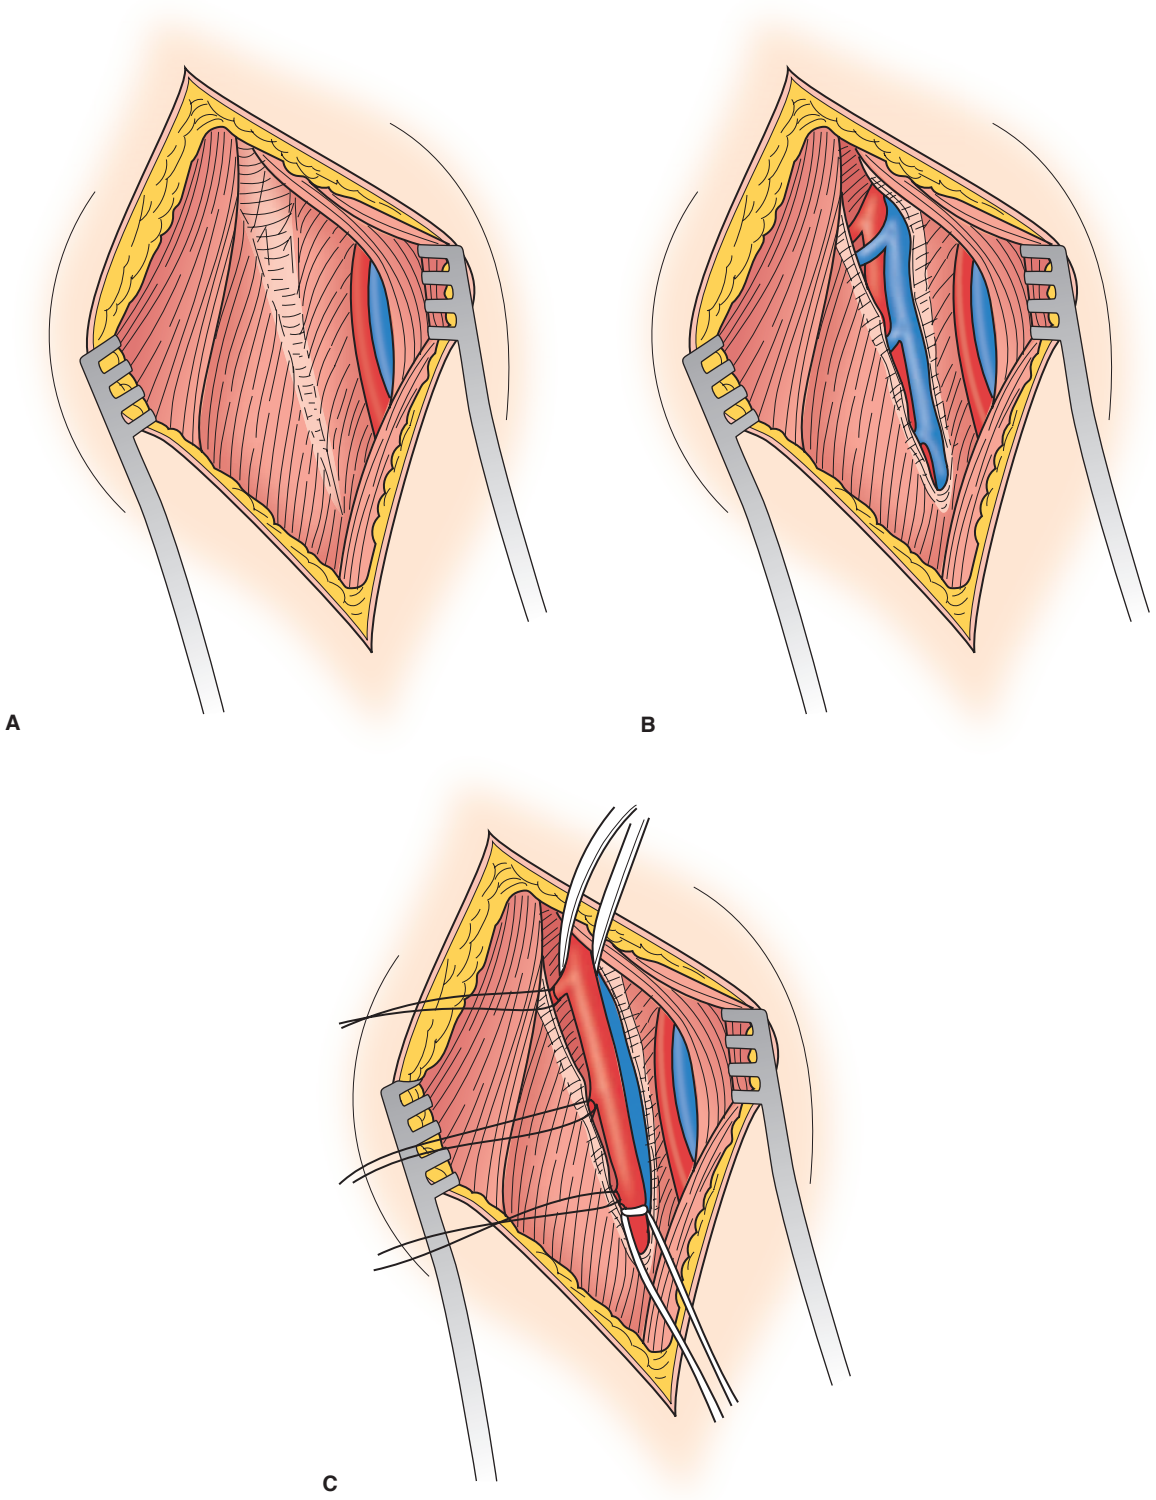

Figure 56.4 (A) There is a raphe formed by the intersecting fibers of the vastus medialis and the adductor longus muscles, which is divided to reveal the (B) deep femoral vessels with the vein lying superiorly. (C) The artery is dissected free from the vein with careful attention paid to the fibers of the femoral nerve. (Figure 73C to E from Rutherford RB. *Atlas of Vascular Surgery: Basic Techniques and exposure*. Philadelphia: WB Saunders; 1993:128-129.)

the popliteus muscle at its inferior border.[1,4] It is important to understand the relationships of the muscles, nerves, fascia, and arteries to perform adequate exposure for safe arterial reconstruction. The vessels are encased in a connective tissue sheath and are loosely adherent to the tibial nerve. The entire neurovascular bundle is enclosed within the fat pad of the popliteal space, which can be quite bulky and extensive, especially in obese individuals. The popliteal artery gives rise to several small arteries around the knee joint that form important collaterals with the DFA.

SUPRAGENICULATE POPLITEAL

Medial Exposure

The patient is placed supine with the leg externally rotated on a bump at the level of the knee. The incision is made in the distal third of the medial thigh along the anterior border of the sartorius muscle at the lower edge of the vastus medialis. Alternatively, the incision is made through the bed of the saphenous vein harvest incision, which results in a slightly more posterior approach. The fascia lata is incised and the sartorius muscle is retracted posteriorly. The deep fascia should be incised slightly inferior to the edge of the vastus medialis muscle. A small artery and vein is often encountered as well as a branch of the saphenous nerve. The artery and vein should be divided but the nerve can often be spared. Upon entering the popliteal space, the popliteal fat pad is encountered. The dissection commences in this envelope of fat in close proximity to the posterior aspect of the femur. The artery is usually firm or calcified and easily palpated even in the absence of a pulse. In obese patients the fat pad is thicker and more extensive and the artery can be difficult to find. In this case, palpation of the firm mass of the adductor magnus tendon is a good reference point, since the artery pierces the tendon to enter the popliteal space and is easily found at its edge. It should be encircled with a vessel loop or tape and placed on some traction by attaching the loop to a self-retaining retractor, which greatly facilitates its exposure, especially during the creation of an anastomosis. The popliteal artery is usually encountered anterior and medial to the vein, which is often paired, with multiple bridging veins across the popliteal artery that must be divided. Like the SFA, this artery is often heavily calcified and rarely free of some degree of atherosclerotic disease. Finding the best place for clamping may require exposure of the entire segment from the adductor hiatus to the point where it crosses under the medial head of the gastrocnemius muscle.

Lateral Exposure

The leg is internally rotated and the knee is flexed. The incision is made in the distal third of the lateral thigh between the iliotibial tract and the biceps femoris muscle. The fascia lata is incised posterior to where the iliotibial tract joins the lateral intramuscular septum. The popliteal space is entered between the short head of the biceps femoris muscle and the lateral femoral condyle. The neurovascular bundle can be palpated in the popliteal fat pad. The popliteal vein, which is located lateral to the artery, is usually encountered first (Fig. 56.5). When dissecting the popliteal artery free from the popliteal vein, careful attention must be paid so as not to injure the common peroneal nerve.[2]

MIDPOPLITEAL

Posterior Approach

The posterior approach to the popliteal artery is especially useful in the repair of popliteal aneurysms[5-7] or for diseases confined to the midpopliteal artery, such as adventitial cystic disease.[8] The patient is placed prone on the operating table with the foot and ankle resting on a pad to slightly flex the knee. An S-shaped incision is chosen to avoid scar contracture across the posterior knee joint. The incision is made from the posterior medial aspect of the thigh across the skin crease and down the posterior lateral leg. The small saphenous vein is identified in the subcutaneous tissue; it can be ligated or dissected free and retracted to expose the deep fascia. The deep fascia is then incised vertically and the sural nerve retracted laterally. The tibial nerve is the most superficial of the neurovascular structures and should be retracted laterally along with the common peroneal nerve, which runs along the biceps femoris tendon. This will expose the popliteal vessels, which lie medial and deep to the nerves (Fig. 56.6). To facilitate distal exposure, the medial and lateral heads of the gastrocnemius muscle are retracted apart. The popliteal artery lies slightly deep and medial to the vein and can be readily dissected free.

The midpopliteal artery can also be exposed from the medial approach through an extended incision by dividing the tendinous attachments of the medial head of the gastrocnemius and sartorius muscles. These are best reattached with heavy-gauge sutures during closure.

INFRAGENICULATE POPLITEAL

Medial Exposure

The patient is placed in the supine position with the knee flexed, using a bump under the thigh. The incision starts at the knee joint, one finger breadth inferior to the medial border of the tibia, which is usually superior to the course of the great saphenous vein. The vein should be identified to avoid inadvertent injury. When the saphenous vein is planned for conduit, it should be mobilized first and the resulting incision used to expose the artery. The crural fascia is then incised to enter the popliteal space. At the proximal end of the incision the semimembranosus tendon is encountered; it can be divided to facilitate exposure. The medial head of the gastrocnemius is retracted posteriorly to reveal the neurovascular bundle, which lies under the medial edge of the tibia. The first structure encountered is the medial branch of the paired popliteal veins. The artery is then dissected circumferentially and encircled with vessel loops or tapes to elevate it into the incision.

Figure 56.5 (A) With the leg internally rotated and the knee flexed, the incision is made in the distal third of the thigh between the iliotibial tract and the biceps femoris muscle. (B) The popliteal space is entered between the short head of the biceps femoris and the lateral condyle of the femur. (C) A cruciate incision is made through the tough fibers of the iliotibial tract to facilitate retraction. (D) The femoral vessels are identified in the popliteal fat pad and the artery is dissected free. ([A] Figure 17.7 (top picture) from Valentine JR, Wind GG. *Anatomic Exposures in Vascular Surgery.* 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2003:448. [B] Figure 76 (B to D) from Rutherford RB. *Atlas of Vascular Surgery: Basic Techniques and Exposure*. Philadelphia: WB Saunders; 1993:139.)

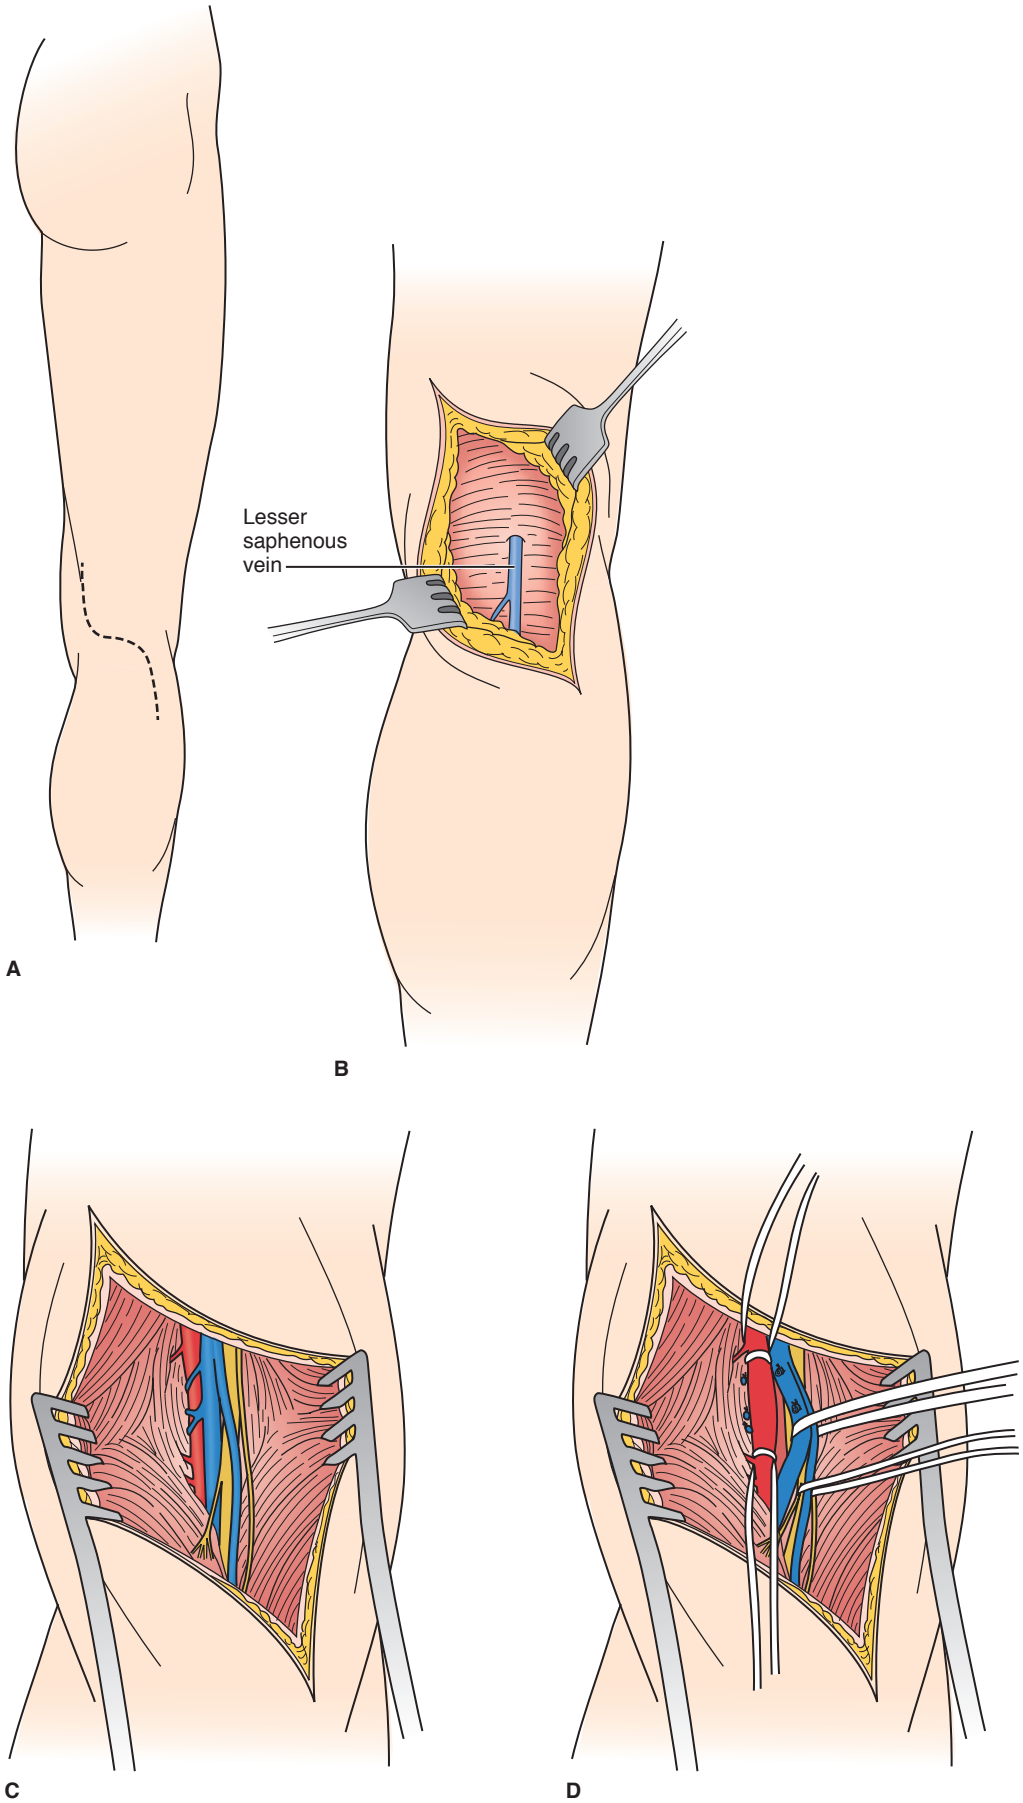

Figure 56.6 (A) The incision for the posterior exposure of the popliteal artery is made as a "lazy S" shape to avoid scar contracture across the knee. (B) The small (lesser) saphenous vein is identified in the subcutaneous tissue. (C) The deep fascia is incised and the sural nerve is gently retracted laterally to facilitate the dissection (D) of the popliteal artery from the popliteal vein and the tibial nerve, which lies most superiorly. ([A, B] Figures 17.35 and 17.36 from Valentine JR, Wind GG. *Anatomic Exposures in Vascular Surgery.* 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2003:462 and 463. [C, D] Figure 77C and D from Rutherford RB. *Atlas of Vascular Surgery: Basic Techniques and Exposure*. Philadelphia: WB Saunders; 1993: 142.)

The artery can then be separated from the veins with sharp dissection. Overlying crossing veins are uncommon but should be divided, while large collateral arterial branches should be preserved.

Lateral Exposure

The patient is placed in the supine position with the leg internally rotated and the knee flexed. A longitudinal incision is then made over the head of the fibula and extended distally. The common peroneal nerve is then identified posterior to the tendon of the biceps femoris muscle. The nerve should be gently dissected and retracted anteriorly as the tendon is divided to reach the fibula. The attachments to the fibula and fibular head are detached bluntly with a periosteal elevator. The proximal third of the fibula is then divided and removed. The popliteal artery is encountered deep to the fibula and can then be dissected free from the veins and encircled with vessel loops (Fig. 56.7).[2]

EXPOSURE OF THE TIBIAL AND PERONEAL ARTERIES

Anterior Tibial Artery Exposure

The anterior tibial artery is the most distal branch of the infrageniculate popliteal artery, arising from its lateral aspect and immediately passing through the interosseous membrane before entering the anterior compartment of the lower leg. Consequently the first 2 or 3 cm are most often not accessible for bypass and are frequently associated with significant atheromatous disease. Although a technique for medial exposure of the anterior tibial artery through the popliteal fossa has been described,[9,10] in the authors' experience it is rarely needed.

The proximal and middle third of the anterior tibial artery is exposed by a vertical incision on the anterolateral aspect of the calf and centered over the location of the planned anastomosis. The anterior tibial artery and vein lie on or in close

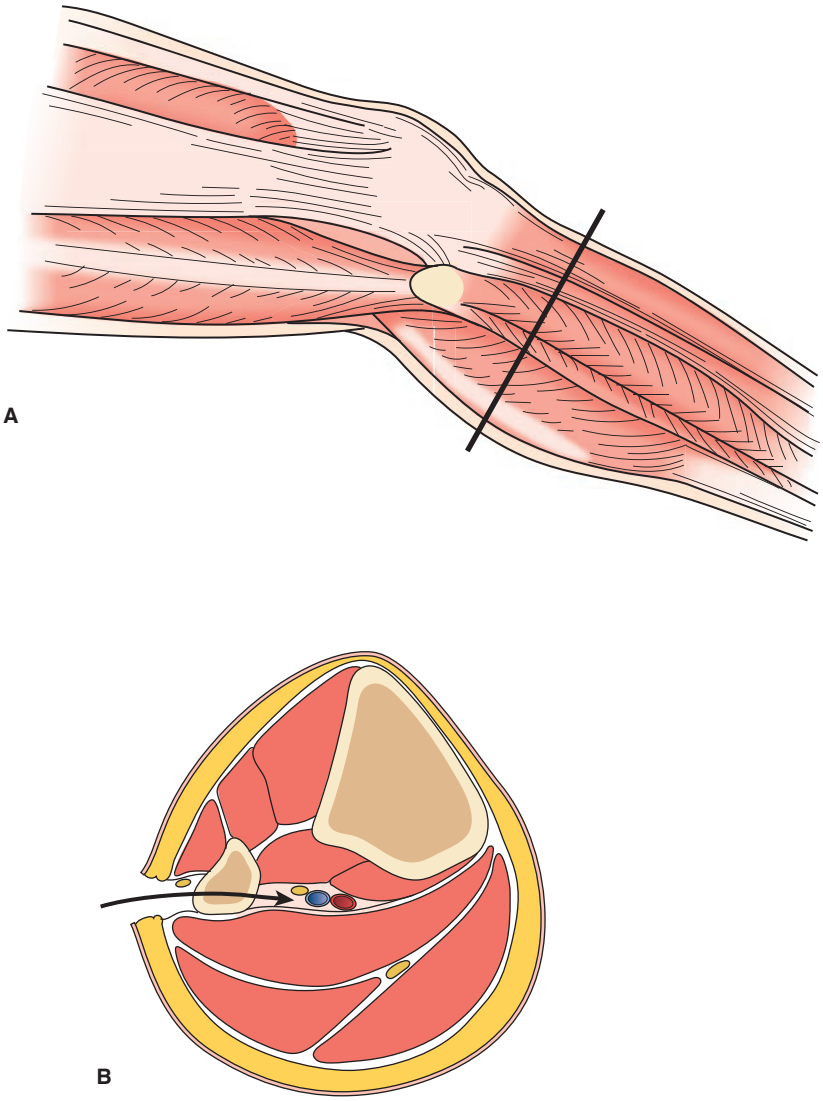

Figure 56.7 The lateral approach to the below-knee popliteal is performed by incising overlying the proximal third of the fibula. The common peroneal nerve is identified and gently retracted anteriorly. The attachments to the fibula are taken down bluntly with a periosteal elevator, and the fibula is then divided proximally and distally to reveal the neurovascular bundle. (Figure 79 from Rutherford RB. *Atlas of Vascular Surgery: Basic Techniques and Exposure*. Philadelphia: WB Saunders; 1993:149.)

proximity to the interosseous membrane. With the foot and ankle relaxed, it is often possible to palpate the cleft between the tibialis anterior and extensor digitorum longus muscles on the lateral calf approximately at the midpoint between the fibula and the tibia. The incision should be made directly over the cleft starting about 2 or 3 cm distal to the head of the fibula. The overlying fascia should be incised in line with the skin incision with the fascial incision extending for several centimeters distal and proximal to the skin incision to facilitate exposure, especially in heavily muscled individuals. Care must be taken to avoid injury to the peroneal nerve with this maneuver. Blunt finger dissection is used to separate the muscle bellies of the tibialis anterior and extensor digitorum longus muscles. Deep in the cleft at the level of the interosseous membrane, the anterior tibial artery and vein are usually easily identified (Fig. 56.8). Self-retaining retractors are crucial in this location. Small branches of the anterior tibial artery are often seen on the surface of the muscle bellies and are easily torn with overly aggressive blunt dissection or retraction. Quite often the vein is anterior to the artery and must be carefully dissected free from the underlying artery to facilitate exposure. A number of small crossing veins are often encountered on the anterior surface of the artery and should be ligated and divided to avoid troublesome bleeding. Similarly, great care should be taken in dissecting to free the artery, which has numerous small side branches; this can also lead to troublesome bleeding if they are torn during dissection. The authors prefer the use of a fine-tipped mosquito clamp to dissect along the surface of the artery and favor encircling the artery with small-caliber vessel loops for proximal and distal control. Heavily calcified anterior tibial arteries are better controlled with tourniquet occlusion after exsanguinating the lower leg with an Esmarch bandage.

The distal half of the anterior tibial artery can be exposed in similar fashion to the more proximal artery. However, if adequate conduit is available, the distal anterior tibial artery is best exposed at the ankle just proximal to the malleoli and flexor retinaculum. The tendons of the numerous extensor muscles of the ankle and foot come together in this location, and care must be taken in deciding the best way to expose the artery to avoid compressing or kinking the vein graft when the ankle is dorsiflexed. The best route is to separate the tendons of the extensor hallucis longus and extensor digitorum longus muscles. Once these tendons have been separated, the artery and vein are usually easily found and dissected free as previously described.

Because of its lateral location, vein grafts arising from the femoral triangle to the anterior tibial artery must be tunneled laterally, either subcutaneously or through the interosseous membrane. This anatomic reality can lead to graft thrombosis from kinking or twisting of the vein graft when done incorrectly.

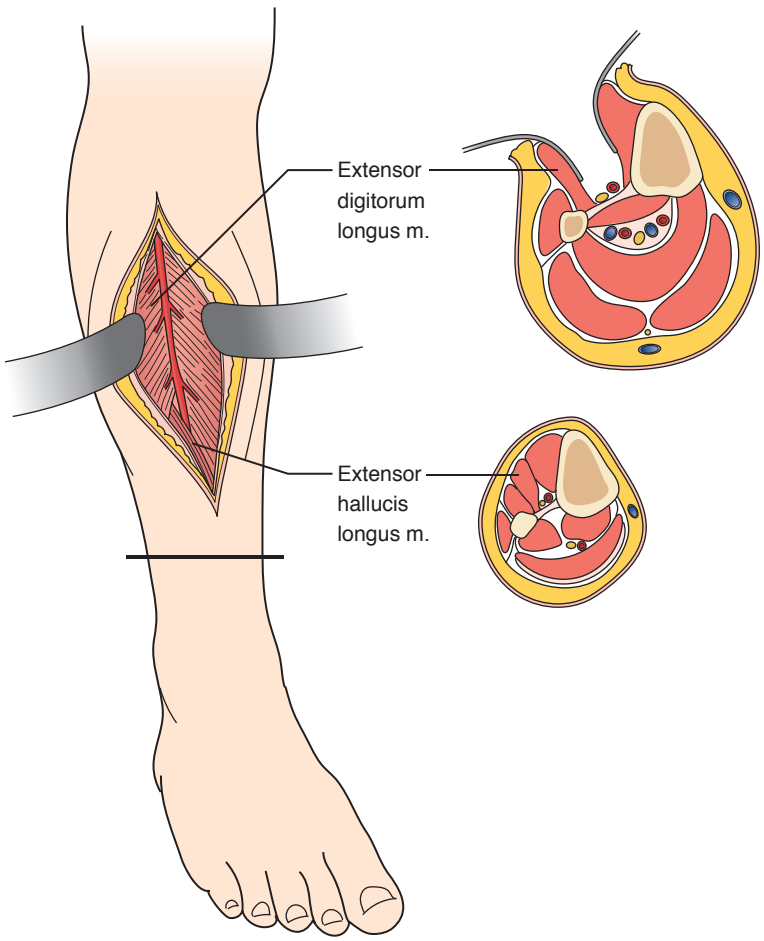

Figure 56.8 The proximal anterior tibial artery is exposed through an incision lateral to the tibia between the tibialis anterior and the extensor digitorum longus muscles. The anterior tibial artery is identified deep in the cleft between these two muscles along the interosseous membrane. (Figure 18.41 from Valentine JR, Wind GG. *Anatomic Exposures in Vascular Surgery.* 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2003:508.)

Subcutaneous vein grafts arising from the groin to the proximal anterior tibial artery can be easily tunneled across the anterior surface of the thigh (the authors' preferred approach), crossing the knee at the midpoint of the lateral femoral condyle and anterior to the head of the fibula, taking care to avoid injury to the peroneal nerve. The graft should not cross the knee joint in a more anterior location to avoid compressing the vein graft with flexion of the knee joint. When tunneling across the anterior thigh, it is important to place the tunnel in the subcutaneous tissue as close to the anterior fascia of the thigh muscles as possible to provide the maximal amount of soft tissue coverage and minimize kinking at the groin. Tunnels created too superficially, especially in obese patients, will result in a kink of the vein graft by the thick layer subcutaneous tissue of the femoral arterial exposure incision at the point where the graft exits the femoral triangle. Tunnels created too deeply may cross underneath the sartorius muscle, leading to graft compression. Often it is necessary and prudent to make a counterincision on the anterolateral thigh midway between the knee and groin dissection to facilitate the creation of the tunnel.

Tunneling an anterior tibial graft through the interosseous membrane has the advantage of needing a shorter length of vein conduit and also reduces the likelihood of graft exposure if there is wound breakdown, especially when the graft is also tunneled under the sartorius muscle and through the popliteal space. For in situ vein grafts and bypasses arising from the above- or below-knee popliteal artery, tunneling through the interosseous membrane is the only feasible pathway for bypasses terminating in the proximal or middle third of the anterior tibial artery. More distal bypasses to the supramalleolar anterior tibial artery can be tunneled across the anterior surface of the tibia. Although this approach is simpler, it may result in graft compression by the underlying tibia in patients where the skin and soft tissue in this location is thin and taut.

When creating the interosseous tunnel, the authors prefer to have the knee flexed at 90 degrees in the "sit up" position. The tunnel is created by simultaneous dissection medially from the below knee popliteal space and laterally from the anterior compartment with surgeon's finger and blunt tipped instrument (Fig. 56.9). The graft should be tunneled several centimeters proximal to the planned point of anastomosis to the anterior tibial artery. Many surgeons will expose the interosseous membrane from the lateral aspect of the leg and perform a cruciate incision to expand the space and prevent compression of the graft by the firm edge of the fascia. Once the membrane has been incised, the authors prefer to pass a gently curved clamp from the popliteal space in close proximity to the point where the anterior tibial artery crosses the membrane. The jaws of the clamp can be partially opened to widen the tunnel. Careless or overly forceful tunneling can lead to very troublesome venous bleeding from the anterior tibial vein.

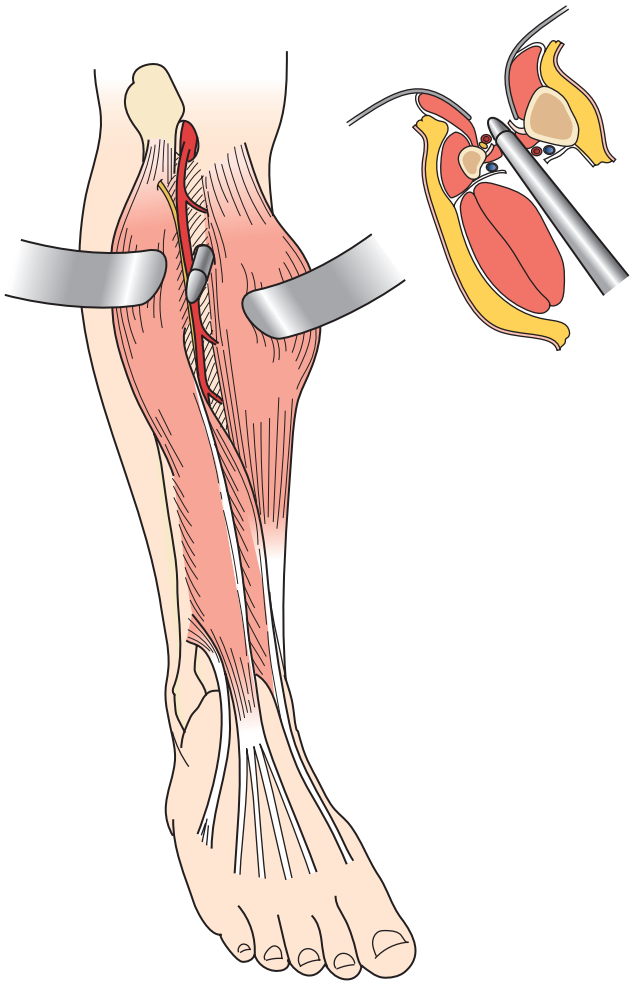

Figure 56.9 Bypass grafts originating from the medial leg can reach the lateral leg by traversing the interosseous membrane. The membrane is exposed with gentle blunt dissection from both the medial and lateral sides. The graft is then tunneled several centimeters proximal to the planned site of the distal anastomosis. (Figure 18.42 from Valentine JR, Wind GG. *Anatomic Exposures in Vascular Surgery.* 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2003:509.)

Tibioperoneal Trunk and Proximal Posterior Tibial and Peroneal Artery Exposure

The tibioperoneal (TP) trunk and proximal posterior tibial and peroneal arteries are found in the deep posterior compartment underneath the soleus muscle. The dissection commences with exposure of the below-knee popliteal artery from the medial aspect of the leg. Once the distal popliteal artery has been identified, the tip of a finger or the end of a right-angled clamp can be used to enter the potential space where the artery crosses beneath the soleus muscle, using cautery to divide the soleus about a finger breadth posterior to where it attaches to the tibia. Starting the dissection is the most difficult part, since large veins can be encountered; these must be carefully ligated or suture-ligated. Once the soleus has been divided, the arteries are usually easily identified. The TP trunk is often found posterior to its corresponding vein, which must be mobilized to facilitate its exposure. The distal TP trunk bifurcates into the posterior tibial and peroneal arteries. The posterior tibial artery is more superficial and easily dissected free from its adjacent vein in this location. Dissection of the peroneal artery can be more difficult, since it lies more deeply as it turns laterally to run in its typical course along the medial side of the fibula. Veins are

often encountered in this area, which must be carefully ligated to avoid troublesome bleeding.

Posterior Tibial Artery Exposure

Exposure begins with an incision on the medial aspect of the calf about one or two finger breadths posterior to the edge of the tibia. Alternatively the incision can be made through the base of the incision of the harvested great saphenous vein. Once the deep fascia has been incised, the soleus muscle will be encountered, which should be detached from the tibia using electrocautery to enter the deep posterior compartment. The posterior tibial vessels are then immediately encountered. The posterior tibial vein is usually slightly superior to the artery, whereas the posterior tibial nerve is usually posterior to both (Fig. 56.10). Crossing veins are often encountered and must be divided. The artery often has small side branches, which must be controlled. Soft arteries are easily controlled with vessel loops, while heavily calcified arteries are best controlled with a tourniquet after exsanguination of the lower leg.

Distal exposure of the posterior tibial artery beyond the lower edge of the soleus muscle is easily accomplished in most cases and is the preferred location for in situ femoral posterior tibial bypasses, since the vein harvest incision can be used to expose the artery as well. The artery is exposed through an incision made posterior to the tibia and anterior to the Achilles tendon (Fig. 56.11). Once the fascia has been incised, the artery and vein will be encountered in an investing layer of fatty tissue. A Doppler probe is useful for identifying the precise location of the artery in this location. Numerous crossing veins are almost always present; these should be divided to expose an adequate length of artery.

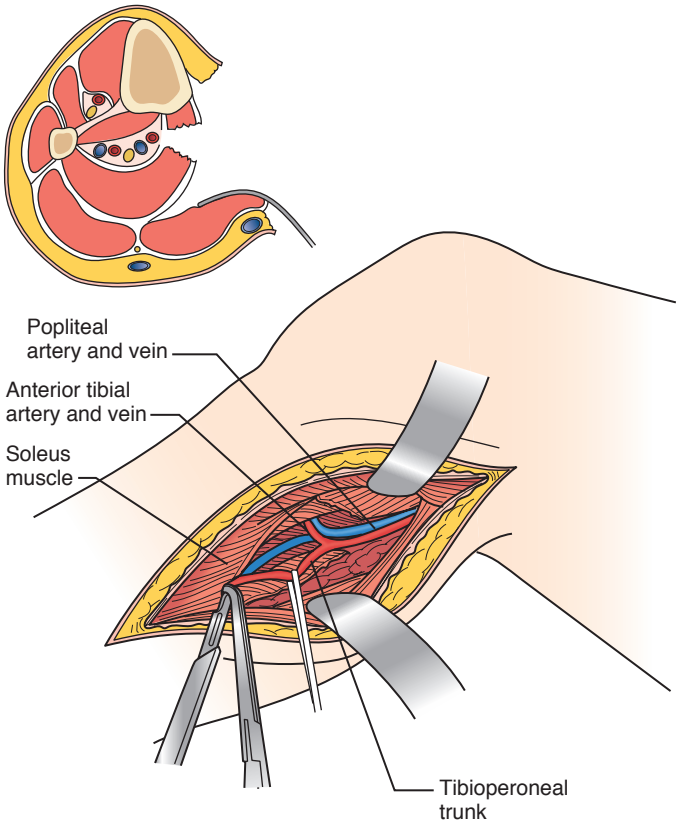

Figure 56.10 Exposure of the posterior tibial artery begins with an incision one to two finger breadths posterior to the edge of the tibia. The deep fascia is incised, and the soleus is detached from the tibia to enter the deep posterior compartment. The posterior tibial vessels are then encountered. (Figure 18.34 from Valentine JR, Wind GG. *Anatomic Exposures in Vascular Surgery.* 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2003:501.)

Peroneal Artery Exposure

Medial Exposure

Medial exposure of the peroneal artery is easily accomplished in its most proximal portion through the identical approach used for exposure of the TP trunk, as previously described. The artery is easily identified at the bifurcation of the TP trunk, and dissection continues along the anterior surface of the artery deep to the location of the posterior tibial artery and vein. The peroneal artery can also be exposed in its middle and distal portion through medial incision by detaching the soleus muscle from the tibia, as previously described. In general, a more lengthy incision should be used than is generally required for the posterior tibial artery due to the deep location of the peroneal artery, especially in individuals with large calf muscles. Once the posterior tibial neurovascular bundle has been identified, dissection is deepened either anterior or posterior to the posterior tibial structures (Fig. 56.12). Deepening the dissection anterior to the posterior tibial neurovascular bundle is probably the more traditional approach. This dissection can occasionally be quite tedious if there are numerous venous connections between the posterior tibial and peroneal veins. As one approaches the peroneal artery posterior to the posterior tibial neurovascular bundle there are fewer veins, but care must be taken to avoid injury to the peroneal nerve, which must also be retracted superiorly. Both approaches are useful in the authors' experience. The peroneal artery is first located by palpating the medial side of the fibula in the depths of the dissection. A continuous-wave

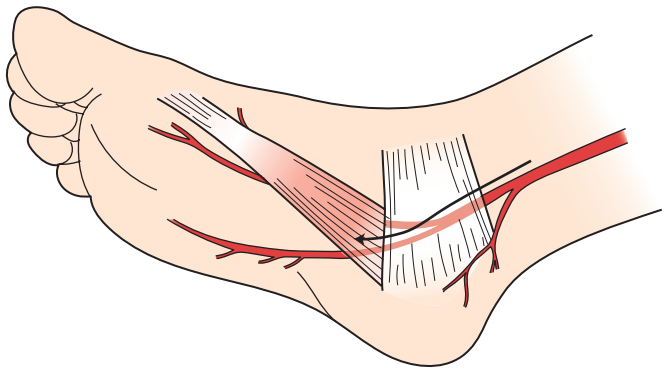

Figure 56.11 The distal posterior tibial artery is exposed through an incision posterior to the tibia and anterior to the Achilles tendon. After dividing the fascia, the posterior tibial artery and vein are identified in an investing layer of fatty tissue. (Figure 85 from Rutherford RB. *Atlas of Vascular Surgery: Basic Techniques and Exposure*. Philadelphia: WB Saunders; 1993:166.)

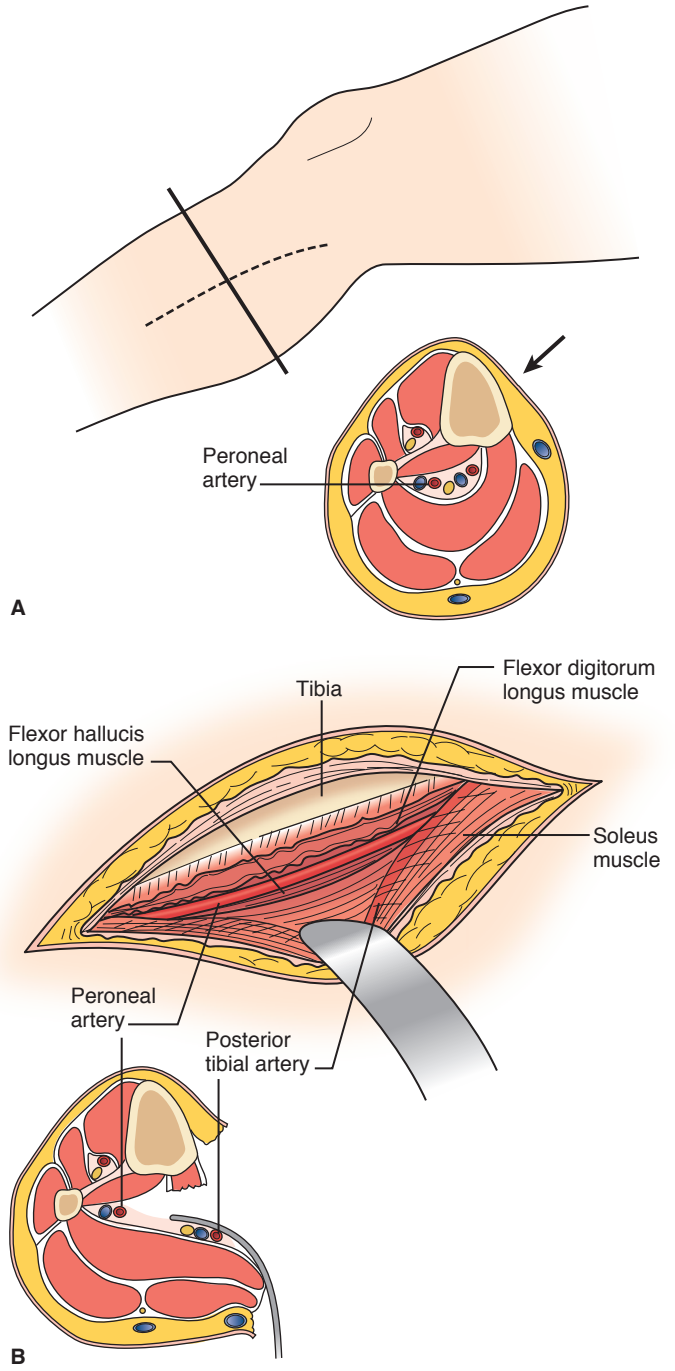

Figure 56.12 The proximal and mid-peroneal artery can be exposed through a medial incision as previously described for the posterior tibial artery. The posterior tibial neurovascular bundle is identified, and the dissection is performed anterior or posterior to the posterior tibial vessels and peroneal nerve. The peroneal artery is located deep in the incision in close proximity to the medial side of the fibula, which is a useful landmark. ([B] Figure 18.46 from Valentine JR, Wind GG. *Anatomic Exposures in Vascular Surgery.* 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2003:513.)

Doppler probe can be used to identify the location of the artery more precisely. The peroneal vascular structures are often covered by muscular fibers of the flexor hallucis muscle, which may have to be divided to expose the artery and vein. Unfortunately the vein is often encountered first and the artery is generally found behind the vein from this approach, which involves multiple small crossing venous branches. These must also be divided to expose the artery. Self-retaining retractors are a must during this exposure. The peroneal artery is often heavily calcified, which can make the creation of an anastomosis most challenging, particularly in its midportion in heavily muscled individuals. Tourniquet control can be very useful in this circumstance.

Lateral Exposure

Many vascular surgeons prefer to approach the peroneal artery from the lateral side of the calf to avoid the often difficult and challenging dissection required from the medial approach. A longitudinal incision is placed directly over the fibula. Once the fibula has been exposed, a periosteal elevator is used to free its muscular attachments on all surfaces. Careful dissection is important in freeing posterior attachments to the fibula to avoid injury to the underlying peroneal vein. Once the appropriate length of fibula has been dissected free of soft tissue, it can be divided with a rib shear or double-action bone cutter. Some authors recommend drilling small holes in the fibula to avoid shattering it. Alternatively, a small oscillating power saw can be used (authors' preference). Once the bone segment has been removed, the underlying fascia is incised longitudinally. The artery is then encountered superficial to the vein and dissected free with minimal difficulty (Fig. 56.13). This approach is particularly useful when exposing the peroneal artery in the distal half of the lower leg. Grafts can be tunneled subcutaneously and laterally as previously described for the anterior tibial artery or medially through the rent in the interosseous membrane created by removal of the fibula.

EXPOSURE OF THE ARTERIES OF THE FOOT

Bypass to the arteries of the foot is frequently used for limb salvage in patients with diabetes mellitus. Exposure of the pedal arteries is generally straightforward due to their superficial location. However, their small caliber, often being calcified, and requiring long venous conduits, can make for a challenging procedure that is lengthy, tedious, and unforgiving. Fortunately when these procedures are performed well, the rates of graft patency and limb salvage are comparable to more proximal reconstructions.[11] Although both the dorsalis pedis and posterior tibial arteries and their branches are suitable targets for bypass, in the authors' experience the dorsalis pedis arterial segment is more commonly spared of significant disease. Unlike the tibial and peroneal arteries, the vessels of the foot taper significantly as they run their course. Consequently it is advantageous to place the anastomosis as proximal as possible on the target artery. The dorsalis pedis and inframalleolar posterior tibial artery segments are connected through anastomoses of the tarsal and plantar arches of the distal foot. Successful bypass to either will often result in the healing of lesions even in angiosomes typically supplied by the other artery.

The anterior tibial (AT) artery runs along the lateral border of the extensor hallucis longus muscle and passes beneath the

Figure 56.13 The lateral approach to the peroneal artery is especially useful in the distal half of the lower leg. (A) The incision is made directly over the fibula, and the muscular attachments are divided on all sides using a periosteal elevator. (B) A segment of fibula is removed, and the underlying fascia is incised to reveal the peroneal artery and vein. (Figures 18.48 and 18.49 from Valentine JR, Wind GG. *Anatomic Exposures in Vascular Surgery.* 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2003:515 and 516.)

inferior extensor retinaculum to become the dorsalis pedis artery, which runs parallel and immediately lateral to the extensor hallucis longus tendon between the first and second metatarsals. It gives off a deep plantar branch between the heads of the first interosseous muscles, connecting with the lateral plantar branch of the posterior tibial artery and forming the plantar arterial arch. The posterior tibial artery is found between the flexor digitorum longus and the flexor hallucis longus muscles and enters the foot after coursing beneath the flexor retinaculum. It travels in a neurovascular bundle with the tibial nerve and accompanying veins. It subsequently divides into medial and lateral plantar arteries, terminating in the anastomotic loop created by the tarsal and plantar arches, as previously described.

Exposure of the Dorsalis Pedis Artery

The dorsalis pedis (DP) artery is found on the dorsum of the foot as the continuation of the AT artery once it crosses under the inferior extensor retinaculum of the ankle.[12] The foot should be supported in a relaxed position with the operating table in reverse Trendelenburg position. Very small Weitlander retractors are very useful. Both good lighting and the use of magnification with surgical loupes are essential. A longitudinal incision should be placed directly over the DP just distal to the retinaculum. When the DP has an audible Doppler signal, its precise course can be marked on the foot prior to making the incision. When no signal is present, the incision should be placed parallel and immediately lateral to the extensor hallucis longus tendon. The location of the artery can also be mapped by duplex ultrasound when preoperative vein mapping is performed. This allows direct access to the artery without creating skins flaps. The dorsal branch of the peroneal nerve is often encountered and can be retracted or divided with no consequence. The artery and its corresponding vein lie under a layer of deep fascia and are often palpable and visible. The length of the DP is variable; it bifurcates into the medial and lateral tarsal arteries, which should both be preserved. Small side branches are always present and should also be preserved. If the artery is heavily calcified, the segment under the retinaculum is often found to be softer due to flexion of the ankle; it is a good place for proximal control.

Inframalleolar Posterior Tibial and Plantar Artery Exposure

The patient's knee should be slightly flexed with the foot elevated on towels or a pad behind the lateral malleolus. This will widen the space between the calcaneus and the medial malleolus, aiding in exposure. A curvilinear skin incision is made between the medial malleolus and the calcaneus, deepening the tissue down to the flexor retinaculum. Marking the course of the artery with a Doppler prior to making an incision is helpful. An investing layer of fat is encountered that occasionally contains small veins; these should be divided and ligated. The artery is invariably calcified and easily palpable beneath the deep fascia, which is incised to expose the distal PT, which is bound by the flexor digitorum longus superiorly and the flexor hallucis inferiorly. The artery is dissected distally until its bifurcation into the medial and lateral plantar arteries. Crossing veins are often present. The calcaneal branch of the PT should always be preserved. The abductor hallucis is then divided for additional exposure of the lateral plantar artery.[13,14]

EXPOSURE FOR OBTURATOR BYPASS

The obturator bypass is most commonly used to treat a severe arterial infection involving the CFA.[15,16] The inflow artery is typically the common or external iliac artery, which is exposed through a retroperitoneal approach. The obturator foramen is exposed through this same retroperitoneal approach. The dissection is performed medial to external iliac vein and posterior to the pubic ramus. The obturator internus muscle is then bluntly dissected to reveal the obturator membrane. Grafts should be tunneled through the anterior medial portion of the membrane to avoid injury to the obturator artery and nerve, which pass through its posterior lateral portion.

The distal target of the obturator bypass is the popliteal or distal SFA. The tunnel between the inflow and target arteries is made in the medial compartment of the thigh in the space between the adductor longus and brevis muscles anteriorly and the adductor magnus muscle posteriorly, which leads directly to the obturator foramen. The SFA is easily identified and controlled in the plane of the tunnel anterior to the adductor magnus muscle (Fig. 56.14). If the popliteal artery is the target, the graft must be either tunneled through the adductor hiatus or brought around the adductor tendon. The proximal and distal anastomoses are then performed in the standard fashion. After completion of the bypass, the surgical incisions are closed and excluded before the groin is explored to remove any infected prosthetic or native material in order to prevent contamination of the obturator bypass.

EXPOSURE OF THE LOWER EXTREMITY VEINS

Great Saphenous Vein

Anatomy

The great saphenous vein arises from the medial aspect of the dorsal pedal venous arch and ascends anterior to the medial malleolus, crossing the tibia at the junction of the distal and middle third of the calf to pass posteromedial to femoral condyle at the knee. The vein then ascends medially in the thigh, remaining parallel to the medial edge of the sartorius muscle. It then perforates the deep fascia and joins the common femoral vein approximately 4 cm below the inguinal ligament. The saphenous nerve lies anterior to the great saphenous vein in the calf and may be injured by procedures extended into the calf. The great saphenous vein usually lies directly on the muscular fascia in the saphenous compartment, a subcompartment of the superficial compartment that is bordered superficially by the saphenous fascia and deeply by the muscular fascia. This compartment is readily visualized in the thigh with ultrasound.

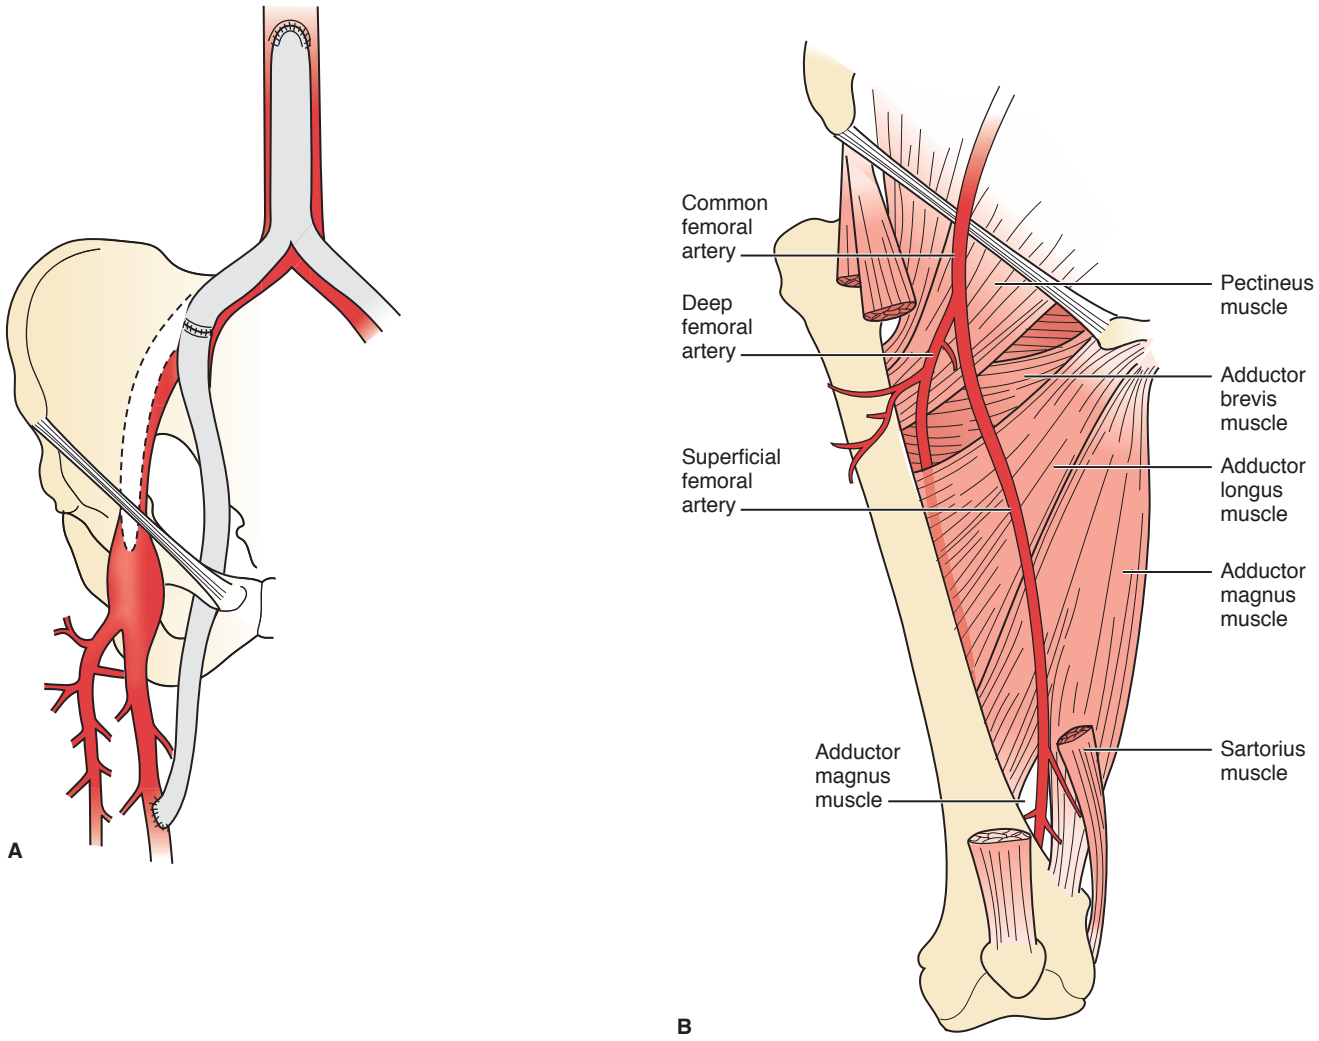

Figure 56.14 (A) The obturator bypass is tunneled through the obturator foramen via a retroperitoneal approach. Dissection is performed medial to the external iliac vein and posterior to the pubic ramus. The obturator foramen is identified by bluntly dissecting the obturator internus muscle. The tunnel is made through the anterior medial portion of the membrane to avoid the obturator artery and nerve. (B) The tunnel through the obturator foramen leads into the medial compartment of the thigh anterior to the adductor magnus muscle, where the superficial femoral artery is easily identified. ([A] Figure 35.3 from Chaikof EL, Cambria RP. *Atlas of Vascular Surgery and Endovascular Therapy: Anatomy and Technique*. Philadelphia: Elsevier Saunders; 2014:431. [B] Figure 16.8 from Valentine JR, Wind GG. *Anatomic Exposures in Vascular Surgery*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2003:418.)

Exposure of the Great Saphenous Vein

If the upper portion of the great saphenous vein is to be used for bypass, the vein harvest typically begins in the groin. A 30- to 45-degree oblique incision is made starting at the femoral pulse at the groin crease. Preoperative evaluation of the saphenous vein with duplex ultrasonography and skin marking of its location may help in better placing the incision and avoiding large skin flaps, especially in overweight patients. It may also help to identify any issues with the quality of the vein preoperatively. The skin is incised sharply and the subcutaneous tissue is divided with electrocautery. The skin incision can be performed with either a continuous technique or using skip incisions based on the surgeon's preference. Comparison of vein harvest techniques using skip incisions versus continuous incisions from the Vascular Quality Initiative shows no difference in the rates of surgical site infection or in graft patency at 1 year.[17] Once the vein has been identified, the anterior aspect is dissected sharply with a Metzenbaum scissors and the subcutaneous tissue is undermined distally over the vein. The skin and subcutaneous tissue are then divided over an instrument superior to the vein. This process is continued until sufficient length of the great saphenous vein is exposed. The authors prefer a modified no-touch technique to remove the vein. The vein is first encircled with a vessel loop to apply gentle countertraction as sharp dissection at a slight distance from the adventitia is used to separate it from adjacent tissues. The vein is not grasped with forceps to minimize the potential for injury to the intima. Branches are ligated with silk

ties. The vein is not removed until all arterial dissections and tunnels are completed. The distal vein is divided first and gently dilated with a mixture of heparinized saline and papaverine instilled with an olive-tip needle to distend the vein gently and identify any untied branches. The proximal aspect of the vein is then clamped at the saphenofemoral junction, often with a cuff of femoral vein, which makes large hood when the vein is used in nonreversed fashion (our most common configuration). Valve lysis is done with a Mills valvulotome under direct imaging with an angioscope. If the vein from the lower leg is to be used, the incision is made just anterior to the medial malleolus and the dissection is continued proximally as described earlier.

SMALL SAPHENOUS VEIN

Anatomy

The small saphenous vein arises from the dorsal pedal arch and ascends posterolaterally from behind the lateral malleolus to a variable termination in the popliteal vein. The small saphenous vein usually has 7 to 10 valves, which are closely spaced along its length. The sural nerve ascends immediately lateral to the vein, beneath the muscular fascia prior to its junction with the popliteal vein. Approximately 75% of small saphenous veins join the popliteal vein, while as many as 25% ascend more proximally into the thigh, with no connection to the popliteal vein.[18] Recognition of this anatomic variant is important in harvesting the vein for bypass. The proximal extension of the small saphenous vein, often referred to as the vein of Giacomini,[19] may ascend in the posterior thigh to communicate with the great saphenous vein through the circumflex vein of the posterior thigh.

Exposure of the Small Saphenous Vein

The small saphenous vein harvest is begun in the lower leg with a vertical incision just posterior to the lateral malleolus. The authors will typically use ultrasound preoperatively just prior to the procedure to mark the location of the vein and facilitate its identification. Dissection of the vein is performed with the modified no-touch technique, as outlined previously. The distal vein is clamped and divided, and the vein is distended as described. The saphenopopliteal junction is then clamped and oversewn and the vein is prepared in a reversed or nonreversed fashion per surgeon preference.

FEMORAL VEIN OF THE THIGH

Anatomy

The femoral vein of the thigh (referred to as the *femoral vein* in the following section) is an excellent conduit for arterial reconstruction. Due to its sturdy structure and large caliber, it is most commonly used for reconstruction after removal of infected prosthetic grafts of the abdominal aorta or iliac and common femoral arteries. It may also be used in venous reconstruction procedures. The deep venous system of the leg is made up of the paired tibial and peroneal veins, the popliteal vein, the femoral vein of the thigh, the deep femoral vein, and the common femoral vein.[1] After passing through the adductor canal, the popliteal vein becomes the femoral vein, lying posterior and lateral to the artery. The vein is generally large in caliber and quite sturdy, making an excellent conduit where a larger-caliber graft than the typical saphenous vein is required. Harvesting of the femoral vein can be a tedious exercise in some patients owing to its typical location somewhat posterior to the SFA and the multiple crossing branches of the SFA that are usually encountered. The femoral vein and the deep femoral vein join together to form the common femoral vein approximately 4 to 12 cm below the inguinal ligament. The deep femoral vein is a critical collateral pathway that must be preserved in harvesting the femoral vein to avoid the significant lower leg edema which would occur if it were removed.

Harvest Technique

The patient is positioned with a bump under the knee to facilitate external rotation at the hip with a flexed knee. A longitudinal incision is then made in the thigh along the border of the sartorius muscle. The sartorius muscle is then reflected laterally and the fascia overlying the abductors is incised to expose the SFA and femoral vein. Branches of the SFA are often encountered which may cross over the femoral vein and can be divided. Distal SFA branches are best preserved if the popliteal artery is occluded, as these are important collaterals around the knee. Branches of the femoral vein are relatively large and should be either doubly ligated or suture-ligated to avoid bleeding when pressurized with arterial blood flow. Proximally, the junction of the femoral vein and deep femoral vein should always be fully exposed. When removing the femoral vein of the thigh, it is critical to preserve the deep femoral vein to prevent severe leg swelling. The femoral vein should be transected at its junction with the common femoral vein and the resulting defect closed with a running continuous polypropylene suture in a manner to both preserve the inflow of the deep femoral vein while not leaving a proximal stump of the femoral vein, which may result in thrombus formation. The distal end of the remaining vein should be suture-ligated or oversewn. The harvested femoral vein can then be used in a reversed orientation or the valves can be cut with a valvulotome to facilitate its use in a nonreversed orientation. The fascia is then reapproximated using a running technique followed by the subcutaneous tissue and the skin.[20]

SELECTED KEY REFERENCES

Rutherford RB. *Atlas of Vascular Surgery*. Philadelphia: W.B. Saunders; 1993.

This classic atlas takes a "how to do it" approach to the surgical exposures used throughout the circulatory system in vascular surgery. The text is written in Dr. Rutherford's typically clear and concise style and contains many personal observations based on his enormous clinical experience. The illustrations are well drawn and accurate, including many highly useful cross-sectional depictions of the anatomic relationships between the blood vessels and adjacent structures in the lower extremity.

Valentine JR, Wind GG. Anatomic Exposures in Vascular Surgery. 2nd ed.

Created by an expert vascular surgeon and anatomist, this well-written text contains a level of anatomic detail not often seen in surgical atlases and provides a unique perspective on the surgical anatomy of the lower extremity circulation. The late Charles Rob said it best in his Foreword: "The illustrations are the strong part of this excellent book." They are beautifully done with a three-dimensional quality that depicts the anatomy from the perspective of the surgeon. It should be required reading for all vascular surgical trainees.

Subclavian Arteries 709
Subclavian Veins 712
EXPOSURE OF THE ARM VESSELS 713

INTRODUCTION

Vascular surgeons who treat thoracic outlet syndrome and perform arteriovenous (AV) access obviously regularly operate in the upper extremities, but expeditious and safe upper extremity exposure is required for the treatment of trauma, complex aortic endograft repair of aortic diseases, and many other conditions.

For purposes of planning exposure, it is convenient to divide the relevant upper extremity vessels into three zones (Fig. 57.1). The intrathoracic zone contains the aortic arch, innominate artery, subclavian arteries on both sides, innominate veins, and superior vena cava. The importance of this classification is that exposure, although straightforward, requires more time than in the limb. The sternum must be divided or the thorax opened. Therefore in trauma cases, because it takes more time to expose the arteries, planning ahead and perhaps a more conservative and safer approach for proximal control should be considered. For venous reconstruction, although usually less emergent, somewhat complex exposure strategies are likewise needed. The next zone is essentially the thoracic outlet, extending from the base of the neck to the axilla, which contains the subclavian, proximal vertebral, and proximal axillary arteries and veins. This area contains critical nerves, which must be preserved, and the clavicle and to a lesser extent deltoid muscle can block access to certain parts of the vessels. Finally, the third zone is the arm itself, extending from the axilla to the fingers. Vascular exposure in the arm is usually much more straightforward, especially if the operative field is sufficiently distal so that a tourniquet may be used.

EXPOSURE OF ARTERIES WITHIN THE THORAX

In patients with normal anatomy, the first branch of the aortic arch after the coronary arteries is the innominate artery, which then bifurcates into the right subclavian and right common carotid arteries. Approximately 13% of patients have a "bovine arch," somewhat inaccurately but commonly used to describe the situation where the left common carotid artery arises from the innominate itself or a common ostium; in most patients the left common carotid artery is the next separate branch from the arch, followed by the left subclavian artery. There are two critical variants. The first is an aberrant right subclavian artery. This situation, occurring in up to 2% of patients, is variable but most typically creates a situation where the innominate artery simply becomes the right common carotid artery, and the right subclavian artery arises as the last branch (usually from the descending aorta, now on the left side), passing behind the esophagus to supply the right arm. Although often asymptomatic, this abnormal artery is sometimes associated with aneurysmal degeneration (diverticulum of Kommerell) and/or can produce dysphagia via a mass effect (dysphagia lusoria). A second important variant is origination of the left vertebral artery from the aortic arch, occurring in 2% to 5% of patients. Although this should specifically be identified ahead of time if direct intervention on this vessel is planned, its major significance lies in planning thoracic endovascular aneurysm repair, to avoid covering this vessel inadvertently.[1,2]

Abstract

Safe and expeditious exposure of the upper extremity vascular system requires a thorough knowledge of the relevant anatomy. Exposure proximally is more difficult than in the periphery, for two reasons: First, the bony thorax restricts and slows exposure, most relevant in traumatic situations. Second, there are several nerves intimately involved with the vessels proximally which should be preserved for best outcomes. This chapter describes exposures from the aortic arch to the wrist, and provides helpful details for safe and efficient surgery.

Keywords

brachiocephalic vessels
thoracic outlet
upper extremity anatomy

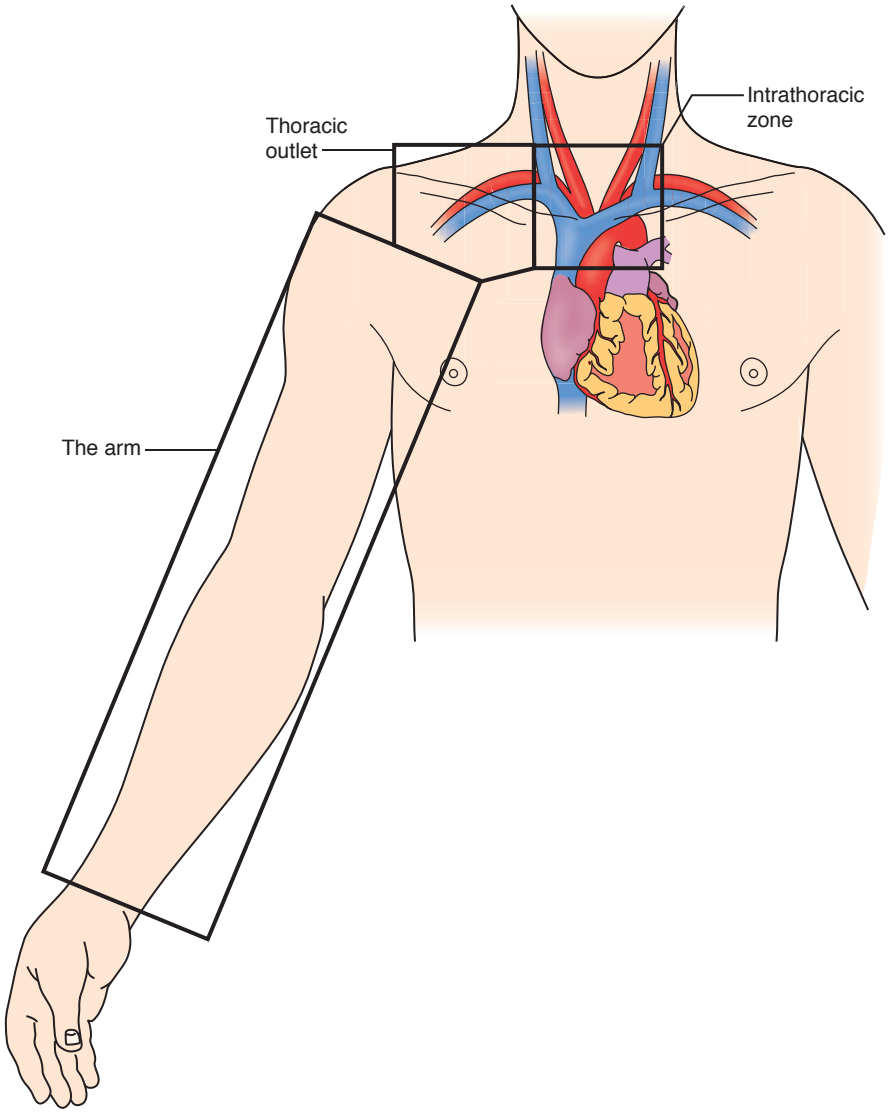

Figure 57.1 The chest and arms (right-side shown) illustrating the three general zones described. The intrathoracic vessels almost always require bony division, hence more thorough preplanning. The vessels in the thoracic outlet are easier to expose, but technical challenges exist. Finally, the vessels of the arm are relatively straightforward to expose.

As described previously, especially with regard to trauma, control of intrathoracic vessels takes more time than elsewhere, and thus a slightly more conservative approach may be considered. Exposure of most extremity vessel injuries directly is straightforward because proximal control is not difficult, although if a supraclavicular injury occurs that is constrained, proximal control may not be possible at the site of injury itself. Although endovascular approaches can be used, surgical control will take much longer than in the arm itself. The implication of this is that if there is any question that control may be needed within the thorax (again, classically an injury to the subclavian artery with a supraclavicular hematoma), it is prudent to obtain this control first, before the injury is approached directly.

Exposure of the arch and proximal great vessels is required for debranching, aortosubclavian and carotid bypass for atherosclerosis or Takayasu arteritis, or occasionally complex AV access and in some trauma cases. In general, exposure of the innominate, proximal right subclavian, and proximal left carotid arteries should always be performed by means of median sternotomy. The proximal left subclavian artery can be reached via median sternotomy, although not quickly, so if such exposure is needed urgently an anterolateral third interspace thoracotomy is the preferred approach.

Innominate, Right Subclavian, and Left Common Carotid Arteries, and Proximal Left Subclavian Artery in an Elective Situation

Median sternotomy provides superb exposure to these vessels, as well as to the ascending aorta. If the aorta does not need to be used, the sternotomy can be limited to the third interspace (Fig. 57.2). Following sternotomy, the anatomy will be very well delineated. The left innominate vein is superficial and should be preserved but can be sacrificed in an emergency. Two nerves are critical to protect. The right recurrent laryngeal nerve loops around the right subclavian artery just as it arises from

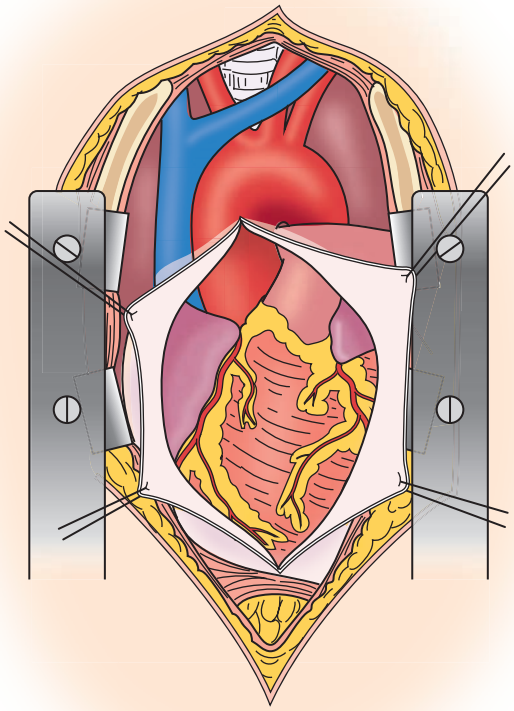

Figure 57.2 Open median sternotomy with arch vessel exposure.

the innominate artery, and the phrenic nerve passes behind the jugular and right innominate vein and anterior to the right subclavian artery and anterolateral to the innominate artery. Both should be easy to identify, but both can be in jeopardy if indiscriminate circumferential dissection of the vessels is carried out without caution.

After teasing away fatty tissue and mobilization and retraction of the overlying veins, this approach yields ideal exposure to the orifice of the innominate and left common carotid arteries, the proximal portions of these arteries themselves, and, by extending the incision onto either side of the neck or the right supraclavicular area, the rest of both common carotid arteries and the right subclavian artery into the thoracic outlet, respectively (Fig. 57.3). Exposure of the subclavian arteries will be limited by the sternocleidomastoid muscles (which can be partially divided, but ideally not fully transected) and anterior scalene muscle which can be fully divided (see later), but the vertebral arteries usually arise proximal to this and this approach can be excellent for proximal vertebral exposure (see Chapter 98). Finally, with further dissection, the proximal portion of the left subclavian artery (and left vertebral artery, if normal) can be reached through this incision. Again, caution should be taken with regard to the left recurrent laryngeal nerve; after looping around the aorta in the region of the ligamentum arteriosum, it ascends anterior to the arteries and can be within the surgical field.

Left Subclavian Artery, Emergent

In emergent situations (trauma with active bleeding) a more immediate need for proximal control may be present. In this situation an anterolateral limited third space thoracotomy, with the patient supine, allows expeditious proximal left subclavian artery control (Fig. 57.4). This approach usually does not permit extensive repair or other work in this area, but once bleeding has been controlled, definitive wide exposure can be obtained. When third space sternotomy and a supraclavicular incision is combined with the thoracotomy, this is termed a "trap-door" exposure (Fig. 57.5).

EXPOSURE OF VEINS WITHIN THE THORAX

Traumatic venous injuries are very often associated with concomitant arterial injury, and the previously described exposure concepts apply.

Exposure of the superior vena cava requires formal sternotomy. However, other techniques can be used for exposure of the central (medial) portion of the subclavian vein as it joins the jugular vein and/or the innominate veins on either side and are useful adjuncts in the treatment of venous thoracic outlet syndrome. The venous thoracic outlet is essentially the junction of the clavicle and sternum anteriorly, with the subclavius muscle and tendon and the ligamentous structures attaching the two bones playing a major role in venous obstruction (see Chapter 123). Over time these structures, especially in those who are muscular and/or participate in activities with arms overhead, can chronically injure the vein in this location. The decision to reconstruct this area is complex and exposure is critical. The injury to the vein is usually fairly central, and it is sometimes difficult to get centrally enough (defined as normal endothelium) from an infraclavicular approach. Molina has described an excellent technique for exposure of either innominate vein to the level of the cava.[3] The patient is supine, and the first rib has been resected using either an infraclavicular or paraclavicular approach. At this point a first interspace median sternotomy is performed (Fig. 57.6A). After the deeper tissues have been incised, the entire sternoclavicular complex (leaving the sternoclavicular junction intact) is then rotated upward, which provides superb visualization of this area. Finally, after the operation is completed, the sternal fragment is reattached to the main portion of the bone, using two sternal wires oriented at right angles to each other (see Fig. 57.6B).

Finally, although technically not a vein, the right atrial appendage can be used as outflow for complex venous occlusive disease (including patients with threatened AV access). This can be accessed fairly easily by means of a limited anterior third interspace thoracotomy (with the patient supine). The pericardial sac must be entered, but then the appendage is immediately accessible and easily clampable with a Satinsky-type clamp.[4]

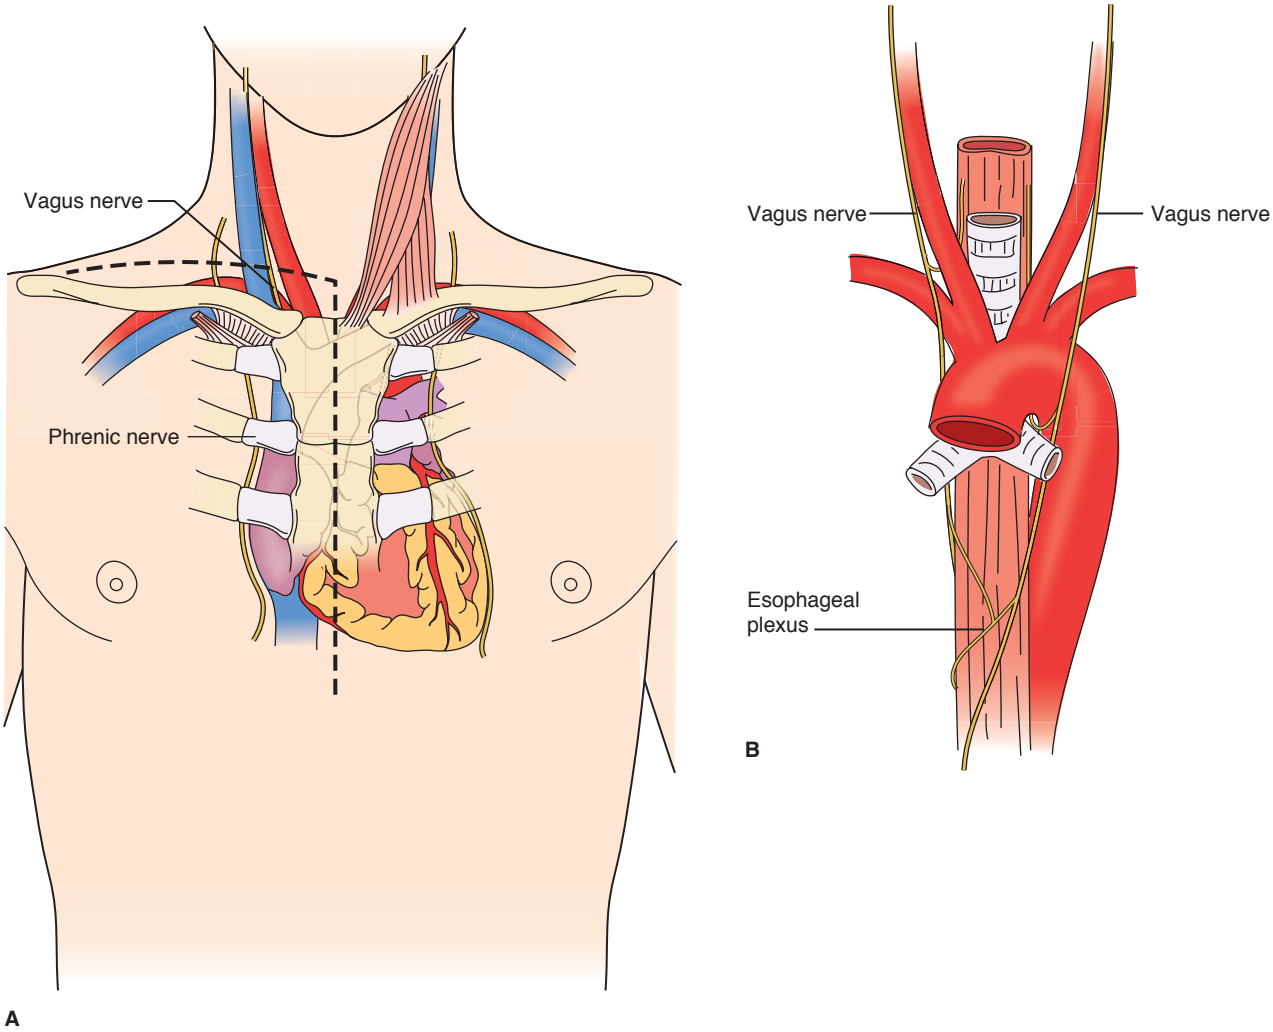

Figure 57.3 Median sternotomy extended to the (right) side, for better exposure of the innominate vessels, proximal subclavian artery and vein, and jugular vein. The sternocleidomastoid muscle can be divided in an emergency but is probably better left intact if possible (A). Note that the phrenic and vagus nerves both pass anterior to the arteries and posterior to the veins; both should be preserved (B).

EXPOSURE OF VESSELS WITHIN THE THORACIC OUTLET

The thoracic outlet broadly includes the neurovascular area from the scalene triangle to the axilla. This chapter will consider arterial exposures from the point at which they pass beyond the sternum to the deltoid to lie within this area. Barring anomalies, the anatomy is symmetric on each side, making descriptions easier.

As described previously, exposure of the vessels from the arch to the supraclavicular fossa, including the proximal vertebral arteries, is best performed by means of limited sternotomy and supraclavicular extension of the incisions. Direct access to the subclavian arteries will be limited by the sternocleidomastoid muscle medially and the anterior scalene muscle deep to it, the latter forming the anterior border of the scalene triangle. Through this triangle run the brachial plexus and subclavian artery, with the artery passing over the top of the first rib (the base of the triangle) (Fig. 57.7).

Subclavian Arteries

De novo exposure in this area can most easily be performed by means of a supraclavicular incision (however, it should again be stressed that in traumatic situations when a supraclavicular hematoma [or suspected subclavian artery injury] is present, strong consideration should be made of conservative, proximal control as described previously). Such a supraclavicular incision can essentially be placed anywhere; we use a convenient skin crease for best cosmetic results. This approach, in addition to being used for carotid-subclavian bypass, is also commonly used for treatment of neurogenic and arterial thoracic outlet syndrome and has been very well described by Thompson (see Chapters 121 and 122).[5] After division of the platysma and clavicular head of the sternocleidomastoid muscle, there is a

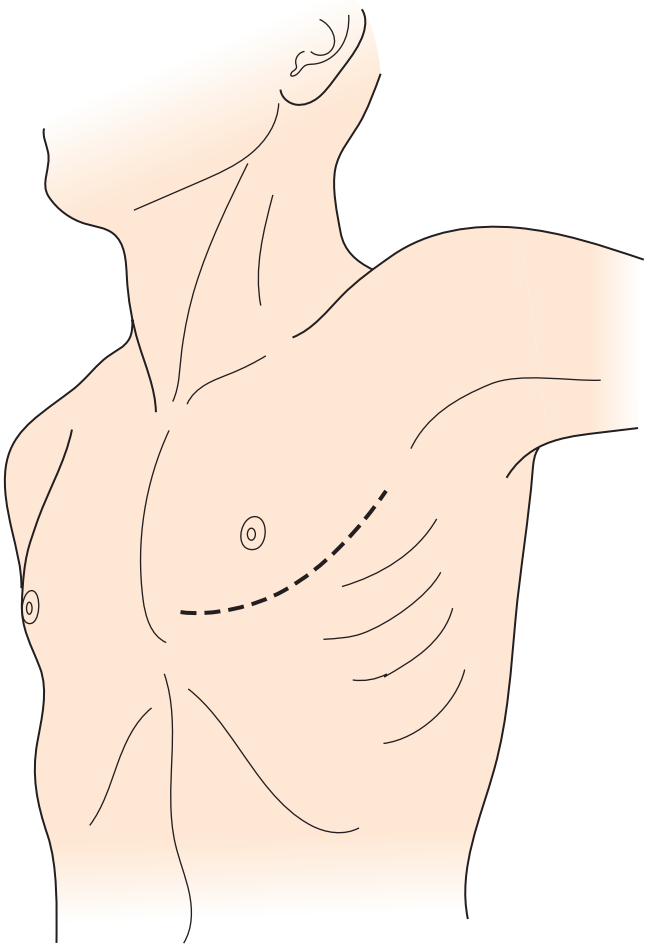

Figure 57.4 Left third interspace thoracotomy is ideal for emergent exposure of the proximal left subclavian artery when a patient is in the supine position. Be aware that the vagus nerve is anterior to the proximal portion of the artery and, after looping around the aorta near the ligamentum arteriosum, the recurrent laryngeal posterior (not shown).

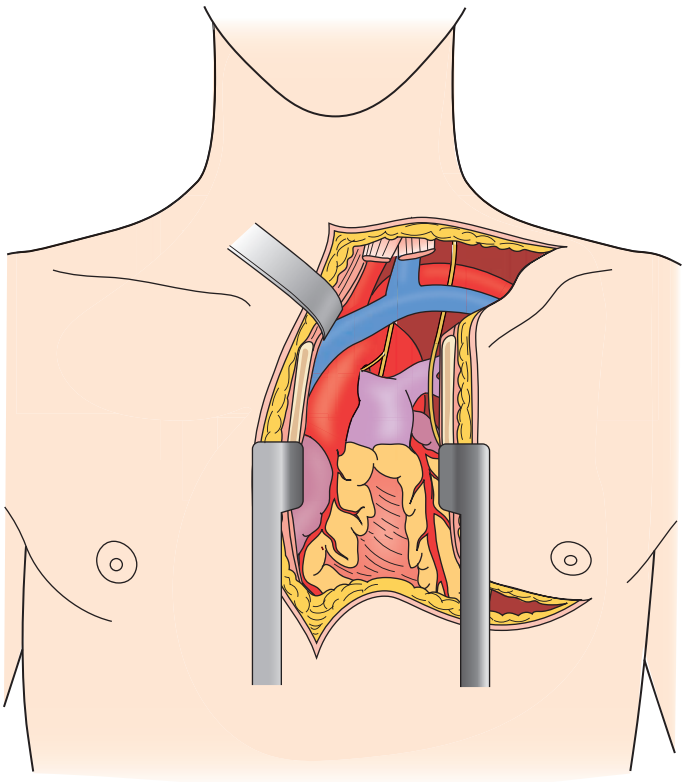

Figure 57.5 By adding median sternotomy and extending the incision to the left, the anterior thoracotomy is converted to a "trap-door" extension, nicely exposing the proximal left-sided great vessels. The sternocleidomastoid is divided in this figure.

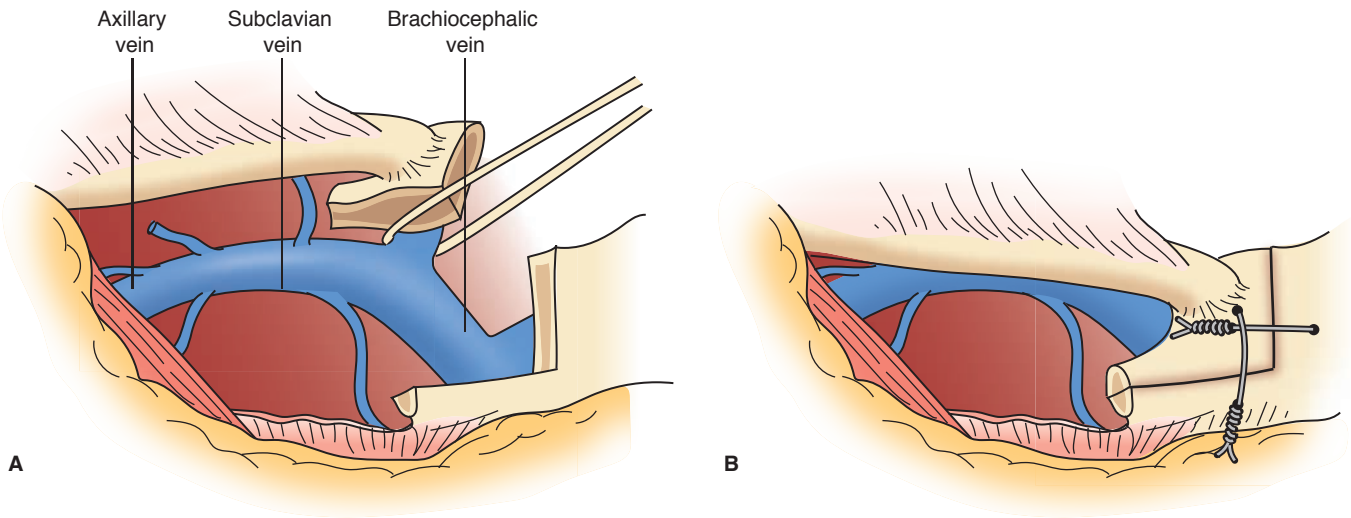

Figure 57.6 After anterior first rib resection, a first interspace sternotomy can be performed, leaving the sternoclavicular joint intact. (A) Initial exposure obtained by rotating this complex upward. (B) Repair using two perpendicularly oriented sternal wires. (From Molina JE. A new surgical approach to the subclavian and innominate veins. *J Vasc Surg*. 1998;27:576-581.)

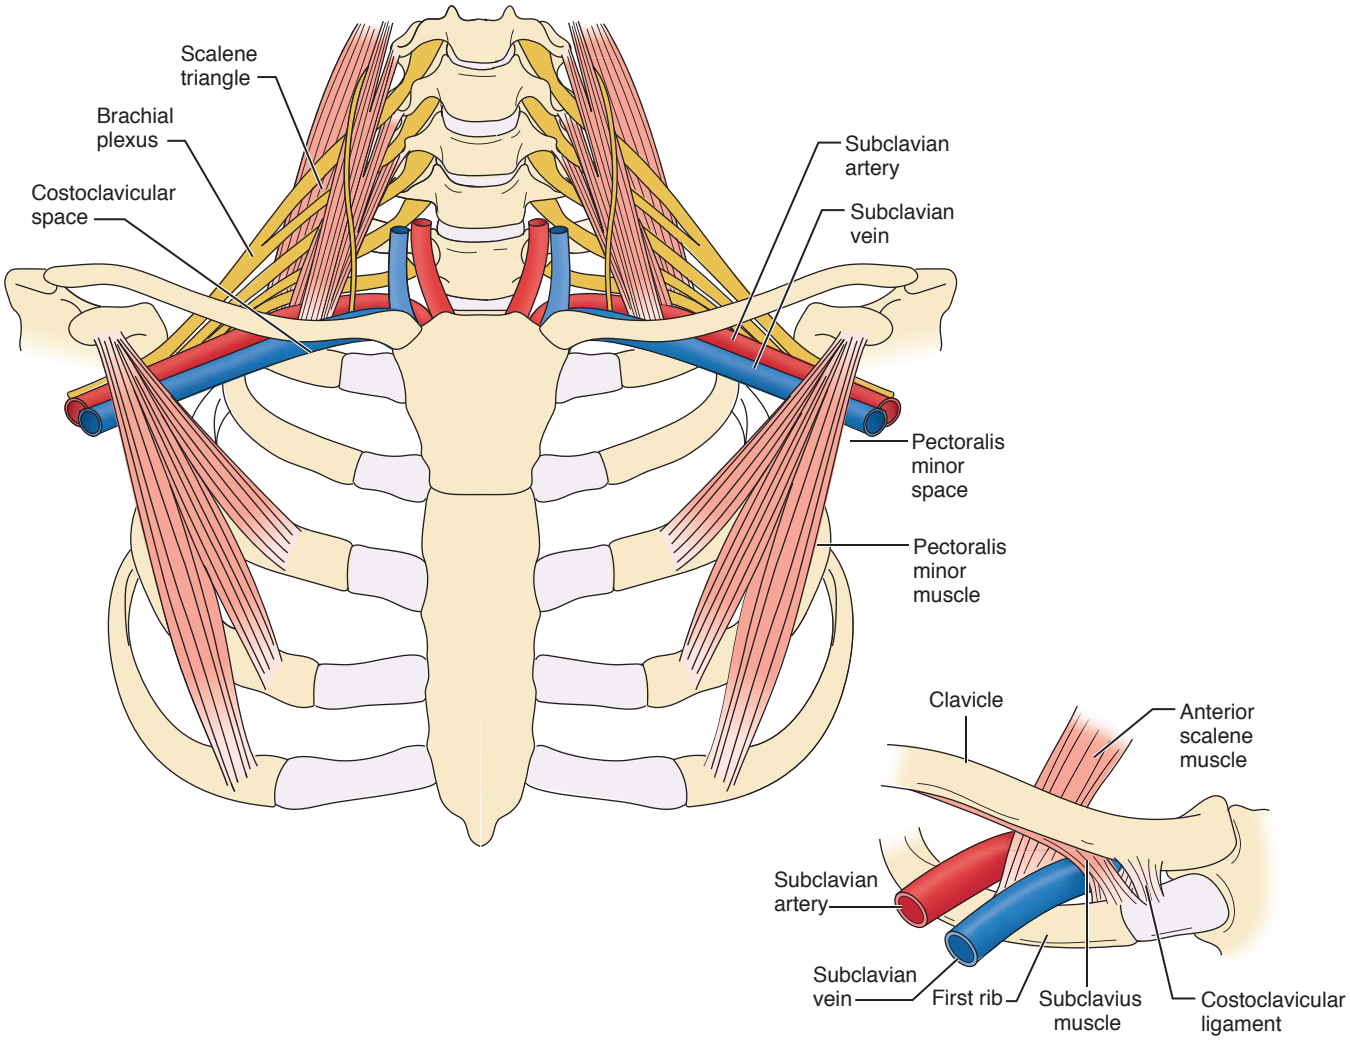

Figure 57.7 The Vessels and Nerves of the Thoracic Outlet. (A) Subclavian artery from its takeoff from the innominate to the pectoralis minor. The vertebral artery, internal mammary artery, and thyrocervical trunk arise proximal to the anterior scalene muscle; the latter two can be sacrificed. The phrenic nerve (and vagus nerve medially) runs anterior to the muscle (and thus artery) but behind the vein; this should not be sacrificed. (B) The anteromedial aspect of the thoracic outlet on the right side showing the subclavian vein running past the junction of the first rib and sternum, potentially compressed by the subclavius muscle, subclavius tendon, and fibrotic costoclavicular ligament.

fat pad of varying thickness, containing the omohyoid muscle. This should be divided and the fat pad teased superiorly or laterally. At this point the anterior scalene muscle will be exposed medially, with the phrenic nerve running in its characteristic (and unique) lateral to medial direction (Fig. 57.8). It is very important to identify and protect this nerve; complete injury can result in significant disability even for sedentary people. If it is not immediately visible, it should be looked for superficially directly anterior to the muscle or medially. If it is still not found, dissection of the muscle should be slow and careful because it may be intramuscular. Note that it is not uncommon to have bifid or duplicated nerves. The nerve can also be identified by first dissecting free the upper nerve roots (C5 and C6), then following them until the nerve is found.

Full division of the anterior scalene muscle is advised if carotid subclavian bypass is to be performed. Not all clinicians do this, and although we believe no data exist, essentially all failures we have treated are in patients whose muscle has been left intact (affecting both length and angles of the resultant bypass). This muscle should be divided as close as possible to the first rib then subtotally removed after the phrenic nerve is identified and protected; in theory, this prevents reattachment and scarring. After this is performed, the entire subclavian artery from beneath the sternocleidomastoid to the rib is nicely exposed. The vertebral arteries are more medial than one would expect. They generally lie beneath the SCM itself and can be reached by retracting this muscle. It should be noted that the clavicular head of the SCM can and may be sacrificed without consequence; in extenuating circumstances the entire muscle can be divided for full exposure from the sternum to the deltoid.

The subclavian arteries technically become the axillary arteries as they cross over the lateral border of the first ribs but obviously

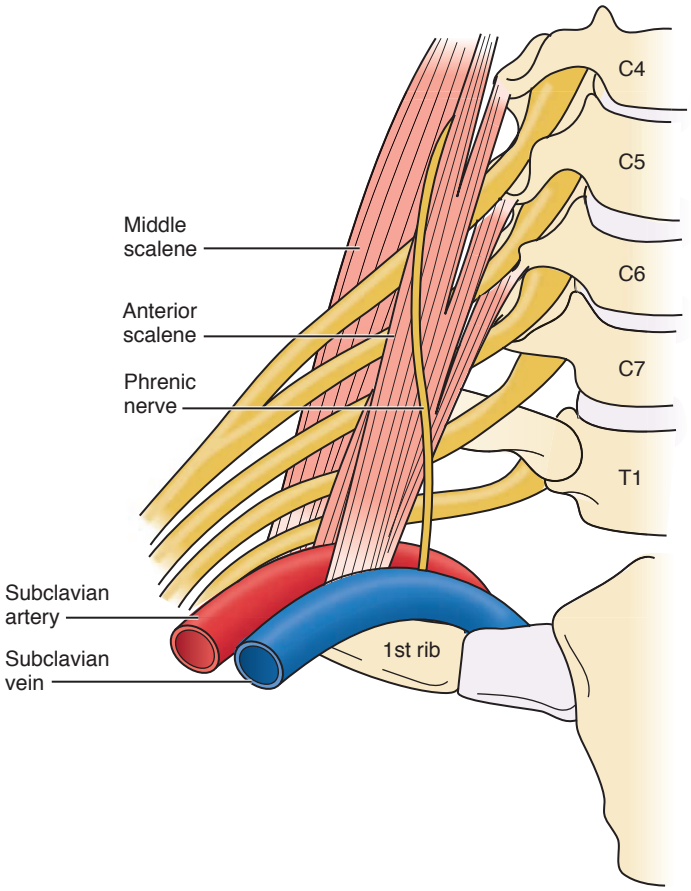

Figure 57.8 Anterior scalene muscle (right side) with phrenic nerve running lateral to medial as it descends (the only nerve in the body to do so).

structurally are the same vessel. They arch over the first rib then pass beneath the clavicle, cephalad to the vein. The area underneath the clavicle itself is difficult to approach, although claviculectomy is very well tolerated[6] and will afford excellent and expeditious exposure of both artery and vein. The axillary artery is easily accessible inferior to the clavicle, although it lies cephalad to the vein and is not always immediately visible (Fig. 57.9). The optimal approach to vessels in this area depends upon the indication. If the problem is a subclavian/axillary artery aneurysm (usually secondary to a bony abnormality: arterial thoracic outlet syndrome), a paraclavicular approach with control of the subclavian artery above the clavicle and axillary artery below, as described, allows bypass with a wide-open tunnel after the cervical rib, Roos band, and/or first rib have been resected. Conversely, if the lesion needs to be addressed directly, the clavicle can be resected with minimal morbidity. For axillary artery exposure inferior to the clavicle for an axillofemoral bypass, most advocate exposure as medially as possible (first part of the axillary artery), with tunneling of the graft deep to the pectoralis minor muscle and a very gradually diverging end-to-side anastomosis, to reduce the risk of axillary pullout syndrome. Again, the pectoralis minor muscle can be resected with impunity to expose the second part of the artery, and, if arterial inflow for an AV graft is needed, this allows excellent exposure.

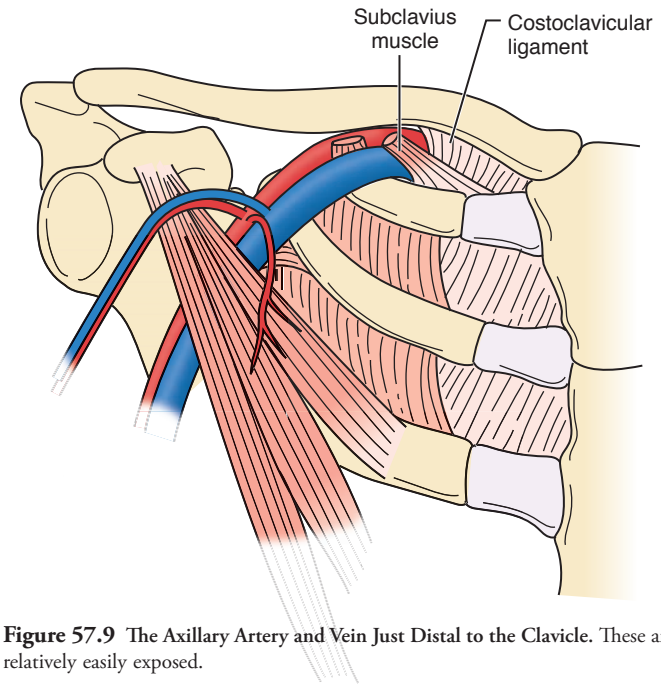

Figure 57.9 **The Axillary Artery and Vein Just Distal to the Clavicle.** These are relatively easily exposed.

Subclavian Veins

The veins lie inferior (caudal) and superficial to the arteries and are most often exposed for treatment of venous TOS. Although supraclavicular exposure is occasionally used, in the vast majority of cases the veins are very difficult to adequately expose from this direction. In addition, they obviously continue inferior to the clavicle as they move laterally, so we strongly advise an infraclavicular approach, usually combined with rib resection if venous TOS is the indication. The patient is supine, so imaging (for lysis, venoplasty, or AV access intervention) can easily be combined with surgery. An incision is made over the usually palpable first rib, extending to varying lengths laterally as the specific indication requires. The upper fibers of the pectoralis major are separated or divided, exposing a lateral fat pad. After this is retracted or resected, the inferior border of the rib can be identified and developed, although it is futile to explore the cephalomedial border at this point. We then identify the vein lateral to the rib and follow it medially; if a bulky subclavius muscle is present, it is resected off the clavicle, again moving laterally to medially. At this point the fibrotic tissue medially, made up to varying degrees of subclavius tendon and costoclavicular ligament, will be very obvious. Rather than incising this only, we advocate full resection from clavicle to rib (Fig. 57.10). At this point the cephalomedial border is exposed and can be developed to the level of the anterior scalene muscle. This muscle is then divided, and the mid- to posterior rib then developed by reflecting the fibers of the middle scalene muscle off of it. The rib is divided as posterior as possible and anteriorly within the cartilaginous segment and removed, after which a rongeur is used to pare back any bony or cartilaginous tissue impinging upon the vein. The vein can be freed at this point. There is often a fibrotic external cicatrix which, when removed, leaves behind surprisingly normal venous adventitia. If more proximal

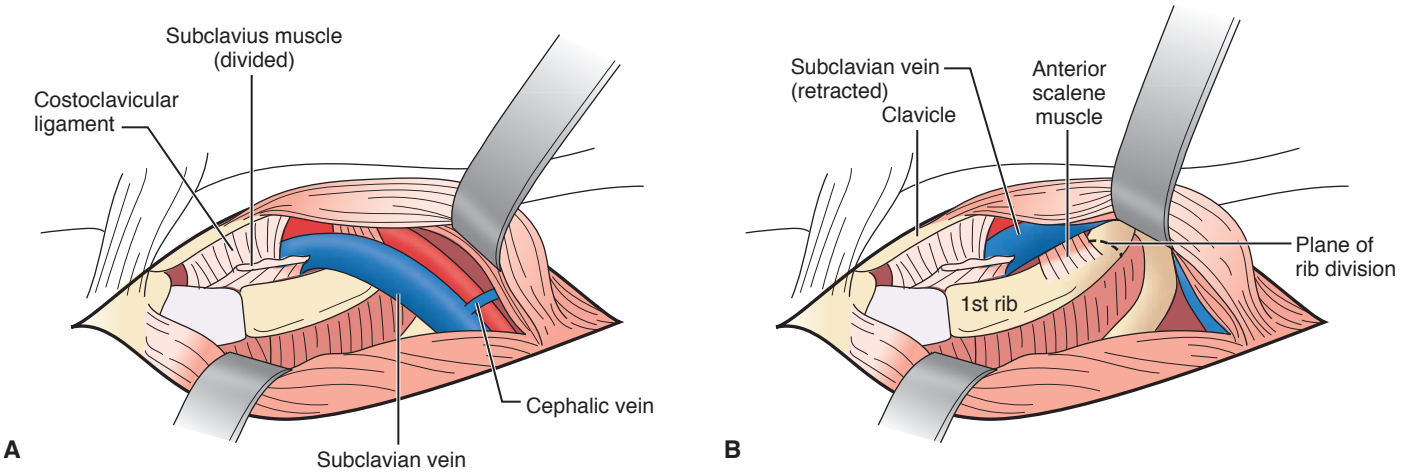

Figure 57.10 Infraclavicular exposure of the subclavian vein, most often used for treatment of venous thoracic outlet syndrome. (A) The intercostal muscle has been incised, exposing the anterior/inferior border of the first rib, and the subclavius muscle (laterally) and tendon (medially) and medial costoclavicular ligamentous structures exposed. The vein has been exposed laterally by resecting fatty tissue and then followed medially, at which point, all nonbony structures medially are resected. (B) The vein is then elevated upward; the anterior scalene muscle is exposed and divided. The phrenic nerve is well medial at this point and not in the surgical field, the medial border of the rib exposed, and the rib divided several centimeters deep to the vein.

exposure is needed, sternoclavicular rotation as, described previously (see Fig. 57.6), can be used; distal exposure requires division of soft tissue only and is relatively trivial.

Ultimately, exposure of the axillary vessels is limited laterally by the deltoid muscle. In an emergency this can obviously been excised, but other than in trauma, there is essentially no indication for exposure of the artery in the area deep to the deltoid itself.

EXPOSURE OF THE ARM VESSELS

Exposure of the vessels in the arm is relatively straightforward. Traumatic injuries can usually be approached directly by an experienced vascular or trauma surgeon. Even if hemorrhage is unroofed, direct pressure is usually trivial, and a tourniquet can be placed without problems.

The brachial artery in the upper arm is most commonly used as inflow for an upper arm AV graft or as inflow for distal revascularization interval ligation (DRIL), whereas the vein is commonly exposed for the venous anastomosis of an upper arm AV graft (see Chapter 175). Parenthetically, although some have described DRIL as being performed with a short bypass component, there is no evidence to support this and solid hemodynamic evidence exists to support as long a segment of interposed native artery as possible,[7] hence the recommendation for exposure as proximally as possible. A longitudinal incision is made in the upper arm distal to the deltoid muscle, and the neurovascular bundle is located just below (medial to) the biceps. The artery is usually deep to the vein (variably paired at this level) and nerve, but exposure is straightforward (Fig. 57.11). Although the median nerve must obviously be preserved, the superficial nerves in this area, some quite large, are all sensory and patients do not typically have significant symptoms after division. Of note, unlike in the leg, the deep brachial vein can

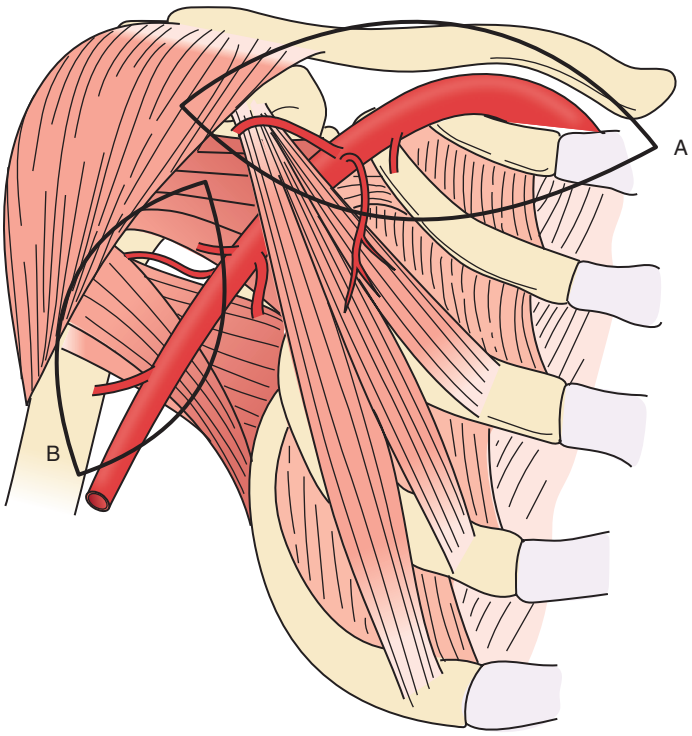

Figure 57.11 Exposure of the Axillary Artery. (A) Between the clavicle and pectoralis minor. (B) Distal to the pectoralis minor. Note that this muscle can be divided with impunity.

be sacrificed without problems; this can be helpful to increase length and eliminate problems caused by tethering at the swing point of a transposed brachiobasilic AV fistula.

More distally, the brachial artery at the antecubital fossa is obviously the most commonly exposed upper extremity artery; it serves as the inflow vessel for approximately 80% of upper

extremity AV access cases, as well as the access vessel for upper extremity imaging and intervention for many thoracic cases. For brachiocephalic fistula creation, a transverse incision is best. It is tempting to stay slightly proximal to the antecubital crease to avoid bending the vein, but as exposure moves proximally the cephalic vein is located more laterally, increasing the distance between the vein and the artery. The author finds that an incision slightly distal to the crease allows the best fistula to be created. In addition to the cephalic vein itself lying close to the artery, various anatomic variants (antecubital vein, perforating veins) can most easily be used for access. A longitudinal incision is most convenient if the antecubital fossa is not crossed; if so, a transverse or "lazy-S" incision will reduce the risk of stricture. The longitudinal incision also provides excellent exposure of the proximal radial artery just distal to its takeoff from the brachial artery. Constructing the AV anastomosis at this level may decrease the likelihood of developing a steal syndrome. Like many superficial arteries, an overlying tendinous band (the bicipital aponeurosis) tends to protect it. The artery is easily palpable; dividing the fibrotic tissue very easily exposes it (Fig. 57.12). Finally, although venous exposure in this area is relatively straightforward, knowledge of which vein is exposed is important for successful AV access. The cephalic vein can be used itself, or the variably located antecubital vein or deep perforating veins can be used to lengthen a brachiocephalic fistula. Similarly, if a first-stage (nontransposed) brachiobasilic fistula is to be constructed, usually a branch traveling into the antecubital fossa can be found. If this branch is not present or usable, the true basilic vein in this location is quite medial.

The artery just distal to this is commonly exposed for the distal anastomosis of a DRIL. The benefit of this operation is to fully perfuse the forearm (distal revascularization) while eliminating all retrograde flow into the fistula (interval ligation); it is thus critical to ensure that the brachial artery itself (above the bifurcation) is ligated. We prefer a longitudinal incision just distal to the takeoff of the AV fistula; formal landmarks are sparse, but the artery should be accessible with minimal exploration (Fig. 57.13). If the artery is not immediately localizable, occlusion of the fistula with localization by palpation or a Doppler probe can help. Once the artery is exposed, attention should be paid to ensure that the brachial artery itself (proximal to the bifurcation) is ligated (the anastomosis can be performed to any site on the vessels as long as continuity between the radial and ulnar arteries is maintained).

The radial artery and cephalic vein are most commonly exposed at the wrist for creation of a radiocephalic fistula. Most prefer a longitudinal incision; the pulse is followed to the artery (which lies between the flexor carpi radialis and brachioradialis tendons). No special precautions are followed, other than preservation of the radial sensory nerve; division or injury of this nerve leads to a surprising amount of disability. The cephalic vein is likewise easy to expose, although usually the lateral branch, "deep" with regard to this exposure, is best to use (Fig. 57.14). There is evidence that decreasing manipulation of this vessel improves early AV access patency, but extensive manipulation allows the vein to lie without tension at the "swing point"

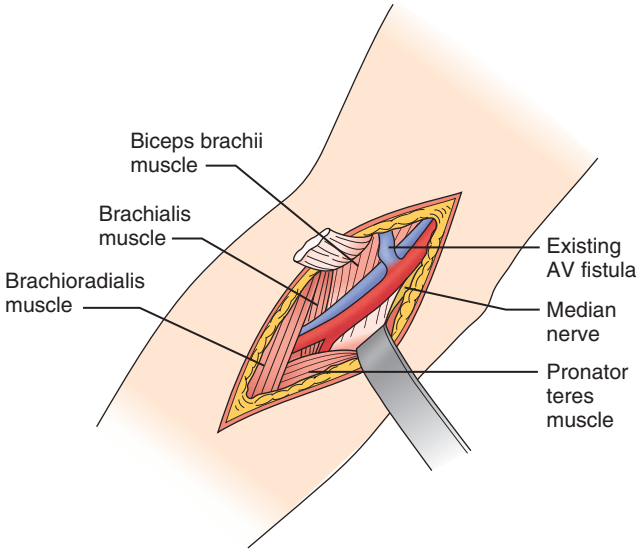

Figure 57.13 Exposure of the brachial artery distal to the antecubital fossa for distal revascularization interval ligation (DRIL) or embolectomy. In both cases the ulnar and radial artery takeoffs should be exposed and controlled. *AV*, Arteriovenous.

where it transitions from "loose" to fixed by tissue. The radial artery can be exposed in the anatomic snuff-box quite easily for a snuff-box fistula, and is quite large in this area (Fig. 57.15).

The ulnar artery is very seldom exposed. Most avoid using this for access because it is the dominant artery to the hand. It is unclear whether this attitude is supported by evidence, but if exposure is needed, the pulse can simply be followed to the artery.

Anterior lumbar interbody fusion (ALIF) was first described by Carpenter[1] in 1932 and promoted by Hogson and Stock[2] in 1956 for definitive treatment of more anteriorly oriented spine pathology and to avoid posterior element injury. The originally described procedure, which required significant operative exposure and was considered to be quite invasive, has undergone a number of modifications that have minimized the extent of required surgical exposure. These surgical modifications have made the anterior approach to the lumbosacral (ALIF) as well as the thoracic (anterior thoracic interbody fusion [ATIF]) spine a widely accepted technique for spinal arthrodesis or for diskectomy/decompression.

Anterior spine exposure for interbody fusion, performed with the patient in either supine or lateral decubitus position depending upon disk level(s) of interest, is usually combined with supplemental posterior fixation with the patient prone to increase the rate of complete spinal fusion. A number of different implants are used to effect anterior interbody fusion (AIF); however, description of them is beyond the scope of this chapter. Advantages of AIF from the orthopedic perspective include preservation of posterior elements, decreased incidence of nerve injury, and avoidance of epidural scarring.[3] From the vascular surgeon's perspective, the key to successful AIF is to provide the spine surgeon with adequate vertebra side-to-side surgical exposure so that diskectomy, decompression, and partial corpectomy (if needed) can be safely performed and so that implants can be accurately inserted on the basis of the disk space midpoint.

AIF for lumbosacral (LS) spine pathology was originally performed through an open retroperitoneal exposure with a large incision, extensive tissue manipulation, and significant patient morbidity.[3] The retroperitoneal approach for ALIF takes advantage of the potential space between the peritoneal contents and kidney and the quadratus lumbar and psoas muscles to afford excellent anterior lumbosacral spine exposure. Other surgical approaches, such as mini-open retroperitoneal, endoscopic retroperitoneal, and endoscopic lateral transpsoas, have also been used to capitalize on the retroperitoneal plane of dissection but to minimize surgical morbidity without compromising anterior spine exposure.[3-18] Laparoscopic transperitoneal spine exposure also has it proponents.[6,8,9,11] However, all the previously mentioned surgical approaches eventually necessitate dissection and mobilization of the thoracic aorta, abdominal aorta, and/or iliac arteries with accompanying major venous structures depending on the disk level(s) of interest.

Notwithstanding the potential for major arterial or venous injury that could occur during anterior spine exposure, there is also the potential for significant injury to other vulnerable structures that are encountered during routine cases.[4] Recognition

Abstract

The chapter begins with a brief historical review anterior lumbar and thoracolumbar interbody fusion. Key issues related to clinical assessment and potential surgical risk factors are discussed as well as patient risk assessment. Diagnostic evaluation from a vascular surgeon's perspective is reviewed including noninvasive and invasive testing. Surgical treatment, indications and contraindications of surgery and relevant anatomy are then fully explored. Operative planning and options with description of various spine level exposures is detailed. Surgical results (early and late) and potential complications of surgery are examined with a brief discussion of postoperative management and follow up. Finally, special anatomical and pathological considerations such as re-do spine exposure and calcified arterial anatomy are reviewed.

of these possible complications has been the impetus for most centers of excellence to develop a two-team (vascular surgery plus either orthopedic surgery or neurosurgery) approach to minimize morbidity and to maximize optimal operative exposure for reconstructive spinal surgery. This chapter explores anterior spine exposure from a vascular surgeon's perspective.

CLINICAL PRESENTATION, DIAGNOSTIC EVALUATION, AND RISK ASSESSMENT

In contrast to the characteristic patient with atherosclerotic disease that a vascular surgeon encounters, the patient needing anterior spine exposure is often younger, has few to no risk factors for peripheral arterial disease (PAD), and, not infrequently, may be overweight due to inactivity. The patient often has associated radiculopathy, a long-standing pain syndrome that may be managed by many different specialists, and many have had a traumatic work-related injury. In short, the typical patient requiring AIF presents with a number of complicating issues that are not necessarily related to PAD.

Lumbosacral spine exposure involves extensive mobilization of major arteries within the abdomen/pelvis as well as their accompanying major veins; therefore, a history of claudication or any abnormality in the peripheral pulse findings should be first evaluated by noninvasive testing. Occasionally, further invasive testing such as arteriography and/or computed tomography is required for severe aortoiliac occlusive disease or aortic aneurysmal disease. Significant aortoiliac artery calcification can be problematic regarding placement of retractors and increases the potential risk of arterial injury or dissection. Extent of arterial calcification can be evaluated with plain radiographs or computed tomography if this diagnosis is suggested by noninvasive testing. The bottom line here is to have an accurate assessment of peripheral pulses prior to surgery because temporary vessel occlusion is part and parcel of mini-open retroperitoneal anterior spine exposure.

Besides a thorough peripheral pulse examination, it is wise to examine the patient's thorax, abdomen, and flank for signs of previous chest or abdominal procedures, the presence of which may influence subsequent incision placement. For instance, the lower lumbosacral spine can be well exposed via a right retroperitoneal approach if the procedure is a "redo" or, if the adjacent proximal or distal disk level will now be exposed, or if there has been prior abdominal surgery with incisions in the left upper or lower quadrant. In our experience, patients undergoing ALIF (particularly in younger individuals) are often focused on incision position and length; therefore, it is prudent to discuss the proposed incision prior to surgery because omission of this minor detail can be very problematic for both surgeon and patient in the postoperative period. Incision length may need to be extended to facilitate adequate spine exposure if there is significant calcific atherosclerotic disease or when the patient has a large body habitus.

Fortunately, the overwhelming majority of patients needing anterior spine exposure are relatively healthy and do not require any other preoperative testing except as mentioned previously. However, older patients may need preoperative cardiac stress testing or pulmonary function studies, particularly if the procedure requires thoracic spine exposure. Needless to say, it is paramount to thoroughly discuss possible complications of surgery with the patient, including but not limited to major artery/vein injury, bowel or ureter injury, deep venous thrombosis, wound infection/seroma, nerve injury, and erectile dysfunction (usually retrograde ejaculation as opposed to impotence) due to disruption of the intermesenteric nerve plexus and superior hypogastric nerve plexus, which course over the left common iliac artery origin.[4] Lastly, it is wise to note that there is often significant anterior spinal scarring with an increased incidence of complications if the procedure is done in the setting of diskitis, previous posterior laminectomy, or if the exposure is one disk level proximal or distal to one that has been previously exposed.

SURGICAL TREATMENT

It is beyond the scope of this chapter to discuss the indications for and contraindications to ALIF and ATIF from an orthopedic perspective, and in this clinical setting, the vascular surgeon must rely upon the expertise of the orthopedic colleague to ensure that surgical indications are sound. Rarely have we advised against surgery after a thorough orthopedic and vascular preoperative assessment except in the occasional case of a grossly morbidly obese patient. In these unusual cases, the risks of surgery far exceed the benefits until significant weight loss has been addressed. Nonetheless, we do have significant experience with successful AIF even in patients with body mass index (BMI) higher than 30.

Operative Planning and Surgical Exposure Options

In the majority of procedures, the disk space(s) of operative interest is exposed by dissection and mobilization of the overlying vessels from left to right across the midline via a left thoracotomy for thoracic spine procedures or via the left retroperitoneal space for lumbosacral spine procedures. No single approach lends itself to all circumstances; therefore, it is wise to become comfortable with the relationship of the target disk level(s) to overlying skin and bony structures such as ribs, costal margin, and anterior superior iliac spine, because the appropriately placed incision will minimize soft tissue dissection and extent of vessel mobilization. Palpation of pedal pulses before and after the procedure is also prudent because temporary arterial occlusion often accompanies disk exposure and spinal instrumentation.

Once the disk level or levels of interest are fully exposed, we have found it wise to remain present in the operating room to assist the orthopedic surgeon with diskectomy, decompression, and spinal fusion. Major vascular injuries may occur when sharp curettes, rongeurs, and drill bits are being used. Prompt, potentially life-saving, vessel repair can be performed only if the vascular surgeon remains close at hand. Finally, and particularly in teaching institutions, thoracic and retroperitoneal

exposure of major arterial and venous structures provides an excellent opportunity for vascular surgery residents to obtain open surgical training and to learn how to safely and effectively manipulate blood vessels.

Thoracic Spine Exposure

Thoracic spine exposure requires the least amount of vessel dissection because the interbody implants are designed to be placed from a more lateral position, unlike lumbosacral spine exposures, in which the implants are usually positioned from a true anterior approach. Therefore a mini-open left or, occasionally, right, thoracotomy with the lung deflated is normally employed for procedures that are limited to the thoracic spine. Very proximal thoracic spine procedures that involve disk pathology from T1 to T3 are usually approached posteriorly except in unusual circumstances that may require medial clavicleculectomy or mini-sternotomy. A limited right thoracotomy facilitates spine access and exposure from T3 to T6, and a limited left thoracotomy is usually utilized for procedures that involve disk pathology from T7 to T12, although one can also obtain spine exposure through the L2 vertebra from a low thoracotomy approach if needed.

Thoracolumbar (T12-L2), lumbar (L2-L5), and lumbosacral (L5-S1) spine exposures necessitate more extensive mobilization of major abdominal and pelvic vessels and risk injury to other vital structures within the operative field.[4] Various surgical approaches including mini-open retroperitoneal, laparoscopic transperitoneal, endoscopic retroperitoneal, and endoscopic lateral transpsoas have been used for ALIF to minimize vessel dissection and surgical morbidity without compromising anterior spine exposure.[4-18] No matter the approach, the key advantages of anterior spine exposure are direct access to and superb visualization of the intervertebral disk level of surgical interest.

Lumbosacral Spine Exposure

The surgical approach for ALIF can pass either through the abdominal cavity or outside the peritoneal contents in an extraperitoneal plane of dissection (see Chapter 54).

Transperitoneal Exposure

Transperitoneal lumbosacral spine exposure requires extensive mobilization of the midgut and hindgut out of the operative field. This can be a demanding exercise, particularly in obese patients or in those who have dense adhesions as a result of a prior abdominal procedure or inflammatory process. Furthermore, the transperitoneal approach is associated with prolonged postoperative ileus, third-space fluid sequestration, and an increased risk of retrograde ejaculation in male patients.[6,12-15] Sasso et al.[15] found a tenfold higher risk of retrograde ejaculation when they compared transperitoneal with retroperitoneal L4 to S1 spine exposure. Mini-open anterior retroperitoneal lumbosacral spine exposure has advantages similar to those that have been described for retroperitoneal aortoiliac vascular procedures.[19] This is particularly true in regard to length of hospital stay, postoperative ileus, and other perioperative complications.

Transperitoneal Laparoscopic Exposure

Transperitoneal laparoscopic interbody spine fusion has been evaluated as a method to minimize open surgical morbidity and potential abdominal wall complications.[6,8,9,16] Katkhouda et al.[16] compared the safety and efficacy of the laparoscopic approach for single- and multilevel degenerative disk procedures. Twenty-four consecutive laparoscopic transperitoneal interbody lumbar fusions were evaluated prospectively (18 single-level procedures were compared with 6 multilevel procedures). Results of the laparoscopic multilevel procedures were further compared with those of 12 mini-open multilevel operations. Twenty of 24 procedures were completed laparoscopically. Four procedures were converted to open procedures to control bleeding from an iliac vein laceration in three patients and a mesenteric tear in the fourth. Overall results were decidedly worse for multilevel laparoscopic procedures than those in the matched open group.

Another prospective, nonrandomized study directly compared laparoscopic with open mini-anterior L4 to L5 retroperitoneal lumbar interbody fusion in 50 consecutive patients.[8] Twenty-five patients underwent anterior laparoscopic interbody fusion, and 25 had open mini-ALIF. There was no statistical difference in operating time, blood loss, or length of hospital stay between the two groups for single-level fusions. However, laparoscopic procedures took 25 minutes longer ($P = 0.035$) than open procedures for multilevel fusions. The rate of complications was significantly higher in the laparoscopic group (20% vs. 4%), and in 16% of patients undergoing laparoscopic surgery, there was inadequate spine exposure. Other writers have commented that the perceived advantages of a laparoscopic approach have not been realized in clinical practice and that variability in vascular anatomy significantly limits its applicability.[6-9] Finally, the endoscopic lateral transpsoas approach does minimize vessel dissection, but has increased risk of groin/thigh numbness and pain from manipulation of the genitofemoral nerve coursing along the psoas muscle.[5]

Anterior Retroperitoneal Exposure

Despite a working knowledge of laparoscopic techniques, we continue to favor open mini-ALIF via anterior retroperitoneal lumbosacral spine exposure, if possible, for the following reasons. Our current experience demonstrates few overall complications for this approach in comparison with other spine exposure techniques.[18] Single-level or multilevel disk exposure can be performed in an expeditious manner with minimal intraoperative complications. Vital structures can be thoroughly mobilized out of harm's way to facilitate complete diskectomy and, in theory, better interbody fusion. Finally, the surgical approaches described in the following paragraphs facilitate the spine surgeon's need to have direct anterior access to the lumbosacral spine.

Relevant Surgical Anatomy

Thoracic Spine Exposure

Patient positioning for exposure of the thoracic spine is similar to the position that is often used for open thoracoabdominal

aortic aneurysm repair (see Chapter 53).[20] After central venous and radial arterial line placement and dual-lumen endotracheal intubation, the patient is placed in a true right or left lateral decubitus position. A beanbag device, or anterior/posterior padded bolster, is helpful to support the patient's position on the operating table. The free upper extremity can be passed across the upper chest and supported on a cushioned Mayo stand. Care should be taken to ensure that padding of the lower extremities is appropriate and that there is no external pressure on the feet or that the feet are severely plantar-flexed. Transcranial motor evoked potential (TCMEP) monitoring and somatosensory evoked potential (SSEP) monitoring of the posterior tibial nerve, with the ulnar nerve as control, is used for all of our spine procedures.

The rib interspace to be entered after the lung is deflated depends primarily on the extent of thoracic spine that is to be exposed, and there is no need to divide the costal margin in the vast majority of cases. In general, the best operating exposure for the spine surgeon is afforded by entering the chest two intercostal levels proximal to the disk level of interest. We often remove the lower rib to facilitate access at multiple disk levels and then morselize the rib for use as bone graft during the procedure. However, removal of the rib facilitates spine visualization at the potential cost of increased postoperative pain, which can be relieved with a multilevel intercostal block. Intraoperative fluoroscopy is vital to identify the appropriate disk space(s) and to limit the extent of surgical dissection. For proximal thoracic spine exposure via a right thoracotomy, incision of the parietal pleura along the lateral aspect of the thoracic vertebra and limited division of ipsilateral intercostal arteries/veins facilitates exposure of the disk space(s) as needed. Venous tributaries coursing into the azygos vein should be divided as needed to prevent injury and troublesome bleeding. These maneuvers are generally all that is needed for proximal thoracic spine exposure, and it is a rare circumstance that one would encounter the esophagus or the vagus nerve, which courses parallel and medial to the azygos vein in the proximal chest.

From the left side, for mid-to-distal thoracic spine exposure, the approach is similar to that already described, except that the descending thoracic aorta is encountered as one dissects across the anterior surface of the thoracic vertebra and disk space. After limited division of ipsilateral intercostal arteries/veins, the descending thoracic aorta can be retracted medially with Omni-Tract (Integra Lifesciences, Minneapolis, Minnesota) renal vein retractors to minimize the risk of arterial injury. Preservation of the blood supply to the spinal cord is critical; therefore, it is wise to ligate intercostal arteries close to the aorta to preserve potential collateral vessels. Brockstein et al. [21] have stressed the importance of the arteria radicularis magna (artery of Adamkiewicz) in providing circulation to the anterior spinal artery. This vessel is a branch of either a distal intercostal or a proximal lumbar artery. It has been identified as proximal as T5 and as distal as L4.[21] However, the artery generally arises between the T8 and L1 vertebral levels. Therefore it is unwise to ligate any large intercostal or proximal lumbar artery unless it is absolutely necessary to do so for adequate disk space exposure. Finally, the diaphragm can be divided in a limited fashion just lateral to its central tendinous portion to extend the dissection distally to facilitate exposure through the L1 to L2 disk space. Alternatively, these disk spaces can be exposed from the chest by "hooking" the central tendinous portion of the diaphragm with a renal vein retractor, pulling caudad, and performing very limited dissection of the diaphragmatic attachments to the proximal lumbar vertebral bodies.

T12 to L2 Exposure

For thoracolumbar (T12-L2) spine exposure, the patient is placed in the right lateral decubitus position on the operating table with the kidney rest at waist level. If needed, the kidney rest can be elevated and the operating table gently flexed to open the space between the left anterior superior iliac spine and the costal margin. The free left upper extremity is positioned as described earlier. A limited flank incision is made over the anterior extent of the 12th rib. This step decreases the chance of injury to the main trunk of the intercostal nerve within the 11th intercostal space.[20] Abdominal/flank muscle fibers should be split in their respective orientations as opposed to transected. Resection of the 12th rib facilitates safe entry into the retroperitoneal space, as well as an extraperitoneal plane of dissection. Alternatively, this limited thoracolumbar spine exposure can be obtained through the 10th or 11th intercostal space as mentioned previously, with dissection just lateral to the central tendinous portion of the diaphragm, rather than inferior to the diaphragm as described here.

Extraperitoneal entry into the upper left retroperitoneal space exposes Gerota's fascia with contained left kidney as well as the spleen, which can then be rotated inferomedially off the diaphragm and proximal psoas muscle. This maneuver facilitates exposure of the left diaphragmatic crus, which will be divided to reveal the underlying vertebra and abdominal aorta. Once again, limited ligation and division of intercostal/lumbar arteries as needed should be performed to preserve spinal blood flow. The Omni-Tract retraction system (Integra Lifesciences), with its multiple and varied blades, is critical for maintaining this exposure. The previously mentioned thoracolumbar spine exposure can also be performed from a right flank approach, requires mobilization of the right lobe of the liver and, in some cases, the vena cava. We have also performed limited thoracolumbar spine exposure via a left upper quadrant paramedian incision, which affords the spine surgeon superb anterior spine exposure.

L2 to S1 Exposure

More distal lumbosacral spine exposures (typically from L2 to S1) are usually performed with the patient supine and via small oblique or longitudinal left (occasionally right) paramedian incisions. The preoperative lateral lumbar spine radiograph can be useful to determine appropriate position of the incision for optimal disk space exposure. The relationship of the palpable iliac wing, which is easily visualized on the lateral radiograph, with the lower lumbar disk levels, provides an excellent landmark to determine incision placement. Oblique/transverse incisions that are centered over (or just between) the target disk(s) are useful for one- or two-level disk exposures, and longitudinal

paramedian incisions facilitate multilevel disk exposure. Electromyography in addition to somatosensory-evoked potential monitoring is used for these cases. A reduction in somatosensory-evoked potential amplitude may signal diminished blood flow and ischemia to the affected limb.

In either orientation, the incision is carried through the anterior layer of the rectus sheath to expose the rectus abdominis muscle. The muscle belly is dissected medially away from the medial aspect of the rectus sheath and retracted laterally to expose the posterior layer of the rectus sheath and/or the transversalis fascia. There is no transection of muscle fibers, so the incidence of muscle laxity or abdominal wall bulge is minimized. The posterior rectus sheath/transversalis fascia is incised to develop an extraperitoneal plane of dissection. Rotation of the peritoneal contents from left inferolateral to right superomedial opens the left lower retroperitoneal space and exposes the major arteries and veins that overlie the distal lumbosacral spine. For higher levels of thoracolumbar spine exposure (T12-L1), we typically utilize a retronephric, extraperitoneal plane of dissection by rotating the kidney and left ureter, as well as the peritoneal contents, medially off the psoas muscle. However, we have found that in most patients, particularly the morbidly obese patient, it is often easier to obtain proximal (L1-L3) lumbar spine exposure if the dissection plane to the anterior spine is developed between the left colon and Gerota's fascia, leaving the left kidney and ureter in place. In this circumstance, care must be taken to protect the left ureter, which will remain in situ and lateral to the spine. It is also important not to injure the very vascular tissue that is medial to the kidney hilum and adjacent to the adrenal gland. Occasionally, the spleen also requires medial mobilization away from the psoas muscle and diaphragm to facilitate some extended thoracolumbar spine exposures.

The maneuvers described previously, depending on their extent, facilitate exposure of the entire abdominal aorta and left common iliac artery with accompanying left common iliac vein (Fig. 58.1). Mobilization of these vessels from left to right across the midline is usually required to anteriorly expose the spine and disk space from side to side. The left ureter is generally swept medially with the posterior peritoneum out of harm's way; however, if the ureter appears to be under too much stretch and at risk for injury, it should be gently dissected away from the medially rotated posterior peritoneum. The ipsilateral vas deferens and testicular/ovarian vessels are gently dissected away from the posterior peritoneum to maintain their normal anatomic positions, and occasionally, division of the round ligament in women facilitates medial rotation of the peritoneal contents and exposure of the distal lumbosacral spine. The vestigial ipsilateral umbilical artery that courses into the internal iliac artery can be divided with impunity. Finally, and particularly in males, a concerted effort is made to protect the condensation of nerve elements (intermesenteric nerve plexus and superior hypogastric nerve plexus) that course over the left common iliac artery origin (Figs. 58.2 and 58.3). The use of bipolar cautery in this area for any small paraspinal and periarterial bleeders also helps decrease inadvertent nerve injury.

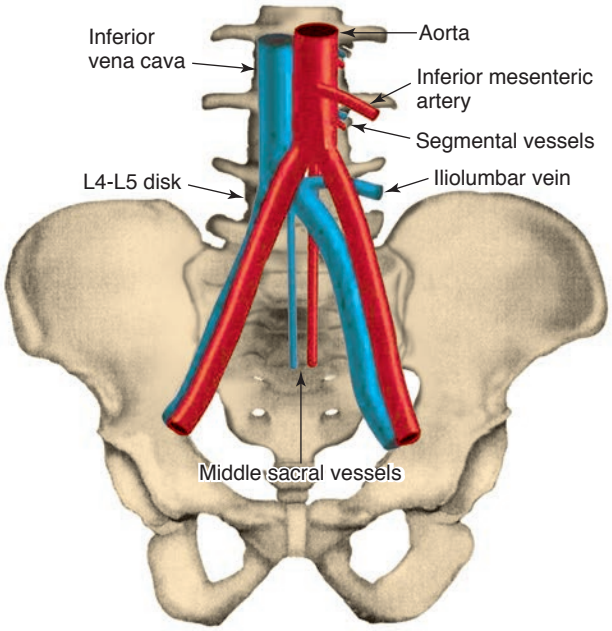

Figure 58.1 Arterial and venous anatomy that is typical for lumbosacral spine exposure. Note that in this case the L4 to L5 disk is just above the aortic and caval bifurcation.

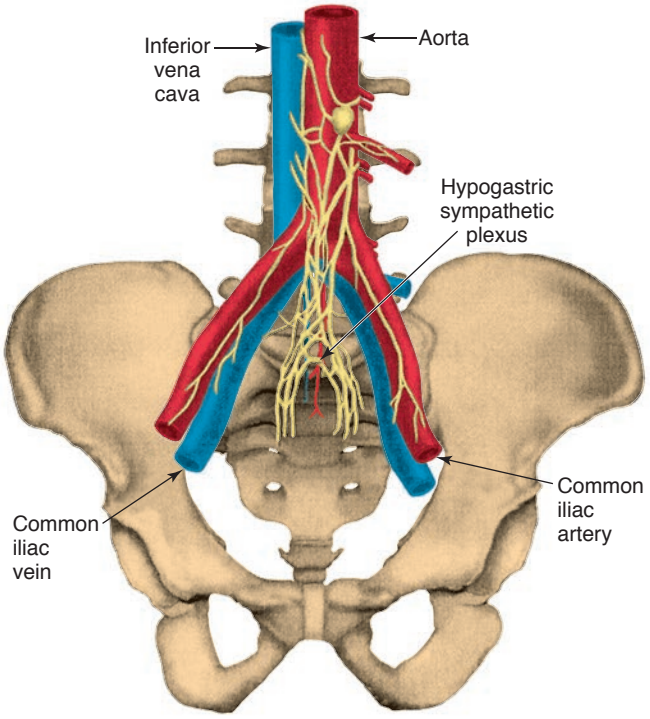

Figure 58.2 Relationship of the infrarenal sympathetic nerves to the aorta and iliac arteries.

L4 to L5 and L5 to S1 Exposures

Exposure of the L5 to S1 disk space is relatively straightforward compared with other levels, because once the rectosigmoid bowel is swept across the midline from left to right, the disk space is readily exposed between the left common iliac vein and the

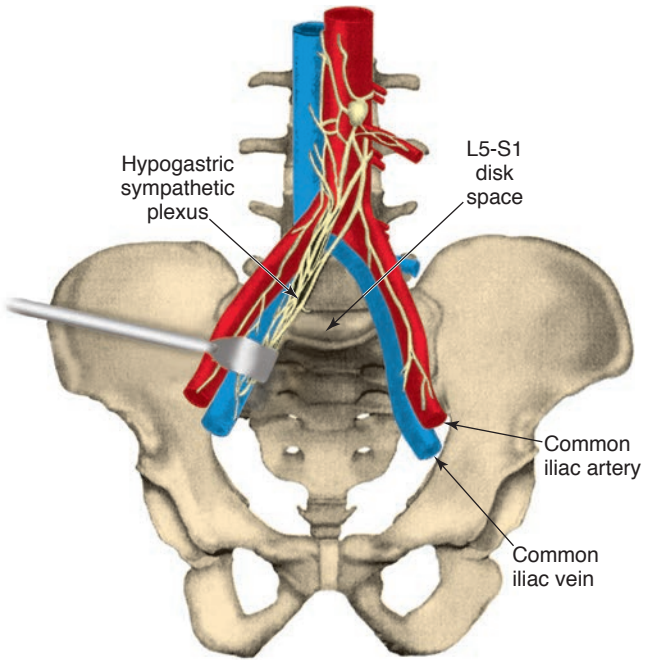

Figure 58.3 To approach the L5 to S1 disk and to protect the sympathetic nerves, it is wise to begin dissection along the medial aspect of the left common iliac vein and then to retract the soft tissue overlying the disk toward the right common iliac artery.

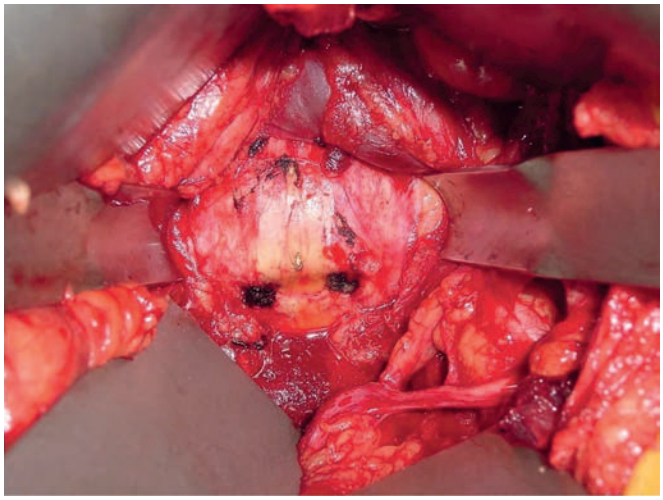

Figure 58.4 Intraoperative photo of the exposed L5 to S1 disk. Note the positioning of the Omni-Tract renal vein retractors (Integra Lifesciences, Minneapolis, Minnesota) as described in the text.

right common iliac artery after division of the middle sacral artery and vein (Figs. 58.4 and 58.5; see also Fig. 58.3). Various incisions can be used for this single-level exposure, including left lower quadrant oblique, transverse, and, occasionally, midline. We rarely utilize a midline approach, thereby avoiding transperitoneal exposure of the peritoneal contents.

Exposure of the L4 to L5 disk space can be technically demanding, particularly if there is significant spondylolisthesis at this disk level because the "tethered" left common iliac vein stretches and flattens out across the lower edge of the disk space, inviting inadvertent injury. L4 to L5 disk space exposure should always be accompanied by division of the iliolumbar

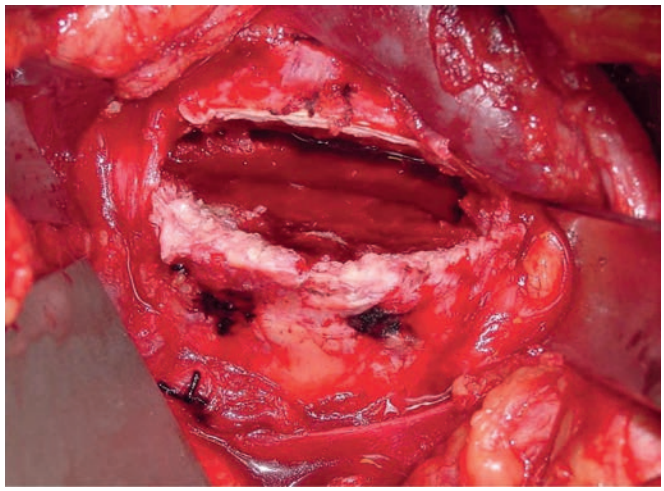

Figure 58.5 Intraoperative photo following diskectomy at the L5 to S1 disk level; subsequent insertion of allograft bone or a synthetic prosthesis to promote spine fusion completes the procedure.

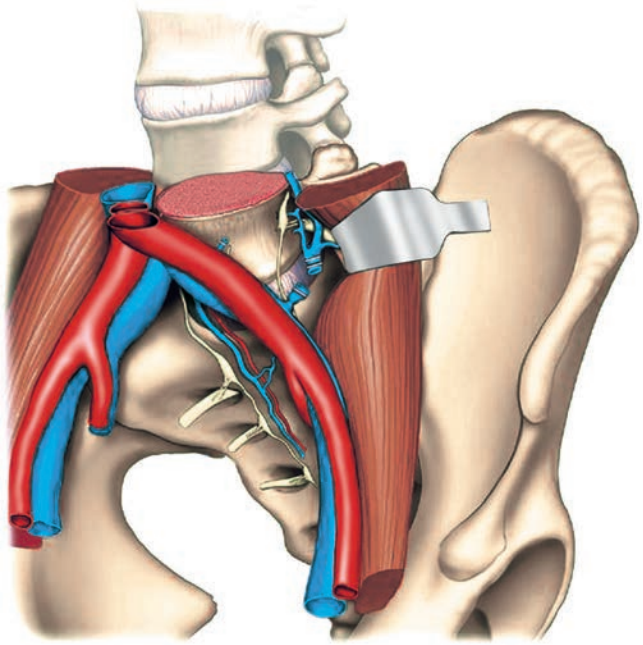

Figure 58.6 Division of the iliolumbar vein (or veins) is key for safe exposure of midlumbar and lumbosacral disk levels.

vein(s), which course toward the posterolateral aspect of the left common iliac vein (Fig. 58.6). Failure to divide this vein can result in a significant tear at this venous junction with bleeding that can be difficult to control. In other more proximal procedures, appropriate disk level exposure requires meticulous left-to-right dissection and mobilization of some portion of the abdominal aorta. Additional dissection of the common iliac arteries and/or iliac veins may also be required to fully expose the natural width of the desired disk space(s). Lumbar arteries and unnamed venous tributaries should be individually ligated and divided to facilitate the spine exposure. One particular advantage of this left-to-right dissection/mobilization plane is that the vena cava remains well protected throughout the procedure.

Exposure of More Than One Disk Space

Although tempting in some cases, it is unwise to perform diskectomy and spinal instrumentation at multiple disk levels simultaneously if this extended exposure occludes the aorta/common iliac artery or risks significant damage to the confluence of the common iliac veins and the vena cava. This is particularly true when the L4 to L5 disk space is involved, because there can be significant variability in the arterial and venous anatomy. On the other hand, in patients with nondiseased, tortuous iliac arteries, we can often simultaneously expose and operate upon multiple disk spaces from L1 to L5 with well-positioned retractors. The retractors are then repositioned to expose the L5 to S1 disk space if diskectomy/decompression is also required at this disk level.

Fig. 58.7 depicts the usual scenario in which the disk is exposed following left-to-right mobilization of the aorta and left common iliac artery across the anterior spine. However, the left common iliac artery and vein occasionally need to be separated and retracted away from each other to fully expose the disk space without prolonged arterial occlusion or arterial injury (Fig. 58.8). Figs. 58.9 and 58.10 depict other, less common dissections we have used to expose the L4 to L5 disk space, in the patient with a high aortic bifurcation, for instance. These alternate dissection schemes are particularly helpful for redo anterior procedures, in which the major overlying arteries and iliac veins may be densely adherent to the anterior surface of the spine, or in dissection being performed after previous posterior lumbosacral spine surgery, in which we have typically encountered significant scarring of the anterior spine surface.

Right-Sided Exposure

Spine exposures performed from a right-sided mini-open retroperitoneal approach necessitate mobilization of the vena cava and, to some extent, the right common iliac vein for lower lumbosacral spine procedures. Medical retraction of the vena cava all the way across the anterior surface of the spine often occludes the vessel and may result in significantly decreased preload, which is not well tolerated in elderly patients. Therefore and depending on arterial/venous anatomy, the disk space(s) may be better exposed by dissecting between the vena cava and abdominal aorta. This alternative causes less compression of each vessel with lateral retraction away from the midline.

Self-Retaining Retractors

Self-retaining renal vein retractors (Omni-Tract Surgical) are typically employed to maintain each exposed disk space and to protect the adjacent vessels/peritoneal contents. These particular retractors are slightly angled backward at their tips, and this angled portion can usually be positioned to hug the disk space laterally, thus protecting encroaching vital structures from

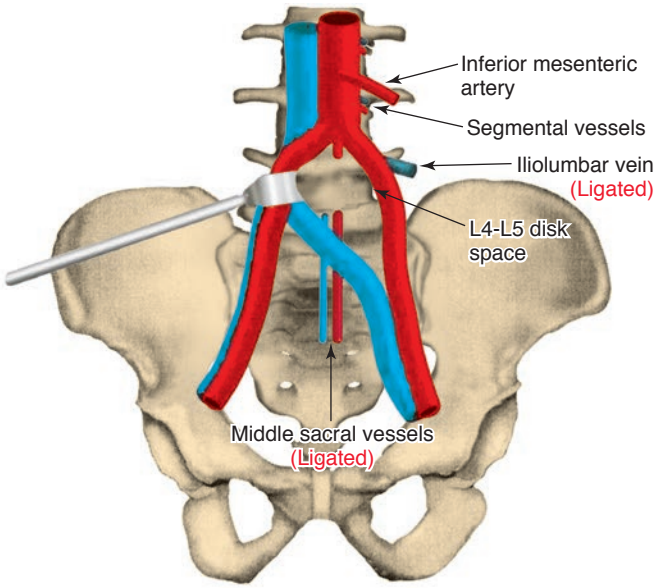

Figure 58.8 L4 to L5 disk exposure between the left iliac artery and vein.

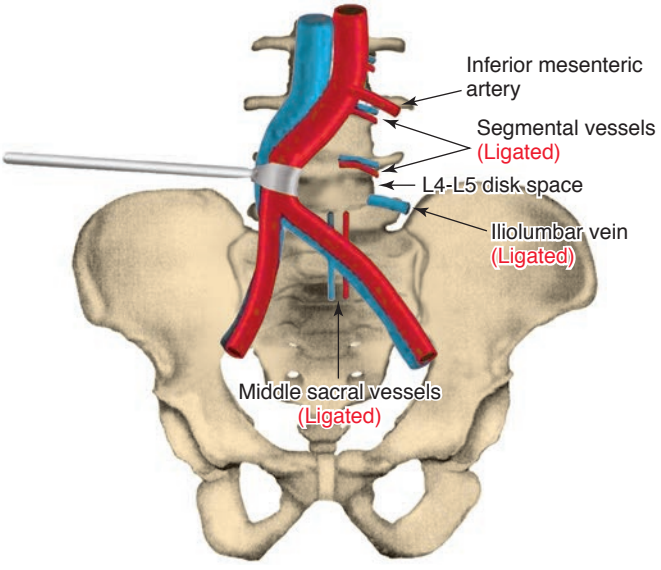

Figure 58.7 L4 to L5 disk exposure when aortic and caval bifurcations are distal to the disk level.

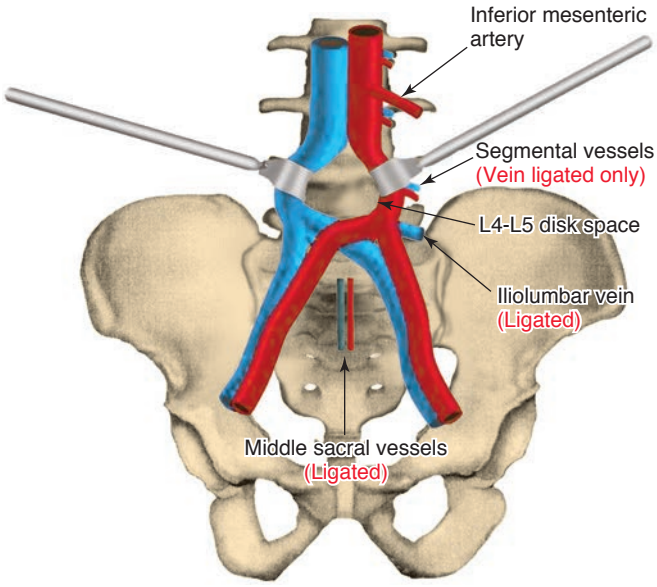

Figure 58.9 L4 to L5 disk exposure between the aorta and the vena cava.

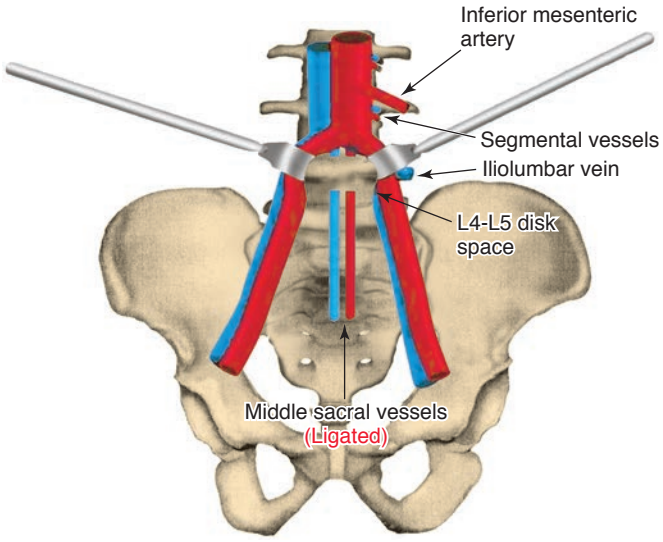

Figure 58.10 L4 to L5 disk exposure when aortic and vena caval bifurcations are proximal to the disk level.

the disk space and giving the spine surgeon just enough room to operate even in very large patients (see Fig. 58.6). These retractors should be placed with care to avoid excessive traction on the mobilized structures and should be positioned just medial to the sympathetic chains that course along the lateral aspects of the vertebra, to protect them from inadvertent injury. It is wise for the vascular surgeon to assist the spine surgeon with diskectomy, decompression, partial corpectomy (if needed), and spinal fusion to ensure swift recognition and repair of inadvertent injury to a vital structure.

Meticulous hemostasis is achieved throughout the operative site after ALIF, and we typically spray a fibrin sealant (Evicel, Ethicon US, LLC.) over each operative disk site to effect complete hemostasis and in theory, to decrease adhesions over the anterior spine surface.[18,22] The peritoneal contents are rotated back into place after confirming a palpable pulse in each common iliac artery. The wound should be closed in anatomic layers and we routinely close skin in a subcuticular manner. A one-inch Steri-Strip applied longitudinally for the length of the incision completes the closure. Pedal pulses are confirmed to be unchanged from preoperative before the patient transfers to the recovery room.

Special Considerations

Redo anterior spine exposure and calcified arterial anatomy deserve special mention as either situation increases the risk of vital structure injury.

Repeat Procedures

"Redo" procedures are often associated with significant scarring of the anterior spine from the previous procedures, which results in very adherent vessels and ureteral fixation. This is particularly true for explantation of artificial disks, which occasionally become displaced or have component failure. Alternative spine access strategies are often employed for these potentially complicated procedures.[18,23,24] In any event, it is wise to prepare for dissection difficulties and potential bleeding. Arteriorrhaphy or venorrhaphy with pledgetted nonabsorbable polypropylene (Prolene) suture is recommended because the vessels tend to be friable when re-dissected off the anterior spine surface. Large venous rents are best controlled with a side-biting vascular clamp, because it may not be possible to completely occlude the vein proximal and distal to the injury site without risking further injury. On rare occasions, transection (or even segmental resection) of the overlying iliac artery may be required to adequately expose a major pelvic venous injury. Standard arterial reconstruction techniques can be used after ensuring an intact vein repair or vein ligation as the case dictates.

Calcified Arteries

Calcified arteries present a unique problem because of the retraction required to expose the disk space. Even pliable vessels are frequently retracted at rather acute angles to limit dissection, but also to afford complete disk space exposure. Therefore the risk of arterial injury/dissection increases significantly when the vessel is heavily calcified. The best way to avoid injury to a calcified vessel is to mobilize more length of the artery proximal and distal to the disk level(s) of interest, even if doing so requires extension of the incision and/or more mobilization of adjacent structures. We have rarely encountered significant arterial injury during ALIF, but would not hesitate to perform appropriate arterial reconstruction as needed, as opposed to risking acute arterial occlusion by applying multiple blindly directed sutures and pledgets to an injured vessel.

SURGICAL RESULTS AND COMPLICATIONS

In our experience, the mini-open thoracic and retroperitoneal approaches described herein are associated with rare intraoperative complications and few perioperative or long-term complications. Tables 58.1 and 58.2 detail intraoperative and perioperative vascular and nonvascular complications associated with various surgical approaches that are used for ALIF.

In our first reported review of ALIF cases, there were two (2.8%) intraoperative complications—a single small bowel enterotomy and an iliac vein laceration, both of which were repaired primarily.[4] No patient or surgical variable was predictive of an intraoperative complication. The two complications occurred during partial corpectomy and spinal instrumentation, not during the spine exposure. Postoperative complications occurred in seven patients (9.7%). They included erectile dysfunction (two patients), transient unilateral lower extremity paresis (one patient), acute acalculous cholecystitis (one patient), femoral vein thrombosis (one patient), pneumonia (one patient), and acute myocardial infarction (one patient). There were no genitourinary or other major vascular injuries. The overall perioperative complication rate with utilization of the two-team approach described above was 12.5%.

Postoperative complications were more common in patients who presented with a history of coronary artery disease or who were older than 50 years at the time of surgery. In addition,

increased operative blood loss and an extended paramedian incision were also associated with a higher risk of perioperative complications.[4] These positive predictors were not entirely surprising in light of the magnitude of the surgical procedure. This was particularly true in patients undergoing exposure of multiple disk levels, in whom significantly more surgical dissection and major vessel mobilization were required.

Another report also utilizing a two-team approach (urology and orthopedics) for anterior spine exposure demonstrated a perioperative complication rate of 10.6%.[14] The reported complications were specific to the actual exposure, and the preferred incision was left paramedian. These complications included one death from widely metastatic lung cancer (spine fusion was attempted for palliation of an unstable spine), two occurrences of prolonged ileus, two occurrences of retrograde ejaculation, one episode of symptomatic femoral vein thrombosis, and one episode of *Clostridium difficile* colitis. There were no major vascular injuries, and consistent with our experience, there were no genitourinary injuries or anterior wound infections.

However, in one report, neurosurgeons reported that 24 perioperative complications occurred in 23 patients (38.3%) from a retrospective review of 60 patients undergoing anterior lumbar interbody fusion over a 2-year period.[13] Experienced general or vascular surgeons performed the spine exposures through a left paramedian or oblique infraumbilical skin incision. The complication list included sympathetic nerve dysfunction (six patients), vascular injury (four patients), somatic neural injury (three patients), sexual dysfunction (three patients), prolonged ileus (three patients), wound dehiscence (two patients), deep vein thrombosis (one patient), pancreatitis (one patient), and bowel injury (one patient). The incidence of complications was not related to age, previous abdominal or spinal surgery, or number of exposed disk levels (all P values >.1).[13] The investigators in this review commented that the complication rate did not seem to represent a learning-curve effect, because the rate was the same during both year-long study periods.[13] They did appropriately point out that it is paramount for the surgeon who is performing the spine exposure to have a keen awareness of the potential complications so that patients can be properly counseled and asked for informed consent prior to surgery.[13] Interestingly, and as in our first published review, there was no correlation between previous posterior spine fusion and perioperative complications—yet we know from experience that procedures in patients with posterior spine infusion are some of the most difficult to perform because dense scarring of the anterior spine surface complicates vessel dissection and mobilization.

Our latest ALIF and ATIF experience involved 617 consecutive patients with mean age of 56 years (16% >69 years).[18] Mean BMI was 29.27; 39% were considered obese, with BMI values greater than 30. One disk level was exposed in 36% of cases, two in 43%, and three or more in 21%. Six percent of patients had prior anterior spine exposure, 42% had previous posterior laminectomy and/or diskectomy, and 3% required disk re-exposure to remove hardware or an artificial disk. There was one major arterial dissection and three major venous injuries. Other complications were extensive deep vein thrombosis (DVT) (2%), debilitating lymphedema (0.5%), wound seroma/hematoma requiring treatment (2%), wound infection (3%), and hospital readmission within 60 days (8%). Multilevel (>2 levels) disk exposure was associated with a significantly increased rate of lymphedema, posterior lumbar wound infection, and hospital readmission. In patients with BMI values greater than 30, there were statistically significantly higher rates of postoperative DVT, posterior lumbar wound infection, and hospital readmission within 60 days.

This review demonstrated that the overall incidence of major vessel and nonvessel injury complications associated with anterior thoracolumbar spine exposure was low. Redo anterior spine exposure as well as redo disk exposure procedures, including those that require hardware removal, can be performed safely. However, multi-disk level exposure was associated with an increased incidence of lymphedema, posterior lumbar wound infection, and hospital readmission within 60 days. ALIF and ATIF in patients with BMI values greater than 30 should be approached with caution because of the significantly higher rates of DVT, posterior lumbar wound infection, and hospital readmission within 60 days in such patients.

POSTOPERATIVE MANAGEMENT AND FOLLOW-UP

Postoperative management is relatively straightforward and primarily is focused on initial rehabilitation for the spine. The retroperitoneal approach for ALIF facilitates early return of normal bowel function and minimizes pulmonary problems.[4,18,19] Paramedian and flank incisions are generally well-tolerated, and subcuticular wound closure minimizes postoperative wound care. Intercostal nerve block is often helpful to improve lung excursion, cough, and deep breathing for the patient undergoing thoracic spine exposure. This maneuver has little downside regarding the risk for pneumothorax because there is already an ipsilateral chest tube in place. Also, such a block enables patient activity to be rapidly progressed during the early postoperative period, so most patients can be discharged to home in 4 or 5 days. Transversus abdominis plane (TAP) block is another, relatively new, regional anesthetic technique that can be used to block sensation to the anterior abdominal wall and decrease postoperative pain after ALIF.[25] Our initial experience with this technique has been encouraging from the perspective of increasing patient mobility as well as decreasing postoperative pain and number of in-patient hospital days.

From the vascular surgeon perspective, the majority of the work associated with spine exposure is immediately preoperative, involving discussion of the surgical approach and potential complications, and intraoperative, to give the spine surgeon unobstructed anterior exposure of the spine. In our practice, intensive postoperative follow-up is usually conducted on an as-needed basis, because there are few to no long-term vascular problems requiring continued care, except in the occasional patient in whom DVT, severe lymphedema, or a chronic wound problem develops.

The management of vascular disease has undergone a major evolution. A decade ago, whenever vascular intervention was deemed necessary, open vascular surgery was the norm. However, with advances in catheter-based technology, endovascular therapy is now the first option in most clinical situations. Endovascular intervention is less invasive, and patient recovery is rapid. The limitations of endovascular therapy are related to specific anatomic considerations and questions of durability.

Open vascular surgery traditionally offered the "gold standard" with respect to durability and efficacy. However, it was associated with the typical morbidity and mortality of all open surgical procedures. These drawbacks included complications of general anesthesia (when used), the physiologic changes of clamping and unclamping major vessels, the significant intraoperative blood loss and fluid shifts in vascular procedures, and the impact of various types of skin, abdominal, and thoracic incisions.

With the goal of decreasing the morbidity of vascular interventions, the shift toward endovascular procedures is well justified. When an endovascular intervention is anatomically challenging, hybrid procedures that combine open vascular

surgery and endovascular techniques can be used to modify the anatomy so that endovascular intervention is possible. For example, a bypass to the common iliac artery or aorta may be constructed to allow the safe passage of a large stent-graft for endovascular thoracic aortic aneurysm repair in a patient with a small or occluded iliac artery. Similarly, debranching procedures, such as iliorenal and iliomesenteric bypasses, in patients with suprarenal aortic aneurysms or carotid-subclavian and carotid-carotid bypasses in patients with thoracic aortic aneurysms can provide a landing zone during the endovascular treatment of a thoracoabdominal or thoracic aortic aneurysm.

Despite advances in endovascular technology and the increase in the number of endovascular interventions, open vascular reconstructions will continue to play a significant role in the management of patients with vascular disease for the foreseeable future.

BASIC PRINCIPLES

The key elements of a successful open vascular reconstruction are choosing the right procedure and vascular exposure and then executing the selected procedure correctly. Appropriate choices for the source of inflow, the target for outflow, and the proper conduit, if needed, are critical for the success of any revascularization. This success also requires the appropriate instruments, graft, and suture materials. In addition, open vascular procedures should be performed under excellent lighting aided by magnifying loupes in select cases. For the operating surgeon, maintaining good ergonomic position during the reconstruction is essential to prevent significant work-related discomfort in the neck, shoulders, or back.

Vascular Instruments and Retractors

A vascular instrument tray typically includes vascular clamps, needle holders, forceps, scissors, and various retractors. Depending on the size of the vessel and the location of the surgical reconstruction, the instruments used will vary.

Clamps

Vascular clamps typically have jaws with rows of fine interdigitating serrations that allow clamping of the vessel without slippage or significant crush injury. Although vascular clamps are considered atraumatic, a vascular clamp applied inappropriately can cause significant intimal damage or may tear the artery if placed over a plaque in an inappropriate manner. Even in a soft, minimally diseased artery, a clamp applied with excessive force can damage the arterial wall and intima.

In general, clamps can be divided into those used for large, medium, or small vessels. They vary in shape and angulation to fit into specific anatomic locations, and they can be used as fully or partially occluding clamps. Clamps with special soft plastic inserts (e.g., Fogarty soft jaw) are also available to allow the clamping of prosthetic grafts without damaging the graft material. Types of vascular clamps and their suggested uses are outlined in Table 59.1. For smaller vessels and branches, various sizes of bulldog clamps or intracranial aneurysm clips,

TABLE 59.1 Vascular Clamps and Target Vessels

Clamp Type	Vessel
Totally Occluding	
DeBakey aortic aneurysm clamp (side-to-side apposition of aortic wall)	Supraceliac, infrarenal aorta
DeBakey-Bahnson aortic aneurysm clamp	Infrarenal aorta
Howard-DeBakey aortic aneurysm clamp with reverse curve shafts (side-to-side apposition of aortic wall)	Infrarenal aorta
Fogarty aortic clamp (side-to-side apposition of aortic wall)	Infrarenal aorta; aortic grafts, calcified aorta
DeBakey aortic aneurysm clamp (apposition of anterior and posterior walls together)	Infrarenal aorta
Lambert-Kay aortic clamp (apposition of anterior and posterior walls together)	Infrarenal aorta
Wylie hypogastric clamp	Iliac arteries, especially hypogastric arteries
DeBakey peripheral vascular clamp (angled handle)	Iliac arteries
DeBakey peripheral vascular clamp (angled jaw, 45 degrees)	Iliac and common carotid arteries
Henley subclavian clamp	Subclavian and common femoral arteries
Partially Occluding (Side-Biting)	
Lemole-Strong aortic clamp	Aorta; aortic grafts
Satinsky clamp	Aorta, vena cava
Cooley anastomosis clamp	Aorta; aortic grafts
Cooley-Derra clamp	Graft limbs
Cooley pediatric clamp	Common femoral artery, saphenofemoral junction
Self-Compressing (No Applicator Required)	
Gregory carotid "soft" bulldog	Small vessels
Potts bulldog—straight and angled jaw	Small vessels
DeBakey bulldog	Small vessels
Dietrich bulldog	Small vessels
Self-Compressing (Applicator Required)	
Yasargil aneurysm clip	Small vessels and branches
Heifitz clip	Small vessels and branches
Kleinert-Kutz clip—straight, angled, curved	Microvascular anastomoses
Louisville microvessel approximator	Microvascular anastomoses

such as the Yasargil or Heifitz clips, are available (see e-Figs. 59.1–59.12).

Needle Holders, Forceps, and Scissors

Needle holders of various lengths and shapes are available. The choice of needle holder is often dictated by the size of the needle used. A Mayo-Hegar needle holder is typically used with large needles, and Castroviejo needle holders are typically used with small, fine vascular needles (see e-Fig. 59.13).

The forceps used during vascular procedures typically have very fine, noncrushing jaws, exemplified by the DeBakey forceps. However, similar to vascular clamps, vascular forceps can crush a vessel wall if they are not used appropriately and delicately. Fine-tip ring forceps or Jarrell forceps are very useful during the construction of vein bypasses to infrapopliteal vessels. Metzenbaum and Church scissors are used for the dissection of blood vessels. Stevens tenotomy scissors with sharp tips are used for dissecting tibial vessels. Special Potts scissors with various angulations are used to enlarge and shape arteriotomies and venotomies. Right-angle clamps with various tip sizes are used to encircle blood vessels and branches (see e-Figs. 59.14–59.19).

Retractor Systems

Retractors can be self-retaining or handheld. Self-retaining retractors should be used whenever possible. The Omni-Flex vascular retractor (Omni-Tract Surgical, St. Paul, Minnesota) is frequently used for open aortic surgery, whether transabdominal or retroperitoneal (see e-Fig. 59.20). This retractor system consists of a wishbone that attaches to a post mounted on the operating room table rail, and it typically offers a selection of blades with different depths, widths, and shapes that can be clamped to the wishbone. Shallow, wide blades are typically used to retract the abdominal walls, whereas deeper splanchnic blades may be used to retract the splenic flexure and other parts of the colon. A wide, fence-shaped blade is typically used to retract the small bowel during aortic dissection, and a narrow, deep blade may be used to retract the left renal vein cephalad. This retractor system is useful during thoracoabdominal aortic aneurysm repair. Modifications of this retractor have also been designed for inguinal, carotid, and spine exposures.

Another self-retaining abdominal retractor is the Bookwalter retractor (Codman Johnson & Johnson, Raynham, Massachusetts; see e-Fig. 59.21). This retractor is often used when conducting abdominal aortic replacement through mini-laparotomy incisions. The retracting blades in the Bookwalter retractor attach to an oval metal ring placed around the abdominal incision instead of a wishbone.

Several single-instrument self-retaining retractors are available for neck and extremity procedures (see e-Figs. 59.22–59.24). The Weitlaner retractor is commonly used for inguinal and popliteal incisions. The Adson cerebellar retractor is angled such that it can also be very useful in groin and below knee exposure. In obese patients with significant inguinal pannus, a Miskimon retractor can be especially useful because of its deeper and wider blades, which provide a larger retracting area. Spring retractors are extremely useful when conducting infrageniculate vessel exposure because they tend to occupy little space. The Gelpi retractor is typically helpful when conducting a first rib resection through a transaxillary approach for thoracic outlet obstruction.

Vascular Sutures and Grafts

Sutures

Nonabsorbable sutures are used for vascular anastomoses and repairs. These sutures typically provide the tensile strength necessary to juxtapose and secure the vessels together until healing is completed. When prosthetic conduits are used in vascular reconstruction, the tensile strength provided by the sutures is needed indefinitely to maintain vascular integrity. Currently, monofilament sutures are most commonly used for vascular reconstructions, although some surgeons still prefer braided polyester multifilament sutures. Vascular sutures are usually double-armed with a needle on each end to allow continuous suturing in both directions from the initial knot.

Commonly used monofilament sutures include polypropylene, polybutester, and polytetrafluoroethylene (PTFE). Polypropylene sutures (Prolene, Ethicon Inc., Somerville, New Jersey; Surgipro and Surgilene, Covidien, Mansfield, Massachusetts) are made of a monofilament strand of synthetic linear polyolefin. These sutures tend to maintain their tensile strength over time. They have little friction and excellent handling characteristics. They are widely popular and are probably the most commonly used suture material in vascular reconstructions. Polybutester is another type of monofilament suture made of a copolymer of polyglycol terephthalate and polytrimethylene terephthalate coated with polytribolate to reduce drag and improve tissue passage. PTFE sutures were developed to minimize the needle hole bleeding that is often seen when polypropylene sutures are used with PTFE grafts or patches. They are designed so that there is minimal difference in the diameters of the needle and the suture. They have excellent handling characteristics, with a low tissue friction and low drag coefficient. The needle and suture sizes vary, depending on the vessel. Suggestions are provided in Table 59.2.

Grafts

Selection of a graft type is an integral part of any vascular reconstruction. Polyester grafts of different shapes and structures are available to replace the thoracic aorta. Polyester and PTFE grafts are available as conduits for the abdominal aorta and infrainguinal vessels. Autogenous vein grafts are favored in many small arterial reconstructions. These grafts are discussed in detail in Chapters 92, 93, and Chapter 94.

BASIC VASCULAR TECHNIQUES

Open vascular surgery is conducted using the general principles of blood vessel exposure with proximal and distal control, along with the basic techniques of vascular reconstruction. These basic vascular techniques include thromboembolectomy, endarterectomy, creation and closure of an arteriotomy, and construction of bypasses or in-line graft replacement using end-to-side or end-to-end anastomoses.

Vascular Exposure and Dissection

An exhaustive discussion of specific vascular exposures is beyond the scope of this chapter; these are addressed in greater detail in procedure-specific chapters. Several excellent resources are also available that describe the vascular anatomy and the variety of exposures available to the vascular surgeon.[1-4]

Initial Vessel Exposure

The basic concept of vascular exposure and dissection is to approach and expose the vessels by the most direct and shortest route possible. Selection of the surgical approach and incision should take into consideration the possibility that the operation may become more complex than originally anticipated, and that surgical control and reconstruction may occur at a more proximal or distal location. Anatomic landmarks, location of the pulse, or a combination of the two is typically used to guide placement of the initial skin incision. In most cases, the vascular structures can be exposed by dissection between existing muscle bellies. If dissection requires extensive muscle transection, the approach to the vascular structures should be reconsidered.

Following incision, proper handling of the skin and soft tissue overlying the vessels is essential to prevent significant wound complications. Lymphatics are typically ligated and divided to avoid lymphorrhea and lymphocele. Use of electrocautery through lymph nodes should be avoided to prevent significant lymph leak or the need to excise lymph nodes, leaving dead space in the wound.

Once the vascular sheath is identified and incised, the adventitia is held and retracted in one direction, and dissection is carried out in the tissue adjacent to the edge of the blood vessel wall. By staying close to the adventitia, the dissection can be maintained in the correct areolar anatomic plane, and the vessel can be circumferentially dissected and encircled with a Silastic loop or umbilical tape (Dow Corning Corporation, Midland, Michigan). The basic surgical technique of traction with countertraction is essential in vascular exposure. Traction on a vessel loop is often used to retract a vessel during dissection or mobilization. Gentle tension on the vessel loop is recommended to prevent injury to the intima.

"Redo" Vessel Exposure

"Redo" vascular exposure poses a unique challenge, given the fibrous obliteration of the normal anatomic vascular planes. When the surgeon is faced with a "redo" operation, sharp dissection with a No. 15 knife blade may allow better management of the scar tissue than scissor dissection, and it may allow the surgeon to stay in the appropriate dissection plane. An inadvertent arteriotomy caused by a small blade may be easier to repair than arterial disruption caused by dissecting scissors. The most common vessel that requires "redo" exposure is the common femoral artery, and the approach to this vessel is illustrative of "redo" vessel exposure in general.

The principle of dissecting from known to unknown can be useful in preventing branch vessel injury during reexposure and to obtain proximal control outside of the scarred area to aid in vascular control, should an inadvertent injury occur. A significant concern with a "redo" femoral artery exposure is injuring the profunda femoris artery. Consequently, the superficial femoral artery is exposed in the most distal part of the incision, where minimal scarring exists. The dissection is then carried along the medial aspect of the superficial femoral artery and progresses proximally. Typically, the common femoral vein is identified during the process, revealing a safe dissection plane. Once the inguinal ligament is reached, the common femoral artery is encircled with a loop. The direction of the dissection is then reversed and continued back distally toward the superficial femoral artery. The area of size transition between the common and superficial femoral arteries exposes the location of the profunda femoris artery. At that level, dissection from the medial and posterior aspect of the common femoral artery identifies a plane that has not been violated and allows dissection of the profunda femoris artery from underneath the common femoral artery. The profunda femoris artery is controlled at its origin by passing a vessel loop underneath the superficial femoral artery and then retrieving it just proximal to the common femoral bifurcation. In cases of extensive scarring, the profunda femoral branch can be controlled with a balloon occlusion catheter after common femoral arteriotomy, to avoid potential injury during profunda dissection.

Anticoagulation

Before interrupting blood flow, the patient must be adequately anticoagulated. Unfractionated heparin at 75 to 100 U/kg is typically administered intravenously, approximately 5 minutes before blood flow interruption. We recommend that the

anticoagulation be monitored by measuring the activated clotting time (ACT), aiming for a value of more than 250 seconds.

Distal limb ischemia following aortic reconstruction or other types of vascular procedures is a dreaded complication and is often attributed to distal embolization. However, an important factor in this complication is unrecognized suboptimal anticoagulation. Hence it is important to maintain adequate anticoagulation throughout the period of blood flow interruption by re-dosing with heparin when necessary, using the ACT for guidance. In patients with known heparin-induced thrombocytopenia, anticoagulation may be achieved with intravenous thrombin inhibitors such as argatroban (see Chapter 35).

Blood Vessel Control

Blood vessel control can be achieved using vascular clamping, balloon occlusion, vessel loops, pneumatic tourniquet, Rumel tourniquet, or internal occluders.

Vascular Clamping

Ideally, vascular clamps should be applied to a disease-free segment of the artery. Palpating the artery against a right-angle clamp can help determine the presence and extent of atherosclerotic plaque, which is often in a posterior location and not appreciated by only palpating the anterior aspect of the artery. In the presence of significant plaque, the artery should be dissected more proximally to identify a less diseased site for clamping. This situation is often encountered when clamping the common femoral artery, where plaque often extends to the level of the inguinal ligament. Further dissection proximal to the external iliac circumflex and inferior epigastric branches, however, usually reveals an external iliac artery that is soft and free of disease. If clamping is necessary across an area of diseased artery, the clamp should be applied in a manner that opposes the soft part of the artery against the plaque without causing plaque fracture or vessel tear.

Occasionally the plaque burden and calcification are so extensive that the only option is to identify a more proximal location for safe clamp placement. One example is supraceliac aortic control through the lesser sac, when clamping in the infrarenal or suprarenal location is not possible because of extensive calcification or scarring from previous surgery or an inflammatory process.

Balloon Occlusion

If the plaque is circumferential or occupies more than 50% of the circumference, vascular clamps can fracture the plaque or tear the wall, and may not provide vascular control. This can be managed by occluding the artery from within using a compliant balloon occlusion catheter, such as the Fogarty catheter normally used to perform embolectomy, or a noncompliant balloon catheter used for angioplasty. There are also several compliant occlusion balloons that can be used to occlude the aorta during ruptured aneurysm repair, including Reliant (Medtronic, Minneapolis, Minnesota), Coda (Cook, Bloomington, Indiana), and Equalizer (Boston Scientific, Natick, Massachusetts). Balloon occlusion can be used to control the external iliac artery in the presence of extensive calcification that extends beyond the most proximal part of the exposure. It is also useful for controlling the right common iliac artery during a left retroperitoneal abdominal aortic aneurysm repair, the profunda femoris artery during repair of a pseudoaneurysm of a femoral anastomosis, or the renal or visceral vessels during a thoracoabdominal aortic aneurysm repair.

Vessel Loops

Vessel loops are ideal for controlling small- to medium-sized vessels, such as the profunda femoris or popliteal arteries and arterial branches. Silastic vessel loops can be traumatic, however, if excessive tension is applied to them. A double loop, or Potts technique, can be helpful in the use of vessel loops by minimizing the tension required to obtain vascular control of small- or medium-sized arteries. Further, excessive tension on Silastic vessel loops for simultaneous proximal and distal control of a vessel may make an anastomosis or repair more difficult to construct. One way to avoid excessive tension on the artery in two opposing directions is to apply a vessel loop on the proximal side of the artery and a small Yasargil aneurysm clamp or bulldog clamp on the distal end of the artery (Fig. 59.25).

Pneumatic Tourniquet

A pneumatic tourniquet can be used for vascular control in the extremities and is ideal for infrapopliteal reconstructions. It allows for minimal exposure, dissection, and handling of the arteries, and may decrease the risk of spasm or injury caused by clamping of the tibial vessels. The tourniquet can be placed around the thigh or below the knee; usually a soft roll is applied first, followed by the tourniquet. The leg is elevated, and an Esmarch compression wrap is used to wrap the leg from the foot in a cephalad direction expelling the venous blood from the leg. The tourniquet is then inflated to a pressure of about 250 or 100 mm Hg above systolic pressure. It is essential to make sure the graft is well aligned and to mark the graft orientation before inflating the tourniquet. Bleeding occasionally occurs

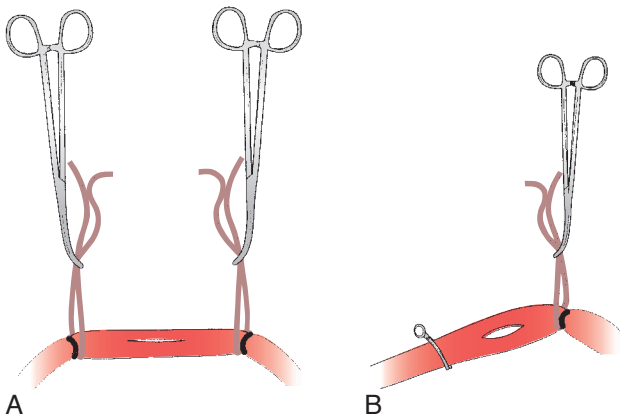

Figure 59.25 A vessel loop on the proximal side of the artery and a small Yasargil aneurysm clamp or bulldog clamp on the distal side of the artery can minimize tension on the anastomosis. (A) Pulling on both loops can result in tension on the arteriotomy. (B) Tension on the anastomosis is minimized when one loop is pulled and the other replaced with a bulldog clamp.

despite the tourniquet, and this can sometimes be controlled by increasing the pressure in the tourniquet. An additional clamp on the profunda femoris artery can also help control persistent bleeding. Sometimes calcified and incompressible arteries at the tourniquet site prevent this technique from completely controlling bleeding at the distal arteriotomy.

Other Techniques

Rumel tourniquets can be used for vascular control, but they can cause arterial wall damage in the presence of significant plaque. The Rumel tourniquet may be most useful during an endovascular aortic aneurysm procedure when there is a large sheath in an artery and persistent bleeding from the arteriotomy around the sheath. Cinching the sheath with a Rumel tourniquet at that level can control the bleeding. Pediatric Rumel tourniquets are useful to atraumatically secure carotid intraluminal shunts to control blood leak around the shunt, keeping blood flow to the brain while carotid endarterectomy is being performed.

When dealing with tibial vessels, direct clamping of the arteries should be avoided to prevent intimal injury or spasm. The use of internal coronary artery occluders in this setting can be useful to achieve vessel control. Florester internal vessel plastic tip occluders (Biovascular, St. Paul, Minnesota) are available in various sizes. However, the surgeon must be comfortable using such occluders, and oversizing should be avoided to prevent intimal damage during insertion.

THROMBECTOMY AND THROMBOEMBOLECTOMY

Basic Considerations

Thrombectomy and thromboembolectomy must be mastered by every vascular surgeon because the need to perform these procedures is inevitable. Even the most successfully performed open or endovascular procedure can be complicated by a distal embolic or a thrombotic event. Although numerous techniques are available to achieve pharmacologic or mechanical thrombectomy, the need for balloon thrombectomy cannot be completely avoided. Balloon thrombectomy allows the removal, inspection, and pathologic examination of the occlusive clot and restores blood flow expeditiously.

A vessel may become acutely occluded because of a thrombotic or embolic process. Thrombosis frequently occurs proximally and distally to the embolus because of the stagnant flow—hence the term *thromboembolectomy*. Balloon embolectomy is often paired with thrombectomy to remove the thrombus. Several issues need to be addressed during the performance of a thromboembolectomy procedure, including the location and shape of the arteriotomy used to extract the thrombus, selection of the thrombectomy catheter, and performance of the procedure with minimal blood loss and injury to the arterial system. In addition, steering the catheter into the appropriate location and extracting all the offending thrombi are essential to the success of the procedure.

Thromboembolectomy Catheters

A wide variety of thromboembolectomy catheters are available (see e-Figs. 59.26 and 59.27). The standard ones are balloon catheters that vary in size, length, and maximal balloon inflation. These catheters are typically available in sizes from 2 to 7F. Saline solution is used to inflate the balloon, except for the 2F balloon, which requires air insufflation for easy deflation. The diameter of the fully inflated balloon is 4 mm for the 2F catheter, 5 mm for the 3F, 9 mm for the 4F, 11 mm for the 5F, 13 mm for the 6F, and 14 mm for the 7F.

Size 2F catheters are typically used for very small pedal or hand vessels. The most commonly used catheters are 3 to 5F catheters. A 3F Fogarty catheter is typically used for tibial vessels. A 4F Fogarty catheter is used for vessels the size of the superficial femoral and popliteal arteries; it can also be used for external iliac arteries. A 5F Fogarty catheter is typically used for external iliac or common iliac arteries. Size 6F and size 7F catheters can be used for thrombectomy of an aortic femoral graft or a saddle aortic embolus. A venous thrombectomy catheter with a large, lower pressure balloon is also available.

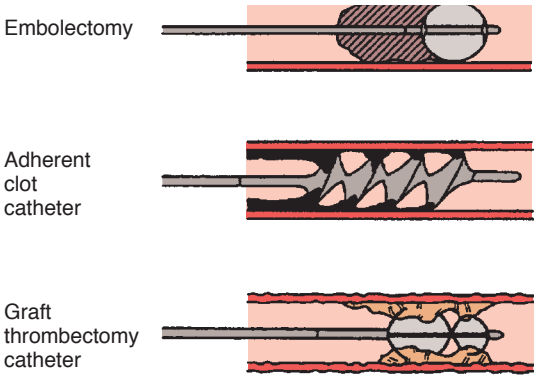
Standard balloons are made of latex; however, latex-free embolectomy catheters are available for patients with latex allergies. In addition, balloon catheters that can be introduced over guide wires for fluoroscopically assisted thromboembolectomy are also available in sizes 3, 4, 5.5, 6, and 7F.

Special catheters have been devised for adherent clots. The Fogarty adherent clot catheter (Edwards Life Sciences, Irvine, California) features a spiral-shaped, latex-covered stainless steel cable that assumes a corkscrew shape when retracted, thus expanding the surface area to entrap fibrous material. It is marketed for adherent clots resistant to removal by standard elastomeric balloons in both native arteries and synthetic grafts. The Fogarty graft thrombectomy catheter (Edwards Life Sciences) is designed to remove tough thrombus from synthetic grafts; it has a flexible wire coil at the distal end and expands when retracted to form a double-helix ring that acts as stripper, forming a plane between the graft and the adherent material. This catheter is not intended for native vessels and is marketed for use in PTFE dialysis grafts and aortobifemoral grafts (see e-Fig. 59.28).

Technique

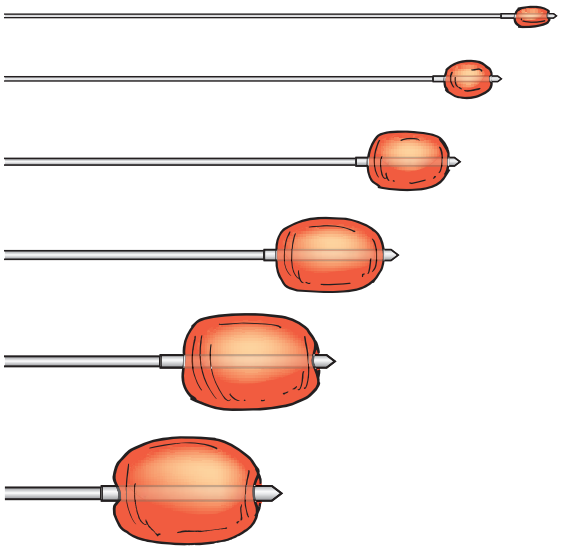
Arteriotomy Location and Shape

The balloon embolectomy catheter is designed to extract thrombi from a site remote from the clot's location. The arteriotomy for clot extraction can be performed in a location proximal or distal to the embolic or thrombotic process. Site selection depends on the ease of exposure, anticipated location of the thrombus, and ease of arteriotomy closure. In patients with acute lower extremity ischemia, the common femoral artery is an ideal site for clot extraction. A patient with an aortic saddle embolus or a popliteal embolus can be managed by thromboembolectomy through the common femoral artery. The common femoral artery and its bifurcation are easy to expose, and closure of the arteriotomy is easily accomplished in this relatively large artery. Further, the procedure can be performed under local anesthesia.



e-Figure 59.26 Thromboembolectomy catheters.

e-Figure 59.27 Thromboembolectomy catheters—diagram.



e-Figure 59.28 Fogarty catheters.

If thromboembolectomy proves to be inadequate, a site closer to the location of the thrombus may be required. Before performing the thrombectomy, it is important to ensure that the patient is adequately anticoagulated.

The selection of a transverse versus longitudinal arteriotomy for catheter access is influenced by the size of the vessel, the cause of the embolus or thrombus, and the presence of plaque in the vessel. A transverse arteriotomy is usually simpler to close and may be preferred when dealing with an embolic process. When the occlusive pathology is due to an atherosclerotic and thrombotic process, or when significant arterial plaque is present, a longitudinal arteriotomy should be used. In such a situation, it is not uncommon for an emergency bypass to become necessary, and the longitudinal arteriotomy can be incorporated into one of the anastomoses. If a bypass is deemed unnecessary, a patch is usually needed to close the longitudinal arteriotomy to avoid significant narrowing of the vessel lumen. Transverse arteriotomy can be easily closed with interrupted sutures to avoid purse-stringing and narrowing of the lumen of the artery at the site.

Minimizing Blood Loss

During the process of establishing inflow, a balloon catheter is passed proximally for an estimated distance, inflated, and withdrawn through the arteriotomy (Fig. 59.29). As the balloon exits the arteriotomy, the surgeon typically allows brief but unrestricted bleeding to flush any debris or thrombi that may still be present in the proximal part of the vessel or the graft. This step can be repeated once or twice to ensure there are no remnants of clot in the artery. A significant amount of blood can be lost in this process. This can be decreased by applying Silastic double-looped vessel tape around the artery and pulling on the loop while the catheter is being advanced proximally or distally. One technique can be used to avoid excessive blood loss; balloon thrombectomy can be repeated to clean up the artery while leaving the most proximal portion of the clot intact holding blood flow. Then, in the final pass, that proximal portion is removed, allowing a vigorous jet of blood to flush the artery for a brief period with a limited amount of blood loss.

When performing thromboembolectomy of a prosthetic bypass or the limb of an aortobifemoral bypass, vessel loops are not adequate to control bleeding. The surgeon can often control bleeding manually by squeezing the arterial wall between the index finger and thumb with one hand and withdrawing the inflated catheter with the other hand. Depending on the anatomy and the presence of scarring, bleeding may be excessive if finger control is used while passing the Fogarty catheter through the proximal artery. In such situations, use of a Fogarty soft-jaw clamp is recommended (Fig. 59.30). The soft jaws are intended to appose the blood vessel walls just enough to prevent bleeding and still allow the thromboembolectomy catheter to be advanced or withdrawn. The jaws are then opened as the inflated thromboembolectomy catheter is being withdrawn. The clamp is reapplied once the balloon catheter is pulled out of the vessel and vigorous blood flushing has occurred.

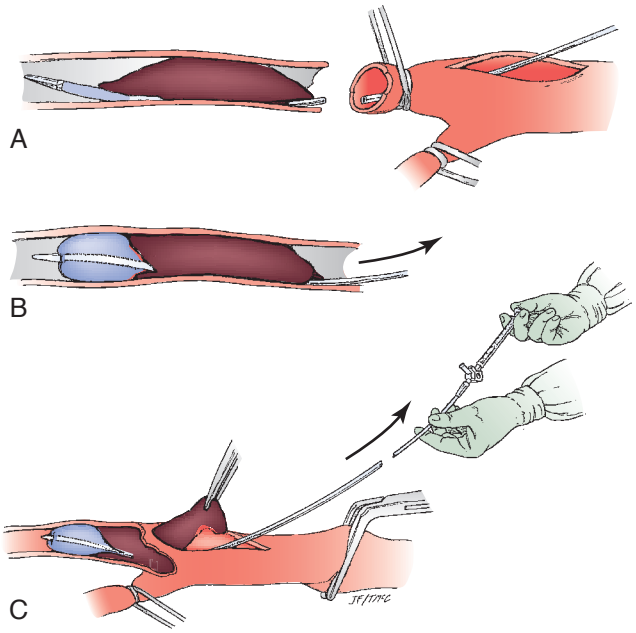


Figure 59.29 A balloon thromboembolectomy catheter is passed proximally for an estimated distance (A), inflated (B), and withdrawn through the arteriotomy, with bleeding controlled by double-looped Silastic tape (C).

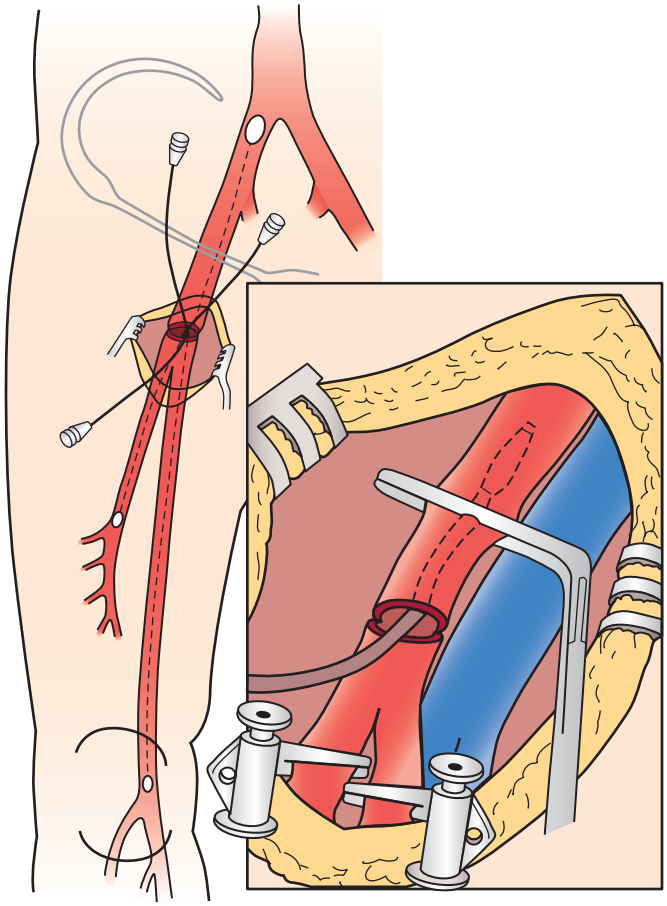

Figure 59.30 The Fogarty soft-jaw clamp may be able to appose the blood vessel walls just enough to prevent bleeding and still allow manipulation of the thromboembolectomy catheter.

Minimizing Vascular Injury

Significant vascular injury can occur from thromboembolectomy and inappropriate manipulation of the balloon catheter. Vascular injury can occur from inadvertent placement of the balloon tip or from excessive inflation of the balloon itself. Injury can also occur during insertion, advancement, or withdrawal of the thromboembolectomy catheter. During insertion, it is important to ensure that the catheter is being advanced intraluminally. It can inadvertently pass in a subintimal plane, and inflation and withdrawal of the catheter in that situation can cause arterial dissection or disruption. Injury is also possible because the procedure is commonly performed blindly or without fluoroscopic control. Hence it is very important to perform the procedure gently and be cognizant of any resistance during passage of the catheter. If the catheter does not advance freely, it may pass into a side branch or abut a curve in the artery. Further forceful advancement can result in either perforation or penetration into the subintimal plane.

Another cause of injury is overinflation of the balloon catheter and its withdrawal; this can result in significant shearing of the intima, with intimal disruption and damage. This technique has long been used to experimentally induce intimal damage or to harvest endothelial cells in animal models. Balloon overinflation can also result in rupture of the vessel or pseudoaneurysm formation.

To minimize vascular injury during balloon thromboembolectomy, several steps are necessary. Selection of an appropriately sized thromboembolectomy catheter is a must. Before inserting a thromboembolectomy catheter, it is important to test the balloon, visualize its size, and get a feel for its inflation. It is a good practice to limit the fluid used in the syringe to inflate the balloon to the minimum amount needed for full inflation. This protects against overinflation of the balloon when it is in the vessel. Another helpful maneuver is to externally measure the distance from the arteriotomy to the location of the thrombus. This helps determine whether the catheter has reached its desired destination. In addition, it may help limit unnecessary pushing of the catheter beyond the thrombus.

Once the catheter has reached its maximal advancement or the desired location, the balloon is gently inflated while the catheter is slowly withdrawn until tactile friction is sensed by the surgeon. At that point, the balloon should not be further inflated. The catheter is then retrieved, maintaining the same amount of friction and tension. The balloon may have to be further inflated as the catheter is being pulled into a more proximal location, where the artery's caliber may increase. The inflation, deflation, and withdrawal of the balloon should be a dynamic and variable process to accommodate changes in vessel caliber.

Fluoroscopy-Guided Thromboembolectomy

To achieve successful thromboembolectomy, the catheter should be advanced to the desired location distal to the occluding thrombus and then used to retrieve the thrombus. Once no more thrombus can be retrieved, the arteriotomy can be closed, especially if distal vessel backbleeding is present. However, the presence of adequate backbleeding does not ensure complete thromboembolectomy. A significant intraluminal thrombus burden may still exist despite multiple balloon passes and the presence of generous backbleeding. This is especially true when performing thromboembolectomy of the infrapopliteal vessels. The catheter may repeatedly pass into the peroneal artery, while significant thrombus remains in the anterior and posterior tibial arteries.

To avoid leaving behind clinically significant thrombus, the reperfused limb or organ is carefully examined following arteriotomy closure. An angiogram may be obtained if the reperfusion does not appear satisfactory. It may also be obtained before closing the arteriotomy to assess the completeness of the thromboembolectomy. Another option is to perform the thromboembolectomy procedure under fluoroscopic guidance.[5] Fluoroscopy can be used from the start of the procedure, or it can be used selectively to retrieve thrombi that cannot be extracted with non-image-guided thromboembolectomy.

Thromboembolectomy under fluoroscopic guidance can be educational even for a seasoned vascular surgeon. The balloon is first tested under fluoroscopy to appreciate its shape when inflated and deflated, and an angiogram through the arteriotomy can be performed before passing the Fogarty catheter. This may allow a better understanding of the anatomy and the location of the thrombus. Visualizing the catheter as it travels down the leg provides significant information about its location and course. When the balloon is inflated under fluoroscopy, the surgeon can appreciate the degree of inflation required. To best image the balloon, it should be inflated using contrast material diluted to 25%. Overinflation can be avoided, and inadvertent positioning of the catheter into a side branch before balloon inflation can be detected and corrected. Further, if the catheter passes through an area of stenosis, a change in the shape of the inflated catheter indicates the location of the stenosis.

When performing an infrapopliteal thromboembolectomy, the catheter can be directed into the desired tibial vessel by bending its tip and rotating it into the desired location. One approach is to use two balloon catheters; one is inflated at the origin of the tibioperoneal trunk, forcing the second one toward the anterior tibial artery (Fig. 59.31). Another technique is to use a 7 or 8F multipurpose guiding catheter, and park the catheter tip at the level of the popliteal trifurcation. The balloon catheter is introduced through the guiding catheter, and using the curve of the guiding catheter, the balloon catheter is directed into the desired location. The balloon is inflated and withdrawn together with the guiding catheter.

Another approach is to use over-the-wire balloon embolectomy catheters. Standard endovascular techniques are used to introduce a wire into the desired vessel, followed by advancement of the thromboembolectomy balloon over the wire. The 5.5F catheter can be advanced over a 0.035-inch wire; the 3F catheter, which is typically the size needed for tibial vessels, is passed over a 0.018-inch wire. The process of withdrawing the catheter over the wire may be frustrating, because often the wire is dislodged and pulled at the same time as the catheter.

The main drawback of thromboembolectomy under fluoroscopic guidance is the inconvenience of using fluoroscopy,

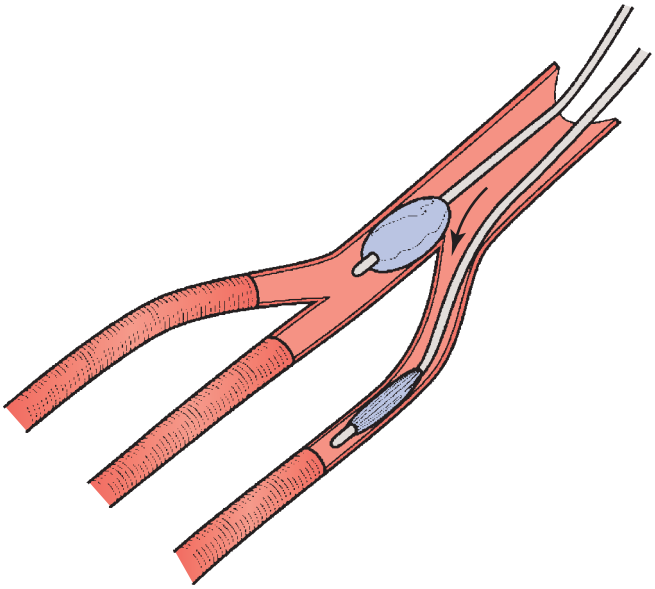

Figure 59.31 One approach to guide the thromboembolectomy catheter into the anterior tibial artery is to use two balloon catheters, inflating one at the origin of the tibioperoneal trunk and thus forcing the second one toward the anterior tibial artery.

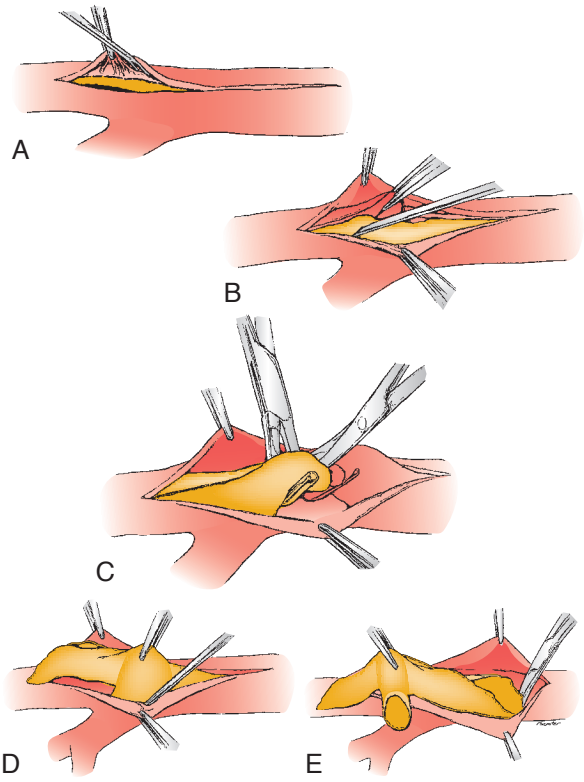

Figure 59.32 (A–E) In the open endarterectomy technique, the vessel is opened longitudinally at the site of disease. The plaque is then separated from the vessel wall in the direction of the arteriotomy and removed.

especially if skilled radiology technicians are unavailable. However, the advantages of fluoroscopy are significant: it allows the performance of a controlled thromboembolectomy, and it allows the opportunity for endovascular intervention when appropriate, such as balloon angioplasty and stenting of a dialysis graft venous stenosis, distal anastomosis of a femoropopliteal bypass, or occlusive iliac pathology.

Thromboembolectomy in Specific Conditions

The approaches to thromboembolectomy in specific vessels and for specific conditions, such as infrainguinal ischemia, aortic saddle embolus, visceral ischemia, graft occlusion, and iliofemoral venous thrombosis, are available in Appendixes e59.1 and e59.2.

ENDARTERECTOMY

Endarterectomy is a basic vascular procedure that should be mastered by every vascular surgeon.

Basic Considerations

This procedure involves the removal of atherosclerotic plaques that compromise the arterial lumen. It can be performed as the sole therapeutic procedure or in combination with bypass or even an endovascular intervention. For example, carotid endarterectomy may be the sole intervention for occlusive disease at the carotid bifurcation and is one of the most commonly performed open vascular procedures. Similarly, endarterectomy of the common femoral and profunda femoris arteries may be the sole procedure to treat lower extremity occlusive disease. However, endarterectomy of the common femoral and profunda femoris arteries can also be included in the construction of the femoral anastomosis of an aortobifemoral bypass to ensure a nonobstructed outflow into the profunda femoris artery. Great care should be taken to achieve a smooth transition at the endpoint of the endarterectomy plane in the direction of arterial flow. "Tacking sutures" can be considered to secure such an endpoint. Endarterectomy can also be incorporated into the construction of the proximal anastomosis of an infrainguinal bypass. Similarly, a common femoral endarterectomy can be performed while the common femoral artery is used as an access to perform an endovascular repair of an abdominal aortic aneurysm. Endarterectomy usually results in removal of the thickened intima and inner media, leaving behind the outer part of the media and the adventitia. It should not be performed in an aneurysmal artery because the remaining adventitial layer is too weak and degenerated to withhold suturing or arterial pressure. Several methods of endarterectomy have been described. These include open, semiclosed, eversion, orificial, and extraction endarterectomy.

Open Endarterectomy

In the open endarterectomy technique, the artery is opened longitudinally at the site of disease. The plaque is then separated from the artery wall in the direction of the arteriotomy and removed (Fig. 59.32). The arteriotomy can be closed primarily or with a patch. Being in the right anatomic vessel wall plane is essential to performing an adequate endarterectomy. This

can be accomplished by holding the edge of the adventitia with a forceps and pulling it away from the plaque. A plane is then developed between the plaque and the media or adventitia. Using the Freer elevator, the outer media and adventitia is typically pushed away from the plaque. The endarterectomy plane is developed on each side of the vessel wall and advanced posteriorly until it becomes circumferential. When dissecting in the appropriate plane, the dissecting instrument meets little resistance. It is very important to stay in the same plane if the endarterectomy is approached from both sides of an artery to meet the same point posteriorly for a clean endarterectomy specimen. Proximally, when a normal part of the wall is reached, either the plaque "feathers out" or it is transected flush with the arterial wall without leaving a significant protruding edge.

Completion of the distal endpoint of the endarterectomy can be challenging. Often the plaque clearly ends as a tongue into a normal soft artery. In this case, the endarterectomy plane is moved to a more superficial level, allowing the plaque to feather out from the wall. This provides a desirable flat distal endpoint, with a very smooth transition from the endarterectomized to the nonendarterectomized surface. On other occasions, the plaque may extend farther distally, with no visible end. In that situation, transection of the plaque in the least diseased segment is necessary, which results in a shelf between the endarterectomized and nonendarterectomized surface of the wall. Suture tacking of the intima and plaque to the adventitia is necessary to avoid plaque lifting, dissection, or thrombosis upon vessel reperfusion. To place a tacking suture, one end of the suture is placed in the remaining plaque, 1 mm distal to the endpoint, and the other end is placed at the junction of the endarterectomy and the endarterectomized surface (Fig. 59.33). Multiple sutures are often required to adequately tack the plaque edge to the arterial wall. If the proximal endarterectomy plaque does not feather out and needs to be transected, the same tacking technique can be used. Some believe that tacking the proximal end is not necessary because the direction of blood flow does not lift or dissect the flap. However, if the proximal plaque is thick and protrudes into the lumen, it may warrant proximal tacking sutures.

Inspection of the completed endarterectomized luminal surface may reveal loose circular fibers in the media and other debris that can be peeled away in a circumferential manner. It is essential to create a debris-free surface area at the endarterectomy site before vessel closure and reperfusion. The endarterectomized surface can be very thrombogenic; this can be alleviated by the administration of antiplatelet agents before the procedure.

Semiclosed Endarterectomy

The semiclosed endarterectomy was designed to avoid opening the artery longitudinally for the full extent of disease and thus circumvent a long arteriotomy closure. Typically, the artery is opened in a proximal and a distal location. The plaque is first dissected and transected at the proximal level; then it is cored out as a cylinder from the intervening segment with special ringed intraarterial strippers, transected again at the level of the distal arteriotomy, and removed (Fig. 59.34). With this technique, closure of what would have been a long arteriotomy is replaced by closure of two small arteriotomies, one proximally and one distally.

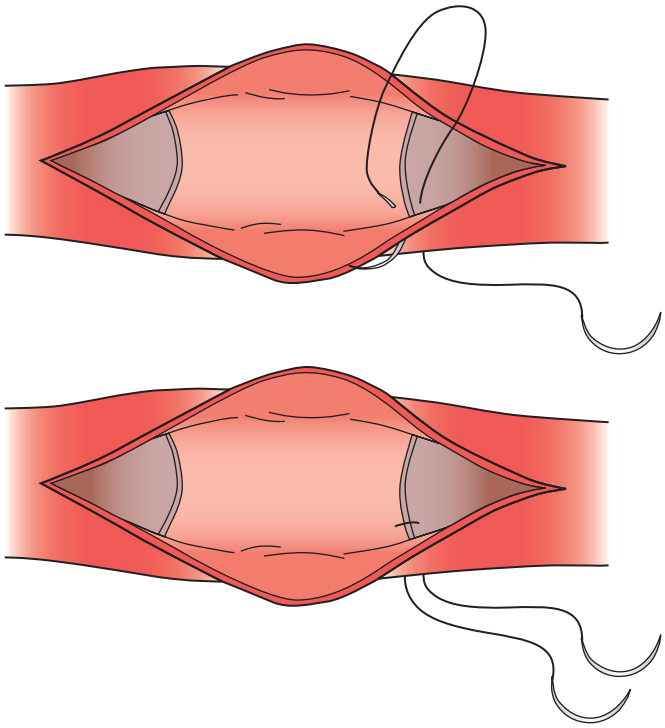

Figure 59.33 Endarterectomy plaque is tacked using multiple interrupted sutures, with one end of the suture placed 1 mm distal to the endpoint and the other end placed at the junction of the endarterectomy and the endarterectomized surface.

In one modification of the semiclosed technique, only one incision is made in the artery. The plaque is crushed manually or with the help of a clamp at the other end, eliminating the need for the second arterial incision, which is usually used to transect the plaque. Moll ring cutters allow sharp transection of the plaque from the remote site (Fig. 59.35)—hence the term *remote endarterectomy*. The disadvantage of this technique is the unpredictability of the endpoint. To address this concern, angioplasty with stent deployment can be performed to secure the distal endpoint. During this portion of the procedure, intravascular ultrasound is helpful to make certain that guide wires and therapeutic devices are intraluminally positioned. This technique has been successfully used in the external iliac and superficial femoral arteries.

Eversion Endarterectomy

In the eversion technique, the artery is transected, and the vessel wall is everted. The outer layer of the blood vessel, which includes the adventitia and part of the media, is held with forceps and gently lifted away from the plaque. The plaque core is developed circumferentially and held firmly with the forceps. As the plaque is being extracted from the artery, the adventitia is retracted backward, and the artery is pushed forward from within, causing the plaque to protrude and be separated from the outer arterial media and adventitia (Fig. 59.36). It is

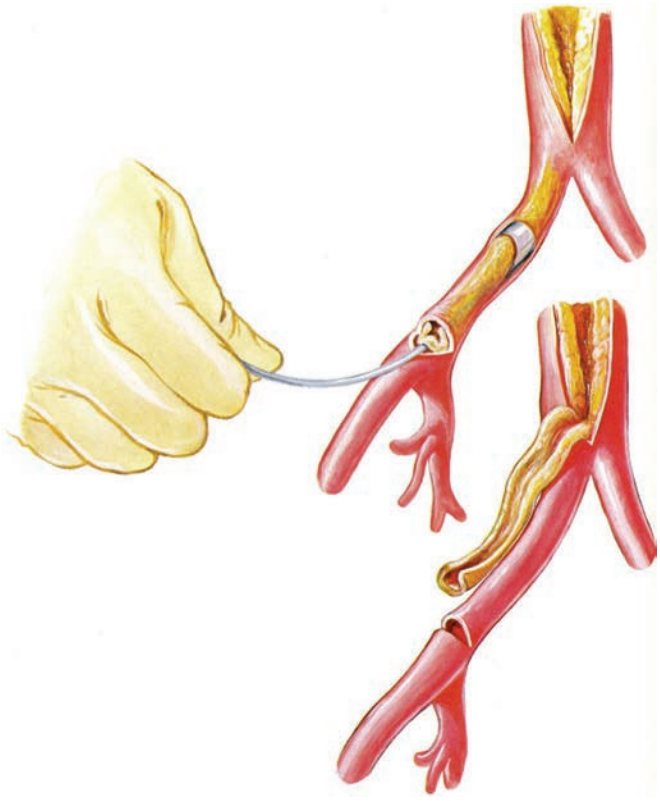

Figure 59.34 Plaque is cored out as a cylinder from the intervening segment, with the help of special ringed intraarterial strippers.

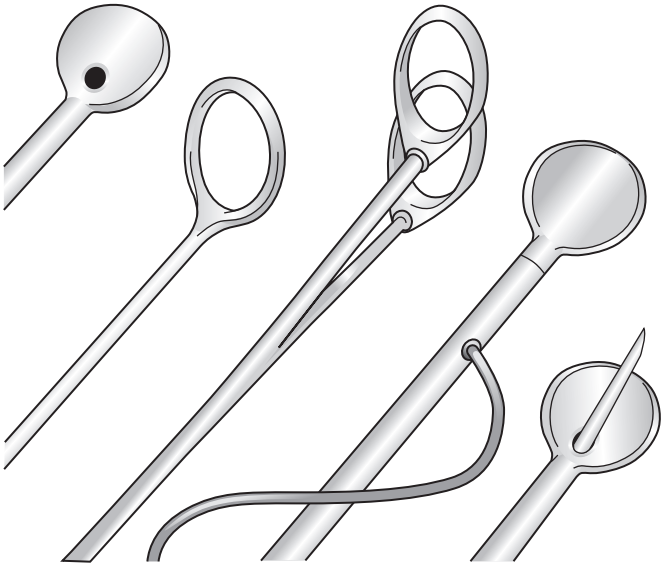

Figure 59.35 Moll ring cutters, spatula, and reentry needle system.

then transected when an appropriate endpoint is reached. This technique requires mobilization of a good segment of the proximal artery to allow eversion.

Orificial and Extraction Endarterectomy

Orificial endarterectomy is a modification of the eversion technique used to treat occlusive disease at the orifice of an

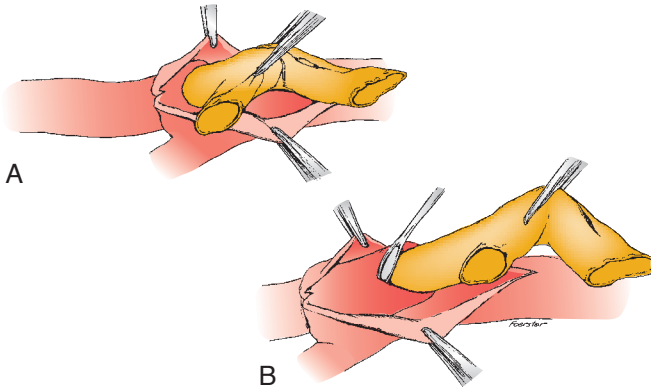

Figure 59.36 (A and B) As the plaque is being pulled out of the artery, the adventitia is retracted backward and the artery is pushed forward from within, causing the plaque to protrude and allowing it to be extracted from the artery.

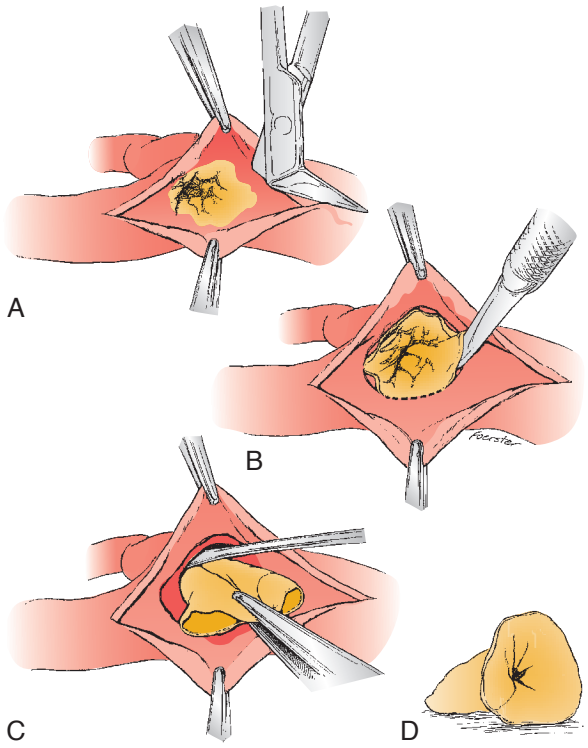

Figure 59.37 (A–D) Orificial endarterectomy is a modification of the eversion technique used to treat occlusive disease at the orifice of an artery.

artery. Typically the orifice of the artery has been exposed through the lumen of the vessel (Fig. 59.37). The plaque is extruded from the orifice by pushing the artery distal to the plaque toward the orifice in an everting manner.

In extraction endarterectomy, a clamp is introduced into the orifice and used to grab the distal plaque or plaque remnant and extract it from the lumen. Generally this technique is applicable only if the plaque ends a short distance beyond the orifice. Furthermore, because the endpoint is not under direct vision, it must be carefully assessed intraoperatively to ensure that a distal flap is not created after restoring blood flow. This is an especially important technique for establishing perfusion to the profunda femoris artery during femoral

thromboendarterectomy. However, if the plaque extends further into the profunda, the endarterectomy needs to be done under direct inspection by extending the incision onto the profunda, and then patching this artery. If the endarterectomy of the common femoral artery needs to be extended to the superficial and profunda femoris arteries, the adjacent walls of both arteries can be sutured together using a running suture to create a common channel, which is then patched. This technique of "syndactylization" can be used in any location where two adjacent branches need to be endarterectomized to avoid patching two arteries separately.

Endarterectomy in Specific Conditions

For approaches to endarterectomy in specific vessels and for specific conditions, such as carotid, arch, visceral, aortoiliac, and infrainguinal disease, see Appendixes e59.1 and e59.2.

ARTERIOTOMY CLOSURE

An arteriotomy can be closed either primarily or with a patch. The choice of a closure method depends on various factors, including the size of the artery, the direction and shape of the arteriotomy, and the degree of atherosclerotic involvement of the artery.

Primary Closure

Primary closure of an arteriotomy is a simple method that can be performed expeditiously. Most transverse arteriotomies in nondiseased arteries can be closed primarily. This can even be done in smaller arteries measuring 2 mm in diameter, such as a radial or posterior tibial artery. Similarly, primary closure can be performed in longitudinal incisions if the vessel is not diseased and has a diameter greater than 5 mm. A typical example is closure of a longitudinal arteriotomy in the common carotid artery or common femoral artery. Some narrowing of the lumen can be expected to occur with primary closure. Such narrowing should be minimal when the arteriotomy is transverse, but it can be significant if smaller arteries (<5 mm) are closed longitudinally.

Primary closure is most expeditiously performed using a continuous running suture technique (Fig. 59.38). A basic concept in the placement of arterial sutures during closure is to include all layers of the vessel wall. Adventitial fibers should be trimmed and not allowed to protrude into the lumen because they can be thrombogenic. The needle is preferentially introduced from the intimal side of the vessel toward the adventitial side, "inside to outside." In the presence of atherosclerotic plaque, a needle introduced from the adventitial side can push the plaque away from the arterial wall and create a site for dissection or thrombus formation.

In the continuous suture technique, the needle is introduced from the adventitial surface of one wall and then from the intimal surface of the opposite wall. For the reasons already cited, it is important that the arterial wall at the incision site and site of closure be free of plaque. Thus primary closure with

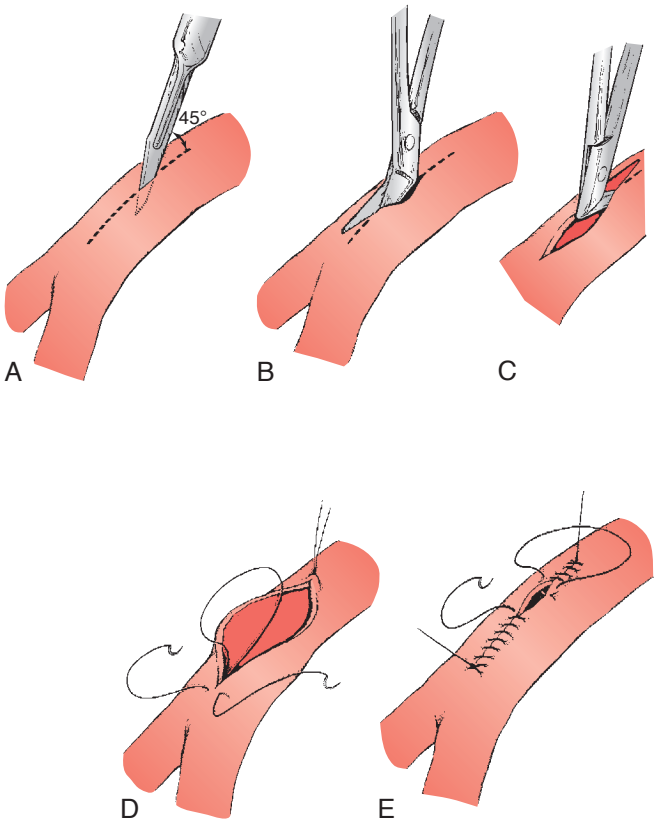

Figure 59.38 (A–E) Primary closure is performed most expeditiously using a continuous running suture technique.

a continuous suture is most suitable in disease-free arteries, endarterectomized vessels, prosthetic bypasses, or veins. The bites should be evenly placed throughout the length of the suture line, and the depth and advancement should be carefully monitored. Bites placed too deep can result in focal narrowing of the lumen.

In the presence of atherosclerotic plaque at the arteriotomy site, primary closure may still be possible; however, an interrupted suture technique is preferable. When closing transverse arteriotomies, interrupted sutures can be placed individually and then tied after all are placed, to allow better visualization of each suture placement (Fig. 59.39). This allows placement of all the sutures, with the needle being introduced from the intimal side and exiting from the adventitial side of the vessel. In addition, the interrupted closure technique is useful in preventing narrowing during the closure of transverse arteriotomies in small arteries.

Patch Closure

When primary closure is expected to cause significant luminal narrowing of an arteriotomy, patch closure should be performed. There are also data to support patch closure to improve the results of carotid endarterectomy. Several technical and nontechnical factors may play a role in the decision to perform patch closure. Technical factors include an artery less than 5 mm in diameter, the presence of significant atherosclerotic plaque

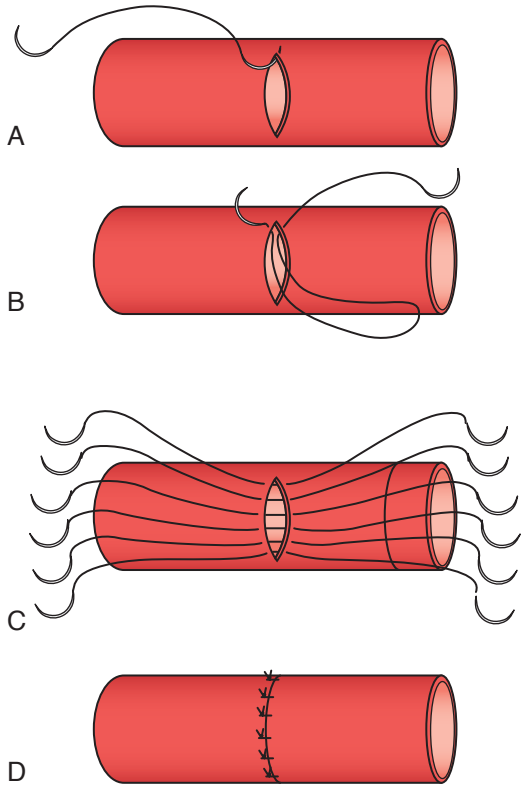

Figure 59.39 (A–D) An interrupted suture technique is preferable in the presence of significant plaque.

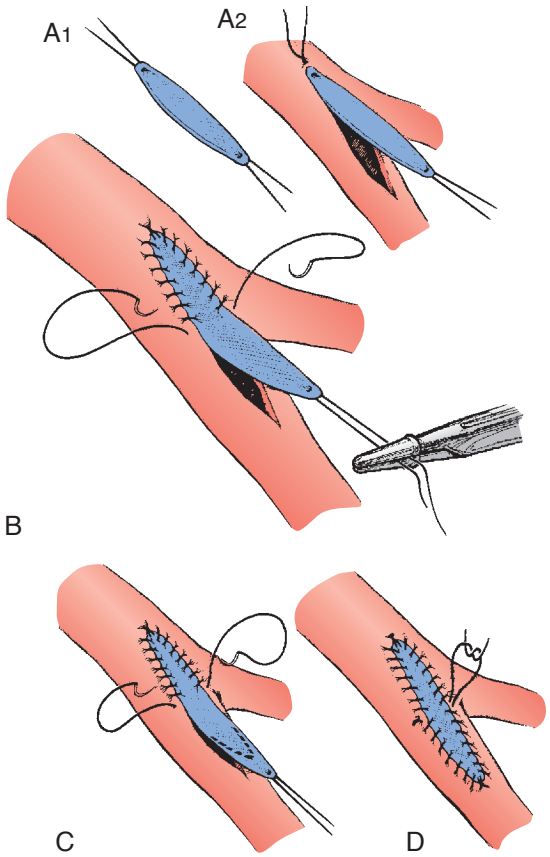

Figure 59.40 (A–D) The simplest technique is to place one suture on each apex of the patch and run both sutures on each side of the patch.

at an arteriotomy site, a jagged arteriotomy, or a very tortuous artery. Furthermore, if there is loss of area in the vessel wall or lumen narrowing pathology that cannot be excised, such as neointimal hyperplasia, closure with a patch is indicated. Nontechnical factors include risk factors that predispose to restenosis, such as hyperlipidemia, heavy smoking, female gender, and a history of recurrent stenosis. The advantage of patch closure is that it allows the needle to be introduced constantly from the intimal aspect of the arterial wall. This eliminates the possibility of pushing a plaque fragment into the arterial lumen and precipitating thrombosis or dissection. Patch closure also allows adequate arterial purchase in the patch and in the artery without compromising the lumen; taking large bites of the artery has the theoretical advantage of controlling the formation of future pseudoaneurysms. Nevertheless, the bites should be placed carefully, with matching depth and even advancement. Otherwise, undesirable lumen narrowing may occur.

When performing patch closure, the width of the patch should be selected to accommodate the vessel size. An overly wide patch can result in excessive redundancy in the arterial patch lumen and act as a nidus for thrombus formation.

Several techniques can be used for closure of a patch. The simplest technique is to place one suture on each apex of the patch and run both sutures on each side of the patch (Fig. 59.40). Alternatively, when suturing in a deep location, the patch can be closed using a parachute technique. In a parachute closure, suturing is started at the apex or a few bites off the apex without tying of the suture (Fig. 59.41). Suturing

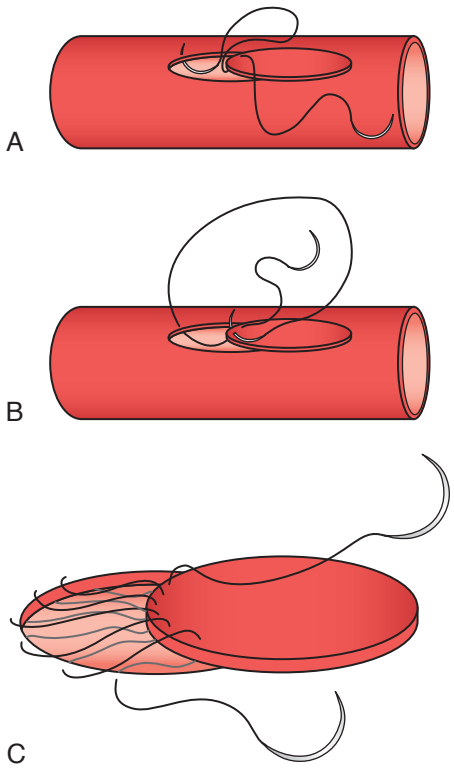

Figure 59.41 (A–C) In a parachute closure, the suturing can be started at the apex or a few bites off the apex without tying of the suture.

is continued until approximately three or more bites are placed on both sides of the center of the apex. The patch is then pulled down while intermittent tension is applied to the suture line. When the suture line is pulled, it is helpful to wet the suture with saline solution; be sure that it is clean from dried blood, and wiggle it back and forth from both ends while pulling the patch with a forceps, keeping the suture between the patch and the arterial apex under slight tension.

Closure of a Transected Vessel

The method used to close a transected vessel depends on its size and intraluminal pressure. Small arterial and venous branches are typically controlled by simple ligature with nonabsorbable suture material or the use of metal clips. Vessels with diameters ranging from 3 to 5 mm are usually controlled by suture ligatures, especially if the vessel is short. Larger vessels are typically closed with a running nonabsorbable suture. If the vessel has a low intraluminal pressure, such as in a large transected vein or the distal end of a transected artery, an over-and-over continuous running suture is usually sufficient to secure hemostasis. However, if the vessel is the proximal end of a transected artery, a single row of continuous sutures may not be adequate. This is especially true when closing an aortic stump after the removal of an infected aortic prosthesis. In such situations, two rows of sutures are preferred to secure hemostasis. The first row is usually constructed using horizontal mattress sutures, which can be placed using a continuous or an interrupted technique. The second layer is typically a continuous over-and-over running suture. The proximal row is meant to decrease the pressure and tension on the distal suture line (Fig. 59.42).

REPLACEMENT AND BYPASS PROCEDURES

Vascular replacement or bypass procedures are typically performed to manage occlusive disease or to replace aneurysmal or injured vessels. A variety of anastomotic techniques are employed in these procedures. The technique selected depends on the procedure, the vascular pathology, and the anatomic location of the operative field. Considerations for bypass anatomy include adequate inflow, outflow, and choice of conduit.

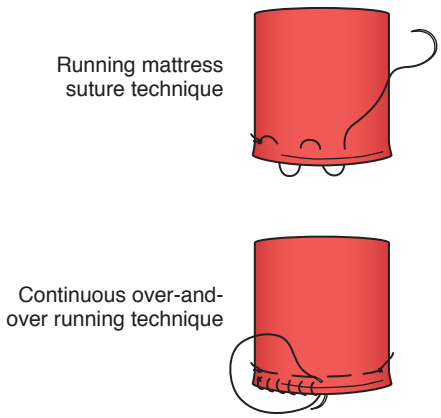

Figure 59.42 The *top panel* shows a running mattress suture technique. The *bottom panel* shows a continuous over-and-over running technique.

Basic Considerations

When creating a bypass to treat lower extremity occlusive disease, the reconstruction should be performed with preservation of the existing circulation. As a result, the proximal and distal anastomoses are typically performed in an end-to-side manner. Such a configuration allows the maintenance of antegrade flow in the native vessel at the level of the proximal anastomosis. Ideally, the distal anastomosis is placed in a disease-free segment of the vessel distal to the occlusive pathology. An end-to-side configuration at the distal anastomosis allows the maintenance of retrograde flow through all patent branches (Fig. 59.43).

Occasionally, disease in the artery requires the creation of an anastomosis with an end-to-end configuration. When treating aneurysmal disease, the aneurysm is typically replaced by interposing a new conduit using end-to-end anastomoses. Aneurysmal pathology is sometimes treated by an end-to-side bypass proximal and distal to the aneurysm and ligation of the aneurysm, as is done for popliteal artery aneurysms.

End-to-Side Anastomosis

An important step in constructing an end-to-side anastomosis is to align the vessels without a twist or kink. Anastomotic failure is more likely to be caused by technical imperfections than by the dimensions of the anastomosis.[6] The anastomosis should be prepared, such that the posterior incision in the conduit is parallel to its long axis; otherwise, a buckle effect may develop at the anastomosis. The ideal arteriotomy length is poorly defined and is influenced by the bypass diameter. Some recommend that the length be twice the bypass diameter.[3] Others recommend an arteriotomy greater than 2 cm.[7,8] In coronary artery vein bypass, a short arteriotomy (4 to 6 mm) is usually recommended.[9] Most often, an arteriotomy measuring 1.2 to 2 times the graft diameter is created. The end of the conduit is transected, and then a slit matching the arteriotomy length is made in its posterior aspect. This allows spatulation of the conduit end to minimize narrowing at the anastomosis. An arteriotomy shorter than 1.2 times the diameter of the conduit results in the bypass's joining the artery at an unfavorably sharp angle. An arteriotomy that is too long requires more time for construction, with no proven additional benefits. An

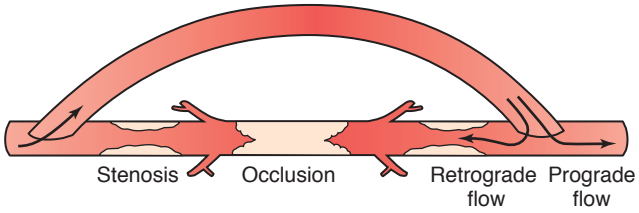

Figure 59.43 End-to-side configuration at the distal anastomosis allows the maintenance of retrograde flow through patent branches.

end-to-side anastomosis can be performed using an anchor or parachute technique.

Anchor Technique

In the anchor technique, the anastomosis is constructed by first placing a suture at the heel of the conduit and the arteriotomy. The suture is tied, thus stabilizing and anchoring the conduit at the heel of the anastomosis. Suturing is continued on one side of the heel to the toe, and then halfway down the other side of the anastomosis. The anastomosis is completed by suturing the other end of the heel suture until it meets the previously placed suture (Fig. 59.44). An alternative is to start another suture at the apex and run it in a continuous manner on both sides of the apex toward the heel to complete the anastomosis, tying the suture on both sides about the middle of the arteriotomy.

There are numerous other variations of the end-to-side anastomosis. The anchoring sutures placed at the apex or the heel can be either simple or mattress sutures. However, in small vessels, mattress sutures at the apex or the heel may cause narrowing of the lumen. Another option is to place interrupted sutures at the apical part of the anastomosis (instead of a continuous suture line). The theoretical advantages of this variation include allowing the anastomosis to stretch and expand with arterial pulsations and not be limited by the length of the continuous suture line. Further, the needle tip in a running suture can become blunted from repetitive piercing, especially of calcified vessels.

The anchor technique is ideal for superficial vessels and larger arteries. The anchoring sutures facilitate traction and countertraction during the anastomotic procedure.

Parachute Technique

In the parachute variation of the end-to-side anastomosis, the sutures at the heel and the apex are not initially pulled down or tied. Suturing is started a few millimeters from the center of the heel. The conduit is typically held with forceps a few centimeters from the arteriotomy. This allows the placement of sutures in deep areas without the conduit obscuring or interfering with suture placement. First, several bites are placed in the conduit and the arteriotomy until the challenging part of the anastomosis is completed. This usually requires a total of three sutures on each side of the center of the heel. Tension is then applied on both ends of the suture, and the bypass is slowly pulled toward the anastomosis, achieving a tight suture line (Fig. 59.45). It is important to avoid excessive, continuous pulling on the suture line during this step, because it could result in tearing of the arterial wall. As described previously, when using the parachute technique in patch closure of an arteriotomy, wetting the suture and wiggling its ends back and forth help in tightening the suture without injuring the arterial wall or breaking the suture line.

The parachute technique is especially useful if the vessels are small or in a deep location where visualization of the first few bites at the apex and heel may be suboptimal. Variations in the parachute technique relate to the site where the suture is started: it can be started exactly at the center of the heel or a few bites off-center. The technique of starting a few bites off-center can be challenging to learn. However, with experience, it may become the surgeon's preferred method of performing an end-to-side anastomosis.

End-to-End Anastomosis

An end-to-end anastomosis is typically performed for replacement of an arterial segment, such as an aneurysmal artery or a vessel that has been transected by trauma. An end-to-end anastomosis is also constructed when a composite bypass is needed or when preservation of retrograde or antegrade flow is not essential.

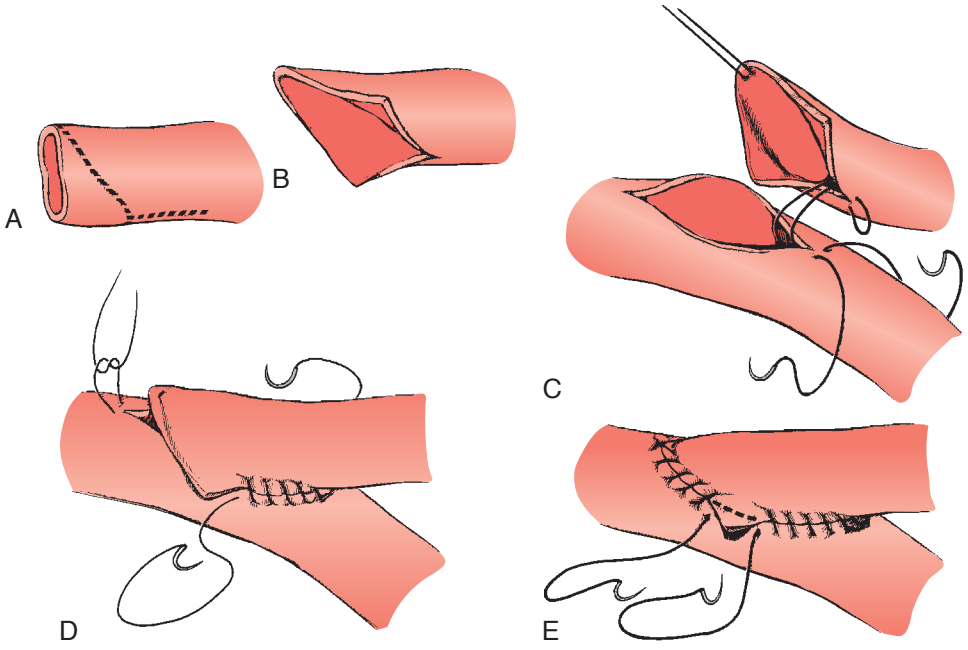

Figure 59.44 (A–E) End-to-side anastomosis anchor technique.

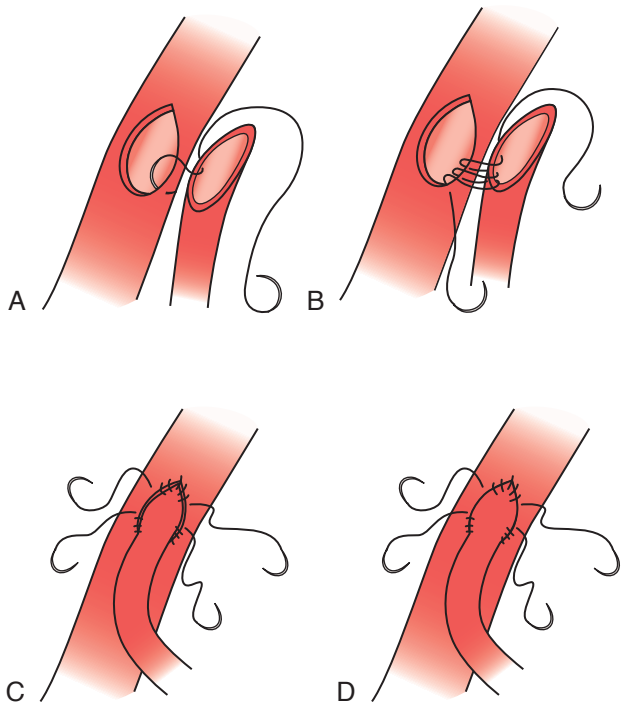

Figure 59.45 (A–D) Parachute technique—another variation of the end-to-side anastomosis.

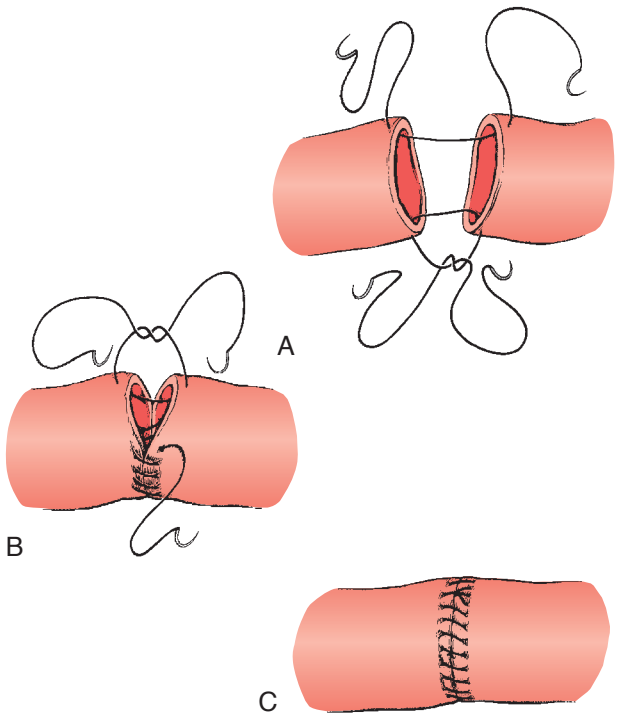

Figure 59.46 (A–C) End-to-end anastomosis in large, movable vessels. The vessels are then flipped 180 degrees, placing the posterior wall in an anterior location for completion of the anastomosis.

The technique varies, depending on the size of the vessels and their mobility. When constructing an end-to-end anastomosis between two large vessels of comparable diameters, the transection of the vessels and the anastomotic suture line are usually in a plane perpendicular to the long axis of the vessel. If both segments are freely movable, a number of techniques have been developed to simplify suturing in a forward manner, maintaining the most favorable angle for suture placement.

One technique involves placing two diametrically opposed sutures in an anterior and posterior part of the vessel. The sutures are tied, and the anterior part of the anastomosis is constructed first. The vessels are then flipped 180 degrees, placing the posterior wall in an anterior location for completion of the anastomosis (Fig. 59.46). This technique is a modification of the triangulation method first described by Carrell. In the triangulation technique, the anastomosis is divided into three parts rather than two parts, anterior and posterior (Fig. 59.47).

When the segments are not freely movable, such as when constructing an anastomosis for aortic aneurysmal disease, the back wall is sutured first, with a continuous suture using a parachute or an anchor technique, based on the depth of the anastomosis and the surgeon's preference (Fig. 59.48). When the back wall is left intact, suturing involves placing a double-layer bite in the posterior wall of the aorta. It is essential to take deep bites; shallow bites may miss the adventitia and do not provide the strength necessary to hold the aortic anastomosis.

When constructing an end-to-end anastomosis between two small vessels, it is essential to spatulate the anastomosis to avoid compromising the lumen. Thus both segments are transected in an oblique manner, and the incision is extended posteriorly.

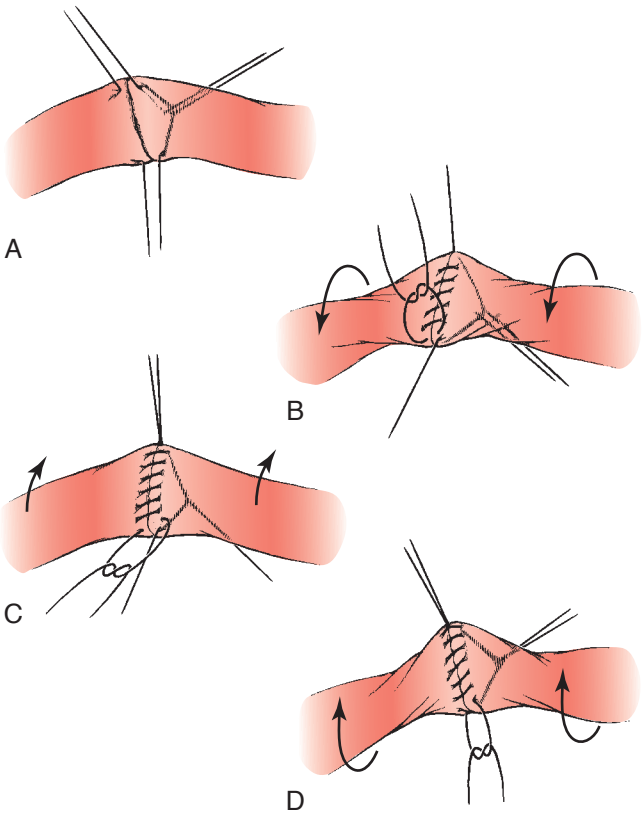

Figure 59.47 (A–D) End-to-end anastomosis using the triangulation method.

An anchoring suture is started at the center of the heel and continued on each side of it (Fig. 59.49). The suturing may be continued around the apex. Alternatively, another suture is started at the apex and continued on both sides of the apex toward the heel to complete the anastomosis. The reason why small vessels should be spatulated when they are to be sutured end to end is a matter of geometry. If the anastomosis is done in a perpendicular fashion to the length of the vessel, it will be a perfect circle with all the bites located in the same plane, which can be narrowed if some bites are too deep. A spatulated anastomosis will produce an oblong shape with the bites in different planes, which makes it more forgiving if some are too deep.

Side-to-Side Anastomosis

A side-to-side anastomosis is rarely performed. It can be used, however, to create a side-to-side radiocephalic arteriovenous fistula for chronic hemodialysis or a side-to-side arteriovenous fistula distal to an infrainguinal prosthetic bypass as an adjunctive procedure to improve graft patency by decreasing outflow resistance.[10] A side-to-side configuration can also be used in the construction of a second anastomosis in a sequential bypass for limb revascularization. To perform a side-to-side anastomosis, the vessels need to be dissected and mobilized so they lie adjacent to each other with minimal tension. The anastomosis is created by longitudinal arteriotomy or venotomy where the walls come in direct contact. The posterior wall of the anastomosis is typically constructed first. The anastomosis is usually 6 to 10 mm long.

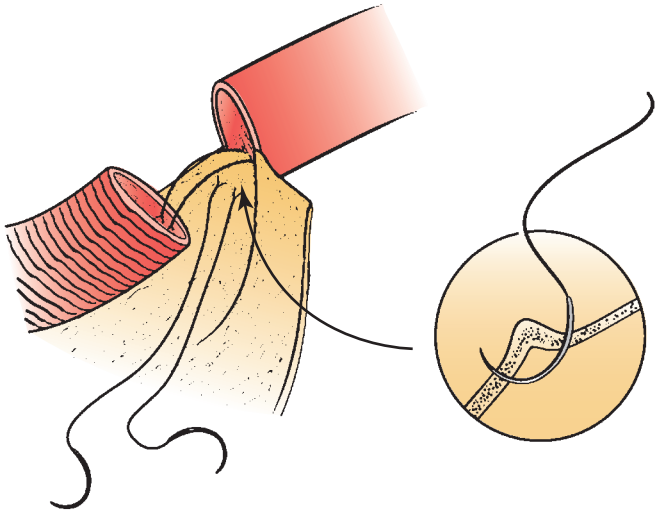

Figure 59.48 When the segments are not freely movable, such as when constructing an anastomosis for aortic aneurysmal disease, the back wall is sutured first with a continuous suture. It is essential to take deep bites because shallow bites may tear.

Adjunctive Techniques for Infrainguinal Bypass Anastomosis

T-Junction

A useful technique to facilitate the construction of an anastomosis in infrainguinal vein bypass is the T-junction technique (Fig. 59.50). In this method, a side branch in the vein is identified. The vein is transected 5 to 10 mm from the branch and then slit along the posterior wall in a fashion to incorporate the side branch in the anastomosis. The shape of that segment of vein looks like a "T." This can be used at the proximal or distal anastomosis and is helpful in minimizing sharp angulation of the bypass and narrowing at the heel of the anastomosis.

Saphenofemoral Junction Vein Cuff

When constructing a greater saphenous vein bypass, the vein can be transected at the saphenofemoral junction with a 1-mm rim of femoral vein (Fig. 59.51). This technique provides a large venous hood for construction of the anastomosis, especially if the artery is thickened and the vein is relatively small.

Venous Cuffs and Patches for Prosthetic Grafts

Several different anastomotic configurations have been described in an attempt to improve bypass results by the interposition of venous tissue between the prosthetic graft and the recipient

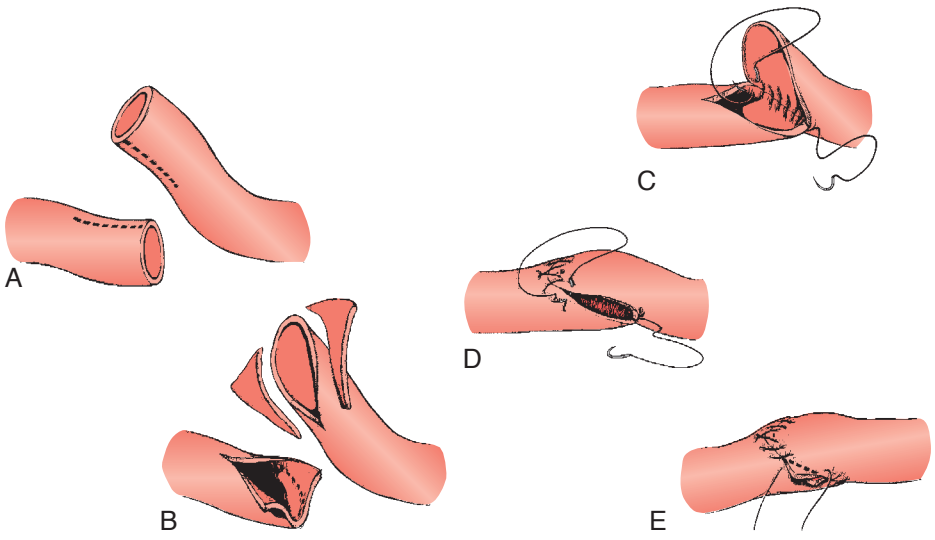

Figure 59.49 (A–E) Spatulated end-to-end anastomosis between two small vessels.

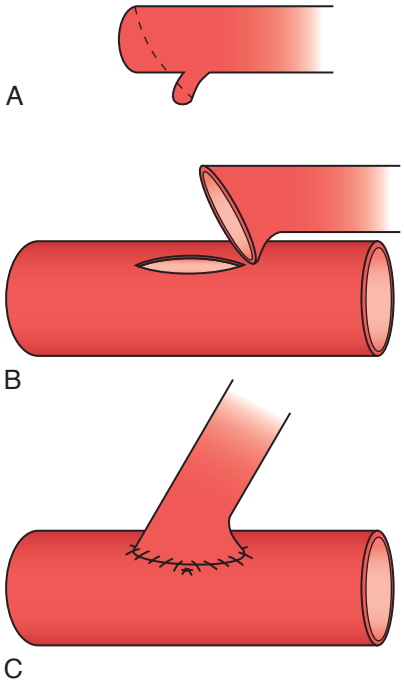

Figure 59.50 (A–C) T-junction technique.

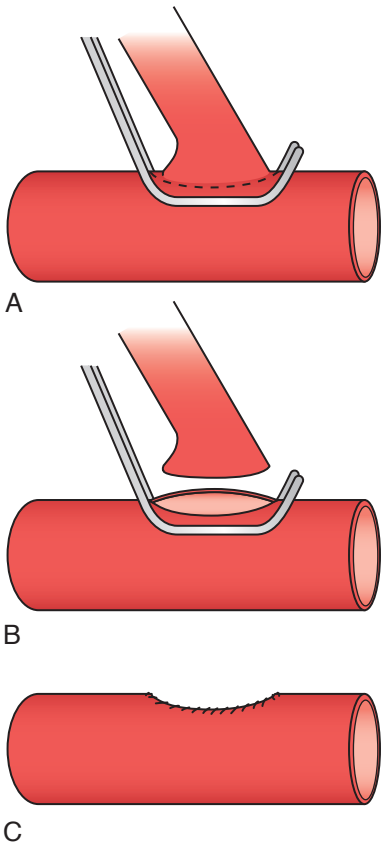

Figure 59.51 (A–C) Saphenofemoral junction technique.

artery, especially to tibial artery targets. Each configuration has certain advantages and disadvantages, both real and potential.

The Miller vein cuff involves the longitudinal opening of a segment of vein and a running suture line to secure the edge of the vein to the arteriotomy. The two cut ends of the vein

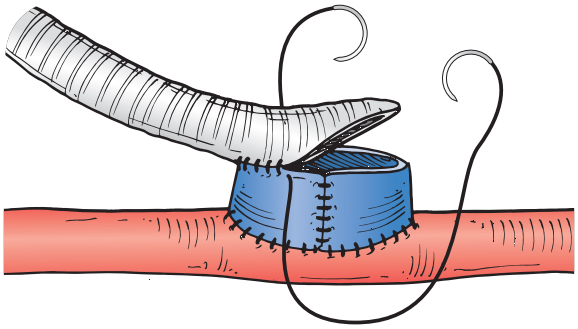

Figure 59.52 Venous cuff at the distal anastomosis of prosthetic grafts.

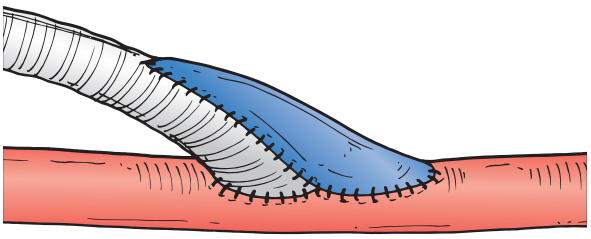

Figure 59.53 Taylor patch.

are then sutured together to construct an oval venous cuff. The prosthetic graft is then sutured directly to the oval vein cuff (Fig. 59.52).[10] However, several potential disadvantages have been recognized in association with the Miller cuff technique. Significant turbulence has been noted due to the deep anastomotic reservoir and the difficulty of achieving a proper angle between the graft and recipient artery. This results in increased turbulence and shear stress at the distal anastomosis. These hemodynamic factors may help to explain the immediate and early graft failures reported in Miller's initial series. In addition, the oval formation of the Miller cuff is difficult to maintain in tight anatomic spaces, such as those involved in very distal bypasses to the dorsalis pedis artery of the forefoot and the plantaris pedis branches of the posterior tibial artery. This feature is especially problematic in the diabetic population where pedal bypass may be required.

The Taylor patch technique requires a long arteriotomy (3 to 4 cm) so that the patch can be constructed longer than the diameter of the prosthetic conduit (Fig. 59.53).[11] A U-shaped slit approximately 1 cm in length is made on the underside of the graft, with minimal angulation to ensure that the graft lays almost parallel to the artery. The heel of the graft is then sutured directly to the proximal portion of the arteriotomy with the suture line continued along each side of the arteriotomy. The anterior surface of the graft is then incised parallel to the arteriotomy to a point 2 cm proximal to the heel of the anastomosis. A vein patch varying from 5 to 6 cm is used to close this elliptical defect. The patch begins distally on the artery with interrupted sutures and is completed proximally onto the PTFE with a running suture. However, there are theoretical and practical disadvantages to the Taylor patch technique. The arterial intima is directly exposed to prosthetic graft material for the proximal portion of the anastomosis, thereby losing the advantage of the venous endothelium for half the anastomosis.

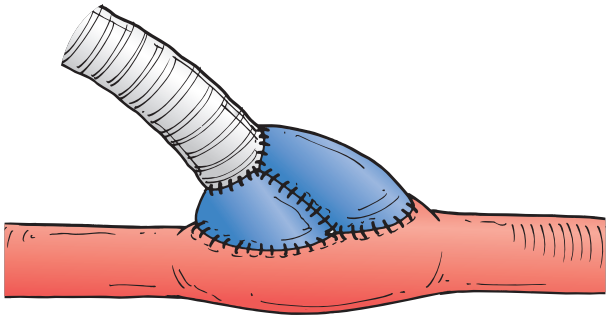

Figure 59.54 Saint Mary's boot

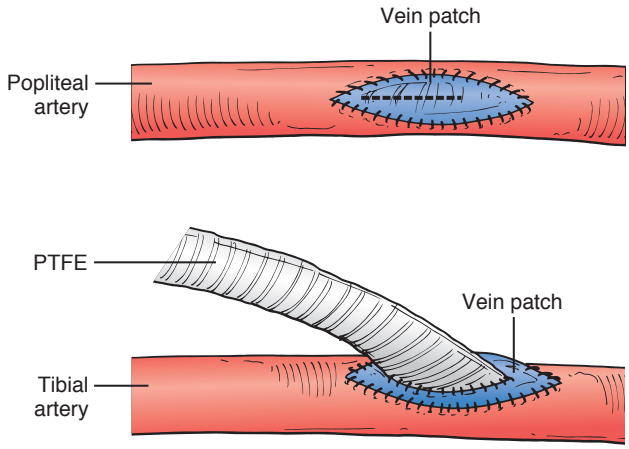

Figure 59.55 Distal vein patch. *PTFE*, Polytetrafluoroethylene.

There is also a point of possible anastomotic constriction where three suture lines converge between the artery, graft, and vein patch. Finally, a significant length of vein must be available to accomplish the anastomosis using the Taylor patch technique.

The Saint Mary's boot technique utilizes a similar arteriotomy and venous harvest as the Miller cuff; however, the corner of the venous segment is sutured to the apex of the arteriotomy to form the anastomotic toe (Fig. 59.54).[12] The remainder of the venous-arterial anastomosis is formed in a similar fashion to the Miller cuff; however, the redundant vein is excised obliquely and sutured to the longitudinal edge. Next, a segment of the posterior collar is incised to increase the size of the anastomosis between the graft and vein collar. Overall, the Saint Mary's boot maintains a fully compliant venous collar, avoids any direct contact between the artery and graft, and maintains the hemodynamic advantages of the Taylor patch. Its main drawback is the technical difficulty of its construction.

This distal vein patch bypass utilizes a technique familiar to all vascular surgeons and requires a shorter arteriotomy, thereby decreasing the amount of venous tissue required for the procedure (Fig. 59.55).[13] A 2- to 3-cm segment of tissue for the patch is suitable and can include saphenous vein remnants, arm vein harvested under local anesthesia, superficial femoral vein, or a segment of occluded superficial femoral artery that is opened and endarterectomized. The venous segment is gently dilated with heparinized saline and opened longitudinally, with valve

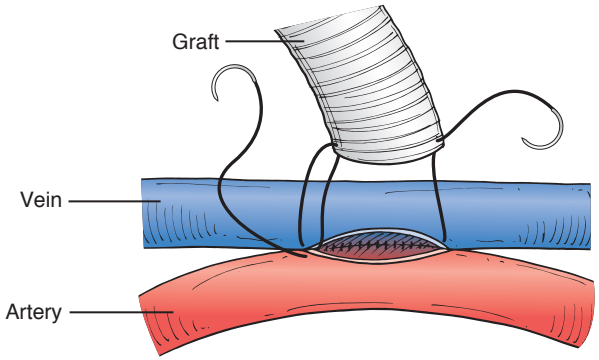

Figure 59.56 Distal arteriovenous fistula.

remnants excised. A 2- to 3-cm arteriotomy is then performed in the target artery, and the venous segment is cut to the appropriate length and width in preparation for the patch. In most cases, the width is left unaltered to allow for a generous patch to permit bulging of the patch under arterial flow to have a functional result similar to that of a vein cuff. The patch is sewn to the artery using 7-0 Prolene monofilament suture in a parachute technique. After the patch is sewn in place, a longitudinal venotomy is made in the proximal two-thirds of the patch, and the graft is sutured to the vein patch using 6-0 Prolene suture. The anastomosis is constructed to maintain a rim of venous tissue interposed between the graft and the entire circumference of the arterial wall. Because the venotomy is made in the proximal two-thirds of the patch, only venous tissue is interposed at the toe of the anastomosis.

Distal Anastomotic Arteriovenous Fistula

The addition of an arteriovenous fistula at the distal anastomosis has also been used to improve graft performance, especially when arterial runoff is poor. Dardik et al.[14] used human umbilical vein grafts and added a common ostium distal arteriovenous fistula to decrease the thrombosis rate by reduction of outflow resistance (Fig. 59.56). When there is no venous conduit and poor arterial runoff, an arteriovenous fistula can be added to the distal anastomosis of a distal vein patch bypass.[15] This modification has been performed in patients with no vein available and severely disadvantaged arterial runoff on the preoperative arteriogram. The target tibial artery is opened longitudinally with a venotomy in the corresponding tibial vein. The opposing walls of the artery and vein are sutured together to create a common ostium connection. The vein patch is then sutured to the common ostium created by this fistulous connection. An anastomosis is then constructed between the vein patch and the PTFE as described in the distal vein patch bypass configuration.

APPENDIX e59.1

Technical Considerations for Thromboembolectomy in Specific Conditions

Although thromboembolectomy is a basic vascular surgical procedure used in various parts of the vascular tree, special techniques have been designed to achieve complete thromboembolectomy in specific conditions.

Infrainguinal Thromboembolectomy

If the thrombus is likely to involve the profunda and superficial femoral arteries, the arteriotomy can be placed half a centimeter proximal to the common femoral artery bifurcation. This simplifies steering of the catheter into the profunda and superficial femoral arteries. If the thrombus is known to be at the popliteal level and farther distally, with sparing of the profunda femoris artery, the arteriotomy can be performed in the superficial femoral artery while maintaining flow into the profunda femoris artery. Maintaining flow into the profunda femoris artery allows some perfusion to the limb while thrombectomy is being performed. It also helps backbleeding from the distal end once the thrombus is removed. During infrapopliteal thromboembolectomy, if the catheter cannot be passed into the tibial vessels despite fluoroscopic maneuvers, exposure of the popliteal artery below the knee, the anterior tibial origin, and the tibioperoneal trunk may be necessary to introduce the balloon catheter in the desired location. Rarely, exposure of the vessels at the ankle may be necessary to achieve complete thromboembolectomy. Occasionally, in very challenging situations, thrombus, cholesterol, or atherosclerotic debris may be packed into the vessels distally. The adjunctive use of intraoperative lytic therapy may improve the chance of successful thromboembolectomy with an irretrievable clot. A thrombolytic agent, such as tissue plasminogen activator 0.02 to 0.1 mg/kg/h, whereas non–weight-based doses generally range from 0.25 to 1.0 mg/h, even though higher doses have been reported, the lowest effective dose has not been determined. Following thromboembolectomy, the luminal area may be very thrombogenic. In addition to maintaining anticoagulation, the administration of intravenous antiplatelet agents, such as dextran 40 at a dose of 25 mL/h, may be useful in the perioperative period to prevent re-thrombosis due to hypercoagulability. Further, it is important to evaluate the patient following thromboembolectomy for any reperfusion injury problems, including compartmental hypertension. A low threshold for performing a fasciotomy should be maintained. All thrombi should be inspected and examined after retrieval. Occasionally, the thrombus may be related to a tumor elsewhere in the body, such as atrial myxoma, and pathologic examination may be necessary.

Aortic Saddle Embolus

In this situation, both groins should be exposed. First, thromboembolectomy is performed on one side. Inflating a balloon catheter at the level of the common iliac artery origin may be useful to avoid further inadvertent showering of thrombi into the revascularized limb while thromboembolectomy is being performed on the other limb. Embolization into the hypogastric artery while the balloon catheter is being withdrawn from the aorta to the femoral incision remains a hard-to-prevent problem. Hypogastric artery thrombectomy under fluoroscopic guidance using an over-the-wire balloon may be attempted to address this condition.

Occluded Bypass

When performing thromboembolectomy of an occluded bypass, the procedure may have to be modified, based on whether the graft is a vein or a prosthetic bypass and whether the occlusion has occurred after a recent or old revascularization. Bypass occlusion following recent revascularization is frequently due to a technical error. The incision in the bypass is usually made at the site where the technical problem is suspected to be, to allow its correction after thromboembolectomy. An incision at the level of the proximal anastomosis, and another one at the level of the distal anastomosis may be necessary to extract the clot if the bypass is a reversed vein, due to the difficulty of trying to negotiate a balloon catheter across the valves. When faced with a graft occlusion following an established prosthetic revascularization, one option is to expose the body of the bypass in the most accessible location and perform thromboembolectomy through a transverse incision. This is followed by an intraoperative angiogram to clarify whether additional intervention is necessary. Dissection of the proximal or distal anastomosis through scarred tissue may be inevitable to achieve complete clot extraction.

Iliofemoral Venous Thromboembolectomy

Thromboembolectomy is not limited to the arterial system. In the rare event of a venous thromboembolectomy required to manage a patient with phlegmasia and diffuse iliofemoral venous thrombosis, the thrombi from the distal leg may not be retrievable with a balloon catheter. After performance of a thrombectomy of the proximal iliofemoral venous segment, the clots in the lower extremity can be extracted from the venotomy site by elevating the leg and applying an Esmarch bandage, thus squeezing and milking the thrombi out of the leg and thigh. Insertion of a caval filter before performing the iliofemoral thrombectomy is often recommended to prevent major pulmonary emboli during the procedure.

APPENDIX e59.2

Technical Considerations for Endarterectomy at Specific Anatomic Locations

The decision to perform an endarterectomy depends on the location and distribution of the atherosclerotic disease pattern and the experience of the surgeon. When the arteries are medium to large (>5 mm diameter) and the atherosclerotic disease process is localized, an endarterectomy is very attractive.

Carotid Bifurcation Disease

Carotid endarterectomy can be performed using different techniques. Traditionally it has been performed using a longitudinal incision starting in the common carotid and extending

into the internal carotid past the disease process. The plaque in the common and internal carotid arteries is shelled out using an open endarterectomy technique, and the plaque in the external carotid artery is typically removed using an eversion orificial technique. The arteriotomy is closed either primarily or with a patch; practice patterns vary, with some surgeons routinely patching and others patching selectively. Another eversion technique has been developed to avoid the issue of patch closure. This technique involves transecting the internal carotid artery at its bifurcation, conducting an eversion endarterectomy, and then reconnecting the internal carotid back to its original location. This technique is expeditious and avoids the use of a patch, but it cannot be performed for recurrent carotid disease. Other factors that may limit the use of eversion endarterectomy include extensive disease in the common carotid artery and the surgeon's comfort level with the technique. Eversion endarterectomy of the internal carotid is possible despite the presence of significant common carotid plaque. After transection of the internal carotid artery, a longitudinal incision is performed in the common carotid artery. The common carotid plaque is removed, followed by closure of the common carotid arteriotomy in a continuous running fashion to the level where the internal carotid was transected.

Aortic Arch Vessels

Endovascular therapies provide attractive options for dealing with occlusive disease at the origin of the aortic arch vessels; infrequently, open surgery may still be recommended. The plaque typically originates in the aortic arch and spills into the origin of the arch vessels. Performing an endarterectomy at that level can be hazardous, and the location and extension of the plaque may not allow safe aortic clamping. Further, closure of the endarterectomy site can be challenging, with a very thinned out aorta. Thus endarterectomy of the origin of the arch vessels has been abandoned in most centers. Many surgeons have replaced this technique with bypass to the involved vessel originating from a nondiseased ascending aorta; this allows safe, partial cross-clamping for construction of the proximal anastomosis.

Abdominal Aorta and Its Branches

In the abdominal aorta, atherosclerotic disease of the mesenteric circulation and renal arteries can be managed by endarterectomy.

Visceral Endarterectomy

Very few centers have solid experience with endarterectomy of the celiac and mesenteric vessels, and these procedures have typically been replaced by aortoceliac and aortomesenteric bypasses, either from an antegrade approach, with the bypass originating from the supraceliac aorta, or from a retrograde approach, with the bypass originating from the infrarenal aorta or iliac arteries. Surgeons who perform endarterectomy of the celiac and mesenteric vessels frequently do so via a retroperitoneal approach. The procedure can also be performed with a transabdominal approach and medial visceral rotation. One of the challenges of this procedure is closure of the endarterectomy site. The aortic wall may appear very thin, and often felt pledgets are necessary to re-enforce the suture lines to allow them to withstand the aortic pressure. Another limiting factor is that the plaque may extend distally in the superior mesenteric artery and may not feather out in a desirable manner. As a result, an additional longitudinal incision may be needed distally in the superior mesenteric artery; this is closed using a patch once all the plaque is removed and the endpoints are tacked.

Renal Endarterectomy

The renal arteries are well suited to endarterectomy procedures, and several techniques have been described. Typically, clamping at the suprarenal or preferably in the supramesenteric location is necessary to allow for a safe endarterectomy. The plaque in the renal artery is typically removed using an eversion technique. One technique for treating bilateral renal disease involves performing a transverse incision in the aorta at the level of the renal arteries. The incision is extended into each renal artery through its respective orifice. The plaque is removed, and the arteriotomy is closed with a patch. This procedure requires a long cross-clamping time and may be very challenging. Another technique is to transect the aorta 1 to 2 cm distal to the origin of the renal arteries. The aortic stump is then lifted upward, and an eversion endarterectomy of the renal arteries and the aortic plaque at that level is performed. This allows the expeditious placement of an aortic graft in the infrarenal position or placement of a clamp in the infrarenal position and construction of a bypass below the renal arteries.

Aortoiliac Endarterectomy

Endarterectomy has also been used to treat aortoiliac occlusive disease. Typically, the aorta is cross-clamped in the infrarenal location, and a longitudinal incision is made in the infrarenal aorta, which allows for plaque removal. Plaques in the common and external iliac arteries are removed using a semiclosed endarterectomy technique. Additional incisions are typically performed at the level of the iliac bifurcation to allow completion and inspection of the endpoint. The main factor limiting the use of this technique is the distal extension of plaque, which may extend all the way down to the femoral bifurcation and the origin of the profunda femoris artery. When such extensive pathology is encountered, this technique may be undesirable and can easily be replaced with an aortobifemoral bypass, with the distal anastomosis connected to the femoral bifurcation or profunda femoris artery.

Infrainguinal Vessels

Atherosclerotic plaques in the common femoral artery extending into the femoral bifurcation and profunda femoris arteries are also amenable to endarterectomy procedures. This can be done in conjunction with construction of the distal anastomosis of an aortobifemoral bypass or as a separate procedure if inflow from the external iliac artery is adequate. One option is to extend the arteriotomy distally into the profunda femoris artery and perform an open endarterectomy. A modification involves making the incision in the common femoral artery, with possible extension into the superficial femoral artery, and then performing

an eversion endarterectomy of the profunda femoris artery. Selection of the reconstruction technique is influenced by the occlusive pathology and the ability to provide maximal revascularization. Attempts to treat the superficial femoral and popliteal arteries with closed and open endarterectomy have not gained popularity because of the extensive dissection required and the poor patency rates. However, interest in superficial femoral artery endarterectomy has been resurrected with the re-introduction of Moll ring cutters. This technique permits a remote endarterectomy under fluoroscopic guidance. Endovascular techniques allow for better handling of the endpoint. Using catheter-based technology, a wire is navigated into the lumen distal to the endpoint, and stents or stent-grafts can be deployed at the endpoint to provide a smooth transition between endarterectomized and nonendarterectomized segments. The value of this technique has yet to be proven, but it represents another option in the vascular surgeon's armamentarium. It may allow use of the popliteal artery as an inflow for constructing a popliteal-to-tibial bypass when a long segment of vein is not available. Endarterectomy has no role in the infrageniculate vessels.

INTRODUCTION

Mastery of endovascular technique is a cornerstone of the modern practice of vascular surgery. Vascular surgeons must be facile with a variety of instruments and techniques used for endovascular access, selective vessel catheterization, image acquisition, and postprocessing, as well as with techniques to mitigate complications that can occur. Access to complete endovascular diagnostic procedures can occur in a variety of arteries and veins located throughout the body. Proper selection of needles, wires, and catheters permits the safe conduct of these procedures. The purpose of this chapter is to familiarize the reader with these tools and techniques for diagnostic purposes. Interventional techniques will be discussed in Chapter 61.

VASCULAR ACCESS

Choice of Site

Most endovascular diagnostic procedures are performed through percutaneous access, the attainment of which being the initial step of the procedure. While recently the use of radial or pedal

artery access has become more popular, the far and away most common access site, arterial or venous, is in the common femoral location, with axillary/brachial access being a distant second in popularity. The key factors that must be considered in choosing a site for access include (1) appropriateness for the procedure being completed, (2) ability to obtain hemostasis once the procedure is completed, (3) ability to safely convert to an open procedure if there is a complication, and (4) ensuring that cannulation of that site will have minimal adverse effects on the tissue being supplied by the access vessel.

Appropriateness of access relates to utilizing a vessel appropriately sized for the catheters or devices intended, an access location that permits subsequent catheterization of the vessels of interest, and an access site that can be readily sealed, either by manual compression or with a closure device. For example, diagnostic angiography of the aorta, iliac arteries, and their subsequent outflow to the legs is most commonly performed via common femoral artery (CFA) access. An alternate site could include the brachial artery if both groins are hostile or there is a known occlusion of both common femoral arteries. If performing diagnostic imaging of the subclavian artery for thoracic outlet syndrome, either a retrograde approach using the brachial artery or an antegrade approach using CFA access can be obtained. In the former case, a wire and catheter are advanced into the proximal subclavian artery and diagnostic imaging completed. In the latter case, a wire and catheter are advanced from the CFA, through the external and common iliac arteries, up the aorta and to the aortic arch.

The ability to obtain hemostasis is critical for the safe completion of diagnostic procedures and one of the reasons that the CFA is such a preferred access site. While there are a variety of devices that can assist with hemostasis, termed *closure devices*, they cannot be used when there is significant calcification of the vessel, in small diameter vessels, or at least in intended fashion, for access sizes exceeding 8 French. Hemostasis is most commonly achieved through manual compression, which is facilitated in the common femoral region by the femoral head posterior to the artery, against which pressure can be exerted. The brachial artery can similarly be compressed against the humerus, but its mobility renders compression less effective and more challenging. Failure to obtain satisfactory compression, and thereby hemostasis, can lead to the development of a pseudoaneurysm or hematoma, potentially requiring operative drainage and repair.

The ability to convert to an open procedure is an important consideration for vascular access. In the event of sudden loss of access such as a sheath being inadvertently pulled out, or failure of hemostasis after intentional sheath removal, converting to an open procedure may be necessary to repair the defect in the vessel. Emergency conversion to an open procedure is facilitated by ready access to the underlying vessel. For example, converting a percutaneous CFA puncture to an open repair involves doing a relatively straightforward groin cut down. On the other hand, percutaneously accessing the subclavian artery is almost never done, as it could involve complex supraclavicular incisions or even a thoracotomy to obtain hemostasis.

Ensuring that occlusion of flow by the access sheath has minimal adverse effects on the tissue supplied by the vessel is another important consideration. Given the relatively small diameters of diagnostic catheters, this is rarely an issue for purely diagnostic angiography, but it must be remembered that blood flow to the distal tissues can be affected by indwelling catheters. While tissue beds such as the extremities are relatively resistant to the ischemic effects of cessation of flow for some time, thrombosis can more easily occur with sluggish flow. Although we would not routinely heparinize a patient undergoing a purely diagnostic procedure, we would give that greater consideration in situations of reduced flow. Furthermore, the cannulation of smaller vessels, such as the posterior tibial artery, has increased the risk of vessel trauma, dissection, and at least transient occlusion of flow.

The principles of venous access are generally similar to those of their arterial counterparts, but the diminished pressure present in the venous circulation allows for easier postprocedure hemostasis and fewer bleeding complications. Even so, the most common venous access sites mirror those typically used on the arterial side, with common femoral venous access being the most common. Another common venous access site is the internal jugular vein (IJV), as this is the optimal access for vena cava filter retrieval. As with arterial access, when planning access to the venous circulation for diagnostic purposes, it is prudent to consider any possible interventions that might be undertaken in the same setting. As such, while a diagnostic venogram in a patient being considered for thrombolysis could be performed from either the ipsilateral or contralateral femoral access, this would not provide a good approach for any subsequent intervention, so a small saphenous or popliteal venous access would usually be more appropriate.

Adjuncts to Obtain Access

The desired "sweet spot" to access the CFA is as it courses along the medial aspect of the femoral head, between the inguinal ligament cephalad and its bifurcation into the profunda femoris and superficial femoral arteries. While obesity makes anatomic landmarks for the inguinal ligament notoriously inaccurate, the desired puncture zone typically corresponds to the middle of the femoral head in the cranial-caudal dimension. This landmark is routinely imaged prior to attempting access. Percutaneous access can be achieved guided by one or more of three modalities: (1) manual palpation of the pulse, (2) radiographic guidance, and (3) ultrasound guidance. Regardless of which type of guidance is elected, the classic Seldinger technique is employed, initially gaining access with a needle, holding that access with a guidewire, and finally positioning a sheath into the access vessel over the guidewire.

Manual Palpation

Manual palpation of the pulse typically involves having two fingers on the pulse—one proximal and one distal and spread out by a few centimeters. Ideally, the vessel will travel in a straight line between the two fingers and the access needle inserted directly between the two fingers into the artery. This approach works well when the pulse is readily palpable and the appropriate bony landmarks are easily identified. However, in patients with significant peripheral artery disease, morbid obesity,

or other factors, the use of fluoroscopy or ultrasound can greatly improve the ease of access.

Fluoroscopy

Radiologic guidance involves the use of fluoroscopy to visualize the relevant bony landmarks described previously and their relationship to the position of the needle.[1] This is most commonly needed in situations where a pulse is either absent, or not able to be appreciated due to overlying scarring. It only provides two-dimensional guidance, but that is often all that is needed. While the radiographic relationships of the access vessel are important to understand and recognize, ultrasound-guided puncture has largely replaced its use in the pulseless or otherwise hostile groin. A variation of radiographic guidance occurs when a guidewire is being advanced into the intended site of access from some other access point, allowing radiographically guided access by directing the needle toward the guidewire.

Ultrasound

While color flow Duplex scanners can certainly aid in the identification of the intended access vessels, it is primarily the grayscale characteristics that are utilized to identify vessels and guide their puncture. Ultrasound guidance allows direct visualization of the vascular structures along with the surrounding anatomy. When seeking to cannulate the CFA, the inguinal ligament and femoral bifurcation can be clearly visualized, along with the common femoral vein (CFV) and femoral nerve. Insonation while advancing the access needle will allow the operator to visualize the needle as it compresses and passes through various tissues, and eventually indenting the artery as it pushes against the wall. This technique also allows small corrections in angle and approach, and facility with this method can allow rapid and safe percutaneous access.[2,3] The technique can be cumbersome, however, especially in patients with a large panniculus, and it is helpful to have an assistant ready to advance the entry guidewire once vessel puncture has been achieved.

Access Location Options

The most commonly used site for arterial access is the CFA, followed by the brachial artery and radial artery when a smaller caliber device can be used and femoral access is disadvantageous. Popliteal and tibial artery access can be used for lower extremity interventions, but are rarely the first choice of access and would not be considered for diagnostic purposes only. The same applies to other alternate sites of access such as the carotid, subclavian, axillary, and iliac arteries. While all of these vessels can serve as "access vessels" for endovascular procedures, the associated complexity and greater risk of complications render them largely reserved for specific vascular anatomy and pathology undergoing endovascular treatment, as adequate diagnostic imaging can usually be obtained through alternative modalities.

Common Femoral Artery

The CFA is the continuation of the external iliac artery as it crosses under the inguinal ligament, typically correlating with the origins of the superficial epigastric and circumflex iliac arterial branches. Existing for only 5 to 8 cm on average, the CFA then bifurcates into the superficial and deep femoral arteries. The CFA courses immediately medial to the femoral nerve, and lateral to the CFV. It overlies the medial aspect of the femoral head. The inguinal ligament is a useful landmark that can be identified using surface anatomy, but it is critical to recognize that in today's population of patients, its location has no correlation to the groin crease. However, radiographic landmarks can reveal the inguinal ligament, being attached to the anterior superior iliac spine laterally and the pubic tubercle medially. Identification of these bony landmarks will determine the location of the superior-most extent of the access site (Fig. 60.1).

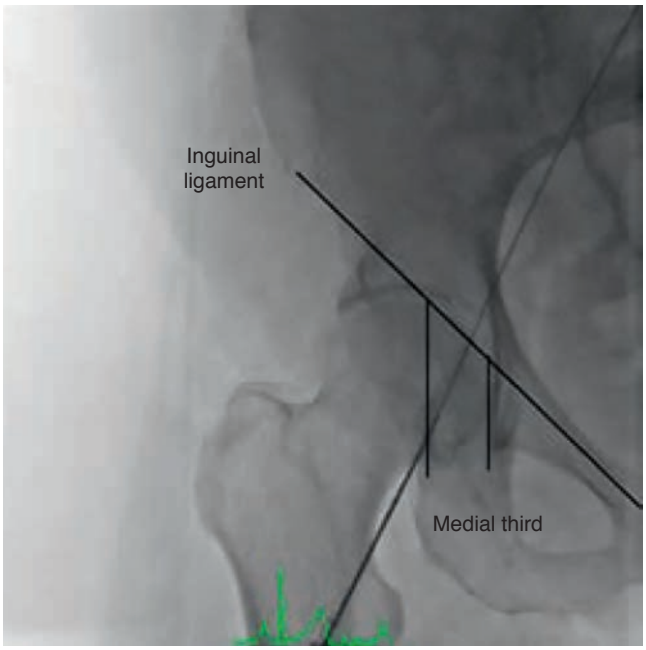

Figure 60.1 Anatomy of the femoral artery with the inguinal ligament and femoral head delineated. The common femoral artery lies over the medial one-third of the femoral head. A wire is located within the femoral artery in this x-ray image.

The CFA is an ideal choice for cannulation, as it meets the four criteria for choosing a site discussed previously and allows one to complete a wide variety of procedures. The large caliber of the CFA permits devices as large as 26F to be used, and the use of suture-based closure devices can permit successful completion of these procedures entirely through percutaneous means. Retrograde CFA access involves obtaining access over the femoral head, just above the femoral bifurcation but below the inguinal ligament with the needle pointing cranially. This permits the insertion of guidewires and subsequently catheters through the iliac system and up into the aorta, thus permitting diagnostic imaging of virtually any arterial bed in the body. Punctures occurring cephalad to the inguinal ligament may be difficult to seal, with or without a closure device, resulting in life-threatening retroperitoneal hematoma, while a too distal puncture increases the risk of an AV fistula from the profunda femoris artery or plaque dissection of the proximal superficial femoral artery (SFA).

In certain circumstances, antegrade CFA access may be desired, again most likely for interventional rather than diagnostic purposes. Antegrade access has the advantage of working in a single plane for distal extremity procedures, and the increased torque and force that can be generated for distal extremity interventional procedures may be well suited for this approach when no other proximal imaging is necessary. However, antegrade access into the CFA is a more complex endeavor than retrograde access. As the needle must still enter the CFA well above the bifurcation, this requires having a steep downward angle. In obese patients with a large pannus, this can be facilitated by having an assistant retract the pannus while obtaining access. Ultrasound-guided access can facilitate proper placement of the access site with care taken not to be too close to the bifurcation. Entering close to the bifurcation will make it difficult to selectively cannulate the SFA, as the downward angle of entry will make the wire and catheter more prone to entering the deep femoral artery.

Popliteal Artery

The popliteal artery is the continuation of the SFA as it exits Hunter's canal in the distal medial thigh. It travels behind the knee and divides into the anterior tibial artery and tibioperoneal trunk, which subsequently divides into the peroneal artery and posterior tibial artery (together, the so-called trifurcation). The popliteal artery is flanked on each side by the duplicated popliteal vein and can be accessed medially either above or below the knee, or posteriorly using a prone position.

While not commonly used for diagnostic purposes, the retrograde access of the popliteal artery in either a supine or prone position is helpful when attempting to cross and reenter an occlusion of the SFA. Ultrasound guidance is extremely helpful in identifying its location and distinguishing it from the popliteal veins. Hemostasis in this location can be difficult, as effective compression in the fatty popliteal space is challenging and there is nothing to compress the artery against.

Tibial Artery

Access to the anterior tibial, posterior tibial, or peroneal arteries is not commonly done for diagnostic purposes. However, as an adjunctive access to recanalize severe tibial disease, it has shown some utility. The cannulation of these vessels is commonly performed using micropuncture access (discussed later) assisted by ultrasound guidance. Small sheaths and soft wires are typically used to reduce the risk of vessel trauma.

The anterior tibial artery is located in the anterior compartment of the leg and dorsal surface of the foot, where it continues as the dorsalis pedis artery. It is this superficial location that is easiest to access and also the most straightforward to obtain hemostasis. The posterior tibial artery is located in the deep posterior compartment of the leg and is palpable near the ankle. This relatively superficial location is also amenable to percutaneous access and can be compressed readily for hemostasis. The peroneal artery is located in the deep posterior compartment of the leg and generally travels between the tibia and fibula; thus it is rarely used for percutaneous access due to the difficulty in reaching this vessel.

Iliac Artery

Iliac artery access at either the common iliac artery or external iliac artery is typically achieved using an open surgical approach. Percutaneous methods for accessing these vessels are contraindicated due to the inability to provide compression and because of the surrounding structures that can be injured. Furthermore, the only reason to access in this location would be for an intervention with a relatively large delivery system, in which case a conduit sewn end-to-side to the iliac artery can then be used to introduce large bore sheaths and devices.[4] Given the larger delivery systems of TEVAR and TAVR devices, common iliac artery conduits are more commonly employed during these procedures.

Axillary Artery

Cannulation of the axillary artery is typically done in the intramuscular groove between the triceps and coracobrachialis muscle with the upper arm in abduction and flexion. This permits ultrasound-guided access and subsequent hemostasis by compression against the humerus. Care must be taken to ensure satisfactory hemostasis as bleeding into the axillary sheath can create a compartment syndrome for the median nerve. As the caliber change between the axillary artery and brachial artery is minimal, most practitioners will use the more accessible brachial artery if upper extremity access is desired.[5]

Brachial Artery

The brachial artery is palpable just over the olecranon process when the arm is supinated. Ultrasound-guided access is often used in conjunction with a micropuncture needle to facilitate safe entry into the vessel.[6] Delineating the bifurcation of the brachial artery is important prior to attempting access, so that entry into the largest portion of the vessel is achieved. 6F sheaths can be used safely in most patients. Similar to axillary artery access, care should be taken to ensure satisfactory hemostasis due to the risk of median nerve compression from a hematoma. Brachial artery access is often used for coronary revascularization procedures, dialysis access imaging, treating diseases related to the subclavian artery such as occlusions or pseudoaneurysms, procedures on the celiac or mesenteric vessels, and occasionally when doing EVAR or FEVAR procedures.

Radial Artery

The radial artery is readily palpable in the distal extremity over the radius, and thus can be cannulated with ease, with or without using ultrasound guidance. Subsequent hemostasis is relatively straightforward through compression against the radius. As most patients are ulnar-dominant, the rare situation in which the radial artery is lost due to vessel trauma may have a minimal downstream effect on perfusion of the hand. The radial artery

can accommodate sheaths between 4F and 6F, thus facilitating endovascular procedures that are using a 0.014" or 0.018" platform (discussed later). Radial artery access is often used for coronary procedures and also for diagnostic purposes related to dialysis access.

Common Carotid Artery

Common carotid artery access is rarely done for purely diagnostic purposes due to the risk of cerebral ischemia and the difficulty with obtaining hemostasis. If cerebrovascular diagnostic imaging is needed, most practitioners will use CFA access with long guiding catheters or sheaths (discussed later) to achieve cannulation of the carotid artery.

Common Femoral Vein

Venous access differs from arterial access in several important ways. First, the pressure is significantly less, and while this can make hemostasis easier, it can also make access more difficult, as there will be less radial force keeping a vessel open against the force of the needle attempting to pierce the vein wall. While veins are capacitance vessels and can be quite large, they cannot stretch as much as arteries and are therefore prone to tearing if too large of a sheath or device is used. The final important consideration is that while a simple access needle can be used to access arteries and confirm vessel entry, a syringe may be needed for venous cannulation. This serves two purposes: first, the plunger can be pulled back to generate a vacuum and confirm proper entry into the vein, and second, inadvertent entry of air into the venous system (air embolism) is avoided. This is particularly important when accessing a vein located above the heart, such as the IJV with the patient's head up, where a negative venous pressure may exist and facilitate the entry of air into the system with potentially fatal consequences.

The CFV is commonly used for access when completing diagnostic procedures in the vena cava or its branches, such as the ovarian and internal iliac veins for pelvic congestion syndrome. The CFV is located medial to the CFA and can be compressed over the femoral head. Ultrasound guidance is often used for access to avoid injury to the CFA and to also avoid going through the back wall of the CFV during cannulation. This access readily allows catheterization of the contralateral extremity venous system, though navigating against the valves can require patience.

Popliteal Vein

The popliteal vein is accessed with the patient in the prone position. This paired structure flanks the popliteal artery, and either vein can be used for access. Ultrasound is used for guidance, which is particularly important when cannulating this vessel to diagnose and treat deep vein thrombosis of the extremity veins, as the access location itself may be thrombosed, rendering blood return via the needle meager or nonexistent. Ultrasound visualization of the puncture and guidewire passage can be very helpful in this situation.

Saphenous Vein

Both the great and small saphenous veins are often cannulated for diagnostic and therapeutic purposes when treating patients for extremity deep vein thrombosis or for chronic venous insufficiency secondary to venous reflux disease. Ultrasound guidance may or may not be necessary for access, but both the great and small saphenous vein will typically accommodate at least a 6F sheath. The proximal small saphenous vein is a commonly utilized access point for thrombolysis of femoral deep vein thrombosis, as it generally feeds directly into the popliteal vein.

Cephalic/Basilic Vein

An arm vein is sometimes accessed for dialysis and vein mapping. The superficial location of the cephalic vein makes it amenable to straightforward cannulation using a butterfly intravenous line if only vein mapping is desired, although most vein mapping is typically done by ultrasound guidance. Ultrasound-guided cannulation of the cephalic or basilic veins can be accomplished with introduction of a sheath if larger bore access is desired.

Internal Jugular Vein

The IJV is lateral to the carotid artery and can be accessed preferably using ultrasound guidance to prevent inadvertent injury to the common carotid artery. Access between the sternal and clavicular heads of the sternocleidomastoid is typically achieved, and relatively large sheaths can be used in this vessel. Access to the IJV is often used when inserting a central line or tunneled and nontunneled hemodialysis catheters. This is also a common site for retrieving IVC filters.

Subclavian Vein

The subclavian vein is not commonly accessed for diagnostic or therapeutic purposes other than the placement of a central line. It is a discouraged site for dialysis catheters due to subsequent stenosis. Although ultrasound guidance is recommended for femoral and internal jugular access, its value in subclavian vein puncture remains debatable due to poor visualization of the subclavian vein from the acoustic shadows of the overlying clavicle. Newer ultrasound probes such as the microconvex pediatric probe have been described to allow cannulation of the subclavian vein under real-time ultrasonography and avoiding trauma to the subclavian artery. Evaluation of pathologies such as venous thoracic outlet syndrome or central vein occlusion would more ideally be accomplished through cannulation of the cephalic or basilic veins.

Access Technique

Access Needles

Both single-wall and double-wall puncture needles are available. Double-wall needles are a blunt-tipped hollow needle with an

inner beveled stylet. Historically, when used in the femoral location, these needles were inserted through both the anterior and posterior wall until contact with the bone was made; the stylet is removed completely, followed by slow withdrawal of the hollow needle until blood return occurs. These needles cause unnecessary trauma to the posterior wall and are no longer used for standard femoral artery cannulation. However, a similar needle is often used for translumbar aortic cannulation of endoleaks, withdrawing the stylet once the aneurysm sack has been penetrated so that further needle advancement cannot puncture the endograft.

Single-wall puncture needles are almost universally used for percutaneous access. The larger 18-gauge needle permits passage of a 0.035-inch guide wire, while the smaller 21-gauge needle permits passage of an 0.018-inch guide wire.

Micropuncture Needle Technique

The micropuncture technique is commonly used for vascular access in a variety of sites. The vessel is identified using manual palpation, fluoroscopy, or ultrasound guidance. A 21-gauge needle is then inserted at a 30- to 45-degree angle such that it pierces the artery wall at the site of visualization. Ideally, ultrasound guidance is used to visualize this entry, as it will permit small corrections in angle and approach as the needle approaches the artery. Once the needle enters the vessel wall, blood return should be evident. When cannulating arteries, the flow is often pulsatile and red; when cannulating veins, a syringe should be used to draw back the darker red venous blood and also to prevent the passage of air into the vascular system.

Once successfully accessed, a 0.018” floppy tip guide wire is inserted into the vessel. Fluoroscopy can be used to confirm successful passage into the vessel. The 21-gauge needle is then removed from over the wire, followed by placement of a 4F introducer sheath. The passage should be without tension as the 0.018” wire is prone to bending from excess torque, leading to loss of access. If difficulty is encountered, a small rotating motion on the introducer sheath can be used to facilitate passage through scar tissue or a thick arterial wall; alternatively, sharp 4F introducer sheaths are now available that can be used to cut through dense tissue.

The inner cannula of the 4F introducer sheath is removed along with the 0.018” guide wire, thus permitting passage of a 0.035” guidewire. This is typically a J-tip wire for atraumatic passage. Nonetheless, fluoroscopy is used to confirm proper passage of the wire to ensure that inadvertent cannulation of a side branch or a dissection plane has not occurred. Manual pressure is held above and below the 4F introducer sheath and it is removed while keeping the 0.035” wire in place. A 5F or 6F by 10 cm long sheath can now be inserted over the 0.035” wire for definitive vascular access. The side port of the sheath is opened, blood return confirmed along with removal of any air in the system, and then flushed with heparinized saline to prevent thrombosis. Throughout all of these sheath exchanges, positive control over the wire is maintained to prevent losing the wire inside the vascular system, or losing access while pulling out the sheath.

Standard Needle Technique

For easily palpable femoral pulses in otherwise uncomplicated anatomy, many practitioners will go straight to an 18-gauge needle and 0.035” J-tip wire instead of using the micropuncture technique. The technique is similar to the micropuncture technique, except there is no exchange of a 4F introducer sheath to the larger 5F or 6F sheath, saving a little time and expense. The primary advantage of the larger initial access is seen in scarred groins, deep vessels, or when accessing Dacron grafts, all being situations where tracking the 4Fr sheath over the less supportive 0.018” guidewire can be problematic.

TECHNIQUE FOR CATHETERIZATION

Guidewires

Once needle puncture is obtained, a guidewire is then passed into the arterial system to maintain the access while the needle is removed and a sheath advanced over the guidewire, to stay resident in the access vessel. The standard entry wire is a 0.035” J-tipped moveable core steel guidewire designed for atraumatic passage up the iliac system. Fluoroscopic observation of the guidewire passage ensures the safest possible passage and also can give clues about underlying pathology. It is critical that hydrophilic-coated guidewires not be used as the initial entry guidewire as the hydrophilic coating is known to shear off and embolize when moved in and out of an entry needle.

Once sheath access is secured, a vast array of guidewires can be utilized to assist in catheter placement for diagnostic imaging. Among the variables are the tips of these wires, which vary in their geometry and flexibility. While guidewire tips are typically soft and floppy so as to be minimally traumatic, the shaft of the guidewire can be quite stiff, to allow tracking of relatively large and stiff devices. These types of guidewires, however, are more the domain of endovascular interventions and will not be discussed further here. Proper wire selection is essential, as choosing a very stiff wire could lead to perforation of a vessel, while a very soft, flexible wire may not provide adequate support to allow for the intended positioning of a catheter.

Guidewires generally come in two size categories—the larger 0.035″/0.038″ wires and the smaller 0.014″/0.018″ wires. Other sizes are made, but they are generally device-specific and rarely used by vascular surgeons. Wires are available in a variety of lengths, typically from 120 to 360 cm. Longer length wires, often referred to as “exchange length” wires, are used when introducing a very long catheter or device remotely from the site of access, but these longer wires require careful attention to ensure that they do not get contaminated by falling off the working table or hitting other objects. Wires can be very stiff (such as steel core wires), or very flexible (such as nitinol wires). Some wires have Teflon or hydrophilic coatings to reduce the friction of their passage, and that of devices passed over them. The stiffness and flexibility of a wire is determined by the construction of the outer spring coil and core wire.

The tip of the wire is also very important. Many wires have a soft, floppy tip that will reduce the risk of vessel trauma.

These are compliant wires, but the drawback of an overly floppy tip is that it cannot be used to cannulate side branches or make turns in a tortuous vessel. Other wires may have a stiffer construction at the tip with a slightly angled bend. These wires can permit navigation of tortuous vessels and cannulation of side branches by manipulating the wire and rotating it along its longitudinal axis. Finally, J-tip wires are ideal for rapidly cannulating vessels and doing sheath exchanges, as the rounded bend will reduce the risk of creating a dissection plane or inadvertently cannulating a side branch.

Sheaths

Sheaths are used for maintaining vascular access and serve as a portal through which any variety of wires, catheters, or devices are passed. Sheaths have a side port that permits aspiration or administration of fluids, and come in a variety of lengths and calibers (Fig. 60.2). The inside caliber of a sheath is measured by French size, where 1F = 0.013″ = 0.33 mm (Box 60.1). Thus a 5F sheath will accommodate catheters and devices up to 0.065″ (5F). Sheaths typically vary in size from 4F to 11F, but much larger sheaths are available to accommodate devices such as endografts (Fig. 60.3). Sheaths have a hemostatic valve on the end that maintains hemostasis whether wires and catheters are indwelling or absent. Braided sheaths may be used when cannulating a vessel through dense tissue or making sharp turns that can lead to kinking of the sheath. Similar to some guidewires, radiopaque markers may be present that can facilitate identifying the end of a sheath or making measurements.

Sheaths come in a variety of lengths, ranging from 5 to 100 cm. For diagnostic purposes, the most commonly used length of sheath will be the standard 10 cm sheath, as any more remote contrast injection will be through a catheter, not the sheath. Short sheaths are helpful when the working distance is very small, such as for dialysis access. Longer sheaths are important when working remotely from the site of access, such as the SFA contralateral to the access or the carotid arteries from a CFA access. Typically a 45-cm sheath will suffice when working on the contralateral iliac system or beyond, and a 90 cm sheath is helpful when intervening on the carotid arteries. Similarly, a 90-cm sheath is helpful when working on the mesenteric vessels from a brachial artery access. While longer sheaths create nice working platforms, it must be remembered that any length of sheath protruding from the body is simply going to mean that longer devices and guidewires will be needed, so the sheath should be no longer than necessary to allow adequate imaging during the intended intervention.

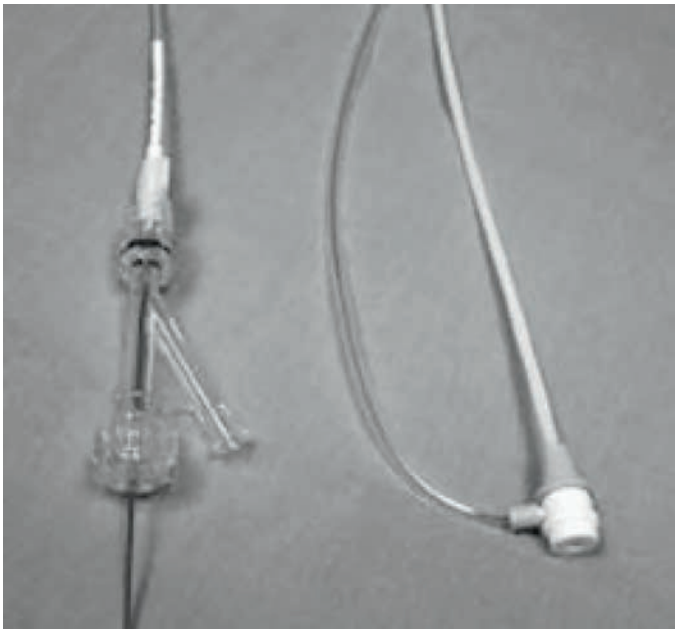

Figure 60.2 Y adapter on a guiding catheter *(left)* and hemostatic valve of a sheath *(right)*.

BOX 60.1 Conversion Between Gauge, French, Imperial, and Metric Units

18 gauge = 0.040 inches = 1.024 mm
21 gauge = 0.028 inches = 0.723 mm
1 millimeter = 3 French = 0.039 inches
3 millimeters = 9 French = 0.118 inches

Diagnostic Catheters

Diagnostic catheters are the vehicles used to deliver the radiographic contrast agent to the area of interest. Diagnostic catheters come in a range of sizes, lengths, and tip configurations (Table 60.1). Some catheters have radiopaque markers at uniform intervals along their length to assist with performing measurements, while others have hydrophilic coatings to facilitate their

Figure 60.3 Color-coded sheath caliber identification.

TABLE 60.1 Commonly Used Diagnostic Catheters

Vessel	Catheter Shape	Catheter Name
Contralateral iliac	Self-forming Manual-forming	Cobra 2, pigtail, Omni flush Simmons 1 or 2
Renal, mesenteric	Self-forming Manual-forming	Renal double curve, Cobra 2, SOS Omni Simmons 1 or 2
Axillary, brachial	Self-forming	Kumpe, Cobra 2
Subclavian, carotid	Self-forming Manual-forming	Headhunter H1, Vitek Simmons 1 or 2

TABLE 60.2 Endovascular Device Size Conventions

Device	Measurement Standard	Unit
Entry needle	Outer diameter	Gauge
Guide wire	Outer diameter	Inch
Sheath	Inner diameter	French
Diagnostic catheter	Outer diameter	French
Guide catheter	Outer diameter	French

TABLE 60.3 Names of Catheter by Type

Catheter Type	Name
Flush catheter	Pigtail, tennis racket, Omni flush, Contra 2
Single curve	Kumpe, vertebral, angled glide, Bernstein, multipurpose A and B
Double curve	Cobra (C1, C2, C3), Headhunter, renal double curve, rim
Reverse curve	SOS, visceral selective (VS1, VS2, VS3), Simmons, Sidewinder (1, 2, 3, 4), Vitek
Crossing catheter	Quick-cross, TrailBlazer, WildCat, CX1, CrossCath, Minnie, Seeker

advancement through long and tortuous pathways. Braided catheter construction renders the catheter more torque responsive and kink resistant. The caliber of diagnostic catheters is measured by their outer diameter; thus a 5F catheter has an outer diameter of 0.065″ and will fit inside a 5F sheath (which is measured by its inner diameter; Table 60.2). Most diagnostic catheters used by vascular surgeons are between 2F and 6F in size; the 2F and 3F catheters, referred to as microcatheters, are used primarily to deliver embolization coils to small distant targets. Diagnostic catheters can be grouped into nonselective selective and crossing catheters (Table 60.3).

Nonselective Catheters

Nonselective catheters are used to inject a high volume of contrast into relatively large blood vessels, typically using power injection, such as when performing aortography or vena cavography. As with all catheters, removal of the guidewire allows the catheter to take its shape, which, for these catheters, is typically some variation of circle. To reduce the "jet effect" of power injection through a simple end hole, and to facilitate contrast dispersal, these catheters also have multiple side holes along the terminal 15 mm (Fig. 60.4). In some situations, some nonselective catheters can be used to cannulate side branches or the contralateral iliac arteries when using contralateral femoral access (see the "Applications" section later in this chapter).

Selective Catheters

Selective catheters are so termed because they have a shape that facilitates their engagement in the orifice of a branch vessel, either for the injection of contrast or the subsequent passage of a guidewire. With but a few exceptions, selective catheters

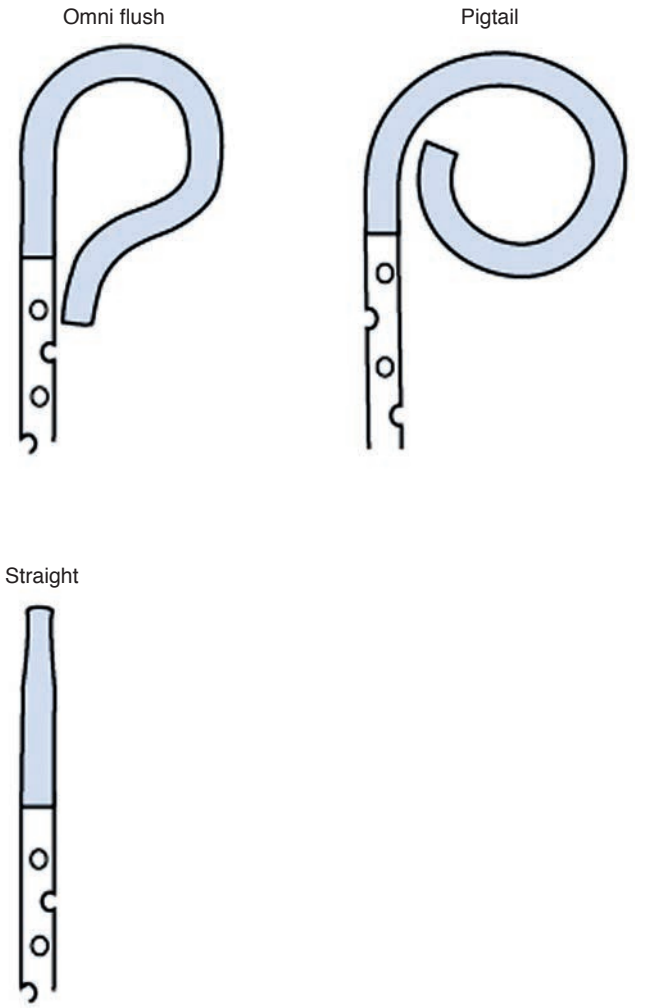

Figure 60.4 Nonselective diagnostic catheters with multiple side holes. (Courtesy of AngioDynamics, Queensbury, New York.)

have an end hole only, with no side holes, and thus should not be used for high pressure administration of contrast, as the resulting fluid jet could be traumatic to vessels. Selective catheters have a variety of shapes and curves that permit selective cannulation of side branches. Generally, selective catheters are divided into single-curved, double-curved, and reverse-curved configurations (Fig. 60.5).

A single-curved catheter is ideal for cannulating a side branch vessel that comes off at less than a 45-degree angle from the aorta. For example, a Kumpe single-curve catheter can be used to cannulate the common iliac artery when using brachial artery access. Double-curved catheters have angles up to 90 degrees and are more suitable for side branches that come off more acutely from the aorta. For example, a renal double-curve (RDC) catheter may be useful for cannulating a renal artery when using femoral access. Finally, reverse-curve catheters typically have a 180-degree curve in the catheter with the tip flaring off at an angle. These catheters are used to cannulate vessels that come off steeply, especially in curved blood vessels such as the aortic arch. For example, a Simmons 2 reverse-curve catheter can be used to cannulate the branches of the aortic arch when using femoral or brachial access. Reverse-curve catheters are

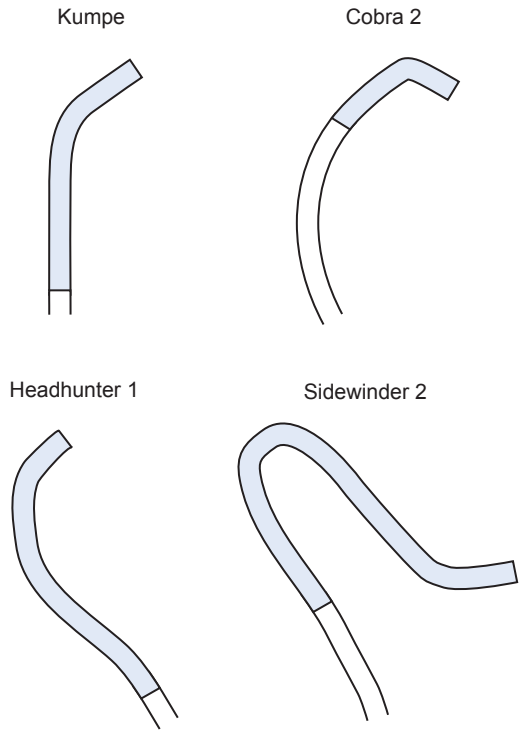

Figure 60.5 Selective diagnostic catheters. (Courtesy of AngioDynamics, Queensbury, New York.)

more difficult to work with, as their unique geometry requires the user to recreate the curves, also known as "forming the catheter," within the blood vessel after the guidewire is removed. The side arm of the catheter is available in varying lengths, depending on the depth of engagement desired, but the longer it is, the less responsive the tip will be to catheter manipulation.

Crossing Catheters

While most commonly used during interventional procedures, crossing catheters, in combination with guidewires, can be used to cross occluded or highly stenotic vessels. Crossing catheters are low profile, relatively stiff catheters with tapered tips that facilitate their passage through a tight stenosis or occlusion. They are available in both small-wire (0.014-0.018") and standard wire (0.035") versions, as well as with angled tips.

Guiding Catheters

Though not really diagnostic catheters, for the sake of completeness and to clarify often misquoted terminology, guiding catheters will be briefly reviewed. When confronted with the need to work remotely from the site of access, it becomes essential to have a sturdy platform through which to do wire and device exchanges and to be able to inject contrast that will opacify the site of intervention while the intervention is underway. There are two approaches for doing this, depending on the specific anatomy—one is to use a very long sheath, and the other is to use a guiding catheter. Guiding catheters are essentially sheaths that come in a variety of tip shapes. They have the advantage of coming in a variety of lengths and shapes to permit selective cannulation of a vessel, similar to that of a selective diagnostic catheter. Guide catheters are distinguished from diagnostic catheters in that their diameter typically remains constant throughout the length of the catheter, thus permitting insertion of a variety of smaller catheters (such as microcatheters), wires, and devices.

Techniques for using these catheters are described later in the "Applications" section.

Closure Devices

There are two primary methods of achieving hemostasis once a procedure is completed. Simple manual compression is effective in the majority of cases, particularly for small puncture sites (4F-8F). Care must be taken to avoid completely occluding the vessel as this can lead to thrombosis. At the same time, insufficient pressure will lead to a hematoma and contribute to the formation of a pseudoaneurysm. Depending on the extent of anticoagulation, the puncture size, and the patient's blood pressure, compression is commonly held between 5 and 20 minutes. The patient's body habitus can compromise effective compression, as can inadequate anesthesia. Compression time, either in the angio suite or in a recovery area, has to be figured into turnover time for the room and ultimate efficiency of practice. Furthermore, most patients have 6 hours of mandated bedrest, which also has to be figured into procedural costs.

To address patient complaints about the traditional 6 hours of bedrest, as well as facilitate patient throughput, a variety of "closure devices" have been developed which in some way or another seal the access hole, minimizing the need for compression and significantly shortening the bedrest period to less than 2 hours. These devices range from an extravascular plug to a suture-based technique for closure. The Angio-Seal device (St. Jude Medical, St. Paul, Minnesota) works by placing an intraarterial absorbable anchor against an externally placed collagen sponge; these are sandwiched together. This device works well on arteries that are at least 5 mm in size and free of significant calcification, and can be used to close puncture sites up to 8F.[7] The Mynx device (AccessClosure, Santa Clara, California) uses a polyethylene glycol polymer to close the tissue track over the puncture site, thereby providing hemostasis for puncture sizes up to 6F.[8] The ProGlide device (Abbott Vascular, Santa Clara, California) uses a single polypropylene stitch to suture close arteriotomy sites up to 6F.[9] Some practitioners have used this device off-label to close much larger puncture sites by placing two ProGlide devices through a single puncture site, thus allowing a totally percutaneous method for doing a TEVAR or EVAR procedure.[10] A variety of other closure devices are available. Closure devices increase the risk of groin infection and leg ischemia but decrease the time needed to achieve hemostasis.[9]

The decision to use a closure device on a given access site should be individualized to the patient's anatomy, clinical circumstances, and likelihood of benefit. Hospital inpatients who will be on bedrest anyway may have little to gain by the potential for early ambulation and discharge. Similarly, for

closure devices to recoup their cost, angio suite throughput really does have to increase and patients do truly have to be discharged sooner. If these can be achieved, however, and complication rates kept at a minimum, closure devices can recover their expense in briefer observation stays and enhanced patient satisfaction.

Applications

Theoretically, diagnostic angiography can be performed in any vascular territory, as long as one can safely position a catheter upstream of the area of interest and infuse sufficient contrast to adequately visualize it. And while there are many similarities to the technique of angiographic evaluation of the different vascular territories, variables such as vessel size, flow rates, cannulation pathway, and downstream organ sensitivity will invariably influence the choice of catheter and infusion technique to be used.

Abdominal Aortography

A standard diagnostic abdominal aortogram typically involves initial imaging in the AP orientation from L1 cephalad to as far distal as the image intensifier size permits, using power injection through a multiside hole flush catheter positioned in the region of the renal arteries (L2). Ideally, using a 48-cm flat panel detector with the patient elevated off the x-ray tube, you can expect to image to at least the mid-external iliac arteries. The catheter is then repositioned into the infrarenal aorta and the table repositioned so that the lesser trochanters are at the caudad-most aspect of the image. Two subsequent power injection runs are obtained in LAO and RAO orientations to splay out the iliac and femoral bifurcations, where stenoses often occur. These images will also ensure proper sheath placement and suitability for subsequent use of a closure device. A standard aortogram usually uses 15 mL of 50% contrast per second for a total of 30 mL of contrast ("15 for 30") at a pressure of 800 mm Hg. Longer catheters can be used if doing imaging of the thoracic aorta, and a catheter with regular 1 cm markings (i.e., "marker pig") can be used for distance calibration and making measurements, particularly relevant for aortic endografting.

Extremity Angiography

Most commonly, aortoiliac evaluation will be followed by unilateral or bilateral extremity imaging. Simultaneous bilateral imaging can be obtained using power injection of contrast into the infrarenal aorta and segmental bilateral extremity imaging, body habitus permitting. Alternatively, more advanced angiographic suites have bolus chase capabilities that allow for continuous bilateral DSA imaging from the aorta to the toes following a single injection of 80 mL of contrast over 8 seconds into the infrarenal aorta. While acquisition of imaging from nonselective catheterization may be more expeditious, image quality can be compromised by differential limb perfusion, less flexible radiographic projections, and contrast dilution. Furthermore, inadequate opacification or delineation of pathology can be problematic, since repeating a bolus chase run involves a substantial increase in contrast administered.

The best quality of imaging occurs with more selective catheterization of the tree of vessels of interest. Having evaluated the abdominal aorta and iliac systems and ascertained the safety of crossover catheterization, a catheter is positioned in the distal contralateral external iliac artery for subsequent imaging down the leg. A variety of catheter shapes can be utilized to effect this contralateral positioning, ranging from the pigtail catheter used for flush aortography to shapes specifically designed to navigate over the aortic bifurcation. Once the contralateral common iliac artery is hooked, the wire is gently advanced into the CFA, followed by the catheter (Fig. 60.6). Extremity imaging can now be completed, typically in the 30 to 45 degrees° ipsilateral anterior oblique projection, so as to splay out the trifurcation vessels and open up the tibia-fibula window. A variety of alternative selective diagnostic catheters are available to facilitate crossing over the aortic bifurcation and selecting other vessels (Fig. 60.7A and B). Extremity angiography on the side of arterial access is typically performed via simple sheath injection of contrast into the ipsilateral iliac system.

While many operators prefer hand injection angiographic runs, once the catheter is in position, a power injector can be used to complete the imaging, with care being taken to reduce injection rates and pressures commensurate to the vessel size and circumstances. An advantage of power injection is the ability for the operator and team to be sheltered from radiation, controlling contrast injection remotely during the angiographic runs. The primary disadvantage is the inability to vary the contrast concentration throughout the course of the evaluation, as can easily be done with hand injection using a manifold setup, as well as vary contrast infusion rates in real time.

Renal/Mesenteric Angiography

In many situations, the combination of preoperative imaging and the diagnostic aortogram is sufficient to make the diagnosis of renal artery stenosis, and selective angiography is unnecessary unless intervention is planned, in which case a guiding catheter would typically next be deployed. However, in cases where the desired anatomic information is not evident from the flush aortogram and selective angiography is elected, it is important to remember that most atherosclerotic disease of the renal and mesenteric vessels occurs near their origins off of the aorta. As such, the ideal diagnostic catheter shape to demonstrate the disease would be one curved and sized to sit softly against the aortic wall with slight downward angulation. Ideally, the catheter curve selected would be oversized enough relative to the aorta to lightly engage the vessel origin when pulled across it, without being so aggressive a curve that the catheter tip pops in, uncontrollably crossing any orificial disease. For diagnostic purposes, a RDC catheter (see Fig. 60.7C) is a commonly elected shape. In our practice, angiographic imaging is performed via hand injection of an already connected manifold system. While power injection imaging can be performed, catheter dislodgement is more likely, and it is more difficult to guide catheter placement with puffs of contrast.

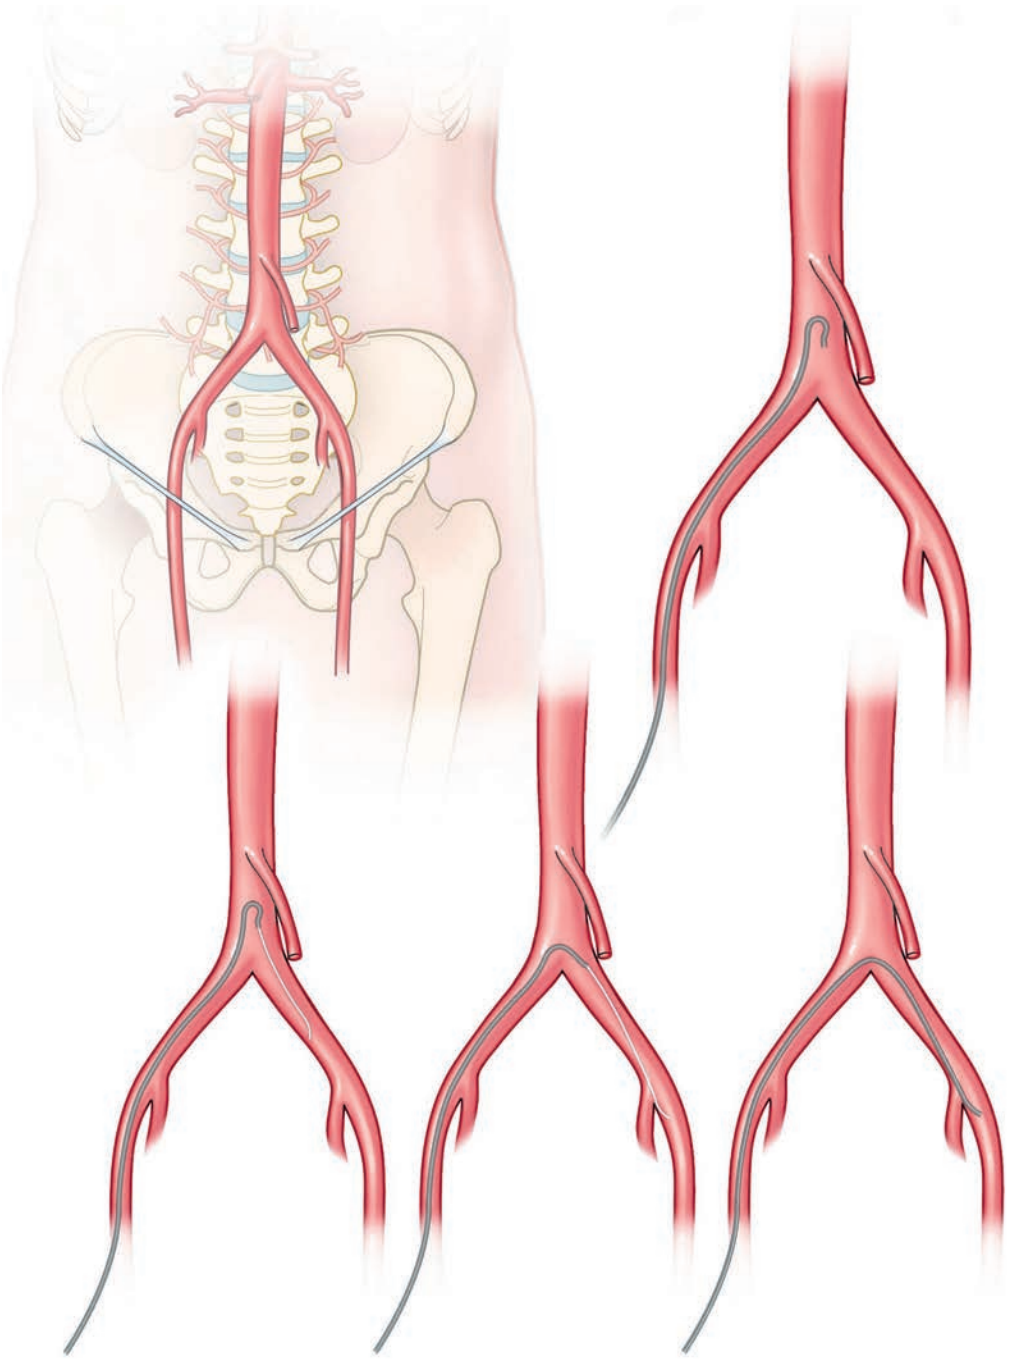

Figure 60.6 Crossing the aortic bifurcation to enter the contralateral iliac artery using an Omni flush catheter and soft angled wire.

As with renal artery disease, most mesenteric disease occurs proximally in the vessel. While AP aortography would still typically be performed to evaluate the entire abdominal aorta and possible mesenteric collaterals, evaluation of the celiac axis and superior mesenteric artery (SMA) will require a lateral projection, along with which often comes diminished image quality due to extra tissue to penetrate. Even more so than with renal arteries, the celiac and SMA can be sloped acutely caudally, sometimes to the extent that it complicates catheterization from femoral access. While rarely necessary for purely diagnostic purposes, the degree of angulation may favor a brachial approach for any necessary intervention. Without the U-turn required by a femoral access, catheters and guidewires should be more easily steered and devices should track better.

Carotid Angiography

Carotid angiography should begin with nonselective arch aortography performed through a multi-side-hole catheter using power injection. While in some situations all of the desired information can be obtained nonselectively, frequently requiring multiple runs in different projections, most commonly selective angiography will be desired, and the primary purpose of arch

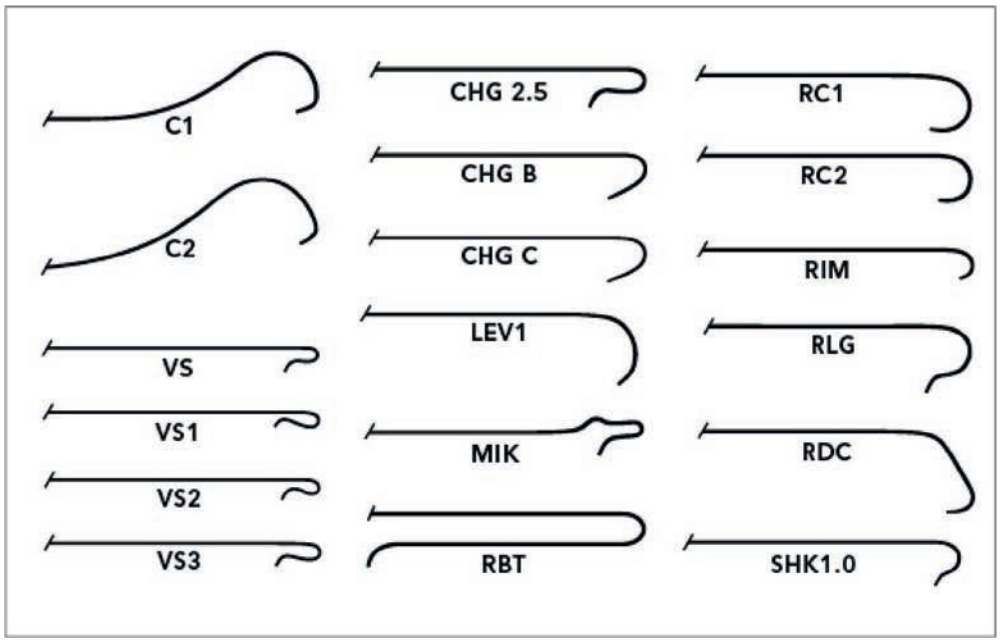

Figure 60.7 Common multipurpose catheters. (Courtesy Cook Medical, Bloomington, Indiana.)

aortography is to determine that it is safe to attempt to select the various brachiocephalic vessels and to help guide the performance thereof. The anatomic feature that complicates selective carotid angiography pertains to the origin of the parent arteries, which are typically proximal enough on the aortic arch that their cannulation requires a U-turn. Two catheterization options are generally available: a forward selecting catheter, usually combined with a guidewire, or a reverse-curved catheter, which will need to be reformed once the guidewire is removed. A commonly used reverse curve catheter, a Simmons 2, is advanced into the proximal aortic arch over a wire (see Fig. 60.7D). The tip is reformed either at the aortic root or by hooking the left subclavian artery or brachiocephalic trunk (Fig. 60.8). The catheter can now be slowly pulled back to selectively cannulate either the brachiocephalic trunk or left common carotid artery. If selective right common carotid access is desired and the innominate artery is long, a Simmons 2 catheter will likely be required. Alternatively, if less side-arm length is needed, a Simmons 1 catheter will be more responsive and easier to negotiate into the left common carotid artery. There are self-forming reverse curve catheters, such as the VTK (see Fig. 60.7D), that negate the need to be manipulated into shape, but their side-arm length, and therefore depth of vessel penetration, is limited.

Once the common carotid artery is cannulated, filming can be performed with either hand-injection of contrast or, if the catheter position is stable, with power injection. Only 4 mL of 50% contrast per second for a total of 6 mL is used at a pressure of 200 mm Hg. The complexity of carotid angiography increases if type II and type III arches, in which the aortic arch branches come off earlier on the curve of the arch, and a more steeply curved catheter may be necessary. At all times, careful manipulation of the wires and catheters in this region is required to prevent embolization from an atheromatous aortic wall, again underscoring the need for an initial arch angiogram to allow appreciation of arch and proximal branch vessel disease prior to attempting to catheterize through it.

Fistulography

Fistulography is typically performed via direct access into the fistula or graft in a location that allows for complete inflow and outflow imaging. These are relatively large-caliber, high-flow vessels that are readily palpable and usually easily accessed. Ultrasound guidance is helpful if the cannulation site cannot be readily palpated, as may be the case with a failing access or one failing to mature. For diagnostic purposes, a simple angiocath or 4Fr dilator are often all that is necessary, with conversion to sheath access if a lesion suitable for endovascular treatment is demonstrated. While outflow imaging is straightforward, demonstration of the aspects of the fistula upstream of the site of access may be facilitated by manual compression of the outflow track or placement of a temporary tourniquet such as a large Penrose drain. If a lesion to be treated is encountered, a shorter than standard sheath (6 cm instead of 11 cm) is often used, due to the close working distances involved.

Pelvic Congestion Syndrome Venography

Cannulating most veins for diagnostic imaging is similar to that described for their arterial counterparts. Pelvic congestion syndrome presents several unique challenges for imaging. Ultrasound-guided access into the CFV is obtained and a diagnostic venogram completed through the sheath using 10 mL of 50% contrast injected by hand. The renal vein orifices can often be visualized on vena cavography as an area of lower opacification, or contrast washout from contrast-free blood entering from the kidney. A suitably shaped catheter such as a

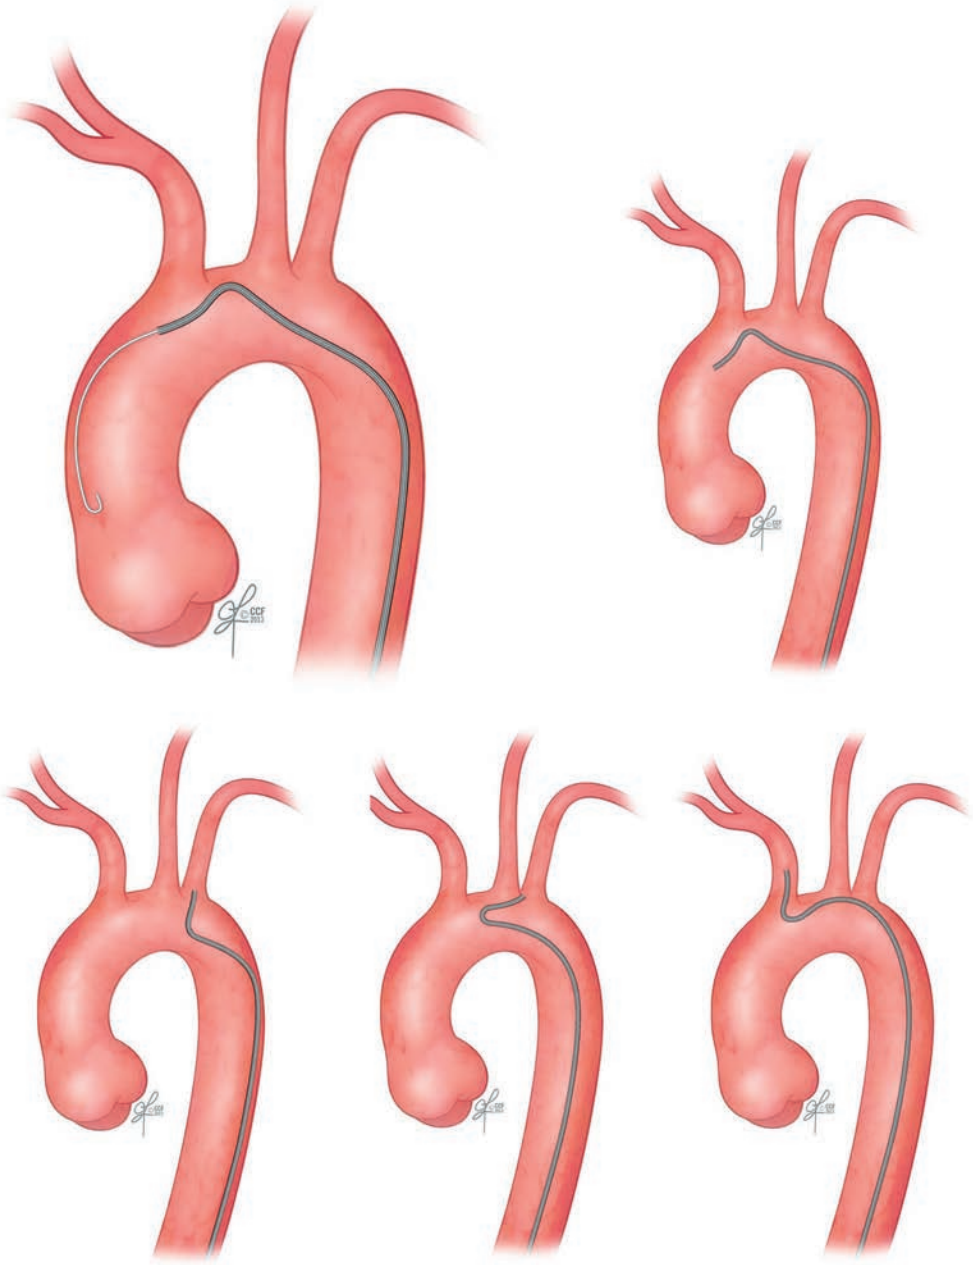

Figure 60.8 Technique for forming a Simmons 2 catheter with the aortic arch and selective cannulization of an arch branch.

RDC catheter is used in combination with a guidewire, if necessary, to cannulate the proximal ovarian vein. Filming is generally performed with hand injection of contrast under low pressure, so as not to traumatize the veins. If necessary, a more distal catheter position can be pursued to enhance opacification of the pelvic venous network. If an intervention is elected a distal catheter position will be required, usually mandating use of a microcatheter (0.022″) to navigate the tortuosity atraumatically. The typical setup in this situation is a guiding catheter in the renal vein, inside of which is a 4Fr hydrophilic catheter into the ovarian vein, inside of which is the microcatheter through which embolization coils or other materials are injected.

While the right ovarian vein can sometimes be accessed directly from the IVC, the acute angle can be problematic, and so the more common approach is via access the right ovarian vein via the contralateral internal iliac vein.

COMPLICATIONS

Access Site

These are the most common areas for complication following endovascular diagnostic procedures. Poential complications and their incidence include clinically significant hematoma (3%),

thrombosis (2%), bleeding (1%), traumatic arteriovenous fistula (0.9%), and pseudoaneurysm (0.6%).[11] There is some evidence that the incidence of these complications can be reduced through the use of either ultrasound or fluoroscopic guidance.[11-13] The incidence of these complications increases in patients who are obese, have diseased access vessels, required large sheath sizes, and who were on anticoagulation.[11-13]

While the majority of postcatheterization hematomas are clinically insignificant, failure to obtain puncture site hemostasis can result in significant local and systemic sequelae. Of greatest risk to the patient is retroperitoneal hemorrhage from an access site cephalad to the inguinal ligament. Punctures in this location are difficult to compress manually, and closure devices are both contraindicated and ineffective. If hemostasis cannot be achieved through simple manual pressure, reversal of anticoagulation may be helpful. Continuing bleeding should be managed with conversion to open technique and direct vessel repair, though endovascular treatment with peripheral endografting is a potential option, as is temporary endovascular balloon control as an adjunctive technique while open exposure is obtained.

The more common access site complication is a hematoma and/or false aneurysm in the groin. Many of these will resolve spontaneously, and therefore their diagnosis alone is no longer an indication for repair. When persistent, enlarging, or symptomatic, most access site false aneurysms these days are treated by simple ultrasound guided thrombin injection. If the hematoma is large and compromising the viability of the overlying skin, or otherwise unsuitable for thrombin injection, open surgical repair with hematoma drainage is indicated.

Access-related arteriovenous fistulae tend to occur with more distal punctures, often of the profunda femoris artery itself, with fistulization to the adjacent or crossing veins. This location is difficult to compress after sheath removal, which may play a role in formation of the fistula. While many are asymptomatic and will close spontaneously, persistent AV fistulae should undergo repair, most commonly through open surgery. Preoperative angiography can be helpful in revealing what should be expected and, in the uncommon scenario, allow for any endovascular treatment deemed suitable.

Catheter- or Guidewire–Related

Catheter- or guidewire-related complications are secondary to damage to the vessel wall from their passage or manipulation, such as the creation of a perforation or dissection, with or without embolization. Observation of wire and catheter advancement under fluoroscopy helps avoid these complications. Similarly, appropriate selection of wires and catheters can also minimize the risk of dissection, perforation, and embolization. Perhaps most important is that the catheter, in its natural shape, is not excessively larger than the diameter of the vessel that it is in, lest the tip inflict trauma on the vessel wall. Perforation of a vessel can be minimized by rigorous control over wires and catheters, particularly relevant when dealing with terminal vascular territories like the renal artery or mesenteric circulation, where excessively deep guidewire penetration can easily lead to perforation. Lastly, the super-stiff variety of guidewires have a rather abrupt transition from the floppy to the stiff areas and, consequently, do not lead out well. These are rarely used for diagnostic purposes, but when used are best positioned initially through a catheter to minimize vessel wall trauma. Dissections, if clinically relevant, can be treated with either bare metal or covered stents, while perforations and AV fistulae are best treated with endografting. Catheter-guidewire induced embolization, often secondary to dissection, is typically microembolic and therefore not amendable to angiographic detection or aspiration. Larger emboli, especially those that occur during thrombolysis, may be extracted or lysed through standard endovascular techniques.

Systemic

Systemic complications associated with endovascular diagnostic procedures are related to the use of iodinated contrast, anticoagulation, and radiation. While there are several protocols available that help identify a patient's upper contrast limit, the best option is to routinely use the lowest dose of contrast possible. This can be facilitated by diluting the contrast, titrating contrast administration to real-time visualization, and by selective catheterization of the territory of interest. In patients with chronic kidney disease, CO_2 can be a useful adjunct when performing arterial imaging procedures below the diaphragm. Similarly, following the principles of ALARA (as low as reasonably achievable) for radiation exposure will help prevent tissue damage from excess x-rays.

Anticoagulation with heparin is associated with a 0.2% incidence of heparin-induced thrombocytopenia (HIT). Severe HIT can lead to the formation of extensive thrombosis and cardiovascular collapse. Prompt recognition, removal of heparin from all sources, and conversion to another anticoagulation agent such as argatroban is necessary.

CONCLUSION

Endovascular diagnostic procedures are relatively safe when used properly. Adjuncts such as ultrasound-guidance and proper wire and catheter selection can decrease the incidence of complications. This valuable diagnostic and therapeutic tool is a mainstay of vascular surgery and mastery of the variety of wires, catheters, and sheaths important for the safe and effective practice of vascular surgery.

INTRODUCTION

Endovascular treatment has currently replaced open surgical procedures as the first-line treatment for many vascular diseases. The durability of endovascular treatment options should be evaluated in comparison with open surgical options during preoperative planning. This chapter reviews the basic principles, the devices, and techniques of endovascular therapy, including indications, limitations, pitfalls, and complications.

BALLOON ANGIOPLASTY

The first percutaneous treatment for peripheral artery disease (PAD) was performed in 1964, when Dotter and Judkins described a transluminal technique using progressively larger dilators in the lower extremities.[1] The balloon catheter, well-known today, was developed to dilate arterial stenotic lesions with flexible polyvinylchloride (PVC) balloons by Gruntzig and Hopff.[2] The mechanism of balloon dilation for stenotic lesions is a blunt dehiscence effect leading to fracture and separation of the arterial media from the intima, with stretching of the media and adventitia. Percutaneous intraluminal angioplasty (PTA) has disadvantages affected by the lesion type. Treatment of severely stenotic lesions and those with dense calcification may result in elastic recoil and/or flow limiting dissection after PTA, and stents are often utilized to overcome such complications. In addition, new technologies such as drug-coated balloons (DCBs) are expected to provide equivalent performance to stents without leaving foreign bodies prone to fracture. However, if the lesion can be treated with PTA alone, it is most cost-effective. In order to maximize the outcome of PTA, one must choose the appropriate balloon for a given lesion. An understanding of the characteristics, behaviors, and techniques of balloon angioplasty is essential.

Balloon Catheter Types

Balloon catheters for PAD are classified into two types: over-the-wire (OTW) and single-operator exchange (SOE) system. In OTW technology, the wire passes through the entire catheter, providing good support and high pushability compared with SOE system. In addition, this technology allows for guidewire exchange when a lesion is difficult to cross. The length of the shaft for OTW balloons ranges from 80 to 150 cm. If a long shaft, such as a 130- or 150-cm shaft, is selected to treat a lesion, a wire of 260 cm or longer is needed to treat the lesion.

In the SOE systems, often referred to as " monorail" or "rapid exchange" (Rx), the wire enters from the distal tip of the catheter and exits from a side hole in the catheter, 20 to 25 cm proximal to the balloon. The SOE balloons, which are generally used in coronary interventions, are supported by a 0.014-inch or 0.018-inch guidewire system. In PAD, these balloons are utilized for below-the-knee lesions, where vessel diameters are much smaller than above-knee lesions. Since an SOE catheter shaft does not have a wire through the lumen, SOE balloons can be inserted, delivered, or exchanged by a single operator who can hold the wire close to the insertion point. Thus, an exchange length wire is not necessary for SOE systems, which can use a wire of any length, shortening the procedural time. When compared to the OTW system, the SOE has generally a lower profile at the expense of less pushability and trackability In addition, it does not allow for exchanging the wire without a transfer catheter or the use of a long sheath or guiding catheter.

Balloon Characteristics

Balloon Compliance

Balloon compliance represents the degree of the expansive ability of the balloon, which is determined by the function of pressure and diameter. Currently available balloons for PAD are usually made of plastic polymer with varying degrees of compliance. The inflated pressure affecting compliance ranges from a stated nominal pressure to a rated burst pressure in each balloon. Nominal pressure is defined as the pressure at which the balloon expands to its determined diameter and length, and ranges generally from 3 to 10 atmospheres (atm). Rated burst pressure (RBP) is the pressure at which less than 1% of tested balloons will burst and beyond which the probability of rupture increases. RBP typically ranges from 6 to 16 atm. Mean burst pressure, defined as the pressure at which 50% of balloons will rupture, is commonly higher than the RBP and ranges from 10 to 27 atm. Regarding compliance, two types of balloons are mainly used: compliant and noncompliant.

Compliant balloons are usually made of polyolefin copolymer and polyethylene. These balloons, including semicompliant balloons, are superior in trackability and are suitable for lesions

in a curved portion of a vessel. Although they produce less vascular damage because of gentle dilation, high-pressure inflation can result in a doggie bone effect that may damage the normal vessel proximal and distal to the lesion. Thus, a compliant balloon is not suitable for severe calcific lesions. However, one advantage of a compliant balloon is that a single balloon may be adapted to various vessel diameters.

Noncompliant balloons are referred to as high-pressure balloons or low compliance balloons. Most noncompliant balloons are composed of polyethylene terephthalate or nylon reinforced polyurethane. These materials improve the radial force of the balloon and allow for high-pressure expansion. Thus, noncompliant balloons, which are constructed to maintain their designed shape and size under high pressure, have a higher RBP compared with compliant balloons. Noncompliant balloons, preferred by most interventional specialists, exert more recoil force when used for severe calcific lesions or following insufficient expansion during postdilation following stent deployment.

Profile and Balloon Ability

Profile is usually expressed in French (Fr.) size and is determined by the cross-sectional area and diameter of the balloon and shaft. A smaller profile is better than a larger profile in terms of deliverability to the lesion and the ability to cross severely stenotic lesions. Most peripheral balloons are deliverable via a 4- to 6-Fr. compatible sheath. The balloon tip is designed to make a smooth transition and to minimize crossing profile. Balloons of 0.014- or 0.018-inch wire systems have a smaller profile compared to the 0.035-inch systems.

The performances of balloons are determined by trackability, pushability, and crossability. Trackability is the ability of the catheter to follow the guidewire without loss of wire position. Balloons with better trackability advance better in tortuous vessels. Pushability is the ability to transmit force along the length of balloon catheter to the target lesion. Hydrophilic, hydrophobic, silicone, or other surface coatings on balloon catheters, as well as balloon stiffness, determine their pushability. Generally, balloons of 0.035-inch systems have higher pushability compared with the 0.014- or 0.018-inch systems. Balloon catheters with OTW systems also have higher pushability compared with similar SOE systems. Crossability is the ability to cross the stenotic lesion. Balloon shapes that are commonly used for the peripheral arteries, including tip features and low-friction surfaces, allow for smooth passage to the target vessels. Torque transmitting performance and kink resistance of the balloon catheter are also important.

Specialty Balloons

PTA is carried out by fracturing the plaque and irregularly dissociating the intima or media of the vessel and therefore often results in dissection and recoil, particularly in severely stenotic and calcified lesions where uneven overpressures are applied. Therefore, specialty balloons have been developed for specific purposes to improve PTA outcomes and to reduce the occurrence of recoil, dissection, and restenosis.

Cutting Balloons

A cutting balloon is a specialized device made of a series of 3 or 4 microsurgical blades (artherotomes) mounted longitudinally along the surface of a standard PTA balloon (Fig. 61.1). A cutting balloon was initially introduced as an angiography device for percutaneous coronary intervention by Barath et al.[3] Previously, only small size (less than 4 mm) balloons were available. However, there are now balloons with a larger diameter (8 mm) that are currently utilized for peripheral lesions. Peripheral cutting balloons (PCBs) require a 0.014- or 0.018-inch guidewire system with a 6- to 7-Fr. sheath. More specifically, small diameter PCBs are supported by a 0.014-inch guidewire system and either an OTW or SOE system, but large diameter PCBs are only used with a 0.018-inch guidewire system with an OTW system. PCB length is typically 1.5 to 2.0 cm. Peripheral lesions that are suitable for the treatment with a PCB are mainly short lesions involving venous graft stenosis following bypass, bifurcation stenosis, no-stenting zone (such as common femoral or popliteal artery), and in-stent restenosis (ISR), as opposed to areas that require primary treatment of occlusive disease. The midterm results of PCBs versus conventional PTA (noncompliant balloons) for the treatment of short lesion of femoropopliteal artery stenosis was reported in a retrospective study by Antonio et al.[4] A total of 142 short occlusive lesions under 3.0 cm were

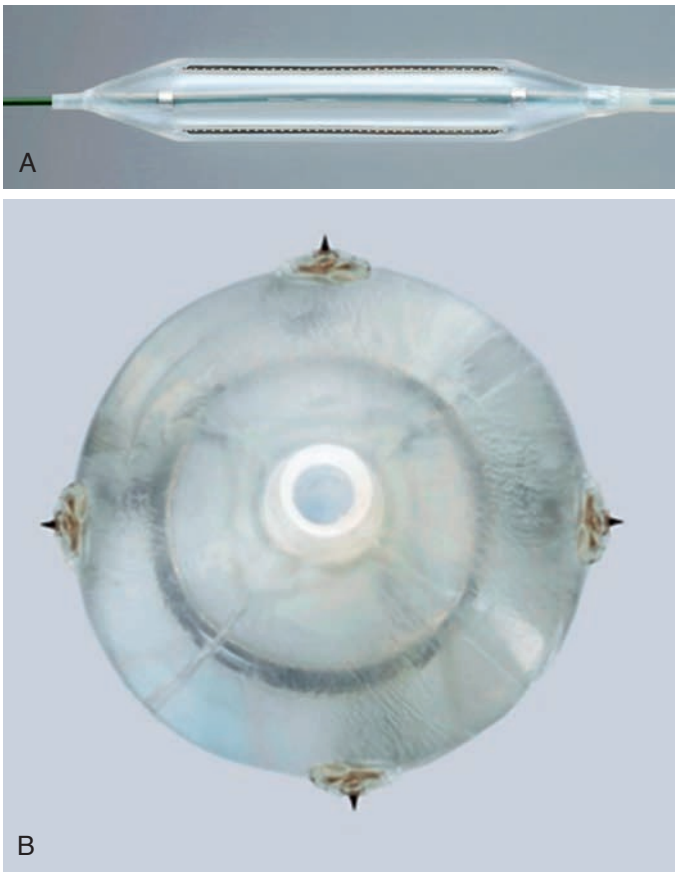

Figure 61.1 Peripheral cutting balloon (Boston Scientific, Natick, Massachusetts), (A) is seen from the side and (B) is from the top of the balloon.

treated in 84 consecutive patients. Forty patients underwent conventional PTA balloon (46 limbs, 67 stenotic lesions) and the remainder were treated with PCBs (44 limbs, 75 stenoses). Target lesions were located in the superficial femoral artery (SFA) in 91 limbs and the popliteal artery of 51 limbs. The primary endpoint was the 24-month patency rate of the treated lesions, and secondary endpoints were the estimation of complications after surgery and the 6- or 12-month patency rates. Technical success was 100%. Baseline reference vessel diameters and postprocedural minimum lumen diameters for the PTA group and PCB group did not show a significant difference. The primary patency rates of the PTA at 6-, 12-, 24-months were 91.0%, 83.1%, and 66.6%, respectively. In the PCB group, the primary patency rates at 6-, 12-, 24-months were 93.2% ($P < .001$ vs. PTA at same period), 90.4% ($P < .001$), and 79.7% ($P < .001$), respectively. Additionally, in 4 (6%) of 67 lesions of PTA, a self-expanding stent was required due to a flow-limiting dissection, but no recoil, dissection, or arterial tears requiring stents were observed in PCBs. There were no adverse events, deaths, or amputation in the two groups. Reintervention rates were 20% in the conventional PTA group and 9% in PCB group ($P < .001$). In another study of 128 patients undergoing treatment of infrainguinal lesions, the primary patency rate following treatment with PCB was 82.1% at 1 and 2 years. In patients with critical limb ischemia (CLI), the primary patency rates at 1 and 2 years were 64.4% and 51.9%, respectively.[5]

PCBs have also been used for hyperplastic stenosis in hemodialysis arteriovenous fistulae. In a review of several randomized trials, the patency of the target lesion at 6 months was significantly higher in the PCB group compared to the control group (conventional balloon dilatation), implying greater freedom from restenosis without a significant increase in the complication rate.[6] Considering the results of these studies, PCBs are recommended for the treatment of short stenotic or occlusive lesions in the femoropopliteal artery, or hemodialysis arteriovenous fistulae, achieving better patency compared to conventional noncompliant balloons.

Cryoplasty

Cryoplasty is a type of balloon angioplasty that uses cooling and pressure to dilate the plaque and vessel wall. This system was expected to reduce dissection and therefore avoid stenting and also reduce restenosis. When the balloon reaches the target lesion, liquid nitrous oxide inflates the balloon and exposes approximately 500 μm of lesion with cooling to 14°F (−10°C), which may induce an inflammatory response in the plaque, temporarily reduce the elasticity of the intima, and reduce smooth muscle cell proliferation by cell apoptosis. In a review of seven randomized controlled trials including 478 patients with iliac, infrainguinal, femoropopliteal, and popliteal lesions treated by cryoplasty or conventional angioplasty, target lesion patency and restenosis rates calculated at various periods in two primary cryoplasty trials demonstrated no statistical difference between the treatment groups. Adjunctive cryoplasty, which was performed for ISR of SFA lesions, was associated with improvements of patency only at 6-month (OR 5.37, 95% CI; 1.09 to 26.49). The authors concluded that the efficacy of cryoplasty over conventional angioplasty could not be proven.[7] Since the effectiveness of cryoplasty is not apparent and there are additional costs ($1700) compared to conventional PTA, the value and role of cryoplasty for the treatment of PAD is limited if nonexistent.

Focal Pressure Balloon

Focal balloons were designed to reduce dissection and restenosis. The AngioSculpt (AngioScore, Fremont, California) and VascuTrak 2 (Bard Peripheral Vascular, Tempe, Arizona) balloons are designed to exhibit focal pressure to the lesions. The AngioSculpt balloon is composed of nitinol wires placed in spiral struts along the surface of a standard semicompliant balloon. The 1-year outcomes of treatment for CLI by the AngioSculpt balloon were reported by Bosiers et al.[8] Thirty-six complex infrapopliteal atherosclerotic lesions, ranging from 6 to 100 mm, were treated in 31 patients. The primary patency and limb salvage rates at a 1-year period were 61.0% and 86.3%, respectively. Eleven patients (35.5%) required stents secondary to dissection or suboptimal angioplasty. The authors concluded that the AngioSculpt balloon catheter was effective and safe for patients with CLI. The VascuTrak 2 balloon catheter has two wires located along the longitudinal axis of the balloon to provide focal pressure, which is estimated to be approximately 50 to 400 times greater than a conventional balloon. Although there is no solid evidence supporting the VascuTrak 2, some authors have reported effective outcomes utilizing this balloon to treat infrapopliteal disease with a 100% delivery rate and only 20% of patients requiring stents as a bail-out.[9]

Drug Coated Balloon

Intimal hyperplasia occurs due to an inflammatory reaction following vascular damage from stenting or balloon expansion. Drug-eluting stents (DES) were developed in 1999 to achieve local administration of an agent capable of inhibiting intimal hyperplasia without systemic side effects. The Cypher stent (Cordis Corporation, Fremont, California), which was developed for the treatment of coronary artery disease, releases Sirolimus, a macrolide antibiotic which also has a potent immunosuppressive drug that controls intimal hyperplasia. Subsequently, the TAXUS stent (Boston Scientific, Natick, Massachusetts), which is coated with Paclitaxel, was developed as a second generation DES. These stents could provide greater durability and reduce restenosis; however, they did not prolong life-expectancy or decrease cardiac events compared to coronary bypass in the SYNTAX trial.[10] Moreover, dual antiplatelet drug therapy (DAPT) was required 3 to 6 months after stent placement, because of an increased risk of subacute thrombosis (SAT) without DAPT following DES deployment.

DCB adopted the DES technology for the treatment of femoropopliteal or below-the-knee (BTK) lesions. Multicenter clinical RCTs of DCBs have been performed. The LEVANT 1 trial, a single-blinded design comparing DCB and noncoated balloons in Europe, evaluated the safety and efficacy of the Lutonix DCB (Bard Peripheral Vascular, Tempe, Arizona) for the treatment of femoropopliteal lesions.[11] The Lutonix DCB

is coated with a low dose of Paclitaxel (2 μg/mm^2) as an antiproliferative drug and is available in diameters of 5 to 6 mm and lengths of 60 to 100 mm. A total of 101 patients who had femoropopliteal atherosclerotic disease with Rutherford class 2 to 5 were enrolled in this trial. The primary outcome was angiographic late lumen loss at 6 months, and the secondary outcome included major adverse events (MAEs), functional outcomes, and pharmacokinetics. Operators were instructed to insert the DCB beyond the margins of the predilation site and to inflate the balloon for over 30 seconds in order to transfer the drug to the lesion. Stenting as a bail-out procedure was permitted in either group for flow-limiting dissections. In this trial, the procedural success rates were 100% in the DCB group and 99% in the uncoated balloon group, respectively. The primary outcome of 6-month angiographic late lumen loss was significantly lower in the DCB group than in the uncoated group by intention-to-treat analysis (0.46 ± 1.13 mm vs. 1.09 ± 1.07 mm, $P = .016$). The primary patency rates were 72% in the DCB group versus 49% in the noncoated group at 6 months, and 67% in the DCB group versus 55% in the noncoated group at 12 months, respectively, which was based on freedom from target lesion revascularization (TLR), and restenosis on angiography at 6 months, and peak systolic velocity ratio (PSVR) ≧2.5 at 12 or 24 months. The MAEs, including death, thrombosis, amputation, and reintervention rate, were 39% in the DCB group compared with 46% in the uncoated balloon group ($P = .045$). This trial suggested that DCB balloons are efficacious for the treatment of PAD in femoropopliteal lesions. Consequently, LEVANT 2, a global, prospective, single-blinded randomized trial, was conducted comparing Lutonix DCB with standard PTA.[12] In this trial, 476 patients with symptomatic intermittent claudication or rest pain were randomly assigned in a 2:1 ratio to undergo angioplasty using DCB or the standard balloon for the treatment of femoropopliteal arterial disease. The primary endpoint was the primary patency of the target lesion at 12 months, defined as freedom from binary restenosis or TLR. Freedom from perioperative death from any cause and freedom at 12 months from limb-related death, amputation, or reintervention were also evaluated. The overall mean lesion length was 62.8 ± 41.0 mm, and the total treated length was 107.8 ± 47.8 mm. No statistical difference was observed between the DCB group and the standard PTA group in terms of procedural success (88.9% vs. 86.8%). Stent placement was more prevalent in the standard PTA group (2.5% in the DCB group, 6.9% in the standard PTA group, $P = .02$). The primary patency rate (primary endpoint) of the DCB group was superior to the standard PTA group (65.2% vs. 52.6%, $P = .02$). Additionally, the proportion of patients free from death or free from limb-related death at 12 months, amputation, or reintervention was 83.9% in the DCB group versus 79.0% in the standard PTA group, with no statistical difference. As a result, the authors concluded that the Lutonix DCB was effective and safe for the treatment of femoropopliteal arterial disease due to superior patency and fewer complications compared to standard PTA in the short term.

Initially favorable outcomes have been presented for several DCB trials, but long-term patency and safety remain unclear. Therefore, further long-term follow-up will be required to decide whether DCB therapy is appropriate for the treatment of complex stenotic lesions or occlusive lesions in infrainguinal PAD or dialysis access venous stenoses.

On a technical note, predilation with the appropriately sized balloon is first performed followed by using the DCB to deliver the Paclitaxel.

STENTS

The term "stent" originated from Charles R. Stent, a British dentist, who developed an apparatus to make dental molds. Thereafter, a mold embedded inner lumen came to be known as a stent. Stenting for vascular lesions is currently widespread as a method to reduce the incidence of restenosis or address balloon PTA failure due to elastic recoil or dissection. In 1964, Charles Dotter, who performed the first PTA, initially reported laboratory experience with a long-term patency of coil spring endoarterial tube grafts in canine popliteal arteries.[13] This was the first report of transluminal metallic stent placement. The nitinol stent, which accounts for the majority of the currently available stents, consists of an alloy of nickel and titanium and was not used until 1983.[14,15] In 1985, Palmaz et al.[16] introduced the first balloon-expanding stent which was approved for peripheral vascular use by the US Food and Drug Administration (FDA). The patency of the Palmaz-Schatz stent compared to PTA was demonstrated in several trials.[17,18] Currently, many available stents have been developed (Table 61.1) and evaluated in clinical studies.

Stent Types

Stents are classified as balloon-expanding (BES) and self-expanding stents, and also either as bare metal or covered stents. Most bare metal stents are composed of stainless steel, nitinol, cobalt chrome, or various metal alloys, whereas covered stents (stent grafts or endografts) are composed of stent with woven, expanded polytetrafluoroethylene (PTFE), polyurethane, or silicon. Stent characteristics, including flexibility, radial strength, kink resistance, and biocompatibility, vary depending on their material and design and may affect the ultimate patency of the stent.

Balloon-Expanding Stents

The first commercially available balloon-expanding bare metal stent is the Palmaz stent. The efficacy of this stent has been validated in clinical trials.[19-21] Balloon-expanding stents are slotted metal tubes that are mounted, or "crimped," onto a balloon suited to the diameter of the target vessel. The balloon is inflated to deploy the stent and secure it to the vessel wall. At first, the proximal and distal ends of the stent are expanded into a "doggie bone" shape and subsequently the middle portion of the stent is expanded. These stents are typically rigid in order to provide resistance against elastic recoil, but they may become irreversibly deformed when subjected to an external compression force. Thus, these stents are suitable for vessels that are not prone to external compression. Other advantages

of balloon-expanding stents are the ability to place them precisely, and that they tend to be more radiopaque than self-expanding stents. Therefore, BES are advantageous for calcific ostial lesions involving the renal, mesenteric, iliac, subclavian, or brachiocephalic arteries. They are contraindicated for vessels prone to external compression including the internal carotid and superficial femoral artery. Balloon-expanding stents may foreshorten if stents are overdistended beyond their intended diameter. Furthermore, most stents composed of a stainless alloy cause artifacts (signal loss) with magnetic resonance imaging (MRI).

Although most balloon-expanding stents are made from stainless steel, newer balloon-expanding stents are composed of cobalt-chromium. Cobalt-chromium stents are stronger than stainless steel stents, and provide greater radial force with a lower crossing profile and with enhanced flexibility.

Self-Expanding Stents

Self-expanding stents are typically composed of nitinol, a nickel-titanium alloy which provides flexibility and shape-memory. Due to the elastic properties of nitinol, stents with a diameter greater than the target reference vessel are selected so that they exert an outward expansible force, resulting in appropriate vessel wall apposition. The diameter of the lesion treated with a self-expanding stent is the result of interference between the recoil of the lesion and the radial expansion force of the stent. In addition, self-expanding stents are more flexible than balloon-expanding stents, which provides greater trackability, allows for the navigation of tortuous vessels, and offers resistance to fracture. As a result of their elastic property, diameter sizing of the stent is more forgiving than balloon-expanding stents and generally apposes well to the vessel with

less chance of vessel perforation. In addition, because nitinol is a nonferromagnetic metal, it is less likely to cause artifact on MRI.

The radial strength, flexibility, and, most importantly, the maneuver of deployment differ by manufacturers. Regarding deployment of a self-expanding stent, most stents are stored in the delivery sheath, and they are deployed from the distal end to the proximal end of the stent by unsheathing. Once deployed, most self-expanding stents cannot be restored or repositioned, with exception of the Wallstent (Boston Scientific, Natick, Massachusetts), which can be sheathed and repositioned many times. With the exception of the Misago stent (Terumo, Somerset, New Jersey), self-expanding stent platforms are OTW systems.

Self-expanding stents are classified as open-cell or closed-cell design. An open-cell stent is a cylindrical shaped structure of stacked serrated metal. The current stents, such as S.M.A.R.T (Cordis Corporation, Fremont, California), Misago (Terumo, Somerset, New Jersey), EPIC (Boston Scientific Corporation, Natick, Massachusetts), Lifestent (Bard Peripheral Vascular, Tempe, Arizona), and E-Luminexx (Bard Peripheral Vascular, Tempe, Arizona), are composed of an open-cell configuration for the body of the stent and a closed-cell configuration for the stent edge. Although the open-cell structure has high flexibility, it is more susceptible to deformation, bending (strut), and could possibly create nonuniform radial force to the target vessel. In addition, due to the large cell size, it is prone to plaque protrusion through the strut. However, the open-cell design allows for better tracking through tortuous vessels. In contrast, in a closed-cell design, all edges and vertices of the stent cells constituting the mesh are shared with an adjacent cell; thus, it is advantageous for lesions at risk for embolization because the stent mesh is very fine. Disadvantages of the closed-cell stent include the fact that it is less flexible, less deliverable, and less conformable to a tortuous vessel compared to an open-cell stent.

Stent Grafts

Balloon-Expanding Stent Grafts

There are two balloon-expanding stents grafts available for use: the i-Cast (Atrium Medical Corporation, Hudson, New Hampshire) and Jostent (Abbott Vascular Inc., Redwood, California). The i-Cast (Advanta V12) is made of 316L stainless steel stent struts encased by PTFE fabric. The stent graft can be expanded beyond the stated stent diameter, although at the cost of stent foreshortening. All stent grafts of i-Cast (<10 mm) require 0.035-inch guidewire and 6- to 7-Fr. sheaths, depending on the diameter. This stent graft is approved by the FDA for the treatment of tracheobronchial strictures but not for PAD. However, it has been used in off-label fashion for various vascular beds such as the iliac or renal artery, for occlusive lesions as well as for perforation after PTA or stenting, ISR, and branch reconstruction for fenestrated endovascular treatment of thoracoabdominal aortic aneurysms. An advantage of the i-Cast stent is that it has the lowest profile. However, as with the balloon-expanding bare metal stent, the device is not suitable for severely tortuous vessels or for lesions that are subject to structural changes due to the rigidity of the stent. The improvement of patency using an i-Cast stent for the treatment of occlusive lesions has been demonstrated, although data are limited.[22]

The Jostent is made of a central layer of PTFE sandwiched between two 316L stainless steel stents. It is commercially approved for use as a bail-out for coronary perforation and is delivered by 0.014-inch guidewires through a 5 Fr. sheath. The superiority of this stent graft was not demonstrated in a study comparing Jostent and a bare metal stent in the treatment of aortocoronary saphenous vein grafts stenosis.[23] Additionally, since restenosis rates with this stent graft are relatively high, its use is largely limited for bail-out of vessel perforation during interventional procedures.

Self-Expanding Stent Grafts

Self-expanding stent grafts are used for various applications. There are three main devices, including the Viabahn (W.L. Gore Associates, Flagstaff, Arizona), Fluency (Bard Peripheral Vascular, Tempe, Arizona), and Flair (Bard Peripheral Vascular, Tempe, Arizona). The Viabahn endoprosthesis consists of heparin-bonded PTFE attached to a nitinol stent. The technology for surface heparin coating was adapted from the Propaten prosthesis (W.L. Gore Associates, Flagstaff, Arizona), which was designed to improve bypass patency. The superior properties of this stent graft, which are significantly different from other endografts, include high flexibility and proven extended patency in the treatment of femoropopliteal disease. The Viabahn endoprosthesis is composed of a single-wire nitinol stent frame without longitudinal connections. The stent frame is attached to the PTFE graft material with a thin film. These two proprietary design features allow for high flexibility. The VIPER trial, a prospective, single-arm, and non-RCT study, was conducted to evaluate primary patency at 12 months or performance of the device for the treatment of long SFA occlusive disease.[24] The overall primary patency was 73%, and notably, patency was not significantly different for the lesion length between over 20 cm and under 20 cm (70% vs. 75%). Furthermore, this trial demonstrated the safety of the Viabahn endoprosthesis, as there were no major adverse events at 1 year in a clinical device-related study. Subsequently, the VIASTAR trial, a randomized, prospective, single-blind, multicenter study, compared the Viabahn endoprosthesis and conventional bare metal stents in 141 patients with symptomatic SFA lesion (Rutherford stage 2 to 5).[25-26] At 24 months, the overall primary patency rates of Viabahn and bare metal stent were 63.1% versus 40.0%, respectively ($P = .004$). The patency rates of the Viabahn at 24 months for lesions ≧20 cm was higher than that of bare metal stents (65.2% vs. 26.7%; $P = .004$). Freedom from bypass surgery and TLR and secondary patency were comparable between the two groups. Restenotic lesion after deployment of the Viabahn are usually focal and limited to both edges of the graft, in contrast to restenosis occurring after bare metal stent that usually develops diffusely throughout the stent. The Viabahn endoprosthesis requires 0.018-inch wires and 6- to 7-Fr. sheaths, depending on the diameter of the device, and the available length ranges from 2.5 to 25 cm. The Viabahn is deployed by

withdrawing the rip cord and is similar to that of the Excluder stent graft (W.L. Gore Associates, Flagstaff, Arizona).

The Flair endograft, like the Viabahn, is composed of a nitinol stent and PTFE fabric. This graft is utilized in hemodialysis patients for the treatment of arteriovenous graft anastomotic stenosis. A tip of the graft has either straight or flared shape. Each graft has demonstrated improved patency compared with the standard PTA. The required delivery sheath is 9 Fr. and is supported by an 0.035-inch wire.

The Fluency stent is approved by the FDA only for biliary application and its vascular use is off-label. This stent graft is made of a nitinol stent based on the design of the Luminexx stent and encapsulated by PTFE along its length except for 2 mm at either end where the stent is flared. Its crossing profile is 9-Fr. sheath compatible. The Fluency is supported by 0.035-inch wires, and the deployment method is similar to other self-expanding bare metal stents in which the stent is deployed by withdrawing the covering sheath. The Fluency is often used for endovascular reconstruction of arch branches or visceral branches during t-Branch or a-Branch (COOK Medical, Bloomington, Indiana) procedures.

Drug-Eluting Stents

Stents have been associated with improved patency for the treatment of PAD compared to conventional balloon angioplasty. However, the incidence of ISR and stent thrombosis due to intimal proliferation became apparent when treating long lesions with multiple stents. In order to overcome this issue, the drug-eluting stent (DES), loaded with agents such as Paclitaxel and Sirolimus, usually using polymers, was initially developed for the coronary artery. The DES has been shown to dramatically improve the patency and ISR rates in the treatment of coronary stenosis.[27,28] Subsequently, the coronary DES technology was applied to the femoropopliteal segment. Sirolimus-eluting stent based on the S.M.A.R.T stent (Cordis Corporation, Fremont, California) was the first peripheral DES and was compared to a bare metal S.M.A.R.T stent in the prospective randomized SIROCCO I and II trials.[29,30] However, the restenosis rates at 24 months were not reduced and this program was terminated (22.9% in sirolimus-eluting S.M.A.R.T stent vs. 21.1% in bare metal S.M.A.R.T stent). The Dynalink stent (Abbott Vascular Inc., Redwood, California), which is an everolimus-eluting stent (unpublished), also failed to show superiority at 12 months compared with historical controls of the STRIDES trial.

The Zilver PTX stent (COOK Medical, Bloomington, Indiana) is a unique DES since it does not utilize a polymer to load the Paclitaxel. The sustained patency and freedom from TLR of the Zilver PTX stent was proven in a landmark multinational RCT with 479 patients, comparing primary Zilver stents with PTA with/without standard stents for the treatment of femoropopliteal (above-the-knee) lesions.[31] In this trial, patients with symptomatic PAD underwent primary DES or standard PTA. When PTA patients suffered from flow-limiting dissection and required placement of a stent, a secondary randomization was performed between bare metal stent and Zilver PTX. The primary patency rates at 12 months for the Zilver DES and PTA were 83.1% and 32.8%, respectively ($P < .001$). In addition, the secondary randomization showed that the primary patency rate of the DESs was superior to the patency rate of the bare metal stent group at 12 months (89.9% vs. 73.0%; $P = .01$). More recently, the sustained superiority of the Zilver PTX stent has been demonstrated up to 5 years.[32] At present, a new DES called the Eluvia stent (Boston Scientific, Natick, Massachusetts) that utilizes a polymer and Paclitaxel based on the Innova stent was developed for SFA lesions. Although not published, the primary patency of this DES platform at 12 months was 96.1% in patients with femoropopliteal disease. Currently, a single-blind RCT comparing Eluvia versus Zilver PTX is scheduled to enroll in the IMPERIAL global study.

Multilayer Stents

Multilayer Flow Modulator (MFM) stent is designed to exclude peripheral or visceral aneurysms while maintaining branch vessel flow. MFM is a three-dimensional braided tube composed of multilayer wire without any covering prostheses. The Cardiatis MFM (Cardiatis, Isnes, Belgium) was approved in Europe in 2009. The first case report detailing implantation in a human was for a patient with a renal artery aneurysm involving a branch of the renal artery.[33] The efficacy of the Cardiatis MFM for the treatment of peripheral and visceral aneurysms was evaluated in an Italian multicenter trial.[34] The primary patency at 1 year was 86.9%, and the cumulative side branch patency was 96.1%. Complete thromboses of aneurysms were achieved in 93.3%, and no aneurysmal rupture was identified. MFM is currently being investigated for the treatment of aortic dissection or as a supplement to endovascular aortic repair.

Bioabsorbable Stents

Bioabsorbable stents that were initially developed for coronary intervention are being applied to the peripheral arterial beds. The first coronary absorbable stent implanted in a human was the Igaki-Tamai stent (Igaki Medical Planning Company, Kyoto, Japan), which is made of poly-L-lactic acid (PLLA) and constitutes a helical coil with a straight bridge configuration. The efficacy of Igaki-Tamai stents was shown in several studies.[35-36] Biodegradable polymers including polyglycolic acid and polycaprolactone, or copolymers such as poly (D-, L-lactide/glycoide), as well as metallic alloys such as magnesium and iron, have been used for absorbable stents. In the peripheral regions, Peeters et al. described preliminary results of an absorbable stent for the treatment of BTK arterial disease in patients with CLI.[37] The Biotronik absorbable metal stents (Biotronik, Berlin, Germany) were implanted in 20 patients enrolled in this study. This stent is a tubular, slotted, balloon-expanding stent sculpted from layers of a single tube of biodegradable alloy containing over 90% magnesium and rare-earth elements. At the 3-month follow-up, the primary clinical patency rate was achieved in 89.5%, and there were no major amputations. However, in the INSIGHT study,[38] a prospective multicenter RCT, superior patency of absorbable stents could not be shown (32% in the absorbable stent vs. 58% in the standard PTA). In addition, a RCT,[39] comparing endarterectomy with absorbable stent

implantation for common femoral occlusive lesions, has also demonstrated less favorable results including primary patency at 1 year (80% in the absorbable stent vs. 100% in the endarterectomy). Considering these results, this technology and development of self-expanding absorbable stents seems to require further research and deployment.

ATHERECTOMY DEVICES (DEBULKING TECHNOLOGIES)

Stenting has improved the short- and mid-term primary patency rates in most stenotic or occlusive lesions and has been widely adopted. However, stenting has several shortcomings including ISR and stent fractures. Percutaneous atherectomy debulking devices were developed to overcome these stent limitations. Since debulking procedures ideally achieve a successful outcome without the need for stenting, it is especially useful for lesions where a stent should be avoided, such as the common femoral artery or popliteal artery behind the knee joint. Currently there are three different types of atherectomy devices including directional (excisional), rotational, and laser atherectomy.

Directional

The SilverHawk and TurboHawk Plaque Excision System (eV3 Inc., Plymouth, Minnesota) were approved by the FDA as directional atherectomy devices. These devices consist of a carbide cutting blade with a variable height and a plunger used to pack the atheroma into the nose cone (Fig. 61.2). The cutting blade rotates at a speed up to 8000 revolutions per minute (rpm), and shaves atherosclerotic material from the luminal portion of arterial wall. The cutting blade of the TurboHawk is designed for treating severe calcification. The devices are composed of a monorail catheter with a 0.014-inch compatible wire system, and the recommended sheath size is 6 to 8 Fr. They can be used in many cases without the need for balloons or stents.

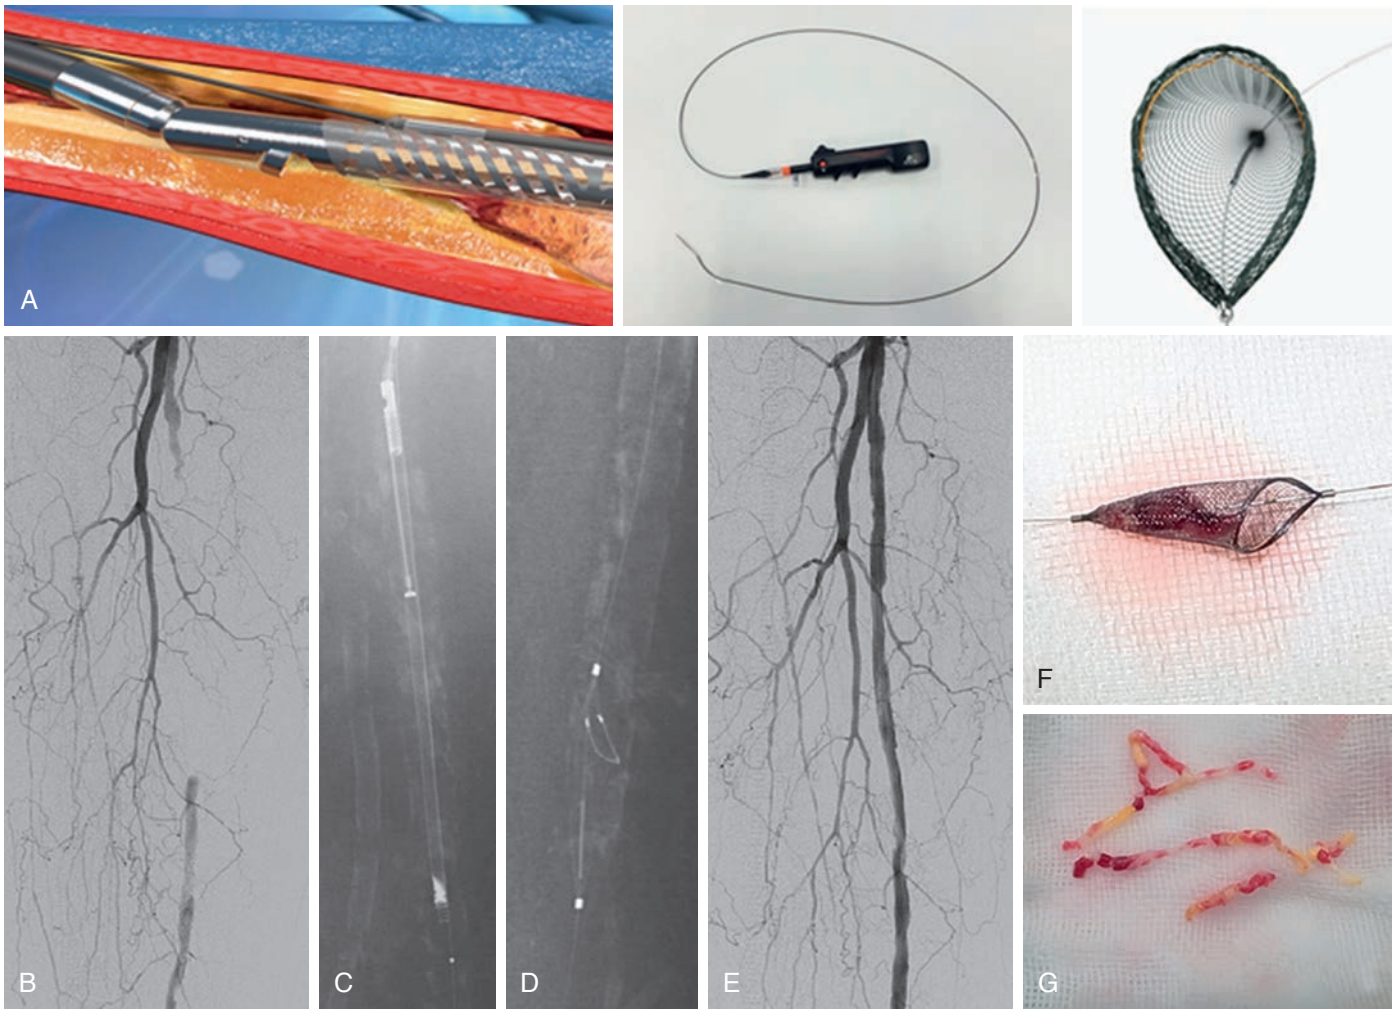

Figure 61.2 (A) TurboHawk atherectomy system (eV3 Inc., Plymouth, Minnesota). (B) Preintervention angiography showing a superficial artery occlusion. (C and D) The plaque is shaved off by the TurboHawk device with a Spider FX located distally to prevent embolization. (E) Completion angiography showing an improvement in vessel flow without distal embolization. (F and G) The shaved plaque captured by the nose cone of the TurboHawk and the filter of Spider FX.

The DEFINITIVE Ca^{++} study[40] demonstrated that the SilverHawk and TurboHawk atherectomy devices coupled with distal embolic protection (Spider FX; eV3 Inc., Plymouth, Minnesota) were safe and effective for the treatment of moderate to severe calcified lesions in the femoropopliteal arteries. The primary endpoint (≤50% residual diameter stenosis) was achieved in 92.0%, and the 30-day freedom from major adverse event rate was 93.1%. Additionally, the DEFINITIVE LE trial,[41] a prospective multicenter trial, and DEFINITIVE Ca^{++} enrolled 800 subjects suffering from claudication or CLI with an infrainguinal lesion up to 20 cm. in length. The primary patency at 12 months was 78%, and the rate of freedom from major unplanned amputation in CLI subjects was 95%.

Rotational

Rotational atherectomy involves inserting a small drill into the artery to fracture a plaque and to create a smooth lumen in the vessel. A high-speed rotating metallic burr abrades the calcified plaque into millions of microscopic particulates, of which 95% are less than 5 microns in size, which is smaller than red blood cells. The burr design is the most important aspect of the mechanism. The currently available rotablator system consists of an elliptical, nickel-plated, bass burr which is coated with 2000 to 3000 microscopic diamond crystals on the leading edge, while rotating at a speed of 160,000 to 180,000 rpm.

The Pathway Jetstream (Pathway Medical Technologies, Inc., Redmond, Washington) is also a rotational atherectomy device equipped with an infusion port of fluid and an aspiration port for removal of the plaque and debris, and this device can be used for both thrombectomy and rotational atherectomy by the same catheter. The system is advanced over a 0.014-inch wire at a maximum rate of 1 mm/s to avoid significant drops in rotational speeds. In a multicenter Pathway trial[42] including 172 patients, device success was 99%, and major adverse events occurred in 1%. The TLR was 26% at 12 months. The device was also evaluated in a prospective cohort study of 29 patients with femoropopliteal ISR lesions.[43] Acute success rate (≤30% residual narrowing with no serious adverse events) was achieved in 91%, and TLR at 6 months and 12 months occurred in 14% and 41%, respectively.

Orbital

Orbital atherectomy is used to reduce the atheroma burden to change the vessel compliance, while decreasing vessel wall trauma. The Diamondback 360 degree Orbital Atherectomy System (Cardiovascular System Inc., St. Paul, Minnesota) provides a versatile solution for removal of peripheral plaque. This device consists of an orbiting diamond-coated crown mounted on the end of a drive shaft. The device can be delivered through a 4 Fr. sheath along a 0.014-inch guidewire. Similar to rotational atherectomy devices, the orbital atherectomy devices reduce the plaque debris to a size small enough to minimize the potential for distal embolization. The CONFIRM series,[44] a prospective multicenter registry, was created to evaluate the performance of orbital atherectomy for PAD of the lower extremities. Plaque removal was most effective in severely calcified lesions and lowest for soft plaque. The overall plaque burden was reduced by more than 50% on follow-up angiogram after atherectomy. In another study,[45] the procedural success of orbital atherectomy combined with balloon angioplasty was 93.1% and for balloon angioplasty alone was 82.4%. The estimated freedom from TLR was 93.3%.

Laser

Advances in laser catheter design and recanalization techniques have resulted in improved outcomes for the treatment of complex PAD. The excimer laser, using a 308-nm wavelength, allows laser light to ablate the plaque and thrombus. The plaque is ablated on direct contact alone, minimizing surrounding thermal injury. In a prospective study of 35 patients, the CVX-300 Excimer Laser system (Spectranetics, Colorado Springs, Colorado) was evaluated as a first-line endovascular treatment for CLI. The clinical success, defined as restored direct arterial flow to the foot, was achieved in 88.2%.[46] The estimated patency rates were 96.6% at 12 months and 82.7% at 24 months, respectively, and limb salvage at 24 months was 94%. Recently, a RCT[47] was conducted across 40 US centers to assess the excimer laser plus PTA versus PTA alone for patients with ISR. The freedom from TLR of the laser plus PTA and PTA alone at 6 months was 73.5% and 51.8%, respectively, and 30-day major adverse event rates for the laser plus PTA were also significantly lower than for PTA alone (5.8% vs. 20.5%).

THROMBOEMBOLECTOMY

Over the years, the Fogarty catheter and other products have been developed to remove thrombi in arterial or venous circulation.[48] New innovations made it possible to perform totally percutaneous thromboembolectomy and has been applied to coronary, peripheral arterial thromboses disease, deep vein thrombosis (DVT) including pulmonary thrombosis, and cerebrovascular regions. Despite its efficacy, catheter-directed thrombolysis (CDT) has potential risks such as cerebrovascular hemorrhage, major bleeding, embolization, and recurrence of thrombosis.[49-51] In order to reduce these risks, several thrombectomy devices such as rheolytic or rotational thrombectomy devices have been developed including aspiration, rheolytic, rotational, and ultrasound enhanced platforms.

Aspiration

The simplest procedure to perform thrombectomy is to aspirate the thrombus with a large catheter or sheath. Currently available aspiration devices are the Export (Medtronic Inc., Minneapolis, Minnesota), PriorityOne (Terumo, Somerset, New Jersey), and Pronto (Vascular Solution Inc., Minneapolis, Minnesota). These aspiration devices are designed as monorail type and are 0.014-inch wire compatible. The Export catheter has a separate lumen for the wire and the aspiration port to maximize aspiration capability, while the PriorityOne catheter has guidewire-style stylet technology. With such devices, the risk of distal embolization due to crushing of the clot remains. Hence, thrombolytic drugs may

be used in combination with aspiration devices. These catheters seem to be well suited for small vessel diameters (<6 mm), and are less effective for a large thrombus burden.

Rheolytic

Rheolytic thrombectomy is a procedure in which a jet of saline is ejected from the tip of a catheter and is used to dissolve the thrombus by creating a "Venturi" effect. The Angiojet catheter (Possis Medical, Minneapolis, Minnesota) is such a hydrodynamic device, and provides a high speed saline jet which travels backward to create a low-pressure zone causing a vacuum effect. This vacuum removes thrombus material, which is then aspirated back into the exhaust lumen of the catheter. In the PEARL registry, a total of 238 patients with acute limb ischemia (ALI) undergoing Angiojet catheter were enrolled.[52] Procedural success was achieved in 83%. Amputation-free rate and freedom from mortality rate at 12 months were estimated to be 81%, and 91%, respectively. Additionally, the device also can be used for DVT and potentially reduce the need for additional CDT. Furthermore, the Angiojet catheter provided comparable outcomes for the treatment of thrombosed hemodialysis graft compared to surgical thrombectomy.[53]

Although complications such as acute myocardial infarction and renal insufficiency have been reported with the use of these devices, the outcomes appear to be superior to thrombectomy compared with simple aspiration devices in several clinical studies.

Rotational

Rotational thrombectomy devices remove the thrombus by rotating the tip of the catheter. The Rotarex (Straub Medical, Wangs, Switzerland) consists of three individual components which can be assembled in a few minutes. This device was evaluated in patients with acute or subacute ischemia due to femoropopliteal bypass occlusion.[54] A total of 22 patients were enrolled, and the technical success rate was 82%. There were no reinterventions at the 6-month follow-up.

The Trellis infusion catheter (Bacchus Vascular, Santa Clara, California) is a hybrid device that combines the delivery of thrombolytic drugs with a thrombus aspiration system. It is composed of proximal and distal balloons and the drug and the debris are trapped between the two balloons. Gupta and colleagues[55] evaluated the Trellis in 24 patients with ALI. More than 90% of vessels had a complete or substantial response. There was one in-hospital death due to severe limb ischemia with extensive occlusion of an axillo-femoral graft, but the amputation rate at 30 days was 0%.

Ultrasound Enhanced

The EkoSonic endovascular system (EKOS, Bothell, Washington) consists of three components, including an intelligent drug delivery catheter, a removal microsonic device, and a reusable EkoSonic control unit. In the SEATTLE II study,[56] including 150 patients with massive or submassive pulmonary embolism, the mean right-ventricular to left-ventricular diameter ratio and mean pulmonary artery systolic pressure were reduced 48 hours after the procedure. Moderate to severe bleeding after procedure occurred in 15 patients (10%). The authors concluded that this procedure has the potential to improve outcomes of the treatment of PE in high-risk patients.

Other Devices

Solitaire stent retriever (Medtronic, Minneapolis, Minnesota) is a new device for mechanical thrombectomy combining the ability to restore blood flow, administer medical therapy, and retrieve the clot. This device is not indicated for peripheral lesions, but is used for cerebrovascular lesions in the treatment of acute ischemic cerebral infarction. The safety and efficacy have been demonstrated in several RCTs.[57,58] In the periphery in a case report, although it represents off-label use, the Solitaire allowed the removal of a BTK thrombus after aspiration thrombectomy had failed.[57,58]

Trevo Xp (Stryker Neurovascular, Fremont, California) is also a stent retriever device, and is the first fully visible device that allows the operator to view placement or strut behavior. In an open-label trial comparing Trevo versus Merci retrievers for revascularization,[59] the stroke score significantly improved in the patients in the Trevo group.

Indigo System (Penumbra Inc., Alameda, California), which became commercially available in 2014, is expected to be a useful device for managing thromboembolic disease in the peripheral circulation, including visceral and upper-extremity lesions, although solid data is not yet available.

INTRALUMINAL DEVICES TO CROSS CHRONIC TOTAL OCCLUSIONS

Endovascular treatment of chronic total occlusion (CTO) is technically challenging and often results in prolonged procedure time and increased patient exposure to contrast agents and radiation. When endovascular treatment is attempted in patients with CTO, the inability to pass a guidewire across the lesion is the leading cause of technical failure. CTO typically involves a plaque or segment of poorly organized thrombus with fibrotic or calcified cap at both the cranial and caudal end. CTO may be generally refractory to crossing with conventional guidewires because of the fact that insufficient axial force is generated to achieve crossing of the lesion. This section describes ancillary devices for recanalization via the true lumen.

Crosser

The Crosser (Bard Peripheral Vascular, Tempe, Arizona) catheter is a high-frequency mechanical recanalization device designed for recanalization of CTO in a peripheral artery. The device is composed of an electronic generator, foot switch, transducer, FlowMate Injector (optional), and a catheter. The catheter is connected to the generator through the high-frequency transducer. When the system is activated, the catheter engages inelastic materials selectively. The elastic materials such as the vessel wall absorb the impact of the device, resulting in a reduced risk of

perforation. In the PATRIOT trial,[60] 85 patients with a previous or concurrent failed attempt to cross a CTO lesion using conventional guidewire techniques were enrolled, the CTO was crossed using the Crosser and the guidewire was successfully advanced into the distal true lumen in 83.5% of the patients, and freedom from perforation was achieved in 98.8% of the patients.

TruePath

The TruePath (Boston Scientific Corporation, Natick, Massachusetts) catheter features a rotating diamond-coated tip that is designed to pass the occluded lesions and facilitate the placement of conventional guidewires for the treatment of PAD. Once the lesion is crossed, the wire is advanced into the distal true lumen beyond the occlusion, as with the Crosser system. The TruePath system requires no capital equipment and is available with an optional extension wire to facilitate catheter exchange and increase the working length up to 300 cm. In the treatment of infrainguinal CTO lesions[61] with the TruePath, the technical success rate was 77%, although some cases required the use of a re-entry device. Clinically driven target vessel recanalization rate at 6 months was only 8% with no periprocedural complications.

Frontrunner XP

The Frontrunner XP (Cordis Corporation, Fremont, California) catheter is a disposable catheter consisting of an articulating, distal tip assembly manually actuated by a proximal rocker handle. The system is specially designed for facilitating placement of guidewire safely across the CTO lesion by steering the distal tip of the device to the occlusion site, and then remotely activating the tip to facilitate blunt microdissection of the plaque. In a retrospective study, 26 patients with TASC D femoropopliteal CTO lesions were treated with the Frontrunner after guidewire failure.[62] The overall technical success was achieved in 88.2%, and no major complications were observed.

RE-ENTRY DEVICES

Outback LTD Re-Entry System

The Outback LTD (Cordis Corporation, Fremont, California) is a re-entry device designed to penetrate the intimal flap and redirect the guidewire from the subintimal plane to the true lumen. It consists of a single lumen compatible with a 0.014-inch guidewire and is deliverable via a 6-Fr. sheath. A 22-gauge controllable curved nitinol needle (cannula) is located at the distal end of the catheter and is used to penetrate the intimal flap. Once the guidewire has crossed the lesion via a subintimal route but failed to return to the distal lumen, the Outback LTD catheter is inserted over this wire. The tip of the catheter is advanced to the distal end of the lesion and adjacent to the true lumen. The needle can then be advanced to penetrate the intima to redirect the guidewire into the true lumen. Correct positioning and direction of the nitinol cannula toward the true lumen is made possible by radiopaque markers located at the tip of the catheter.

Gandini and colleagues[63] evaluated the Outback LTD in a RCT in patients with TASC-DSFA CTO lesions. Subintimal angioplasty was performed in all patients (26 patients in both Outback and manual re-entry groups). Technical success was achieved in all patients. However, 15 patients who underwent a manual re-entry technique experienced extension of the dissection 5 cm beyond the distal end of the CTO. Furthermore, three cases required a bidirectional approach in order to achieve crossing the wire. Procedural time and fluoroscopic time were both shorter for the Outback group.

Pioneer Catheter

The Pioneer (Volcano Corporation, San Diego, California) utilizes intravascular ultrasound (IVUS) for visualization. This device is deliverable via a 6-Fr. sheath and is 0.014-inch wire compatible. The IVUS attached to the device allows for real-time imaging that shows not only the catheter position in the dissection plane, but the intimal flap and the true lumen on the other side of the flap. The adjustable 24-gauge needle is then advanced to penetrate the intimal flap and the guidewire can then be redirected toward the true lumen.

Enteer Catheter

The Enteer system (Covidien, Plymouth, Minnesota) consists of a catheter and guidewire, which is compatible with a 0.014- or 0.018-inch wire. This device involves a flat balloon with a side exit lumen for the catheter in the middle of the balloon. Inflation of the balloon in a subintimal plane provides the orientation of the exit point of the catheter toward the true lumen. A stiff 0.014-inch wire is then advanced from the side hole in order to penetrate the intimal flap and to achieve true lumen re-entry. The advantage of this device is low cost, but the penetrating ability of the Enteer is less compared with the needle-tipped device.

OffRoad Catheter

The OffRoad re-entry system (Boston Scientific, Natick, Massachusetts) is composed of a balloon catheter combined with needle-tipped hypotube (Fig. 61.3). The laser-cut stainless-steel hypotube with a straight needle tip is advanced out of the balloon catheter end to penetrate the intimal lumen or calcified plaque to achieve true lumen re-entry. The balloon catheter is 0.035-inch wire-compatible and is delivered through a 6-Fr.

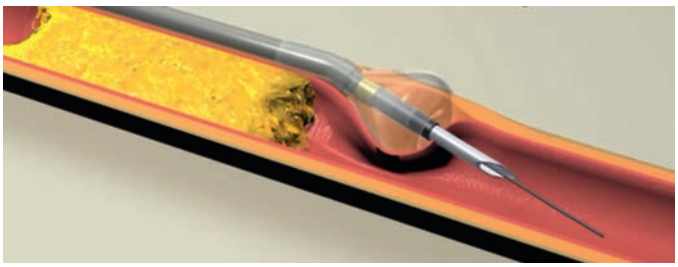

Figure 61.3 The OffRoad re-entry system (Boston Scientific, Natick, Massachusetts).

sheath. The needle can be advanced toward the desirable true lumen owing to inflation of the balloon in the subintimal plane.

In the Re-ROUTE trial, a total 92 patients with CTO lesions of femoropopliteal artery were assigned in a prospective and a single-arm study.[64] The technical success was 84.8%. At 30-day postprocedure, 75% of the patients experienced an improvement of at least one category in the Rutherford classification. The major device-related adverse event rate at 30 days was 3.3%, which was below the pre-specified trial goals.

EMBOLIZATION DEVICES AND AGENTS

Endovascular embolization is a minimally invasive procedure to treat various vascular conditions such as bleeding, small aneurysms, fistulas, or endoleaks following endovascular aortic aneurysm repair (EVAR) (see Chapter 72). The devices for embolization are categorized as mechanical (coils and vascular plugs; Table 61.2), particulates (polyvinyl alcohol, gelatin microspheres), and liquid agents (absolute ethanol and n-butyl cyanoacrylate [NBCA]).

Vascular Coils

In 1975, Gianturco and colleagues[65] described a novel occlusive device designed to allow transcatheter delivery, consisting of a metal coil attached with cotton threads. Thereafter, the Gianturco coil (COOK Medical, Bloomington, Indiana), which is composed of a stainless steel spring guidewire with the inner mandrel removed, became commercially available in 1976. Currently there are a number of coils with various designs. The vascular coil is classified as fibered and nonfibered coil, and pushable and detachable, based on deployment method. Generally, fibered coils are superior in their ability to embolize the vessel and induce thrombosis compared with nonfibered coils. However, nonfibered coils can also treat aneurysms although they may utilize more coils. These coils allow not only precise control and placement especially for the treatment of the tortuous anatomy, but also provide the capability to reposition if necessary. Most current materials consist of Inconel or platinum. These coils are accommodated to MRI, but the platinum coils tend to produce a strong halation on computed tomography (CT) examination. The coils ranging from 0.014- to 0.052-inch sizes are available. Coils have to be selectively used with respect to the lesions or pathologies, and approximately 20% larger coils compared with reference vessels (20% oversize) is recommended for framing. Although the diameter and the length of coils are different depending on the type, the available diameter ranges from 1 to 32 mm and the length ranges from 0.5 to 60 cm.

Vascular Plugs

Embolization of a large vessel, including left subclavian artery or internal iliac artery, to prevent a type 2 endoleak during EVAR is being performed with increasing frequency. However, coil embolization is often time-consuming and micro-platinum coils are costly. The Amplatzer Vascular Plug (St. Jude Medical, St. Paul, Minnesota), composed of 144 nitinol wire-mesh technology, allows full cross-section coverage of the target vessel and facilitates precise deployment with a single device. The plug has the ability to be recaptured and repositioned similar to the detachable coils. There are four types of plugs designed to treat various anatomies. Amplatzer Vascular Plugs I and II are commonly used to occlude large vessels including the subclavian or hypogastric artery. These plugs are compatible with 4- to 6-Fr. sheaths or 6- to 8-Fr. guiding catheters, depending on device size. The device diameters range from 3 to 22 mm, while the length ranges from 6 to 18 mm. Amplatzer Vascular Plug IV is deliverable through a 0.038-inch diagnostic catheter eliminating the need for exchanges, and is used for relatively small-diameter vessels.

TABLE 61.2 The Characteristics of Coil and Vascular Plug

Coil and Plug		Characteristic
Pushable		
0.035-inch	Tornado (COOK)	Platinum, Fibered, Vortex shape
	MReye (COOK)	Inconel, Fibered, Spinal shape
0.018-inch	Tornado (COOK)	Platinum, Fibered, Vortex shape
	Diamond (Boston Scientific)	Platinum, Fibered, Diamond shape
	Trufill (Codman)	Platinum, Fibered, Complex shape
Detachable		
0.035-inch	Flipper (COOK)	Inconel, Fibered, Screw type, Spiral shape
	Interlock (Boston Scientific)	Platinum, Fibered, Lock system, Spinal shape
0.018-inch >	GDC (Stryker)	Platinum, Nonfibered, Electrical, Complex shape
	Fibere vortex GDC (Stryker)	Platinum, Fibered, Electrical, Vortex shape
	Target (Stryker)	Platinum, Nonfibered, Electrical, Complex shape
	Interlock (Boston Scientific)	Platinum, Fibered, Lock system, Spiral shape
	Cashmere (Codman)	Platinum, Nonfibered, Hydraulic, Complex shape
	Matrix 2 (Boston Scientific)	Platinum, Nonfibered, Polyglycolic/polylactic acid polymer coated, Electrical, Complex shape
	Cerecyte (Micrus)	Platinum, Nonfibered, Polyglycol acid loaded, Electrical, Complex shape
	Azur (TERUMO)	Platinum, Nonfibered, Hydrogel polymer coated, Electrical, Spiral shape
Plug		
	Amplazer vascular plug	Nitinol, Screw type, Self-expanding

Liquid Embolic Agents

Liquid embolic agents are commonly used to treat persistent endoleaks after endovascular aneurysm repair or for arteriovenous malformations. These agents lack radiopacity and tend to penetrate deeper into the vasculature, resulting in difficulty controlling the distribution and thus may result in nontarget embolization.

Cyanoacrylate

NBCA is one of the most commonly used substances in vascular beds. NBCA is polymerized by mixing the blood that contains the ion, and is often mixed with lipiodol to ensure visibility and polymerization time adjustment. A microcatheter is required to inject NBCA to the target vessel. Although this agent is effective for the treatment of arterial bleeding, pseudoaneurysm, persistent type 2 endoleaks, or malformation unsuitable for coil embolization, attention should be paid to prevent the "stuck" phenomenon involving occlusion or transection of the microcatheter, or adhesion of the vessel wall and catheter.

Fibrin Sealant

In surgical hemorrhage or tissue sealing, fibrin sealant is commonly used. Fibrin glue is composed of two solutions of fibrinogen and thrombin. Usually, it is used for the treatment of persistent type 2 endoleaks in addition to type 1 endoleaks.[66,67] Fibrin sealant has also been used to effectively treat pseudoaneurysm or trauma-related hemorrhage. However, such uses are off-label. In addition, fibrin liquid injection is difficult to control and can result in unintended site embolization.

Ethylene Vinyl Alcohol

Onyx is nonadhesive polymer composed of ethylene vinyl alcohol dissolved in dimethyl sulfoxide (DMSO). This agent gradually solidifies once it comes in contact with blood. Therefore, unlike NBCA, it can be injected through a long tube and over time under fluoroscopic guidance. However, because DMSO dissolves the catheter material, it requires using an adaptable microcatheter. The FDA approved Onyx in 2005 for the treatment of arteriovenous malformations, but it has been used for the treatment of peripheral AVMs as well as for graft-related endoleaks. Bosiere et al.[68] described the efficacy of Onyx for the treatment of persistent type 2 endoleaks after EVAR. Technical success was achieved in 92% of the patients, and the extravasation of Onyx out of the aneurysmal sac into the vena cava occurred in one patient. The aneurysm sacs remained stable or decreased in diameter during follow-up after Onyx injection. Each liquid agent carries the risk of nontarget embolization.

VASCULAR CLOSURE DEVICES

Vascular access site complications are one of the important and most frequent causes of morbidity following endovascular therapy. Manual compression is still the gold standard method for obtaining hemostasis at the access site. However, manual compression is time-consuming and carries certain failure rate. In addition, with the introduction of newer interventional devices with large profile, there was a need to develop a better method to obtain hemostasis. The ideal vascular closure device (VCD) is able to achieve secure hemostasis without any complications. In the RCT trial (ISAR-CLOSURE trial),[69] 4524 patients undergoing coronary angiography with a 6-Fr. sheath via the common femoral artery were enrolled. Patients were randomized in a 1:1:1 ratio between two closure devices and manual compression. The primary outcome was the incidence of vascular site complications, including major bleeding, infection, leg ischemia, and the need for surgical repair or endovascular treatment. The study found that the access site–related complications were identified in 6.9% assigned to the VCD groups and 7.9% assigned to the manual compression group, confirming the noninferiority of VCDs. Additionally, the multicenter PEVAR trial[70] enrolled 151 patients undergoing aneurysm repair in a 2:1 ratio comparing percutaneous VCD and open femoral exposure. The primary endpoints were defined as procedural technical success, absence of major adverse events, and incidence of access-related complications. Similar to the ISAR-CLOSURE trial, noninferiority was demonstrated in VCD compared with standard open femoral exposure.

Extravascular Plug

Angio-Seal

The Angio-seal (St. Jude Medical, St. Paul, Minnesota) device exerts hemostatic effect by sandwiching the arteriotomy with a bioabsorbable anchor connected with sutures and a collagen sponge that dissolve within 60 to 90 days. The device is compatible with 5- to 8-Fr. sheaths (5, 6 Fr. are applied to 0.035-inch wire, while 7, 8 Fr. are 0.038-inch). In brief, the device sheath is exchanged with the procedural sheath, confirming the proper location by withdrawing and reinserting the device until blood flow resumes. The inner core (locator) and wire are removed, leaving the device's outer sheath in place. The body of Angio-seal is then inserted into the outer sheath. The anchor is released into the vessel by fully connecting the body and the outer sheath. The body and sheath are pulled back until the colored compaction marker is revealed as a guide. The effectiveness of this device has been reported in several studies.[71-73]

Exoseal

Exoseal (Cordis Corporation, Fremont, California) is a percutaneous closure device, based on a bioabsorbable polyglycolic acid plug to achieve hemostasis. The device is compatible with 5- to 7-Fr. sheaths. A small plug is stored in the distal end of the device and is fully absorbable within 60 to 90 days. This unique system involves a marker band, bleed-back indicator, and an indicator window. For deployment, appropriate Exoseal is inserted in the procedural sheath, advancing to the level of the black marker band. The combination of the procedural sheath and the Exoseal is then pulled out until back flow from bleed-black indicator is encountered. Then the sheath and the Exoseal are retracted further until the blood flow becomes slow. When flow from the black-back indicator is interrupted, and when the indicator window to changes to "all black," the plug is deployed just outside and adjacent to the vessel wall.

In the ECLIPSE trial,[74] including 401 patients undergoing diagnostic or interventional procedures with a 6-Fr. sheath, the use of this device significantly reduced time to ambulation compared to manual compression.

FISH (Femoral Introducer Sheath and Hemostasis)

FISH (Morris Innovative, Bloomington, Indiana) utilizes a bioabsorbable extracellular matrix of porcine small intestinal submucosa. The plug is remodeled into native arterial wall tissue and absorbed in 30 days. The device comes in a 5- to 8-Fr. version. In a RCT,[75] 191 patients were randomized to the FISH devices and 106 patients to manual compression. The mean time to hemostasis and ambulation were superior in the FISH group compared to manual compression. Major access-related bleeding requiring transfusion occurred in one patient. In the FISH group, there were five minor adverse events; three access-site hematomas, and two pseudoaneurysms that were treated with thrombin injection.

Mynx

The Mynx (AccessClosure, Mountain View, California) utilizes a polyethylene glycol sealant that is deployed outside the artery while a small balloon inflates the arteriotomy site to create temporary hemostasis within the artery. The device is compatible with 5- to 7-Fr. sheaths, and the sealant is absorbed in 30 days. Among 766 patients undergoing a cerebral angiogram or intervention using the Mynx device,[76] procedural success was achieved in 92%, and device-related complications occurred in 2.5% of the patients.

Suture-Based Devices

ProGlide

The ProGlide (Abbott Vascular Inc., Redwood, California) is a suture-based device that deploys a suture on either side of the arterial wall at the arteriotomy site, mimicking open surgical closure. The polypropylene sutures are pulled together outside the body, resulting in closure of the arteriotomy site. Since it is a mechanical closure, there are theoretically no limitations to re-access or the administration of antiplatelet and anticoagulant. The ProGlide can track over a standard 0.035-inch (or smaller) wire and accommodate 5- to 21-Fr. arteriotomies, but with a larger than 8-Fr. sheath, at least two devices are required to close the arteriotomy. Therefore, the device facilitates EVAR as well as transcatheter aortic valve implantation through percutaneous femoral access. In such cases, the ProGlide is deployed prior to the insertion of the large bore devices and is often referred as Perclose technique.

Prostar XL

The Prostar XL (Abbott Vascular Inc., Redwood, California) is designed for large bore device closures. It also utilizes a polyester suture to close the arteriotomy site. The device has two polyester sutures and four nitinol needles, is deliverable over a 0.038-inch (or smaller) guidewire, and is indicated for 8.5- to 10-Fr. closure. Similar to the ProGlide device, a vascular access can also be maintained throughout deployment, and the device can be used for EVAR or transcatheter aortic valve implantation.

ENDOVASCULAR THERAPEUTIC TECHNIQUES

Percutaneous Transluminal Balloon Angioplasty

Puncture and Approach to the Lesion

Puncture is the most basic and important procedure for the percutaneous treatment of PAD in terms of reducing postoperative complications, including bleeding or pseudoaneurysm formation. Selection of the most appropriate puncture site should take into account the location and extent of the target lesions. The common femoral artery (CFA) is the most common puncture site in endovascular treatment. However, the location of the CFA bifurcation differs in each patient. If the CFA bifurcation is located cranially, there may be a risk of high puncture, resulting in difficulty in compressing the access site after the procedure, which may lead to retroperitoneal hemorrhage. If there is severe calcification of the CFA, the puncture may cause dissection or arterial occlusion. In such cases, one should consider utilizing the contralateral CFA, brachial artery, radial artery, or SFA. Prior to puncturing the artery with the needle, sufficient local anesthesia should be administered subcutaneously and also around the femoral sheath. As most endovascular interventionists are right-hand dominant, generally, the needle is held and advanced to the puncture site with the right hand, while palpation of the pulse of the target artery is performed with the left hand. In addition to palpation, ultrasound and/or fluoroscopic guidance is helpful in difficult cases. Retrograde contralateral or ipsilateral approaches are commonly used for the treatment of various lesions, involving aortic, visceral, and iliac arteries. However, when treating the BTK lesion, an ipsilateral antegrade CFA approach may be selected due to the limited length of various catheters and balloons and better pushability. Bidirectional approaches (see below) via popliteal or tibial artery are often effective for the treatment of SFA or BTK CTO lesion. A retrograde brachial or radial artery approach is often preferred for the treatment of celiac or superior mesenteric artery disease because the angle between aorta and visceral branches is sharp.

When arterial access is obtained, a sheath is inserted into the vessel over the guidewire using the Seldinger technique. The guidewire should be advanced under fluoroscopic guidance to avoid accidental cannulation of the side branches. Most of the currently available endovascular devices, including guidewires, catheters, balloons, or stents, allow for delivery through a 6-Fr. sheath. It is important to choose an adequate sheath in order to avoid sheath-related complications. The diagnostic catheter is then deliverable via a sheath. It is important to place the image intensifier or the detector panel at the appropriate cranial-caudal and oblique angle to obtain a good image and outcome (see Chapter 60). Additionally, to achieve maximal support and

effective visualization with contrast, the sheath or catheter should be placed as close to the target lesion as possible. Systemic heparinization is desired once the decision is made to treat the lesion. Typically, 50 to 100 U/kg of heparin is administered via a venous bolus infusion, and the activated clotting time (ACT) is maintained at approximately 200 to 300 seconds during the endovascular procedure. For cerebrovascular intervention, the ACT should be maintained at above 250 seconds to prevent thrombus formation and brain infarction.

Lesion Crossing

Although there is no single standard technique, the most important principle is to pass the wire through the lesion via the true lumen. However, the techniques vary based on the location, degree of stenosis, presence or absence of CTO, or nature of the plaque. Due to the innovation of guidewires with hydrophilic coating, supportive devices, and new techniques, a stenotic lesion can be crossed almost in every case. A 0.035-inch hydrophilic wire is the wire of choice and has the ability to penetrate through hard plaques, although the wire tends to follow the path of least resistance which is the subintimal space. A 0.014- or 0.018-inch guidewire may be a better choice for highly stenotic or CTO lesions and if used along with support microcatheters, including the CXI (COOK Medical, Bloomington, Indiana), the Quick-Cross (Spectranetics, Colorado Springs, Colorado), or the TrailBlazer (Covidien, Plymouth, Minnesota), the chances of lesion crossing through the true lumen may increase. Intraluminal devices, as previously described, or ultrasound-guided techniques are also useful for passing through the true lumen. Furthermore, if the wire is inserted into the subintimal plane, it is possible to come back toward the true lumen by utilizing a reentry device. Additionally, the IVUS is a useful device to identify whether the wire is in the true lumen or not. Once the lesion is crossed and the wire enters the distal true lumen, as indicated by back bleeding, contrast injection via the catheter is performed to confirm that the wire is intraluminal.

Balloon Selection

A balloon is typically chosen based on the diameter of the reference vessel and the length of the lesion. Available balloons for various lesions are shown in Table 61.3. Currently balloons are available up to 30 cm in length and can be used to treat long segments of the SFA or BTK lesions with a single inflation. Most interventionists first verify the ease of expansion and stiffness of the lesion using an undersized-diameter balloon, and then upsize to an appropriately sized diameter balloon. In a severely calcified lesion, a conservative dilation balloon may be required to avoid rupture of the artery. The measurement of the reference vessel diameter is important to choose an appropriate balloon. Measurement with digital subtraction software, preoperative CT, IVUS, catheters with graduated markers, or using a predilation balloon as a reference are also useful for selecting the appropriate balloon size. Balloon shafts come in 80 cm to 150 cm. The shorter 80-cm shaft is suitable for the treatment of visceral, iliac, and proximal contralateral SFA lesions when approached from the CFA. Conversely, cerebral, contralateral popliteal, and BTK interventions via the CFA approach or visceral and iliac interventions via the brachial artery require a longer shaft.

TABLE 61.3 Commercially Available Balloon Size for Specific Artery

Lesion Location	Balloon Diameter (mm)	Balloon Length (cm)
Internal carotid artery	4-6	2
Common carotid artery	6-8	2-4
Vertebral artery	3-5	2
Subclavian artery	6-10	2
Axial artery	5-7	2-5
Brachial artery	2-4	2
Aorta	10-20	2-4
Celiac artery	5-8	2-4
Superior mesenteric artery	5-8	2-4
Renal artery	5-7	2-4
Common iliac artery	6-10	2-4
External iliac artery	6-8	2-10
Superficial femoral artery	5-7	2-15
Popliteal artery	4-6	2-4
Tibial artery	2-3	2-300

Balloon Placement

Contrast is injected though the sheath or catheter to accurately identify the lesion just before the balloon is placed. If difficulty is encountered during balloon passage due to severe stenosis or tortuosity of the access vessel, it may be necessary to exchange the wire for a stiffer wire, advance the sheath or guide catheter closer to the target lesion, or switch to a lower profile balloon or one with greater pushability.

Balloon Inflation and Completion Angiography

Preparation of the balloon is an important maneuver to avoid air embolization in the case of balloon rupture and visualization of the balloon under fluoroscopic guidance. The guidewire lumen of the balloon catheter is flushed with heparinized saline solution in the OTW balloon, and the guidewire lumen of SOE balloons should also be flushed from the distal end hole. The balloon is prepped by replacing preexisting air inside balloon with 25% to 50% strength contrast.

The balloon should be positioned so that the most severe stenotic lesion aligns with the center of the balloon. When inflated, the diluted contrast, commonly a 1 : 1 ratio of contrast agent and saline solution (undiluted contrast is typically used for 4-mm balloons or smaller), is used to inflate the balloon with the inflation device, and the balloon shape should be monitored with the fluoroscope in real time, confirming capture of the lesion during inflation. Additionally, based on a reference screen or by marking the reference vessel diameter on the screen, the operators need to avoid excessive overexpansion beyond the reference vessel diameter. Inflation of the balloon is typically

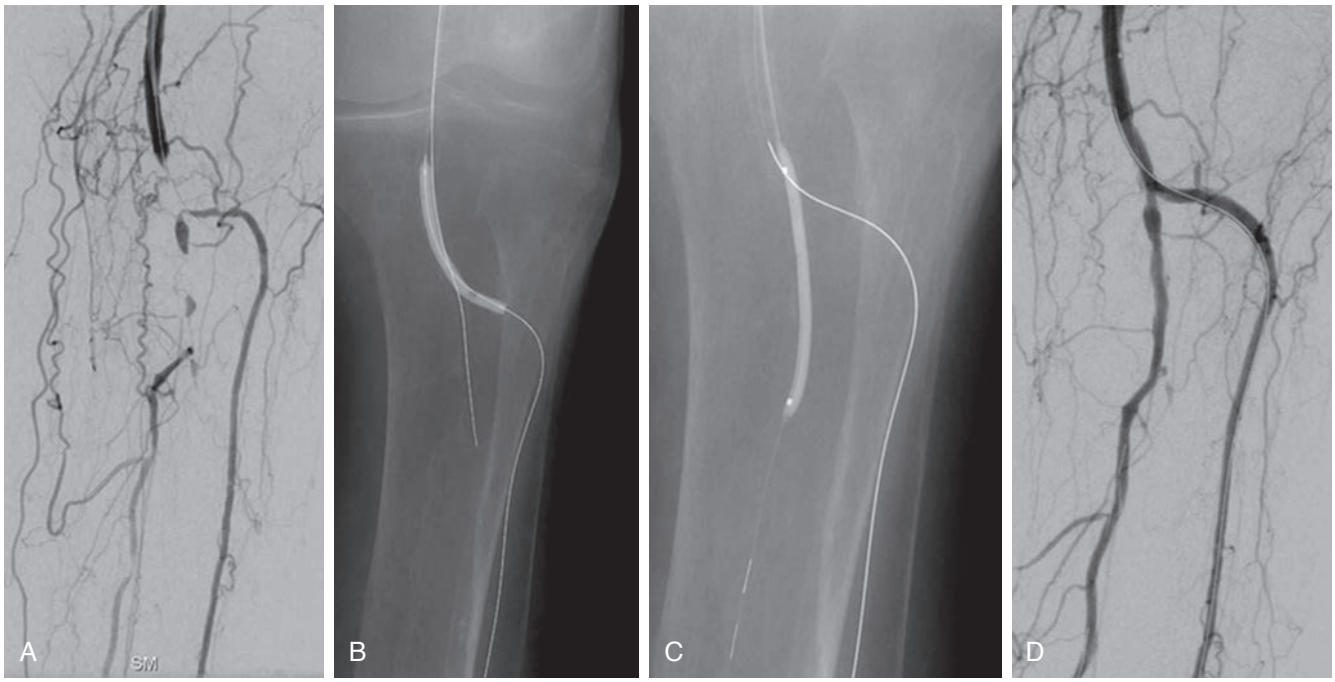

Figure 61.4 (A) Initial angiography shows a complex occlusive lesion of the below-the-knee arteries. (B and C) The wire is inserted to prevent an occlusion by a plaque shift. (D) Completion angiography shows an improvement in run-off.

performed for 30 to 60 seconds. Then, the balloon is deflated and inflated again for the same amount of time. While deflating, the balloon catheter should not be retracted into the sheath immediately since the remaining wings of the balloon may be caught by the tip of the sheath. It should be noted that there is a risk of vessel rupture when a patient complains of the severe pain during dilation of the balloon. The most important thing is to maintain guidewire position across the dilated lesion in case additional treatment is required. After the balloon catheter is removed, completion angiography is performed to evaluate the results of PTA.

Double Wire Technique

If cannulation of the target vessel cannot be accomplished with the wire, or the risk of nearby vessel occlusion due to plaque shift is anticipated, a double wire technique may be an effective option. For example, when cannulation of the SFA is attempted, the wire would be advanced first into the DFA, without entering the SFA. In this case, the sheath is inserted into the DFA first, and subsequently, the sheath is withdrawn to the bifurcation of the SFA and the DFA, maintaining the position of the DFA guidewire. A second thin wire is then inserted to cannulate the SFA. This technique has been applied to other lesions, such as renal interventions, and is known as nontouch isolation technique. For bifurcational lesions, the lesions are cannulated by two wires and the kissing balloon technique is used to prevent occlusion from plaque shift (Fig. 61.4).

Angiosome Concept

Most CLI lesions extend to the BTK area. According to the BASIL trial,[77] patients with a life-expectancy of less than 2 years

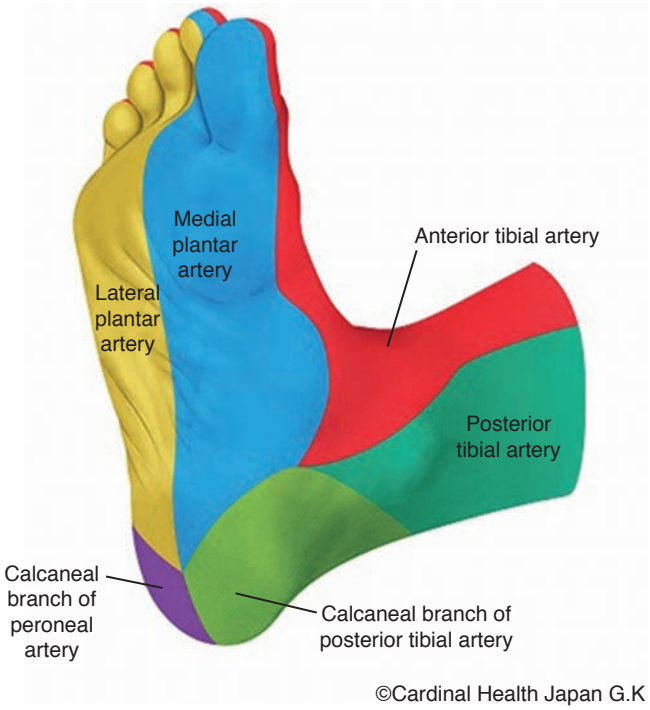

Figure 61.5 Angiosome concept.

are best treated with endovascular therapy. Taylor and Palmer[78] introduced the angiosome concept in 1987 (Fig. 61.5), which categorizes the limb into three vascular territories supplied by source arteries and has been clinically helpful in endovascular treatment. The six angiosomes of the ankle and foot are divided by the blood supply of the anterior tibial, posterior tibial, and

peroneal artery. For example, when treating gangrene of the great toe, it is most effective to revascularize the anterior tibial artery based on the angiosome concept. However, this concept has limitations in that angiosome varies among patients.

Dissection Grade

Arterial dissection often occurs after PTA, and may require a stent placement. Dissections after the PTA are classified into six grades:

Grade A is a small radiolucent area within the lumen of the vessel disappearing with the passage of the contrast material. *Grade B* is a filling defect parallel to the lumen of the vessel disappearing with the passage of contrast material. *Grade C* is a dissection protruding inside the lumen of the vessel persisting after passage of contrast material. *Grade D* is a spiral-shaped filling defect with delayed run-off of the contrast material in the distal vessel. *Grade E* is a persistent luminal filling defect with delayed antegrade flow. Grade F is a filling defect accompanied by total occlusion. Stenting is typically required with Grade C to F dissections.

Subintimal Angioplasty

The first subintimal angioplasty for an occlusive femoropopliteal artery was reported by Bolia and colleagues in 1989.[79] Subintimal angioplasty has become widespread to overcome long occlusive segments. With this technique, a guidewire is intentionally inserted into the subintimal plane to create a new track. The tip of a hydrophilic guidewire is formed into a loop shape above the level of the occlusive lesion. The wire is then advanced with a support catheter along the subintimal plane until the occlusive lesion is passed. The wire and catheter will naturally re-enter to the true lumen distal to the occlusion where the intimal flap is thin and is broken by the wire loop. The resistance of the guidewire in the subintimal plane disappears once it reenters into the true lumen. Recanalization of the true lumen is confirmed by injecting contrast from the tip of the catheter or by IVUS. The recanalization segment is then dilated with an appropriately sized balloon. Typically, stenting is not required with this technique, and it should only be used in cases of flow-limiting dissection or severe elastic recoil. Subintimal angioplasty is technically successful in approximately 80%, and limb salvage is achieved in over 80%, with primary patency at 12 months of 60% to 70%,[80] although subintimal angioplasty fails in approximately 20% of the patients. The most common reason for failure is inability to re-enter the true lumen. Re-entry devices were developed to overcome such failures.

CART

If re-entry into the true lumen is not possible and if re-entry devices are not available, the controlled antegrade and retrograde subintimal tracking (CART) technique may be useful. CART technique utilizes a bidirectional approach, in which the two wires are simultaneously inserted via antegrade and retrograde access. For example, in an SFA CTO lesion, the wire is first passed into the subintimal plane in a prograde manner. If it is impossible to redirect the wire into the true lumen, then a retrograde wire is inserted from a site distal to the lesions, including the distal SFA, tibial, or pedal artery, to approach the target lesion. The distal, prograde wire is also placed into subintimal space using directional catheters until both wires cross each other within the subintimal space. Then, PTA balloons are inserted over each wire and placed next to each other. By inflating both balloons, the intimal flap or the septum separating the two balloons will be broken, allowing the antegrade wire to enter the subintimal plane that eventually leads to the distal true lumen. PTA and stenting should be performed in the same manner as described earlier (Fig. 61.6).

STENTING

Indications

In treating iliac lesions, the primary patency for primary stenting at 5 years was superior to selective stenting. This difference was significant in complex lesions categorized as TASC C or D lesions.[81] Selective stenting or provisional stenting is performed as a bail-out procedure including dissection, residual stenosis, presence of residual pressure gradient, and acute occlusion following the PTA.

Dissection

Some degree of dissection commonly occurs following PTA. Angiography and IVUS are useful for the assessment of dissection. If the contrast flow is impeded by the flow-limiting dissection, or if a false channel is created, a stent should be placed. Extension of the dissection into the disease-free segment beyond the target lesion also requires stenting.

Residual Stenosis

Residual stenosis is typically defined as over 30% stenosis of the lesion by angiographic measurement following PTA. In such cases, repeat PTA with a longer inflation time or additional stenting should be considered.

Pressure Gradient

A systolic pressure gradient that exceeds 10 mm Hg across the lesion after PTA usually requires repeat PTA or stent placement.

Acute Occlusion

If acute occlusion is encountered during endovascular therapy, placement of a stent is usually necessary. If acute occlusion occurred in a lesion in the so-called no stent zone including CFA, popliteal artery, or BTK lesions, justification whether stent placement or not is controversial. Therefore, it is best to perform interventions of such lesions where surgical backup is available.

In-Stent Restenosis

Recurrent stenosis after stenting is referred to as in-stent restenosis (ISR) and is usually caused by intimal hyperplasia. Although

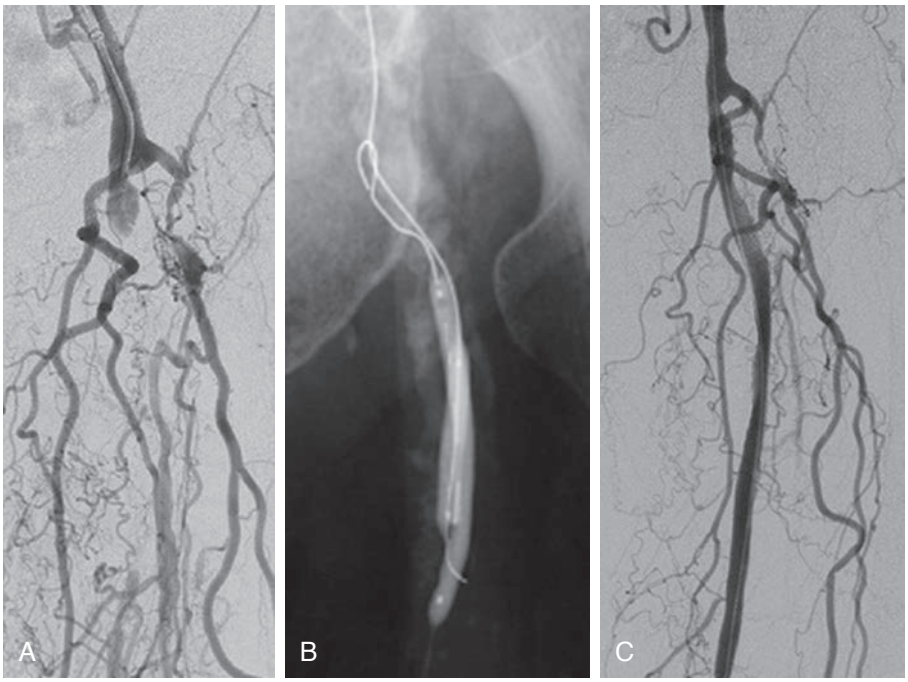

Figure 61.6 (A) Initial angiography shows an occlusive lesion of the proximal superficial femoral artery. (B) Two wires and balloons are inserted via both antegrade femoral artery and retrograde distal superficial femoral artery access sites (CART technique). (C) Completion angiography.

various treatments have been performed, including cutting balloon, atherectomy, stenting, and covered stent placement, due to absence of good quality data, it is difficult to make solid recommendations.

Stent Fracture

Stent strut fractures are commonly categorized into five types. *Type 0* means that there are no strut fractures. *Type I* is a single strut fracture only. *Type II* involves multiple single strut fractures that can occur at different sites. *Type III* involves multiple strut fractures resulting in complete transection of the stent, without displacement of the stent segments. Finally, *type IV* involves multiple strut fractures resulting in displacement of segments of the stent, including spiral fractures.

Stent Selections

The pros and cons of using a balloon-expanding stent versus a self-expanding stent are outlined in Table 61.4. Short or focal lesions are optimally treated with balloon-expanding stents because balloon-expanding stents can be placed with accuracy, expanded further using a larger balloon, and have high radial force which may be necessary to treat a calcified lesion. The balloon-expanding stents are often selected to treat ostial lesions of the visceral or aortoiliac artery since these lesions require accurate placement of the stent and since plaques are often calcified. When treating orificial common iliac lesion, a "kissing stent" technique may be necessary to prevent obstruction of the contralateral artery from plaque shift. In contrast, the self-expanding stents, which have the flexibility and kink resistance, are suitable for long and tortuous lesions along with superficial arteries that are subjected to external compression. Self-expanding stents are typically used for internal carotid, external iliac, SFA, and dissections secondary to stent graft insertion.

TABLE 61.4 The Characteristic of Balloon-Expanding and Self-Expanding Stents

	Balloon-Expanding Stent	Self-Expanding Stent
Pros	Precise deployment High radial force Further expansion with larger balloons Radiopaque	Flexibility Long length Kink resistance Ability to clamp
Cons	Rigid Short length Prone to fracture Less kink resistance	Low radial force Less precise deployment Insufficient radiopacity
Indications	Ostial lesions Focal lesions Calcified lesions Resistant lesions	Superficial lesions Long lesions Tortuous vessels Dissections

Technique of Balloon-Expanding Stents

The stent size is selected based on the reference vessel diameter. Although the stent diameter is typically selected to be 5% to 10% oversized compared to the reference vessel, it should also be determined based on the nature of the lesion including degree of calcification or thrombus. An adequately sized long sheath or guiding sheath is selected to pass the lesion. In order to prevent dislodgment of the balloon-mounted stent, the lesion should be adequately predilated and the tip of the long sheath should be advanced beyond the lesion using a dilator of the sheath or the PTA balloon to act as a dilator. After insertion of the sheath, the wire is advanced under fluoroscopic guidance. Once beyond the lesion, contrast is injected from the sheath

or IVUS interrogation is performed to confirm that the wire is located in the true lumen. The location of the lesion is then marked, and the sheath is advanced using the dilator or the balloon until it crosses the lesion. In severe stenotic or CTO lesions, an undersized predilation balloon is often used to facilitate insertion of the stent and is also useful in selecting the appropriately sized stent. A stent is then passed through the sheath across the lesion. After additional contrast is injected through the sheath to confirm proper stent location, the sheath is withdrawn to expose the stent. Then, the balloon is inflated to expand the stent with adequate pressure under fluoroscopic monitoring. During inflation, a "doggie bone" shape, with the proximal and distal ends of the balloon expanding, initially confirms that the stent has not dislodged. If a stent is not mounted properly on the balloon, then it should be exchanged with a new stent. A completion angiogram is performed to check for residual stenosis and adequate stent apposition. IVUS may be useful where visualization with fluoroscope is difficult. The wire purchase must be maintained until the procedure has been completed. Balloon-expanding stents can be further dilated to a certain extent with a larger balloon if necessary.

Technique of Self-Expanding Stents

The best features of self-expanding stent are the flexibility and the long length. The selected stent should be 1 to 2 mm larger than the reference vessel because the stent cannot be expanded beyond the stated diameter. As with balloon-expanding stents, after the wire is across the lesion, predilation is performed. Unlike the balloon-expanding stent, the introducer sheath is not always required to cross the lesion since self-expanding stents are stored in a covering sheath and there is no risk of stent dislodgement. The stent is deployed by withdrawing the covering sheath. Fluoroscopic guidance is necessary during deployment because most self-expanding stents tend to "jump" forward as they are unsheathed. Self-expanding stents cannot be resheathed once deployed, with the exception of the Wallstent (Boston Scientific, Natick, Massachusetts). After stent placement, postdilation with appropriate diameter and length is required.

The Viabahn (W.L. Gore & Associates, Flagstaff, Arizona), a newer endograft for SFA lesions, has been indicated for the treatment of long lesions due to better results. In VIASTAR trial, as previously described, the primary patency of this endoprosthesis was superior to bare metal stents even if the lesion exceeded 20 cm. The Viabahn may become an alternative for bypass surgery for the patients with serious comorbidities and long, complex lesions.

HYBRID THERAPIES

A hybrid approach utilizing both endovascular and surgical repair has currently gained wide acceptance, and includes debranching techniques, bypass or endarterectomy with stent placement, or application of an "elephant trunk" with endografts following arch replacement. In the periphery, an iliac lesion with a CFA occlusion is often best treated with an iliac stent and CFA endarterectomy (Fig. 61.7). The long term patency of the hybrid repair has been demonstrated to be comparable to open surgical repair.[82,83] Patients undergoing hybrid therapy for TASC C/D lesions experienced a shorter intensive care unit (ICU) stay and hospital stay than open surgery. The authors recommended that hybrid therapy should be performed for a high surgical risk patient regardless of TASC classification. Although stenting may be acceptable treatment for complex iliac lesions, it remains controversial whether TASC C/D infrainguinal lesions should be treated by endovascular therapy.

EMBOLIZATION

Technique of Coil Embolization

In order to minimize the risks and maximize the efficacy of coil embolization, it is best to position both the wire and the catheter as close to the target vessel as possible. Catheters with various shapes are useful for cannulating the target vessel, and the microcatheter which can be inserted into a diagnostic catheter enables it to reach target vessels that 4-Fr. catheters cannot reach due to tortuosity and distance of the access vessel. Once the catheter is cannulated selectively, a coil, plug, or liquid embolization can be performed.

Coil embolization is currently widely used for the treatment of peripheral and cerebral vascular diseases. In the periphery, coils are typically used for the treatment of a visceral aneurysm, prevention of type II endoleaks during stent graft procedure, or treatment of persistent endoleaks after stent graft placement. Coil embolization for a saccular aneurysm with a narrow neck requires packing, which commonly consists of three steps: "Framing," "Filling," and "Finishing" (Fig. 61.8A). The coil for the purpose of framing is typically oversized by approximately 20% of the target diameter. Equal size to the aneurysm or undersized coils is then deployed to fill and thrombose the aneurysm. An additional, smaller coil may be inserted into the remaining free space to finish the coiling.

Stent-Assisted Coil Embolization

Stent-assisted coil embolization is an effective technique for treating a wide-neck aneurysm and to protect the parent vessel. First, a bare metal stent with 10% to 20% oversize is placed in the parent vessel across the neck of the aneurysm. A microcatheter is then delivered into the aneurysm through the stent strut. The coils of adequate size are then used to pack into the aneurysm. This technique allows for safe embolization since the stent protects the parent vessel from protruding coils (see Fig. 61.8B-F). Both pushable and detachable coils are currently available. Detachable coils allow one to reposition the coil multiple times, thereby resulting in precise deployment. However, they are more expensive and also usually create a strong artifact on CT scans. The pushable coil cannot be repositioned and precise sizing and deployment can be challenging especially if the landing zone is short.

Coil Embolization for Type II Endoleak

Persistent type II endoleaks are usually treated by embolization with coils or embolic agents. The complex connections

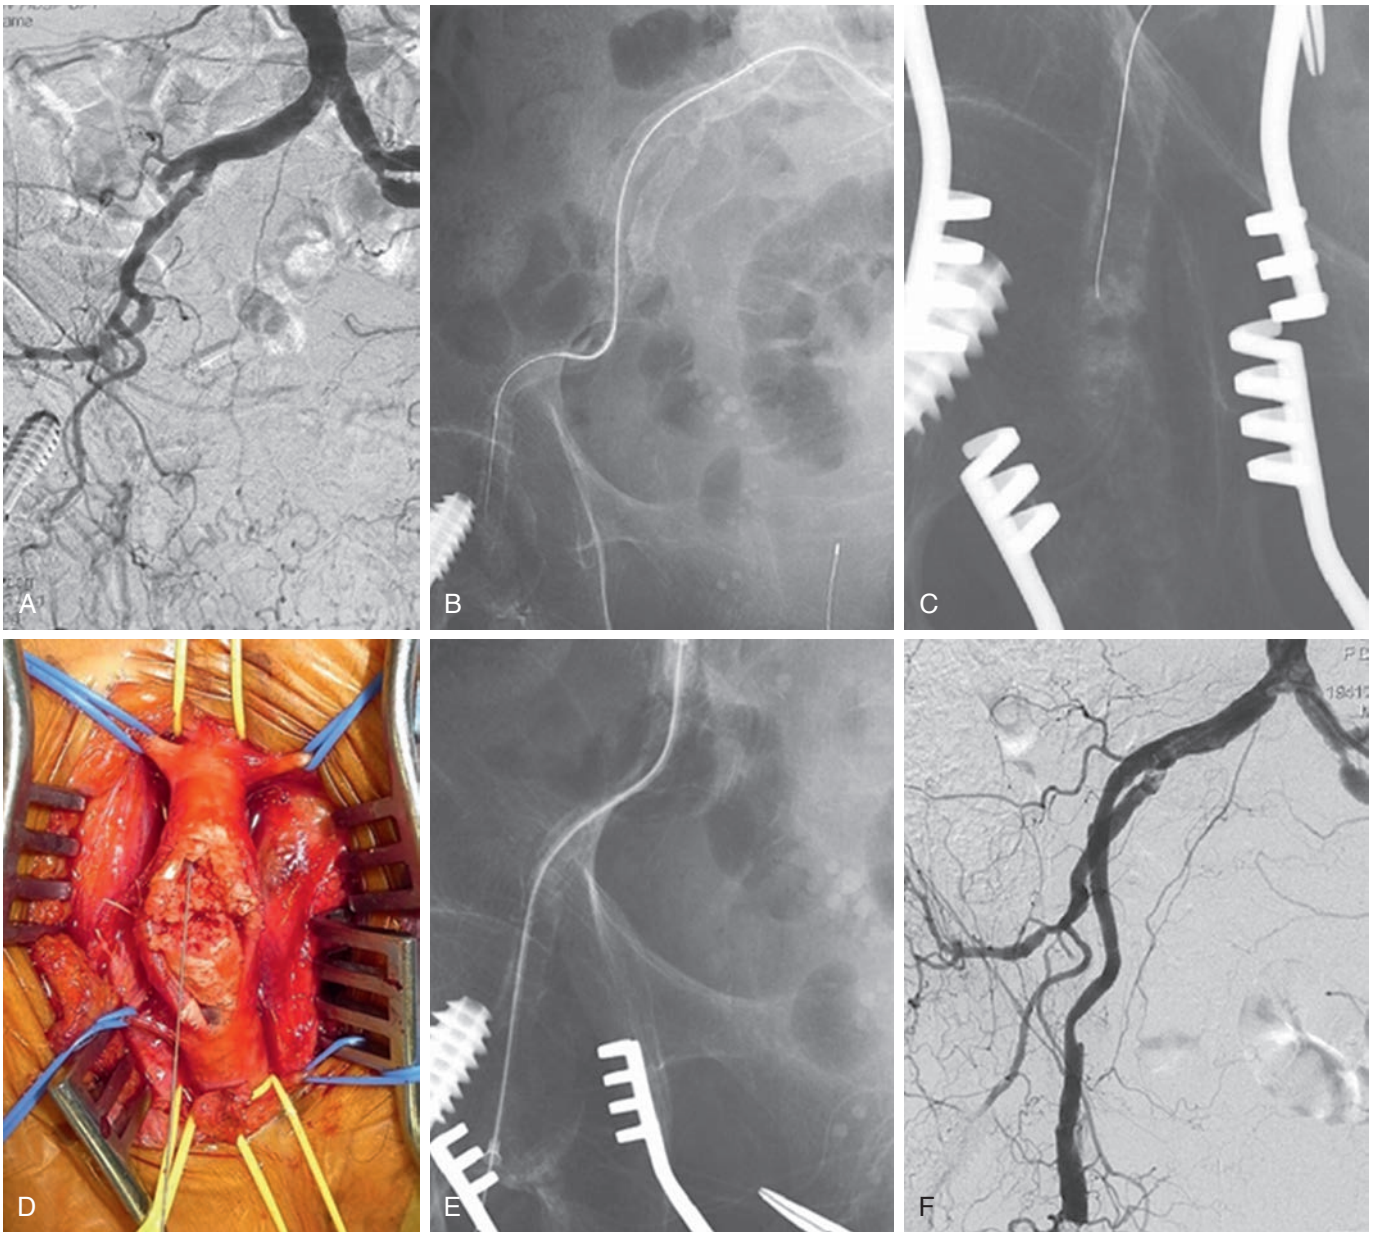

Figure 61.7 Hybrid Treatment. (A-C) The wire is inserted via the contralateral femoral artery to treat the iliac occlusion. When the wire reaches the common femoral artery, the wire is stabilized at that position. (D) Endarterectomy is performed for the common femoral occlusion and the wire is caught. (E) The new sheath is inserted via the common femoral artery following endarterectomy to make a "pull-through" wire. (F) The iliac stent is deployed.

of the inflow and outflow vessel in many persistent type II endoleaks are one of the reasons these endoleaks are difficult to treat. Even if some inflow and outflow lumbar arteries are successfully embolized, some type II endoleaks will not resolve since there are remaining feeding arteries. There are two strategies to treat type II endoleak following endovascular aortic repair: transarterial approach and translumbar approach. Although it is unclear which approach is better, the most important principle in the treatment of type II endoleaks is to embolize the nidus of endoleak within the aneurysm sac and interrupt the communications between multiple inflow and outflow vessels.

Technique of Vascular Plugs

A vascular plug allows precise and secure deployment. It is increasingly used for the treatment or prevention of type II endoleaks during stent graft procedures. Embolization of the left subclavian artery during endovascular thoracic aneurysm repair or embolization of the internal iliac artery during endovascular aneurysm repair to prevent of type II endoleak are ideal indications for the vascular plug. When deploying a vascular plug, the tip of the corresponding sheath must be inserted beyond the intended deployment site. The plug, in the folded state, is then advanced to the target location through the sheath and

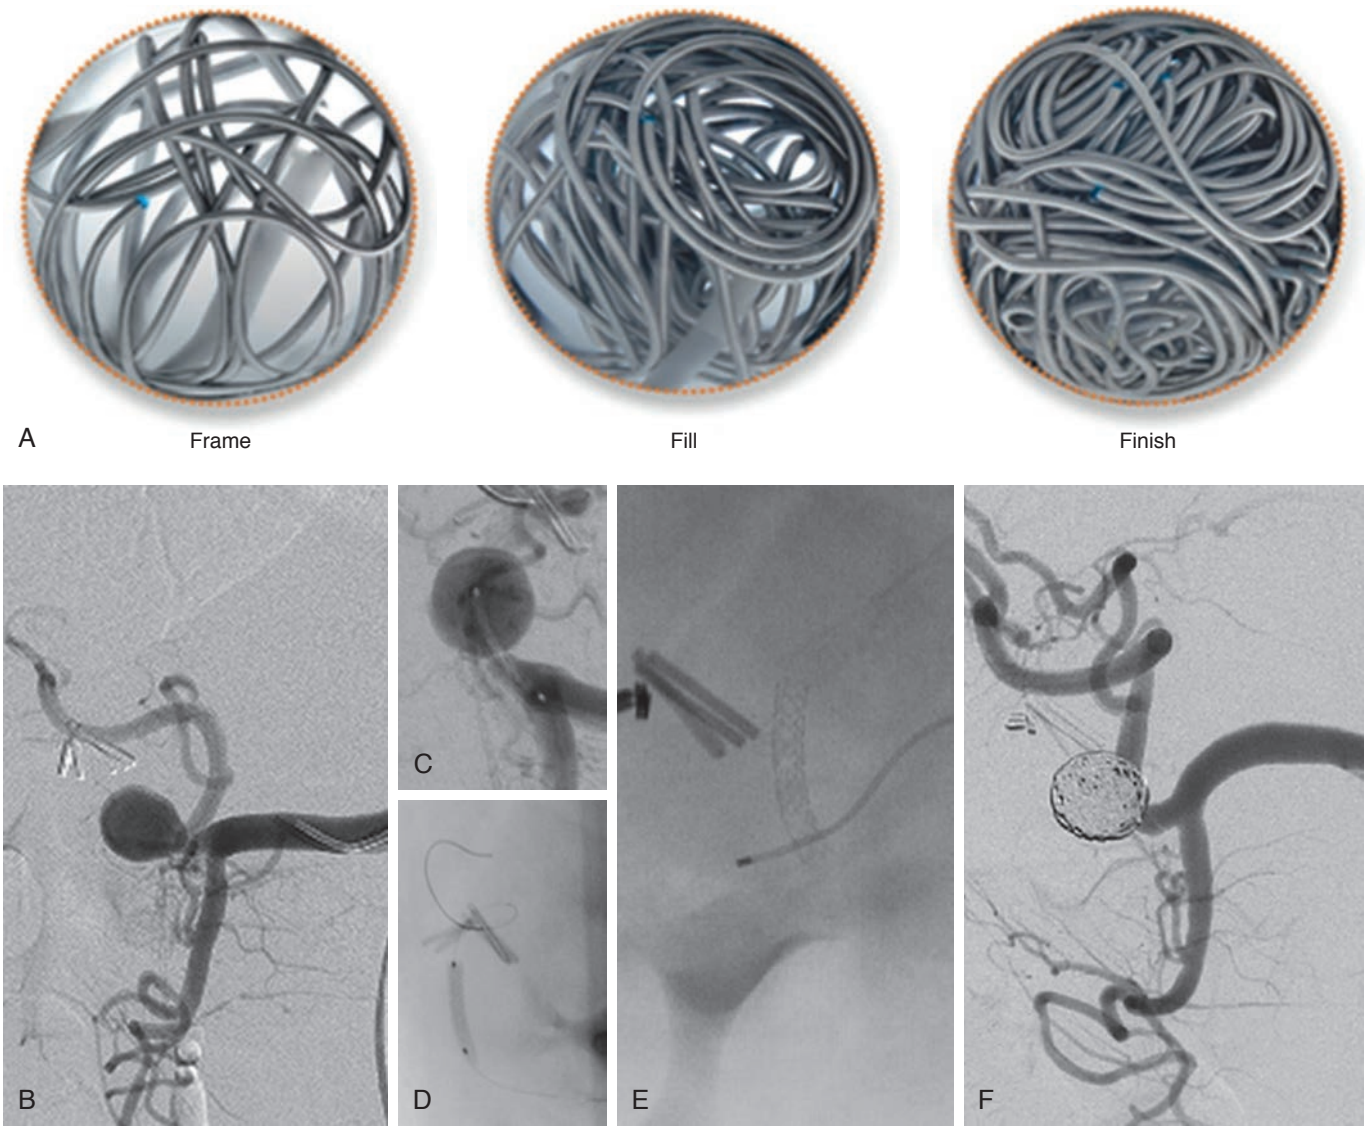

Figure 61.8 (A) Basic technique for embolization packing with coils. (B) Initial angiography shows a common hepatic artery aneurysm near the branch of the gastroduodenal artery. (C-E) A coronary stent is inserted to maintain hepatic vessel flow, and a microcatheter is inserted into the aneurysm via a stent strut. (F) Completion angiography following coil embolization.

by unsheathing the plug, is deployed and can be detached from the wire. The advantage of the plug includes secure and accurate occlusion of the vessel and may be more cost-effective than using multiple detachable coils. The fact that it requires a 5- to 6-Fr. sheath to be intubated across the target vessel could be traumatic in certain conditions or even impossible to use. In such situations, coil embolization that can be performed in an atraumatic fashion should be selected.

When performing embolization in the subclavian artery during thoracic endovascular repair, it is important to deploy the coils or plug proximal to the vertebral artery. When done in the internal iliac artery, it is best to deploy it proximal to the iliolumbar artery to maintain the distal collateral circulation to minimize complication.

INTRODUCTION

As in other surgical specialties, minimally invasive laparoscopic techniques have evolved progressively in vascular surgery with a number of reports describing laparoscopic aortic repair for occlusive and aneurysmal disease.[1-3] There are no large randomized trials to support laparoscopic aortic repair over open or endovascular surgery for abdominal aortic aneurysm (AAA) or aortoiliac occlusive disease (AIOD). The lack of trained vascular surgeons with the skills to perform laparoscopic aortic repair and the improved outcomes after aortoiliac stenting and endovascular aneurysm repair (EVAR) have led some to question the need for laparoscopic aortic repair, although there is a subset of patients who will benefit from a potentially less invasive alternative to open repair when EVAR or iliac stenting are not in their best interests. In this setting, laparoscopic aortic surgery may also be considered as a cost-effective option.

Here we describe the current laparoscopic techniques used for aortic reconstruction, including hand- and robot-assisted laparoscopic surgery, their results, and the conditions required to master these procedures.

TOTAL LAPAROSCOPIC AORTIC SURGERY

The following four approaches have been described to perform total laparoscopic aortic bypass:

- Retrocolic prerenal transperitoneal approach
- Retrocolic retrorenal transperitoneal approach

Abstract

This chapter describes and evaluates the results of different laparoscopic techniques used to treat aortic disease, including (1) total laparoscopic aortic surgery, (2) laparoscopy-assisted procedures including hand-assisted laparoscopic surgery, and (3) robot-assisted laparoscopic surgery, with their current indications.

Results of these techniques are analyzed in a systematic review of the clinical series published with complete information concerning operative time, clamping time, conversion rate, length of hospital stay, morbidity, and mortality.

Heterogeneity of the studies and selection of the patients made comparison with current open or endovascular surgery difficult. Analysis of these series shows that laparoscopic aortic surgery can be performed safely provided that patient selection is adjusted to the surgeon's experience and conversion is liberally performed. The future of this technique in comparison with endovascular surgery is still unknown, and it is now time for multicenter randomized trials to demonstrate the potential benefit of this type of surgery

Retrocolic Prerenal Transperitoneal Approach for Aortoiliac Occlusive Lesions

The transperitoneal procedure described by Dion et al.[4] and simplified by Coggia et al.[2] involves exposure of the aorta by a left prerenal colon dissection. The patient is placed in the dorsal decubitus position with an inflatable pillow under the left flank. The left arm remains free and the right arm is placed on an armrest. The lower extremities are flexed at 30 degrees and attached parallel to each other. Two supports must be placed on the right side of the thorax and flank in order to stabilize the patient when the table is titled to the right (at 45 degrees) and the pillow is inflated (to 35 degrees). After these maneuvers (i.e., tilting and inflation), the patient is in the complete right lateral decubitus position (Fig. 62.1). It is possible to move the patient from the right lateral decubitus position, used during exposure of the aorta, to the dorsal decubitus position for exposure of the femoral arteries, simply by tilting the operating table.

The operating surgeon and first assistant stand in front of the patient's abdomen and the second assistant stands opposite the operating surgeon. A pneumoperitoneum is insufflated up to 14 mm Hg through a Veress needle inserted in the left hypochondrium. A 45-degree endoscope is positioned on the left anterior axillary line below the costal margin. Five trocars are introduced under visual control after establishing a pneumoperitoneum. Two operating ports are placed 6 to 7 cm apart on the left transrectal line parallel to the midline (port no. 2 for scissors and needle holder and port no. 3 for fenestrated forceps). Two trocars for the first assistant are introduced in the left iliac fossa and on the midline 5 cm from the pubis (port no. 4 for suction catheter and port no. 5 for fenestrated forceps followed by the distal clamp). The last trocar (port no. 1) is positioned on the midline 2 cm below the xiphoid process for the proximal aortic clamp (Fig. 62.2).

The left laterocolic approach involves left colic dissection to achieve prerenal exposure of the aorta. The table is tilted as far as possible to the right (i.e., 45 degrees) and the pillow is inflated to enhance the right lateral decubitus position by 30 degrees. The Toldt fascia is incised from the left colic angle to the mesosigmoid to allow complete dissection of the left mesocolon. After identification of the genital vein, prerenal dissection is continued to the left renal vein. Because the patient is in the right lateral decubitus position, the small bowel and left mesocolon drop to the right side of the abdomen (Fig. 62.3). The mesocolon is then attached to the abdominal wall with transparietal sutures to form an apron providing stable exposure of the aorta.[4]

(B) Operative view: operators and position of ports for total laparoscopic retrocolic prerenal transperitoneal approach.

In case of extensive infrarenal aortic calcifications, mobilization of the renal vein is necessary to expose the juxtarenal aorta (Fig. 62.4). Dissection is then extended to the common iliac arteries.

For exposure of the femoral arteries, the table is rotated to the left and the pillow deflated. After conventional femoral exposure, the table is again tilted to the right to allow introduction of the bifurcated prosthesis through one of the ports. The right branch of the prosthesis is tunneled in the anatomical position before making the proximal anastomosis. The extremity of the left branch is ligated and left in the abdomen.

Aortic clamping is performed with laparoscopic clamps introduced through ports no. 1 and no. 5, which stabilize the left colon during completion of the proximal anastomosis. Anastomosis between the aorta and prosthetic graft is made by two running sutures using 3/0 or 4/0 polypropylene. Suturing is performed using an 18-cm polypropylene 3/0 suture with one end previously sutured to a pledget to avoid having to tie the first knot (Figs. 62.5 and 62.6). In case of an end-to-end aortic anastomosis, closure of the infrarenal aorta is accomplished with a double running polypropylene 3/0 suture. A technical alternative may be the use of an automatic stapler without cutting knife (Endopath ETS-Flex45, Ethicon , Somerville, New Jersey) to safely close the distal aortic stump. This alternative saves time on laparoscopic suturing but, to be effective, requires a moderately calcified aortic wall.

The left branch of the prosthesis is then tunneled with the help of an aortic clamp introduced through the left groin. The tip of the clamp is located under laparoscopic control and routed behind the left ureter. Femoral anastomoses are performed conventionally on a patient in dorsal decubitus position. After removing the clamp, the surgeon decreases the gas pressure to 6 mm Hg to check the hemostasis of the aortic anastomosis and reveal any venous bleeding hidden by the high-pressure pneumoperitoneum. The mesocolon is then repositioned under laparoscopic control to separate the graft from the bowel. This retrocolic prerenal approach achieves an adequate aortic exposure and provides a large operating space. The small bowel falls to the right part of the abdomen by positioning the patient in a right lateral decubitus position with the left mesocolon acting as a peritoneal apron.

Retrocolic Retrorenal Transperitoneal Approach

The retrocolic prerenal transperitoneal approach is used in most standard cases. However, in very thin patients, where dissection of the Toldt fascia is impossible, or in patients with previous left kidney or colon surgery or for suprarenal aortic clamping, a transperitoneal left retrorenal approach is preferred.[5] In this case, the dissection is conducted by elevating the left colon and the left kidney with section of the renoazygos lumbar vein to achieve a right medial visceral rotation.

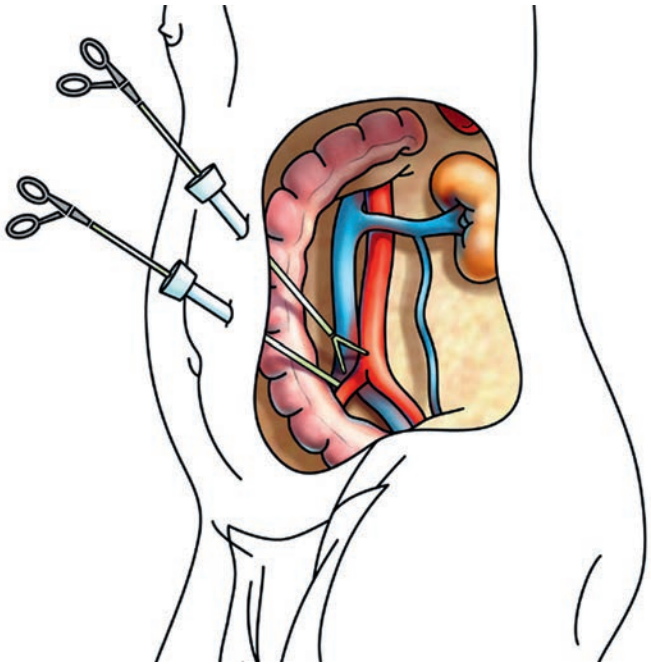

Figure 62.3 Aortic exposure through a left retrocolic prerenal approach. The patient is in right lateral decubitus. The intestinal loops collect on the right side of the abdomen, with the mesocolon forming an apron. This technique provides a stable exposure of the aorta.

Specificity for Abdominal Aortic Aneurysm

The retrocolic retrorenal transperitoneal approach is used most often for total laparoscopic aortic aneurysm repair, particularly in patients with a juxtarenal AAA.[5] After the aorta is clamped, a stitch is placed into the aneurysm's wall and pulled out through the abdominal wall to maintain the aneurysmal sac open. The right iliac clamping is performed through an infraumbilical trocar and left iliac clamping through another trocar inserted in the left iliac fossa. A bulldog clamp serves to occlude the inferior mesenteric artery. Mural thrombus is removed in a

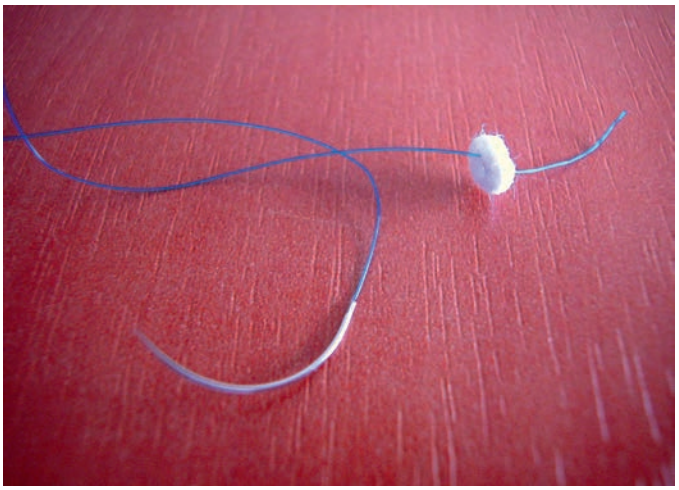

Figure 62.5 Aortic anastomosis performed with a prepared 18-cm polypropylene 3/0 suture with one end sutured to a pledget to avoid having to tie the first knot.

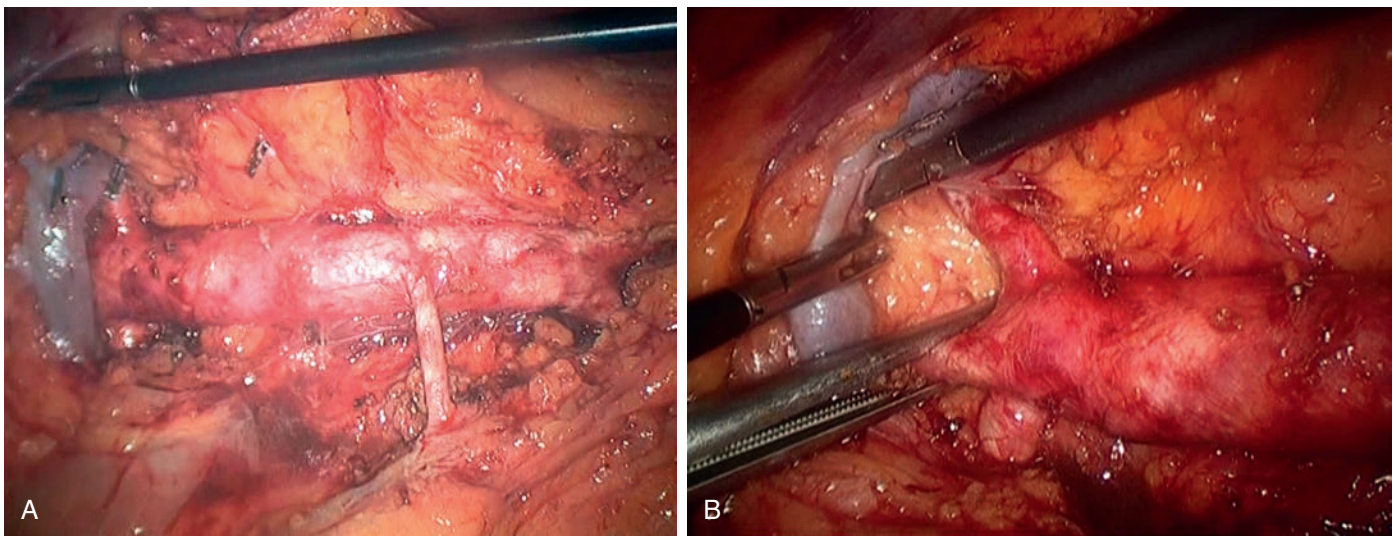

Figure 62.4 (A) Complete exposure of the aorta, iliac arteries, and inferior mesenteric artery through a left retrocolic prerenal approach. (B) Cross clamping of the suprarenal aorta for extensive occlusive disease and calcification of the infrarenal aorta (same approach).

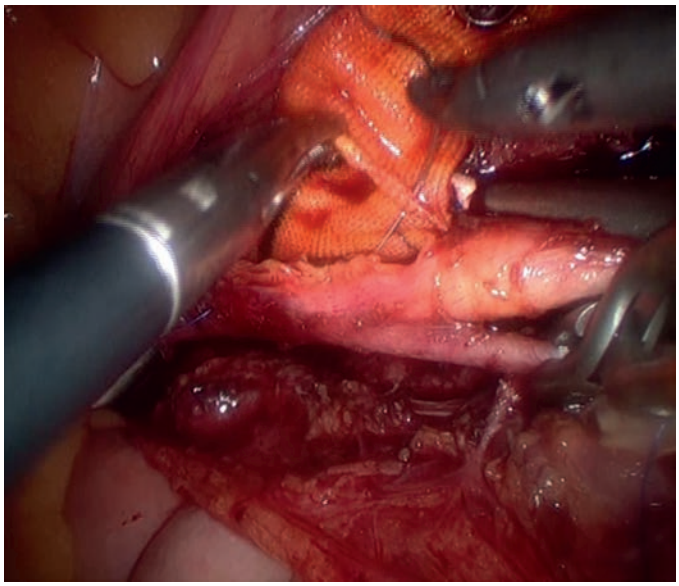

Figure 62.6 End-to-side totally laparoscopic aortic anastomosis with a 3/0 polypropylene running suture using curved jaws and axial handle needle holder.

container. Lumbar arteries are controlled with 3/0 polypropylene stitches as described in the Creech technique or by external hemoclips or staples. Anastomoses are performed as previously described.[6]

Combined Transperitoneal and Retroperitoneal Approach

This approach was first described by Dion.[7] The main feature of the technique is the creation of a peritoneal apron that retains the intestinal loops without reducing the size of the operating cavity. A 10-mm trocar is introduced at the level of the umbilicus to establish the pneumoperitoneum at a pressure of 12 mm Hg. The patient is then placed in the Trendelenburg position at 10 degrees with the table tilted to the right. As initially described by Dion, the technique involves two distinct retroperitoneal and transperitoneal maneuvers for dissection of the left parietal peritoneum and attachment to the wall by three transparietal sutures to form a peritoneal apron. The procedure begins with an incision of the left parietal peritoneum about 8 cm anterolateral to the Toldt fascia. Dissection is followed in front of the kidney up to the renal vein. The infrarenal aorta proximal to the inferior mesenteric artery is then dissected. The surgeon moves to the patient's left side to complete the procedure. The apron is then attached to the wall to keep the bowel out of the operating field. As previously described, this technique was subsequently simplified by Coggia.[8]

Retroperitoneal Approach

This laparoscopy-assisted technique with a short laparotomy to facilitate the aortic anastomosis was first described by Said et al.[9] and developed by Edoga et al.[10] for AAA repair. The patient is placed in a right lateral decubitus position as for the retrocolic transperitoneal approach. The viewing endoscope is introduced through a 15-mm incision above and medial to the iliac crest using the open retroperitoneoscopic technique with a prior hand dissection of the retroperitoneal space. This dissection should be extended up to the midline to avoid peritoneal tears. Although rarely used, the retroperitoneal procedure is a suitable alternative when the transperitoneal procedure is contraindicated in patients with hostile abdomen and peritoneal adhesions or when a complete exposure of the left common iliac artery is needed.[11] The main advantage of the retroperitoneal route is to exclude the visceral organs from the operative field, albeit at the expense of a smaller working space the risk of peritoneal tears. One reason that this surgical approach is rarely used for aortoiliac procedures is diffusion of the gas through the peritoneum, thus creating a "passive" pneumoperitoneum, which progressively replaces the pneumoretroperitoneum and reduces the working space.

HAND-ASSISTED LAPAROSCOPIC AORTIC SURGERY

Hand-assisted laparoscopic surgery (HALS), which enables the surgeon to introduce his nondominant hand through a special port while maintaining the pneumoperitoneum, has been routinely used by some authors for aortic occlusive lesions or AAA repair.[12-15] The patient is placed in the supine position. A midline incision of 7 to 8 cm is performed to allow placement of the port-site device. Through this port, the hand of the surgeon is introduced into the abdominal cavity without any carbon dioxide loss. The incision site is carefully selected to gain vision of the assumed anastomotic sites. A 10-mm trocar is then placed along the midline below the umbilicus with introduction of a 30-degree laparoscopic optic and for carbon dioxide insufflation to create a pneumoperitoneum of 12 mm Hg. At that point, with the nondominant hand, the surgeon pushes away the bowel loops to the right by tilting the operating table to the right and in the Trendelenburg position. A trocar is then introduced lateral to the border of the left rectus abdominis muscle for dissection of the infrarenal aorta and another trocar is inserted lateral to the border of the right rectus abdominis muscle. After laparoscopic dissection of the aorta, the abdominal cavity is deflated and the special port-site device removed, the bowel being left in place in the right abdomen with the aid of laparoscopic sponges. The incision is kept open with an autostatic retractor. The proximal anastomosis between the aorta and the graft is performed under direct vision with conventional instruments. If a distal anastomosis on the external iliac is planned, an oblique suprainguinal incision is done to expose the artery. HALS has proven in many studies to be a reliable technique to overcome the technical challenge of total laparoscopy aortic surgery, mainly the performance of vascular anastomoses. It may have increased the feasibility and reproducibility of this type of surgery, but its invasiveness compared with total laparoscopic aortic repair is a drawback.

TOTALLY ROBOTIC AORTIC AND ROBOT-ASSISTED PROCEDURES

The robot may be used in laparoscopy-assisted procedures as well as in total laparoscopic surgery.[16] Its usefulness becomes more evident when suturing the aortic anastomosis because robotic arms support five degrees of freedom. Optimal placements of the robot's arms are usually in ports located on the left axillary line.[17-21] The use of robots in vascular surgery is thought to result in a better surgical performance by overcoming the long learning curve of vascular suturing. But the system also has some disadvantages, including its complexity and high cost. The robot may be used in laparoscopy-assisted procedures as well as in total laparoscopic surgery.[16]

With more than 3000 Da Vinci robots (Intuitive Surgical, Sunnyval, California) in use around the world, robotic surgery has become unavoidable in the surgical field.[22]

Robotic aortic surgery takes the fundamentals of laparoscopic surgery.

The initial uses of robots have focused on the performance of anastomoses[23] and arterial reconstructions, but the system is now increasingly used for completing the entire intervention, from the incision to aortic reconstruction.[24]

Totally Robotic Aortic Surgery

The da Vinci surgical system is composed of three main parts, one patient-side cart with four articulated arms, one instrument tower with video command, and the surgeon's work station with the operating console. The fundamental difference between laparoscopic and robotic techniques is that the latter provides the surgeon with a surgical theater similar to that of open surgery. Indeed, with the robot, the surgeon uses his or her hands in the same manner as in open surgery. In addition, it provides seven degrees of freedom for the tips of the robotic instruments (Endo-Wrist technology), following rotational movements of the hands and wrists. Added to a three-dimensional-like vision, these characteristics explain why there is a faster learning curve with the robot.

Patient placement is similar to that described for total laparoscopic techniques. Only the placement of the trocars requires a different strategy.

With the patient under general anesthesia, an 80-degree rotation of the patient is obtained by adding a 45-degree right tilt to the table and placing a 35-degree inflated Pelvic Tilt pillow (O.R. Comfort, Branchburg, New Jersey) under the patient's left flank. One support is placed on the right side of the thorax, leaving the area below the xyphoid free for placement of a proximal aortic clamp trocar. The second trocar is placed facing the right hip, leaving the surgical approach of the right groin free in case aortobifemoral reconstruction should be required. Both lower limbs are maintained in line with the body; only the right leg is attached to the table; the left leg is flexed to 30 degrees to avoid any psoas elongation. In the cases involving aneurysm repair, the patient is immediately installed on the operating table as well and the robot is docked. In the case of aortobifemoral reconstruction for occlusive disease, the patient is first placed in the dorsal position to achieve femoral exposure and then rotated on the right side.

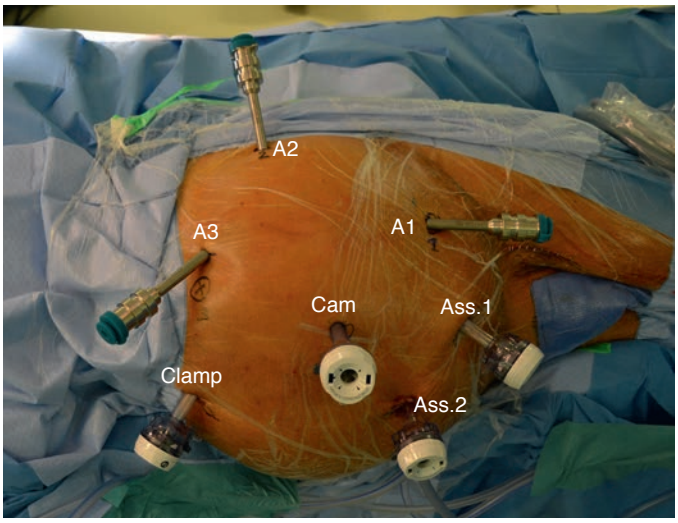

Figure 62.7 Placement of trocars for robotic aortoiliac surgery. *Clamp*, A 12-mm laparoscopic trocar placed just below the xyphoid, on the abdominal median line, is used by a surgeon's assistant during the surgical approach and dissection of the aorta and for the proximal laparoscopic clamp; *Ass.1*, 12-mm laparoscopic trocar placed up to the pubic symphysis, used by a surgeon's assistant during the surgical approach and dissection of the aorta and for the distal laparoscopic clamp; *Ass.2*, 12-mm laparoscopic trocar at the umbilicus, introduced by open technique, used for the creation of the peritoneum and for surgical assistance; *A1*, 9-mm robotic trocar docked on the articulated robotic arm 1, inserted close to the left iliac spine shifted 5 cm below, used by the right hand of the surgeon; *A2*, 9-mm robotic trocar docked on the articulated robotic arm 2, inserted close to the robotic trocar of the arm 3, shifted to the patient back, used by the left hand of the surgeon alternatively with the arm 3; *A3*, 9 mm robotic trocar docked on the articulated robotic arm 3, inserted close to the left costal margin, on the left axillary line, used by the left hand of the surgeon; *Cam*, 12-mm laparoscopic trocar inserted on a slightly lower line left pararectal, midway between trocars A1 and A2 with triangulation and docked on the robotic camera arm.

A pneumoperitoneum of 14 mm Hg is performed by an open technique at the umbilicus using a 12-mm trocar that will be used later by an assistant. Two other 12-mm trocars are inserted respectively below the xyphoid and above the pubic symphysis, using as assistant or for proximal and distal clamping of the abdominal aorta (Fig. 62.7).

As opposed to basic laparoscopy, the main problem encountered with the robot is the external conflict between the articulated arms. For this reason, robotic trocars of three main arms, right and left surgeon's hand, and camera are placed on the left axillary line and spaced as far as possible from each other. The right arm (arm 1) is close to the left iliac spine, shifted 5 cm below, and the left arm (arm 3) is close to the left costal margin. The camera trocar (camera arm) is placed midway between the remaining two trocars on a slightly lower line left pararectal. With the S and Si models, which are most used, placement of the robot is decided by the placement of the camera articulated arm. The last articulated arm (arm 2) is placed when a last trocar is used close to the trocar of arm 3, shifted to the patient's back. One 5-mm trocar can be added

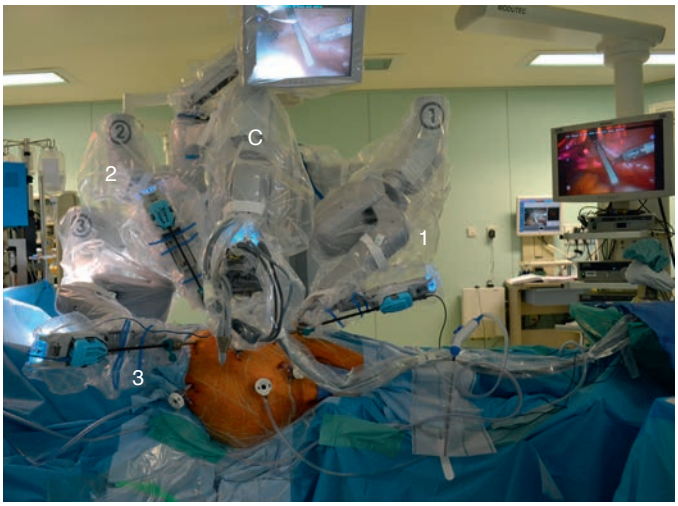

Figure 62.8 Side-docking method for robotic aortoiliac surgery. The robot is docked from the left side of the patient at an approximately 90-degree angle to the central axis of the table. *1*, articulated robotic arm 1, used by the left hand of the surgeon; *2 and 3*, articulated robotic arms 2 and 3 are used alternatively by the right hand of the surgeon; *C*, camera articulated robotic arm, with a 0- or 30-degree endoscope providing three-dimensional vision and used by both of the surgeon's hands independently of the operative robotic arms.

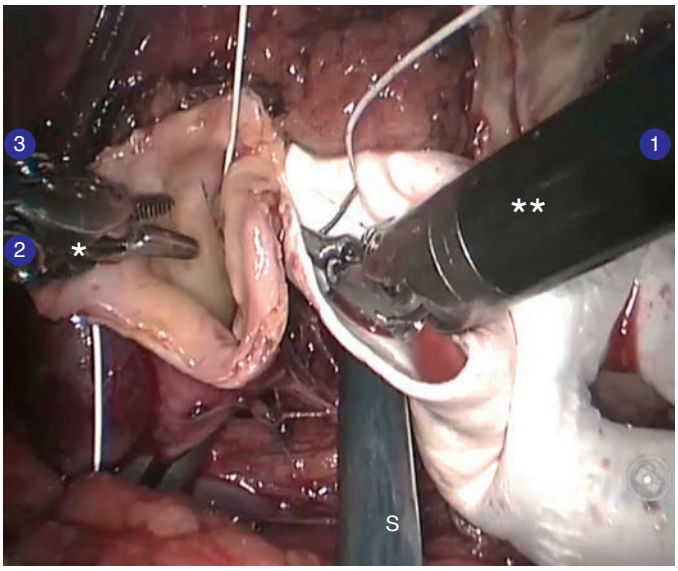

Figure 62.9 Robotic proximal anastomosis for abdominal aortic aneurysm repair with a polytetrafluoroethylene bifurcated graft. * Left robotic needle holder, used by the surgeon's left hand; ** Right robotic needle holder, used by the surgeon's right hand; *S*, Laparoscopic surgical suction.

between the proximal clamp trocar and the umbilicus on the median line.

The patient-side cart is docked from the patient's left side, placed at 90 degrees relative to the central axis of the operating table (Fig. 62.8). The assistant and operative nurse face the patient and, the surgeon works from the operating console at a remote place. The main dissection is done with a monopolar scissors on the right arm (arm 1) and a bipolar fenestrated forceps on left arm (arm 3). Another arm can be used as a robotic assistant with a second fenestrated forceps (arm 2). Most of the time, a 0-degree endoscope is used with the camera (camera arm), but a 30-degree endoscope may also be used, especially for obese patients with difficult exposure due to the intraperitoneal fat.

With total robotic technique, both retrocolic prerenal and retrocolic retrorenal dissections are achieved using the same principles as the total laparoscopic technique described earlier. However, there are some striking differences between the two techniques that give an advantage to the robot in performing aortic surgery. Because of the stable three-dimensional vision and capability of the instrument's movements in a close and deep space, the robot pushes the limits of laparoscopic dissection. The suprarenal aorta, origin of the superior mesenteric artery, origin of the right renal artery, and left renal artery are dissected. This offers the opportunity of temporary suprarenal aortic clamping for extensive aortic occlusive disease close to the renal arteries or for an aneurysm with a short aortic neck. Similarly, the right iliac bifurcation can be easily reached and dissected to perform the distal anastomosis in case of an aortoiliac aneurysm.

The retrocolic retrorenal approach is mostly performed for occlusive disease, and the retrocolic prerenal approach is preferred in the case of AAA repair. In this case, after clamping the proximal neck of the aneurysm, the lumbar arteries are clipped, helping to mobilize the aneurysmal sac with a fenestrated grasp (arm 2) without any risk of distal embolization. The distal aorta is clamped by a laparoscopic clamp through the distal trocar, and common iliac arteries are clamped selectively by removable bulldog clamps. In case of severe calcifications of the iliac arteries, transparietal aortoiliac clamps may be used instead of these ineffective bulldogs.

Aortic and iliac anastomoses are carried out with 3/0 or 4/0 Gore-Tex suture, which provides more strength than polypropylene. Robotic suturing with the help of a shorter learning curve provides better dexterity and pushes the limit of laparoscopic suturing. Proximal and distal aortic anastomoses are carried out with a unique running suture 25 cm long, blocked at one end by a pledget (Fig. 62.9). The same technique is applied for iliac anastomoses, with a 15-cm running suture. One challenge during robotic suturing is to judge the degree of tension needed on the suture line, as the tactile sensation cannot be transmitted to the hands of the surgeon from the robotic arms and is developed with experience.

Robot-Assisted Aortic Surgery

Some surgical teams have decided to use the robot only to perform one part of the aortic surgery with minilaparotomy for graft implantation.[24] In other cases, the robot is installed after completion of aortic exposure with a classic laparoscopic technique[19,21] and used only to perform arterial sutures. The robot makes it possible to facilitate the achievement of the suture while reducing its completion time and thereby the clamping time.[25]

PUBLISHED SERIES

Clinical studies eligible for inclusion in this chapter were identified by a thorough search of the PubMed database from 1995 to 2016. The present authors worked independently using the following key words: *laparoscopy, laparoscopic, endoscopy, aortic aneurysm, aortic occlusive disease, robot,* and *robotic*. In addition, we checked the references of relevant reviews. From 378 articles, we excluded those with fewer than five patients. Only studies with complete data on operative time, clamping time, length of hospital stay, morbidity, mortality, and conversion were selected. In case of duplicate material, the larger of the studies or the study with the best-documented data was included for analysis. Consequently 48 studies were found to be eligible, with 24 reporting total laparoscopic aortic surgery (TLAS), 14 reporting HALS and minilaparotomy-assisted laparoscopic surgery, and 10 reporting robot-assisted laparoscopic aortic surgery.

Total Laparoscopic Aortic Procedures

Total laparoscopic aortic procedures for AIOD were analyzed in 16 studies,[26-40] regrouping 932 patients (Table 62.1). Total laparoscopic procedures for AAA were reported in nine studies[3,5,10,28,34,41-44] regrouping 410 patients (Table 62.2).

Hand-Assisted and Laparotomy-Assisted Laparoscopic Surgery

Hand- or minilaparotomy-assisted laparoscopic aortic procedures for AIOD (Table 62.3) and AAA (Table 62.4) were reported in 14 studies[3,14,15,45-55] regrouping 860 patients.

Robot-Assisted Laparoscopic Surgery

Robot-assisted laparoscopic aortic procedures were analyzed in 11 studies[18,21,23-25,56-58] regrouping 525 patients (Table 62.5).

Robot-Assisted Laparoscopy

Results of robot-assisted aortic laparoscopy were analyzed separately with regard to the specificity of robotic technologies, with the first two cases published in 2002 by Wisselink et al.[58a] As shown in Table 62.5, results obtained from these studies showed that the robotic system was effective in performing aortic anastomoses with the surgeon operating from a console away from the operating table. Comparison of the performance of robot-assisted and standard laparoscopic surgery revealed the superiority of the former, with shorter suturing and clamping times. Only one comparative study of TLAS and robot-assisted procedures[28] demonstrated advantages in the time taken to complete the aortic anastomosis, 40.8 ± 4.1 minutes for robot-assisted procedures versus 52.7 ± 9.0 for total laparoscopic procedures ($P < .05$), although the procedure time was increased because of the robot setup time.

PERIOPERATIVE OUTCOMES

Operative Time

Total operative times, excluding robot-assisted aortic laparoscopy, varied widely from 199 minutes to 391 minutes (Table 62.6). HALS had the shortest median operating time but with a wide range of values (149 to 350 minutes).

[a]In the series of Lin,[57] total robotic aortic surgery was performed in three patients with aortoiliac occlusive disease (AOID); robot-assisted with a minilaparotomy was performed in all patients with abdominal aortic aneurysms and in nine remaining patients with AOID.
Eleven studies (525 patients) of robot-assisted laparoscopic aortic surgery.
Operative time, clamping time of the aorta, and length of stay in the hospital are presented as median values. *NR*, Value not reported.

TABLE 62.6 Main Data for Eligible Series of Laparoscopic Aortic Surgery

	TLAS (AIOD)	TLAS (AAA)	HALS (AIOD)	HALS (AAA)	ROBOT (AIOD)	ROBOT (AAA)
Patients	932	410	211	649	421	94
Operative time (min)	(199-390)	(210-391)	(149-350)	(175-330)	(188-405)	(215-396)
Clamping time (min)	(45-99)	(75-146)	(28-54)	(25-112)	(37-111)	(76-96)
Hospital stay (days)	(4-8)	(5-13)	(4-8)	(4-7)	(4-8)	(5-7)
Conversion	85 (9.1%)	35 (8.5%)	10 (4.7%)	17 (2.6%)	12 (2.8%)	12 (12.7%)
Death	18 (1.9%)	14 (3.4%)	6 (2.8%)	9 (1.4%)	2 (0.4%)	1 (1.1%)

Operative time, clamping time (aortic), and length of stay in the hospital are presented in each category as median values of the series with the shorter and the longer time periods.
AAA, Aortic abdominal aneurysm; *AIOD*, aortoiliac occlusive disease; *HALS*, hand or minilaparotomy-assisted laparoscopic aortic surgery; *ROBOT*, robot-assisted laparoscopic aortic surgery; *TLAS*, total laparoscopic aortic surgery.

Clamping Time

Aortic clamping extended from 28 minutes with HALS for AIOD to 146 minutes with TLAS for AAA, with a wide range of values for the same pathology and also for the same technique within different centers (see Table 62.6).

Conversion to Open Surgery

Conversion to open surgical repair with TLAS for AIOD was 9.1% (95% CI, 7.4–11.1) and 8.5% (95% CI, 6.1–11.6) in patients with AAA ($P = .75$). Rate of conversion was significantly higher with TLAS than with HALS or minilaparotomy-assisted laparoscopy for AIOD (9.1% versus 4.7%, $P = .03$) and also for AAA (8.5% versus 2.6%, $P = .001$), respectively. Reasons for conversion were multiple, including calcified aorta, bleeding from the lumbar veins or from the aortic anastomosis, and self-imposed operative time or aortic-clamping time limits.[30,32,35]

A significant number of specific complications occurred during laparoscopic aortic procedures, including bleeding lumbar veins that quickly retract behind the spine, retroperitoneal hematoma due to extended laparoscopic dissection, ureteral lesion in relation to dissection, and acute occlusion of the prosthetic graft in some patients due to a long aortic clamping time or inadequate tunneling of the graft.

Mortality

The 30-day postoperative mortality rate was 1.8 % (95% CI, 1.4-2.4) for the whole series ($n = 2717$). Postoperative mortality

among patients with an AAA treated by TLAS (3.4%, 95% CI, 2.1-5.3) was significantly higher than that of patients treated by HALS (1.4%, 95% CI, 0.7-2.6, $P = .03$).

Morbidity

Hemorrhage ($n = 34$) and transient renal insufficiency ($n = 27$) were the most frequently reported operative and postoperative complications occurring during the first 30 days after the procedure. Other complications were lower limb ischemia ($n = 13$), ischemic colitis ($n = 7$), thrombosis of the prosthesis ($n = 12$), and myocardial infarction ($n = 14$). These complications occurred more often after TLAS for AAA. However, many of the studies do not define their complications, and these data should be viewed with caution.

Hospital Stay

In all 48 studies, median hospital stay varied from 4 to 13 days regardless of the laparoscopic technique used (see Table 62.6).

SUMMARY

Almost all surgical specialties— gastrointestinal surgery, gynecology, and urology— incorporated laparoscopic techniques many years ago. Although several studies have demonstrated the feasibility of laparoscopy in aortic surgery,[4,33,59] vascular surgeons have been slow to adopt laparoscopic aortic techniques. One of the reasons is that the best way to begin doing laparoscopic aortic surgery is in dealing with aortic occlusive disease. However, even for common iliac artery occlusion, traditional bypasses have been replaced by stenting with a low morbidity and excellent results. Therefore aortoiliac bypasses are now reserved for complex aortoiliac occlusion or endovascular failure. This reduces the case load and increases the technical challenge of laparoscopic procedures.

The basic concept of laparoscopic aortic surgery is to combine the excellent and durable results observed after conventional open arterial repair with the advantages of a less invasive laparoscopic approach. For most authors, initial laparoscopic procedures were performed with HALS or with the assistance of a minilaparotomy through which the aortic anastomosis was performed under direct vision. Following this initial experience, some authors have developed total laparoscopic aortic procedures to enhance the major advantage of minimally invasive surgery with easier and faster recovery.

After the pioneering efforts of Dion et al.,[27,60] the key to total laparoscopic technique for aortoiliac disease was presented by Coggia et al.[8] who described the transperitoneal left retrocolic approach of the abdominal aorta. This technique with a patient in the right lateral decubitus position provides a large work space, allowing dissection of the abdominal aorta and completion of the aortic anastomosis.

Total laparoscopic bypass is safely performed by a few centers of expertise for complex AIOD or infrarenal aortic aneurysm.[61] Despite these encouraging results, the importance of prior training to obtain the required level of expertise to perform laparoscopic aortic anastomoses has been emphasized,[35,46] with the option of assisted laparoscopy to lessen the risk of totally laparoscopic aortic anastomosis.[45,46,51] Because of these technical challenges and the associated steep learning curve, no large randomized controlled trials have been done so far to prove the benefit of laparoscopic aortic surgery as compared with open or endovascular techniques. We observed in these series a trend toward decreased pulmonary complications as compared with open surgery; this could be related to avoidance of large abdominal incision and reduced pain. However, data from these series showed that even for well-trained surgeons, operative time and aortic clamping time were longer than usually observed during open aortic surgery. Specific operative difficulties were observed particularly with TLAS in treating aortic aneurysmal disease, leading to a high rate of conversion not seen with HALS or other laparoscopy-assisted techniques (see Table 62.6). Among all series, median blood loss was comparable to outcomes reported for open aortic surgery. Extreme blood loss was observed in some patients with AAA or with AIOD and a severely calcified aorta. Infrarenal circumferential aortic calcifications are not a contraindication for TLAS if suprarenal clamping is possible through a left transperitoneal retrorenal approach.

Concerning AAA repair, one small randomized trial with a 12-month follow-up[54] concluded that HALS could be a less invasive alternative for sexually active males who are unsuitable for EVAR. Coggia et al.[5] reported a prospective cohort study of 148 patients undergoing TLAS for juxtarenal AAA repair with no mortality and low morbidity. However, limitations of this study included strict patient selection before TLAS was considered; therefore, it may not be truly applicable to the general population. Ricco et al.[44] published the results of a cohort of 228 consecutive cases using propensity score matching to compare the outcomes after open and TLAS for aortic surgery through a composite primary end point of pertinent adverse events (AEs). Logistic regression analysis of the groups adjusted for propensity score showed that only two variables, TLAS (OR 4.50; $P = .01$) and coronary artery disease (OR 4.67; $P = .02$) were independently related to the occurrence of an AE during the postoperative period. In this study, the occurrence of AEs during follow-up was analyzed using the Cox model and TLAS (HR 4.40; $P = .02$) and coronary artery disease (HR 2.70; $P = .02$) were independently associated with the occurrence of an AE during follow-up. In this series, the small number of patients prevented a separate analysis with regard to AAA and AIOD. This study suggests that even with a well-trained team, TLAS increases the risk of AEs observed in the course of aortic surgery.

To overcome these technical difficulties, robotic systems have been recommended to facilitate advanced laparoscopic techniques, such as suturing, knot-tying, and the performance of aortic anastomoses. Laparoscopy creates a closed space in two-dimensional vision with a dissociation between eye-hand coordination; the robotic technology can compensate for these restrictions. We have identified eight studies of robot-assisted laparoscopic aortic surgery (see Table 62.6). The conversion rate ranged from 2.8% for AIOD to 12.7% for AAA with technical problems related to the robotic system and bleeding

from the lumbar arteries. Despite these limitations, robotic assistance goes beyond the making of aortic anastomoses; robotic techniques allow greater visualization and facilitate aortic dissection. There are several limitations to robotics in laparoscopic aortic surgery, the most obvious being the high cost of the system. In addition, the setup of the system may be time-consuming before the staff is fully trained. The robotic learning curve seems to be quicker and easier than that of laparoscopic surgery for developing the technical skills needed to perform an aortic anastomoses.[62] In addition, the postoperative length of stay ranges from 4 to 13 days in most series, with the majority being 6 days or greater, which is comparable to that with open aortic surgery and much longer than that with any endovascular procedure. Furthermore, endovascular procedures can be performed under regional or even local anesthesia, whereas the laparoscopic and robot-assisted procedures require general anesthesia. Therefore the development of robot-assisted aortic laparoscopy has not yet been widely adopted and experience is restricted to only a few centers worldwide.

CONCLUSIONS

Our review shows that laparoscopic aortic surgery can be performed safely with low mortality and morbidity provided that patient selection is adjusted to experience and conversion liberally performed. The future of this technique is still unknown; it is now time for multicenter randomized trials to demonstrate the potential benefit of laparoscopic aortic surgery for aortic occlusive and aneurysmal disease not amenable to an endovascular treatment.

Coggia M, Javerliat I, Di Centa I, et al. Total laparoscopic bypass for aortoiliac occlusive lesions: 93-case experience. *J Vasc Surg*. 2004;40(5):899–906.

The authors describe a new technique of total laparoscopic bypass surgery to treat aortoiliac occlusive lesions with 93 total laparoscopic bypass procedures for TASC grade C or D aortoiliac occlusive lesions. The authors used a transperitoneal left retrocolic or retrorenal approach to the infrarenal abdominal aorta. Median operative time was 240 minutes (range, 150-450 minutes). Median aortic clamping time measured to unclamping of the first prosthetic limb was 67.5 minutes (range, 30-135 minutes). Median hospital stay was 7 days (range, 2-57 days). The authors demonstrated the feasibility of total laparoscopic aortic bypass in patients with TASC C and D aortoiliac occlusive lesions.

Dion YM, Katkhouda N, Rouleau C, Aucoin A. Laparoscopy-assisted aortobifemoral bypass. *Surg Laparosc Endosc*. 1993;3(5):425–429.

A seminal paper. The authors described the first case of laparoscopy-assisted aortobifemoral bypass. The patient's postoperative period was uncomplicated; the patient had minimal pain that allowed for a quick return to ambulation. This procedure appeared to be of interest for some patients with aortoiliac disease.

Lecot F, Sabbe T, Houthoofd S, Daenens K, Fourneau I. Long-term results of totally laparoscopic aortobifemoral bypass. *Eur J Vasc Endovasc Surg*. Elsevier Ltd; 2016;52(5):581–587.

Other papers have described safety and short-term outcomes of totally laparoscopic aortofemoral bypass, but this study estimates the long-term patency of this procedure for the first time. An estimate of long-term patency is a crucial parameter for weighing options for treatment of severe aortoiliac occlusive disease.

Lucereau B, Thaveau F, Lejay A, et al. Learning curve of robotic-assisted anastomosis: shorter than the laparoscopic technique? An educational study. *Ann Vasc Surg*. 2016;33:39–44.

The da Vinci robot could theoretically minimize the technical challenge of laparoscopic surgery. The aim of this study was to compare the learning curves of performing vascular anastomoses on an expanded polytetrafluoroethylene (ePTFE) abdominal aortic graft as model by trainees with no experience in using laparoscopic versus robotic techniques. The trainees were randomly assigned to the laparoscopic or robotic groups. Minimally invasive laparoscopic technique training demonstrates a learning curve to perform vascular anastomoses. The robotic learning curve seems to be quicker than that of laparoscopic surgery. The robot allowed faster, more accurate, and easier learning of technical skills on the first anastomoses. The authors conclude that robotics may offer the opportunity for surgeons to more easily acquire skills to perform laparoscopic aortic anastomosis and may provide better reproducibility.

Nio D, Diks J, Bemelman WA, Wisselink W, Legemate DA. Laparoscopic vascular surgery: a systematic review. *Eur J Vasc Endovasc Surg*. 2007;33(3):263–271.

The objective of this early systematic review was to evaluate the results of clinical studies on laparoscopic surgery for aortoiliac disease. Thirty studies were identified. These were all descriptive and included nine comparative studies. Operative times varied widely, the shortest being for hand-assisted procedures and the longest for totally laparoscopic procedures.

The conversion rate varied from less than 5% up to 16% in smaller series. The mortality rate was approximately 5%.

This systematic review has shown that the observational, noncomparative character and selection bias of most published series are their major limitations. More data are required to define the value of laparoscopic vascular surgery in comparison with endovascular and open surgery.

Ricco JB, Cau J, Biancari F, et al. Outcome after open and laparoscopic aortic surgery in matched cohorts using propensity score matching. *Eur J Vasc Endovasc Surg*. Elsevier; 2016;52(2):179–188.

This propensity score-matched cohort suggests that even in a well-trained laparoscopic surgical group, a total laparoscopic approach increases the risk of adverse events observed in the course of aortic surgery. This negative result contrasts with those reported in most observational studies, probably because the propensity score avoids the heterogeneity of the previous studies published on this subject and limits the confounding and selection biases.

Stádler P, Dvorácek L, Vitásek P, Matous P. Robot assisted aortic and non-aortic vascular operations. *Eur J Vasc Endovasc Surg*. Elsevier; 2016;52(1):22–28.

This study evaluates the results of a large experience with 310 robot-assisted vascular procedures. The authors demonstrate that robotic systems provide a real opportunity for minimally invasive surgery in the field of vascular surgery. The authors have shown that robotic systems remove fundamental disadvantages of laparoscopy and suggest the possibility of expanding robot-assisted laparoscopic surgery in this area.

Despite ongoing attempts to develop prosthetic or bioengineered materials for bypass grafting in the lower extremities, autologous vein graft remains the conduit of choice for infrainguinal revascularization. Though it was sporadically used for repair of popliteal aneurysms in the early 20th century, the first report of the routine use of autogenous vein for the treatment of occlusive arterial disease was provided in 1944 by Dos Santos, who used segments of vein as patch material after superficial femoral artery endarterectomy.[1] This was followed several years later by the report of Kunlin, who described the use of reversed saphenous vein grafts for the treatment of focal lesions within the superficial femoral artery.[2] Based on these initial reports, expanded use of the saphenous vein for both endarterectomy and grafting was attempted, but creation of the anastomoses with the standard surgical techniques of the day proved difficult. With long-term patency negatively influenced by a high rate of anastomotic stricture and an inability to replicate the promising results of Kunlin, the majority of practitioners in the 1940s and 1950s used arterial homografts or the newly developed prosthetic grafts for infrainguinal arterial reconstruction. Reinvigorating the use of autogenous vein, however, was a small group of surgeons who traveled to Europe to observe Kunlin's vein grafting procedures.[3] Characterized by a spatulated end-to-side anastomosis using a small-caliber running silk suture, these meticulous techniques

Abstract

Autogenous vein remains the conduit of choice for bypass grafting, with great saphenous vein proving to be the most durable. Alternate conduits, such as arm vein, femoral vein, or small saphenous vein are viable options, but are notably compromised. Significant effort has been expended in trying to optimize the technique and conditions of vein harvest, with a use of a gentle-touch technique, storage in isotonic buffered crystalloid, and avoidance of over-distention emerging as the most important aspects of this procedure. Placement of the graft in a reversed, non-reversed, or in situ configuration are all viable options, with no clear patency benefit among these options. Angiography, duplex scanning, and angioscopy are the most widely used intra-operative techniques to evaluate for technical issues prior to completing the procedure. Post-operatively, duplex scanning is widely accepted as the test for of choice to identify the failing vein graft, although definitive clinical evidence to support this practice is lacking.

allowed Linton, Darling, and others to duplicate the reported success with autogenous vein grafting.[4]

In the 1960s, wider interest in the use of autogenous vein was fueled by the observation that acceptable long-term patency of prosthetic bypass grafts could be achieved only with distal anastomoses placed in the above-knee position.[5] Treatment of critical limb ischemia in patients with compromised outflow via femorotibial bypass was a natural extension for autogenous vein grafting, with the first published report by Dale in 1963.[6] Although initial published reports of the use of saphenous vein for tibial bypass grafts suggested it to be notably inferior to femoropopliteal grafts,[7,8] further refinements in the techniques have proved the durability of tibial as well as inframalleolar bypass grafting with autologous vein.[9] Along with these technical improvements in the 1980s came increasing experience with alternative autogenous vein sources (i.e., arm, small saphenous, and femoral veins),[10] thereby expanding the potential for autogenous tissue reconstruction to 95% of patients undergoing infrainguinal bypass.[11]

HISTOLOGY

Analogous to other vascular structures, veins are composed of three layers—the tunicae intima, media, and adventitia (Fig. 63.1). The intima consists of a continuous monolayer of cuboidal endothelial cells supported by a subendothelial layer of loose connective tissue. In contrast to the arterial endothelium, where cells are tightly packed and highly aligned in the direction of flow, venous endothelial cells are cuboidal with poorly developed interendothelial tight junctions.[12,13] The resulting enhanced permeability to blood solutes, in conjunction with the underlying physiologic differences between arterial and venous endothelium, is thought to be among the underlying mechanisms for the accelerated intimal hyperplasia characteristic of vein grafts.[14] The intima is separated from the media by a poorly developed internal elastic lamina with large fenestrae that allow diffusion of substances into the wall. The media is composed of vascular smooth muscle cells and extracellular matrix, with type I collagen being the dominant component of this layer. Unlike arteries, which function in a pulsatile pressure environment and correspondingly have high elastin content, veins are exposed to small excursions in pressure and demonstrate only sparse elastin fragments. Transposition of a vein into the arterial circulation induces a marked increase in intraluminal wall tension that greatly exceeds the dynamic range of the elastic elements and therefore leads to a rigid graft with substantial compliance mismatch in comparison to the adjacent artery.[15]

External to a poorly developed external elastic lamina is the adventitia, a loose connection of extracellular matrix with a sparse vasa vasorum. Though traditionally thought to have limited influence on biologic function of the vein, evolving evidence suggests that remodeling of an implanted vein graft is very much dependent on adaptation within the adventitia. Recruitment of myofibroblasts, production of cytokines, and the influx of inflammatory cells into the adventitia are thought to have an important influence on the biology of the early vein graft.

Superficial extremity veins are prone to the development of a range of pathologies such as varicose degeneration, thrombosis with luminal recanalization, and phlebitis with intramural calcification. Limitations in available autogenous conduit frequently require these "compromised" vein segments to be included as a conduit in a revascularization procedure. Histologic evaluation of harvested vein segments, coupled with long-term clinical follow-up, has demonstrated that grafts with low endothelial cell coverage, stenosis of the lumen, and thick walls are at an increased risk for early graft failure.[16] Grafts with subendothelial spindle-shaped cells, which demonstrate a proliferative smooth muscle phenotype on electron microscopic examination, and calcification within the wall at the time of graft implantation are notably prone to the development of aggressive hyperplastic lesions.[17] Unfortunately, preoperative ultrasound is unable to reliably identify many of these abnormalities.[18]

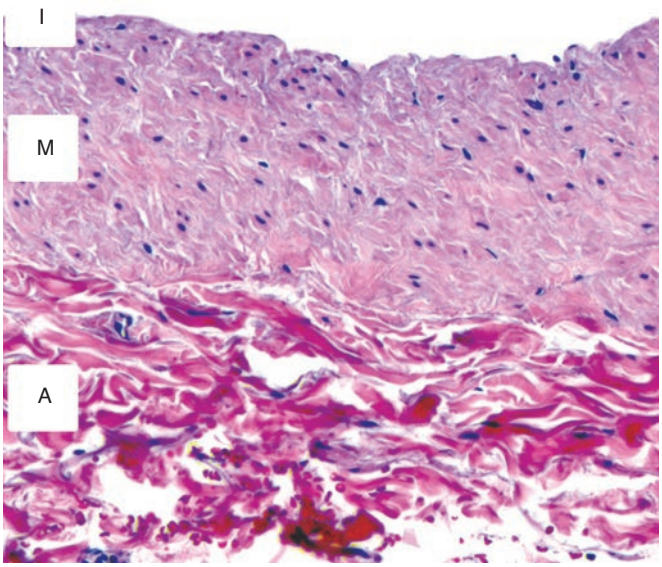

Figure 63.1 Cross-sectional histology of the normal saphenous vein. The intima *(I)* is composed of a single layer of endothelial cells and a thin basement membrane. The media *(M)* consists of smooth muscle cells surrounded by a tightly packed extracellular matrix. The adventitia *(A)* is a loose network of collagen-dominated extracellular matrix with sporadic inflammatory cells and fibroblasts.

ANATOMY

Lower Extremity Veins

The veins of the lower extremities are classified into three general groups: the deep, superficial, and perforating systems. The deep veins are encompassed by thick fascia and are contained within the muscular compartment of the leg. Superficial veins are bounded deeply by the muscular fascia and superficially by the dermis. Short veins piercing through the fascia and running between the superficial and deep systems are the perforating veins. Increasing interest in accurate description of the venous structures in the leg and confusion between the clinical and anatomic terminology used in naming them have prompted a review and standardization of the nomenclature. The following

descriptions are based on this consensus terminology,[19,20] with reference to the older nomenclature as appropriate.

The *great saphenous vein* (formerly called the greater or long saphenous vein) begins just anterior to the medial malleolus, crosses the tibia, traverses medial to the knee, and ascends in the medial-posterior aspect of the thigh to the groin. Duplicated systems within the great saphenous vein are relatively common and occur at a 25% and 8% incidence in the calf and thigh, respectively.[21] The *accessory great saphenous veins* run parallel to the main trunk within the thigh and leg, in an anterior or posterior location. Although these veins are at times mistaken for the great saphenous vein during surgical exposure, they are usually of inadequate diameter for use in bypass grafting. The saphenous veins, but not their tributaries, are covered by a fibrous sheath termed the *saphenous fascia*. Less well developed than the deep fascia, this fascia, in combination with the deeper muscular fascia, forms a subcompartment that extends along the length of the lower extremity. Recognition of this fascia can be useful in localizing the great saphenous vein during surgical dissection. In the proximal portion of the thigh, the great saphenous vein receives one or two large tributaries from the anterior or posterior accessory great saphenous vein (or both) and enters the fossa ovalis approximately 4 cm inferior and lateral to the pubic tubercle, where it joins with the superficial circumflex iliac, superficial epigastric, and external pudendal veins to create the *confluence of superficial inguinal veins* (formerly called the saphenofemoral junction) on the anterior surface of the *common femoral vein*.

The *small saphenous vein* (formerly called the lesser or short saphenous vein) ascends lateral to the Achilles tendon in the calf. It runs in the subcutaneous adipose tissue in the lower two-thirds of the calf, pierces the muscular fascia, and courses between the medial and lateral heads of the gastrocnemius. The small saphenous vein usually joins the popliteal vein in the popliteal fossa about 5 cm proximal to the knee crease. Rarely, the small saphenous vein ends high, either emptying into the femoral vein or running superficially to the posteromedial aspect of the thigh to join the great saphenous vein.

Particularly useful in arterial reconstructions within infected fields, the *femoral vein* (formerly called the superficial femoral vein) has increasingly become a potential source of autogenous conduit. The femoral vein originates from the popliteal vein at the upper margin of the popliteal fossa and courses in the femoral canal. The femoral vein is lateral to the femoral artery in the distal part of the thigh but crosses under and runs medial to the femoral artery in the proximal portion of the leg before joining the *deep femoral (profunda femoris) veins* approximately 9 cm below the inguinal ligament. During the harvest of the femoral-popliteal vein segment for use as an autogenous graft, preservation of the junction of the profunda femoris vein with the common femoral vein is critical for maintaining adequate venous outflow from the limb.[22,23]

Upper Extremity Veins

Veins of the upper extremity are also divided into superficial and deep groups, although direction of flow from superficial to deep is not as distinct as in the lower extremity. The *cephalic vein*, which originates on the posterolateral aspect of the wrist, gradually swings across the lateral portion of the forearm, ascends lateral to the biceps muscle into the deltopectoral groove, and passes through the clavipectoral fascia to join the axillary vein. The *basilic vein* swings across the posteromedial side of the forearm, passes lateral to the antecubital fossa, and ascends medially in the arm, where it joins the *brachial veins* to become the *axillary vein*. The *median cubital vein* starts at the apex of the antecubital fossa as a branch of the cephalic vein and ascends medially to enter the basilic vein.

Approximately 10 cm proximal to the antecubital fossa, the basilic vein passes through the deep fascia to reside along the medial side of the brachial artery. Harvest of the basilic vein proximal to this location requires longitudinal division of this fascia and ligation of multiple communicating branches coursing between the basilic and brachial veins. During this portion of the dissection, the medial cutaneous nerve of the forearm is often first identified as it travels anterior to the basilic vein. Injury to this nerve can lead to paresthesias along the medial portion of the forearm.

VEIN GRAFT PREPARATION

Preoperative Vein Mapping

As surgeons have increased the complexity of lower extremity reconstruction and become more aggressive with repeat revascularization after graft failure, assessment of available autogenous conduit has evolved into an essential component of preoperative planning. Initial attempts to evaluate available conduit centered around the use of routine preoperative saphenous venography, with information obtained from these studies influencing the operative approach in up to 30% of patients.[24] Although useful in defining the anatomy and dimensions of the greater saphenous system, broad application of this technique was limited by its requirement for percutaneous access, frequent underestimation of conduit diameter, and the small but worrisome risks of nephrotoxicity or chemically induced thrombophlebitis.

With refinements in ultrasound instrumentation and the increasing availability of skilled technologists, investigations into the merits of B-mode imaging for preoperative conduit evaluation were initiated.[25-28] By providing the ability to determine vein size and quality in a physiologic environment and facilitate operative exposure, duplex vein mapping generated significant enthusiasm. Early reports were mixed, however, with concern that duplicate saphenous systems were frequently not identified and diameters measured on B-mode imaging were not representative of in vivo graft geometries.[25] Although the former issue has essentially been solved by increased experience of vascular technologists and an understanding of anatomic variants, difficulties with direct correlation of preoperative mapping and graft size remain. Among the important issues in minimizing this variability is the development of a standard preoperative evaluation protocol.

Warming the examination room, placing warmed blankets on the extremities, and using prewarmed ultrasonic gel

minimize peripheral venous vasoconstriction. Imaging with a high-frequency probe (≥8 MHz) provides maximum resolution with 0.3-mm point-to-point discrimination. Veins are assessed in cross-section to evaluate compressibility, wall thickening, and the presence of intraluminal echoes, and sites of thrombus, intraluminal webs, and sclerotic walls are noted. Vein wall abnormalities have been described in 12% of potential conduits, with preoperative duplex evaluation correctly identifying 62% of these diseased segments.[29] To assess the great saphenous vein, patients are placed in a modified reversed Trendelenburg position and images collected for measurement of lumen diameter at six locations along the length of the limb. Evaluation of the small saphenous vein is performed with the patient in a prone position and the diameter measured at three locations within the calf. If either of the saphenous veins is of good quality but inadequate size, the patient is placed in a standing position and diameter measurements are repeated. Alternatively, a tourniquet may be placed on the proximal part of the thigh to facilitate this reassessment. For segments identified to be of adequate size and quality for bypass grafting, the overlying skin is marked with indelible ink. Routine evaluation of the femoral vein may also be warranted, depending on local clinical practice. In addition to lumen diameter, examination should include a thorough assessment for deep venous thrombosis and valvular incompetence. Use of standardized reference zones facilitates the reporting of relevant information, with zones 2, 3, and 4 corresponding to the proximal, middle, and distal portions of the thigh and zones 5, 6, and 7 corresponding to the proximal, middle, and distal portions of the calf, respectively.[30] Evaluation of the upper extremity cephalic and basilic veins should follow a similar protocol. An upper arm tourniquet may be used selectively or routinely to facilitate these measurements. Reference zones have also been established for the upper extremity, where zones 3, 4, and 5 correspond to the proximal, middle, and distal portions of the arm and zones 6, 7, and 8 correspond to the proximal, middle, and distal portions of the forearm, respectively.[30] Measurements of upper extremity vein diameter seem even more variable than those of the lower extremity. Although the underlying etiology is open to speculation, this variability should be recognized, and repeat testing of borderline upper extremity veins may prove valuable in preoperative planning.

Despite multiple attempts to define acceptable conduit size, no clear consensus has emerged. Smaller-diameter veins have repeatedly been shown to negatively influence long-term patency,[31,32] and a minimum suitable diameter ranging between 2.0 and 3.0 mm has been proposed.[33] Among the confounding issues is the variable effect of the mapping technique on approaching an accurate in vivo graft diameter. These variations are nonlinear and in part dependent on the initial size of the conduit; whereas a 2.5-mm vein increases 27% in diameter when placed in the arterial circulation, a 6-mm vein increases only 8%.[27] In the absence of a universally accepted vein mapping protocol, absolute delineation of a minimum acceptable vein size is problematic, and development of size criteria within an institutional practice is most appropriate.

Vein Handling Considerations

Research over the last decade has uncovered the importance of the endothelium in vascular injury and repair. Previously thought to be a passive monolayer with predominantly barrier functions, endothelial cells have been identified as central mediators in the maintenance of vascular homeostasis. Advanced by the work of Ross and his development of the response-to-injury hypothesis,[34-36] loss of endothelial integrity induces platelet deposition and elaboration of growth factors. Coupled with recruitment of inflammatory mediators, these growth factors stimulate smooth muscle proliferation and matrix deposition, which lead to the formation of an occlusive arterial lesion. Analogous mechanisms are thought to be fundamental in the pathologic remodeling of vein grafts, with early endothelial injury among the initiating events in the development of intimal hyperplasia.[37] Accordingly, maintenance of an intact endothelial monolayer during vein graft harvest is thought to provide improved long-term patency of autogenous vein grafts. Work by LoGerfo[38] and others[39] in a canine model supports this contention by demonstrating that smooth muscle cells are maintained in a contractile (nonproliferative) phenotype and that leukocyte infiltration is reduced when endothelial injury is avoided. Analogous work by Conte's group confirmed that the surgical manipulation of human vein segments results in a significant increase in monocyte adhesion.[40] However, direct evidence linking improved endothelial integrity to a reduction in intimal hyperplasia, enhanced outward remodeling, or improved patency is lacking. Nonetheless, significant indirect evidence supports the concept that endothelial preservation minimizes the early biologic perturbations within vein grafts, and therefore harvest techniques aimed at reducing endothelial dysfunction seem reasonable.

Dissection

Precise, atraumatic dissection and minimal direct manipulation of the vein via a "no-touch" technique have been demonstrated to reduce endothelial damage during harvest (Fig. 63.2).[41-44] Though somewhat a misnomer, the "no-touch" technique involves limited handling of the vein without direct application of forceps or vascular clamps. Major branches are ligated away from the wall to avoid narrowing of the lumen and promote outward remodeling after implantation. Opinions regarding the importance of maintaining continuity of the vein during dissection versus early ligation for intermittent infusion of isotonic fluids are mixed. Despite not being studied in a directed manner, continued continuity of vein has been shown to reduce the formation of small thrombi on the wall, and cannulation and division of the distal vein promote the direct application of antithrombotic and smooth muscle relaxants directly into the lumen. Although limited vein graft handling is universally considered an important component of promoting both short- and long-term graft patency, this concept is challenged by the nearly identical clinical outcomes for reversed, nonreversed, and in situ vein grafting techniques.[45,46] If limiting vein manipulation is a dominant factor, one might intuitively expect improved outcomes with in situ grafting, where direct vein manipulation can be essentially eliminated, and compromised outcomes with

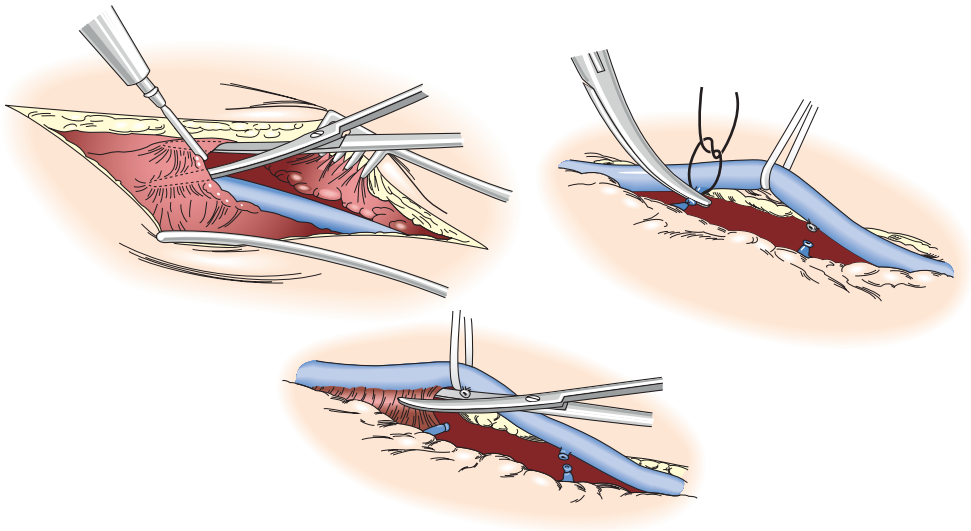

Figure 63.2 "No-touch" technique used in the harvest of autogenous vein. To minimize spasm, papaverine (120 mg/L) is injected into the periadventitial plane before surgical exposure. Side branches are identified and ligated several millimeters away from the wall to prevent luminal narrowing after implantation and outward remodeling of the vein graft. Using a Silastic vessel loop to control the vein without direct manipulation with surgical instruments, the periadventitial tissues are divided and the vein is excised.

nonreversed/excised grafts, which require complete mobilization with valvulotomy. The absence of such differences suggests that careful dissection of the vein is prudent, but absent extensive injury, it is of only modest importance to final outcomes.

Though not examined in the setting of peripheral vein grafts, saphenous vein encased by a thick pedicle of surrounding adipose tissue has been used for coronary bypass grafting with promising results. Morphologic and physiologic studies have confirmed reduced endothelial injury and increased expression of endothelial nitric oxide synthase when compared with the standard technique for vein harvest.[47,48] Prospective randomized clinical testing has demonstrated improved short- and long-term patency with use of the pedicle harvest technique, with 90% versus 76% patency rates at 8.5 years for pedicle versus standard grafts.[49,50] Although this technique may not be applicable to the long-segment grafts required for lower extremity revascularization, it is interesting to speculate on the underlying mechanisms for these improved outcomes, which could include decreased endothelial injury, maintenance of an intact vasa vasorum, or the potential delivery of biologic mediators from the surrounding periadventitial tissue.

Distention Pressure

Cannulation of the vein is required before implantation to evaluate the potential diameter of the graft, assess for leaks, and identify adventitial bands compromising the lumen. Use of a standard small-volume syringe can produce intraluminal pressure in excess of 700 mm Hg.[51] A number of investigations have examined the effect of distention pressure on endothelial integrity and almost uniformly have observed that pressure in excess of 100 mm Hg causes patchy endothelial denudation and that pressure in excess of 500 mm Hg leads to disruption of the underlying media.[52-54] The intrinsic biomechanical properties of the graft are negatively impacted, with a resultant decrease in wall compliance secondary to disruption of the elastic elements within the wall.[55] Biologic function is also influenced, with distention injury initiating an increase in *c-fos* expression, an upstream regulator of platelet-derived growth factor production.[56] Among the few studies to contradict this observation is the work of LoGerfo et al.,[54] who observed no significant injury up to a distention pressure of 500 mm Hg and speculated that their aggressive use of papaverine prevented vasospasm and minimized the effect of overdistention. Nevertheless, a variety of pressure-sensing devices have been developed to allow the surgeon to monitor or control distention pressure. Ranging from syringes with intrinsic pressure transducers to reservoir inflation bulbs that generate a fixed pressure, these devices have undergone only sporadic testing and have never been accepted into widespread clinical use.

Irrigating Solution

An array of irrigating solutions ranging from crystalloids to colloids to autogenous blood has been used during vein harvest. Among the first and still the mostly widely used solutions are the isotonic crystalloids normal saline (pH 5.5, 308 mOsm), lactated Ringer's (pH 6.5, 273 mOsm), and Plasma-Lyte (pH 7.4, 292 mOsm). Although the extent of injury and the magnitude of biochemical perturbations with these solutions are variable and depend on confounding variables such as temperature and the use of pharmacologic adjuncts, the bulk of the literature would suggest that unbuffered, isotonic crystalloid solutions are most damaging to the endothelium.[39,42,51,57] Simple buffered and modified crystalloid solutions (such as tissue culture and whole-organ preservation media) have been investigated and have demonstrated reductions in endothelial denudation and improvements in both cell viability and contractility when compared with an unbuffered saline perfusate.[54,58-61] While buffered crystalloid solutions (e.g., Plasma-Lyte) are readily accessible, the expense and limited availability of complex, modified solutions have limited their widespread adoption into clinical practice. The available literature regarding the efficacy of autologous blood is conflicting. Despite some concern for fibrin deposition, predominantly at higher temperatures, storage in heparinized autologous blood is among the best options for maintaining endothelial confluence.[39,42,51] Published reports, however, are not unanimous, with several suggesting equivalent results when using standard crystalloid solutions with pharmacologic

adjuncts.[60,62] Coupled with more recent studies that demonstrate reduced smooth muscle cell injury and enhanced endothelial relaxation when comparing normal saline against autogenous blood, buffered crystalloid has emerged as the best option for short-term storage of excised vein.[63]

Temperature

Focusing on maintaining endothelial integrity, LoGerfo et al. put forward the concept that warmer perfusate temperatures during active dissection would prevent vasospasm, whereas storage of the graft and minimization of metabolic insult would be best accomplished at a much cooler temperature.[54] Supporting this hypothesis, they demonstrated that infusion of 37°C perfusate during active vein harvest and storage of the distended vein at 4°C minimized the extent of endothelial damage. Notably the influence of this dual-temperature approach was most prominent in saline-treated grafts. Subsequent investigations using a single-temperature approach also favored perfusion with a 4°C irrigation solution,[39,54,57] with blood preferred over saline because of the mural edema associated with cold saline infusion.[42]

Although initial studies focused on endothelial morphology as the primary endpoint, further work in the field diversified to examine the effect of solution temperature on biologic activity of the vein graft wall. Nitric oxide–mediated vasodilation is greatly impaired after storage at 4°C, with room-temperature blood and Plasma-Lyte demonstrating little deterioration when compared with control veins tested immediately after harvest.[64] Analogous studies examining endothelial prostacyclin production and functional thrombomodulin activity support the use of room-temperature perfusates as the best option for preserving metabolic activity.[65,66]

With conflicting experimental evidence, delineation of the most favorable storage temperature is difficult, and reasonable arguments for either cold- or room-temperature treatments can be crafted. Although no definitive recommendation can be proposed, the increased effort required to supply and maintain cold perfusate in the operating suite has prompted most clinicians to favor the use of room-temperature solutions.

Pharmacologic Adjuncts

Unfractionated heparin has universally been included in most vein harvest solutions. Aimed at reducing fibrin deposition and the formation of microthrombi, doses ranging from 4 to 10 U/mL are typically used.[39,57,67]

Prevention of vasospasm is widely identified as being critical in maintaining an intact endothelium, and the use of pharmacologic agents to facilitate this goal may be the most important component of the vein harvest regimen. The most widely studied vasodilator for this purpose is papaverine. Although its exact mechanism of action is unclear, papaverine appears to induce smooth muscle cell relaxation through inhibition of phosphodiesterase and an increase in intracellular cyclic adenosine monophosphate levels. Percutaneous injection of papaverine (120 mg/L) along the outside of the vein before skin incision has been described as an important step to minimize spasm,[67,68] although this can prove challenging in all but the thinnest patients. Application of papaverine along periadventitial tissues and within the lumen perfusate is more easily accomplished and continued throughout vein harvest. Though not rigorously studied as an independent variable, most regimens containing papaverine have shown reduced endothelial injury in comparison to controls.[39,54,57,62]

Other vasodilators have been examined, and a combination of glyceryl trinitrate (8.3 mg/L) and verapamil (16.7 mg/L) appears to be particularly beneficial.[69] In direct comparison to papaverine, glyceryl trinitrate/verapamil demonstrated notable improvement in endothelial coverage.

Even though extensive research has been conducted in this area, no consensus has been reached regarding the optimal techniques for vein graft harvest, with each variable demonstrating unique advantages and shortcomings. Box 63.1 provides a practical summary protocol for the preparation of autogenous vein conduit. The relative importance of these variables is in part illustrated by the work of Adcock et al., who examined the combined benefits of papaverine, autologous blood, and limited pressurization in maintaining endothelial integrity.[39] Even though this combined regimen achieved a significant reduction in endothelial loss at the time of implantation, 71% of the endothelial cells exhibited morphologic abnormalities by the second postoperative day (vs. 92% for the "standard" regimen). More recent work by Brophy et al. expanded on these observations, identifying the application of blue marker dye to the adventitial surface for the purpose of tracking graft orientation during tunneling, over-distension, and storage in a nonbuffered isotonic crystalloid solution as critical factors that accentuate the hyperplastic response.[59,63,70-73] Avoiding these factors improved vasomotor function and limited the widespread metabolic decompensation associated with vein graft preparation.[58]

Although the majority of published regimens have sought to optimize variables to maintain an intact endothelial monolayer or reduce smooth muscle cell injury at the time of implantation,

BOX 63.1 Recommended Vein Graft Harvest Protocol

Handling

- Precise atraumatic technique
- Ligation of tributaries away from the wall
- Lysis of adventitial bands
- Minimization of time from vein excision to implantation

Solution

- Buffered isotonic crystalloid (e.g., Plasma-Lyte)

Temperature

- No definitive recommendation

Distention

- Maximum pressure of 100-150 mm Hg

Pharmacologic Adjuncts

- Heparin (4000–10,000 U/L)
- Papaverine (120 mg/L) or glyceryl trinitrate (8.3 mg/L)/verapamil (16.7 mg/L)

few reports have challenged their techniques to extended exposure in an in vivo environment. Among the clinical investigations in this area was the PREVENT IV trial, which sought to evaluate the efficacy of an E2F decoy in improving coronary vein graft patency.[74] Within the context of this study, three back table storage solutions (unbuffered saline, buffered saline, and blood) were used in a nonrandomized fashion. Given the caveat of potential confounding covariates, the use of buffered saline (compared with either unbuffered saline or blood) yielded a 30% reduction in the vein graft failure rate at 1 year.

Minimally Invasive Vein Harvest

Among the significant complications associated with a single continuous incision for lower extremity vein harvest are wound infection and dehiscence, observed in up to 40% of patients.[75] Minimally invasive approaches to saphenous vein harvest have been developed to reduce incisional length and diminish the attendant morbidity. Early investigations of this technique were initiated without specialized instrumentation but used a series of small, sequential incisions overlying the vein. The use of such "skip incisions" significantly improved primary wound healing, with wound complications developing in 28% of patients with a continuous incision, as opposed to 9.6% of patients in the "skip incision" group.[76] Over the past 2 decades the concept has evolved with the marriage of endoscopic visualization and specialized instrumentation to facilitate minimally invasive vein harvest. Several different devices have been developed for this purpose, all using three small incisions to access the vein and ligate side branches. Used predominantly for harvesting of vein for coronary bypass surgery, prospective randomized human trials have demonstrated significant reductions in wound morbidity when compared with single-incision saphenectomy.[77-79] Increased manipulation of the vein is inherent with this approach and raises concern about increased endothelial damage and accelerated graft failure. Blinded morphologic examination of harvested human vein specimens[80,81] and clinical outcome studies[79] have demonstrated no significant differences in vein injury or graft patency. Universally noted throughout these reports is the steep learning curve that accompanies endoscopic saphenous vein harvest, with many centers identifying a core group of practitioners who focus on this aspect of the procedure. Although performance of these studies at large-volume medical centers can provide insight into the optimum outcomes with this approach, extrapolation to lower volume centers may not be as promising.

Probably related to the long segments of vein required for lower extremity bypass and the prolonged learning curve inherent in this approach, endoscopic vein harvest for peripheral revascularization has not been uniformly embraced. A small number of centers have championed its use, with mixed results. With no randomized trials comparing single-incision with endoscopic saphenous vein harvest for peripheral bypass, experiences have predominantly been reported through case series with retrospective controls.[82-88] These reports generally support the observations in the cardiac literature and suggest that endoscopic harvest offers reduced wound complications with no notable deterioration in short- and long-term graft patency. Not all reports have been favorable, however, with several investigative teams detailing inferior patency rates with little improvement in wound complications after endoscopic vein harvest.[88,89] Compilation across centers, within the context of the Vascular Quality Initiative database and a meta-analysis of 18 published studies, has underscored this observation, where the primary patency was reduced in patients undergoing endoscopic harvest (vs. either continuous or skip incision techniques) with no associated improvement in the incidence of surgical site infection.[90,91]

Among the important conclusions in these studies is the significant learning curve inherent in this technique, with an estimated 40- to 50-patient experience required to become fully competent in harvesting the more difficult below-knee saphenous vein.[92,93] It is noteworthy that the center reporting inferior results performed an average of only one endoscopic harvest per month, probably an insufficient volume to master this technique. Concerns about increased cost of the procedure secondary to additional equipment expenses are relatively unfounded, with these costs more than offset by decreased length of stay during the primary admission and a reduction in the number of readmissions for wound complications.[86]

AUTOGENOUS VEIN GRAFT CONFIGURATIONS

In the preoperative planning stage before open lower extremity revascularization, the surgeon is faced with a number of variables concerning the suitability of various inflow and outflow arteries and the length and quality of the available conduit. Invariably, because of some discordance among the available options, assessment of the potential risks and benefits for each choice is required. Preoperative arteriography and duplex vein mapping provide the baseline data through which primary and secondary operative plans are developed. Direct operative assessment of the intended proximal and distal anastomotic sites and the quality of the autogenous conduit may initiate reevaluation and modification of the intended plan during the course of the operation. A summary of the various factors that influence this decision is provided in Table 63.1.

The conduit of choice is the ipsilateral great saphenous vein, with the contralateral saphenous vein being an appropriate secondary option. To preserve the great saphenous vein in the contralateral limb for future revascularization procedures, some surgeons have advocated the use of alternative conduit as a secondary option.[94] Studies examining this issue are in general agreement that in the absence of advanced ischemia (disabling claudication, rest pain, or tissue loss), use of the contralateral saphenous vein is recommended over alternative conduit because of its length, superior performance, and minimal risk to the donor limb.[95-97] Independent risk factors predictive of the need for future vascular intervention in the contralateral limb include age younger than 70 years, diabetes, coronary artery disease, and an ankle-brachial index (ABI) of less than 0.7. In patients demonstrating three out of these four risk factors, the potential for requiring contralateral revascularization within the next 5 years ranges from 25% to 43%, and the use of alternative

TABLE 63.1 Vein Graft Configurations—Preoperative Planning

Configuration	Advantages	Disadvantages
Reversed	Intraluminal manipulation and valve lysis not required Option for anatomic or nonanatomic tunnel placement	Potential size mismatch at the anastomoses Hemodynamic effect of intact valves Intact valves can complicate graft thrombectomy
Nonreversed	Improved vein-to-artery size match at the anastomoses Option for anatomic or nonanatomic tunnel placement	Intraluminal manipulation and valve lysis required
In situ	Facilitates the use of limited skin incisions Reduced manipulation of the vein with the potential benefit of less traumatic injury Improved vein-to-artery size match at the anastomoses Subcutaneous position assists in operative graft revision	Not an option when using alternative autogenous conduit (arm vein, small saphenous vein) Intraluminal manipulation and valve lysis required Subcutaneous position presents an increased risk for graft exposure with wound infection Construction of the proximal anastomosis may be dictated by length of the proximal saphenous vein

conduit over the contralateral saphenous vein may be a reasonable consideration in this select population.[98]

The approach of using the "best" available autogenous conduit has been advocated[99]; this practice is used routinely by most vascular surgeons. Although vein segments with chronic phlebitis, calcification, or organized intraluminal thrombus are prone to accelerated failure and should be excluded from use,[16,17] the other characteristics that define the "best" vein have been an active area of investigation. Even though single-segment saphenous vein has universally been identified as the most durable conduit, an array of single-institution, retrospective studies has attempted to define the effect of such characteristics as vein diameter, graft type, and orientation on long-term patency.[11,31,100-104] Though useful in framing this question, the most comprehensive examination of this issue can be obtained from the prospective, multiinstitutional PREVENT III (Project of Ex-vivo Vein Graft Engineering via Transfection) database.[32,105] Examining conduit diameter and using veins greater than 3.5 mm as the reference standard, this trial found that grafts ranging from 3.0 to 3.5 mm had a 1.5-fold risk for primary failure. Grafts smaller than 3.0 mm in diameter had a 2.4-fold higher risk for primary failure and a 37% loss of secondary patency at 1 year. In terms of graft type, composite veins had a 1.5-fold increase and arm veins a 1.6-fold increase in primary failure when compared with single-segment great saphenous vein. Graft orientation did not influence patency, with reversed and nonreversed configurations demonstrating equivalent patency rates. As these data demonstrate, deviation from using an adequately sized single-segment saphenous vein carries increased risk for failure, and understanding the magnitude of these risks is critical in operative planning and maximizing the potential for a durable outcome.

Reversed Vein Grafts

Excision of the vein with orientation in a reversed configuration while maintaining antegrade flow through intact valves offers the most straightforward method for vein graft implantation and is suitable for most clinical situations. Difficulty may arise when significant tapering of the saphenous vein in the distal part of the limb creates a size mismatch between the artery and vein graft at both the proximal and distal anastomoses. The proximal vein graft appears to be a common site for luminal narrowing and vein graft failure, and use of small-diameter conduit at this location may accentuate this problem.[106] The size mismatch can be most problematic, however, when performing a tibial or pedal artery anastomosis. A fourfold to fivefold difference in diameters may be encountered, and tailoring the proximal great saphenous vein into a suitable anastomotic configuration can be challenging in these situations.

Examination of normal venous physiology has demonstrated that complete effacement of the valves does not occur during periods of prograde flow. In the low-flow, nonpulsatile hemodynamic environment that characterizes the superficial venous system, the mild to moderate stenosis created by these partially open valves does not translate into a significant loss of pressure or impediment to flow. After implantation into the arterial system, the hemodynamic significance of the valves becomes more pronounced. Though not significantly narrowing the lumen during peak systole, a transition to turbulence with localized regions of stasis is noted within the valves.[107] Lysis of these valves leads to a 15% decrease in hydrodynamic resistance and a 15% to 30% increase in graft flow rates.[108-110] Intact valves have not been proved to adversely influence the long-term patency of reversed vein grafts, but based on these observations, routine valve lysis within these antegrade flow grafts has been proposed.

Less well studied is the biologic effect of the hemodynamic microenvironment within the valve regions, which serve as a nidus for the development of a hyperplastic lesion and focal graft narrowing. Strandness et al. prospectively evaluated the long-term remodeling of these valves in reversed saphenous vein grafts.[111,112] Ten percent of the valves were associated with greater than 50% stenosis, but only 2.5% progressed to a critical stenosis requiring operative intervention; these valves accounted for 17% of the total graft revisions within the 18-month follow-up period. Notably, valve morphology was dynamic, with 60% of the hemodynamically significant valve lesions showing regression to less than 20% stenosis in a mean period of 3 months.

Nonreversed Vein Grafts

Challenges in constructing a reversed-configuration vein graft include significant proximal-to-distal tapering of a vein and the resulting size mismatch at the proximal or distal anastomoses (or both). Although the use of an in situ grafting technique can be one solution to this issue, the combination of complete excision of the vein, lysis of the valves, and orientation in a nonreversed configuration offers an alternative technique. Despite the fact that initial attempts with this approach suggested results inferior to the in situ method, these early efforts were probably compromised by the use of an eversion valvulectomy technique and extensive injury to the vein wall.[113] With subsequent refinements in the approach to valve lysis, nonreversed vein grafts have proved as durable as other available techniques.[114-117]

Although nonreversed vein grafts inherently require increased manipulation with the potential for injury during valve lysis, this shortcoming is theoretically offset by the improved hemodynamics offered by this approach. After valve lysis, nonreversed grafts offer a 20% improvement in flow rates over nonlysed, reversed conduits.[109] This hemodynamic effect is most pronounced in smaller diameter vein grafts ranging from 2.0 to 2.5 mm, where the leaflets from intact valves encompass 45% of the luminal cross-sectional area.[108]

In Situ Vein Grafts

The concept of using the great saphenous vein as a graft with mobilization of only the proximal and distal segments while maintaining the interval region within its subcutaneous bed was initially suggested by Rob's group in 1959.[118] Interested in the potential hemodynamic advantages offered by removal of the valves and retrograde perfusion of the conduit, Rob believed the procedure to be too time-consuming for routine application. Hall, a visiting fellow from Norway, became intrigued by this approach, refined the techniques for routine clinical application, and published the first report of the in situ vein graft technique in 1962.[119] His version of the procedure, requiring valve excision by opening the vein at multiple locations along the graft, was tedious, required significant technical expertise, and failed to gain widespread acceptance. The development of efficient instrumentation for valve lysis provided the opportunity to reduce vein manipulation and maintain an intact vasa vasorum and fueled renewed enthusiasm for the in situ approach. Initial reports of this approach, championed by Leather et al.,[120] suggested improved patency over excised vein grafts.[121] These early analyses are compromised by the use of historical controls, however, and contemporary comparisons of in situ versus reversed or nonreversed grafts fail to demonstrate significant differences in long-term outcomes.[46,116,122]

Preparation of the saphenous vein for use in situ as an arterial bypass entails (1) mobilization of the proximal and distal segments for construction of the anastomoses, (2) removal of the valvular obstructions to arterial flow, and (3) interruption of the venous side branches to prevent the formation of arteriovenous fistulae. The objective is to accomplish these tasks in the most expeditious manner while minimizing traumatic injury to the vein.

Proximal and Distal Anastomoses

The common femoral artery serves as the most common source of inflow for infrainguinal revascularization, and the relative position of this artery and the confluence of the superficial inguinal veins dictates construction of the proximal anastomosis. Mobilization of the proximal great saphenous vein is accomplished by secure ligation of the superficial branches, placement of a side-biting vascular clamp across the common femoral vein, transection of the great saphenous vein flush with the wall, and repair of the femoral vein with running nonabsorbable suture. Lysis of the most proximal great saphenous valve can be difficult with standard valvulotomes, but localized eversion of this segment permits excision of the valve under direct vision. Intrinsic atherosclerotic disease in the common femoral artery may dictate more proximal placement of the anastomosis. Additional proximal vein length can be obtained by harvesting a segment of the superficial epigastric vein and extending the venotomy proximally along the posterior surface of this vein to provide an autologous patch for repair of proximal common femoral artery disease. Care should be taken to minimize longitudinal stretching of the graft, which can accelerate the development of intimal hyperplasia.[123] Extensive common femoral or profunda femoris origin disease (or both) may necessitate endarterectomy with patch angioplasty or graft replacement of the common femoral artery. In the absence of significant proximal artery occlusive disease, defined as greater than a 50% reduction in lumen diameter, the superficial femoral, profunda femoris, or popliteal artery can be considered for placement of the proximal anastomosis.[124]

The posterior tibial, peroneal, and dorsalis pedis arteries provide the most straightforward options for placement of the distal anastomosis. Although the below-knee popliteal artery can also be used, fashioning the anastomosis can be problematic because of the nearly 90-degree angle that is formed between the graft and artery. With most hemodynamic analyses detailing an increase in flow separation and activation of proliferative metabolic pathways with right-angle anastomoses, grafts configured to this segment of the popliteal artery may benefit from excision and placement in an anatomic tunnel. Distal anastomoses to the above-knee popliteal artery do not offer the same constraints on their configuration; however, after mobilization of the proximal and distal graft, the segment that remains in situ can be quite short and of limited benefit.

Valve Lysis

Although limited transverse venotomies were used in initial development of the in situ bypass graft, this approach to render the valves incompetent has given way to less invasive techniques. Valvulotomes have undergone a variety of revisions over the last several decades, and the current generation of devices can be classified into three categories—the modified Mills valvulotome, the adjustable valvulotome, and the fixed valvulotome (Fig. 63.3).

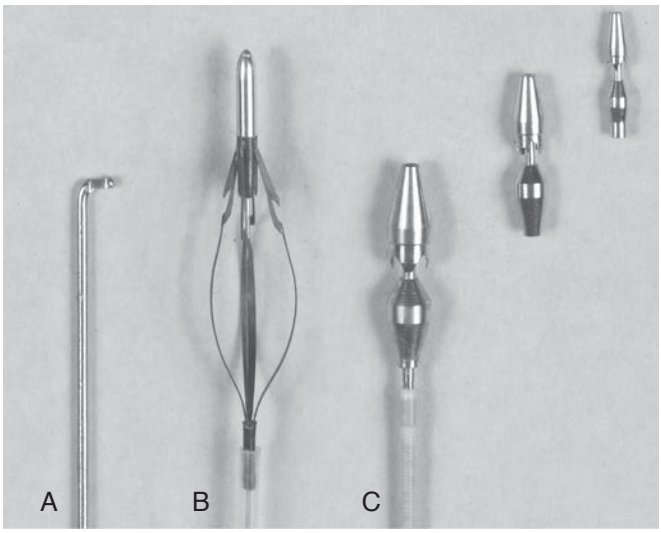

Figure 63.3 Valvulotomes. (A) Modified Mills. (B) LeMaitre adjustable. (C) Uresil fixed with 2-, 3-, and 4-mm cutting heads.

The modified Mills valvulotome (see Fig. 63.3A) was initially described in 1976 for application to coronary artery bypass surgery.[125] With limited modification, this device was rapidly adopted for use in peripheral vascular surgery. Introduced into a side branch or the distal end of the vein, the device is advanced through the valve leaflets (Fig. 63.4). The proximal vein graft is distended by arterial inflow or manual infusion to induce valve closure, and the valvulotome is slowly withdrawn until the reverse cutting blade engages the valve leaflet. The tip of the valvulotome is maneuvered toward the center of the lumen, and a short burst of inferior traction is applied to transect the valve.

Popularized by LeMaitre et al., the expandable valvulotome offers four cutting blades encompassed within a self-centering series of wire hoops (see Fig. 63.3B).[126] With the blades encased in a protective sheath, the device is advanced to the proximal end of the vein graft. The vein is distended, the cutting system deployed, and the device slowly withdrawn. Because of the mobility of the wire hoops, the position of the cutting blades is self-adjusting to accommodate vein diameters between 1.8 and 6 mm.

Fixed-diameter valvulotomes were developed from the original work of Hall, in which a blunt-tipped vein stripper was passed proximally to distally through the graft to avulse the valve leaflets and render them incompetent.[127] The addition of cutting blades and detachable heads of varying size led to the current generation of devices (see Fig. 63.3C).[128] A 2-, 3-, or 4-mm head is secured to a flexible shaft and reintroduced into the lumen of the vein. As with the other devices, the proximal vein is distended and the valves are lysed with a rapid burst of inferior traction.

Visualization studies after the application of valvulotomes report that complete disruption occurs in approximately 70% to 95% of the treated valve leaflets.[129,130] Proximal segments of the vein, where the size mismatch is most pronounced, are most likely to demonstrate only partial valve disruption; thus careful attention to this region seems warranted.[129] Limited

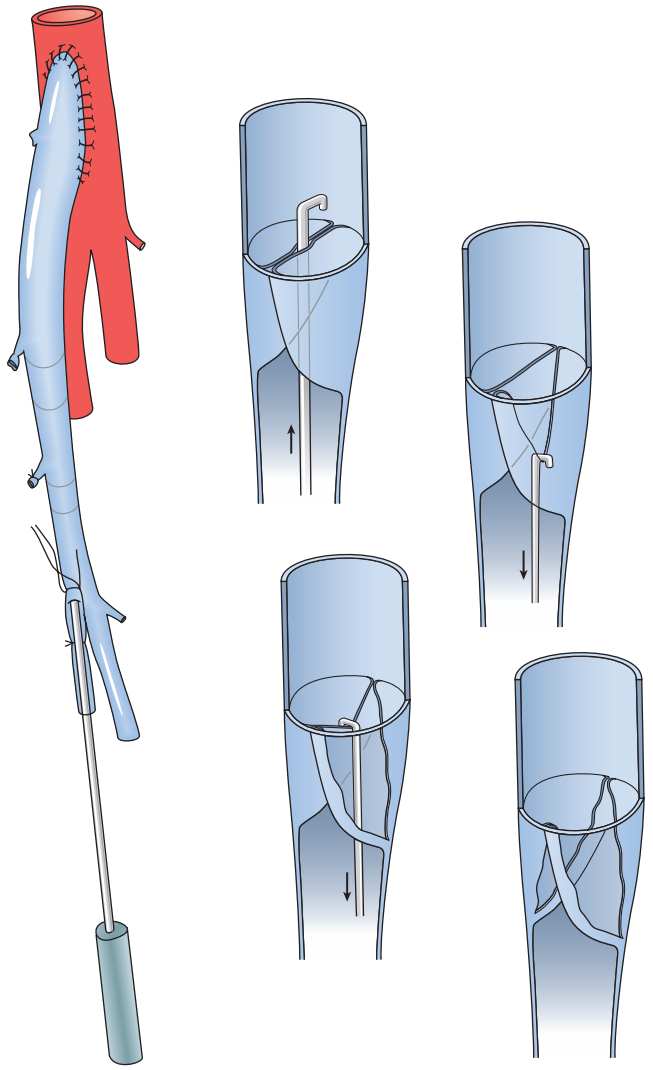

Figure 63.4 Valve lysis using the modified Mills valvulotome. The valvulotome is inserted into a long side branch and advanced into the proximal vein. Competent valves within the graft are maintained in closed position by arterial inflow pressure, and the valvulotome is withdrawn until resistance is encountered. After ensuring that the instrument has not engaged a side branch, a short burst of inferior traction is delivered and the valve leaflet transected. Short advancement and 180-degree rotation of the valvulotome permit division of the opposite valve in analogous fashion.

data providing a direct comparison among the types are available, with one study suggesting incomplete valve lysis to be more common with expandable valvulotomes[130] and another suggesting no differences among the groups.[131] A prospective randomized trial comparing clinical outcomes for fixed and expandable devices failed to show any difference in short-term patency.[131]

Intraoperative angiography, duplex scanning, and angioscopy have been proposed as suitable adjuncts to evaluate the completeness of valve lysis during in situ bypass grafting. Angiography and duplex scanning are relatively insensitive modalities for identifying retained valves and detect only about 20% of such valves; angioscopy is much more sensitive.[132] Used for either direct visualization during valve lysis or graft surveillance, angioscopy is successful, with a sensitivity of identifying retained

valve cusps approaching 100%. The clinical implications of identifying these valve abnormalities are uncertain, and several studies suggest no long-term improvement in graft patency with the routine use of angioscopy.[133,134] Potentially the most notable benefit from routine angioscopy may be the identification of significant preexisting venous disease. Veins with preexisting pathology have a high rate of early graft failure, and intraoperative recognition of these compromised vein segments may be the most important role for prebypass angioscopy.[76,135] Angioscopy may also be especially important in the evaluation of arm vein conduits because of their documented increased frequency of intrinsic vein abnormalities (see the "Arm Vein and Composite Grafts" section later in this chapter).

Side Branch Ligation

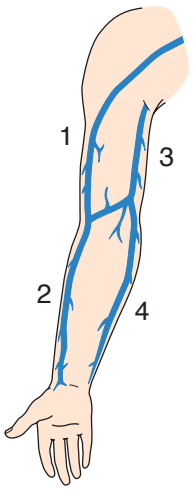
Without the need to mobilize the vein from its subcutaneous bed, multiple options are available for treatment of the venous side branches. The standard approach would be complete exposure of the great saphenous vein with a single continuous incision that extends the length of the leg. Although this open approach simplifies side branch ligation and valve lysis; it has been associated with a wound complication rate in excess of 40% in some reported series.[75,136] These complications are of even more significance because of the superficial location of the in situ bypass. Even though extended rehospitalization and operative débridement may be required, these wounds can usually be managed without loss of graft patency.

Noninvasive identification of the major side branches offers the opportunity for a limited-incision or semiclosed in situ technique. Intraoperative venography and duplex scanning are two readily available options for this task, but these methods can be surprisingly inaccurate and fail to recognize almost 50% of the side branches.[132] Using the angioscope to identify the orifice and transcutaneous illumination to guide the location of the skin incision has proved somewhat more successful, with detection of approximately two-thirds of patent side branches.[132,136] Commensurate with the smaller size of the incisions, these approaches offer notable improvement in wound complication rates.[133,136] Graft patency rates are relatively unaffected by the operative approach, but an increased incidence of persistent arteriovenous fistulae has been documented with most semiclosed techniques. Studies examining persistent fistulae have generally recommended their ligation; however, such an aggressive approach has been called into question. Conservative management of these fistulae results in spontaneous closure in a third of cases, with eventual revision for reduced distal graft velocity in a third, and a third remaining stable without intervention.[137,138]

Arm Vein and Composite Grafts

The ipsilateral great saphenous vein is clearly the most desired conduit, but reports suggest that it is absent in up to 45% of patients requiring infrainguinal revascularization.[139] Use of single-segment or composite arm grafts provides an important alternative in such challenging patients. The most extensive experience with arm vein bypass is detailed through a series of reports from the Beth Israel Deaconess Hospital.[94,103,140] Preoperative duplex evaluation of the upper extremity veins is critical in the operative planning for patients with inadequate or previously harvested ipsilateral saphenous vein. A summary of the advantages and disadvantages of available arm vein conduits, along with an estimate of their relative frequency of use, is provided in Fig. 63.5.[94]

To take advantage of the larger veins in the upper part of the arm, the basilic-cephalic loop graft has been proposed.[141,142] Using the median cubital vein as the connecting segment, the cephalic and basilic veins are harvested in a continuous loop from the antecubital fossa to their termination in the axillary vein. With the larger basilic vein serving as the proximal vein



Upper extremity vein segment	Frequency of use	Comment
1. Cephalic vein (arm)	70%	Uniform diameter 4-6 mm Implant reversed due to thin walls for lysis Can be harvested within the deltopectoral groove
2. Cephalic vein (forearm)	45%	Intraluminal webs and phlebitis common Wall thickness adequate for valve lysis
3. Basilic vein (arm)	50%	Significant diameter change along the length Valve lysis difficult due to large proximal diameter Located subfascial in its proximal portion
4. Basilic vein (forearm)	2%	Smallest caliber of the upper extremity veins Posterior position minimizes previous iatrogenic injury

Figure 63.5 Superficial upper extremity veins available for use in bypass grafting, including individual considerations and relative frequency of their use. (Hölzenbein TJ, Pomposelli FB Jr, Miller A, Contreras MA, Gibbons GW, Campbell DR, Freeman DV, LoGerfo FW. Results of a policy with arm veins used as the first alternative to an unavailable ipsilateral greater saphenous vein for infrainguinal bypass. *J Vasc Surg.* 1996;23(1):130–140.)

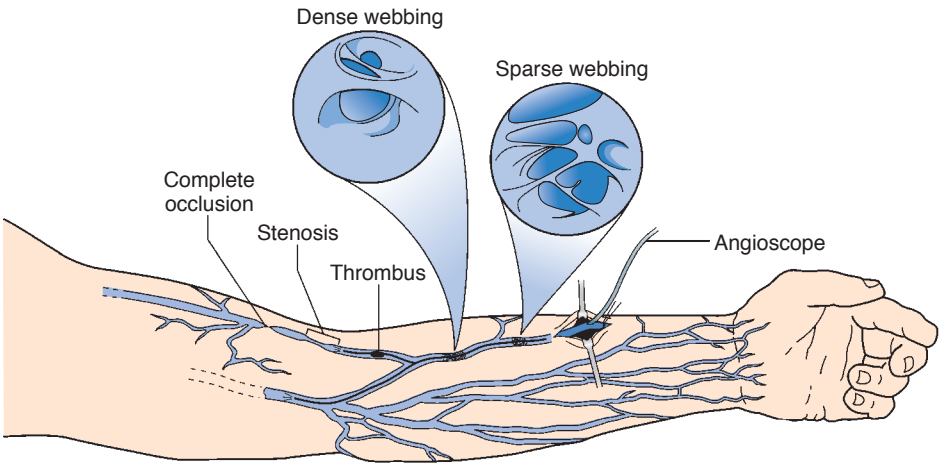


Figure 63.6 Iatrogenic injury to upper extremity veins leading to stenosis or segmental occlusion is common. Although preoperative duplex vein mapping can be helpful, intraoperative angioscopy offers the potential for precise localization of these compromised areas.

graft, a valvulotome is introduced into a midgraft side branch to facilitate lysis of valves in the basilic and median cubital segments. The cephalic vein segment, which tends to be thin-walled and troublesome for valve lysis, is maintained in a reversed configuration and used for the distal anastomosis.

Similar to the approach when using lower extremity veins, single-segment arm vein is preferable. Through extensive use of the median antecubital vein as a bridge, success can be achieved in up to 80% of cases requiring the use of arm vein.[94] Limiting this effort, however, is the inherent iatrogenic injury that occurs from repeated cannulation (Fig. 63.6). Veins that are most superficial and anatomically accessible, such as the forearm cephalic and median antecubital, are most frequently damaged, with 30% to 50% of these veins demonstrating a variety of pathologies.[143] Angioscopic evaluation of the quality of the arm vein and identification of compromised segments are thus fundamental to achieving long-term patency in these grafts. Minor abnormalities such as sparse webbing or an adherent thrombus can be successfully treated by endoluminal repair to restore a widely patent lumen. Other pathologies such as dense webbing or focal stenosis may require local repair with vein patch angioplasty. Marked abnormalities such as sclerosis with long-segment stenosis or occlusion cannot be repaired locally and require resection of the abnormal segment. Using such a treatment strategy, 25% of arm veins required local repair and 16% required resection, with no difference in long-term patency when compared with a good-quality arm vein that required no intervention.[94] In the subset of grafts in which a segment of suboptimal-quality vein was used, failure within 6 months of implantation was common.

Small Saphenous Vein Grafts

Although lacking the length offered by the great saphenous vein, the small saphenous vein can be a useful source of autogenous conduit in the vein-limited patient. Arising from tributaries lateral to the calcaneus and terminating in the popliteal fossa, this conduit is predominantly used in combination with other vein segments in a composite configuration. Preoperative duplex evaluation is critical to evaluate adequacy, with a lumen diameter of 3.0 mm considered suitable for grafting. Small saphenous vein is usually the third choice of autogenous vein (behind great saphenous and arm vein) because of the inherent difficulties in surgical exposure and harvest. While initial reports described use of a medial leg incision with development of a subfascial plane along the enveloping fascia of the superficial posterior compartment,[144] most surgeons currently use a posterior leg incision for surgical exposure of this conduit.[145-148] Short, unilateral segments of vein can be harvested with the patient in the traditional supine position by elevating the leg, with the surgeon positioned inferior to the extremity. However, extensive unilateral or bilateral harvests are best accomplished using an initial prone position, in which the veins are excised, wounds closed, and the patient rotated into a supine position for completion of the procedure. In an attempt to use the posterior leg veins as a single conduit for femorotibial bypasses, the Giacomini vein can be harvested in continuity with the small saphenous vein.[149] Although this extension of the small saphenous vein into the thigh is present in approximately two-thirds of individuals, details regarding the size distribution for this conduit and intermediate to long-term patency have not been reported.

Patients with isolated tibial artery occlusive disease may be candidates for in situ bypass using the small saphenous vein. Employing a posterior approach for exposure of the proximal and distal anastomotic sites, popliteal-crural bypasses to each of the three tibial arteries can be performed. Cumulative 1- and 3-year primary patency for these grafts is 75% and 60%, respectively,[147,148] approximating the same results observed with in situ grafting using the great saphenous vein. However, the durability of small saphenous vein used in composite grafting is notably inferior, with 1- and 3-year primary patency of 50% and 35%, respectively.[148]

Femoral-Popliteal Vein Grafts

Although primarily used for intraabdominal vascular reconstructions in most current day treatment algorithms, the

femoral-popliteal vein was initially investigated as the potential conduit of choice for lower extremity bypass procedures.[150-153] With promising results demonstrated in a retrospective review of their clinical practice, Schulman et al. initiated a prospective, randomized trial comparing autogenous femoral-popliteal vein to saphenous vein as the preferred conduit for infrainguinal bypass.[153] Based on a total enrollment approaching 100 patients, no significant differences in 5-year primary patency (55%) and limb salvage rates (70%) were observed. Thirty-day mortality and early postoperative complications were also similar in both groups. Follow-up examination to evaluate the long-term sequelae of deep vein harvest demonstrated chronic calf swelling and an obstructive pattern on venous plethysmography, but no significant increase in stasis dermatitis or venous ulceration.[154] Although no objective differences were observed between the femoral-popliteal and saphenous vein groups, the authors concluded that the increased complexity associated with femoral vein harvest made the saphenous vein the preferred conduit for lower extremity revascularization. Nonetheless, these data support the use of femoral-popliteal vein as a viable source of alternative conduit in select patients.

Superficial Femoral Artery Grafts

Patency of an occluded segment of excised superficial femoral artery can be restored via an eversion endarterectomy, providing an autogenous conduit up to 25 cm in length that is suitable for short interposition or composite grafting.[155] Although conceptually these conduits were thought to be useful in the salvage of patients with prosthetic graft infection, rupture of the anastomosis was observed in 75% of those grafts placed in an infected field.[156] When used in combination with an autogenous vein, patency rates for these composite grafts have demonstrated marginal 1-year primary patency rates (60%).[156,157] Frequently the mechanism of failure for these conduits was acute thrombosis in the absence of a stenotic lesion, which is different from what is usually seen in autogenous vein grafts.[157]

Hypogastric Artery Grafts

Facilitated by the rich collateral network in the pelvis, the hypogastric artery offers an available source of autogenous conduit for short segment, intraabdominal reconstructions. With a cascade of associated branches, this graft offers the ability to create several distal anastomoses from the primary graft, an advantageous configuration for use in complex aortorenal bypass procedures.[158] Although used sporadically in the adult population,[159,160] this segment of artery is the conduit of choice for renovascular reconstructions in the pediatric population.[161,162] Autogenous vein grafts, because of the propensity for late aneurysmal dilation in children, are rarely used for pediatric aortorenal bypass procedures. Although no detailed analysis of hypogastric artery patency has been performed, anecdotal experience across multiple centers support that a normal autograft placed without technical error should provide lifelong patency.[158-162]

ETIOLOGY OF VEIN GRAFT FAILURE

Technical Factors

Traditionally, graft occlusions within 30 days of implantation have been thought to be related to technical factors that could potentially have been corrected at the time of graft placement. Although flow-limiting lesions within the bypass graft are a clear component of these failures, estimated at about 20%,[163] the events leading to graft thrombus are clearly more complex. Similar to the etiology of venous thrombosis, Virchow's classic triad is probably at the intersection of early graft failure. Not uncommon is the scenario in which early graft failure prompts reexploration, which fails to identify any clear underlying cause.[163] Endothelial injury related to manipulation of the graft, hypercoagulability in the early postoperative period, and reduced graft flow because of inflow, outflow, or graft stenosis are factors that contribute to these early failures.

With insufficient time for formation of significant intimal hyperplasia, graft failures within 30 days are thought to be technical if they are associated with one of four categories: inadequate inflow, inadequate outflow, extrinsic lesions, and intrinsic lesions.[164] Inadequate inflow may be secondary to an unrecognized lesion in the proximal arteries or inflow graft. More common is the scenario in which the importance of the proximal lesion is underestimated, only to have its hemodynamic significance unmasked after placement of the distal graft. The resulting increase in flow leads to an accentuated drop in pressure across the lesion and converts a previously innocuous lesion into one that now has important hemodynamic implications. Cardiovascular compromise, such as systemic hypotension or a low cardiac output state (e.g., cardiogenic shock), can also be the cause of inflow-related graft failure.

Inadequate outflow as a result of extensive, preexisting tibial and inframalleolar occlusive disease is an established risk factor for early graft failure; patients demonstrating the most severe disease have a 10-fold increased risk for 30-day graft thrombosis.[165,166] Vasospasm of the target artery is a less well-studied but possible contributor to early postoperative outflow compromise. Though difficult to quantify and monitor postoperatively, a subset of patients demonstrate severe luminal narrowing and delayed reperfusion despite minimal atherosclerotic disease in the distal artery (Fig. 63.7).

Extrinsic causes of early graft failure include extrinsic compression because of tunneling errors or hematomas that may compromise graft flow. Other extrinsic causes of graft failure, such as hypercoagulability, are systemic. Alterations in the coagulation system are detectable in more than 25% of patients undergoing lower extremity revascularization.[167] Although some studies have suggested that 10% of early graft failures are primarily related to an identified hypercoagulable state,[163] the contribution of transient abnormalities in coagulation is unclear and perhaps underestimated.

Intrinsic vein graft defects include focal, flow-limiting lesions such as a retained valve leaflet, an intimal flap, or inappropriate placement of anastomotic sutures. Limitations in flow can result from the use of an undersized conduit, with vein grafts less

Figure 63.7 Intraoperative digital subtraction arteriogram of a vein bypass graft to the distal anterior tibial artery. Severe distal spasm of the outflow artery *(arrow)* has led to diminished diastolic flow in the graft.

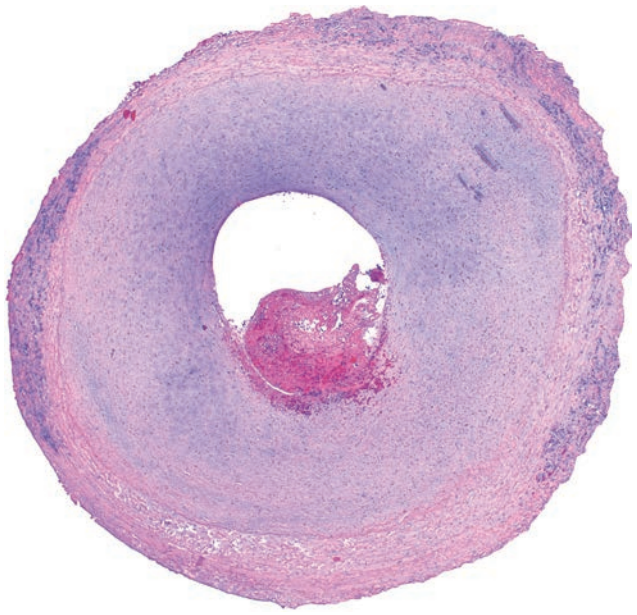

Figure 63.8 Cross-sectional histologic image of an 8-month-old vein graft demonstrating severe intimal hyperplasia. Adherent thrombus is present within the severely compromised lumen.

than 3.0 mm in diameter being at significant risk for early failure.[166] Independent of luminal narrowing, intrinsic vein graft defects, such as sclerosis and calcification, also contribute to graft thrombosis.[17]

Recent data from the multi-institutional PREVENT III trial have detailed a 5% incidence of thrombosis or reexploration within 30 days of graft implantation.[105] Whereas endovascular management of these early graft occlusions is of limited value, open surgical revision provides a reasonable opportunity for durable graft salvage, with a 90% 1-year patency rate reported after successful exploration and revision.[168]

Intimal Hyperplasia and Pathologic Remodeling

Surgical manipulation of the vein combined with the acute exposure to elevated shear and tensile forces elicits a complex series of biologic events in the vein wall that begins immediately on implantation. Analogous to the events that occur in generalized wound healing, repair of the damaged vein graft is initiated by the local synthesis of a wide variety of cytokines and growth factors. Chemokines induce the recruitment of neutrophils and mononuclear cells, which further amplifies these pathways. Activated by these chemoattractants and mitogens, smooth muscle cells begin to dedifferentiate from a contractile to a synthetic phenotype and replicate within the media. By tracing the gradient of chemokines, liberated smooth muscle cells migrate from the media to the intima, where continued proliferation and abundant matrix deposition are stimulated. Progressive thickening of the intima leads to narrowing of the lumen, a reduction in graft flow, and intraluminal thrombosis (Fig. 63.8).

Despite the relative uniformity of the surgical trauma and hemodynamic insult, vein graft lesions demonstrate a strong tendency to be focal rather than diffuse.[169] With a peak incidence at 4 to 12 months after implantation, 30% to 45% of autogenous grafts will fail or require revision secondary to significant narrowing of the lumen.[105,170] Stenotic lesions are more likely to be associated with the proximal or distal anastomosis (53% incidence) but occur not infrequently in the midbody of the graft (30% incidence).[106] It has been postulated that these midgraft lesions are associated with valve leaflets; detailed evaluation of this issue demonstrated substantial remodeling within valve sites, but progression to high-grade stenosis was rare and accounted for less than 20% of the intrinsic graft lesions requiring repair.[112] Despite such general observations, the underlying biologic mechanisms for development of this segmental pattern of intimal hyperplasia remain poorly understood. Although the local flow environment plays a significant role, physical forces in isolation fail to explain these observations. More likely, critical lesion development occurs at the intersection of localized trauma, ongoing hemodynamic stress, and an altered ability for local repair after injury.

Although much of the emphasis in vein graft pathology has focused on intimal hyperplasia, graft morphology is actually dictated by the balance between outward expansion and wall thickening. As Glagov et al. demonstrated, the normal vascular adaptive response is an increase in overall wall circumference to compensate for luminal narrowing in the presence of a developing occlusive lesion.[171] In response to hemodynamic and biochemical stimuli, smooth muscle cells degrade and reorganize the rigid matrix structure of the wall to facilitate these changes. Examination of early vein graft morphology

demonstrated a 20% increase in diameter within the first month after implantation; failure of this outward remodeling has been correlated with subsequent graft failure.[172] Inflammatory pathways appear to further modulate this shear-mediated adaptive response, thus providing potential mechanistic insight into the heterogeneity that is observed clinically.[173]

Graft Atherosclerosis

Although the peak incidence of vein graft failure occurs within the first year, delayed progression of intrinsic lesions leads to a 4% annual loss of graft patency in the 2- to 10-year time frame.[9,170] Because studies have focused predominantly on the mechanisms of early graft failure, insight into the pathology of delayed lesion development in peripheral vein grafts is limited. Much of our understanding of late graft failure is derived from coronary bypass grafts examined at the time of autopsy. Replacement of the fibrotic wall with lipid-laden macrophages and intramural calcification is common.[174-176] Degeneration of the vein graft wall with intramural thrombus formation, characteristic of ruptured atherosclerotic plaque, is also frequently observed.[177,178] Supporting these observations is the clinical impact of lipid-lowering therapy on coronary artery graft patency, where reductions in total serum cholesterol significantly enhance vein graft durability.[179-181]

With few relevant animal models, examination of these events in peripheral bypass grafts has been relegated to the analysis of sporadic samples obtained at the time of graft revision. The initial report published by Szilagyi et al. in 1973 identified atherosclerotic changes in 8 of 21 grafts ranging in age from 8 to 96 months.[169] These observations are supported by Walton et al., who described apolipoprotein B deposits, ulceration, calcification, and aneurysm formation in the majority of failed grafts that had been implanted for more than 2 years.[182] More recent reports, however, present a more variable picture and predominantly describe a fibrocellular hyperplastic intima with rare atherosclerotic degeneration as the cause of late failure.[183] Although investigators have speculated that modulation of early intimal hyperplasia will have an impact on cholesterol-driven atherogenesis and provide an avenue to improve graft patency, this view remains speculative with limited data to support it.[184,185]

Autogenous Graft Modifications to Improve Durability

For the last two decades, the prevailing concept in vein graft biology was that the initial stages of adaptation were critical in defining the long-term future of the conduit. Specifically, it has been hypothesized that inhibition of the early wave of smooth muscle cell proliferation would mitigate the development of stenotic lesions months to years following implantation.[186] Emanating from this strategy, edifoligide emerged as the most promising approach to improve vein graft durability. The regulation of cell cycle kinetics and DNA replication are under the control of the E2F pathway, and the double-stranded oligodeoxynucleotide edifoligide was designed to bind and inactivate the E2F family of transcription factors. Applied to the harvested vein, this therapeutic agent was developed to inhibit the burst of smooth muscle cell proliferation that is initiated in the first several days following implantation.

Based on successful preclinical studies in a rabbit vein graft model, human phase I and II clinical studies examining edifoligide were initiated.[187-189] Demonstrating safety and a suggestion of possible efficacy,[190,191] two phase III clinical trials (PREVENT III and IV) were undertaken to investigate the use of edifoligide in infrainguinal and coronary artery revascularization. Following randomization of 4400 patients, treatment with edifoligide was demonstrated to have no influence on vein bypass graft durability.[192,193] Although these were landmark trials in their attempts to directly modulate the biology of an implanted vein graft, the lack of a significant clinical effect has led to a reassessment of the fundamental paradigms in the field and the current wave of investigative research.

- *Delivery vehicles*—Founded in the concept that mitigation of the early vein graft response to injury prevents unchecked intimal hyperplasia, the PREVENT trials used a naked oligonucleotide approach to inhibit E2F binding to the promoter sites. The lack of clinical efficacy has brought into question such approaches using a single, ex vivo application of a therapeutic agent at the time of graft implantation. A more sustained but still transient delivery method, such as that offered by adenovirus, or the stable integration of a biologic modifier into the genome, using adeno-associated virus or lentivirus, may be more effective strategies for achieving a durable clinical outcome.[194,195]
- *Biologic processes*—Interrupting E2F binding, along with the transition from G1 to S phase within smooth muscle cells, was thought to be the critical event in improving vein graft survival. Although the conceptual model that smooth muscle cell proliferation leads to intimal hyperplasia and results in luminal narrowing and graft thrombosis is attractive in its simplicity, vein graft injury and repair occurs via a coordinated series of overlapping events.[196] Endothelial damage and recovery, local thrombosis, smooth muscle cell apoptosis, and matrix deposition are all components of the adaptive process. Accentuating or inhibiting one or more of these parallel events may be required.
- *Molecular targets*—Genomic analyses following vein graft implantation have failed to identify a single target that dominates the adaptive process.[197] Instead, the enhancement or repression of various biologic processes occurs via the broad modulation of the entire set of integrated pathways.[198] Central mediators offer the best opportunity for successful modifications, and this is supported by the recent investigations in the association between single nucleotide polymorphisms in the cyclin-dependent kinase inhibitor 1B (p27Kip1) gene and vein graft patency.[199] Influencing cell cycle progression at G1, this inhibitor protein acts as a gatekeeper to modulate cell division. While promising for further investigation, it is likely that a multitarget approach at specific times during the adaptation process is required for a robust and durable impact on vein graft morphology. An alternate approach is to develop a response system that adapts to the local biology of the environment. This concept is the

foundation for use of autogenous cells, which, when placed in a perivascular position, modify the signaling milieu to positively impact the local biology of the vein graft wall. Such approaches have been examined in early phase human trials and are moving toward phase III testing.

PREVENTION OF VEIN GRAFT FAILURE

Intraoperative Evaluation

Despite improvements in surgical technique, 5% of autogenous vein grafts fail within 30 days of implantation.[105] Retained valve leaflets, abnormal twists or kinks, intimal flaps, other unrecognized obstructive lesions, and technical defects at the time of graft placement are estimated to account for between 15% and 25% of early failures.[200,201] The initial technical adequacy of an infrainguinal bypass graft can be judged intraoperatively by the external appearance of the bypass and anastomoses and by the restoration of distal pulses and perfusion. Continuous wave Doppler is a useful intraoperative adjunct that permits evaluation of anastomoses and areas of concern within the body of the graft for localized increases in the audible sound frequency. Though adequate for gross defects, a more detailed assessment to ensure technical success and to optimize short- and intermediate-term graft patency has been advocated. Recent investigations report a 15% intraoperative graft revision rate for abnormalities identified on secondary imaging.[202] Although it is unclear to what extent these irregularities increase the risk for graft failure, the significant morbidity resulting from early reintervention for graft failure supports an aggressive approach to intraoperative repair.[203]

Angiography

Contrast-enhanced angiography remains the diagnostic standard for arterial anatomic imaging and is the most widely used method for intraoperative vein graft assessment. Facilitated by the increasing availability of high-quality intraoperative angiographic equipment, this technique provides the current standard for determination of technical adequacy of a bypass graft. Though particularly useful for identifying a kink or twist in the graft, a patent side branch or branch ligature stenosis, and distal arterial disease requiring sequential bypass,[204] angiography has several notable shortcomings. Limited by a single projection plane and the dense opacification provided by iodinated contrast material, retained valve leaflets and intraluminal webs can be difficult to identify, with one study reporting failure rates approaching 80%.[132] Particularly troublesome is the angiographic evaluation of the distal anastomosis and delineation of a structural abnormality versus spasm in the outflow artery (see Fig. 63.7). Significant spasm occurs in approximately 50% of tibial and pedal artery bypasses, but it is of no clinical consequence in the large majority of cases.[205,206] Routine intraluminal injection of papaverine hydrochloride (30-60 mg in 1-2 mL of 0.9% saline) into the vein graft before performing completion angiography has been advocated to alleviate vasospasm.[207]

With these technical limitations, the use of a standard evaluation algorithm (consisting of visual inspection, palpation, and interrogation with continuous wave Doppler) with selective arteriography has been proposed. Mills et al. noted that these simpler techniques failed to identify 80% of the vein graft and outflow abnormalities that were detected by completion angiography and required revision.[208] Focusing on 1-year patency as the primary endpoint, other investigators examining this issue arrived at the opposite conclusion and stated that the additional expense of routine arteriography outweighs its benefit.[209] In the latter retrospective review, where no difference in graft patency was observed in association with routine or selective angiography, patient enrollment was modest and statistical analysis insufficiently powered to allow firm conclusions. Completion angiography provides useful anatomic information, especially with regard to the status of the outflow arteries; its major weakness is that it fails to provide any hemodynamic assessment.

Flow Rate Measurements

Non-imaging-based modalities such as measurement of blood flow rates have been advocated as useful adjuncts in the intraoperative evaluation of vein grafts. Based on the assumption that flow-limiting stenoses could be detected by reductions in flow, investigators identified 80 mL/min as the critical threshold below which there was a high probability of a technical problem within the reconstruction and for which further evaluation with angiography was suggested.[210] Although of interest, this approach has largely been supplanted by duplex imaging. The use of intraoperative flow measurements has also been described as an independent predictor of graft patency. Despite being unreliable in identifying grafts at risk for early (<30 day) failure,[211] extensive literature confirms the importance of graft flow rates in determining intermediate- and long-term patency.[212-214] Not surprisingly, flow rates demonstrate high correlation with the angiographic runoff score[165] and can serve as a surrogate for this well-established risk factor with limited direct application to intraoperative decision-making. More quantitative assessments of graft hemodynamics, such as the resistive index and longitudinal impedance, have also been proposed.[215,216] Similar to flow rate measurements, these parameters have prognostic significance but little utility in therapeutic decision-making.

Duplex Scanning

After angiography, duplex scanning has developed into the next most commonly used intraoperative method for evaluation of vein grafts. Duplex uses B-mode imaging and velocity spectrum analysis to detect lesions and grade lesion severity, thus providing both anatomic and hemodynamic assessment. Initially described by Bandyk et al. for the assessment of in situ bypass grafts,[217] duplex scanning proved effective in the identification of competent valve leaflets, anastomotic narrowing, arteriovenous fistulae, hemodynamic stenosis caused by small-caliber conduit, and the intraoperative formation of fibrin-platelet aggregates. With evolving diagnostic criteria, duplex scanning was initially thought to be too sensitive and best suited for use as a screening tool in combination with selective arteriography to better define

suspect areas. Subsequent refinements in both instrumentation and interpretation have yielded improved accuracy, with multiple studies supporting the replacement of intraoperative angiography with duplex scanning.[218-220] Although the published literature has been unequivocal regarding the value of intraoperative duplex, application has been limited predominantly to centers of excellence where sufficient skilled vascular technologists are available to support these efforts.

A standardized procedure for intraoperative duplex graft scanning has been proposed by Johnson et al.[202] Before scanning, papaverine (30-60 mg) is injected into the distal vein graft segment with a 27-gauge needle. Using a linear-array 7- to 15-MHz transducer (for superficial grafts) or 5-MHz transducer (for tunneled grafts), velocity spectra along the distal anastomosis and outflow artery are recorded while maintaining a 60-degree Doppler angle. The entire length of the graft is then scanned in a distal to proximal direction to evaluate color-flow images and velocity spectra for retained valves and residual arteriovenous fistulae (if applicable). Evaluation is completed with scanning of the proximal anastomosis and inflow artery. Diagnostic criteria for elevated velocities and an appropriate management algorithm are presented in Table 63.2. In one center using this protocol, a normal intraoperative duplex scan has been associated with a reduction in 90-day graft thrombosis to 0.4%.[221]

A significant advantage of this technique is its ability to detect low-flow bypass grafts, defined as an average peak systolic velocity (PSV) of less than 45 cm/s (see Table 63.2). Subsequent analysis of these low-flow grafts has identified two clinical subgroups based on the presence or absence of diastolic flow. The majority of grafts with high peripheral vascular resistance and absent diastolic flow failed within 6 months of implantation,[222] and surgical revision consisting of either a sequential graft to an alternative target or placement of an arteriovenous fistula has been advocated to salvage these threatened grafts. Low-flow grafts with low peripheral vascular resistance (characterized by antegrade flow throughout the pulse cycle) were at intermediate risk of failure (30% failure rate at 6 months) and may benefit from postoperative anticoagulation.[202]

Angioscopy

Angioscopy provides an alternative image-based modality for intraoperative assessment of vein grafts. Not only does it assist in preparation of the conduit by allowing accurate and complete valvulotomy, detecting unsuspected intraluminal pathology, and assisting in the selection of optimal-quality vein segments for composite grafting, it also provides a tool for assessment of technical errors at completion of the procedure. However, successful application of angioscopy requires an investment in new instrumentation and a commitment to overcome its inherent learning curve. Several groups have examined the potential benefits of completion angioscopy, with a generalized consensus that angioscopy is significantly more sensitive in identifying intraluminal abnormalities than either angiography[223,224] or duplex scanning.[132] The most informative study to date, conducted by Miller et al., was a 250-patient prospective randomized evaluation of angioscopy versus angiography.[225] Intraluminal abnormalities were identified in a fifth of the enrolled grafts, with 75% of them determined to be of sufficient severity to prompt surgical correction. Intraoperative revisions were fourfold more likely to be performed after angioscopic evaluation and led to a 50% reduction in 30-day graft failure (3% after angioscopy vs. 6% after angiography). Although this difference did not reach statistical significance, it suggested that some improvement in early graft patency may be obtained with the use of completion angioscopy and aggressive intraoperative revision of any abnormalities identified. Not examined in this trial were the potential intermediate- and long-term benefits in graft patency afforded by this approach, which may

TABLE 63.2 Intraoperative Duplex Monitoring—Diagnostic Criteria and Management Options

Category	PSV (cm/s)	V_r	Interpretation and Intraoperative Management
Stenotic Lesion			
Normal/minimal	<125	1.0-2.0	Normal flow pattern; no further evaluation
Moderate	125-180	2.0-3.0	Residual flow abnormality; rescan after 5 min with papaverine flow augmentation; consider arteriography
Severe	>180, with spectral broadening	2.5-5.0	Significant abnormality, repair defect; if not repaired, perform arteriography to verify normal bypass graft segment
High-grade	>300	>5.0	Critical lesion, typically associated with a pulse pressure deficit and low graft flow
Low-Flow Graft			
Low flow, low PVR	<40	—	Consider systemic anticoagulation Caveats: large-caliber veins may have low peak systolic flow velocities; reversed veins to pedal outflow arteries may also have low distal graft flow velocities
Low flow, high PVR	<40	—	Consider an adjunctive procedure to increase graft flow (distal arteriovenous fistula, jump/sequential graft to an alternative target)

PSV, Peak systolic velocity; *PVR*, peripheral vascular resistance—low (antegrade flow throughout the pulse cycle) or high (antegrade flow only during systole with minimal diastolic flow); V_r, velocity ratio ($PSV_{at\ lesion}/PSV_{proximal}$).

have been even more pronounced than the effects on early patency.

Postoperative Surveillance

Physical Examination and Physiologic Assessment

As initially established by the seminal work of Szilagyi et al.[169] and reinforced by multiple other studies, it is now known that autogenous grafts develop segmental foci of luminal narrowing that lead to reductions in flow and precipitate thrombosis. Attempts to salvage thrombosed grafts outside of the early postoperative period have largely been unsuccessful, with 30% 1-year patency rates after thrombectomy.[226] These observations contributed to the concept of routine graft surveillance, or periodic evaluation to identify grafts with evolving lesions before the development of thrombosis. Resulting from a combination of intimal hyperplasia and pathologic (inward) remodeling, these lesions have a peak incidence within the first 12 months, with 30% becoming hemodynamically significant within this 1-year time frame.[106,227] These observations form the basis for graft surveillance protocols in which frequent evaluations are recommended during the first 12 to 18 months after implantation.

Clinical protocols for graft surveillance focus on physical examination with physiologic assessment of distal perfusion. Patient histories are elicited to detect new onset of claudication or ischemic pain at rest, and physical examination is performed to identify notable changes in the lower extremity pulse. The ABI is used as the quantitative measure of perfusion, with a reduction of greater than 0.15 being considered significant. Changes in any of these parameters should prompt further evaluation to identify the lesion or lesions that have precipitated the hemodynamic deterioration. To improve the sensitivity of physiologic testing, pulse volume recording with a transfer function index protocol has been proposed.[228] Pulse volume recordings are collected from upper extremity (inflow) and ankle (outflow) cuffs and subjected to a Fourier transform algorithm to produce discrete spectra for review. Direct comparison of the frequency response curves provides a numeric value that can be used to identify at-risk grafts. Proof-of-concept testing of this device has suggested accuracy equivalent to that of duplex scanning, but this approach has failed to gain acceptance outside the research arena.

Duplex Scanning

With the recognition that clinical surveillance parameters were insensitive until the lumen was severely compromised,[208,229] duplex scanning was identified as a method for earlier detection of these developing lesions. After an initial focus on reductions in PSV and the absence of diastolic flow,[230,231] changes in velocity along the length of the graft were recognized as a more useful approach for lesion localization.[232,233] Though not generated through a formal series of receiver operating characteristic curves, a duplex classification has evolved to correlate PSV and the velocity ratio (V_r) with the approximate degrees of vein graft stenosis (Table 63.3).[234] Complicating management of vein graft stenosis is the dynamic remodeling that occurs in 12 to 18 months after implantation, during which the appearance and subsequent regression of focal regions of luminal narrowing are frequently observed.[112,235] Retrospective reviews correlating duplex-derived hemodynamic data with lesion morphology suggested a PSV of 300 cm/s (or a V_r of 4.0) to be the critical threshold above which lesion regression was relatively unlikely (Fig. 63.9).[236,237] Intermediate stenoses (200 cm/s < PSV < 300 cm/s; $2 < V_r < 4$) are notably dynamic, with 20% to 30% of these lesions demonstrating significant regression within 2 years. Complicating these retrospective analyses, however, was the preexisting bias that high-grade stenoses mandate intervention, so the natural history of these high-grade lesions has been incompletely defined. Although the number of grafts with

Less 20% stenosis (normal)	<150	<1.5	Absent or mild spectral broadening in systole	Rescan in 6 months
20%-50% stenosis (mild)	>150	1.5-2.0	Spectral broadening throughout systole with no change in waveform	Rescan in 6 months
50%-75% stenosis (moderate)	>180	>2.5	Severe spectral broadening in systole with reversed-flow components	Rescan in 4-6 weeks; if lesion does not progress during two cycles of testing, increase scan interval to 3 months
Greater than 75% stenosis (severe)	>300	>3.5	Severe lumen reduction with a "flow jet"; damped distal velocity waveform	Recommend repair (urgent if average PSV < 45 cm/s or change in ABI > 0.15)
Low-Flow Graft				
Low flow	<40	—		Angiography and repair of a non–flow-limiting stenosis should be considered

ABI, Ankle-brachial index; *PSV*, peak systolic velocity; *V_r*, velocity ratio ($PSV_{at\ lesion}/PSV_{proximal}$).

Modified from Bandyk DF. Infrainguinal vein bypass graft surveillance: how to do it, when to intervene, and is it cost-effective? *J Am Coll Surg*. 2002;194(1 Suppl): S40–S50.

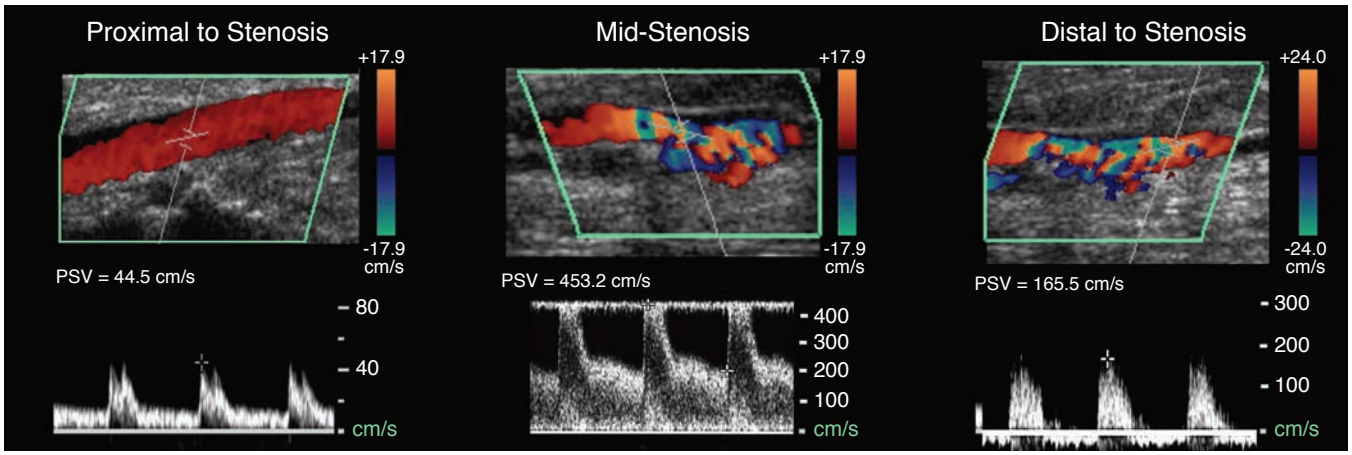

Figure 63.9 Postoperative duplex scan of a vein graft demonstrating markedly elevated peak systolic velocity and spectral broadening within an area of stenosis. Distal to the lesion, disordered flow is evident on color-flow imaging, and a significant reduction in diastolic velocity is observed.

high-grade stenoses that did not undergo elective revision is relatively small, the risk of occlusion of these unrepaired grafts appears to be in excess of 75%.[231,237] Predominantly based on these observations, an algorithm for the management of postoperative vein graft stenosis has been proposed,[234] with the key elements of this approach outlined in Table 63.3. Of particular concern are grafts with a PSV of greater than 300 cm/s and a change in the ABI of greater than 0.15 or significant dampening of the distal waveforms. These findings are generally thought to be preocclusive lesions, and initiation of systemic anticoagulation with prompt repair is indicated.

In parallel with these observational studies, multiple single-institution cohort studies have clarified the role of duplex surveillance in improving patient outcomes. Results from these studies are in general agreement and demonstrate an approximate 15% improvement in graft patency rates with routine duplex evaluation versus clinical follow-up alone.[238-240] Recommendations for the frequency of vein graft surveillance have been proposed and focus on the intermediate period (1-18 months), when lesion remodeling is most active. After an intraoperative or early postoperative scan to identify technical problems, outpatient duplex evaluations at 1, 3, 6, 12, and 18 months and annually thereafter are recommended. The development of moderate stenosis or the need for vein graft revision would prompt closer follow-up, with interval scans at approximately 6 weeks until lesion stabilization or regression is confirmed.

The economic benefits of a graft surveillance program have been investigated by a number of investigators, who have focused on major amputation as the dominant outcome variable.[241,242] Duplex scan surveillance was the least expensive ($2823) and resulted in the fewest major amputations (17 per 1000 patients examined) when compared with clinical follow-up alone ($5072 and 77 amputations per 1000 patients).[241] With the recognition that 90% of lesions that will require revision between 1 and 18 months will demonstrate some element of flow abnormality within 4 weeks,[243] investigators have questioned the need for continued aggressive surveillance after normal 1- and 3-month graft scans.[244] Longer-term follow-up has clarified this issue; one study reported that 30% of the flow abnormalities that ultimately required revision were not observed until after 6 months.[245] Annual examination to evaluate for graft atherosclerosis or aneurysmal degeneration and progression of native inflow-outflow arterial disease therefore seems warranted.

In an attempt to derive the potential benefit of routine surveillance while mitigating the expense, investigators have developed a risk prediction model for the development of stenotic lesions in the postoperative period. Combining the results of a 1-month duplex scan, location of the distal anastomosis, and a patient's smoking and diabetes status, patients are assigned to a relative risk category and a recommended protocol for postoperative surveillance.[246-248] While intriguing in its concept, the lack of prospective, multiinstitutional databases have limited its validation and potential application to clinical care.

Although the large array of cohort studies presents compelling data to support a routine duplex surveillance program, consensus on this issue is not uniform. Three randomized prospective trials were performed to evaluate vein graft surveillance and reached variable conclusions regarding its benefits. The first and smallest of these studies, published by Lundell et al. in 1995, randomized 156 patients after vein bypass grafts to either intense duplex surveillance or intermittent clinical follow-up.[249] Although major amputation was not explored as an endpoint, implementation of an intensive duplex protocol provided a 25% absolute improvement in both primary-assisted and secondary graft patency rates at 3 years. Among the confounding factors in this trial, however, was their use of frequent (every 3 months) follow-up in the duplex group but only annual follow-up in the clinical group. Consequently, a definitive conclusion on the value of duplex scanning versus more frequent clinical follow-up could not be obtained. The second trial randomized 342 patients between duplex and clinical surveillance and demonstrated no difference in graft patency or limb salvage at 1 year.[250] Though methodologically sound, the duration of follow-up was probably insufficient to realize the full benefit of serial duplex evaluation. The largest trial, in which 594 patients were randomized to a duplex or clinical protocol, demonstrated no difference in

major amputation or graft patency at 18 months.[251] Despite the use of a prospective randomized methodology, significant concern has been raised in regard to the validity of these findings.[252,253] Use of nonstandard duplex criteria resulting in an aggressive treatment approach to intermediate stenoses, delay in randomization until 4 to 6 weeks postoperatively (reducing the early benefit of duplex examination), and the short follow-up time were among the major issues that were raised.

Despite these potential methodologic flaws in the randomized trials, the available literature presents two diametrically opposing views on the relative value of a duplex surveillance program. Multiple cohort studies have exhaustively detailed the natural history of vein graft lesions and the perceived benefits of early detection and repair of high-grade lesions, yet all lack an appropriate control group. In contrast, the randomized trials suggest little benefit of duplex surveillance, but such generalization may be limited by notable methodologic flaws. Faced with this dilemma, the 2007 Inter-Society Consensus for the Management of Peripheral Arterial Disease came forth with a grade C recommendation supporting clinical surveillance only, with a focus on history taking for new symptoms, complete vascular examination of the extremity, and resting and postexercise ABI at 6-month intervals for a minimum of 2 years.[254] The consensus statement notes that the previous recommendation for routine duplex scanning after autogenous lower extremity bypass has not yet proved cost effective. Nevertheless, most surgeons continue a program of vein graft surveillance and remain skeptical of these negative findings.

INTRODUCTION

Arthur Voorhees and colleagues first described the use of a prosthetic graft to bridge arterial defects in 1952.[1] Since then, numerous advances have been made in fabric technologies, and a large variety of prosthetic grafts are currently available on the market. Currently, vascular surgeons use prosthetic grafts for several different indications, including aortic aneurysm repair, arterial bypass in the upper and lower extremities, and dialysis access creation.

Prosthetic grafts can play an important role in the management of vascular disease for those patients who do not have adequate autogenous conduit. Although surgical bypass with autogenous vein has a well-established record with documented long-term patency rates, a growing proportion of patients needing bypass surgery lack suitable venous conduit.[2,3] Reasons for this include previous harvesting of the veins for coronary artery bypass or prior lower extremity procedures, small vein caliber, active infection at the vein harvest site, and vein varicosities or thrombosis.

The advent of endovascular technology has resulted in a corresponding reduction in the number of surgical bypasses performed in vascular patients, with a concomitant increase in the complexity of patients that do require bypass, such as the scenario of failed endovascular intervention.[4] As such, lower extremity bypass with a prosthetic conduit continues to serve as a therapeutic choice in the revascularization of patients with limb ischemia.

Abstract

Arthur Voorhees and colleagues first described the use of a prosthetic graft to bridge arterial defects in 1952.[1] Since then, numerous advances have been made in fabric technologies, and a large variety of prosthetic grafts are currently available on the market. Currently, vascular surgeons use prosthetic grafts for several different indications, including aortic aneurysm repair, arterial bypass in the upper and lower extremities, and dialysis access creation.

Prosthetic grafts can play an important role in the management of vascular disease for those patients who do not have adequate autogenous conduit. Although surgical bypass with autogenous vein has a well-established record with documented long-term patency rates, a growing proportion of patients needing bypass surgery lack suitable venous conduit.[2,3] Reasons for this include previous harvesting of the veins for coronary artery bypass or prior lower extremity procedures, small vein caliber, active infection at the vein harvest site, and vein varicosities or thrombosis.

The advent of endovascular technology has resulted in a corresponding reduction in the number of surgical bypasses performed in vascular patients, with a concomitant increase in the complexity of patients that do require bypass, such as the scenario of failed endovascular intervention.[4] As such, lower extremity bypass with a prosthetic conduit continues to serve as a therapeutic choice in the revascularization of patients with limb ischemia.

BASIC PRINCIPLES

Materials

The ideal prosthetic conduit would be impermeable, compliant, biocompatible, durable, easy to sterilize, facile to implant, available in different sizes, resistant to thrombosis and infection, and cost-effective. Properties such as surface electronegativity, graft porosity, endothelial seeding, and heparin bonding have all been considered to improve graft function. Electronegativity on the graft surface plays a role in the inhibition of platelet aggregation with theoretic enhancement of this property by carbon-coating of the luminal graft surface. Graft porosity has not been shown to significantly affect graft thrombosis, but may be implicated in tissue ingrowth. Currently the most commonly used prosthetic materials are Dacron and expanded polytetrafluoroethylene (ePTFE), although there are several commercially available graft materials (Table 64.1).

TABLE 64.1 Selected Commercially Available Vascular Grafts in the United States

Material Type	Company	Product	Description
Standard			
ePTFE	Angiotech/Edwards Life Sciences (Irvine, California)	Lifespan	Re-enforced
	Atrium Medical Corporation (Hudson, New Hampshire)	Advanta VXT	Softwrap technology
		Advanta SST	Trilaminate, allows pulsation
		Advanta VS	60/20-μm through-pore design
		Flixene	Laminated with biomaterial film
	Bard Peripheral Vascular, Inc. (Tempe, Arizona)	Impra CenterFlex	Unmodified
	Boston Scientific (Natick, Massachusetts)	Exxcel Soft Vascular Graft	Unmodified
	B. Braun (Melsungen, Germany)	VascuGraft	Unmodified
	Vascutek, Ltd. (Renfrewshire, United Kingdom)	Maxiflo Ultrathin	Thin wall, external ePTFE wrap
		Maxiflo Wrap	Regular wall, external ePTFE wrap
	W.L. Gore & Associates Inc. (Flagstaff, Arizona)	Gore-Tex	Unmodified
		Gore-Tex Stretch	Stretch
		Gore Intering	Unibody, intrawall radially supported
Dacron	Braun	Protegraft	Knitted, double velour
	InterVascular, Inc. (Mahwah, New Jersey)	InterGard Ultrathin	Unmodified
	Vascutek, Ltd.	VP1200K	Unmodified
Sealed			
ePTFE	Vascutek, Ltd.	SealPTFE Ultrathin	Gelatin sealed, thin wall
		SealPTFE Wrap	Gelatin sealed, regular wall
		Taperflo	Gelatin sealed, tapered
Dacron	Atrium Medical Corporation	Ultramax	Knitted, gelatin sealed, double velour
	Bard Peripheral Vascular, Inc.	Vasculour II	Knitted, albumin sealed
	Boston Scientific	Hemashield Gold Microvel	Knitted, collagen sealed, double velour
		Hemashield Platinum	Woven, collagen sealed
	B. Braun	UniGraft	Woven, gelatin sealed, single/double velour
	InterVascular, Inc.	InterGard Woven	Woven, collagen coated
		InterGard Knitted	Knitted, collagen coated
	Vascutek, Ltd.	Gelseal	Knitted, gelatin sealed
		Gelsoft	Knitted, gelatin sealed
		Gelsoft Plus	Köper knitted, gelatin sealed
Heparin Modified			
ePTFE	W.L. Gore & Associates, Inc.	Propaten	Carmeda bioactive heparin coating
Dacron	InterVascular, Inc.	InterGard Heparin	Knitted, collagen coated

ePTFE, Expanded polytetrafluoroethylene.

Dacron

British chemists Whinfield and Dickinson developed the polyester fabric Dacron in 1941, and it is one of the oldest continuously used fabrics on the market.[5,6] Dacron grafts can be knitted or woven, and can also be reinforced by external rings for support (Fig. 64.1). Knitted grafts have the advantage of better compliance, but have larger pores that tend to leak and require preclotting. As such, modern versions of knitted Dacron grafts are coated with albumin to prevent leakage from such pores.[7] Dacron is a highly resilient fabric that is estimated to last more than 30 years, but these grafts are at a higher risk of dilation compared with other graft materials.[8] It is currently used primarily as a large-diameter graft in aortic and lower-extremity bypass surgery.

Expanded Polytetrafluoroethylene

ePTFE was described by Matsumoto and colleagues from Japan in 1973.[9] It is configured on a mandrel process with a nodal-fibril porous configuration with carefully constructed internodal distances to optimize function and healing properties. ePTFE grafts are available in several configurations: thin walled, ringed, and precuffed (Fig. 64.2). The precuffed configuration was an attempt to optimize graft hemodynamics, but this has been difficult to confirm.[10] The graft is produced by extruding a low porosity tube, producing a graft that is compliant, easy to suture, and does not need to be preclotted, in contrast to knitted Dacron grafts.[11]

Polypropylene and Polyurethane

Developed in the early 1990s, the early experience with the use of this hydrocarbon material was promising. Polypropylene's high tensile strength and relative inertness gave it an advantage over other prosthetic materials.[12] It also had a long history of successful use in suture and hernia mesh. Polyurethane grafts are produced by the reaction of isocyanates with an alcohol group.[5] The main advantage of polyurethane is high elasticity, but this material demonstrates poor biostability and loss of compliance after implantation limiting widespread clinical use.[6]

Composite Grafts and Allografts

The successful implementation of prosthetic grafts has triggered the development of novel materials such as composite grafts—biologic materials using human umbilical vein or ovine collagen.[13] While this type of material has yet to be used for lower extremity bypass, the conduit has been used in a hemodialysis access.[14,15]

Cryopreserved Vein and Human Umbilical Vein Grafts

Cryopreserved vein and human umbilical veins are alternative conduits that were first utilized in the 1960s. Cryopreserved grafts are relatively expensive compared with other prosthetic conduits and have a greater incidence of aneurysmal degeneration and thrombosis from late rejection. The current data from multiple centers reported a 30% to 58% patency rate at 1 year using cryopreserved veins for infrapopliteal bypass, which are inferior to autologous conduits and heparin-bonded ePTFE grafts.[16-18] However, given the biologic nature of the material, this graft may have value in bypasses that traverse infected fields in the absence of any autogenous conduit options, even as a temporizing procedure.

CLINICAL APPLICATIONS

Peripheral Bypass Grafts

Numerous studies have been carried out to compare Dacron and ePTFE grafts for lower-extremity bypasses. Rychlik and colleagues published a meta-analysis in 2014 that reviewed 91 publications and assessed 1192 patients who underwent above-knee femoro-popliteal bypass using Dacron versus ePTFE.[19] The authors reported similar 10-year primary patency between the grafts at up to 10 years, and no difference in the incidence of amputation, morbidity, or mortality between the patient

populations. A Cochrane review published in 2010 found that vein grafts were superior to prosthetic grafts, but that long-term outcomes using Dacron or standard ePTFE in the lower extremities were similar.[20] The inherent thrombogenicity of available polymeric materials and stimulation of hyperplasia, especially at the anastomosis, eventually leads to graft failure, whether a synthetic conduit is used for lower extremity revascularization or for arteriovenous (AV) hemodialysis access. A study of 4 mm lower extremity polypropylene grafts implanted in dogs by Greisler and colleagues from Illinois reported a 16-month patency of 81%, compared with 69% and 20% for Dacron and ePTFE, respectively.[12] Due to susceptibility to oxidation, however, polypropylene is only used as part of multicomponent grafts that render the polypropylene inert.[5] The use of human umbilical vein grafts has been impeded by aneurismal degeneration of the graft material. This complication has been addressed with recent modifications of the graft design, resulting in 61% patency at 36 months.[21] However, these grafts have also met with limited success when used for tibial bypass.[22] In a large National Surgical Quality Improvement Program (NSQIP) database, human umbilical vein composite grafts had a higher 30-day failure rate of 15.4%, compared with 10.5% in PTFE grafts and 7.5% in GSV conduits.[23]

Hemodialysis Access

The Fistula First Initiative has resulted in an increase of AV fistula use from 24% to 52% between 2000 and 2008. In that time frame, graft use decreased from 58% to 22%, and catheter use increased from 17% to 26%.[24] Prosthetic grafts for AV access can be indicated in patients with failed AV fistulas and lack of venous conduit. The most commonly used grafts are constructed from ePTFE, with early-access grafts having the advantage of earlier use and decreased need for catheter access.[25,26] Advantages of prosthetic AV grafts include ease of placement, shorter time from operation to utilization, and a potentially large surface area for cannulation. Grafts fail because of restenosis from intimal hyperplasia at the venous anastomosis as well as thrombosis and infection, which occur at higher rates compared with AV fistulas.[27,28]

Other Locations

Prosthetic grafts can deliver excellent long-term patency for visceral and renal arterial reconstruction because of the short

length that is required, high flow arterial beds, and the absence of extrinsic mechanical compression. Large-caliber venous reconstruction of the inferior or superior vena cava and the iliofemoral, jugular, and portal veins, including portosystemic shunts, can be performed with externally supported ePTFE grafts.[29-36]

Strategies for Improving Prosthetic Graft Patency

Autogenous vein remains the acknowledged ideal conduit for distal bypass, but there is a growing group of patients that either lack vein for bypass or have a disadvantaged vein as a conduit. This scenario has been identified for those veins with a diameter less than 3 mm, grafts of spliced vein segments, or a nonsaphenous venous conduit. Morbidity from vein harvest is also not insignificant, especially when greater saphenous vein is not available and construction of an autogenous conduit requires harvesting several segments, especially arm and lesser saphenous vein. Operative time can also be increased compared with bypass with a prosthetic conduit through two limited incisions. Improvement in outcome with prosthetic grafts may create an option for patients who lack autogenous material or have disadvantaged vein.

However, initial clinical outcomes with prosthetic grafts were severely suboptimal, with 1-year patency rates varying between 20% and 50%, with 3-year patency in 12% to 40%.[2,37-39] The results with prosthetic grafts were especially poor for tibial bypass. A comparison of venous and prosthetic conduits for infrapopliteal bypasses demonstrated a markedly inferior 2-year patency for prosthetic bypass to tibial arteries.[40] Thus efforts to improve outcomes for prosthetic grafts have focused on a reduction in the incidence of graft thrombogenicity and myointimal hyperplasia, venous adjuncts at the anastomosis, heparin bonding to the luminal surface, and the addition of a distal AV fistula.[41]

Vein Patches and Cuffs

Anastomotic techniques have been utilized to improve prosthetic graft performance. These efforts include interposition of venous tissue at the distal anastomosis. The Miller cuff involved interposition of autogenous vein at the distal anastomosis (Fig. 64.3A and B).[42] Miller reported on 114 infra-inguinal procedures using this vein cuff technique with a patency rate of 72% noted at 18 months.[42] However, several disadvantages have been recognized with this configuration, including significant turbulence at the anastomotic reservoir and difficulty in achieving an adequate angle between the graft and recipient artery. These factors might explain the immediate and early graft failures reported in Miller's initial series.

Subsequently, Taylor described a technique to address several of these concerns in which a composite of the prosthetic graft and a vein patch are anastomosed to the target artery (Fig. 64.4A and B). Reporting on 256 grafts with 83 tibial bypasses, Taylor and colleagues' 1-, 3-, and 5-year patency rates were 74%, 58%, and 54%, respectively.[43] However, using this technique, the tibial artery is directly exposed to PTFE graft material for the proximal half of the anastomosis, thereby losing the advantage of venous endothelium for half the anastomosis. There can also be a point of anastomotic constriction where the three suture lines converge between the artery, ePTFE, and vein patch. Finally, a significant length of vein must be available to accomplish the anastomosis using the Taylor technique. In addition, there can be difficulty in placement at the inframalleolar position due to space constraints.

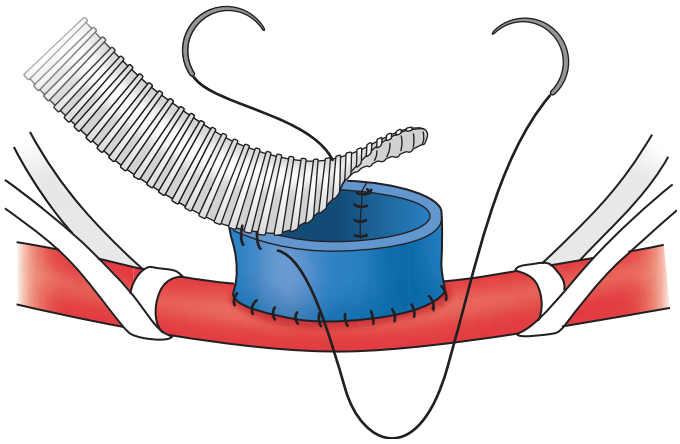

Figure 64.3 The Miller Cuff Technique. A venous cuff is interposed between a prosthetic graft and the target artery. (From Fischer's Mastery of Surgery, 7th ed., 2018; Kayssi A, Lee K, Neville RF. Section IX: Vascular Surgery, 198;1-8 Lippincott, Williams and Wilkins, Philadelphia, PA.)

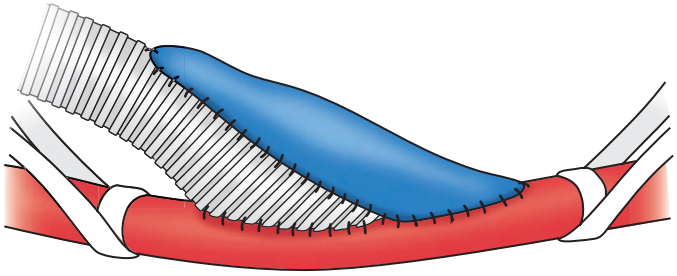

Figure 64.4 The Taylor Patch Technique. The graft is partially sutured onto the target artery, and a vein patch is used to suture the rest of the graft onto the artery and increase the anastomotic surface area. (From Fischer's Mastery of Surgery, 7th ed., 2018; Kayssi A, Lee K, Neville RF. Section IX: Vascular Surgery, 198;1-8 Lippincott, Williams and Wilkins, Philadelphia, PA.)

Several authors have studied clinical results and compared these techniques. Pappas and colleagues reported improved patency for prosthetic bypasses with the Miller cuff as compared with historic controls with standard ePTFE.[44] A prospective, randomized trial utilizing ePTFE grafts with and without a Miller vein cuff was reported by Stonebridge, who did not demonstrate a statistically significant benefit for the vein cuff technique in tibial bypasses, although there was a trend toward improved patency at 24 months.[45] Kreienberg compared grafts using ePTFE with a vein cuff versus composite saphenous vein grafts, and reported a similar primary patency at 2 years of 49% for the vein cuff patients versus 44% for the composite vein patients, with secondary patency rates somewhat better for the composite vein group.[46] The Albany group compared all bypasses with spliced vein segments to ePTFE and a Miller

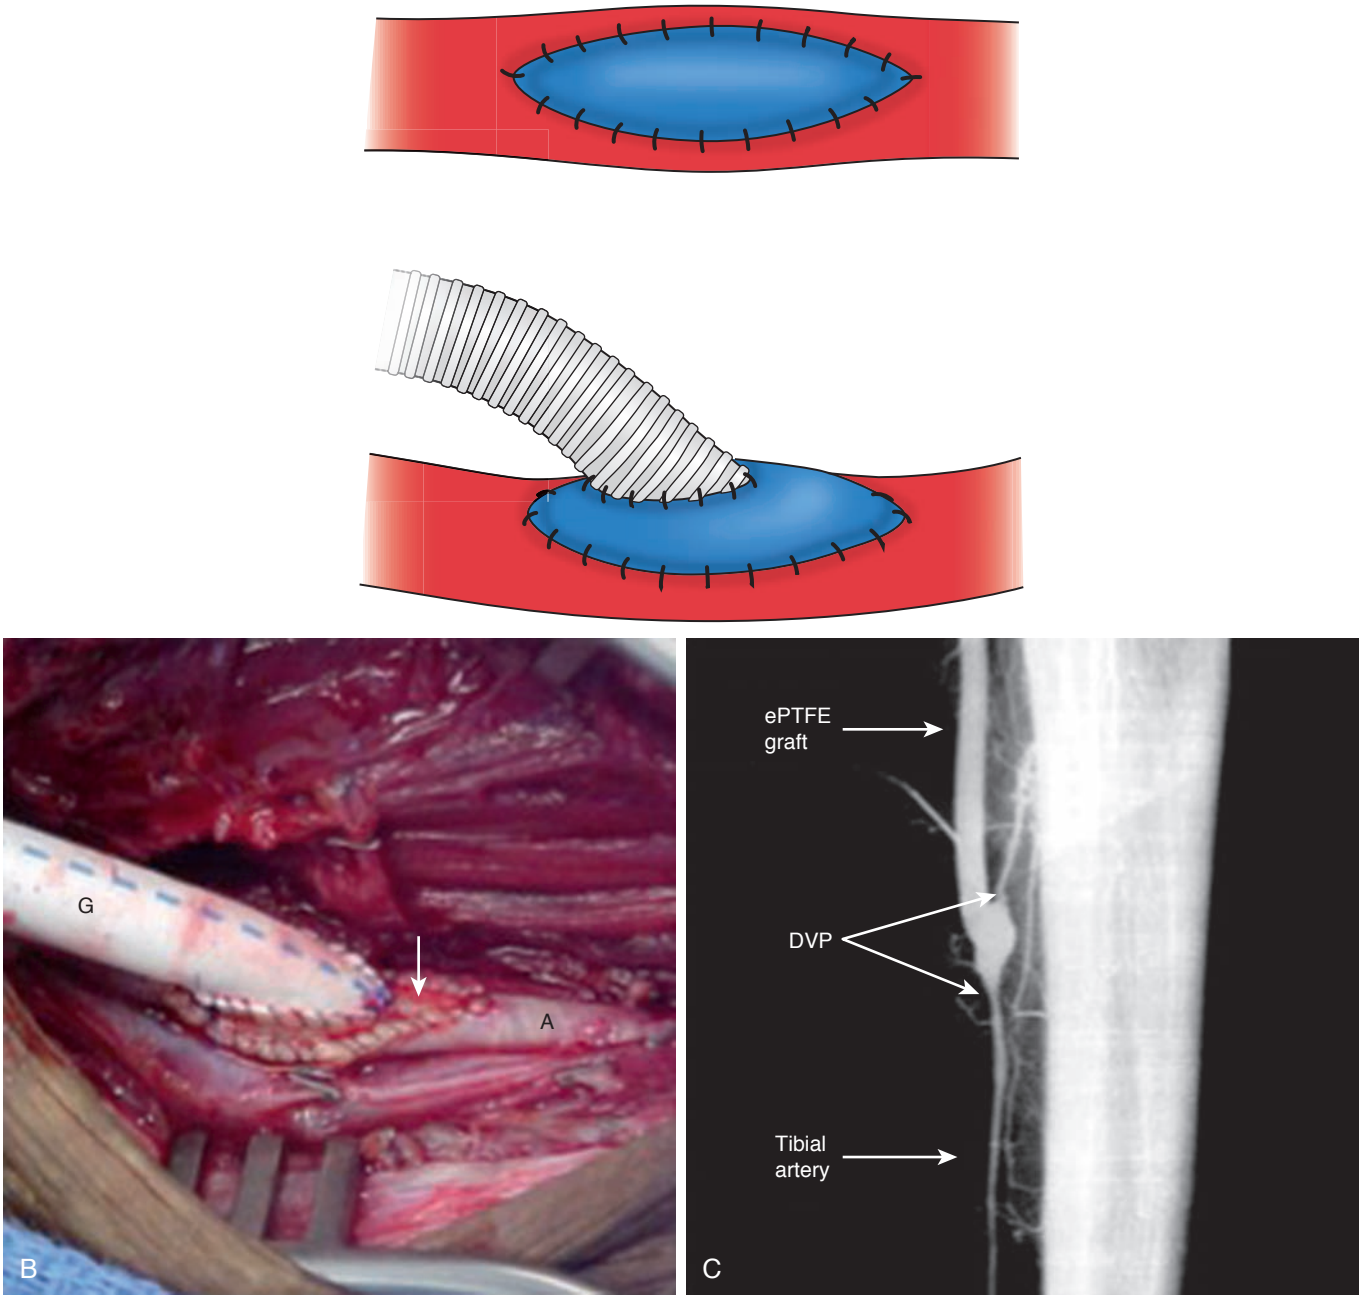

Figure 64.5 Distal Vein Patch (DVP) Technique. The distal arterial target is patched with a vein, and a prosthetic graft is sutured onto the proximal 2/3 of the patch. (Source: [A] Fisher's Mastery of Surgery.)

vein cuff.[47] The primary patency was better with the vein bypasses, although 25% of the spliced vein procedures required secondary revision to obtain these results. In addition, spliced vein procedures involved increased operative time, longer hospital stays, greater intraoperative blood loss, and greater perioperative morbidity.

The distal vein patch (DVP) technique was developed to take advantage of standard techniques known to all vascular surgeons with the potential benefit of a venous adjunct at the distal anastomosis of the prosthetic graft. While prior procedures were somewhat complex, involving multiple intricate suture lines while requiring a significant length of vein, the DVP technique incorporates ease of technique, with maintenance of the proposed advantages leading to improved outcomes for prosthetic grafts (Fig. 64.5A to C). The initial series of tibial artery bypasses using DVP for patients with limb-threatening ischemia was reported in 1997.[48] The DVP technique resulted in improved 4-year patency (62%) and limb salvage (79%) in

Comparative table including data gleaned from articles that reported results on specific data points with the Miller cuff, Taylor patch, St. Mary's boot, and distal vein patch. Data may have been collected in the context of a trial involving other techniques, and only data that could be gleaned from the publication regarding vein interposition techniques were used. While not a statistical comparison, this is as near a comparison of like-kind data as possible.
Source: Neville RF, Lidsky M, Capone A, et al. An expanded series of distal bypass using the distal vein patch technique to improve prosthetic graft performance in critical limb ischemia. *Eur J Vasc Endovasc Surg.* 2012;44:177-182.

a group of patients without adequate saphenous vein conduit options.[49] Since that report, the DVP technique has been used to perform more than 400 cases representing 23% of the authors' total tibial experience during that period. A report of this larger cohort resulted in 50% primary patency at 4 years (Table 64.2).[50] Secondary patency through thrombectomy and revision of the distal anastomosis can be obtained under local anesthesia. Prosthetic grafts often fail due to hyperplasia at the suture line between the graft and recipient artery, resulting in thrombosis of the recipient artery. When the DVP bypasses fail, the recipient artery rarely occludes because the hyperplastic response occurs primarily between the vein patch and ePTFE material, leaving the native artery patent and available for revision. This allowed reestablishment of graft patency by thrombectomy with revision of the distal anastomosis by extension of the patch (Fig. 64.6).

The advantages of a venous adjunct at the distal anastomosis derive from both biologic and mechanical factors. Venous endothelium may confer a beneficial effect through fibrinolytic and antiplatelet activity, although these effects remain unproven. The mechanical factors of shear stress and compliance mismatch have also been implicated in prosthetic graft failure. Theoretically, vein interposed between a stiff prosthetic graft and a more

pliable artery would minimize the expansibility mismatch created with pulsatile flow and thus decrease mechanical injury at the anastomosis. Anastomotic geometry may be altered by the presence of vein at the distal anastomosis, thereby positively effecting turbulence and shear forces that play a role in the hyperplastic process. The DVP anastomosis configuration results in a small vortex of turbulent flow at the heel and a more streamlined flow pattern at the toe (Fig. 64.7A and B).[10] Finally, it is possible that venous tissue simply enlarges the distal anastomosis so that the formation of hyperplasia must encroach on a wider lumen before becoming clinically significant. The venous tissue is also technically easier to suture to small, calcified tibial arteries, as the secondary suture line between the PTFE and vein is more technically appealing.

Heparin-Bonded Grafts

The bonding of heparin on the inner surface of a prosthetic conduit has been used in an attempt to reduce graft thrombosis and hyperplasia.[10] End-point covalent bonding of heparin to the luminal surface of the graft maintains the bioactivity of the heparin molecule.[51] This process reduces platelet adherence, acute thrombosis, and anastomotic intimal hyperplasia in canine and primate models.[52] Heparin bonding using the Carmeda bioactive surface technology (CBAS, Carmeda, Upplands Vasby, Sweden) allows binding of the heparin molecule to the luminal surface of ePTFE grafts while maintaining the morphology of the heparin molecule and hence its bioactivity. This process leads to a reduction in platelet deposition on the graft surface in animal and human models. Heparin bonding also reduces thrombus formation on the surface of the graft, with a subsequent decrease in graft thrombogenicity in acute and chronic models. A reduction in myointimal hyperplasia at the anastomotic site has been demonstrated with heparin-bonded biomaterial surfaces. Decreased platelet adherence, thrombus formation, and inhibition of myointimal hyperplasia could be hypothesized to decrease both early and late graft failure.

Initial clinical experience with heparin-bonded grafts was encouraging as compared to historical results with standard prosthetic grafts. Walluschek reported 80% 1-year patency for below-knee bypasses.[53] Furthermore, Bosiers reported primary and secondary 1-year patency rates of 82% and 97%, respectively, with little difference between popliteal and tibial bypasses.[54] A multicentered randomized-controlled trial of heparin-bonded Dacron versus ePTFE for femoropopliteal bypass reported greater patency rates with Dacron than with ePTFE at 3 years, but the advantage was not sustained at 5 years.[55] This was a small study of primarily above-knee bypasses that limits its generalizability to the infrapopliteal vascular beds. In regard to tibial bypass, recent data implies that heparin-bonded ePTFE grafts may be statistically noninferior to venous conduit although autogenous vein remains the ideal conduit for lower extremity bypass.[50,56-59] Comparison of primary patency and amputation rates achieved for tibial bypass with heparin-bonded ePTFE and great saphenous vein support the dictum that an intact, quality vein remains the preferred conduit for distal bypass (Fig. 64.8). However, the results with heparin-bonded ePTFE indicate that this conduit is an acceptable alternative choice when a quality, intact great saphenous vein is unavailable for tibial bypass.

A comparison of tibial artery bypass performed with heparin Bonded ePTFE and greater saphenous vein to treat critical limb ischemia. *J Vasc Surg.* 2012;56(4):1008-1014.)

Heparin-induced thrombocytopenia is a potential concern with implantation of heparin-bonded grafts. This phenomenon has been described in few case reports of patients undergoing lower-extremity bypass grafts despite the larger number of implants performed worldwide.[60-63] However, platelet counts were improving prior to graft explantation in cases where covalently bonded grafts were used, as compared with older grafts that used ionic interaction with the graft surface, leading to subsequent release of the heparin into the bloodstream.[64] Furthermore, a study of covalently bonded grafts found no increase in the systemic markers of hemostasis in vivo, and no antibodies against heparin were detected up to 6 weeks after implantation.[65]

Spiral Laminar Flow Grafts

Stonebridge and colleagues have reported that physiologic flow in blood vessels may not be laminar in the conventional sense, but a spiral laminar pattern of blood flow.[66] It was hypothesized that inducing such a spiral laminar flow pattern in prosthetic grafts may result in an inhibition of formation of neointimal hyperplasia and stabilize flow patterns through stenotic areas. Conceptually, a reduction of the laterally directed forces on the vessel wall, thereby improving shear forces, as well as reducing the expression of adhesion molecules, would inhibit the formation of neointimal hyperplasia.[67,68] A spiral laminar flow graft was developed (Vascular Flow Technologies, Dundee, United Kingdom; Fig. 64.9). Stonebridge and colleagues reported primary patency rates of 86%, 81%, and 81% (12, 24, and 30 months) for above-the-knee bypasses and 73%, 57%, and 57% for below-the-knee bypasses, respectively.[69] To date, there are no published randomized controlled trials comparing the efficacy of spiral laminar flow grafts with ePTFE or Dacron grafts.

Distal Arteriovenous Fistula

When the target artery outflow of a distal bypass is compromised, the addition of an AV fistula at the distal anastomosis has been used to increase the chances of bypass success. Dardik used a common ostium AV fistula in an attempt to decrease graft thrombosis by reduction of outflow resistance.[21] Ascer and colleagues described a technique involving construction of an AV fistula between the target tibial artery and corresponding tibial vein with a ePTFE bypass to the involved vein.[70] Reported patency rates with this technique were 62% at 36 months, despite a fistula thrombosis rate of 37%. A prospective, randomized trial compared distal bypasses using ePTFE with a Miller vein cuff with and without an AV fistula demonstrated that the fistula conferred no benefit, but the authors did not stratify patients based on arterial runoff.[71]

The addition of a common ostium AV fistula to the distal anastomosis of a DVP bypass has also been described. This modification has been performed in patients with no vein available and severely disadvantaged arterial runoff. The target tibial artery is opened longitudinally and a venotomy is created in the corresponding tibial vein (Fig. 64.10). The vein patch is then sutured to the common ostium created by this fistulous connection. An anastomosis is then constructed between the vein patch and the ePTFE, as described in the DVP bypass configuration (Fig. 64.11). Theoretically, the distal AV fistula decreases outflow resistance, reduces overload on a fixed arterial circuit, and increases flow velocity in the graft above the critical thrombotic threshold to improve graft function and decrease the incidence of thrombosis with bypass in the setting of disadvantaged runoff. Results using this technique have been reported and resulted in a 62% primary patency and 57% limb salvage rate at 24 months in a series of patients who would otherwise have undergone primary amputation.[72]

Adjunct Medical Therapies

The role of adjunct medical therapy in improving prosthetic graft patency has been debated, and there is no clear, consistent data to suggest an ideal adjunct medical therapy to improve prosthetic graft function. A Dutch multicenter randomized study compared 2690 patients who underwent infra-inguinal bypass both using vein or prosthetic grafts and randomly assigned patients to aspirin versus warfarin therapy. Overall data did not show any advantage of one therapy over another, but when separated into prosthetic conduit versus vein, the prosthetic group had better results with aspirin alone, whereas the vein

group had better results with warfarin alone.[73] The Boston Veterans Affairs Hospital Prospective Study compared dual therapy (aspirin and warfarin) versus aspirin alone, and showed no difference in overall patency between the two groups. The dual therapy seemed to show benefit for smaller (6 mm) prosthetic grafts. However, there was a twofold increase in major hemorrhagic complications and a higher mortality rate.[74] Finally, the Clopidogrel and Acetyl Salicylic Acid in Bypass Surgery for Peripheral ARterial Disease (CASPAR) trial looked at the efficacy of dual therapy with clopidogrel and aspirin versus aspirin alone in distal bypasses. Dual therapy did not appear to reduce the occlusion rates in venous bypasses. However, in a subgroup of patients with prosthetic grafts, such dual antiplatelet therapy reduced the relative risk of graft occlusion by 35% without any deleterious side effects or major hemorrhagic event.[75] Bedenis and colleagues published a Cochrane Review on the role of antiplatelet medications in preventing postoperative thrombosis after lower extremity bypass, and similarly reported an improved graft patency with aspirin for up to 12 months in patients with prosthetic grafts.[76] The role of direct thrombin inhibitors and factor Xa inhibitors for peripheral bypass graft has not been adequately explored in literature. Some attempts have also been made to develop novel agents to prevent intimal hyperplasia in order to improve graft patency. So far, however, no new agents have been shown to have successfully achieved this goal.[77]

Graft Surveillance

Despite technological advances leading to improved performance of prosthetic conduits, graft failure continues to occur either perioperatively to "technical error" or after a prolonged period due to development of myointimal hyperplasia or acceleration

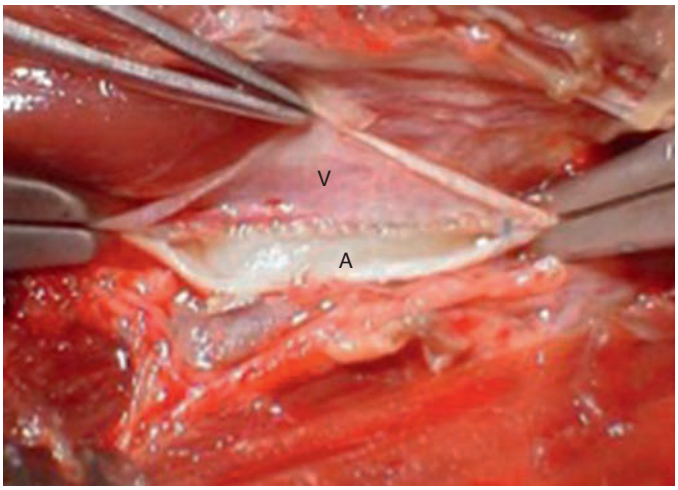

Figure 64.10 **"Patchula" Technique.** The target tibial artery and corresponding tibial vein are opened longitudinally and a common ostium is created with an onlay patch.

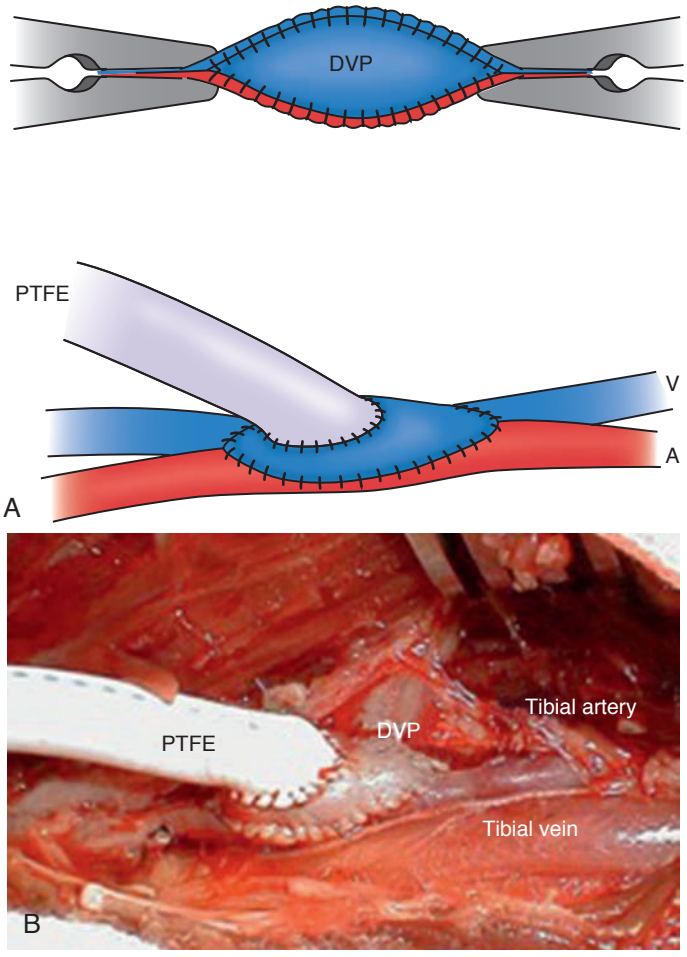

Figure 64.11 **"Patchula" Technique.** A distal vein patch (DVP) bypass is constructed using the patch over the common ostium in the usual manner. This creates a DVP bypass with concomitant anastomotic arteriovenous fistula. *PTFE*, Polytetrafluoroethylene.

of atherosclerosis in the proximal or distal arterial bed.[50,78] As such, it is important to detect the failing graft prior to thrombosis because the management and treatment of such grafts is often more complex than procedures required prior to graft occlusion. Early identification of these patients allows for a more tailored medical therapy that may improve outcome in the future. The addition of warfarin, though not without its side effects, has been shown to have benefit in patients with low velocity grafts.[79] Close surveillance also allows for early endovascular intervention, which may assist in maintaining patency for a longer period of time. A Dutch study, using aggressive surveillance and endovascular intervention, was able to achieve a near 90% patency rate for infra-inguinal bypasses at 2 years.[80] A failing graft can often be managed with endovascular techniques or more simplified surgical procedures such as local revision with patch angioplasty, resulting in enhanced secondary patency and enhanced limb preservation. Therefore graft surveillance programs have been incorporated in most vascular surgical practices to detect failing grafts and intervene early enough to improve graft function and secondary patency rates.

Graft surveillance involves clinical evaluation for recurrent or new symptoms of limb ischemia, as well as an examination of pulses and an ankle brachial index.[81] However, clinical assessment alone does not always identify significant stenoses that threaten graft function, especially in patients initially treated for critical limb ischemia. Therefore vascular laboratory imaging has been added to surveillance protocols as a noninvasive assessment of graft function. While the overall benefit of graft surveillance has not been well documented for prosthetic grafts, regular interval duplex ultrasound studies obtained at 3, 6, and 12 months postoperatively and then annually have been employed in many practices to identify threatened bypasses before they occlude.

Numerous authors have attempted to define the Doppler ultrasound criteria that should prompt further workup and potential repair of a "failing" graft. Bandyck has suggested that a peak systolic velocity exceeding 300 cm/s on Doppler ultrasound and a peak systolic velocity ratio across the stenosis exceeding 3.5 correlates with more than 70% stenosis in a graft.[82] Another study by Brumberg and colleagues demonstrated that mid-graft peak velocity of 45 cm/s or less was predictive of graft failure.[83] Sanchez and colleagues reported a series looking at surveillance in order to detect failing ePTFE grafts.[84] These authors reported on a 12-year experience with more than 90 ePTFE grafts and surmised that ultrasound surveillance was useful despite the observation that the progression of proximal and distal arterial disease was the primary cause of ePTFE graft failure in the series. These authors concluded that frequent graft surveillance may allow for the detection of hemodynamically threatening lesions prior to graft thrombosis and enhance long-term graft patency and function as the 5-year patency and limb preservation rate for treating "failing" ePTFE grafts was substantially improved over that for ePTFE grafts that have gone on to occlude. A smaller study from Sweden randomized 156 patients between clinical surveillance and surveillance that included Duplex ultrasound evaluation. Although only 40 of

the grafts in the trial were ePTFE grafts, the authors noted improved assisted primary and secondary patency in the group with regular Duplex ultrasound surveillance.[85] More recently, a combined experience from Boston and the Netherlands found ultrasound surveillance to be effective in leading to a reduction in amputation and cost.[86]

LIMITATIONS AND RISKS

Graft Failure Modes

The failure of prosthetic conduits can be classified as early, midterm, or late. Early failures that occur in the first month after surgery are commonly due to technical problems during surgery and the presence of underlying thrombophilia. Technical problems encompass more than procedural and suturing issues, such as poor/limited choice of inflow or outflow targets, or other operational related difficulties. Midterm graft occlusions occur between 6 and 24 months after surgery and are usually due to myointimal hyperplasia at an anastomosis. The interaction among blood, host artery, and graft initiates a complex set of biochemical and cellular responses that ultimately limit implant function. Finally, late graft thrombosis occurs several years after implantation and is frequently secondary to the progression of proximal or distal atherosclerotic disease.

The Blood-Material Interface

Prosthetic grafts with blood-compatible materials attempt to minimize activation of the body's prothrombotic and hyperplastic responses. The full spectrum of this response includes a combination of lipids, proteins, and cells that act in concert to provide localized amplification. A series of negative feedback mechanisms control the propagation and termination of these responses. The inability of current prosthetic materials to replicate these complex systems plays a role in graft failure.

Cellular Interaction and the Coagulation Cascade

When blood encounters an artificial surface, adsorption of proteins activates the complement and coagulation cascades. Activation of the complement system may contribute to surface-induced thrombosis through platelet activation, as well as monocyte and neutrophil infiltration, which also have been implicated in the development of myointimal hyperplasia.[87] Discussion of the coagulation system is beyond the scope of this chapter, but binding of plasma factor XII to prosthetic surface results in a conformational change that yields an activated form, XIIa, which catalyzes this cascade.[88,89] Blood flow modulates this process by controlling the rate at which coagulation proteins and activated factors are delivered to or removed from the graft surface. Locally disturbed flow or turbulence at an anastomosis creates recirculation regions that stimulate coagulation factors. Platelets are the major cellular component of the thrombotic response and are involved in both complement-mediated and T-cell–mediated immune responses.[90] Increased levels of platelet-generated thromboxane continue to be observed 1 year after graft implantation in animals, and clinical studies have revealed persistent platelet deposition on Dacron grafts for at least several months.[91-94] Antiplatelet agents can reduce platelet deposition onto prosthetic grafts.[95,96] Despite their role in the phagocytosis of foreign material and bacteria, neutrophils recruited to a biomaterial surface do not protect against infection.[97] Activated macrophages express tumor necrosis factor-α as well as growth factors that may stimulate smooth muscle cell (SMC) proliferation and contribute to intimal hyperplasia.[98,99]

Migration of endothelial cells from the peri-anastomotic area results in the formation of a neointima extending no more than a few centimeters from the anastomosis with little coverage of the midportion of the graft. However, scattered islands of endothelial cells have been observed far from the anastomotic regions due to transmural ingrowth of microvessels from perigraft tissue or adherence of blood-borne endothelial progenitor cells (EPCs).[100-106] Endothelial cells that grow onto prosthetic graft surfaces often display a procoagulant phenotype and promote rather than hinder graft thrombosis. Activated endothelial cells may increase growth factor production and thereby encourage SMC proliferation.

Graft Complications

Complications after placement of a prosthetic graft include bleeding, infection, occlusion, seroma formation, pseudoaneurysm, and rarely steal phenomenon secondary to inadequate proximal blood flow. A detailed discussion of all graft-related complications is beyond the scope of this chapter, but the two most important complications, graft thrombosis and infection, are briefly outlined as follows.

Graft Thrombosis

As previously discussed, implanted prosthetic grafts can develop myointimal hyperplasia and eventually thrombose, leading to graft occlusion. When myointimal hyperplasia results in the development of a hemodynamically significant stenosis prior to graft thrombosis, the bypass is referred to as a "failing graft," with diminished function.[107] Flow in a "failing graft" is hemodynamically compromised, but may not result in clinical signs or symptoms of diminished flow. Revision of failed grafts often requires a more complex procedure with increased morbidity and mortality as compared with an intervention to maintain assisted primary patency. Therefore routine surveillance is often performed to monitor graft function prior to total occlusion.

When graft failure does occur, the result is often a return of the patient's original symptoms or a significant increase symptom severity. Prosthetic graft occlusion might also lead to significant morbidity. Thrombosis of bypasses performed for intermittent claudication can lead to limb threatening ischemia and possible limb loss.[108] The treatment of lower extremity prosthetic bypass graft occlusion is tailored to the patient and guided by the clinical presentation and patient's anatomy. A patient with an occluded graft but no concurrent signs of critical limb ischemia, such as rest pain, night pain, or tissue loss, would benefit from a trial of thrombolysis to both restore flow within the graft and unmask any underlying stenotic lesions that would be amenable to endovascular or open surgical treatment. Conversely, a patient with critical limb ischemia or a

chronically occluded graft should undergo operative exploration for an open thrombectomy or creation of a new bypass.

Since its introduction in the 1970s as a technique to restore occluded arteries, thrombolysis is now a commonly used modality for treating occluded arteries, veins, and prosthetic grafts.[109] Thrombolysis can be administered systemically or as part of a catheter-directed or mechanical approach using specialized catheters. However, there are numerous contraindications to this treatment approach, including recent surgery, hemorrhagic strokes, bleeding disorders, and a nonviable limb.[110] Several retrospective studies have described an early technical success of 48% to 90% and a limb-salvage rate of 56% to 82% with thrombolysis.[111-117] The Surgery or Thrombolysis for the Ischemic Lower-Extremity (STILE) trial and the Thrombolysis or Peripheral Arterial Surgery (TOPAS) trial investigators assessed thrombolysis versus thrombectomy for limb ischemia, and reported that thrombolysis was superior to surgical thrombectomy in patients with fewer than 2 weeks of symptom duration, whereas surgical thrombectomy was superior to thrombolysis when symptoms lasted for 2 weeks or longer.[118,119]

Patients with more than 2 weeks of symptom duration should be considered for operative intervention and placement of a new bypass graft if feasible. Conversely, patients with acute (fewer than 2 weeks' duration) prosthetic graft occlusions and no evidence of critical limb ischemia can be considered for a trial of thrombolysis, but can also undergo a new bypass graft especially if there is a suitable outflow target vessel and an adequate length of autogenous conduit is available.[120]

Graft Infection

Prosthetic graft infection occurs in 1% to 6% of patients undergoing lower-extremity bypass and 0.5% to 2% of patients undergoing abdominal aortic repair.[121,122] These infections are associated with considerable morbidity, including amputation rates of 10% to 70%, and mortality rates up to 20%.[123,124] The most common causative organisms are *Staphylococcus* species, *Staphylococcus aureus* and *Staphylococcus epidermidis*.[122,125] The origin of the graft infection is often microorganisms seeded at the time of the operation, or postoperatively through wound complications, adjacent infections, or a bloodstream infection from a distant source. Predictors of prosthetic graft infection include reoperative bypass, female gender, diabetes, and active infection at the time of bypass.[126] There is no evidence that a particular type of graft material, such as Dacron or ePTFE, is more predisposed to infections compared with other materials.[127]

The diagnosis and management of graft infections is guided by the patient's clinical status and the type and extent of the infection. Patients typically present with fever and malaise, with or without a wound infection and purulent discharge. Elderly, malnourished, and frail patients may not mount an adequate inflammatory response to indicate an active infection. Patients with suspected graft infections should have blood cultures, and if applicable, cultures should be sent. Patients should then be started on broad-spectrum antibiotics that are reviewed when the culture results and antibiotic sensitivities are reported. Imaging should be obtained in the workup of patients with a suspected graft infection. Acceptable modalities include computed tomography (CT) angiography, ultrasonography, magnetic resonance imaging, Gallium scanning, and rarely labeled white blood cell scanning. Radiologic findings suggestive of graft infection include perigraft air, fluid or soft-tissue attenuation, and pseudoaneurysm formation.[128]

There are several treatment strategies for graft infections, depending on the patient's status and the type of infective organism. Graft preservation is sometimes possible in patients with limited infections and no signs of sepsis or extensive graft involvement with sparing of the anastomosios.[129] Grafts that are infected with *Pseudomonas* and methicillin-resistant *Staphylococcus aureus* (MRSA) are particularly virulent organisms that require removal of the infected graft.[121,130] In patients with graft thrombosis and clinical evidence of adequate collateralization, graft excision alone might be sufficient. In patients who require revascularization of the excised graft segment, an in situ graft can be placed or an extra-anatomic bypass might be created. Conduit options include autogenous, cryopreserved, and rifampin-soaked prosthetic grafts. The graft excision and replacement may be done concurrently or in a staged manner, depending on the patient's clinical status.

If patients are known to be MRSA-positive, then a decolonization strategy should be pursued prior to the surgery whenever possible. Moreover, given the devastating complications associated with prosthetic graft infections, some have advocated for regular pre-operative screening and, when detected, decolonization of MRSA. Lee and colleagues analyzed the economic impact of screening all vascular surgery patients prior to a vascular surgical procedure, and demonstrated that testing and decolonizing patients for MRSA may be cost-effective.[131]

FUTURE ADVANCES

Despite substantial advancements in prosthetic graft technologies and their associated clinical outcomes, current grafts are still inferior to autogenous vein grafts. As such, the quest continues for a durable prosthetic conduit that is resistant to intimal hyperplasia and infection while providing patients with long-term patency. Bioengineered human acellular vessels have emerged as a promising technology. These conduits are constructed from banked human vascular SMCs cultured on a biodegradable polymer. A process of decellularization then removes viable tissue elements, leaving an intact conduit with preservation of mechanical properties. A recently published trial utilized this conduit for dialysis access at six centers in the United States and Poland.[132] Trial endpoints were freedom from adverse events (immune reaction, pseudoaneurysm, infection) and patency rates. The acellular vessel was implanted into 60 patients with mean follow-up of 16 months. These bioengineered conduits demonstrated no dilation and minimal post cannulation bleeding with 6-month primary patency of 63% (primary assisted patency 73%, secondary patency 97%). Thrombosis at 12 months resulted in a 28% primary patency (primary assisted patency, secondary patency 89%). The rate of reintervention was similar to reported rates with ePTFE, including 16 venous anastomotic revisions showing no demonstrable reduction in

anastomotic hyperplasia. There were, however, no reports of systemic immune reaction or excessive inflammatory response. Although cannulation-related pseudoaneurysms were noted in some patients, no true aneurysmal degeneration of the vessels occurred. Although patency rates were acceptable, there was not an obvious improvement over prosthetic graft results, and patency was not as good as that with AV fistula construction. However, the potential benefits and significant scientific efforts surrounding this conduit support further testing and a larger controlled clinical study.

Another future avenue for improving prosthetic conduit outcomes includes the use of remote monitoring of graft function to detect early hemodynamic changes prior to graft failure. As noted previously, prosthetic grafts fail due to myointimal hyperplastic stenosis and thrombosis. Graft surveillance is used to monitor function; however, graft failure can occur between these episodic examinations. An innovative micro sensor with wireless, microchip technology may allow automated surveillance with assessment of graft function using a cloud-based algorithm. In vitro flow data has demonstrated the ability of the device to determine factors related to prosthetic graft function under varied hemodynamic flow conditions. Wireless signal acquisition using Bluetooth technology allows remote data analysis reflecting graft flow parameters through changes in microsensor voltage and frequency. Waveform analysis was applied to construct an algorithm using proprietary software, thereby determining parameters for graft flow characteristics as well as determination of degree of stenosis and location of stenosis. Subsequent in vivo experiments have confirmed the ability of the system to generate signal acquisition through skin and soft tissue under biologic conditions.[133] This automated system shows promise to deliver real-time data that can be analyzed by cloud-based algorithms alerting the clinician of a change in graft function or development of stenosis for further diagnostic study or intervention prior to graft failure.

In the field of vascular surgery, the use of surgical bypass is fundamental to the treatment of a wide variety of arterial and venous disorders. In turn, the technical conduct and success of surgical bypass are directly dependent on the conduit used. The ideal conduit should be readily available, easy to handle, resistant to thrombosis and infection, durable, inexpensive, and should have characteristics similar to the vessel that it is replacing.

Although the perfect conduit does not exist, autogenous blood vessels are closest to the ideal. Autogenous arterial conduits, such as the internal mammary, radial, and gastroepiploic arteries, have been used with great success in the coronary circulation.[1-3] The internal iliac and radial arteries have been used in the visceral vascular bed,[4,5] and the superficial temporal artery has been used for extracranial-intracranial bypass.[6] Unfortunately, short conduit length and invasive harvest have limited the use of autogenous arterial grafts to a relatively small number of clinical scenarios.

Autogenous vein has been the preferred conduit for infrainguinal bypass because long lengths of vein can be harvested, removal is inconsequential, and harvest complexity is minimal.[7] Autogenous veins have been used for the bypass of upper extremity,[8] carotid,[9] coronary,[1] and visceral[10] arterial beds. They have also been preferentially used in the construction of arteriovenous fistulae (AVFs) for hemodialysis.[11]

Although autogenous vascular grafts perform well, there are multiple clinical situations in which these conduits are inadequate, unavailable, or improperly matched to the recipient vascular bed. These unmet demands led to the development of artificial grafts. Although multiple materials have been tried, polyethylene terephthalate (Dacron, DuPont, Wilmington, Delaware) and polytetrafluoroethylene (PTFE) have emerged as the standard materials for prosthetic vascular grafts. These grafts have been used with excellent success for the bypass of large vessels, such as the aorta and iliac arteries,[12] and medium-sized vessels, such as the subclavian artery.[9] Prosthetic grafts have also been used extensively for dialysis access[11] and with mixed results for infrainguinal revascularization.[13] Dacron and PTFE grafts offer "off-the-shelf" availability and a variety of sizes to permit replacement of even the largest vessels. In general, however, they cannot be used in infected fields, and compared with autogenous conduits, are at increased risk for infection,

Abstract

Certain circumstances cause limitations for the use of autogenous and prosthetic grafts, and other potential conduits are often needed in clinical practice. Extensive research has led to the development of numerous biologic grafts, which are useful under different clinical scenarios. Although they are still not the ideal conduits, these biologic grafts have become an important part of the armamentarium available to vascular surgeons.

structural deterioration, and occlusion. Although patency rates are acceptable for aortoiliac reconstruction because of high flow rates and low outflow resistance, bypass to smaller targets, such as the tibial arteries, is associated with low graft patency.

Limitations of autogenous and prosthetic grafts have fueled exploration for other potential conduits, and this investigative effort has led to the evaluation of biologic grafts for bypass. Biologic grafts, or biografts, are bypass conduits made of nonautogenous biologic vessels modified for use in clinical practice. Allografts or homografts refer to arteries or veins that are transplanted from one individual to another within the same species. Xenografts or heterografts are vessels transplanted from an individual of one species to an individual of another species.

Carrel[4] was first to experiment with fresh allografts and xenografts in dogs during the first decade of the 20th century. The first recorded human use of allografts, obtained from casualties, occurred during World War I.[14] In 1948, Gross et al.[15] described the first clinical series of fresh arterial allografts, and less than a decade later, Linton[16] published his series of fresh venous allografts. Various methods of allograft cryopreservation were developed in the 1950s,[16] refined in the 1970s,[17,18] and finally standardized and commercialized in the late 1980s.[19] In parallel, enzymatically treated and tanned bovine carotid artery (BCA) xenografts were evaluated and first described in a clinical setting in 1966.[20] Application of similar techniques to human vessels led to development of the human umbilical vein (HUV) graft by Dardik and Dardik in 1976.[21]

Theoretically, biografts promise to be the optimal vascular conduit. They can potentially offer "off-the-shelf" availability, a wide variety of sizes, excellent handling characteristics, and patency rates similar to those of autogenous vessels. These attractive features prompted scientific investigation and clinical use of these conduits that has spanned the course of almost a century. Although this collective experience with an assortment of biografts in a variety of clinical settings led to specific clinical indications for their use, biologic grafts have failed to become the "Holy Grail" of vascular surgery.

GRAFT PROPERTIES

Fresh Vascular Allografts

Fresh arterial and venous allografts have been studied in animal experiments.[22-24] In one canine model, fresh venous allografts had a patency rate of 69% at 20 months. Pathologic analysis of explanted veins revealed intimal proliferation, medial inflammation, medial degeneration, and periadventitial fibrosis.[23] In another canine venous allograft experiment, dogs that were immunosuppressed with azathioprine demonstrated slightly better graft patency than those that were not.[24] Conversely, in a murine model, fresh venous allografts implanted in rats had excellent patency rates and minimal intimal thickening on histologic analysis.[24]

In humans, fresh venous allografts used for infrainguinal bypass had a failure rate of 55% in one series, which failed grafts either occluded or became aneurysmal. Patency rates of allografts appeared to be higher in patients whose grafts were harvested from blood types that were ABO compatible donors.[25] In another study, fresh arterial allografts placed in the aortic position were noted to be highly immunogenic, with evidence of both a humoral and cellular immune response.[26] These animal and human data suggest that fresh vessel allografts initiate a host immune response. Furthermore, the patency of these grafts appears to vary among species.

Aside from their immunogenicity, the use of fresh vascular allografts in the clinical setting has been hampered by logistic factors. Scarce availability of fresh arteries and veins and a need to successfully store such vessels for future use have led to the development of a number of preservation and modification techniques. These techniques can be divided into those that involve preservation without a planned significant change in graft integrity and those in which the graft is intentionally chemically altered. Cryopreservation is the most common example of the preservation technique, whereas proteolytic enzymatic digestion and dialdehyde starch tanning are examples of the modification technique. In addition to creating a conduit that would be more readily available, it is hoped that these techniques will inhibit the host immune response and thereby increase graft patency.[27]

Over the past century, multiple vessel preservation techniques have been tested. Grafts were stored in a number of solutions, including nutrient broths,[15] glycerol,[28] and plasminate.[29] A variety of storage temperatures ranging from room temperature to −70°C were tried.[17,28] Finally, a number of adjunctive sterilization techniques, including ethyl dioxide and irradiation, were attempted.[17] Early techniques focused on preservation without much regard to viability of the vascular tissue. Initial results with preserved vascular grafts were inconsistent, probably because significant cellular and structural damage occurred in many of these vessels and made them nonviable.[25,30]

Cryopreserved Allografts

Methods of Preparation

There is evidence that cryopreservation can result in significant cellular damage unless appropriate precautions are taken.[31] During the cryopreservation process, the extracellular matrix freezes at a higher temperature than cellular cytoplasm. This leads to a vapor pressure gradient between the intracellular and extracellular components. When cooling occurs slowly, this gradient can result in cellular dehydration, whereas rapid cooling can lead to plasma membrane rupture. Work with cell suspensions, such as blood and semen, has revealed that certain substances, when added during the freezing process, can significantly improve cell viability.[32] These substances, called cryoprotectants, include dimethylsulfoxide and glycerol. Their mechanism of action is to enter cellular cytoplasm and decrease the vapor pressure gradient that exists between the intracellular and extracellular components.[19]

Over the last 20 years, cryopreservation techniques have been optimized and commercialized. Important variables inherent in modern cryopreservation processes include the type and amount of cryoprotectant used, freezing rate, storage temperature,

duration of storage, and additives used.[19] The most common cryoprotectant in use today is dimethylsulfoxide at 10% to 20% dilution. The freezing rate varies among protocols, and there is some evidence that rapid freezing at 5°C/sec may work best. Storage temperature may vary from −102°C to −196°C. The duration of cryopreservation may also be important, and longer duration has been shown to have an adverse influence on vessel wall morphology but not on graft patency in one animal model.[33] Finally, there is evidence that the addition of certain additives such as chondroitin sulfate to the storage solution enhances vein viability and function.[34]

Histology and Physiology

Cryopreserved arteries and veins are affected by both cryopreservation and immune rejection, and a large body of research has been performed to define and dissect these processes from one another.

Cryopreservation has effects on the mechanical properties, histology, and physiology of the treated vessel. Elasticity and compliance of a vessel are important mechanical characteristics that affect its performance as a conduit. Changes in these properties lead to an increased difference in compliance between the conduit and host vessel, which can adversely affect graft patency. In vitro models comparing the mechanical properties of cryopreserved and freshly harvested arteries and veins reveal that cryopreservation does not significantly affect elasticity, contractility, compliance, and the mechanical buffering function of the treated vessel.[18,35,36]

Cryopreservation of blood vessels leads to changes in the intima, media, and adventitia. Although appropriate cryopreservation does not affect the gross morphology of the endothelial layer, histologic changes such as focal microvillous projection, cytoplasmic vacuolization, nuclear prominence, and interruption of tight junctions have been visualized.[33,37] These changes increase with the duration of cryopreservation[33,37] and lead to partial endothelial cell loss.[37-39] Endothelial loss is significant when the cryopreserved graft is exposed to arterial flow. Although autogenous grafts reestablish an endothelial layer, only minimal re-endothelialization is observed in allografts.[19,29] Because of a compromise in intimal integrity, cryopreserved grafts accumulate low-density lipoprotein cholesterol at an accelerated rate as measured in an ex-vivo organ perfusion system.[40]

Endothelial vasodilatory function, as measured by response to acetylcholine, thrombin, and calcium ionophore, appears to be retained, but it is somewhat diminished with cryopreservation.[41] With regard to coagulation homeostasis, although cryopreservation of vein grafts is not associated with increased platelet deposition,[41] it does cause decreased thrombomodulin activity.[38] Fibrinolytic activity appears to be similar in both fresh and cryopreserved canine jugular veins, but this activity may be adversely affected by the duration of cryopreservation.[37]

The medial layer of cryopreserved vascular grafts appears to have grossly normal smooth muscle cells, although slight lysis and minimal mitochondrial edema were observed in a rabbit model. In that model, implantation of autologous veins into an arterial circuit led to the preservation of both smooth muscle cells and the elastic lamina. The smooth muscle cells displayed a synthetic, rather than a contractile, phenotype characterized by dilatation of the endoplasmic reticulum.[33] Despite these findings, collagen synthesis in cryopreserved veins was diminished in a canine model.[39] Smooth muscle cells in cryopreserved canine saphenous autografts were noted to have a diminished relaxation response to nitric oxide,[41] although contraction induced by norepinephrine, potassium chloride, and serotonin was unaltered.[19]

Immunology

Allogeneic implantation of cryopreserved vessels leads to a different histologic and physiologic picture than that seen with cryopreserved autologous grafts. These observed changes are caused by immune mechanisms. Endothelial loss, encountered when an allograft is exposed to arterial flow, is not appreciably reversed, and exposed subendothelial elements are noted on electron microscopy.[19,29] In addition, smooth muscle cell viability is lost,[23,42] severe medial fibrosis and disruption of elastic fibers occur,[23,29,42] and medial necrosis has been described.[43] Significant lymphocytic infiltration of the media and adventitia has also been observed.[29] However, these alterations in vessel wall biology are not routinely observed with autologous conduits.[43]

Although it is well known that transplanted allograft and xenograft organs elicit an immune response, it was initially believed that the host-mediated immune response of transplanted vessel allografts was minor[44,45] and could be successfully blunted by the cryopreservation process.[27] Recent literature, however, suggests that vascular allografts do trigger a significant immune response.[19,26] Endothelial cells present surface antigens that stimulate a cell-mediated immune response[46] against the donor graft and an immunoglobulin-G-mediated humoral immune response to donor-specific antigens has been described.[26,47] Transplanted canine venous allografts, but not autografts, demonstrated extensive medial fibrosis and lymphocytic infiltration consistent with immunologic rejection.[48] In a human model, the analysis of 22 explanted cryopreserved saphenous vein (CSV) allografts revealed moderate to severe intimal, medial, and adventitial inflammatory infiltrates. Immunohistochemical analysis demonstrated an abundance of activated T lymphocytes containing cytotoxic granules.[49] In another experiment, cryopreservation did not alter antigenic expression and the immunologic response of a murine host to allograft transplantation in a number of studies.[50,51] Chronic immunologic rejection clearly plays a role in allograft biology and appears to be responsible for both diminished patency of cryopreserved vascular grafts and the predilection of these grafts to aneurysmal degeneration.[43]

A number of investigators hypothesized that manipulating the host immune response to vascular allografts may attenuate immune rejection and improve graft patency. Matching of ABO blood groups was suggested by Ochsner et al.[25] who noted improved patency of allografts transplanted to ABO-matched patients. In animal models, immunosuppression with cyclosporine has been demonstrated to diminish immunologic rejection of aortic[43] and venous allografts.[52] Azathioprine has likewise been shown to decrease the effects of rejection in venous allografts.[24]

Based on these findings, attempts were made to improve the results of allograft use in humans by modulating the host immune response. Carpenter and Tomaszewski[53] performed a prospective, randomized trial of 40 CSV allografts implanted in patients treated with low-dose azathioprine, but they failed to show a significant improvement in graft patency at 1 year. Azathioprine immunosuppression, however, was associated with a decreased presence of T-lymphocyte cytotoxic granules in that study.[49] In another small human trial, a combination of low-dose cyclosporine, azathioprine, prednisone, warfarin, aspirin, and vasodilators was used in patients who underwent CSV bypass. Grafts treated with this immunosuppressive regimen demonstrated increased patency rates. This regimen, however, was associated with an increased incidence of complications and graft aneurysmal degeneration.[54] In one series of patients with prosthetic aortic infection, 10 of 30 patients who underwent aortic allograft replacement were concomitantly treated with cyclosporine. Although the measured humoral immune response was blunted in patients who received cyclosporine, no differences in graft patency or graft complication rates were appreciated.[26] In contrast, Randon et al.[55] contended that a low-dose cyclosporine immunosuppressive regimen for lower extremity bypass using CSV was effective at reducing the risk of rejection while facilitating host cell repopulation of biograft endothelium.

Furthermore, an immunologic response evoked by a cryopreserved allograft can induce allosensitization, which may interfere with future organ transplantation. This mostly affects the use of cryopreserved femoral vein (CFV) allografts in hemodialysis access. A case-matched series of 20 patients who underwent creation of hemodialysis access with this graft demonstrated host allosensitization in all patients as measured by the panel-reactive antibody assay.[56] Allosensitization, however, did not occur when the CFV graft was processed to remove cellular elements.[57] Diminution of the immune response by removal of antigenic epitopes has led to multiple attempts to structurally modify biologic grafts.

Structurally Modified Biologic Grafts

In parallel with the development of cryopreservation techniques, further research was conducted to modify blood vessels so that an acceptable vascular substitute could be developed. The goal was to transform a harvested blood vessel into a durable nonimmunogenic graft that could be easily produced and stored. During early experiments in the 1950s, animal arteries were modified by enzymatic digestion of the musculoelastic portion of the vessel wall with ficin, a proteolytic enzyme isolated from figs, to remove immunologically reactive proteins. The resultant collagenous vascular skeleton was strengthened by collagen cross-linking through subsequent tanning with dialdehyde starch.[20,58] This modified graft was then sterilized and stored in a 1% propylene oxide-50% ethanol solution.[20]

In the earliest experiments, modified BCA grafts were implanted as xenografts first in dogs and then in patients with symptomatic lower extremity occlusive disease. Although no graft ruptures had occurred at 3 years of follow-up, early neointimal hyperplasia and diminished patency were observed.[20] An unacceptable late rate of graft infection and aneurysmal degeneration led to a change to glutaraldehyde-based tanning protocols.[58,59]

Bovine mesenteric veins (BMVs) have also been modified by a patented process of glutaraldehyde cross-linking and sterilized by γ radiation.[60] Both BCAs and BMVs have been used as xenografts in several clinical applications.

HUV is a modified biologic conduit that was first evaluated in baboons[21] in the early 1970s and subsequently used in humans[21,61] in 1975. Umbilical vessels are uniform in caliber, valveless, and branchless. The umbilical vein was removed from the umbilical cord by a variety of techniques, including enzymatic digestion and mechanical stripping. After a rinsing process with a cold isotonic solution, this vein was tanned with glutaraldehyde. Polyester fiber mesh was then sutured in place about the length and outside circumference of the graft for added support.[21]

Although thrombosis and aneurysm formation were common in early experiments, tanning and external support modifications significantly reduced these complications. Increased adherence of platelets to the luminal surface of these grafts has been observed in a canine model.[62] Histologic analysis of modified HUV grafts explanted from baboons revealed an early neutrophil and late macrophage response in the vicinity of the surrounding polyester mesh. The inner collagen layer appeared thickened and dense but was free of significant inflammation.[21] The reduced immunogenicity of this graft was hypothesized to be secondary to pretreatment with glutaraldehyde, which was thought to bind to graft histocompatibility antigen sites and thereby shielded them from the host immune response.[63]

Other Grafts

The search for an ideal blood vessel substitute led to the investigation of a number of nonconventional biologic grafts in animal models. Vascular prostheses fashioned from pericardium[64] and small intestinal mucosa[65] have been evaluated, and chemically modified human[66] and bovine[67] ureters have been used as vascular conduits with some success. Modified bovine ureters have also been used clinically with acceptable patency rates in femoral to popliteal bypass in one small Australian series.[68] In addition, a small randomized trial claimed clinical equivalence between bovine ureters and PTFE used for hemodialysis access in patients with no vein options.[69] More recently, tissue engineered vascular conduits have been developed with the hopes of providing new dependable options for challenging situations.[70]

CLINICAL USE IN PERIPHERAL VASCULAR SURGERY

Indication

Biologic grafts have been used in modern peripheral vascular surgery mostly in three distinct clinical settings: extremity bypass in the absence of suitable autogenous conduit, arteriovenous (AV) access for hemodialysis, and replacement of infected prosthetic grafts.

Extremity Bypass

Acute or chronic ischemia of an extremity is caused by a number of conditions, including atherosclerosis, trauma, embolization, and in-situ thrombosis. Treatment of extremity ischemia involves revascularization by endovascular or surgical techniques. During infrainguinal surgical bypass, autogenous great saphenous vein has proven to be the preferred conduit for infrainguinal revascularization.[71,72] When the autogenous great saphenous vein is not available, alternative autogenous conduits, such as an arm vein,[73] the small saphenous vein,[74] and the composite autogenous vein,[75] have been used with good results. The ever-increasing age and complexity of patients with infrainguinal arterial occlusive disease has brought about increasingly frequent clinical scenarios in which the autogenous vein is not available, and an alternative conduit must be found. Although prosthetic grafts have been used with moderate success above the knee, they have been disappointing when used for infrageniculate bypass.[76,77] Distal modification of prosthetic grafts with a vein cuff or distal AVF may improve patency rates,[78-80] but it is more cumbersome.

Given the absence of reliable conduit options for infrageniculate bypass when a suitable autogenous vein is lacking, the feasibility of biologic grafts has been evaluated. In this setting, CSV allografts,[81] cryopreserved femoro-popliteal artery (CFA) allografts,[42] HUV grafts,[82] BCA xenografts,[58] and BMV xenografts[83] have been used with varying degrees of success.

Arteriovenous Access

End-stage renal disease is a significant public health problem in the United States; its prevalence is increasing steadily, and it is forecasted that by the year 2030 more than 2 million patients will be undergoing hemodialysis.[84,85] Long-term hemodialysis is best performed through a surgically created AVF that connects the arterial and venous circulations via a conduit. The ideal AV conduit carries high flow for efficient dialysis, is superficial enough for easy access, is sufficiently durable to withstand multiple cannulations, allows rapid sealing of cannulation sites, and is resistant to infection, stenosis, and thrombosis. A mature, native vein AVF comes closest to the ideal, and its use is strongly encouraged.[11] Unfortunately, many individuals lack suitable veins for native AVF construction because of small vein size, previous access procedures, or vein harvest for peripheral or coronary bypass. Furthermore, up to 60% of native AVFs fail to mature and therefore cannot be used successfully.[86,87] Although prosthetic AV grafts are widely used, they have lower patency rates, require more frequent revision, and are at higher risk than vein AVFs for infection.[88] The search for optimal hemodialysis access in patients who are not candidates for a native vein AVF has led to the use of biologic grafts. CFV allografts,[89] BCA xenografts,[90] bovine ureter xenografts,[69] and BMV xenografts[60] have been used in a variety of settings with variable results.

Replacement of Infected Prosthetic Grafts

Prosthetic graft infection, particularly when the aorta is involved, is one of the most dreaded complications in vascular surgery and is associated with high morbidity and mortality.[91] Treatment of an infected aortic prosthesis includes excision of the infected segment and extraanatomic prosthetic bypass[91] or reconstruction with an antibiotic-soaked or antibiotic-bonded prosthetic graft,[92] femoral vein,[93] or aortic allograft.[94] In addition, extraanatomic bypass and aortic ligation are associated with long operative times, risk of remote infection, bypass thrombosis, and aortic stump rupture.[91,95] Antibiotic-soaked prosthetic grafts may work well for infections caused by relatively indolent *Staphylococcus epidermidis*, but they are much less effective against more virulent organisms.[92] Finally, use of the femoral vein for aortic reconstruction is tedious and associated with harvest-related complications.[93]

Cryopreserved aortic allografts offer "off-the-shelf" availability, good handling properties, and the potential for expeditious in-situ repair. Cryopreserved aortic allografts were more resistant than prosthetic grafts to *S. epidermidis* infection in a canine model.[96] Resistance of vascular allografts to infection has led to the wide use of arterial allografts to treat aortoiliac infection,[97] CFV allografts to treat infection involving prosthetic AV grafts,[98] and CSV allografts to replace infected infrainguinal prosthetic bypass grafts.[99]

Biologic Graft Preparation

Cryopreserved Allografts

A number of tissue banks and commercial companies prepare, store, and supply cryopreserved blood vessels. Despite similarities in conduit preparation, many have proprietary cryopreservation protocols.[100] The great saphenous vein, femoral vein, and arterial segments are harvested from multiorgan donors who are screened for an array of viral, bacterial, and fungal infections. Branches are suture ligated, and the allografts are sized with calibrated dilators. They are tested for presence of pathogens, rinsed in an antibiotic solution, placed in a proprietary cryoprotectant solution, and stored in the vapor phase of liquid nitrogen at −110°C to −196°C. Allografts are shipped and stored in a solution of dimethylsulfoxide at −96°C until needed. The vein, but not artery, is usually matched for ABO/Rh compatibility with the recipient to decrease the risk of rejection. At the start of the procedure, the allograft is rapidly thawed by submersion in a warm water bath at 37°C to 42°C for 20 minutes, and after rinsing in a series of solutions provided by the manufacturer, it is ready for use.

CSV allografts are available in a number of lengths and diameters. Most commonly, the vein measures 3 to 5 mm in diameter. These grafts look, feel, and handle like the autogenous saphenous vein. During an infrainguinal bypass, the allograft is usually reversed and placed in a superficial tunnel for easy access.[81] Postoperative surveillance was not considered useful in one large series.[81]

CFV allografts are usually less than 25 cm in length and have a diameter between 5 and 7 mm, and they have most commonly been used in hemodialysis in the setting of prosthetic AV graft infection. When used for dialysis access, this allograft is appropriately reversed and tapered to a 5 mm diameter at the arterial anastomosis to decrease the incidence of ischemic steal syndrome.[89] It is allowed to mature for 3 to 4 weeks before

it is accessed for hemodialysis. Revision of these grafts is very difficult because of their thin wall and surrounding fibrosis.[98]

Arterial allografts have most frequently been used for aortic replacement in the setting of primary or prosthetic aortic infection. Given this clinical setting and the need to replace a large artery such as the aorta, these allografts must withstand particularly hostile conditions. Technical modifications for the use of these allografts have been developed, including vigilance in following thawing instructions, use of appropriately long grafts, and construction of tension-free anastomoses, taking great care that suture ligation of branches is performed with polypropylene sutures that include the graft wall along with the branches. Aggressive excision of infected tissue and wound drainage is required, and other adjuncts include circumferential anastomotic reinforcement with allograft strips, use of gentamicin-impregnated fibrin glue, and coverage of the graft with viable tissue, such as a pedicled omental or muscle flap.[94,101]

Structurally Modified Allografts

The HUV graft (Fig. 65.1) is shipped and stored in 50% ethanol and provided on a glass mandril. It is irrigated up to 10 times with a low-molecular-weight dextran-containing solution and rinsed with a high-concentration heparin solution (10,000 U/L). This graft does not tolerate traction or the application of standard vascular clamps. To avoid injury, it needs to be passed through a metal or plastic conduit during tunneling and preferably controlled with a tourniquet. To decrease the risk of pseudoaneurysm formation during suturing, both the vein and the Dacron mesh need to be incorporated into the suture line. Finally, infusion of low-molecular-weight dextran has been recommended in the early postoperative period by the manufacturer to decrease the risk of early thrombosis.

Manufacturing of the umbilical vein graft by Synovis Life Technologies, Inc. (St. Paul, Minnesota) stopped in May 2005 in compliance with new US Food and Drug Administration (FDA) guidelines governing combination tissue–medical devices.[102] To date, a next-generation HUV graft that will fulfill FDA regulations is not yet available, although developers are actively seeking corporate industry support for such a venture (Herbert Dardik, personal communication, April 13, 2016).

The BCA graft (Fig. 65.2) is supplied in a specially designed tube containing a proprietary solution of 1% propylene oxide in 40% aqueous ethyl alcohol. It is naturally compliant, soft, and relatively easy to use. It is presently available in 6-, 7-, and 8-mm diameters and 15- to 50-cm lengths (Artegraft; Artegraft, Inc., New Brunswick, New Jersey). The BMV graft (Fig. 65.3) is shipped in a sterile saline solution and is available in 6-mm diameters and 10- to 40-cm lengths (ProCol Vascular Bioprosthesis, Hancock Jaffe Laboratories, Irvine, California). This graft is compliant and handles much like a saphenous vein.[60] Both xenografts require a series of rinsing steps in the operating room before use.

CLINICAL OUTCOMES

Cryopreserved Saphenous Vein Allografts

Numerous reports on the utility of CSV allografts for infrainguinal revascularization have been published (Table 65.1).[53-55,69,70,81,87,103-161] However, this literature has confounding factors that may affect

the interpretation of outcomes. CSV has been distributed by a number of vendors who use similar, but not identical, cryopreservation techniques. There is significant variability pertaining to patients, location of the proximal and distal anastomoses, use of anticoagulation, and use of immunosuppressive agents. The majority of these reports are retrospective, and the two largest studies contain 115[104] and 240[80] grafts. One of the more recently published reports spanned a 15-year period of implantation.[55] Four prospective studies have been published, but they include small numbers of patients.[53,54,81,107]

Graft Patency

Although use of CSV allografts has been reported in a number of settings, these grafts are generally used for the treatment of limb-threatening ischemia.[81,108] The primary patency rate of CSV grafts has been noted to be relatively low in most retrospective series (see Table 65.1).[81,105-111] The largest case series reported a 30% primary patency rate at 1 year,[81] which is similar to the 37% primary patency rate noted in the second largest series.[108] Although Buckley et al.[111] published an impressive 87% primary patency rate in their prospective study of 26 patients, Carpenter and Tomaszewski[53] found a dismal 13% primary patency rate in their prospectively monitored patient cohort. Randon et al.[55] showed slightly better than average patency and limb salvage rates in CSV recipients treated with low-dose cyclosporine, and Chang et al.[104] reported that CSV performed better in patients with rest pain compared to tissue loss when evaluating amputation-free survival, particularly in those who could be anticoagulated with warfarin.

Secondary procedures on failing or failed grafts generally seem to yield little gain. Primary-assisted and secondary patency of CSV grafts were not significantly higher than primary patency in the two largest allograft series.[81,108] Once the graft failed, it was abandoned, and secondary grafting was performed when indicated.[81] Other authors, however, almost doubled their secondary patency rates by adopting an aggressive posture toward allograft thrombectomy and revision.[110,161]

Multiple patient and procedural variables were evaluated for their influence on allograft patency. In the largest published series, multivariate analysis identified that diabetes negatively affected graft patency. Age, gender, hypertension, smoking, renal dysfunction, indication for surgery, history of bypass grafting, and site of distal anastomosis did not have an effect.[81] A recent series likewise noted a negative effect of diabetes on graft patency,[160] although others found no significant effect.[108,110] Two separate investigations found that secondary and composite allograft reconstructions adversely affected graft patency.[109,161] Lastly, in a recent study, statin use was noted to improve graft patency.[55]

Role of Anticoagulation and Immunosuppression

A number of studies have evaluated the effect of anticoagulation on allograft patency. Aspirin and warfarin, alone or in combination, did not improve graft patency in most series.[53,81,106,108,109] Although Chang et al.[104] identified a benefit to anticoagulation with warfarin in terms of limb salvage, this benefit was most pronounced in patients with rest pain and not tissue loss. Buckley et al.[111], however, reported an impressive 87% primary patency rate in their prospective cohort of 26 patients who were treated with an intensive anticoagulation protocol consisting of preoperative aspirin, perioperative low-dose heparin and dextran, and postoperative warfarin, aspirin, and dipyridamole. Of note, 42% of grafts in that series underwent distal anastomotic modification with either vein cuffs or AVFs. A limitation of most retrospective studies is that the precise level of therapeutic anticoagulation was not rigorously followed for each individual patient. The true effect of an anticoagulation protocol on allograft patency awaits a prospective randomized study that will closely monitor the adequacy of postoperative oral warfarin therapy.

Immunosuppressive regimens have been evaluated clinically. In a prospective randomized trial of 40 grafts in patients treated with low-dose azathioprine, Carpenter and Tomaszewski[53] failed to show a significant improvement in graft patency at 1 year. In contrast, Randon et al.[55] declared their low-dose cyclosporine immunosuppressive regimen to be effective at reducing the risk of graft rejection and thrombosis, and reported minimal side effects. Although immunosuppressive protocols may be effective, potentially serious side effects of therapy may not justify routine use in this patient population.[54]

Limb Salvage

Despite discouraging graft patency, use of CSV allografts has been associated with acceptable limb salvage rates (see

Table 65.1). In the largest published series, a 71% 2-year limb salvage rate was achieved,[81] whereas Randon et al.[55] reported a 5-year limb salvage rate of 64%. The discrepancy between graft patency and limb salvage can be explained, in part, by secondary bypass procedures performed after primary graft failure. Others have reported that repetitive bypass grafting significantly extends limb salvage.[112] Another possibility is that the saphenous allografts remained patent long enough to enable healing of lower extremity ulceration in a large proportion of patients. The ulcers may not have recurred despite graft failure.[81,107,108] Unfortunately, this hypothesis can be proven only in a trial in which ulcer healing is prospectively monitored, along with limb salvage.

Of the various clinical factors that could potentially influence limb salvage, multivariate analysis found the site of distal anastomosis to be significant.[81] Patients who underwent allograft bypass to the popliteal artery had better limb salvage than did those who underwent tibial bypass. Martin et al.[108] found patient age to be inversely related to limb salvage.

Aneurysmal Degeneration

CSV allografts that remain open for a prolonged period are prone to aneurysmal degeneration,[4,81,108] which is probably related to the immune response by the recipient against the graft. The true incidence of allograft aneurysm formation cannot be accurately determined because the majority of these grafts occlude long before a clinically detectable aneurysm can develop. In one series, aneurysmal degeneration developed in nine grafts, for a 2-year aneurysm incidence of 44%.[81] Martin et al.[108] reported a 25% aneurysm formation rate at 2.5 years. The development of aneurysms in allografts necessitates close surveillance of those few patients whose graft remains open for a prolonged period. Because allograft aneurysm rupture has been reported,[54,81] preemptive graft revision is recommended.

Summary and Indications for Use

Although CSV allografts look, feel, and handle like an autogenous vein, they are far from being the "Holy Grail" of conduits for infrainguinal reconstruction. Their poor patency rates are worsened by several risk factors, including diabetes, previous bypass, and composite reconstruction. Postoperative anticoagulation has not significantly improved graft patency,[81] although some authors believe that an intensive peri- and postoperative anticoagulation regimen has merit.[111] Given the immunologic mechanism of graft failure, it is unlikely that anticoagulation alone is sufficient to prevent graft occlusion. Grafts that stay open for extended periods, perhaps as a result of chance matching of important immunologic loci, are prone to aneurysmal degeneration. Finally, CSV allografts are expensive, costing approximately $9000 to $11,000 (in 2016 dollars) depending on the length of the graft.

Given published clinical data, many authors conclude that the use of CSV allografts should be limited.[54,81,105,107,108] Nevertheless, these grafts clearly have a place in the armamentarium of the modern vascular surgeon. Because they have been reported to be relatively resistant to graft infection,[99] they have an advantage when revascularization needs to be performed in an infected field. They also have an advantage when distal bypass needs to be extended onto the foot because closure of the wound is considerably easier than if a prosthetic graft is used. Finally, CSV allografts typically remain patent long enough to allow healing of an ischemic ulcer or minor amputation. The final piece of evidence supporting the continued role of this graft is persistent demand for the product by the vascular surgery community, as evidenced by the number of grafts that continue to be sold.

Cryopreserved Femoral Vein Allografts

Femoral vein allografts have been used for hemodialysis access in the setting of prosthetic AV graft infection, multiple graft failures, or compromised venous outflow sites. In one series of 48 allografts, 1-year primary and secondary patency rates of 49% and 75%, respectively, were achieved. No allograft infection or aneurysmal degeneration was noted.[89] In another series of 45 allografts, a cumulative 1-year patency rate of 68% was reported. Although no infection was noted during follow-up, two pseudoaneurysms required repair.[114] Madden et al.[115] compared the outcomes of 90 femoral allografts with 100 concurrent PTFE AV grafts and noted similar patency rates. No infections were seen in the allograft group, whereas 10% of the PTFE AV grafts became infected. In 18% of the allografts, however, aneurysmal degeneration developed.[115] In a prospective, randomized trial between CFV and PTFE grafts (suspended by the FDA after enrollment of 27 patients into each group), need for fistulography and aneurysmal degeneration was higher in the CFV cohort.[162] Others found that the use of CFV for AV access was associated with a 55% rate of infection, which was particularly common in thigh grafts. Allograft rupture occurred in 46% of infected grafts.[116]

CFV allografts do not have a primary role in hemodialysis access. They may have a secondary role in the setting of infected prosthetic access in a patient with limited reconstructive options. Because of allosensitization, they should not be used in patients who are candidates for future kidney transplantation,[56] although de-cellularized femoral vein allografts appear be safer in that regard.[57] Symptomatic pseudoaneurysms may develop in these allografts and should elicit a low threshold for repair. Finally, CFV placement in the thigh should be avoided.

Cryopreserved Arterial Allografts

Although most experience with arterial allografts has been gained with aortic replacement in the setting of prosthetic graft infection, CFAs have been used for infrainguinal revascularization. Cryopreserved femoropopliteal arterial allografts used for infrageniculate revascularization had a primary patency rate of 51% at 17 months of follow-up in one series of 17 bypasses[42] and 61% at 1 year of follow-up in a more recent series of 35 bypasses.[163] Because of short conduit length, a composite bypass was necessary in 53% of cases. Another series of 35 allografts reported a 39% primary patency and 59% secondary patency rate at 18 months of follow-up, and two grafts required replacement as a result of aneurysmal degeneration.[117] A 5-year primary patency rate of 16% was achieved in a retrospective multicenter

trial of 165 fresh and cryopreserved arterial allografts.[118] A more recent study compared 39 peripheral reconstructions using CFAs with 35 non-CFA bypasses including extraanatomically tunneled prosthetic grafts, autogenous veins, and endarterectomized superficial femoral artery grafts performed in the setting of infection. Total graft-related morbidity was 18% in the CFA group and 57% in the non-CFA group.[163] In this study, mortality at 18 months of follow-up was high in both groups: 31% in the CFA group and 43% in the non-CFA group.[163] These results suggest that in lower extremity bypass, cryopreserved arterial allografts have low patency rates, are predisposed to aneurysmal degeneration, do not offer any significant advantage over the use of saphenous vein allografts, and have the additional potential drawback of the need to connect two or more arterial segments together to create a conduit of sufficient length.

Arterial allografts have been used extensively for the management of primary and prosthetic aortic infection. To this end, fresh aortic allografts stored for less than 1 month at 4°C have been used with some success.[94,119,120] An Italian study of 44 patients treated with 13 fresh and 31 cryopreserved aortic allografts did not find a difference in patient outcomes.[119] A French study of 179 patients treated with 111 fresh and 68 cryopreserved grafts, however, did note long-term differences in graft behavior: fresh allografts were associated with allograft rupture and an increased incidence of late graft-related complications.[94]

There are eight published studies using more than 40 grafts that provide information about the outcomes of cryopreserved aortic allografts for the treatment of aortic infection (Table 65.2). Most of these represent multi-institutional registries with relatively short follow-up periods.[97,121,122,164] Although many patients had polymicrobial aortic infections, staphylococcal species were the most common organisms cultured.[97,101,119,122-124] As expected, perioperative mortality rates were high and ranged between 5% and 36%. Factors associated with increased mortality included emergent or urgent surgery and the presence of an aortoenteric fistula.[101,122] Aortic allograft repair in patients with aortoenteric fistulae was associated with prohibitive long-term mortality rates of 80% in one recent series[165] and 83% in an older series.[122]

As expected, these patients had very high perioperative complication rates ranging between 18% and 55%. Allograft rupture was seen in the immediate postoperative period and up to 4 years of follow-up,[101] and this devastating complication occurred in 2% to 14% of cases and was associated with high mortality. Allograft aneurysmal dilatation also was noted to occur in as many as 8% of patients in one series.[122] Graft stenosis and thrombosis were more often associated with grafts extending to the iliac or femoral arteries.[94] Amputation rates ranged between 1% and 14%. Despite these sobering statistics, 87% and 60% of patients were free of aortic and iliofemoral complications or interventions, respectively, at 7 years in one large single-institution series.[94] Furthermore, the largest study of cryopreserved aortoiliac allografts indicates that this modality allows aortic reconstruction in the setting of infection or those at high risk of infection, with lower early and long-term morbidity and mortality than previously reported.[164]

Aortic infection is one of the gravest conditions in peripheral vascular surgery. Therefore, allograft performance needs to be viewed against the results of other treatment options for the management of infected aortic grafts. Graft excision with extraanatomic bypass was associated with a 30-day mortality of 13% and an amputation rate of 10%.[91] Similarly, in-situ aortic graft replacement with a rifampicin-bonded prosthetic graft had a perioperative mortality rate of 18%.[92] Although cryopreserved aortic allografts clearly have a place in the

management of prosthetic aortic graft infection, their precise role has yet to be clearly defined. They are associated with allograft dilatation and rupture, probably because of the previously discussed immunologic mechanisms.[19,23,29,42,43] Graft surveillance protocols have yet to be standardized and validated. Although the use of current immunosuppressive regimens in these very ill patients is not practical, the development of more focused immunosuppressive therapy in the future may better define the role of aortic allografts in the armamentarium of vascular surgeons.

Human Umbilical Vein Grafts

Patency and Limb Salvage

The first large clinical experience with the use of HUV grafts was reported in 1988 by Dardik and Dardik,[82] which had 907 lower limb bypass procedures performed in 799 limbs of 715 patients. The 5-year primary-assisted patency rates were 57% and 32% for femoropopliteal and femorotibial bypasses, respectively. The 5-year limb salvage rate ranged between 70% and 80%. Fifty-seven percent of the grafts exhibited aneurysmal dilatation at a mean follow-up of 5 years. In 1989, ownership and manufacture of the HUV graft changed hands, and in an attempt to address the issue of time-dependent graft degradation, efforts were made to improve the graft manufacturing process. Improved cross-linking with glutaraldehyde and upgraded quality control procedures, including time, temperature, and pressure determinants during manufacture, led to the development of a second-generation graft that was resistant to aneurysmal degeneration.[102] In parallel, Dardik et al.[80] attempted to improve the patency of femorotibial HUV grafts by using adjunctive distal AVFs. These investigators published an updated experience with 283 second-generation HUV grafts in 2002. The 5-year primary patency rates for this graft were 60% and 50% for below-knee popliteal and tibial bypass, respectively; and 5-year limb salvage rates were 80% and 65% for below-knee popliteal and tibial bypass, respectively. No graft aneurysmal degeneration was noted on duplex surveillance of these grafts.[125]

Neufang et al. published three series of patients treated with the HUV graft for popliteal bypass,[126] composite bypass,[127] and composite sequential bypass.[128,166] Two hundred eleven patients treated by HUV femoropopliteal bypass had 5-year primary and secondary patency rates of 54% and 76%, respectively, but reported complications included early graft thrombosis in 17% and aneurysmal degeneration in 7%. This group did not use adjunctive distal AVFs, but they did recommend an aggressive anticoagulation protocol with peri- and postoperative aspirin and clopidogrel, early postoperative heparin, and long-term warfarin to keep the international normalized ratio at 2.5.[126]

Fifty-four patients with critical limb ischemia treated by a HUV–autologous vein composite bypass to tibial targets had 4-year primary patency, secondary patency, and limb salvage rates of 53%, 67%, and 88%, respectively. Patients who did not undergo anticoagulation had a significantly higher incidence of early graft thrombosis.[127] HUV–autologous vein composite sequential femoral-tibial bypasses demonstrated lower long-term patency rates.[128,166] Patency and limb salvage results in the most recent (and largest) studies using HUV grafts are listed in Table 65.3.[82,125,126,129-132]

Comparison of Human Umbilical Vein With Other Grafts

A number of studies compared the utility of HUV grafts with other conduits for infrainguinal revascularization. Cranley and Hafner[133] reported a 3-year cumulative patency rate of 74% for umbilical vein grafts, 41% for PTFE grafts, and 76% for saphenous vein grafts when used for bypass to the popliteal artery in the setting of critical limb ischemia. HUV patency was comparable to PTFE graft patency when tibial targets were evaluated (31% vs. 35%, respectively). A small Scandinavian multicenter, prospective randomized trial compared outcomes of HUV grafts with PTFE for below-knee femoropopliteal bypass, and the 4-year primary-assisted patency rate was 42% for umbilical vein grafts versus 22% for PTFE grafts.[134] The New England Society for Vascular Surgery Registry revealed HUV to have improved 5-year patency rates in comparison to

PTFE grafts for bypass to the below-knee popliteal artery (45% vs. 20%, respectively).[135]

Another small, prospective randomized trial evaluated the outcomes of first-generation HUV grafts and PTFE grafts in above-knee femoropopliteal bypass. At 6 years, the primary patency rate of HUV was significantly higher than that of PTFE grafts (71.4% vs. 38.7%, respectively). Thirty percent of HUV grafts demonstrated aneurysmal dilatation.[136] The largest randomized trial of HUV grafts was a Veterans Administration–sponsored trial in the United States in which the outcomes of HUV, saphenous vein, and PTFE grafts were evaluated in 752 patients who underwent above-knee femoropopliteal bypass. At 5 years, primary-assisted patency rates were 73%, 53%, and 39% for saphenous, umbilical vein, and PTFE grafts, respectively. Although HUV grafts outperformed PTFE grafts, they were associated with a higher incidence of early graft thrombosis and amputation.[132] This study prompted the manufacturer of this graft to recommend low-molecular-weight dextran in the postoperative period. Some investigators routinely recommend antiplatelet agents, postoperative heparin, and long-term warfarin therapy.[125,126]

Aside from thrombosis, umbilical vein grafts are associated with a number of complications, including infection, stenosis, dissection, and pseudoaneurysm. These complications vary between the first- and second-generation HUV grafts.[125] Although HUV grafts have demonstrated adequate outcomes and improved patency rates compared with PTFE grafts, they have never made it into the mainstream of vascular practice. Many factors, including perceived handling difficulty, complexity of adjunctive distal AVF creation, and industry bias, partially account for this observation. Nevertheless, vascular surgeons must be aware of the HUV graft and its unique complexities and complications given the likelihood of encountering a patient with this type of bypass in clinical practice. Currently, the HUV graft is not commercially available.

Bovine Carotid Artery Xenografts

The BCA xenograft was first used for dialysis access by Chinitz et al.[137] who found that the graft tolerated frequent cannulation and maintained flow sufficient for successful hemodialysis. Patency rates of this graft range from 21% to 86% at 1 year and 45% to 76% at 2 years.[167,141] With the advent of PTFE and its use in hemodialysis access in the mid-1970s, multiple studies comparing BCA xenografts with PTFE grafts have been published (Table 65.4).[55,69,70,87,103,104,138,139,159-168] A prospective, controlled, randomized trial of 140 BCA and PTFE AV grafts found no significant differences in patency and complication rates.[145] Other studies, however, including a recently published small randomized trial, revealed PTFE grafts to have superior patency rates.[138,140,143,168] BCA xenografts are associated with higher infection[138,140] and aneurysmal degeneration[138,143] rates than PTFE AV grafts. A 9% to 20% infection rate[138,140,147] and a 1% to 8% aneurysmal degeneration rate[138,141,143,147] have been observed.

Although BCA xenografts elicit a dense desmoplastic reaction, they are predisposed to aneurysmal degeneration, which is exacerbated by repeated cannulation during hemodialysis. They are prone to infection, and when it occurs, they are very difficult to excise because of intense inflammation and the fragile nature of the graft.[143] Finally, they are more expensive than PTFE grafts. These issues have limited widespread use of this graft for hemodialysis access.[146]

There have been a few published series on the use of different BCA xenografts for infrainguinal revascularization. In one series, 30% of the grafts underwent degeneration within 4 months of insertion.[148] A study of 112 grafts used for femoropopliteal bypass yielded a 1-year primary patency rate of 90%.[149] Another study of 58 grafts used for above-knee femoropopliteal bypass yielded a 56% 5-year primary-assisted patency rate. No graft infections or aneurysmal degeneration was noted.[58] Short available lengths, wide availability of PTFE, and concern about graft degeneration have dampened enthusiasm for the use of BCA xenografts in lower extremity bypass.

Bovine Mesenteric Vein Xenografts

BMV xenografts have been successfully used for hemodialysis access. In one series of 50 grafts placed in 49 patients who had an average of 3.6 previous AVFs, a primary patency rate of 62% was noted at 30 months. Four infections but no aneurysmal

degeneration developed.[150] In one prospective, multicenter registry, 183 patients with previously failed synthetic grafts were treated with a BMV hemodialysis access. Outcomes were compared with a concomitant nonrandomized group of patients who received PTFE grafts. One-year primary and secondary BMV patency rates were 36% and 66%, respectively. Although primary rates were similar to those of PTFE AV grafts, secondary rates were significantly higher for bovine xenografts. Graft infection was less common in the BMV xenograft group, and the pseudoaneurysm formation rate was similar to that seen with PTFE grafts. However, significant dilatation occurred in six grafts.[60] In another recent series of 62 BMV grafts used for hemodialysis access, 30% primary and 58% secondary patency rates were reported. Thirteen infections occurred, and six (10%) grafts required surgical excision. Significant graft dilatation was noted in two patients.[151]

BMV xenografts appear to have acceptable patency rates that are similar to those seen with PTFE grafts. Although data are limited, these grafts do not appear to be any more predisposed than PTFE grafts to infection or pseudoaneurysm formation. The significance of the dilatation that occurs in some of these grafts is not yet clear. More research will be required before the role of this graft for hemodialysis access is more precisely defined.

BMV xenografts have been used for infrainguinal revascularization. In one small trial involving six patients, all grafts failed within 4 months.[83] In another trial of 32 patients with critical limb ischemia, a 16% primary patency rate was noted at 1 month. Most of the occlusions occurred within 1 day of the operation.[152] Given these results, this conduit cannot be recommended for infrainguinal bypass.

Tissue-Engineered Vascular Grafts

Spurred by repeated failures of commercially available xenografts and allografts, numerous researchers started to focus on tissue engineering as a tool to improve functionality of current biologic grafts. These new graft concepts aim to utilize the patient's own cells grown on a variety of supportive scaffolds. Such grafts hold promise to eliminate immunogenicity and propensity for infection that have plagued many biologic grafts. A number of researchers have experimented with different scaffold systems and have created both in vitro and animal models for such grafts.[55,69,70,87,103,104,153-169] Despite these trends, the optimal tissue-engineered vascular graft has yet to be identified.

Cytograft Tissue Engineering, Inc. (Novato, California) has been actively involved in this line of research and has incorporated their novel sheet-based tissue engineering scaffold into the creation of the Lifeline vascular graft for use in humans.[159] Sheets of living fibroblasts grown from cells extracted from patient biopsy samples (skin and superficial veins) are wrapped around a stainless steel mandrel and allowed to fuse in culture during a 10-week maturation phase.[103] Seven days before surgery, the lumen of the new vessel is seeded with autologous endothelial cells and preconditioned to both flow and pressure; the total production time for these grafts ranges between 6 and 9 months (mean 7.5 months).[104] In the first study of its kind, 10 patients in need of hemodialysis were implanted with their own autologous Lifeline grafts. The primary patency of these grafts was 78% and 60% at 1 and 6 months, respectively.[104] There was one graft aneurysm, one graft dilatation, and one immediate graft thrombosis that required replacement with a PTFE graft. The remaining eligible patients continued to undergo successful dialysis through their grafts, with only one intervention required to maintain patency at short-term follow-up. To circumvent the prolonged time period required to create these unique and personalized grafts, the manufacturer has begun experimenting with an "off-the-shelf" version of their Lifeline graft for hemodialysis and has followed three patients for up to 11 months.[55]

CorMatrix Cardiovascular, Inc. (Roswell, Georgia) has been developing innovative biomaterial devices that restore the native tissues of a patient with no foreign material left behind. Their extracellular matrix material acts as a scaffold into which the patient's own cells migrate and integrate to stimulate natural wound healing mechanisms and form permanent tissue. DuBose et al.[69] conducted a prospective study of CorMatrix for AVF aneurysm repair in 15 patients and were able to avoid prosthetic grafts and hemodialysis catheters; cannulation of repaired segments was allowed after 6 weeks.

Future Directions

Biologic grafts differ from one another in composition and method of preparation. They are useful in a number of clinical scenarios and have earned a place in the armamentarium of modern vascular surgeons. They have not, however, delivered on the expectations that many early vascular surgeons had for these conduits. Despite an enormous amount of basic and clinical investigation they have failed to become the ideal conduit. The search for such a conduit is still progressing.

Significant research is currently being conducted in an attempt to create a biologic nonimmunogenic graft, mainly through improvements using vascular tissue engineering. It is still conceivable that in the future a biologic graft with little or no immunogenicity and characteristics similar to that of a normal artery or vein can be developed, in an acceptable period of time and without prohibitive cost.

BASIC PRINCIPLES

The use of endovascular techniques to manage vascular disease has become increasingly widespread; however, surgical repair or replacement of diseased blood vessels remains a mainstay of modern vascular surgery. This includes a wide variety of procedures, including aortic reconstruction for aneurysmal disease, bypass of occlusive atherosclerotic lesions, vascular trauma, oncologic vascular reconstruction, and creation of durable arteriovenous access for hemodialysis. All of these procedures require implantation of a vascular conduit to replace diseased vessels or to augment normal anatomy. When available, autogenous blood vessels are generally the conduit of choice.[1] This is limited because individuals have a finite number of available vessels to be used for reconstruction and options may be limited due to concomitant disease of the desired vessels. Wound complications and infection from vessel harvest sites remain a vexing problem. Devitalization of the vessel during surgical excision prematurely injures the conduit and may contribute to poor performance or failure. Even in the best of conditions, autogenous venous tissue eventually remodels in high-resistance arterial or high-flow arteriovenous circuits in a manner that more closely resembles a hyperplastic injury response than the more desirable development of a vessel-like structure with functional adventitial, medial, and intimal layers. Synthetic alternatives provide additional options when autologous conduit is not available, but these grafts pose a clear disadvantage to host tissue in terms of patency, compliance, infection, and durability.

Despite their widespread adoption, none of these options reliably provide the desired long-term functionality and durability inherent to native vascular tissue. Indeed the development of an ideal arterial substitute has been referred to as the "Holy Grail" of vascular surgery.[2] Such a conduit would need to be designed to have a low immunogenic profile and an antithrombotic blood-contacting surface. It would have long-term patency approximating that of autogenous tissue and a resistance to the infectious complications seen with synthetic materials. It would need to combine durability, both for maintaining suture strength and resistance to subsequent mechanical stresses, with a capacity

Abstract

The development of a bioengineered vascular conduit has been a major focus of research within vascular surgery since the inception of the field in the early 20th century. Despite considerable investment of effort and resources the goal of an implantable, non-immunogenic, and mechanically durable vessel remained unfulfilled nearly a century later. In recent years, advances in tissue engineering have led to the development of several promising products that have the potential to revolutionize the field of vascular surgery.

This chapter provides an overview of the historical progress towards developing a bioengineered blood vessel and a detailed description of products in usage now, currently undergoing testing, and potential future directions of this research.

to remodel into a functional tissue and to respond to physiologic stimuli. Lastly, it would need to be cost effective and ready to use "off the shelf."[3,4] Although the search for this ideal conduit remains ongoing, dramatic advancements have been made, particularly in the past two decades, due to developments in the field of tissue engineering.

In this chapter, we will review a brief history on the field of bioengineered grafts, highlight important advances in the field, provide an update on current clinical activity, and look to the future of bioengineered vascular conduit.

Initial History

The origin of vascular surgery is frequently traced back to the development of the triangulated vascular anastomosis in the early 20th century by Alexis Carrel.[5] Although venous interposition grafts had been used for trauma and aneurysmal disease, it was not until 1948 that saphenous vein was used successfully as a bypass graft for atherosclerotic vascular disease.[6] Shortly thereafter in the 1960s the field of nephrology was revolutionized when Michael Brescia and James Cimino developed the radiocephalic arteriovenous fistula as an alternative to the Scribner shunt.[7,8] Even as this early work defining the role for autogenous materials in vascular surgery was being done, there were pioneering investigations into the use of synthetic materials as vascular conduits. In the 1950s Michael DeBakey, Denton Cooley, and colleagues reported the use of Dacron grafts for aortic reconstruction.[9] By the 1970s polytetrafluoroethylene (PTFE) and expanded PTFE (ePTFE) were being used as replacements for small arteries and as hemodialysis access.[10,11]

In light of this history of autogenous and synthetic vascular conduits, it is somewhat surprising that the first investigations into the use of bioengineered blood vessels were conducted in the 1940s, when Robert Gross and colleagues experimented with aortic transplantation in dogs.[12] This work demonstrated that, although preservation of graft vessels by freezing alone carried unacceptable rates of thrombosis and hemorrhage, biologic modification of donor aortas by storage in a nutrient solution at temperatures slightly above freezing resulted in long-term patency even after several weeks of extracorporeal storage. The successes of those experiments led to the successful translation of these techniques to human tissue. Cadaveric human arteries were successfully treated and used both for aortic reconstruction in pediatric patients with aortic coarctation and as shunt material in patients with tetralogy of Fallot. This type of tissue preservation strategy, although successful, was quite volatile and required significant improvement to produce a therapy that was reliable and readily available.

Intact Isolated Blood Vessels

The earliest examples of bioengineered blood vessels, stemming from the work done by Gross, were intact blood vessels isolated from either animals (xenogeneic grafts) or later from humans (allogeneic grafts).[13] Although the structure of intact isolated blood vessels comes from donor cells, they can be considered bioengineered grafts because they undergo an extensive process to biologically modify the tissue so that it can be implanted without producing an immune-mediated response. A common way to prepare xenogeneic grafts for use is by treating the tissue with a chemical decellularization process and then fixation of the remaining collagen, connective tissue proteins, and cells with glutaraldehyde to reduce antigenicity. This technique fixes or "tans" the tissue, cross-linking proteins to prevent an immunogenic reaction. Unfortunately, variations in xenogeneic graft fixation may lead to the potential for aneurismal degradation, because some have reported a possible mechanism of host degeneration of medial layer if it is not fixed completely.[14] Although the use of isolated intact blood vessels was first reported in the 1960s, there are several grafts currently commercially available.

Artegraft

Rosenberg and colleagues can be credited with the successful translation of enzyme treatment of bovine arteries and then chemically fixing the vessels to preclinical and clinical models. In this early work, bovine arteries were stripped of most of their parenchymal proteins and subjected to "decellularization" by controlled enzyme action, leaving a tubular prosthesis composed mostly of collagen.[15] The first clinical application of this technology was reported in 1966, when a conduit made from collagen matrix of a bovine carotid artery treated with enzymatic removal of the musculoelastic portion of the vessel was used for lower extremity bypass.[13] These processes were refined, and the bovine carotid artery graft technology ultimately was developed by Artegraft (North Brunswick, New Jersey). In 1970 these xenogeneic grafts were FDA approved for use as conduit for dialysis access, and the graft is also currently approved for peripheral arterial bypass and as an arterial patch.

Procol

Decades after the introduction of bovine carotid artery xenografts, Hancock Jaffe Laboratories, Inc. (Irvine, California) developed a method to treat bovine mesenteric veins with a decellularization process, followed by fixation with glutaraldehyde cross-linking and gamma radiation.[16] The muscle content of the bovine mesenteric vein, as well as its relatively high content of elastin, provided a theoretical advantage of improved vessel compliance and thus decreased rate of venous stenosis. This xenograft technology, Procol (now LeMaitre Vascular, Inc., Burlington, Massachusetts) was FDA approved in 2003 for vascular access in patients who have failed at least one prosthetic access graft.

CryoVein

Efforts to develop vascular homografts from either cadavers or living donors extended beyond the work done by Gross in the 1940s. Although the work of Ochsner and colleagues in the 1970s demonstrated the superiority of venous homografts to arterial homografts, due to the dependence of arteries on the *vasa vasorum*, the techniques used for fixation and decellularization of xenogeneic grafts did not translate to allogeneic grafts.[17] Ultimately a combination of cryopreservation and fixation with either glutaraldehyde or dialdehyde improved upon early results

in terms of vein integrity and tissue handling; however, long-term patency remained a significant concern with allogeneic grafts through the remainder of the 20th century.[18,19] Subsequent improvements in cryopreservation and tissue fixation led to the development of the CryoVein graft by CryoLife (Kennesaw, Georgia). This product is currently approved for both hemodialysis access and as a peripheral bypass conduit.

Luminal Modification (Biohybrids)

The endothelium is a dynamic environment, not simply an inert blood-contacting surface. The endothelium and particularly vascular endothelial cells (ECs) play a central role in regulating cardiovascular physiology. ECs regulate vascular tone and thus modulate hemodynamics. In addition to providing an antithrombotic surface for blood flow under normal conditions, ECs control platelet activation and adhesion, as well as the adhesion and migration of both leukocytes and vascular smooth muscle cells (VSMCs) in response to pathologic stimuli.[20] The benefits of an intact and functional endothelium are clear. The clear benefits of an intact and functional endothelium led several investigators to develop "biohybrid" grafts by modifying the luminal surfaces of conduits to recreate the physiologic function of the native endothelium.

The concept of transplanting autogenous ECs into grafts emerged in the late 1970s. This can be done as either a single stage or two-stage method. In one-stage methods, ECs are both harvested and seeded at the time of surgery. In contrast, two-stage methods require seeding of the recipient graft with ECs via serial passaging in a bioreactor and incubation for several weeks prior to implant.[21] Later investigators were able to improve cell retention, as well as cell growth structure and adaption, by exposing the EC-treated conduit in vitro to hydrostatic pressure, laminar shear stresses, and circumferential and longitudinal stretching.[22,23] Indeed, some suggest that shear stresses from prolonged laminar flow (as opposed to turbulent flow) play a crucial role in the signal transduction, gene expression, cell proliferation, and cell survival of both ECs and VSMCs. This is hypothesized to reduce the incidence of both thrombotic complications and the development of atherosclerotic lesions in vivo.[24-26]

Tissue-Engineered Vascular Grafts

Tissue-engineered vascular grafts (TEVGs) are cellular or tissue-based vascular conduits designed to have any synthetic components degrade over time with progressive replacement by autogenous tissues, resulting in a functional blood vessel with an intact endothelium and a capacity to respond appropriately to physiologic stimuli. This technology has been made possible only recently by groundbreaking advances in the field of tissue engineering, although it truly represents the extension of half a century of continuous exploration and improvement.

TEVGs may be classified by the method used to construct the conduit. At present, there are three main categories of TEVGs: grafts created in vivo by "bioreactors," scaffold-based TEVGs, and sheet-based TEVGs.

Grafts Created in vivo ("Bioreactors")

One of the earliest methods used to generate TEVGs leverages the ability of a host's body to generate a foreign body reaction when a cylindrical mandrel or inert tubing is inserted into the body. The result of this is formation of connective tissue around the foreign body, which can be isolated and used as vascular conduit. This process is usually described as using the host's body as a "bioreactor."

The first descriptions of the bioreactor technique come from the late 1960s, when Charles Sparks and colleagues implanted a prosthetic tube into the subcutaneous tissues of subjects. This tube was composed of an inner cylindrical steel mandrel and an outer Dacron graft. After 5 to 12 weeks the tube was explanted and both the mandrel and Dacron layers were removed and the tube of fibrocollagenous materials that formed in the interval was implanted for use as a vascular conduit.[27,28] Although this technique was used in several human patients in the late 1960s and early 1970s, it was not widely adopted, due to poor patency, aneurysmal degeneration, and the prolonged incubation period.[28,29] Several decades later a modification of Sparks' techniques was reported by Julie Campbell and colleagues.[30,31] This entailed placement of Silastic tubing into the peritoneal cavities of rats, rabbits, and dogs. The resulting host response produced a structure with an inner layer of collagen, a middle layer of myofibroblasts, and an outer layer of mesothelium. After removal of the synthetic material, the tube could be turned inside out thus producing a conduit lined entirely with mesothelium. Histologic examination demonstrated that the myofibroblasts in the graft were derived of a bone marrow origin.[32] Although the conduits were relatively successful in animal models, this technique was not successfully translated to humans, largely owing to the need for a prolonged incubation period of several weeks and the requirement for an additional surgical procedure.

To eliminate the need for an incubation period within the intended recipient, Ketharanathan and colleagues experimented with the use of sheep as a bioreactor for grafts to be inserted in humans. Silicone tubes were implanted beneath the subcutaneous layer of adult sheep. Upon explantation 12 weeks later, the tubes were covered with ovine collagen.[33,34] The collagen tubes were then fixed in a glutaraldehyde solution, rinsed in a buffered saline, and then stored in 50% alcohol at room temperature. Early results in dogs were extremely positive, with the ability to comply with arterial pressures and resist degradation for up to 3 years.[35] This initial design was later augmented by the incorporation of a polyester mesh over the tube to improved burst strength and reduce the risk of aneurysmal degeneration.

Eventually Bio Nova (North Melbourne, Australia) used this technology to produce Omniflow, a glutaraldehyde-tanned ovine collagen tube grown around a Dacron mesh template in a sheep bioreactor.[36] These grafts were first approved for use as a hemodialysis access in Australia, Germany, and Canada. An improved version of the original Omniflow device, the Omniflow II (now LeMaitre Vascular, Inc.), was released in 1990.[37] Subsequent studies have demonstrated primary and secondary patency rates approaching that of an arteriovenous fistula, with

reported secondary patency at 2 years of 75%, as well as a lower infection rate than ePTFE.[38]

More recently, Rothuizen and colleagues have rekindled work on creating TEVGs by foreign body response. This group has successfully modulated the histologic composition and architecture of the fibrocellular capsule produced by the foreign body reaction by using templates with different physiochemical properties.[39,40] Following early work using polymer rods in rats, the investigators have more recently used a large animal porcine carotid interposition model. Their early results demonstrate acceptable patency and acceptable mechanical and physiologic characteristics, as well as positive vascular remodeling of the graft post implant.[41]

Scaffold Based

Weinberg and Bell are credited with the creation of the first TEVG prototype. They developed a process using bovine aortic tissue to create the TEVGs that took approximately 4 to 6 weeks. First a rigid scaffold was created in vitro by casting a culture medium of collagen and smooth muscle cells and molding around an annular mold. This mixture was dehydrated over the course of a few days to form a rigid lattice before a Dacron mesh sleeve was slipped over the lattice to improve the TEVG integrity. Adventitial fibroblasts were then cast around the collagen/Dacron structure and allowed to cure for 2 weeks. The tube was then slipped off the mandrel and seeded with ECs over the course of 1 week.[42] The result was a TEVG with three distinct layers of vascular cells with physical and biosynthetic function. Although the inner aspect of the conduit was successfully lined with endothelium, the surrounding synthetic conduit was still subject to many familiar problems, including infection and stenosis. Others attempted to improve upon this initial design by surrounding the inner cell lining with stronger biologic materials; however, none of these solutions were able to combine adequate strength to resist high pressure and degradation with sufficient compliance comparable with native vessels.[43,44]

Biodegradable Scaffolds

Early work on the development and use of bioabsorbable polymers as a scaffold for cell transplantation and tissue engineering can be attributed to Joseph Vacanti and Robert Langer. Their investigation into cell transplantation and experimentation with various polymers as tissue scaffolds had far-reaching effects on hepatic, cartilage, and bone tissue bioengineering.[45-50] By the mid-1990s considerable progress had been made toward the development of tubular structures composed of biodegradable polymer scaffolds.[51,52] The initial foray into the cardiovascular system came when Christopher Breur and Toshiharu Shin'oka developed autologous lamb heart leaflets on a polyglycolic acid (PGA) scaffold.[53,54] PGA is the same polymer that has been used commercially for biodegradable surgical sutures for decades (i.e., Vicryl, Ethicon, Somerville, New Jersey).

As techniques to develop tubular structures improved, this technology was translated to clinical applications. In 2001 Shin'oka and colleagues reported the first successful application of a TEVG produced in vitro with autologous bone marrow cells (BMCs) on a biodegradable scaffold composed of L-lactide and E-caprolactone reinforced with a PGA woven fabric.[55] A pediatric patient with a single ventricle and pulmonary atresia underwent a pulmonary artery reconstruction after the patient's ECs were used to seed the conduit prior to surgical implant. After this initial success, this method was applied to two other successful cases, followed by clinical success in 22 more patients.[56] This approach provides the potential benefit of producing a tissue graft that may continue to grow with a young child, thereby minimizing the need for re-interventions. Ultimately, although this TEVG was acceptable for the low-pressure system, it was not structurally robust enough to be used under systemic arterial pressure. One point of concern was that PGA, a foreign material, may generate an inflammatory reaction that could weaken the integrity of the graft.[57]

Further improvements came as Langer and Laura Niklason focused on improving the integrity of the bioengineered vessels to withstand systemic arterial pressures.[58] A comparison of autologous bovine vessels grown under pulsatile conditions mimicking systemic pressure demonstrated improved vessel integrity and strength relative to vessels grown without exposure to pulsatile flow.[59,60] When examined histologically, vessels exposed to radial strain and pulsatility demonstrated improved SMC deposition, alignment, and orientation, as well as increase extracellular byproducts. VSMCs in these vessels also exhibited contractile reactivity to chemical stimuli. This work yielded the strongest bioengineered vessels created to that point with the support of a biodegradable matrix. Burst strengths were greater than 2000 mm Hg, and suture retention strengths were recorded as high as 90 g; these represented the strongest bioengineered vessels to that point.

Following the validation of the structural integrity and mechanical durability of this conduit, attention turned to the challenge of developing an appropriate decellularization process to eliminate antigenic materials.[61] Although several decellularization processes have previously been outlined, none of these had been successfully applied to bioengineered tissues. Ultimately a protocol described in 1995 was found to adequately treat the conduit without unacceptably compromising the compliance and mechanical properties of the graft.[62] Importantly these experiments led these investigators to hypothesize that bioengineered vessels may not require reseeding of the vessels with host cells prior to implant, owing to the migration of host cells, such as VSMCs, into the conduit extracellular matrix.

These findings were successfully translated into several large animal models including canine, porcine, and Old World primates. In 2011 Dahl et al. (now as Humactye, Inc., Morrisville, North Carolina) reported success in a translational model of TEVGs created from allogeneic dog cells to be used in the canine models and from allogeneic human aortic cells in the Old World primate baboon models, combining decellularized technology and biodegradable scaffolds.[63] This species of primate was chosen to provide a genetic phylum that was the most similar to humans, which could allow non–cross-linked human matrix–containing bioengineered vessels to be implanted without immunosuppression. Canine vessels were reendothelialized with autologous cells prior to implant, but the human vessels were not.

For primate experiments, allogeneic smooth muscle cells from human donors were grown on biodegradable PGA mesh scaffolds, positioned over a Silastic mandrel. The PGA mesh degraded slowly as the vessels grew in vitro over the course of 8 to 12 weeks. A final decellularization process using a series of detergents and hypertonic solution rinses rendered the vessels acellular and free from antigenic material—a human acellular vessel (HAV).[63] As Table 66.1 shows, this model is robust enough for arterial pressure, with burst strength in vitro of between 2651 and 3337 mm Hg while retaining compliance between saphenous vein and internal mammary artery. The Humacyte HAV has been implanted in primates in a model for dialysis access, with 88% patency when measured at various time points between 1 month and 6 months. Fig. 66.1 shows the graft in situ in a nonhuman primate with angiography demonstrating graft patency. Fig. 66.2 shows histology of the graft, with the decellularized allogeneic tube composed of collagen, fibronectin, and vitronectin and containing only minimal residual PGA.

Xenogeneic Tissue Scaffolds

An alternative approach to that taken by Vacanti, Langer, Niklason, and their colleagues is to use xenogeneic tissue as the scaffold for a bioengineered vessel. The benefits of this method are that animal tissue is readily available and their vessels have

TABLE 66.1 Suture Strength, Burst Pressure, and Compliance for Tissue-Engineered Vascular Grafts: Human Internal Mammary Artery and Saphenous Vein Parameters Provided for Comparison

	Suture Strength (g)	Burst Pressure (mm Hg)	% Compliance Per 100 mm Hg
Human Saphenous Vein[88]	196 ± 29	1,599	0.7-1.5
Human Internal Mammary Artery[88]	138 ± 50	3,196	11.5 ± 3.9

a supportive extracellular matrix premanufactured and, with adequate decellularized, their connective tissue matrix could be used as a scaffold for human EC seeding. In 2000 Augustinus Bader and colleagues reported the first such "humanization" of a xenogenic vessel. Porcine aortas were enzymatically decellularized before being seeded sequentially with human ECs and myofibroblasts were isolated from human great saphenous vein. The result was a porcine extracellular matrix, now fully endothelialized with human ECs and a myofibroblast media.[64] This work was expanded upon by Jörg Heine and colleagues, ultimately demonstrating that these "humanized" xenogeneic vessels regained vasomotor contractility and function.[65]

Human Tissue Scaffolds

Analogous to the method generating "humanized" xenogeneic grafts is the work done by Michael Olausson and his group in Sweden. This group performed the first and only procedure using a bioengineered vessel that they created from a decellularized human donor iliac vein.[66] This was done for a pediatric patient with thrombocytopenic purpura with extrahepatic portal vein thrombosis. With no autogenous options for conduit available, and with a family extremely resistant to the immunosuppressive medications required for transplantation, it was decided that a bioengineered vessel would be most suitable. The donor vessel decellularization process was similar to that described, and ECs and VSMCs differentiated and isolated from the recipient BMCs were seeded to the luminal surface of the decellularized human vessel scaffold over the course of 1 week.

Tissue-Engineered Sheets

The last subcategory of TEVGs is sheet-based grafts, which are cells grown in culture to create a sheet of cells that can then be formed into a tubular structure by wrapping the sheet repeatedly around a mandrel. Initial work with this methodology by Nicholas L'Heureux and colleagues was limited by the same difficulties with structural integrity that had previously limited Weinberg and Bell.[67] However, by 1998 this group had created a completely biologic tissue-engineered human blood vessel with sufficient burst strength and suture retention to be used in humans.[68] This relied upon a novel sheet-based manufacturing process. In brief, human umbilical vein ECs and VSMCs were isolated. VSMCs and fibroblasts were cultured in flasks to form sheets of cells and corresponding extracellular matrix. A fibroblast sheet was wrapped around a mandrel and dehydrated. A subsequent sheet-layer of SMCs, followed by fibroblasts, were wrapped around the initial dehydrated scaffold, and finally the luminal surface of the conduit was seeded with ECs. The total duration of this manufacturing process is approximately 4 to 6 months. Overall, if cell expansion time is factored in, this process requires approximately 4 to 6 months to complete.

In preclinical studies, L'Heureux and colleagues were able to demonstrate positive results with placement of human-derived xenografts in rodent, canine, and nonhuman primate models.[69] The group (Cytograft, Novato, California) demonstrated that these bioengineered vessels had structural integrity for human use and entered clinical trials and developed the Lifeline.[70,71] Indeed the tubular structure was capable of burst pressures greater than 3500 mm Hg, greater than that needed to support arterial pressure, with vessel compliance between that of saphenous vein and internal mammary artery (Table 66.2).

Cytograft has subsequently experimented with use of frozen, devitalized autologous vessels which allow autologous tissue biopsies to be taken far in advance of when the need for a vessel is anticipated. The vessel can then be manufactured, a process that takes 6 to 7 months, and stored safely at −80° C until it is needed. The vessel requires just 2 weeks of lead time to thaw and seed the lumen with ECs prior to implant. In the first case report of this device the vessel maintained patency and high flow rates up to the time of publication (8 weeks).[72] An alternative attempt to improve production efficiency has been the use of decellularized allogeneic tissue from healthy donors. Production of these vessels occurs as described previously up to the point of EC seeding, which is deferred. The vessel is dehydrated and frozen to −80° C until needed. Results from a case series of three patients, demonstrated acceptable results without any rise in either immunologic or inflammatory blood markers following implantation.[70]

CLINICAL EXPERIENCE

Intact Isolated Blood Vessels

The first significant clinical experience with intact isolated blood vessels came in 1970 after FDA approval of Artegraft. As a hemodialysis vascular access, patency rates have been similar to ePTFE.[73,74] However there have been reports of the medial layer of the bovine artery developing calcifications which have in some cases resulted in structural degradation and aneurysmal degeneration.[75] Although early experience with the bovine mesenteric vein xenograft Procol reported improved patency over ePTFE for dialysis access, with primary patency at 2 years of 70%, these findings did not translate to improved outcomes in infrainguinal reconstruction.[76-78] Indeed despite the positive performance of this product in terms of patency and decreased infection, Procol has not gained widespread clinical adoption.

CryoVein is currently approved for use as a conduit for both hemodialysis access and for peripheral bypass. Patency for CryoVein used as primary conduit for dialysis access was reported to have comparable but decreased patency when compared with ePTFE.[79] Due to the presumed resistance of CryoVein to infection relative to synthetic materials, some report using this as a salvage option for localized prosthetic graft infection.[80,81] Importantly other investigators report no decrease in infectious complications, at least not when these are used as thigh grafts.[82] In addition, despite treatment to remove blood type proteins and reduce immunogenicity, these grafts carry concerns about blood type compatibility and elevating panel-reactive antibodies in patients on the kidney transplant waiting list.

Biohybrids

The first clinical application of the luminal modification process was reported in 1978. Malcolm Herring and colleagues used ECs harvested from superficial veins to seed the luminal surface

TABLE 66.2 Comparison of the Preparation, Patency Rates, Complications, and Availability Between Isolated Vessels and Tissue-Engineered Vascular Tubes

	Preparation	Patency (Primary)	Patency (Secondary)	Complication Rate	Availability
Isolated Vessels					
Artegraft[98,99]	Bovine carotid artery treated with glutaraldehyde	87% (87/100) at 18 months 60.5%—12 months (16/26)	n/a 60.1%—12 months (16/26)	3% (1/26) thrombosis	Off the shelf
Procol[16,77]	Bovine mesenteric vein treated with glutaraldehyde	80%—12 months 70%—24 months (*n* = 25) 35.6% at 12 months (*N* = 183)	65.6% at 12 months 60.3% at 24 months (*N* = 183)	0.77 thromboses/year	Off the shelf
CryoVein (CryoLife)[79]	Cryopreserved human saphenous vein	60%—6 months 30%—12 months (*N* = 93)	82%—12 months 63%—24 months	18% aneurysmal 12% thromboses	Off the shelf
Tissue-Engineered Vascular Tubes

of a Dacron graft at the time of a peripheral bypass.[83] Unfortunately, subsequent trials using this technique failed to reproduce the promising outcomes seen in early reports.[84,85] In later decades investigators were able to improve upon this early methodology by extracting ECs from fat, omentum, and other tissues rich in ECs to improve cell density and performance in preclinical models.[20,21,86]

An alternative to seeding vascular grafts with differentiated ECs is to use endothelial progenitor cells.[20] In the 1990s Noishiki and colleagues seeded BMCs harvested from dogs onto ePTFE grafts, which resulted in fully endothelialized grafts with superior patency to nonseeded ePTFE grafts at 6 months.[87] Ultimately, despite these and other advances, investigation into biohybrid grafts has declined in favor of fully TEVGs.

Tissue-Engineered Vascular Grafts

The earliest clinical experiences with totally autologous grafts on biodegradable scaffold were reported in 2001 after Shin'oka performed a reconstruction of the pulmonary artery of a pediatric patient using autologous BMCs seeded onto a PGA-reinforced L-lactide and E-caprolactone.[55] Although this technique was subsequently replicated, the limited mechanical strength of this material prevented use in the adult systemic circulation.[56]

Cytograft—Tissue-Engineered Vascular Grafts for Hemodialysis Vascular Access

In the mid-2000s L'Heureux and McAllister formed the company Cytograft. Between 2004 and 2007 the company conducted their first phase I/II clinical trial using the Lifeline sheet-based TEVG as hemodialysis access conduit in patients with end-stage renal disease.[69,71] This was the first clinical trial using autologous cells to create a patient-specific bioengineered vessel and the first human use of TEVG in the high-pressure systemic arterial circulation. Fig. 66.3 shows a Lifeline TEVG implanted in human subject. Fig. 66.4 shows a histologic cross-section of the graft demonstrating the sheet-like structure of the TEVG.

Even though the Lifeline is composed of human cells, which should have minimal immune reaction, investigators noted an early failure rate of approximately 30% within 90 days. This was ultimately attributed to the use of bovine proteins used during early vessel production, which generated an immune

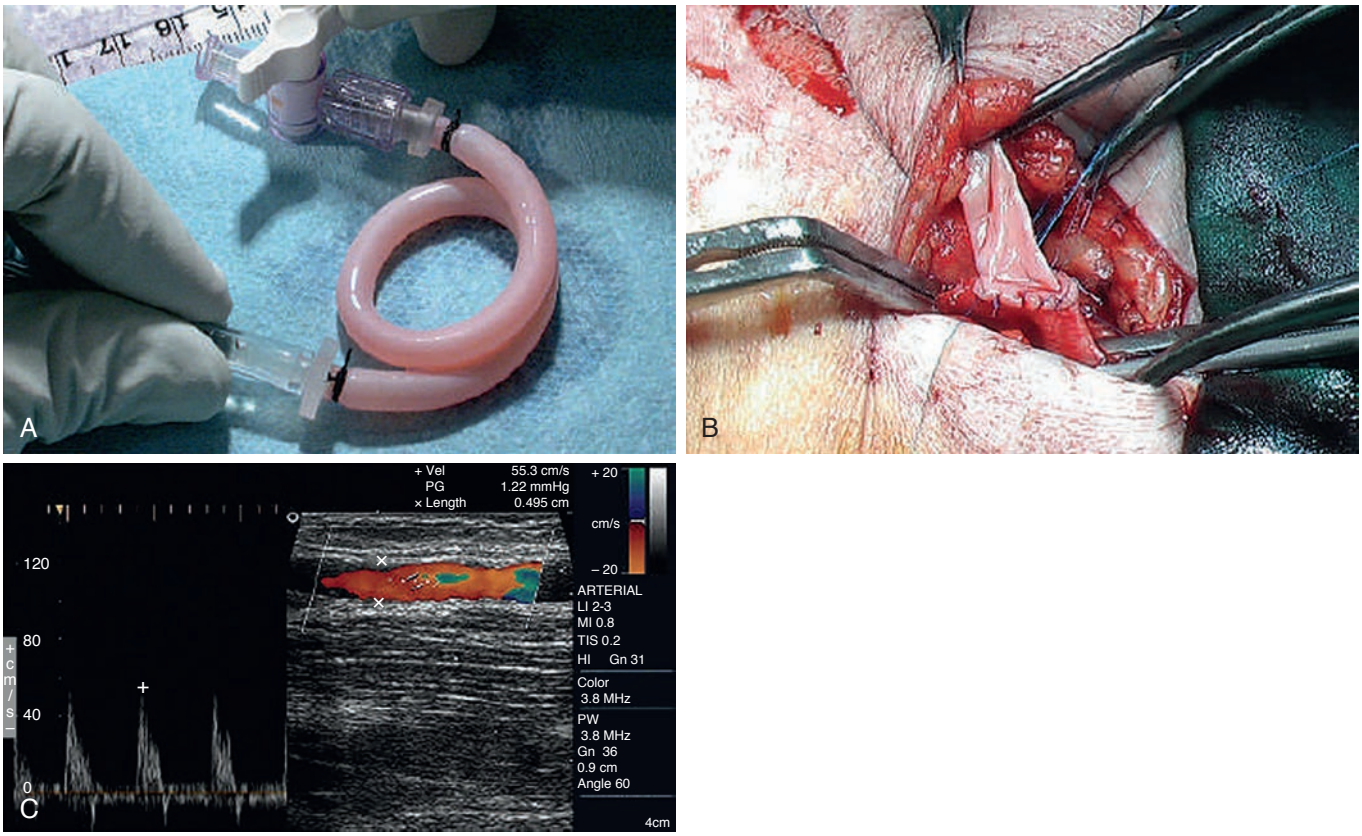

Figure 66.3 Images of a Sheet-based Graft (Lifeline, Cytovein, Novato, CA). (A) An autologous graft was implanted in a human recipient as an arteriovenous shunt between the humeral artery and the axillary vein. (B) The tissue-engineered blood vessel during implantation. (C) On duplex at 6 months the graft maintains high flow without signs of restenosis or aneurysm. (Reproduced with permission from Konig G, McAllister TN, Dusserre N. Mechanical properties of completely autologous human tissue engineered blood vessels compared to human saphenous vein and mammary artery. *Biomaterials*. 2009;30(8):1542–1550.)

reaction that was not seen in subsequent productions. Despite these successful clinical applications, the Lifeline is not available as a truly off-the-shelf conduit because the manufacturing process requires autologous cell culture over 24 weeks. Decellularized allogeneic grafts and devitalized, frozen grafts may expand the use of this vessel; however, further investigation is needed to define the long-term results with these modified devices.[88]

Olausson—Decellularized Human Donor Vessel Scaffold

The 2012 use of a decellularized human iliac vein for bypass of an extrahepatic portal vein thrombosis in a pediatric patient remains the only reported use of a TEVG derived from a fully decellularized intact human blood vessel.[66] The direct application of this technique to further clinical practice is limited both by the availability of suitable donor tissue and by the need for prolonged seeding of the conduit with recipient cells.

Humacyte, Inc.—Tissue-Engineered Vascular Grafts for Hemodialysis Vascular Access and Peripheral Arterial Bypass

Following successful preclinical work in baboons with decellularized, allogeneic human bioengineered vessels, Humacyte entered into its first phase I/II clinical trial in December 2012 using the HAV as a conduit for hemodialysis access. This study was conducted as two single-arm trials in the United States and Poland. The vessel was implanted into the arms of 60 patients with ESRD who were not candidates for AVF creation, and subjects were followed for a period of 24 months. Overall, the acellular vessel was tolerated well by all subjects without evidence for immune response to the HAV, as evidenced by no significant change in a panel of reactive antibodies. The incidence of HAV infection in the phase II AV access studies was extremely low. Only one vessel became infected during more than 82 patient-years of follow-up. Mean follow-up was 16 months, and there were no reports of spontaneous aneurysmal dilation or postcannulation bleeding. At 6 months, 63% of patients had primary patency, 73% had primary assisted patency, and 97% had secondary patency. At 12 months, 28% had primary patency, 38% had primary assisted patency, and 89% had secondary patency. Histology from isolated HAV explants (see Fig. 66.1) during surgical interventions revealed evidence of host VSMC and EC infiltration into the walls of the vessel, essentially rendering the bioengineered vessel a new living tissue in the recipient host.[89]

In May of 2016 the company commenced the first-ever phase III clinical trial for a bioengineered implantable tissue. This clinical trial is a multinational, double armed, randomized

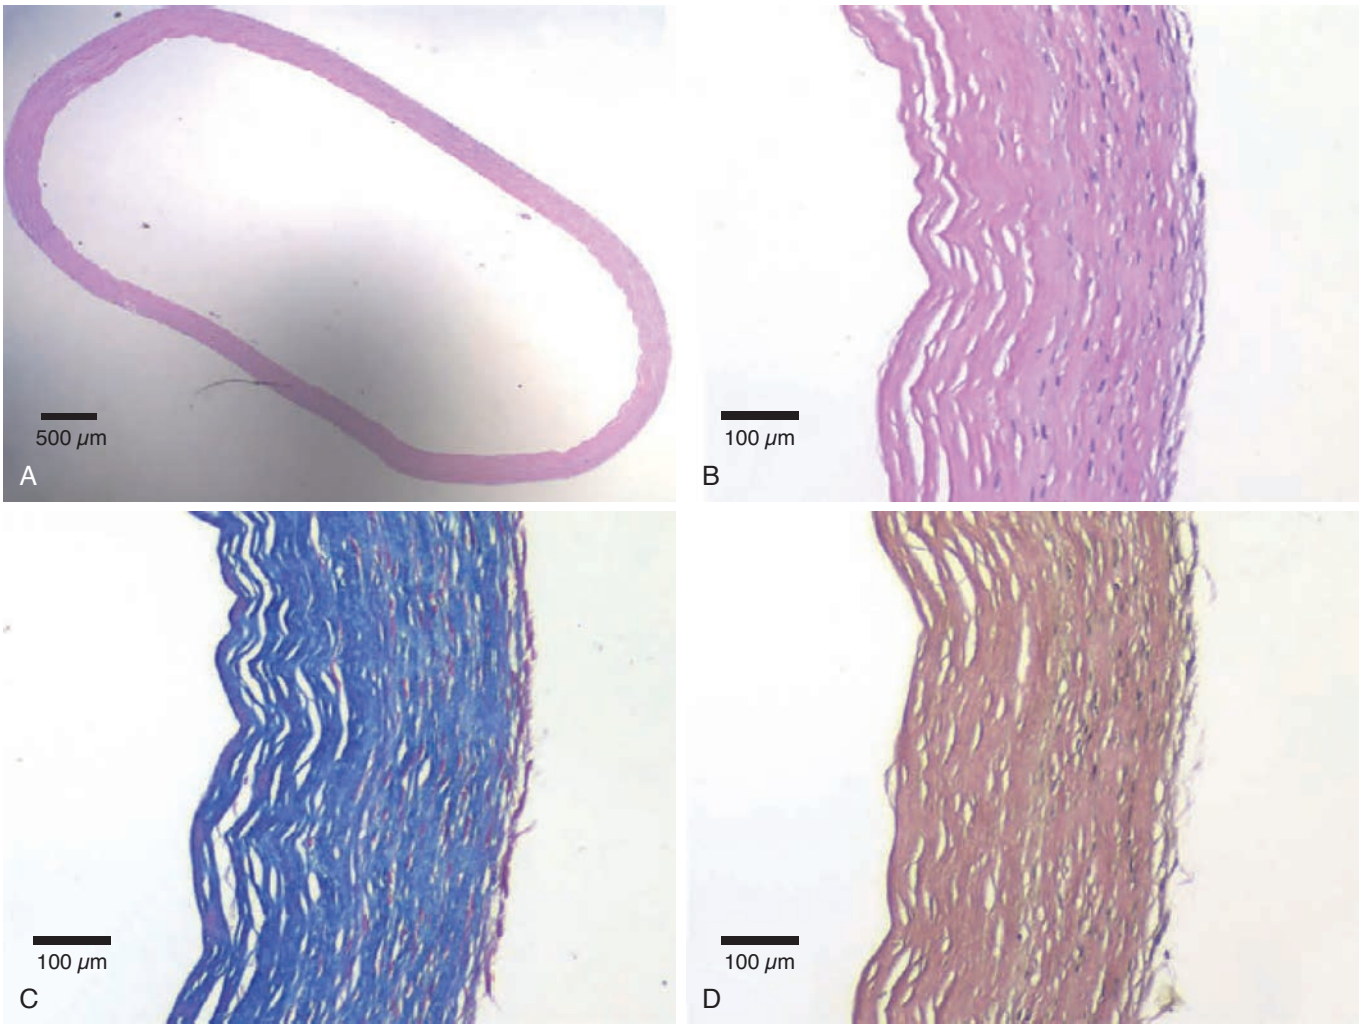

Figure 66.4 Histologic Analysis of a Sheet-based Graft (Lifeline, Cytovein, Novato, CA). (A) H&E stain of the graft at 2× original magnification. (B) H&E stain of the graft at 10× original magnification. (C) Masson trichrome stain at 10× original magnification, which stains collagen *blue*. (D) Verhoeff-van Gieson stain at 10× original magnification, which stains collagen *red* and elastin *black*. (Reproduced with permission from Konig G, McAllister TN, Dusserre N. Mechanical properties of completely autologous human tissue engineered blood vessels compared to human saphenous vein and mammary artery. *Biomaterials*. 2009;30(8):1542–1550.)

clinical trial to compare the HAV with the current standard of ePTFE for patients not suitable for creation of an AVF. The primary endpoint is secondary patency at 2 years, and the goal for total enrollment is 350 patients.

Humacyte has competed a phase II study in Poland using the HAV as a bypass conduit for above-knee superficial femoral artery occlusion, and the company has recently commenced a similar trial in the United States. Both studies are single armed and safety focused, with a goal to enroll a total of 40 patients (20 in the United States, 20 in Poland). Results from these studies have yet to be published.

To date, clinical experience indicates that the HAV remains mechanically strong over implantation periods of more than 45 months, with no evidence of dilation. During more than 150 patient-years of follow-up across the three phase II studies (ESRD and PAD), only one case of infection of the HAV material itself has been reported. The serious adverse event profile has been typical of that expected in the dialysis and PAD populations. Secondary patency of the HAVs is substantially higher than the historical data for both ePTFE and AVF (accounting for nonmaturation). No evidence of immunogenicity of the HAV has been found, and the HAV remains mechanically robust even after repeated puncture for hemodialysis. The HAV in the decellularized form has a shelf life of at least 6 months according to tests, but there is ongoing work to extend that window to 12 to 18 months.

LIMITATIONS AND RISKS

Despite rapid progress in the development of durable bioengineered vascular grafts, each of the products and technologies presented in this chapter have limitations. Use of intact isolated blood vessels continues to raise concern for decreased patency and durability. Biohybrids have fallen out of favor due to the

difficulty of harvesting and seeding ECs, as well as the potential need for a two-stage surgery. Although early clinical experience with fully TEVGs has shown promising results, large-scale clinical trials remain ongoing. Thus both cost effectiveness and long-term outcomes remain incompletely understood.

FUTURE ADVANCES

Three-dimensional (3D) printing is a rapidly evolving technology that holds significant promise for the future of bioengineered blood vessels. This process, in which the repetitive deposition of materials layer by layer is used to generate complex 3D structures, has been adapted to produce biologic and biocompatible materials in a process known as "bioprinting."[90] Using a combination of cells and biologic polymers as "bio-ink" this has already been used to produce in-vitro models of blood vessels lined with ECs, and this may ultimately overcome some of the limits of existing methods for bioengineered vessel production.[91-93]

Another technology that is being investigated for its potential applications for bioengineered blood vessels is electrospinning. This is an established technology in which an electrical field is used to guide the deposition of polymers onto a grounded platform. A source material (which can be chemicals, biopolymers, nanoparticles, or cells) is "sprayed" onto this platform, with an electrical charge guiding the orientation of the resulting structure.[94] This can be used to produce either tubular structures or flat sheets and provides the potential benefit of producing improved scaffolds that more accurately reproduce the triple-layered structure of human blood vessels. In addition, co-spinning of multiple substrates may result in improved strength and compliance of conduits relative to existing methods.[95,96]

The field of bioengineered vascular tissues spans a period of more than 50 years. In this time, we have benefited from the brilliant and diligent works of several teams from around the world. The processes of developing conduit for use as blood vessel replacements have progressed at an astonishing rate. Early work to use autologous conduit gave way to later processes attempting to decellularizing these vessels and ultimately the creation of entirely TEVGs.

Tissue-engineering technologies have now advanced to the degree that the manufacturing of an allogeneic, readily available, biomimicking vascular tube is feasible. There is now evidence to support that strong, nonimmunogenic, human-derived vessels are well received by the recipient host and may even become a living tissue within the patient who requires blood vessel replacement. Cost, scale, manufacturing, biocompatibility, thrombogenicity, and durability remain important questions on the horizon for this innovative technology. Continued careful, safety- and efficacy-focused clinical trials with progression to long-term, randomized clinical studies will be necessary to eventually validate this promising technology in hopes that it may one day provide a benefit to the millions of patients in need.

NEW DEVELOPMENTS 865
Absorbable Stents 865
FUTURE DEVELOPMENTS 866

Endovascular therapy has changed the landscape of vascular surgical practice. A major thrust into catheter-based therapy was initiated in 1999 with the US Food and Drug Administration (FDA) approval of endografts for aneurysmorrhaphy. As this important technique became ubiquitous, surgeons began to utilize stents in other vascular beds both for initial therapy and as secondary treatment after failed vascular grafts. Endovascular therapy with stents is now utilized throughout the vascular system, including arteries and veins ranging from the intracranial circulation to the tibial arteries.

As the use of endovascular stents has undergone more critical study, it has become evident that various vascular beds react differently to stent placement.[1-3] Furthermore, angioplasty and stenting alter the biology of the treated vessel, a finding that has implications for both short-term and long-term results. The nature of the lesion, as well as the vascular bed to be treated, dictate specific nuances that guide the surgeon in choosing an appropriate stent.

This chapter focuses on factors that relate to the choice of stents and stent grafts for endovascular intervention in nonaortic vascular beds. The indications for stent use in conjunction with balloon angioplasty as well as the interaction between vessel and stent are reviewed. The multiple factors that influence the optimal stent choice in a given circumstance are considered, including device characteristics relating to the mechanics of stent deployment, cell design, precision, treatment length, deliverability, and adjunctive stent designs that may affect therapy.

HISTORICAL BACKGROUND

Isolated dilation of vessels using dilation catheters was first introduced in 1964 by Dotter et al.[4] This technique was refined in the 1970s by Gruentzig et al,[5] who used smaller catheters with attached balloons that could be delivered through the vascular tree from a remote location. Balloon angioplasty became a popular technique in the 1980s but remained inferior to surgical reconstruction because of the high acute occlusion rate and intermediate restenosis rate. Acute technical failure occurred as a result of elastic recoil, vasospasm, plaque rupture, or dissection. Recurrent stenosis, caused by an intense hyperplastic response, was commonly seen within the first 2 years after intervention. In the initial series of coronary angioplasty, interval restenosis occurred in 30% to 50% of treated lesions.[6-8] Likewise, angiographic failure of isolated angioplasty in the renal, iliac, and femoropopliteal arteries occurred in up to 26%,[9,10] 32%,[1] and 50%,[11,12] of cases, respectively.

Abstract

Implants within the hemodynamic milieu of the vascular system undergo unique stress/strain relationships. The choice of stent composition and stent type—balloon expandable, self expanding, covered, non-covered, etc—have profound affect on long term patency and integrity. The failure modes of endovascular stent placement are related to both mechanical stress and biologic response of the host to the implant. Mitigation of mechanical failure can be achieved through proper selection of stent based upon vessel location, mobility, and external compression. Similarly, several novel strategies seek to limit the neo-initimal response and promote long term success with stenting. This chapter focuses on the construct of various stent types and reviews the mechanical advantage posed by them. In addition, we will review novel therapies to influence long term success.

drug-elution
plaque morphology

Stenting was introduced to improve results of angioplasty by ensuring an adequate lumen, maintaining flow, and reducing embolic load. Achieving optimal luminal diameter lessens the impact of in-stent neointimal formation. However, paradoxically, the stent itself has inherent properties that alter the development of normal vascular intimal formation and can lead to maladaptive remodeling through direct intimal damage related to the procedure and the interaction between the arterial wall and the stent itself.

STENT-VESSEL INTERACTION

Vessel Injury

The degree of intimal response to stent placement has been linked directly to the extent of vessel injury. Sullivan et al[13] used an experimental stent with beveled struts to demonstrate this negative remodeling effect in vivo, utilizing a swine model. This experimental stent was designed to violate the internal elastic lamina. In comparison with Palmaz stents deployed in control animals, the experimental stent was associated with significantly greater neointimal formation. Furthermore, the extent of vessel injury demonstrated a linear effect on the absolute neointimal formation.

In addition, an inflammatory response to stent placement has been demonstrated histologically. In an early autopsy series, Farb et al[14] demonstrated inflammatory cell infiltration in the area of the vessel directly adjacent to the stent struts. The absolute number of inflammatory cells present was significantly increased when stent struts violated the internal lamina and penetrated into the lipid core of the plaque. Subsequent analysis demonstrated that inflammatory mediators were present more than 6 months after implantation. Another study showed that, in addition to the effect of the stent itself, bacterial contaminants introduced to the vessel wall during stent delivery also play a role in neointimal formation.[15]

Fluid Dynamics

Endovascular stents also alter the fluid dynamics of the stented segment. The most widely studied impact of stent placement on flow and negative remodeling is the creation of areas of low (<5 dyne/cm^2) wall shear stress (WSS). Alteration in WSS occurs both as a result of a change in luminal diameter of the treated vessel and secondary to the presence of the stent itself. In a computational flow model, LaDisa et al[16,17] demonstrated several characteristics of stent placement that create a low shear stress environment. The factor that led to the most significant increase in the proportion of vessel wall exposed to a low shear environment was overdistention of the stented segment. Although some degree of stent oversizing is necessary for appropriate apposition of the stent to the vessel wall, LaDisa's group demonstrated a 13-fold increase in the total native vessel exposed to low WSS with 20% stent oversizing over that with 10% oversizing. The low WSS can subsequently lead to greater neointimal hyperplasia and recurrent stenosis. This finding is validated clinically because most surgeons aim for a 10% oversizing when stenting infrainguinal occlusive lesions.

Strut Characteristics

The tolerances for stent construction are very strict, and minimal alteration of the strut height can have a significant impact on shear stress and neointimal formation. Intuitively, the area of the vessel wall adjacent to the stent struts has the greatest potential for negative remodeling. Eddy currents created as blood flows over the stent struts lead to regions of low shear. This effect results in a proportional change in shear stress with alterations of strut thickness. The formation of neointima in such areas of low shear stress has been reproduced in several models, and the thickness of the resultant neointima correlates with strut coverage, configuration, and thickness.[18-20] Sprague et al[21] demonstrated that positive remodeling, as measured by endothelial cell migration, is hampered in low WSS environments. In normal shear models, migration of endothelial cells increased 2.5-fold within 1 week after implantation of steel struts onto the endothelial surface. However, in stented models with low shear, this migration was delayed up to several months.[22] The clinical effect of these findings was demonstrated by the angiographic restenosis rates of two nearly identical coronary stents that differed only by stent heights of 50 μm and 140 μm. The stent with the lower-profile design had less restenosis.[23]

Stent Composition

The material composition of the stent also plays a role in neointimal formation. The most common bare metal stent components are stainless steel, nitinol (nickel and titanium alloy), cobalt chromium alloy, and tantalum. Although the actual mechanism of vessel injury from stent components is unclear, corrosive products from alloys have been found within sections of vessel wall. In addition, hypersensitivity of some patients to certain metals has been observed.[24] Palmaz et al.[25] demonstrated that galvanic currents are created within stented arteries and lead to corrosion and subsequent vessel injury.

STENT TYPES AND CHARACTERISTICS

Each stent has intrinsic properties that determine whether or not it is suitable for any given lesion.[25-31] On the basis of the biologic interaction between vessel and stent, an ideal stent would be easy to deliver through a small-caliber sheath, be readily visible on fluoroscopy, conform to the vessel upon deployment, prevent acute procedural failure, provide long-term resistance to negative remodeling, and be fracture-resistant.

Generally, stents are divided into two groups according to their construction and mode of deployment—self-expanding (SE) versus balloon-expandable (BE) (Table 67.1).

Important Characteristics

In a comparison of SE and BE stents, the major characteristics that determine suitability are radial force, flexibility, and precision of deployment. Both SE and BE stents can be covered with polytetrafluoroethylene or polyester, and such stent grafts combine the advantages of a stent with those of a graft.

TABLE 67.1 Comparison of Balloon-Expandable and Self-Expanding Stents Based on Intrinsic Characteristics and Clinical Use

Characteristic	Balloon Expandable	Self-Expanding
Radial force	High	Low
Flexibility	Low	High
Requires delivery sheath	Yes	No
Radiopacity	High	Variable
Oversizing recommended	No	Yes
Treats lesions with variable diameter	No	Yes
Resistant to external compression/bending	No	Yes

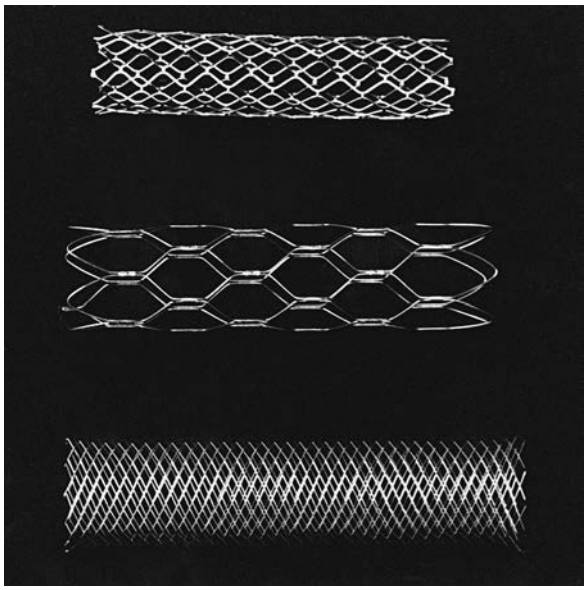

Figure 67.1 Comparison of stents. From top to bottom are the balloon-expandable Palmaz stent, the self-expanding nitinol Symphony stent, and the self-expanding stainless steel Wallstent.

Radial force is defined as the force required to produce a 50% reduction in the luminal diameter of the stent. The radial force of the stent maintains its apposition to the vessel wall and tacks down intimal flaps that may obstruct flow. It also provides the support to resist immediate vessel recoil and acute occlusion. This outward force may lead to a better technical result than that of balloon angioplasty alone. As the stent is incorporated into the vessel, the radial force resists deformation and negative remodeling to maintain luminal diameter over time.

Ultimately, radial force is a product of both stent design and composition. The original Palmaz stent has a stainless steel slotted/diamond design. The slotted configuration allows the stent to maintain a low profile for loading on the balloon. Once expanded, the slots become diamonds, resisting further conformational change and providing a high radial force. The Wallstent (Boston Scientific, Natick, MA, USA) also has a diamond configuration, but is designed to change lengths with its diameter. Therefore, its radial force is related to both its design and the degree of endothelialization within the artery. As the stent becomes more securely anchored, it resists shortening and actually leads to increased radial force. Various BE and SE stents are shown in Fig. 67.1.

Conversely, nitinol stents rely on the inherent nature of their metallic composition to provide resistance to deformation. The nitinol alloy assumes a predetermined configuration at a desired temperature. At low temperatures, the alloy exists in the martensite state (metallurgic property of shape-memory alloys in which the crystalline structure of the alloy is elongated or asymmetric at cooler temperatures), which is flexible and aids both mounting on the catheter shaft and deliverability. At higher temperatures, the alloy adopts a crystalline austenite state (metallurgic property of shape memory alloys in which the crystalline structure is symmetric) which makes the stent rigid, thereby providing more radial force.

Flexibility is determined by the same properties that govern radial force. BE stents require a force to change conformation. Thus these stents are less able to maneuver through tortuous vessels. BE stents are susceptible to deformation in mobile arteries because the torque required to maneuver them may enact a conformational change in the stent. In contrast, the nitinol stent, while in the martensite state, can be easily deformed and, therefore, is more suitable for arterial anatomy, which requires significant maneuverability to reach the target lesion. Interestingly, nitinol may change states not only in the setting of temperature change, but also in response to external compression. Such qualities afford nitinol stents improved flexibility in mobile arteries after implantation. Such is not the case for BE stents (Fig. 67.2).

Radiopacity is a consideration important in stent deployment. The material used in stent construction is a major determinant of radiopacity. Stainless steel is more visible than nitinol; thus BE stents are, generally, more visible on radiographic imaging than SE stents. Improved visibility leading to increased accuracy of deployment must be considered in the choice of the appropriate stent for a given indication (Fig. 67.3).

Cell Size: Open and Closed Cells

Stent cell size should be considered in the selection of the best stent for a given clinical situation. *Cell size* refers to the area outlined by connected metallic components within a stent. Stents with a large cell size are labeled "open cell" stents, and those with a small cell size are termed "closed cell" stents. The cell size of a stent and the connection of the metallic wires to each other may influence performance.

A closed cell stent has consistent interconnection of all stent wires throughout its length. This consistency provides a fixed area of interstices within the stent and uniform coverage of the vessel wall. Such construction decreases the free cell area, and may trap fractured plaque at the time of deployment, limiting distal embolization. However, this configuration makes a stent less flexible and conformable. Considering the previously

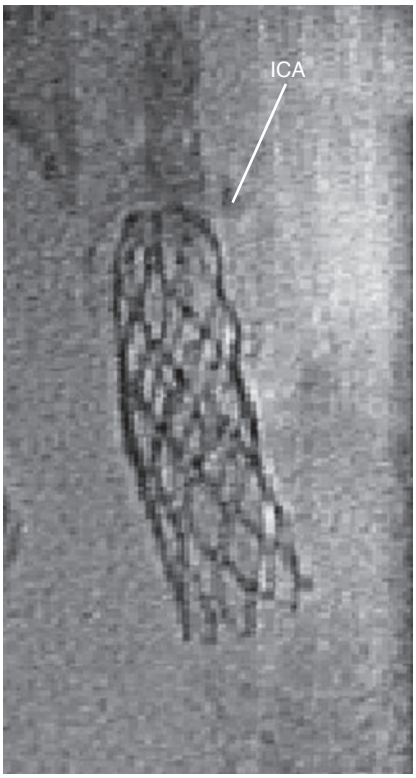

Figure 67.2 This balloon-expandable stent in the cervical portion of the carotid artery is deformed at the distal endpoint where the carotid artery is mobile and susceptible to external compression.

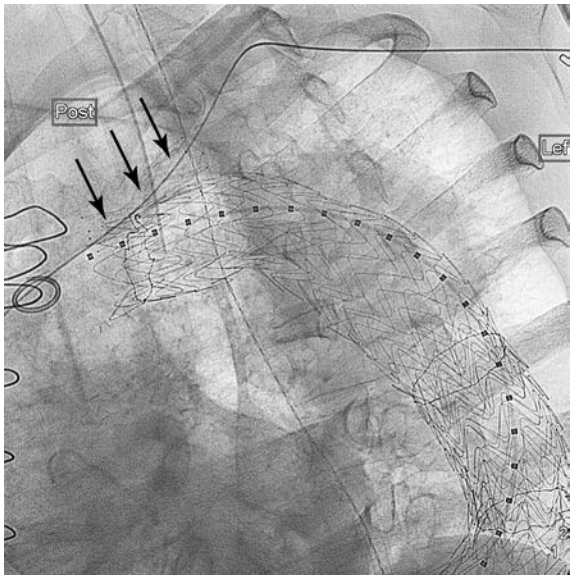

Figure 67.3 A flexible nitinol stent is placed across the subclavian artery origin *(arrow)* to maintain patency when a thoracic endograft has covered the ostium.

mentioned advantage of the SE stent, the closed cell stent may have more difficulty matching the tortuosity and change in luminal diameter across a vessel length.

Conversely, in open cell stents, the wires are not interconnected throughout the entire stent. This feature allows for a greater range of movement between the stent components and leads to added flexibility and conformability. It also results in significantly more vessel wall exposure between stent struts and greater potential for debris to embolize during deployment or balloon dilatation. Free cell area can vary from 1.08 mm^2 in the smallest closed cell stent to 11.48 mm^2 in the largest open cell stent.[26]

The efficacy of cell design to lower embolic phenomena during stenting has yet to be determined. Stent cell size has received the most attention in the treatment of carotid lesions but may also have implications at other sites. Hart et al[32] demonstrated a significant reduction in rates of stroke, transient ischemic attack, and death when closed cell stents were compared with open cell stents in a series of 701 carotid stents. The odds ratio was most significant in treatment of symptomatic lesions. A larger study combining patients from 10 European centers demonstrated no significant difference, even in symptomatic lesions, between the two stent designs.[27] Because closed cell stents are less flexible, a bias may exist to use them in straighter, less complicated lesions. Ultimately, the use of an open or closed cell stent remains the prerogative of the clinician because there is no convincing evidence of the superiority of one over the other. The operator should seek ideal stent characteristics based on both the nature of the lesion and its location.

Balloon-Expandable Stents

BE stents are optimal in clinical scenarios where high radial force and precise deployment are imperative. Unfortunately, the characteristics of BE stents may also limit deliverability to target lesions. Because they are mounted on balloons, BE stents are at risk for dislodgement both during transit to their target and while crossing the lesion. For this reason, it is recommended that a BE stent be delivered through a guiding catheter, or sheath, over a stiff guide wire. The guiding sheath should be advanced beyond the target lesion before the stent is delivered to the deployment site. Once the stent is positioned at the lesion, the sheath is retracted to allow for stent deployment. The BE stent is deployed as the balloon is inflated to nominal pressure. The balloon is designed to inflate at both ends simultaneously, so as to prevent a forward slippage ("watermelon seeding") of the stent off the balloon before complete deployment.

The BE stent achieves a size corresponding to the degree to which the balloon is expanded. Because this stent is deployed by expansion, vigorous oversizing of the stent in relation to the vessel is not recommended. However, one advantage of the BE stent is that it can be further distended to a larger diameter if optimal vessel apposition is not obtained. Of note, aggressive oversizing of the stent with a larger balloon will foreshorten the stent and weaken its struts, leading to increased risk of stent failure.

Innate characteristics of BE stents, including minimal displacement with deployment, make them ideal for treating difficult lesions in which precise placement is paramount. Thus, BE stents are widely used to treat ostial lesions of aortic branch vessels, such as renal, common iliac, and subclavian arteries, where the lesions are anatomically fixed and thus have little potential for stent deformation with movement. In addition, plaque at bifurcations tend to be more calcific and prone to

dissection. In our experience, deployment of "kissing" BE stents in such lesions results in a lower incidence of dissection than balloon angioplasty alone.

The construction of the BE stent also accounts for its major limitations. When the segment being treated transitions across a branch point from a larger into a smaller artery, the high radial force across arteries that have different radii make a BE stent inappropriate; examples of such branch points include the iliac and carotid bifurcations. In these settings, the rigid size constraints of the BE stent may not allow for adequate apposition to the entire treated segment. Furthermore, these transitions are frequently mobile and may lead to stent deformation. Additionally, the higher profile needed to deliver both stent and balloon may necessitate predilation for delivery of the stent to the desired location. In certain situations, such as treatment of renal and carotid stenoses, the consequences of embolization are severe. Predilation should be considered with small balloons to improve subsequent stent deliverability and to prevent embolism or dissection. Embolic protection devices can also be considered in territories at risk of embolic complications. Finally, a BE stent may fracture or retain a new conformation when stressed by outside forces. This risk of deformation affects the decision to use a BE stent across the inguinal ligament or joints. In these positions, the risk of stent compression with fracture and subsequent vessel occlusion is increased. Care must also be taken when one is operating on an artery treated with a BE stent. Clamping of such an artery may lead to a permanent conformational change or stent fracture that may require redilatation or surgical removal of the stent.

Self-Expanding Stents

SE stents are better suited for tortuous lesions or those traversing vessels of variable diameters. These stents are more flexible than BE stents (Fig. 67.4). Therefore, they can be delivered through vessels that create more torque within the catheter. To maintain the stent in its constrained form during transit to the lesion, the stent is covered by an outer sheath on the mounting catheter. When this sheath is withdrawn, the stent is allowed to take its natural shape. As such, SE stents do not require that guiding catheters or sheaths be advanced beyond the target lesion. Actual deployment of an SE stent requires sequential removal of the constraining sheath from the distal end of the catheter to its proximal end. During this maneuver, the stent can either inadvertently jump forward or be retracted by the operator. This potential jumping forward of the stent can lead to maldeployment and must be considered by the operator prior to final deployment maneuvers.

Another factor to consider in the use of an SE stent is the need for adequate oversizing. As mentioned previously, flow dynamic models demonstrate optimal shear environments at a 10% oversizing. Nevertheless, it is essential to choose a stent that opposes the vessel wall on deployment because an SE stent cannot be overdilated. In the instance in which an SE stent is undersized for a given vessel, a second, larger-diameter stent can be deployed within the initial stent to aid with stent fixation. A BE stent is the preferred choice in this circumstance because its increased radial force can overcome the nominal diameter of the SE stent.

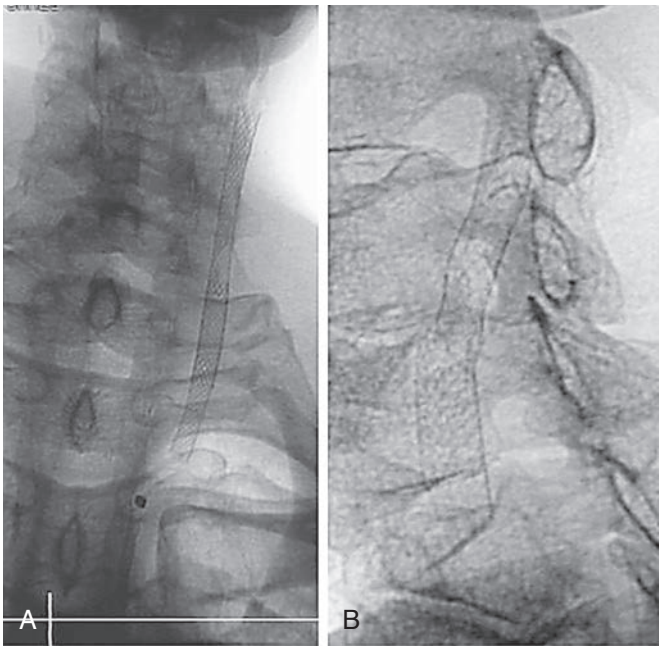

Figure 67.4 Plain radiographs of a stainless steel self-expanding stent **(A)** and a nitinol self-expanding stent **(B)** show the improved visibility of the stainless steel stent.

Because SE stents have less radial force and, conversely, improved elasticity, they are ideal for lesions that cross tortuous vessels, joints, or vessel branches. Common locations where SE stents are used include the carotid bifurcation and the transition zone from the common to the external iliac artery. SE stents are used preferentially in infrainguinal arteries because they can accommodate movement within the limb with less likelihood of fracture and subsequent failure.

Stent Grafts (Covered Stents)

Stent grafts, or covered stents, have expanded the use of endovascular technology beyond their contribution to the treatment of aortic aneurysms. A covered stent may be considered the ultimate closed cell stent, with the inherent applications and limitations of complete coverage of the treatment area. Stent grafts can be organized on the basis of graft material and deployment characteristics. Polyester (e.g., Wallgraft [Boston Scientific]) and polytetrafluoroethylene stent grafts (e.g., VIABAHN [W.L. Gore, Flagstaff, Arizona], iCAST [Atrium USA, Hudson, NH], Jostent [Abbott, Abbot Park, Illinois], Fluency [Bard Peripheral Vascular, Inc., Tempe, Arizona]) are currently available. Some stent grafts are balloon-expandable (e.g., iCAST) whereas others are self-expanding (e.g.,VIABAHN, Jostent, Wallgraft). This stent-graft variety is further complicated by different deployment mechanisms and delivery characteristics that affect clinical utility. Even within the SE category, deployment can be distal to proximal (Jostent, Wallgraft) or proximal to distal (VIABAHN). This variability allows stent grafts to be utilized in a wide variety of lesions.

Stent grafts provide the inherent advantage of continuous exclusion of the vessel wall from luminal flow. Historically, this feature allows complete exclusion of vessel defects, such as aneurysm, arteriovenous fistula (AV), pseudoaneurysm, embologenic plaque, and frank perforation. Several case reports have demonstrated the utility of stent grafts in acute vascular trauma. True aneurysms of peripheral arteries, such as popliteal or visceral artery aneurysms, are also amenable to treatment with covered stents.[33] Stent grafts have been deployed into the subclavian artery to treat aneurysmal degeneration, although special care should be taken to rule out an associated outlet syndrome in those patients who may require further surgical cervical or first rib excision.[30]

Stent grafts can be utilized to "trap" debris within the treated lesion. This approach, in theory, lessens the risk of embolization during inflation. The embolic source can be trapped by inflation of a BE stent graft, or an SE stent graft can be deployed followed by post-deployment molding. Embolization has been shown in both ex vivo and in vivo models of angioplasty in several arterial beds.[31,34,35] Therefore, the use of stent grafts may prove to be an effective treatment of renal, iliac, or subclavian lesions, in which embolization may add significant morbidity. However, the covered stent may have limited use in certain locations because it will exclude any branch points or collateral vessels covered by the stent during placement.

Another potential use for stent grafts is to treat long lesions of the superficial femoral artery (SFA). In this position, the covered stent provides protection from embolization during deployment and theoretically provides a barrier to smooth muscle cell migration and neointimal growth within the treated segment. The SFA often has a large plaque burden that can hasten failure of a bare metal stent due to an aggressive neointimal response and ingrowth by medial smooth muscle cells (Fig. 67.5). In a randomized comparison, Kedora et al[36] demonstrated equivalent rates of patency and limb salvage in a stent graft and a prosthetic bypass for various lesions in the above-knee position, treating various Trans-Atlantic Inter-Society Consensus for the Management of Peripheral Arterial Disease (TASC) lesions with comparable runoff. However, a rigorous, randomized trial has not compared stent-graft placement with popliteal bypass from femoral to above the knee using a vein conduit. A drawback of stent graft use is the potential of exclusion of important branches or collaterals. When the stent graft is deployed, collaterals may be covered within the treated segment; therefore, subsequent stent thrombosis may lead to worse limb ischemia than in the original limb before treatment.

Figure 67.5 Angiographic image of dense neointimal reaction through the interstices of a stent that was placed in a superficial femoral artery 12 months earlier.

SELECTION OF STENT

After consideration of the various stent characteristics, the selection of an appropriate stent depends on plaque morphology, external forces, anatomic location, and branch locations. Foremost, the stent must treat the primary lesion.

Plaque Morphology

If there is concern about microembolization of debris with stent deployment, a covered stent or closed-cell stent should be used. Procedural and early postprocedural embolization associated with carotid stenting can have important clinical sequelae (Fig. 67.6). Additional data about plaque morphology may help predict which lesions are more likely to embolize through the interstices of the stent. Some researchers have used ultrasound technology to evaluate a gray-scale median to determine the embolization potential of a specific carotid plaque.[37] Magnetic resonance or computed tomographic imaging may also provide morphologic plaque information about lipid content that can help the clinician choose a stent type.[38]

Additionally, if stenting is indicated in the setting of possible fresh thrombus, one should consider selecting a covered stent. Although it may be difficult to differentiate a stenotic plaque from an organized thrombus, clinical or angiographic evidence of distal embolization in the lower extremity should raise concern about a proximal iliac, femoral, or popliteal lesion that is unstable and prone to repeated embolization during manipulation. In addition, an evaluation of the size and filling of collaterals at the level of occlusion may indicate a chronic rather than acute process. If a covered stent cannot be used, one should consider various embolization protection methods, such as filter wires, reversal of flow devices, and open arterial exposure, to flush debris away from the distal vascular bed.

External Forces

After assessment of the luminal surface of the artery and its lesion-specific pathology, the clinician must also consider the potential external forces that may affect the stent in its designated location within the proposed arterial or venous circulation. Extrinsic forces on the origins of supra-aortic trunks are often

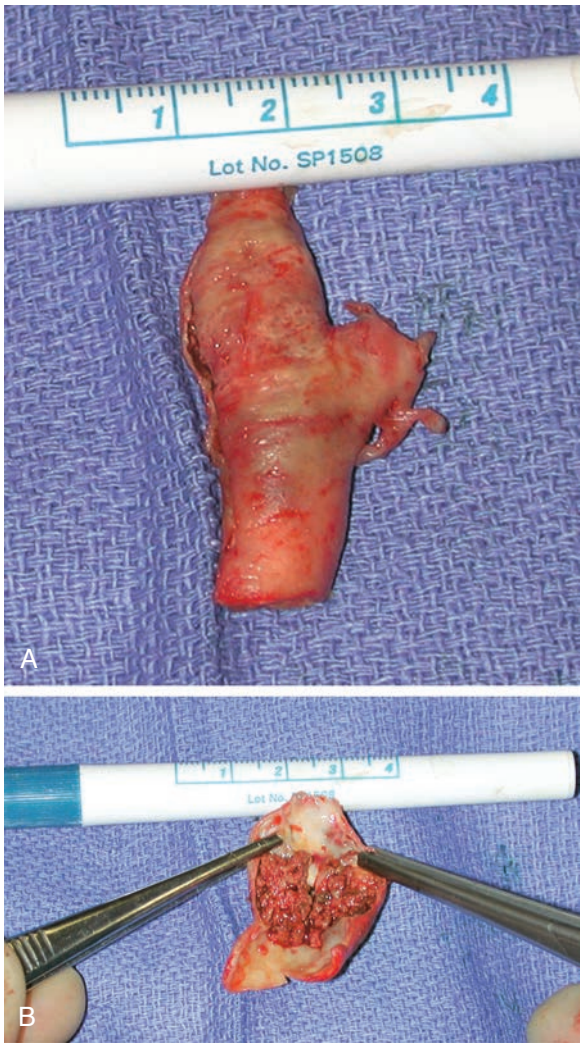

Figure 67.6 **(A** and **B)** Photographs of an endarterectomized carotid plaque that had embolized and caused symptoms. This type of plaque is thought to be a greater risk for periprocedural embolization when an open cell stent is used to cover the stenosis.

minimal, but the extrathoracic carotid or subclavian arteries can be subject to significant compressive forces from the surrounding musculoskeleton. Examples include compression of the subclavian artery by a cervical rib, or an axillary artery altered by a hypertrophic pectoralis muscle or axillary manipulation. A potentially catastrophic example includes compression or possible thrombosis of a carotid stent from aggressive rotation or external pressure on the neck, resulting in decreased cerebral perfusion or stroke (see Fig. 91.2). Because of these concerns, SE stents are often chosen for these more mobile areas given their greater resistance to external forces.

Anatomic Location

The **celiac artery** origin can be compressed by the median arcuate ligament. In our practice, treatment of this defect most often requires open surgical or laparoscopic division of the arcuate ligament followed by endovascular or open reconstruction of the celiac lesion.

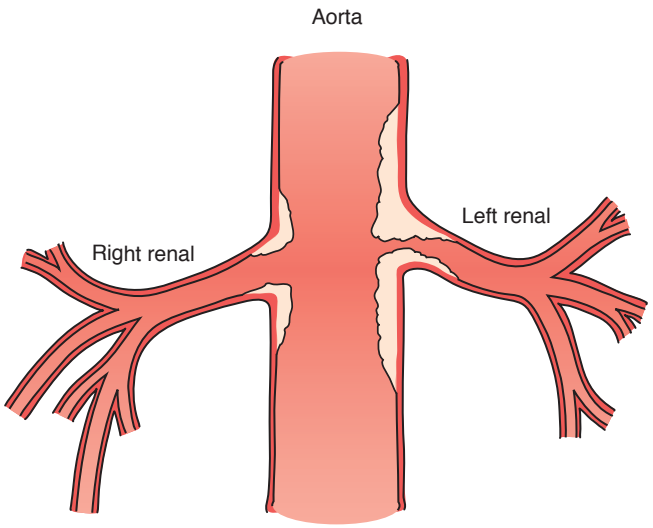

Figure 67.7 The atherosclerotic plaque of a renal artery stenosis actually originates in the aortic wall as the line drawing depicts. This type of plaque is susceptible to elastic recoil with angioplasty alone, and is often better treated with a balloon-expandable stent that protrudes slightly into the aortic lumen to maintain an improved luminal flow.

In atherosclerotic lesions involving the celiac artery, BE stents are commonly used and are associated with good patency. Although access can be gained by either the brachial or femoral approach, the brachial approach is preferred because it allows for easier cannulation of the celiac artery. Careful angiographic evaluation in multiple planes is warranted to ensure exact deployment of the stent short of the main division of the celiac artery.

Superior mesenteric artery and renal ostial stenoses are typically treated with BE stents because disease affecting these ostia is typically associated with extensive atherosclerotic plaque in the aortic wall (Fig. 67.7). An adequate landing zone before the middle colic and inferior pancreaticoduodenal arteries must exist to avoid occlusion of these important branches. A covered BE stent may provide better embolic protection than a bare metal stent. There are some preliminary reports that covered stents may have more resistance to restenosis than bare metal stents in the mesenteric circulation.[39] Covered stents in mesenteric and renal arteries are commonly used as adjuncts in complex endovascular thoracoabdominal aneurysm repair with good patency.

SE stents may be superior for nonorificial lesions, particularly those associated with dissection. A covered SE stent can be ideal in nonatherosclerotic pathologies, such as pseudoaneurysms associated with pancreatitis. More distal lesions of the mesenteric and renal circulations often can be treated with balloon angioplasty alone because of the high flow and small caliber of these vascular beds.

The **left common iliac vein** is another anatomic location where stents are often used to treat compression from the right common iliac artery (May-Thurner syndrome). Although most patients are asymptomatic, edema or deep venous thrombosis (DVT) may result (see Chapter 62). After lytic therapy for DVT, the underlying stenosis/compression may be exposed,

leading to an indication for treatment. Most clinicians recommend utilizing an oversized SE stent in this anatomic location to provide the appropriate radial force and avoid stent migration. BE stents are more likely to cause perforation and are relatively contraindicated in venous disease.

The **distal abdominal aorta and the iliac arteries** are prone to extensive plaque formation that can cause ischemic symptoms. Treating a proximal common iliac stenosis often requires a "kissing stent" technique, in which stents are placed concurrently in both common iliac arteries to prevent the shift of the aortic bifurcation plaque into the contralateral lumen. The two stents are deployed simultaneously, matching their position in the distal aorta and proximal iliac arteries. Although both stent types are used in the proximal iliac arteries, the BE type are more often used for short lesions and the SE type for longer lesions that traverse the change in artery caliber past the iliac bifurcation. Lesions in the external iliac artery are usually treated by SE stents because of the usual tortuosity of the artery. Occasionally, the more distal segment of the external iliac can be better treated with a precisely placed, short BE stent to avoid excessive material load in this smaller artery. Plaque characteristics that suggest a high risk of embolization would favor treatment with a closed cell or covered stent in the iliac arteries. Primary patency of endovascular repair falls short of open revascularization for complex aortoiliac pathology, but secondary patency rates are favorable.[40] Published clinical series are showing promise for the use of covered SE stents in the distal external iliac arteries extending into the common femoral arteries.[41,42] Fewer fractures are noted with these stents in other vascular beds, such as the popliteal. The covered construction theoretically would make a stent fracture less relevant because the graft would prevent the stent from injuring the underlying vessel wall. Stent grafts in this position also can be sewn directly, allowing for a femoral patch angioplasty or interposition graft in the femoral artery, if needed, to obtain adequate outflow.

For the **infrainguinal arteries,** SE stents are utilized preferentially with a few exceptions. Stents in the common femoral arteries are generally contraindicated for two reasons. First, the stent could cover the origin of the profunda femoris artery and compromise flow into this vital artery. Although arteries often remain patent after they have been "jailed" (e.g., hypogastric artery, external carotid artery), the extent of disease in the common femoral artery and the potential consequences of occluding the profunda femoris have a more serious effect on the long-term salvage of the leg. Second, the common femoral artery remains a major access point for vascular procedures throughout the body, and a stent in this position may adversely affect subsequent access through that artery. In addition, the common femoral artery is easily accessible surgically, and repair or endarterectomy of the vessel can be performed with minimal risk.

Stenting of the infrainguinal arteries for occlusive disease is indicated for the failure of primary angioplasty. YaJun et al[43] demonstrated in a meta-analysis that acute results are better with adjunctive stenting, but long-term patency is no different.

Dialysis outflow tracts are prone to treatment failure owing to the unique hemodynamic environment created by AVFs or AV grafts (AVGs). Stent-supported revascularization of the axillo-subclavian veins and cephalic arch have been proven to improve access salvage over that with angioplasty alone.[44] Because central stenosis often occurs in areas of significant mobility, careful evaluation for the contribution of thoracic outlet compression should be made before deployment of a stent. Given these considerations, a large SE stent is recommended. The failure mode in these situations relates to neointimal hyperplasia, so the use of a stent graft is not unreasonable. It is preferred in cases of venous disruption from high-pressure angioplasty. However, no significant data has demonstrated a benefit of covered over uncovered stents in treating central stenoses.

Much like venous anastomotic complications, the hemodynamics of the cephalic arch results in a common failure mode of cephalic vein-based access. Initial experience with bare metal stenting demonstrated a high incidence of recurrence. SE covered stents have been shown to be superior to bare metal stents in the treatment of these lesions.[45] (Care must be taken to avoid encroachment of the stent into the axillary vein.)

The venous anastomosis is the most common failure site of prosthetic arteriovenous grafts.[46] The use of covered stents has been especially promising in treating these lesions. In a randomized trial, Haskal et al[47] demonstrated the superiority of stent grafts over angioplasty alone for the treatment of venous anastomotic stenosis. Covered stents change the hemodynamics of these anastomoses to a functional end-to-end anastomosis, and retard the neointimal hyperplastic response. Stent grafts in dialysis access commonly fail secondary to thrombosis. However, secondary patency of these grafts is promising, and they appear to be an appropriate first-line of therapy in venous anastomotic complications of AV grafts.

Branch Location

Once the external forces that may affect stent choice have been reviewed, the clinician must also consider the extent of the disease relative to branch points of the artery. When a plaque radiographically appears at the origin of a vessel, histologically it will extend into the "parent" artery (Fig. 67.8). For example, an ostial renal artery stenosis may appear isolated to the renal artery on subtraction angiography when, in fact, the majority

Figure 67.8 This endarterectomized specimen shows the extent of the plaque that originates in the aortic wall but affects flow through the branched vessel.

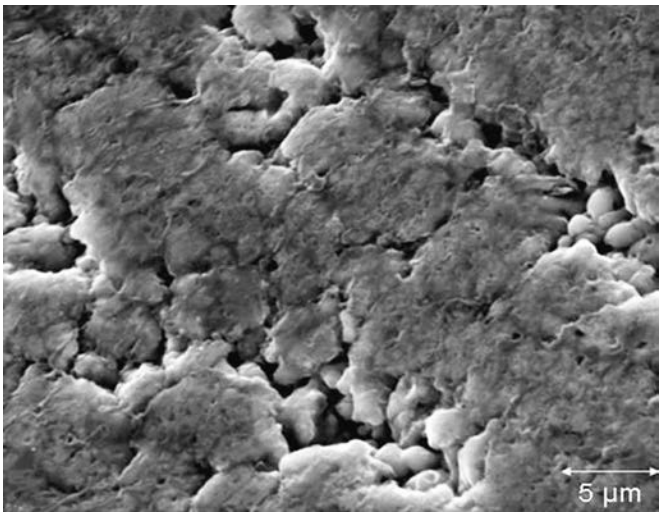

Figure 67.9 Scanning electron microscopy of nitinol stent that had been deployed in an iliac artery. The stent occluded and the patient ultimately required aortobifemoral bypass. (Photo courtesy Dr. Britta Brott.)

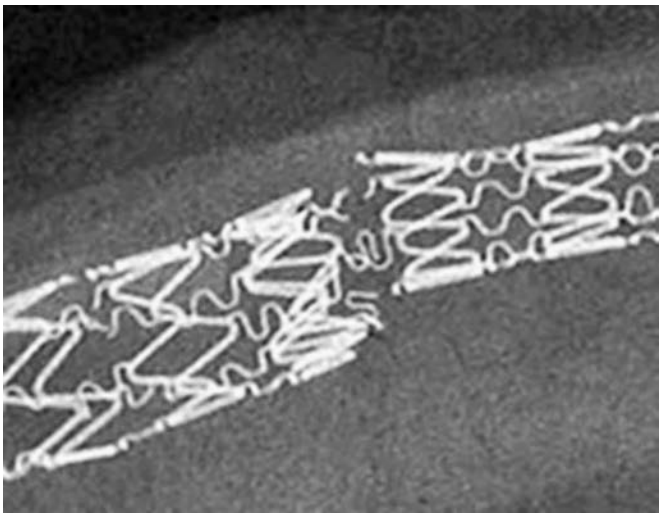

Figure 67.10 Two overlapping coronary stents placed at a tortuous portion in the coronary artery created a stress point that led to stent fracture and recurrent stenosis. (Photo courtesy Dr. Britta Brott.)

of the plaque is in the wall of the aorta (Fig. 67.9). This extensive plaque requires a high radial force stent with accurate deployment, and therefore the BE stent works best in this scenario. The BE stent is typically deployed with a small portion extending into the aorta to fully address the aortic portion of the plaque.

FAILURE MODES

Although stents are designed to maintain patency of the treated vessel, the presence of a foreign material in the arterial bed may actually lead to failure through neointimal hyperplasia and vessel restenosis or thrombosis. Studies have demonstrated that acute inflammatory changes occur with the disruption of the endothelial surface. After the acute phase, the arterial wall continues to react through a remodeling process, which includes acute and chronic changes with a smooth muscle response that can be seen as neointimal hyperplasia.[14] This chronic inflammatory change can actually lead to an obstructing lesion that creates a recurrent stenosis or in situ thrombosis.

Stents are designed of various metallic components that have long, but finite, lifespans under the mechanical stress of the cardiac cycle. Stent fracture or failure may be related to metallic corrosion, which may, in turn, be related to the local vascular environment, external forces, and interaction of other intravascular material.[48-52] Fig. 67.9 shows surface corrosion of an iliac stent that ultimately failed and was removed during the course of an aortobifemoral bypass. The figure shows pitting corrosion that may have contributed to device failure, recurrent stenosis, and eventual iliac artery thrombosis. In a common clinical scenario, when two overlapping stents are placed, the materials of the two stents can be additive in the corrosive process. Fig. 67.10 shows two overlapping stents in the coronary circulation that ultimately fractured, likely as a result of galvanic corrosion between the stents. In this patient, a recurrent stenosis developed at an angulated area of a coronary vein graft.

Long (>200 cm) SE stents are now available. The use of an appropriate-length stent to avoid overlap may lead to fewer fracture-induced occlusions. In addition, overlap within tortuous segments seems to be especially prone to failure.[53] Strategies to decrease occlusion within stented segments include the use of drug-eluting stents in overlapped segments[54] and telescoping of a covered stent inside a bare stent. The graft material theoretically inhibits the corrosive effect of metal-on-metal interaction.

Stents can also release ions into the local vascular environment that can adversely affect the treated lesion. Both stainless steel and nitinol stents have been shown to release cytotoxic agents that may contribute to smooth muscle necrosis, affecting the response of the artery to such a stent.[55,56]

Drug-Eluting Technology for Neointimal Failure

Many modalities have been investigated to control the hyperplastic response to an arterial implant. Specifically, stents have become a conduit to deliver medication to the local vascular environment in an effort to limit this response to injury. Three chemotherapeutic agents have been attached to BE stents for utilization in the coronary arteries: paclitaxel, sirolimus, and everolimus. These agents have been shown to aggressively inhibit the neointimal response and thereby improve patency rates. Paradoxically, drug-eluting stents (DESs) have created a new late-failure mode of delayed stent thrombosis, due to the lack of endothelialization and minimal incorporation into the associated vessel wall. The exposed raw surface of the stent carries a risk of stent thrombosis as high as 4% after 1 year.[57] When evaluating the use of DESs in the peripheral circulation, one must consider that late stent thrombosis of the femoral artery carries a significantly different risk from that of a coronary artery.

Initial clinical trials of DESs in the SFA did not demonstrate better patency than with bare metal stents. The Sirolimus-Coated Cordis Self-Expandable Stent (SIROCCO) trial compared the results of a drug-eluting SE stent and a bare metal SE stent, and found near-equivalent restenosis rates: 22.9% in for the DES and 22.1% for the bare metal SE stent at 2 years.[58] A

prospective industry-sponsored trial of a nonpolymer, paclitaxel-coated SFA stent (Zilver PTX, Cook Medical, Bloomington, Indiana) has shown more promising results. The main arm of the study demonstrated noninferiority of the DES to primary angioplasty, although these data may be unreliable because of an overly high primary failure rate of percutaneous transluminal angioplasty. More interestingly, a separate arm directly compared bare metal stents to DESs in patients with failed percutaneous transluminal angioplasty and showed statistically significant better patency with DESs at 1 year.[59] Enthusiasm for DES-supported intervention in the SFA on the basis of these results is hampered by the large number of short lesions and the high percentage of patients with claudication (90%) enrolled in the trial. Subsequent analysis from 12-month results for patients with *de novo* TASC II C & D lesions treated with Zilver PTX stents showed results similar to those of open surgical bypass (77% primary patency rate), fueling the argument for continued investigation into long-term efficacy.[60]

The PReventing Amputations using Drug eluting StEnts (PaRADISE) trial attempted to quantify the impact of DES technology on patients at greatest risk of amputation.[61] In this noncontrolled prospective study of DESs in tibial intervention, the major amputation rate was 6% at 3 years in patients presenting with critical limb ischemia. Maintenance of limb salvage required a re-intervention rate of 36% at a mean of less than 1 year, but overall survival, renal failure, and limb salvage rates were better than those in historical controls.

Treatment of in-Stent Restenosis

As primary endovascular interventions have become increasingly common for the management of *de novo* femoropopliteal stenoses, strategies for maintaining patency have also become of utmost importance. The long-term interaction between stent and vessel over time can lead to the development of late stenosis or occlusion, chiefly through the mechanism of neointimal hyperplasia. Various mechanisms have been proposed for the management of in-stent stenosis, including repeat PTA, stenting, atherectomy, and angioplasty or stenting with drug-coated technology. The EXCITE ISR Trial (EXClemer Laster Randomized Control Study for Treatment of FemoropopliTEal In-Stent Restenosis) demonstrated superiority of laser atherectomy with PTA compared with PTA alone in patients with in-stent stenosis following the prior placement of bare nitinol stents, for both TLR and 30-day MAEs.[62] The FAIR (Femoral Artery In-Stent Restenosis) Trial examined the effect of drug-coated balloon angioplasty for SFA in-stent restenosis, in comparison with conventional PTA alone. The results of this investigation showed a lower rate of recurrent restenosis at both 6- and 12-month intervals following intervention with a drug-coated balloon (DCB) compared with conventional PTA.[63] Building off known data regarding utility of drug eluting stents for coronary in-stent stenosis, data from the Zilver PTX Global Registry showed favorable results for the treatment of femoropopliteal in-stent restenosis with implantation of the Zilver PTX stent, with 6- and 12-month primary patency rates of 96% and 79%, respectively.[64] The Viabahn-covered stent also demonstrated superiority over PTA at 1- and 2-year primary patency in the RELINE trial.[65] Interestingly, the lesion lengths treated were nearly double in the RELINE trial compared to trials of drug coated technology indicating that stent graft treatment is likely the modality of choice in complex restenotic lesions of the SFA.

NEW DEVELOPMENTS

Absorbable Stents

The long-term interaction between stent and vessel can result in late stenosis and occlusion. One approach to mitigate this effect is to create stents composed of biodegradable material. Bioabsorbable stents theoretically provide scaffolding for healing of the vessel before they are eventually absorbed. Although lower extremity data are sparse, absorbable stents in the coronary arteries have shown a 30% mass reduction of neointimal hyperplasia at 12 months, and 60% reduction at 18 months.[66] Tamai et al[67] reported the use of a poly-L-lactic acid (PLLA) bioabsorbable stent in the coronary arteries of 15 patients with a restenosis rate of 10.5% at 6 months. Even with imaging at 4 years, these investigators found some hyperplasia related to the local stent reaction, but there were no late stent thromboses in these patients.[68]

The clinical effect of this expected degradation may lead to some late events, such as embolization with resulting small vessel ischemia. However, this clinical phenomenon has not been well documented. After the initial reports of success with the PLLA stent, Ormiston et al[66] reported the success of attaching everolimus to the PLLA stent to obtain the benefit of a medicated stent that reduces the intimal response while potentially removing the nidus for late stent thrombosis. These investigators found a decreased neointimal response and reduced cardiac event rate (3.3%) in a series of 30 patients.

The bulk of the data regarding the use of bioabsorbable stents in the peripheral circulation examine their efficacy in the femoral segments, with only a small number evaluating their utility in the infrapopliteal circulation. Substantive conclusions regarding efficacy relative to standard therapies are limited, due to the small sample size and heterogeneity in the study designs, but initial 30-day results in the femoral segment appear promising; however, longer term examination of data regarding 6-month data demonstrated patency that decreased as low as 60%.[69] The AMS INSIGHT trial compared infrapopliteal PTA versus PTA and stenting with bioabsorbable stents. These data showed no difference in initial 30 day outcomes of amputation or death, but the stenting group showed a worse 6-month primary patency than PTA alone.[69] Ultimately, the currently studied bioabsorbable scaffolds demonstrate safety and technical success in implantation without long-term clinical success in the infra-inguinal circulation; however, future research may improve this by combining various drug technologies to the scaffolds.[70]

Drug Delivery Without Stenting

Success in the use of drug delivery technology in the SFA has led to examination of this in the smaller crural vessels. Due to

the unique extrinsic compartment forces and smaller diameter, several institutions examined use of DCB without stenting the tibial vessels. Initial enthusiasm for DCB in the tibials has been tempered by the results of two larger multicenter, randomized trials (BIOLUX P-II and IN.PACT DEEP) demonstrating equivalent and inferior results, respectively, with the use of DCB compared to PTA alone.[71] Although there has been a fairly wide body of evidence to promote the utility of DCB technology in the femoropopliteal arterial segments, further information is needed to elucidate the differences in behavior between that and the below-knee vessels.

FUTURE DEVELOPMENTS

The progressive miniaturization of revascularization technology remains a consistent goal for clinicians treating vascular disease. Considering that open surgery has been refined over the last 50 years, the endovascular era is still relatively young. Simple dilation of diseased vessels has had limited clinical success, thus leading to intensive efforts to improve those results with intravascular devices, such as stents, and with antiproliferative medications. As with any new technology, new problems have been created. The alteration of hemodynamic variables, such as vessel compliance and shear stress, continues to limit the patency of endovascular intervention. Fortunately, this alteration appears to come at the cost of repeat interventions rather than limb loss. Stents have improved some of these catheter-based treatments, but further modifications are necessary to provide more effective therapy for the patient with vascular disease.

Looking forward, the modification of existing technology, such as bioabsorbable scaffolds, DCB, or novel treatments for occlusive disease, will likely focus on the elimination of stents, and their inherent limitations, completely. The combined use of debulking with drug technology is already being utilized in clinical practice, but has not been studied in a systemized fashion. Similarly, the introduction of stem technology or genetically engineered constructs, such as viruses to modulate the neointimal response, may render stenting obsolete.[72]

INTRODUCTION

The paradigm change in the management of aortic disease started in the late 20th century with minimally invasive techniques and endovascular devices has continued largely unabated to the present day. With advances in both technique and technology, the number of patients who are candidates for these endovascular approaches has increased, while the complications associated with the procedure has continued to decrease.[1] Whether it is superior to open surgery, patient expectations for a short hospital stay and smaller incisions has made endovascular aortic surgery the de facto standard of care.

The management of thoracic aortic aneurysm (TAA) and abdominal aortic aneurysm (AAA) has evolved greatly over the past 20 years. With approximately 45,000 AAA repairs per year in the United States, over 90% were repaired using open means at the turn of the century. Today, the situation is reversed and over 90% are repaired using endovascular (endovascular aneurysm repair [EVAR]) means.[1] A similar transformation has occurred for TAA over the past decade due to the advent of thoracic endovascular aneurysm repair (TEVAR) devices.[2]

The success of these endovascular devices is dependent on suitable anatomy for endograft sealing without essential branch vessel compromise. Failure to meet the instructions for use (IFU) neck lengths and angles is associated with an increased rate of complications, such as endoleak, device failure, device migration, conversion to open, and aneurysm rupture.[3] To address patients with aneurysms outside standard IFUs for neck length, branched and fenestrated endovascular devices have been used with increasing success for both juxtarenal and suprarenal AAAs.[4] On the thoracic aortic side, a similar revolution is on the horizon for zone 0 and 1 TAA due to the advent of branched TEVAR devices (Fig. 68.1).

This chapter reviews the current state of the art and upcoming technology for the treatment of aortic disease, including aneurysms, dissection, trauma, and other pathologies.

THORACIC AORTA

Current Practice

Aneurysms of the thoracic aorta have traditionally been amenable to endovascular repair if they are in zone 3 or 4 and have at least 2 cm of neck length. Achieving adequate proximal apposition may necessitate landing the TEVAR device across the left subclavian artery, thus entering zone 2. In an elective situation, this is often preceded by a carotid-subclavian bypass or subclavian to carotid transposition; in emergency situations, pre-TEVAR extraanatomic bypass grafting is required primarily for patients who have a LIMA-LAD graft, a left vertebral artery that terminates as an end artery (PICA syndrome), and preexisting left arm arterial disease.[5]

Open Repair

Open repair of thoracic aortic aneurysms has a variable morbidity and mortality depending upon how much of the arch and proximal aorta is replaced, and complications increase if a concomitant root replacement is also completed.[6] A median sternotomy is required along with cardiopulmonary bypass, and each of which have significant morbidity for the patient. Prior to the development of TEVAR, this was the only surgical option available for the patient with any type of thoracic arch aneurysm. With the advent of TEVAR, only patients with a zone 0 or 1 TAA remain the predominant candidates for open repair, and this landscape is changing rapidly.[5]

Standard Thoracic Endovascular Aneurysm Repair

The standard IFU for completing a TEVAR requires the thoracic aorta to be within a certain size threshold, a length, and quality of proximal and distal landing zone to provide adequate sealing, and satisfactory iliac or femoral access to permit passage of the device. Typically, a native aortic diameter between 16 and 42 mm is necessary with 2 cm long sealing zones. The minimum size requirements for iliac or femoral delivery vary by the size of the device, but they range between 5 and 9.8 mm. Iliac access vessels that are too small to permit delivery system passage may necessitate either a retroperitoneal "transplant" incision or a laparotomy to place a conduit onto the aorta or one of the common iliac arteries so that a TEVAR device can be inserted.

Ideally, the requisite 2 cm of the landing zone would be achievable without coverage of either the left carotid or subclavian arteries or the celiac artery. However, when left subclavian artery coverage is required to effectively exclude a TAA, the combination of a carotid-subclavian bypass with elective coverage of the left subclavian artery has been shown to be safe.[5] Similarly, coverage of the celiac artery, when the superior and inferior mesenteric arteries are patent, has been shown to be associated with a reasonably low rate of complications.[5,7] Despite these modifications, patients with more extensive aneurysms who require more aggressive coverage of arch or abdominal aortic branches presently need to undergo either a hybrid open endovascular procedure or chimney grafting in addition to the TEVAR.

Hybrid Procedure

Hybrid operations are options for patients whose anatomy does not meet standard IFU. For example, in a patient who will require coverage of both the left subclavian and left common carotid arteries (zone I TEVAR), a right common carotid to left common carotid artery bypass, followed by a left common carotid artery to left subclavian artery bypass can be completed prior to coverage by a TEVAR device.[8,9] An alternative approach is to do a subclavian-subclavian bypass, followed by a left subclavian artery to left common carotid artery bypass (Fig. 68.2). For patients with even more proximal disease who require coverage of all of the aortic arch branches (zone 0 TEVAR), two solutions have been used. One is a hybrid approach that begins with a de novo bypass from the proximal ascending aorta to the left subclavian artery, followed by the extraanatomic bypass described above.[10] This approach requires a median sternotomy but offers a less invasive repair option than standard open surgical repair, as cardiopulmonary bypass is not required. A second approach for zone zero TEVAR uses a chimney technique (parallel endografts) to maintain flow to the innominate artery, deploying it from the right brachial approach with simultaneous deployment of a TEVAR device.[11]

Best surgical option for arch extension of type B dissection: the endovascular approach. *Ann Cardiothorac Surg*. 2014;3:292–299. doi:10.3978/j.issn.2225-319X.2014.04.04)

Chimney Technique

The chimney technique mentioned previously is associated with several major pitfalls. First, it relies on two cylindrical grafts being sandwiched together, and the inevitable gutters between them can be the source of an endoleak. The limited length of ascending aorta available for endograft deployment translates into relatively short gutters, further increasing the risk of endoleaks. On the distal end, the length of innominate artery available for endograft sealing prior to its bifurcation into the right subclavian, and right common carotid arteries can be inadequate for obtaining a seal and may necessitate another sandwich graft configuration, further increasing the complexity, risk, and potential failure modes. The second major pitfall is collapse of the innominate branch by the much larger TEVAR device, leading to loss of flow in the sole branch providing perfusion of the brain, a complication with usually fatal consequences. For these reasons, the use of a chimney technique to facilitate a zone 0 TEVAR should be used sparingly and only in the most infirm patient who would not tolerate a hybrid repair.[12]

Fenestrated Technique

An alternative method for revascularizing the branches of the aortic arch without resorting to extraanatomic bypass or chimney is to use laser fenestration to create holes in the endograft followed by balloon dilation and stent-graft placement to reestablish flow. Three-vessel fenestration can be completed to cover the entire aortic arch. The major pitfalls of this technique are that if the hole in the endograft does not line up with the ostium of the vessel, trauma to the aortic arch can occur through use of the laser, and modification of the endograft in this manner can lead to type II endoleaks.[13]

Laser fenestration involves placing a wire and catheter combination directly against the fabric of an endovascular device. The catheter is removed and a laser is then placed over the wire. Rotational angiography may be completed to ensure that the laser is directly apposed to the stent graft. The laser is activated for a short time, often just seconds, followed by advancement of the wire through the new hole in the stent graft. A balloon dilation is then completed, followed by deployment of a stent graft to ensure patency into the branch vessel.

Branched Endografts

There are two major endografts being tested that have a side-branch attached to a TEVAR endograft.[14] The Gore conformable thoracic aorta graft (C-TAG) branch endoprosthesis (W.L. Gore & Associates, Flagstaff, Arizona) and Medtronic Valiant Mona LSA thoracic graft system (Medtronic, Minneapolis, Minnesota) both offer a single side-branch that can be used to revascularize the left subclavian artery without the need for a carotid-subclavian bypass.

The Gore TAG thoracic branch endoprosthesis is similar to the existing C-TAG device but has been modified to have greater resistance to the tremendous forces within the aortic arch. The enhanced conformability further improves device deployment within angulated and curved aortic arches. The new branched endograft has three components: the first is an aortic component that is delivered over a stiff wire (Fig. 68.3). A side branch wire is precannulated through an internal docking portal and both wires

Figure 68.3 Gore thoracic aorta graft thoracic branch endoprosthesis device with side branch. (Courtesy W.L. Gore & Associates.)

are used to place the aortic component in the proper location within the arch. The aortic component is deployed and a side branch introducer sheath used to deliver a side branch device through the internal docking port over the side branch wire. The side branch device is then deployed, and both this and the aortic component are balloon molded to the arch (Fig. 68.4). Both proximal and distal aortic extension can then be completed using a variety of devices to ensure satisfactory coverage.

The Medtronic Valiant Mona LSA stent graft system is similar to the Gore device, but instead of having an internal docking port, there is a flexible external cuff that is used for placing the left subclavian artery stent graft.

A third novel device is being developed to permit zone 0 TEVARs and differs in construction compared to the Gore and Medtronic devices. Called the Relay Plus double branch arch system (Bolton Medical, Sunrise, Florida), this device builds upon the Relay Plus stent graft to have two parallel tunnels that can be separately cannulated and used to revascularize the innominate and left common carotid artery (Fig. 68.5). A left carotid-subclavian bypass would still be necessary with this graft. Cook Medical has developed a somewhat similar device known as the Zenith arch branched graft (Cook Medical, Canton, Illinois) that has two side branches that are used to cannulate the innominate and left common carotid artery. This graft is notable for having four trigger wires to sequentially deploy and stabilize the graft.[15]

ABDOMINAL AORTA

Current Practice

EVAR has become the standard of care for the treatment of AAAs with favorable anatomy for well over a decade. In patients who

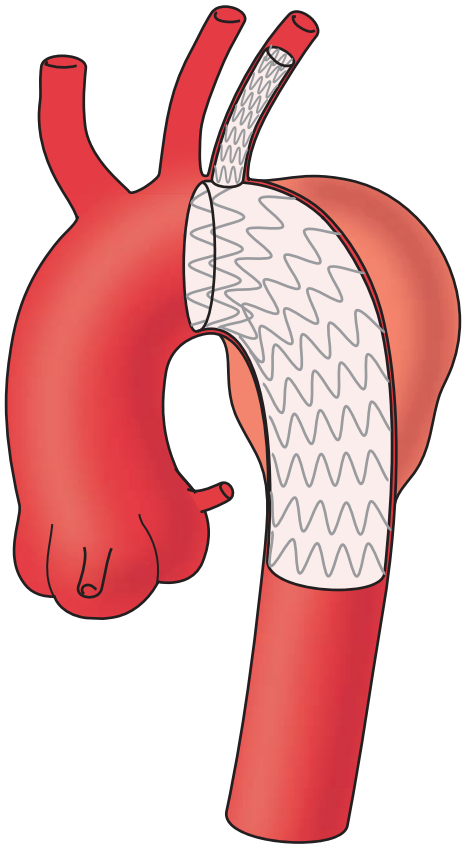

Figure 68.4 Gore thoracic aorta graft thoracic branch endoprosthesis device with side branch in a zone 2 configuration within the thoracic aorta. (Courtesy W.L. Gore & Associates.)

Figure 68.5 Bolton Medical double branch arch system. (Courtesy Bolton Medical, Sunrise, Florida.)

do not meet the anatomic criteria to undergo a standard, "on-label" EVAR, there are a variety of supplementary endovascular techniques available to exclude the aneurysm. These options have variable durability and include the chimney technique, P- and T-branched EVAR, fenestrated EVAR (FEVAR), hybrid techniques, and open repair.

Standard Endovascular

Commonly used EVAR devices are reviewed elsewhere in this textbook. Generally speaking, EVAR devices require a proximal neck diameter between 19 and 32 mm, a proximal neck length of at least 1.0 to 1.5 cm with less than 60-degree angulation, a distal landing zone of at least 1.5 cm, iliac artery diameters between 8 and 25 mm, and satisfactory iliac or femoral access to deploy the device. In contemporary practice, however, there has been significant deviation from the IFUs with corresponding increases in EVAR failures. Newer devices to the market now allow the treatment of patients with greater than 60% neck angulation, eliminating one of the more common reasons for "off-label" EVAR. The remaining major limitation of the standard EVAR technique is that juxtarenal or pararenal aneurysms cannot be treated using this method without covering the renal arteries, mandating adjunctive measures to maintain renal perfusion such as the chimney technique.

Chimney Endovascular

The chimney technique is similar to that described above for chimney TEVAR repair. Up to a four-vessel chimney can be constructed with complete coverage of the celiac, superior mesenteric, and right and left renal arteries. This technique requires independent four-vessel cannulation using axillary or brachial artery access and deployment of the EVAR device while simultaneously deploying the appropriate visceral stent graft. Complete exclusion of the aneurysm can be obtained while maintaining flow to the visceral segments. While this is an effective treatment in patients for whom a branched or fenestrated device is not available and who are not otherwise candidates for open repair, its major limitations are the potential for endoleak around the multiple gutters between the visceral stent grafts and the aortic endograft, migration of one of more visceral stent grafts, kinking leading to loss of flow to the viscera, and endograft migration from poor proximal fixation.[16,17] Of note, there are several series that have demonstrated equivalency of this technique to fenestrated endografts.[17]

Hybrid Technique

A hybrid technique has been used at some centers with increasing success and this technique is primarily reserved for thoracoabdominal aortic aneurysms (TAAA). The first portion of the procedure is a visceral debranching in which bypasses to the celiac, SMA, and/or renal arteries are performed. This is done using either the supraceliac aorta or a common iliac artery for inflow to the bypass. The choice of inflow is based on the extent of coverage expected with subsequent endografting. With the viscera supplied by remote bypasses, a subsequent EVAR can be performed, usually staged, that completely excludes the aneurysm. The advantage of this technique is that a complete reconstruction of the abdominal aorta can be avoided and partial-occlusion clamping of the aorta, if used as the inflow source, is less physiologically stressful than complete aortic clamping. Outcomes have been mixed with a greater than expected morbidity and mortality rate at some centers, potentially due to patient selection.[18]

Open Repair

Open repair of TAAA is performed with variable frequency across the American landscape, tending to be more concentrated in a handful of centers. And for good reason, high-volume centers that include distal aortic perfusion, moderate hypothermia, and spinal cord protection have been demonstrated to have the best outcomes.[19,20] Nonetheless, the magnitude of the operation cannot be minimized. Open repair requires cardiopulmonary bypass, a long thoracoabdominal incision, and replacement of the affected portion of the aorta along with its branches, the end organs of which invariably suffer some degree of ischemic injury. And while high-volume centers and practitioners have had excellent outcomes, those surgeons and centers less familiar with the challenges of these patients may not. Given the impracticality of regionalized treatment at this time, less invasive alternatives continue to be pursued. The strategies involved range from fenestrated and branched endografts to multilayer stents and, most recently, to endovascular aneurysm sealing (EVAS).

Fenestrated Endografts

Fenestrated endografts (FEVAR) have one or more fenestrations in their proximal aspect that permit deployment in the visceral aorta, as high as needed for secure attachment and seal, with flow to the visceral aortic branches being through bridging stent grafts. FEVAR endografts are custom constructed to each patient's specific vascular anatomy and geometry and, therefore, require several weeks of lead time. "One size fits many" FEVAR endografts have not yet been successfully developed. Scallops can be integrated into the design to permit a visceral branch to "peek out" over the top of the endograft, extending proximal attachment without the more complicated deployment of a fenestration. Over 1500 fenestrated grafts have been deployed since 2011 with an overall 98% technical success rate, 2% perioperative mortality rate, and 1% spinal cord ischemia (SCI) rate.[21,22]

Commercially available endografts include the Cook Medical Zenith fenestrated AAA device (Fig. 68.6) and the Anaconda Fenestrated device (available in Europe only). With multiple fenestrations that permit maintained perfusion of visceral branches, each endograft is customized to the patient based off a high-resolution CT scan. Fenestrated endografting has outcomes that are similar to open repair of type IV TAAA.[23,24] Laser fenestration of existing endografts has also been done by some investigators, although this technique is less commonly done now that there is a commercially available product.

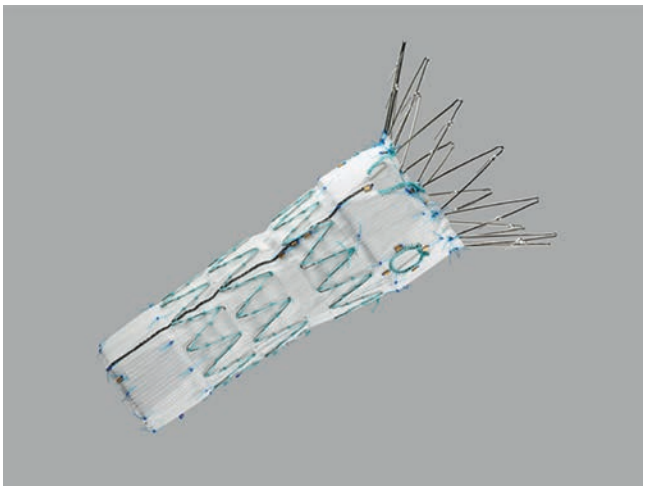

Figure 68.6 Cook Medical Zenith fenestrated endovascular graft. (Courtesy Cook Medical, Canton, Illinois.)

IFU for the Cook device include a nonaneurysmal infrarenal neck of 4 mm, proximal aortic neck diameter between 19 and 31 mm, neck angulation of less than 45 degrees, at least a 3-cm distal landing zone, and satisfactory iliac and femoral vessels for device introduction. More specific limitations regarding the placement of fenestrations and scallops exist, but they are beyond the scope of this chapter. The complexity of measuring for and manufacturing FEVAR endografts translates into a 4 to 6 weeks delay in treatment. Furthermore, this customization is labor intensive, costly, and can be quite inflexible with even minor degrees of malalignment. Hoping to eliminate these inflexibilities, effort has been exerted to develop branched endografts that offer a flexible platform that may allow an off-the-shelf solution to treating TAAA.

Branched Endografts

There are two types of branched endografts, termed P-branch and T-branch endografts. P-branch endografts are essentially fenestrated endografts designed so that the fenestrations emanate from a "turret" or outpouching of the endograft, creating a sort of pivoting fenestration that is more adaptable to a range of anatomic configurations (Fig. 68.7). T-branch endografts have tapered stent graft "sockets" for the visceral vessels connected to a Z-stent configuration endograft. In the ultimate four-branch version, the ability to maintain perfusion to all four visceral vessels permits full coverage for EVAR treatment of TAAA (Fig. 68.8).

The advantage of T-branch endografts over standard fenestrated endografts is that the risk of a type III endoleak from a component disconnection is significantly lower since the visceral endograft telescopes into the receiving socket of the aortic endograft with much greater component contact than what is available in a P-branch device or standard fenestrated endograft. The primary drawback of the T-branch devices is their delivery system size, 20 French for the Cook system with 8 mm celiac and SMA cuffs, and 6 mm renal artery cuffs. Theoretically, this design should have high utility in a variety of anatomic configurations due to the relative flexibility of the T-branches, especially when compared to the rigorous measurement and planning required for FEVAR.

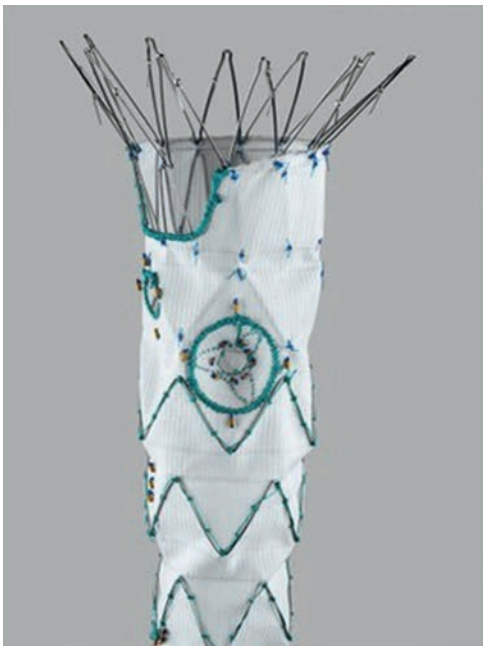

Figure 68.7 Cook Medical P-branch abdominal aortic aneurysms stent graft. (Courtesy Cook Medical, Canton, Illinois.)

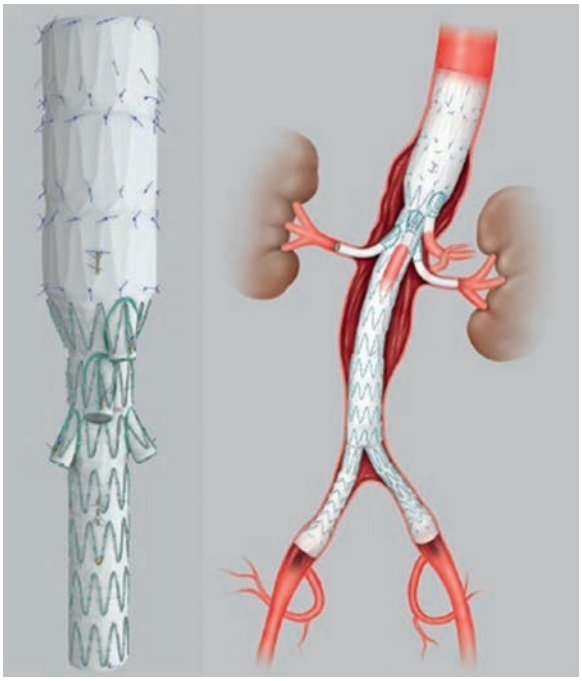

Figure 68.8 Cook Medical T-branch abdominal aortic aneurysms stent graft. (Courtesy Cook Medical, Canton, Illinois.)

P-branch devices have a pivot fenestration for the renal arteries and SMA and a scallop for the celiac artery. The configuration is such that two versions of this off-the-shelf device are suitable for almost 75% of all juxtarenal and pararenal AAA variations.[25] These P-branch devices differ from standard fenestrated

endografts in that a custom tailored solution for a patient's anatomy is not necessary, obviating the 4 to 6 weeks waiting time and allowing immediate repair. This same flexibility facilitates deployment of all of the components and mitigates errors in measurement or visceral vessel orientation.

There are other devices in development to treat TAAA. The Gore Excluder TAAA branch endograft is a T-branch device similar to the Cook device, and it differs somewhat in having renal artery branches that are oriented more cranially and is based on their Excluder platform. The precise orientation of the renal artery branches is debatable—some type IV TAAA have renal artery branches that are oriented more caudally than the standard anatomy, in which these branches tend to come off at a right angle to the aorta.

A modular graft being developed by Medtronic based off their Valiant platform is also being developed in a T-branch configuration. Similar to the Gore device, the main body is deployed via femoral access, and each of the four visceral branches catheterized and stented from the brachial artery.

Multilayer Endografts

A unique design for an AAA endograft has been developed by Cardiatis (Isnes, Belgium). This type of stent uses a multilayer flow modulator through multiple layers of a braided alloy to direct the majority of the blood flow within the reshaped lumen, leading to a pressure drop of over 90% within the aneurysm sac (Fig. 68.9).[26] Good outcomes have been seen with both infrarenal AAA and type B dissections. Other devices using a similar configuration have been successfully used in TAAA.[27] Additional studies using this novel design need to be completed to assess its long-term outcomes and overall patency.

Endovascular Aneurysm Sealing

The latest concept in endoluminal AAA repair to undergo a US-FDA clinical trial is the Nellix EVAS system (Endologix, Inc., Irvine, California), which uses a four-step system to fill aneurysm sacs with a polymer after bridging them with endograft limbs, conceptually preventing type 2 endoleaks by sac filling. The procedure begins with advancement of 17 French catheters, followed by aligning and expanding the stent grafts, filling the aneurysm sac to 180 mm Hg of pressure and confirming a satisfactory seal, and finally filling that space with a polymer. Anatomic requirements are similar to other aortic endografts and include a proximal neck diameter between 18 and 32 mm, a neck length of at least 10 mm, and less than 60 degrees of neck angulation. The luminal diameter of the sac should be less than 6 cm, and while satisfactory iliac artery diameters are necessary for access, no minimum iliac landing zone is required.[28]

Figure 68.9 Cardiatis multilayer braided stent. (Courtesy Cardiatis, Isnes, Belgium.)

In 150 patients who have had this procedure completed as part of a US-FDA clinical trial, 100% technical success has been achieved. The average time to implantation is 30 minutes for a total procedure time of about 88 minutes. On average, the volume of polymer needed to fill the aneurysm sac is 75 mL (29-215 mL range). Complications are similar to that seen with traditional EVAR devices, with an all-cause mortality of 0.7% at 30 days, and major adverse events occurring in about 2.7% of patients at 30 days. One-year all-cause mortality has been reported at 4.0% with a major adverse event rate of 6.7%.[28,29] Secondary interventions have been necessary in 3.7% of patients, and sac expansion was noted in two patients (1.5%). At 1 year, the only endoleaks that were noted included one patient (0.8%) with a type IB endoleak and three patients (2.3%) with a type II endoleak. Overall, these results are similar to that reported by other manufacturers of EVAR devices but with a lower rate of endoleaks and secondary interventions. Freedom from sac enlargement is similar to that reported by other manufacturers.[29]

FUTURE DIRECTIONS

While there have been numerous advances in endograft technology leading to an increase in patients who are candidates for this minimally invasive approach, the concept of total endovascular aortic treatment remains a work in progress. The new generation of thoracic devices seeks to avoid having to perform subclavian revascularization when completing a zone 2 TEVAR. It is likely that we will be seeing this generation of single-branched TEVAR devices being implanted as a zone 1 device with the branch used to revascularize the left common carotid artery followed by a carotid-subclavian bypass. There will undoubtedly be investigators who also use it to revascularize the innominate artery as part of a zone 0 TEVAR followed by a subclavian-subclavian bypass and left common carotid to subclavian bypass, thus obviating any need for a median sternotomy or chimney approach. Multi-branched TEVAR devices will not be far behind.

Regarding AAA and TAAA, we have seen a shift from custom-made devices individualized to a particular patient's anatomy to off-the-shelf designs that are suitable for a majority of patients. T-branch devices in particular offer tremendous flexibility in a safe, proven durable platform that is suitable for the repair of a variety of TAAAs. Not only do these advanced designs expand the population of patients that can be treated, but their deployment flexibility expands the population of vascular surgeons willing and able to embrace this new technology.

While devices continue to improve, one of the most significant problems that remains to be solved is that of SCI, because the rate of SCI remains between 1% and 8% when completing complex endovascular TAAA repairs.[28-32] The rate of SCI appears to be related to the extent of coverage and how much is covered

in a single setting. The use of staged procedures and adjuncts for spinal cord protection have decreased the rate of SCI. Cerebrospinal fluid drainage, preventing hypotension, neuromonitoring via motor and somatosensory evoked potentials, and ensuring flow within the internal iliac arteries are all strategies that can help reduce the incidence of this complication.[32,33] Advances in patient management to avoid this devastating complication are continuing in multiple novel areas, such as the use of dedicated institutional protocols, leukotrienes, and an "open branch" technique to permit some flow into the aneurysm sac after the initial stage, followed by completion coverage by a stent graft at a later date.[33-35]

CONCLUSION

Technology continues to advance rapidly in this area with improving morbidity and mortality for patients with complex aortic pathology. While each particular approach has advantages and disadvantages, altogether there has been an expansion in indications for minimally invasive aneurysm repair. Continuing advances in spinal cord protection seek to decrease the incidence of this devastating complication.

GENERAL CONSIDERATIONS

The term *aneurysm* describes dilatation of any blood vessel. Arterial aneurysms located extracranially occur throughout the body but are most prevalent in the infrarenal aorta (abdominal aortic aneurysm [AAA]). These aneurysms represent the primary cause of the significant death and morbidity attributed to arterial aneurysm disease. In the United States, AAA were directly responsible for approximately 9900 deaths in 2014, and approximately 120,000 AAA procedures were performed to prevent subsequent rupture.[1-3] The incidence of aneurysms increases with age, but aneurysmal disease can occur in any decade of life. These lesions may be the result of several degenerative processes, including inflammatory, infectious, genetic, and traumatic conditions. Although aortic aneurysms can cause a variety of clinical conditions, such as embolism, compression on adjacent organs, and fistulas, the primary danger from aortic aneurysms is rupture with uncontrolled hemorrhage, leading to death. Nonaortic aneurysms may also rupture, but they more often embolize, thrombose, or compress surrounding structures, and they rarely rupture into an open space where blood loss is catastrophic.

The risk of rupture of any aneurysm is related to both the absolute size of the aneurysm and its size relative to the normal diameter of the inflow and outflow artery from which it arises. A variety of other factors, including location, etiology, growth rate, and aneurysm morphology (i.e., fusiform vs. saccular) can also be critical in assessing aneurysm risk.

Abstract

The term aneurysm describes dilatation of any blood vessel. These can occur throughout the body, and can present risks of rupture, embolism, thrombosis and other complications. Such lesions are categorized based on their size, involved artery, morphology and etiology. The specific artery involved often plays the leading role in the risk of aneurysm-related complications. For example, abdominal aortic aneurysms are associated with rupture and life-threatening hemorrhage, while popliteal artery aneurysms are associated with embolization, thrombosis and acute limb-threatening ischemia. Aneurysms can also be associated with underlying conditions that predispose to formation of multiple lesions. This phenomenon is seen in the association between aortic aneurysms and popliteal aneurysms, the multiple aneurysms seen in some connective tissue disorders and with cystic medial degeneration. This chapter introduces all of these topics.

inflammatory aneurysm

HISTORICAL PERSPECTIVE

The presence of arterial calcification and atherosclerotic change has been documented in Egyptian mummies from 3500 years ago. The Ebers Papyrus (c.2000 BC) clearly identifies an arterial aneurysm, recommending, "Treat it with a knife and burn it with a fire so that it bleeds not too much."[4] Antyllus repaired aneurysms of the extremities with proximal and distal ligation, followed by packing of the aneurysm sac.[5] Few advances occurred during the next 1000 years; John Hunter ushered in the era of modern vascular surgery, based on a more scientific understanding of anatomy and physiology. He studied the collateral circulation resulting from the occlusion of arteries, and in 1785 successfully ligated the superficial femoral artery to treat a popliteal aneurysm. The patient did well and maintained function of his lower extremity.[6]

Rudolph Matas (1860–1957) made numerous contributions to the field of vascular and arterial reconstruction. In 1888, he was the first to perform endo-aneurysmorrhaphy in the treatment of a brachial artery aneurysm. This procedure augmented the principle of proximal and distal ligation by Hunter, using evacuation of the aneurysm sac and ligation of tributaries from within the sac while preserving important collaterals, and remains an important principle in the era of modern vascular surgery.[7,8] In 1923, Matas performed the first successful aortic ligation; the patient survived 18 months before succumbing to tuberculosis.[9] Little progress was made during the next two decades; Bigger's summary of surgical therapy for aortic aneurysms at the 1940 annual meeting of the American Surgical Association probably represented the consensus of the era: "Judging from the literature, only a small number of surgeons have felt that direct surgical attack upon aneurysms of the abdominal aorta was justifiable, and it must be admitted that the results obtained by surgical intervention have been discouraging."[10]

The modern era of aneurysm therapy was ushered in by Charles Dubost in 1951, with the first successful replacement of the aorta with an aortic homograft. The introduction of Vinyon N cloth in the construction of aortic prostheses by Voorhees, Jaretski, and Blakemore[11] addressed the poor availability of existing aortic homografts and initiated the era of prosthetic vascular reconstruction.* The eventual introduction of polyester, championed by DeBakey, and the introduction of new knitting machine technologies to make seamless grafts of multiple sizes and shapes led to a wider availability of materials and ultimately the diffusion of surgical techniques for repairing aneurysms.[12] Further refinements in surgical, anesthetic, and critical care, in the setting of increasing surgical volume, defined the ensuing decades until the 1990s, when many surgical series documented perioperative mortality for open aortic aneurysm repair below 5%, with some at 1% or lower.

The era of endovascular, or transcatheter, repair of aortic and other peripheral aneurysms was made a clinical reality in 1991 by Juan Parodi, when he used available balloon-expandable stents in combination with standard polyester grafts to create a device that could be delivered from the femoral artery to the abdominal aorta, where it was deployed and effectively excluded an infrarenal aortic aneurysm. Today there are numerous endografts available for use, and current estimates are that more than 70% of all aortic aneurysm treatment is performed with endograft technology. More recently approved devices and off-label combinations of various other endovascular devices have been increasingly used where critical branches are present, leading to the technical ability to repair virtually any aneurysm, from the aortic valve to the popliteal and brachial artery.

Historically, aneurysms of the upper and lower extremity arteries were the first to be treated, and the development of those techniques dates into antiquity. Modern approaches to peripheral aneurysm and nonaortic intraabdominal aneurysm (e.g., splenic, renal) repair typically uses techniques to bypass critical vessels following proximal and distal ligation of the aneurysm; their development has paralleled the techniques used for arterial bypass performed for occlusive disease. As with aortic aneurysms, a variety of endovascular techniques for treating peripheral aneurysms have been introduced during the last 20 years. Embolization techniques have also been selectively used for the treatment of saccular visceral artery aneurysms and other aneurysms providing blood supply to noncritical organs, or where good collateral circulation exists.

ANEURYSM CLASSIFICATION

Size Definitions

The size required to describe an artery as aneurysmal has been defined as "a permanent localized (i.e., focal) dilatation of an artery having at least a 50% increase in diameter compared with the expected normal diameter of the artery in question" by the Ad Hoc Committee on Reporting Standards of the Society for Vascular Surgery in 1991.[13]

Aortic

Magnetic resonance imaging of 70-year-old men and women in Sweden determined aneurysmal size and ratio to normal based on a two-standard deviation variance from normal diameters in the ascending and descending thoracic aorta, supraceliac aorta, and infrarenal aorta (Tables 69.1 and 69.2). Other definitions for infrarenal aortic aneurysms have used a 3.0-cm threshold for definition across all adults, or a 50% increase relative to an adjacent normal-appearing segment. Women generally have smaller aortic diameters than men; this becomes clinically relevant when determining the size threshold for intervention for aortic aneurysms in both sexes.

*Large samples of Vinyon N were made available for research following World War II. The material was manufactured to make parachutes for an invasion of Japan, which was cancelled following the atomic bombings of Hiroshima and Nagasaki and Japan's subsequent surrender. Interestingly, polytetrafluoroethylene (PTFE) was used to help contain uranium hexafluoride, a toxic byproduct of atomic bomb production during the Manhattan Project. Modified from Johnston KW, Rutherford RB, Tilson MD, et al. Subcommittee on Reporting Standards for Arterial Aneurysms, Ad Hoc Committee on Reporting Standards, Society for Vascular Surgery and North American Chapter, International Society for Cardiovascular Surgery: Suggested standards for reporting on arterial aneurysms. *J Vasc Surg*. 1991;13:452-458.

Peripheral

Iliac, popliteal, and femoral aneurysms follow aortic aneurysms in the hierarchy of prevalence and are often coexistent with aortic aneurysms. Aneurysms throughout the rest of the peripheral vascular system, although usually degenerative in nature, may also be related to other pathologic processes, such as arteritis, infection, and connective tissue disorders. The "normal" diameters of a variety of peripheral arteries, as determined from imaging studies, are listed in Table 69.3. Irrespective of the ratio of an aneurysm to its normal arterial diameter, the physical forces of wall tension are dictated by the absolute radius rather than by any ratio to a standardized normal size.

True Versus False Aneurysms

The distinction of true or false aneurysms (usually termed pseudoaneurysms) is dependent on whether the lesion represents a dilatation of the entire vascular wall (i.e., true aneurysm) or is a locally contained hematoma resulting from disruption of the vessel (i.e., pseudoaneurysm). In pseudoaneurysms, the "wall" of the pseudoaneurysm is connective tissue formed in reaction to the contained hematoma. This distinction usually does not affect decisions regarding the necessity of intervention, since progressive enlargement and its consequences are indications for intervention in both aneurysm types. However, certain types of pseudoaneurysms may have an increased tendency toward rupture. Many peripheral pseudoaneurysms are the result of trauma, which is often iatrogenic during peripheral arterial access required for imaging or therapy (Fig. 69.1). These pseudoaneurysms often have a "neck" or narrow conduit between the affected artery and the main pseudoaneurysm cavity. When this morphology exists, therapy directed at inducing aneurysm thrombosis is often effective in treating the aneurysm.

Another frequent cause of pseudoaneurysms is the loss of anastomotic integrity at the site of a prior surgical anastomosis. These peri-anastomotic pseudoaneurysms represent actual dehiscence of the original suture line from the graft to the vessel (Fig. 69.2). Endovascular techniques have greatly simplified the repair of these lesions in many cases.

Location and Extent

Aneurysms are classified by their location (e.g., aortic, splenic) and their extent. *Ectasia* refers to an intermediate stage of enlargement, when an artery is abnormally large, but less than 50% greater than normal, whereas *arteriomegaly* refers to diffuse, continuous enlargement of multiple arterial segments, dilated

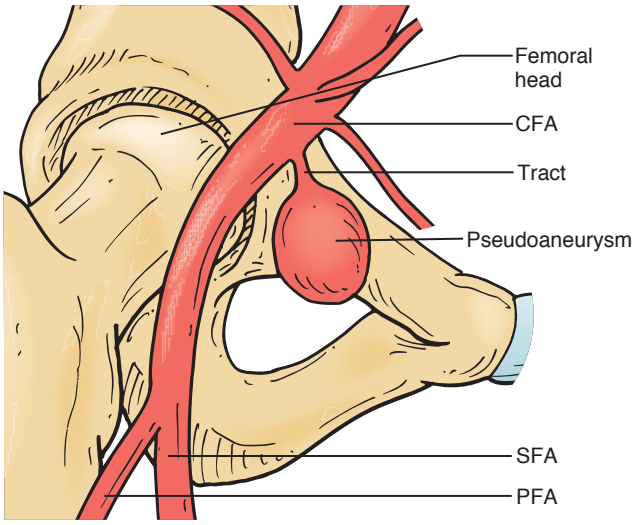

Figure 69.1 Iatrogenic femoral false aneurysm or pseudoaneurysm after percutaneous femoral arterial puncture. *CFA,* Common femoral artery; *PFA,* profunda femoris artery; *SFA,* superficial femoral artery. (From Kronzon I. Diagnosis and treatment of iatrogenic femoral artery pseudoaneurysm: a review. *J Am Soc Echocardiogr.* 1997;10:236-245.)

to greater than 50% of normal. Arteriomegaly is a descriptive term, rather than representative of a specific diagnosis, and likely constitutes part of a not yet clearly defined genetic syndrome of arterial degeneration. Both arterial ectasia and arteriomegaly are associated with an increased risk for aneurysm disease in first-degree relatives of affected patients.[14] The term *aneurysmosis* is often used to describe multiple aneurysms in several anatomic locations, or the combination of aneurysmal degeneration in the setting of arteriomegaly.[15]

Morphology

The shape of aneurysms is typically described as fusiform or saccular. Fusiform aneurysms represent a generalized increase in the entire diameter of the affected vessel, while saccular aneurysms are more localized and often eccentric in shape. Some saccular aneurysms are eccentric defects arising from a focal ulcer or weakness in the arterial wall, often because of trauma or infection (Fig. 69.3). In general, pseudoaneurysms are more likely to have saccular morphology, while true degenerative aneurysms are more likely to have a fusiform configuration.

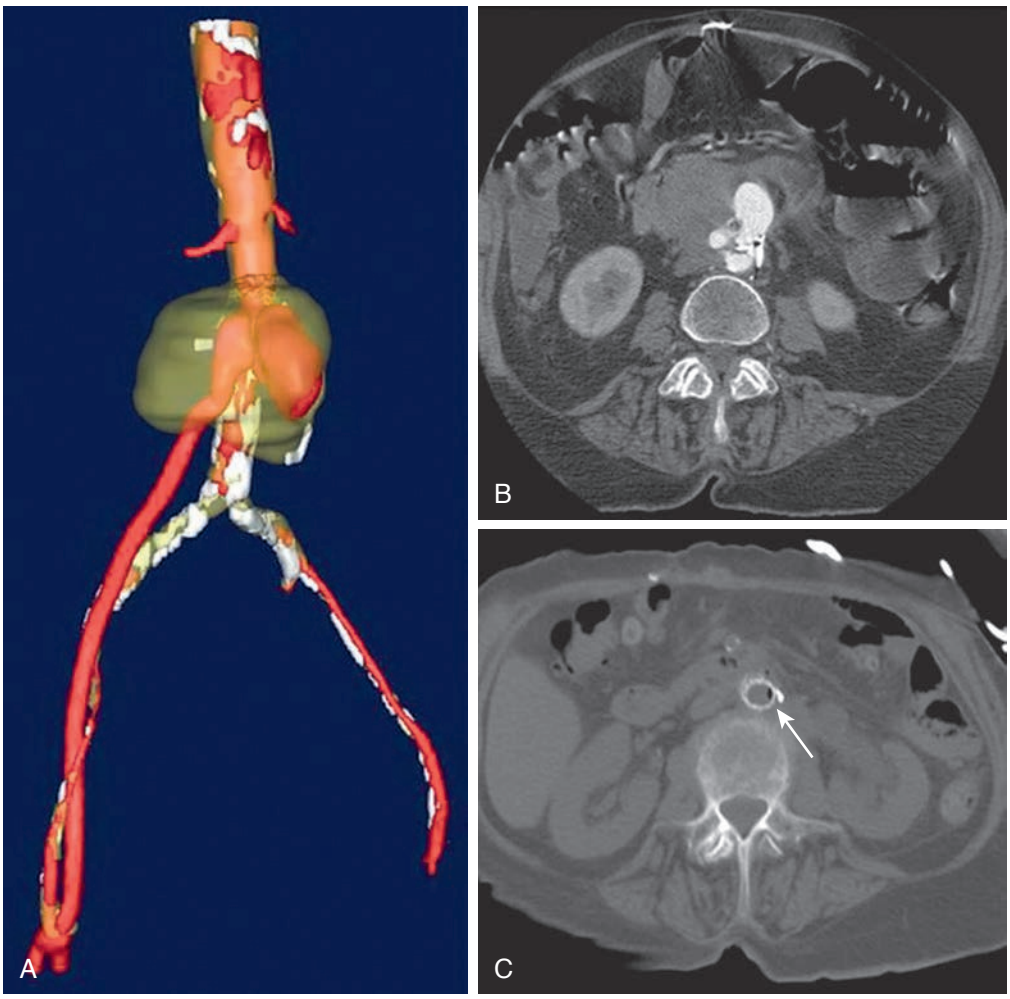

Figure 69.2 Three-dimensional reconstruction (A) and axial computed tomography imaging (B, C) of a proximal infected anastomotic pseudoaneurysm in an aortofemoral bypass graft. *Arrow* shows gas formed by infecting bacteria. (From Lew WK, Rowe VL, Cunningham MJ, Weaver FA. Endovascular management of mycotic aortic aneurysms and associated aortoaerodigestive fistulas. *Ann Vasc Surg.* 2009;23:81-89.)

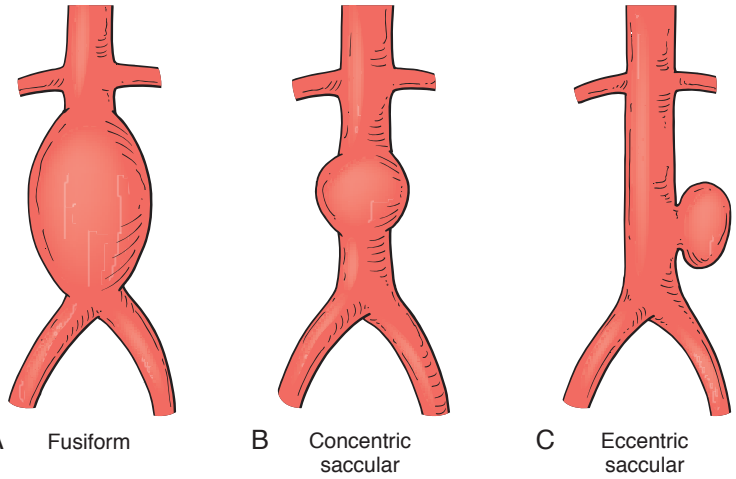

Figure 69.3 Fusiform and saccular (concentric or eccentric) aneurysm morphology.

Most peripheral arterial aneurysms are associated with atherosclerotic degeneration of the entire wall, which usually results in a fusiform or concentric saccular morphology. Eccentric saccular morphology is typical of renal aneurysms and intracranial or cerebral aneurysms but is less common in noncerebral locations, except for the kidney. However, most pseudoaneurysms do have an eccentric saccular shape. Whereas fusiform and concentric saccular aneurysms result from a generalized weakening of the entire circumference of the affected vessel, saccular aneurysms result from a focal weakness that may be due to an intrinsic abnormality or an extrinsic process causing focal arterial damage. Intrinsic causes associated with saccular aneurysms generally involve a focal "tear" or partial disruption of the arterial wall at that location. Penetrating atherosclerotic ulcers and intramural hematomas are examples of focal tears in the aortic wall that fail to completely propagate down the wall in the medial layers, resulting in frank aortic dissection, and have a morphology consistent with eccentric saccular aneurysms. These entities have become more recognized in the past decade with respect to their presentation, prognosis, and treatment, particularly as relatively straightforward endovascular techniques are often effective therapies for these lesions.[16,17] The risk of rupture is better characterized for fusiform or saccular shapes but is less well understood for eccentric saccular aneurysms. Saccular aneurysm morphology and associated symptoms are often used as factors in advising intervention at a diameter less than that for fusiform aneurysms, and many saccular aneurysms are easier to treat with endovascular techniques because of their focal nature. However, definitive data suggesting that saccular aneurysms are more prone to rupture versus fusiform lesions of the same size are lacking. Symptoms, size, growth rate, and amenability to repair are often significant factors in the decision to repair or to observe these unusual lesions.

Etiology

Degenerative

The terms *degenerative* and *atherosclerotic* are often used to describe the most common type of aneurysms. Some authors prefer the term *degenerative* to *atherosclerotic* in describing the common form of aneurysm to avoid the unproven causative relationship between aneurysms and typical atherosclerosis. The relationship of atherosclerosis to aneurysm formation is complex, but both aneurysms and obstructive manifestations are often found in the same patient cohort, with either the aneurysmal or obstructive manifestation predominating. Specific factors associated with degenerative aneurysms include the presence of abnormal levels of metalloproteinases in the media of aneurysm specimens.[18,19] In addition, there is evidence for a deficit of antiproteolytic enzymes that inhibit metalloproteinases—specifically the tissue inhibitor of metalloproteinase-1.[20] The intensity and duration of cigarette smoking by patients affected with aneurysm disease is the most significant risk factor for the development of these degenerative aneurysms[21] and represents the most attractive target for risk reduction.

Inflammatory

The term *inflammatory* refers to an aneurysm with an exaggerated inflammatory component, which often incites a fibrotic reaction around the aneurysm. The infrarenal abdominal aorta is most often affected by this inflammatory process and has the appearance on axial imaging of a thick inflammatory so-called rind around the exterior of the affected vessel, which may or may not envelope adjacent structures. Inflammatory infrarenal aortic aneurysms may be associated with ureteral obstruction as the process envelops the ureters in the retroperitoneal space (Fig. 69.4).

Efforts to determine a genetic susceptibility for inflammatory aneurysm formation have yielded only similarities, rather than differences, in the genetic background of patients with degenerative versus inflammatory aneurysms.[22] Detailed studies of the cellular infiltrate and cytokine profiles documented in patients with inflammatory aneurysms may eventually lead to a better understanding of this challenging and enigmatic disease state.[23] The primary surgical challenge associated with these lesions is the difficulty of dissecting surrounding structures safely during the open repair of these lesions. The complications associated with traditional open surgery for inflammatory aortic aneurysms have included duodenal perforation and ureteral injury. Endovascular repair of inflammatory aneurysms has been reported

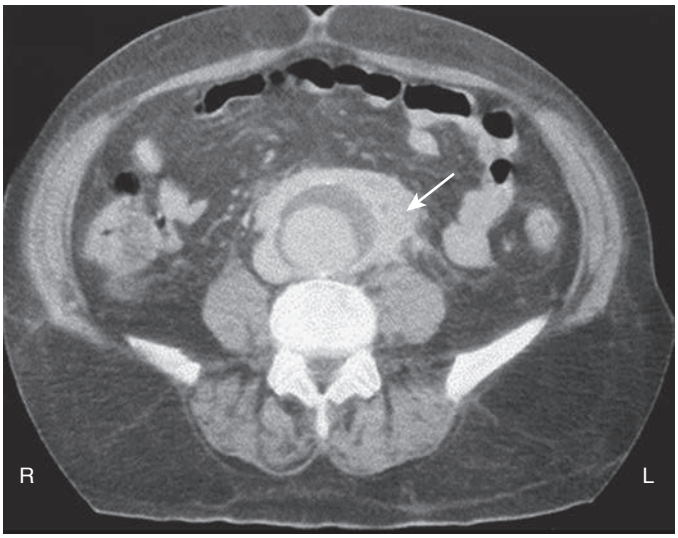

Figure 69.4 Typical appearance of inflammatory aortic aneurysm on computed tomography with thick peri-aortic fibrotic process. (From Speziale F, Barigia E, Grossi R, et al. Inflammatory aneurysms of the abdominal aorta involving the ureters: is combined treatment really necessary? *J Urol.* 2001;165:27-31.)

to result in regression of the peri-aneurysmal inflammation and fibrosis.[24]

Takayasu arteritis, giant cell arteritis, polyarteritis nodosa, Behçet disease, Cogan syndrome, and cystic medial necrosis represent other inflammatory arterial conditions that are associated with aneurysmal degeneration. The location and severity of these aneurysms are related to the specific diagnosis and the ability to control the primary process with medical therapy (see Chapter 137).

Aneurysms Associated With Arterial Dissection

Spontaneous arterial dissection occurs most often in the aorta, but can also occur in peripheral arterial locations. Arterial dissection describes a spontaneous tear of the intima of an artery and the subsequent propagation of that tear along the anatomic plane within the media (see Chapter 81). The failure of the initial intimal tear to propagate may result in a penetrating aortic ulcer or intramural hematoma, as discussed earlier. Arterial pressure and acute arterial distention as the result of mural delamination are the driving forces behind the propagation of the dissection. The most common clinical symptomatic presentation of this process is thoracic aortic dissection in either the ascending or descending portion, or both. The structural integrity of arteries is dependent on the integrity of their composite (three-layer) structure. The primary morbidities associated with arterial dissection are acute occlusive symptoms and subsequent aneurysmal degeneration. Aneurysmal degeneration resulting from dissection can take the form of acute distention and rupture, or a less severe acute dilatation followed by progressive dilatation over time, similar to that seen with degenerative aneurysms. Chronic aneurysms due to dissection are generally treated by the same guidelines for size, growth, and symptoms that are used for the management of degenerative aneurysms.

Traumatic

Aneurysms that result from trauma are pseudoaneurysms, due to perforation of an artery that results in local containment of hemorrhage rather than uncontrolled bleeding. The location of these aneurysms parallels the location and incidence of trauma (see Chapters 181 to 184).

Developmental and Congenital Anomalies

Aneurysms associated with anomalous arterial and cardiac structures are not uncommon but are highly variable, depending on the nature of the primary structural defect. These lesions are usually further representations of the embryologic defect that resulted in the primary arterial or cardiac anomaly. One such embryologic arterial anomaly is the persistent sciatic artery. More than 40% of these patients will develop aneurysmal degeneration. Kommerell diverticulum is another form of aneurysmal degeneration related to a developmental anomaly, located at the origin of an aberrant right subclavian artery. Aneurysm development in this location can intensify the esophageal obstruction associated with an aberrant right subclavian artery (*dysphasgia lusoria*).[23] Congenital AAAs have also been reported in young patients, such as those with tuberous sclerosis, but without other known connective tissue disorders, and are thought to represent a congenital defect in the aorta itself.[25] Although it is not strictly a genetic disorder, aortic aneurysm increases in incidence from approximately 5% in the general population to approximately 20% to 30% in male siblings of an aneurysm patient, suggesting a significant familial linkage.[26]

Infectious

Aneurysms may result from primary infection of the arterial wall, which can occur due to hematogenous seeding or the extension of an adjacent infectious process that then envelops and primarily infects the arterial tissue externally (Fig. 69.5). Most primary infected arterial aneurysms, as opposed to secondary infection of a preexisting aneurysm, have an eccentric saccular shape, and all such aneurysms should be evaluated for an infectious etiology. A wide variety of organisms, including many strains of bacteria[27] and fungi (e.g., *Candida, Aspergillus*), tuberculosis, and syphilis have been documented to be causative. Infected aneurysms can occur in essentially any vessel, and their incidence is increased in patients with a history of illicit drug injection/abuse and in patient populations that are severely immunosuppressed (e.g., transplant recipients, oncology patients, patients infected with human immunodeficiency virus, and patients with acquired immunodeficiency syndrome).[28]

Repair of infected aneurysms is difficult because prosthetic material is usually contraindicated and there are limited durable autogenous substitutes available. In addition, the open approach to these lesions is made more challenging by the inflammatory response to the infected structure, making tissues friable and tissue planes difficult to define. Surgical repair utilizing antibiotic-impregnated prosthetics, cryopreserved allografts, and primary endovascular stent-grafting in these cases remains controversial (see Chapter 144).

Figure 69.5 An infected aortic eccentric saccular aneurysm. (From Macedo TA, Stanson AW, Oderich GS, et al. Infected aortic aneurysms: imaging findings. *Radiology*. 2004;231:250-257.)

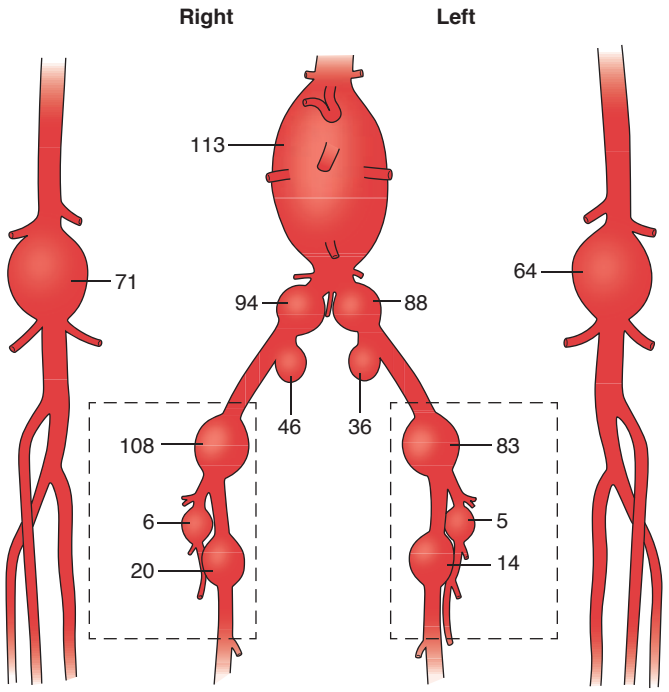

Figure 69.6 The locations and distribution are shown of degenerative femoral artery aneurysms (FAAs; *dotted boxes*) and additional synchronous and metachronous aneurysms. Forty-seven patients (26%) had bilateral degenerative FAAs. (From Lawrence PF, Hartlander-Locke MP, Oderich GS, et al. The current management of isolated degenerative femoral artery aneurysms is too aggressive for their natural history. *J Vasc Surg*. 2014;59(2):343-349.)

Specific Arteries

Arterial aneurysms occur throughout the vasculature from a wide variety of causes. Their prognosis and therapy are largely dependent on their anatomic location. Aneurysms located in circulatory beds that have robust collateral circuits can often be embolized or excluded from the circulation by ligation or other means without concomitant vascular reconstruction. Aneurysms in critical locations of the circulatory system require replacement of that arterial segment with an adequate substitute, in the form of an autogenous or prosthetic graft.

Aortic

Aneurysms occur throughout the length of the aorta, with a majority occurring in the infrarenal segment. Aneurysms occurring in the ascending aorta are typically degenerative or the sequela of prior aortic dissection; the aortic arch and descending aorta are similarly affected in their predilection for aneurysmal disease. Isolated thoracic aortic aneurysms were found in 0.9% of autopsies in Sweden[29] and represent 3% of aortic aneurysm repairs in the United States.[30] The infrarenal location is by far the most common for aortic aneurysms, and AAAs are at least nine times more common than thoracic aneurysms.[31] Approximately 1.7% of women and 5% of men older than 65 years have an infrarenal aortic diameter greater than 3 cm, and the incidence of aortic aneurysm increases by about 6% for each decade after that age.[32] Aneurysms involving segments of the thoracic and abdominal aorta, thoracoabdominal aneurysms, are less frequent than either isolated thoracic or isolated AAAs, but represent some of the most formidable challenges for repair in vascular surgery.

Iliac

Aneurysms are most frequently found in the common iliac artery, often in the presence of a concomitant infrarenal aortic aneurysm. A review of patients with iliac aneurysms in 1994 revealed that only 11% presented without a concomitant aortic aneurysm.[30] Internal iliac aneurysms are the next most frequent lesion in this circulatory bed. Although internal iliac aneurysms are often found in association with common iliac aneurysms, these lesions more commonly occur in isolation. Isolated internal iliac artery aneurysms present with rupture in 40% of patients and are associated with a 31% mortality rate.[33] Isolated internal iliac aneurysms are less frequently diagnosed when asymptomatic and are more difficult to control surgically when ruptured; these are two potential reasons for the elevated rates of rupture and death from lesions in this location. External iliac aneurysms are rare and usually associated with traumatic lesions or other nondegenerative causes.

Femoral

The incidence of true aneurysms of the femoral artery is relatively low, likely on the order of 5/10,000 patients.[34] Nevertheless, true degenerative femoral artery aneurysms do occur, and a recent study suggests that these lesions typically do not cause complications unless they are greater than 3.5 cm or contain thrombus.[35] These aneurysms are frequently bilateral (26%), and 88% of patients have a synchronous aneurysm at another site (see Chapter 83; Fig. 69.6).

Femoral pseudoaneurysms most commonly result as a complication of percutaneous femoral access or disruption of prior surgical bypass anastomoses. The most serious and high-risk femoral aneurysms are infected pseudoaneurysms from illicit injection drug abuse.[36] These lesions can be challenging to repair and are often not easily amenable to endovascular techniques.

Popliteal

The most common peripheral arterial aneurysm, popliteal aneurysm, occurs in approximately 1% of men aged 65 to 80 years.[37] Popliteal aneurysms are frequently bilateral and often occur concomitantly with aortic aneurysms,[34] making investigations for their presence an important part of the examination and workup of any patient with an AAA. As opposed to aortic aneurysms, the primary morbidity associated with popliteal aneurysms is acute thrombosis or embolization with resulting limb ischemia and potential limb loss, rather than rupture and hemorrhage.[38]

Visceral

There are different estimates of the prevalence of aneurysms occurring in the trunk or branches of the celiac and superior mesenteric arteries; a reasonable estimate is that these occur in approximately 1% of the population, based on postmortem series.[39] Splenic artery aneurysms lag behind only the aortoiliac segment as the second most common aneurysmal lesion in the abdominal cavity, and account for approximately 60% of all visceral or splanchnic aneurysms.[39] Splenic aneurysms occur more frequently in women and are also associated with portal hypertension. Pregnancy is a specific risk factor for rupture. Many visceral aneurysms can be managed with endovascular techniques including endografting or embolization. In the case of splenic artery aneurysms involving the hilum, laparoscopic splenectomy can also be performed (see Chapter 85).

Renal

The renal circulatory bed is characterized by its low resistance and high flow characteristics, and this profuse flow is an explanation for the location and frequency of renal aneurysms. Aneurysms involving the renal circulatory bed occur in approximately 0.1% of the population.[40] Renal artery aneurysms are often saccular rather than fusiform, and when associated with a disease concomitant condition, it is most often fibromuscular dysplasia. Renal aneurysms can also result from the full spectrum of associated aneurysmal causes, including connective tissue disorders, arteritides, trauma, and spontaneous dissection (see Chapter 128). The morbid sequelae of renal artery aneurysms include thrombotic and embolic events, poorly controlled hypertension, and rupture. Whereas the overall rates of rupture are rare, the risk of rupture is particularly elevated in the third trimester of pregnancy, with resulting maternal and fetal mortality rates of 70% and 100%, respectively.[41] Current recommendations for repair include size greater than 2 to 3 cm, lesions occurring in women of child-bearing age, refractory hypertension, flank pain, and hematuria. The size criteria for intervention are not based on rigorous data, and this may represent too aggressive an approach in some patient populations.[42] Both endovascular and open surgical reconstruction play a role in the treatment of these lesions.

Cerebrovascular

Whereas intracranial aneurysms are relatively common and represent a major area of therapeutic activity for neurosurgeons and interventional neuroradiologists, the extracranial cerebral arteries are rarely affected by aneurysmal degeneration. The few aneurysms that do occur in the carotid are in the internal, common, and external segments in order of decreasing frequency. Dissection, which may occur after trauma, can lead to late aneurysmal degeneration in both the internal carotid and vertebral artery territories (see Chapter 94).[43]

Upper Extremity

Subclavian artery aneurysms can result from the repetitive trauma associated with thoracic outlet syndrome.[44] Iatrogenic brachial pseudoaneurysms as a consequence of percutaneous arterial access are the only other upper extremity aneurysms that occur with any significant frequency (see Chapter 84).

MULTIPLE ANEURYSMS

Aortic

The fact that patients with a diagnosis of an infrarenal aortic aneurysm are more often found to have a concurrent thoracic aortic aneurysm or popliteal aneurysm has been known for many years. Crawford noted that more than 50% of patients with thoracic aneurysms also had abdominal aneurysms and that 12% of patients with abdominal aneurysms had thoracic aneurysms.[45] Gloviczki et al.[46] characterized their experience managing patients with multiple aneurysms during a 2-decade period in 1990, noting that this group represented only 3.4% of all aneurysm procedures performed at the Mayo Clinic during this period (Fig. 69.7). Patients with connective tissue disorders or other systemic conditions that predispose to aneurysmal degeneration obviously have a significantly higher prevalence of multiple aneurysms and recurrent aneurysm disease. These patients must be monitored closely throughout their lives for the development of aneurysms in both typical and atypical locations.

Peripheral

Popliteal aneurysm is the most frequently occurring peripheral aneurysm and is the most common aneurysm to be bilateral; synchronous and metachronous aneurysms in other sites are also common. Galland reviewed a 17-year experience with popliteal aneurysms and noted that 59% of the patients had bilateral aneurysms and 49% had coexisting AAAs.[47] Other peripheral aneurysms can occur in multiple locations, but their prevalence is far less, so they do not typically warrant a heightened suspicion for synchronous aneurysmal disease, as in the case of popliteal and infrarenal aortic aneurysms.

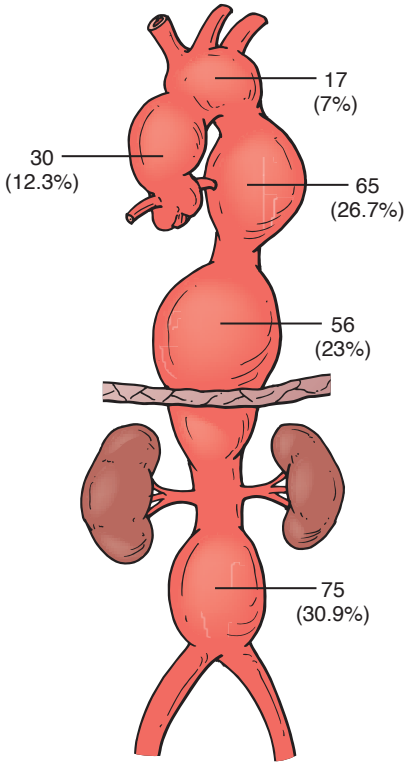

Figure 69.7 Incidence and location of 243 aneurysms in 102 patients with multiple aortic aneurysms. (From Gloviczki P, Pairolero P, Welch T, et al. Multiple aortic aneurysms: the results of surgical management. *J Vasc Surg*. 1990;11:19-27.)

Familial

Patients with a family history of aneurysm disease have a 30% increased risk of having an aneurysm, although the specific genetic explanation for this susceptibility has not been elucidated.[48] This is true for AAAs discovered outside the context of a diagnosed congenital disorder or connective tissue disorder. Although it is not completely understood, this is the most common familial risk factor for aneurysm disease and warrants screening of siblings and children of affected patients.

Connective Tissue Disorders

Connective tissue disorders are primary causes of familial aneurysmal disease and require careful genetic characterization and counseling. As the technology to completely delineate a single individual's genetic code becomes a clinical reality, this area of diagnosis and management is very likely to see significant changes in the coming years. Conditions with familial inheritance of aneurysmal disease include Ehlers-Danlos, Marfan, and Loeys-Dietz syndromes, and a variety of less common connective tissue defects (see Chapter 140).

Cystic Medial Degeneration

A familial pattern of thoracic aortic aneurysm has been termed *familial thoracic aortic aneurysm syndrome*. Whereas no overt connective tissue disorder has been recognized in these patients, they do share the characteristic of cystic medial degeneration.[49] The presence of a bicuspid aortic valve has been associated with a high incidence of ascending aortic aneurysm, and cystic medial degeneration has been proved by tissue biopsy in 75% of these patients.[50] Turner syndrome is also associated with ascending aortic aneurysm, aortic dissection, and bicuspid aortic valve.[51]

HISTORY

Since aneurysms of the aorta were first described in ancient Egyptian scrolls dating to 1550 BC, advances in the understanding of the anatomy, pathophysiology, epidemiology, and natural history of this entity have driven improvements in care.[1-3] During the era in which Galen produced the first detailed anatomic plates of abdominal aortic aneurysms (AAAs), Antyllus attempted treatment through ligation of these vessels, with poor results. In the 14th century, medical knowledge of aneurysms again advanced, as Vesalius used cadaveric dissections to help refine anatomic descriptions. Also in the late 14th century, Pare and Morgagni independently noted the development of aneurysms in prostitutes and correctly attributed them to syphilis.[3-5] The 20th century marked a period of rapid advances in the open surgical management of aortic aneurysms by proximal ligation or obliteration (Cooper, 1817; Matas, 1888), extra-arterial wrapping (Poppe, 1946), and direct reconstruction with autologous (Carrel, 1948; Dubost, 1951) or synthetic (Voorhees, 1952) material.[6-8] DeBakey and Cooley continued to advance the techniques of open aortic aneurysm repair.[9] Operative intervention techniques remained fairly static until the development of catheter-based intervention by Parodi, who performed the first endovascular stenting of an infrarenal aortic aneurysm in 1990.[10,11] Since the U.S. Food and Drug Administration (FDA) approved the first stent grafts for use in repair of infrarenal aortic aneurysms in 1999, endovascular techniques have overtaken traditional open repair as the most common approach to the elective management of this condition.

DEFINITIONS

A true arterial aneurysm is defined as an increase to 1.5 times the normal arterial diameter with involvement of all three anatomic layers. In the infrarenal abdominal aorta, an aneurysm is traditionally defined as a diameter greater than 3 cm or more than 50% larger than a normal proximal segment measured in either anteroposterior or transverse dimension in a plane

perpendicular to the longitudinal axis of the aorta. Although anatomic studies have identified a median-range diameter of 2.2- to 2.3-cm for the infrarenal aorta in 70-year-old Caucasian subjects, population studies have also identified variations in mean diameter at various levels of the aorta based on patient sex and race. This has led to the suggestion that truly evidence-driven guidelines may ultimately recommend different criteria for defining aneurysms and size thresholds for intervention by sex and race at each anatomic level.[12] The authors of the Aneurysm Detection and Management (ADAM) Veterans Affairs Cooperative Study Group concluded that variations in average aortic size based on age, sex, race, and body size (weight, body mass index [BMI] or BSA) were not of great enough magnitude to justify departing from the standard definition given previously.[13] Although pseudoaneurysms and penetrating aortic ulcers may also result in focal increases in arterial diameter, these entities differ in pathophysiology and are not evaluated by the same criteria as the more typical degenerative aneurysm.

EPIDEMIOLOGY

Although aneurysms may occur along the length of the aorta from the root through the bifurcation, the infrarenal aorta is the most commonly reported location, representing approximately 30% of aortic aneurysms.[14] Inferences regarding the affected patient cohorts, incidence, and prevalence of AAAs are drawn from autopsy and screening studies designed to target groups thought to be at increased risk for aneurysm, primarily based on age or sex (Table 70.1). These studies suggest a prevalence of aneurysms 4 cm or larger in approximately 1% of men between the ages of 55 and 64 years. This prevalence increases with advancing age by 2% to 4% per decade.[15,16] It has also been consistently demonstrated that AAAs occur with greater frequency in men,[14,17-19] smokers, and those with a family history of aortic aneurysm.

There is a direct correlation between the incidence of AAAs and the duration of smoking history[18] as well as decreased aneurysm growth rates in association with duration of smoking cessation. Although family history is reported in a small proportion of those with AAAs, it is a strong positive risk factor.[18] Additional risk factors with less strong associations include atherosclerotic disease, history of myocardial infarction, peripheral vascular disease, and hypertension.[19,26] Negative risk factors include female sex, African American race, and diabetes.[18,26]

Aneurysm incidence increases with age, peaking later in women than in men, although most screening studies have been conducted in primarily Caucasian populations. The Veterans Affairs Aneurysm Detection and Management (ADAM) study was a multicenter randomized trial study that documented that 99% of those with AAAs 4 cm or larger in diameter were male and 94% were white.[17]

Associated Aneurysms

The involvement of adjacent arterial segments is not uncommon in infrarenal AAAs, with 5% to 15% extending to the juxta- or suprarenal aorta and 10% to 25%[25] involving the iliac arteries. Synchronous lesions of the thoracic aorta (12%)[27] and femoral or popliteal artery (14% among male patients)[21] are also common. Popliteal artery aneurysms (PAAs) are the most common true peripheral artery aneurysms. The occurrence of PAAs in the general population is approximately 1%.[28] Risk factors for PAAs include age, male sex, presence of other arterial aneurysms, history of smoking, family history, cardiac disease, hypertension, and atherosclerotic disease. Careful evaluation for the presence of these lesions in patients with known AAAs is indicated, particularly given the potential for limb loss associated with undetected aneurysms of the popliteal artery.[22] Conversely, AAAs have been reported in 62% of patients with popliteal artery aneurysms and 85% of those with femoral artery aneurysms (see Chapter 83).[29,30]

Iliac artery aneurysms occur most frequently in the common iliac artery (CIA) (70%), typically in conjunction with an AAA. The largest published series of common iliac artery aneurysms (CIAAs) reports that 86% of patients with CIA aneurysms presented with concurrent or previously treated AAAs. Isolated aneurysms of the CIA are relatively infrequent (6.4% of patients), although approximately one-quarter of these are bilateral. Isolated aneurysms of the internal iliac artery (IAAA) are quite rare and thought to occur in conjunction with AAAs in less than 2% of cases. IAAAs are bilateral in 10.9% of cases. The defined size of an IAA is any vessel 1.5 times the diameter of the normal

vessel or a diameter greater than 1.85 in males and greater than 1.5 in females.[31] The prevalence of IAAs in patients with clinically relevant AAAs is anywhere from 15% to 40%. A retrospective study showed that 86% of patients who were diagnosed with an IAA had a corresponding AAA.[32] Risk factors for IIAs are thought to mirror those of other aneurysms. Although most IAAs are degenerative in nature, injury from penetrating trauma or iatrogenic injury from operative intervention in the area of the iliac arteries may also play a role in their development. There is also an association of IAAs with vasculitides, such as Behçet disease, fibromuscular dysplasia, Takayasu arteritis and connective tissue disorders. There have been reports of mycotic IAAs, but these are very rare.[33,34]

The natural history of iliac artery aneurysms, particularly those occurring in isolation, is less well understood but deserves special mention. The Mayo Clinic group reported a median expansion rate in CIAAs of 0.29 cm per year and reported no ruptures at less than 3.8 cm.[35] A recent review of the literature on IAAAs noted that these aneurysms are quite large when they initially present, likely due to an anatomic location that precludes detection on physical examination unless the aneurysm impinges on surrounding anatomic structures sufficiently to produce symptoms associated with the compression of nerves or urogenital/colorectal structures. Asymptomatic aneurysms, discovered by physical examination or incidentally through imaging, averaged 5.1 cm in diameter, whereas nonruptured and ruptured symptomatic aneurysms averaged 7.6 and 8.3 cm, respectively.[36]

Rupture Risk

Maximal AAA diameter is the standard basis for predicting rupture risk, with larger diameters associated with increasing risk of rupture (Table 70.2). The UK Small Aneurysm Trial reported an annual rupture rate of 2.2%, with most occurring in patients with an AAA diameter of 5 to 5.5 cm. This study also found that the risk of rupture was independently associated with female sex, larger initial AAA diameter, smoking, lower FEV_1, and higher mean blood pressure. Risk of rupture was not independently associated with age, BMI, serum cholesterol, or the ankle/brachial index. This study documented that females have a threefold increase in rupture risk compared with males with similar aortic diameters. Risk of rupture declined when hypertension was controlled or with smoking cessation.[37]

There are other features of AAAs in addition to diameter that correlate with increased risk of rupture. Saccular aneurysm morphology appears to portend an increased risk of rupture compared with fusiform aneurysms.[38] Certain imaging characteristics on CTA can also indicate an increased risk of rupture, including the presence of a dissection, mural thrombus, or a dissection of the peripheral calcification of the aneurysm sac.[39] The UK morphology of ruptured AAA study reported that the most likely site of rupture is in the middle third of the aneurysm at the point of greatest diameter.[40]

In discussing the natural history of AAAs, growth rate must be considered. This is challenging to assess on a consistent basis and depends on the imaging modality used for surveillance. In considering ultrasound-based assessment, it has been well documented that there is significant variability in diameter size depending on the ultrasonographer.[41] A Canadian study specifically showed that this variability is decreased when a measured change in diameter is greater than 0.78 cm.[42] Current practice guidelines indicate intervention based on AAA growth when the rate of expansion is greater than or equal to 10 mm in a 12-month period.[43]

AAA, Abdominal aortic aneurysms.

PATHOPHYSIOLOGY

The descending thoracic and abdominal aortas are formed through embryonic fusion of the paired dorsal aortas, which communicate with the developing heart via the aortic arches. The wall of the mature aorta is composed of three layers: the intima, with its single layer of endothelial cells; the media, made up of smooth muscle cells within a structural protein matrix; and the adventitia, a tough layer of collagen fiber and fibroblasts.

The embryologic process appears to give rise to regional heterogeneity in different parts of the aorta, with variation in the response of neural crest–derived smooth muscle cells of the thoracic aorta versus mesoderm-derived smooth muscle cells in the abdominal aorta. This regional variation clearly affects the secretion of and susceptibility to various cytokines and growth factors thought to be implicated in aneurysm development. This heterogeneity is also reflected in the tissue characteristics of the aortic media within different anatomic segments. In the thoracic aorta, the media contains 55 to 60 lamellar units, with adventitial vasa vasora penetrating the vascular zone of the outer layers, whereas there are 28 to 32 lamellar units in the abdominal aortic media. This makes the abdominal aorta relatively avascular compared with the more proximal aorta, relying more on the transintimal diffusion of oxygen and nutrients.[44]

Aneurysm formation has been associated with the inflammatory degeneration of the connective tissue matrix and smooth muscle cells of the aortic media and, less commonly, with inherited or sporadic defects of these components (Table 70.3). The accumulation of intraluminal thrombus (ILT), which has been described as "a biologically active neo-tissue," is associated with aneurysm progression. It is proposed that this effect is

TABLE 70.3 Connective Tissue Syndromes Associated With Abdominal Aortic Aneurysms

mediated through a cascade of platelet activation ultimately leading to increased oxidative stress and proteolytic injury. The thrombus itself is laminated, progressing from an initial luminal layer with fresh thrombus and cross-linked fibrin to an outer layer in contact with the aortic wall, the latter being characterized by advanced fibrinolysis. At this level, plasmin serves to activate matrix metalloproteinases (MMPs) and TGF-β and participates directly in matrix protein degeneration. Oxidative injury may occur through enhanced oxidase activity or inhibition of antioxidants, both of which have been observed in human AAA tissue. Within ILT, the process of hemagglutination releases pro-oxidant free hemoglobin. The importance of the biologic activity of the ILT is underscored by the observation that increased thrombus burden is associated with an increased AAA growth rate even though wall stress modeling suggests modest reductions in local aortic wall stress with locally increased thrombus load. Wall thinning, medial loss of smooth muscle cells, elastin degradation, and adventitial inflammation have all been associated with the presence of ILT (Fig. 70.1). It has been suggested that the impact of thrombus burden may also be associated with aortic wall hypoxia.[44]

Although much attention has been focused on medial degeneration, marked changes in the adventitia have also been observed in AAAs. Inflammation—in the form of extensive periaortic and adventitial infiltration by lymphocytes, macrophages, and mast cells—is noted histologically. Adventitial degeneration is also characterized by extensive fibrosis. This fibrosis, driven by macrophage/TGF-β–mediated fibroblast proliferation and activation, may provide some degree of protection from rupture, but it may also be associated with pathologic retroperitoneal fibrosis, with adherence to and injury of adjacent retroperitoneal structures. Neoangiogenesis, typically limited to the adventitia and outer media, is also observed in AAAs.

Frank bacterial infection of the aortic wall is clearly associated with the development of mycotic aneurysms. It has been proposed that bacterial colonization of either the aortic wall or ILT may contribute to AAA formation and progression either directly or indirectly through alteration of the immunologic milieu. *Chlamydia pneumoniae* and oral flora, such as *Porphyromonas gingivalis* and *Streptococcus mutans*, have been identified in AAA tissue either through culture or isolation of bacterial DNA in tissue specimens.

DIAGNOSIS

History

Patients with AAAs are typically asymptomatic. Those who are symptomatic and previously undiagnosed often present with diffuse nonspecific abdominal and/or lower back pain. This pain is usually described as unique and different from their standard chronic abdominal or lower back pain. Patients may also state that they can feel pulsations in their abdomen. Those who are thin may state that they can see a pulsatile mass in their abdomen. Certainly there is a high probability that these patients have as part of their medical history hypertension, atherosclerotic disease, and tobacco usage.

Physical Examination

An AAA may be detected on physical examination as a palpable pulsatile (expansile) mass, most commonly supraumbilical and in the midline. The location, however, may be variable, as aortic tortuosity can result in a lateral and/or infraumbilical location. The sensitivity of physical examination depends on the aneurysm's size and the patient's habitus. Owing to the previously mentioned high probability of concomitant femoral artery aneurysms and PAAs, these areas should also undergo examination.

Ultrasound

The detection and characterization of aneurysms is greatly aided by modern imaging techniques. Ultrasound (US) examination has been demonstrated to afford excellent sensitivity and

specificity (Fig. 70.2). US may be limited by patient habitus or bowel gas, but, importantly, it avoids the complications associated with more invasive testing, radiation, and exposure to a contrast medium. US is an excellent choice for screening and evaluation of diameter. It must also be noted that US is not an ideal method for detecting rupture, as it is unable to image all portions of the aortic wall. In addition, in the nonfasting emergently examined patient, ideal image acquisition may be precluded. It has been estimated that US may fail to detect up to 50% of aneurysm ruptures.

Computed Tomography

Computed tomography (CT) provides excellent imaging of AAAs, with greater reproducibility of diameter measurements than US. CT, particularly with the adjunctive use of iodinated contrast to perform a CT angiogram (CTA), provides a wealth of anatomic information, including defects in vessel calcification,

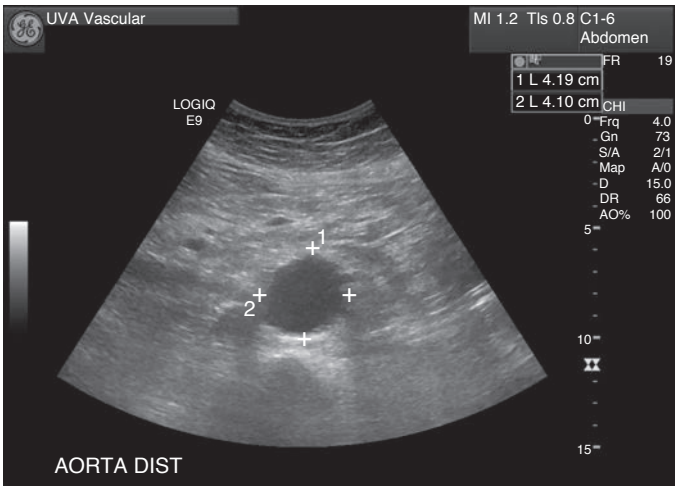

Figure 70.2 Ultrasound of the abdominal aorta documents an abdominal aortic aneurysm noted with maximal measurement of 4.19 by 4.10 cm in the anteroposterior and transverse dimensions.

Figure 70.3 Computed tomographic angiogram of the abdomen and pelvis shows an infrarenal abdominal aortic aneurysm measuring approximately 5.6 by 6.5 cm with extensive mural thrombus along the right lateral posterior aspect.

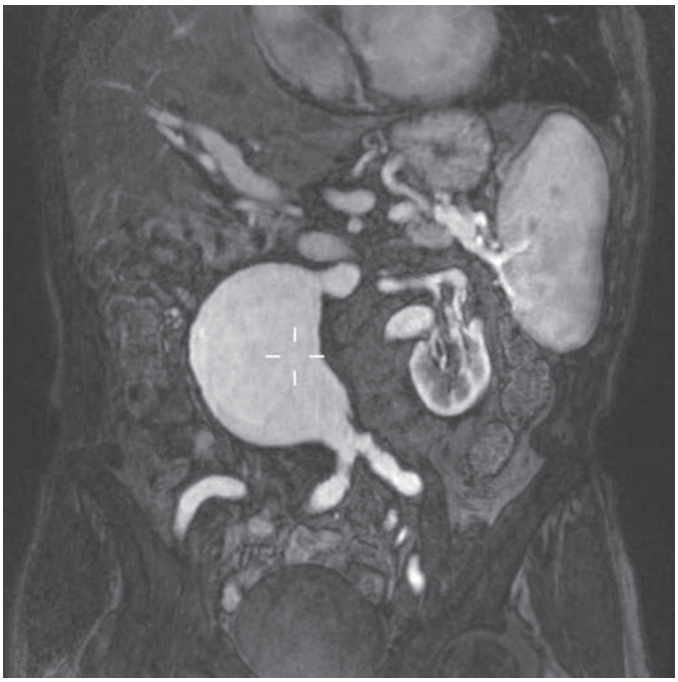

Figure 70.4 Magnetic resonance (MR) angiogram of the abdomen and pelvis performed on a 3 Tesla MR scanner with contrast. Imaging shows an infrarenal abdominal aortic aneurysm measuring 7.8 by 7.8 cm.

thrombus, and concurrent arterial occlusive disease. CTA also permits invaluable multiplanar and three-dimensional reconstruction and analysis for operative planning (Fig. 70.3). Drawbacks associated with CTA include substantial exposure to radiation, particularly in the setting of serial examinations, and the use of iodinated contrast media is problematic in a population with a high incidence of associated kidney disease (see Chapter 27).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) are, like CT, quite sensitive in the detection of AAAs (Fig. 70.4). Unlike CT, MRI does not demonstrate aortic wall calcification, which may be quite important in operative planning. Although the study does not require the use of iodinated contrast, MRA utilizes gadolinium, which has been associated with the development of nephrogenic systemic fibrosis in patients with a low GFR. The availability of MRI may also be limited by the presence of incompatible metallic implants or foreign bodies. However, the ability to acquire dynamic images throughout the cardiac cycle may ultimately prove clinically useful (see Chapter 28).[44]

Angiography

Due to its invasive nature, contrast angiography is not the preferred method for screening or surveillance for AAAs. Typically, per the imaging guidelines developed by the American College of Radiology, it is reserved for cases where further detailed characterization of an aneurysm is required or for intervention, as in the case of preoperative embolization of an accessory renal artery prior to endovascular aneurysm repair.[48]

SCREENING AND SURVEILLANCE RECOMMENDATIONS

Guidelines for screening and surveillance for AAAs have been developed and promulgated by a variety of sources from various professional organizations and national healthcare entities. These guidelines are based on several key population-based screening studies. Their final recommendations are informed by a range of considerations, including the quality of evidence, the characteristics of the screening modality, and cost.[49]

There is controversy around the selection of specific populations for initial screening, including several issues such as the age at which screening should be performed, the influence of additional risk factors—such as smoking and family history for AAA on screening recommendations—as well as the appropriateness of screening for women (Table 70.4).

The screening of women with additional risk factors for aneurysm remains particularly controversial.[51] There is evidence of a strong association between smoking and AAA formation in women. Although mortality data suggest that the gender differences in aneurysm-related mortality narrow with advancing age as aneurysm prevalence rises in women, the overall benefit of screening has been questioned, considering poorer postintervention outcomes in women.[55] The paucity of population-based data on women is problematic, particularly to the extent that this complicates the demonstration of cost-effectiveness.

TABLE 70.4 Screening and Surveillance Recommendations

Year	Organization	Initial Screening	Referral for Treatment	Surveillance	Repeat Screening
2010	European Society for Vascular Surgery[49,50]	• Men should be screened with a single US at age 65 • Population screening of older female smokers does not reduce incidence of rupture	• Men should be considered for intervention when maximal diameter reaches 5.5 cm		
2009	Society for Vascular Surgery[51]	• One-time US screening for men aged ≥65 • Screening recommended for first-degree relatives of patients with AAA	• Smoking cessation is recommended to reduce risk of AAA growth and rupture • Elective repair is recommended for patients with a fusiform AAAs ≥5.5 cm in maximal diameter		
2007	National Screening Committee (UK)[50]	• US screening available for all men aged ≥65			
2007	Canadian Society for Vascular Surgery[52]	• All men aged from 65 to 75 to be screened • Individual selective screening for those at high risk: women aged > 65 with high risk secondary to smoking, cerebrovascular disease, and family history • Men aged < 65 with positive family history			
2005	American College of Cardiology/American Heart Association[53]	• Screening for men aged ≥65 • Screening for women aged 60–85 with a family history of AAA	Intervention is not recommended for asymptomatic infrarenal or juxtarenal AAAs if they measure less than 5.0 cm in diameter in men or < 4.5 cm in diameter in women	Patients with infrarenal or juxtarenal AAAs measuring 4–5.4 cm in diameter should be monitored by ultrasound or computed tomographic scans every 6–12 months to detect expansion	
2004	Society for Vascular Surgery/American Association for Vascular Surgery/ Society for Vascular Medicine and Biology[54]	• Screening for all men aged 60–85 • Screening for women aged 60–85 with a family history of AAA			

AAA, Abdominal aortic aneurysm.

Controversy also inevitably attends the suggestion that screening not be offered to other subgroups in whom racial or ethnic background is apparently associated with decreased aneurysm incidence.

Recommendations regarding the follow-up and rescreening of patients with initial aortic diameters less than 3 cm is controversial, particularly in considering cost-effectiveness. The incidence of AAAs exceeding 4 cm following "negative" initial screening is lower than that after initial screening, but both the ADAM trial and others have demonstrated that a subset of patients deemed "normal" at a first screening will go on to develop aneurysms susceptible to rupture.[19,26]

Payer policies regarding reimbursement do not precisely track any of the recommendations. Medicare, for instance, because of the Screening Abdominal Aortic Aneurysms Very Efficiently (SAAAVE) act, reflects an intermediate approach in offering a screening benefit for men with a personal smoking history and men *or* women with a family history of AAAs as part of a "Welcome to Medicare Physical Examination." This benefit was initially available only during the first 12 months of enrollment. This benefit was subsequently expanded in 2011, under the Patient Protection and Affordable Care Act (ACA), to an annual wellness visit that is free to Medicare beneficiaries. Early evaluation suggests that the uptake rate has remained low

(approximately 10% of eligible Medicare beneficiaries) in the early years of the program.

MEDICAL THERAPY

Medical Management

The current approach to the medical management of infrarenal aortic aneurysms focuses mainly on small aneurysms. Although multiple agents—including statins, angiotensin converting enzyme (ACE) inhibitors, β-blockers, and antibiotics including tetracycline and doxycycline—have been shown in animal models to slow aneurysm progression, effectiveness has not been clearly demonstrated in humans. Targeted mechanisms for potential medical management include the inhibition of immune function, dyslipidemia, hypertension, connective tissue degradation, oxidative stress, and vascular smooth muscle degradation.

It has also been proposed that increasing aortic blood flow through exercise may slow the growth of aortic aneurysms. However, this has not been proven in human modeling. It has been shown that patients with small aneurysms tolerated exercise programs well for the 3 years of the study. Concurrently, this same study showed that there was no significant increase in the size of AAAs during that time period.[56]

Beta blockers have been shown in animal models to be effective in stopping the expansion of AAAs.[57,58] Some earlier small randomized human trials supported this claim. However, more recently conducted large randomized controlled trials did not find a significant reduction in growth of AAAs in patients on beta-blocker therapy.[59,60]

Other antihypertensive medications have also been studied to determine their effectiveness in inhibiting AAA growth.[61-64] ACE inhibitors were reviewed with initial reports from small, retrospective studies resulting in positive effects in helping slow the growth of small aneurysms.[65] Again, further investigation in larger retrospective studies refuted these early claims and showed no demonstrable effect.[66,67] In fact, the UK small aneurysm trial indicated an increase in the growth rate of aneurysms in patients taking ACE inhibitors.[68] Although ACE inhibitors themselves have not been shown to significantly affect aneurysm growth, overall control of hypertension and initiation of statin therapy have a positive effect on the perioperative risk of those who will later undergo operative intervention.

Doxycycline has been the subject of many trials, as it inhibits the activity of multiple MMPs. Although doxycycline has been shown to be effective in multiple animal models,[69-72] this finding has not yet translated into humans. A decrease in inflammation with doxycycline was found but no change in aneurysm growth rate was noted as compared with placebo.[73,74]

Statin therapy has also been shown in animal models to slow the expansion of AAAs, but once again it has not clearly been shown to be effective by any randomized controlled trials in humans.[75-77] The UK Heart Protection Study showed that the requirement for AAA repair was unaffected by statin therapy. This same trial, however, showed a relative reduction of 22% in major adverse cardiovascular events.[78]

The use of antiplatelet agents to reduce thrombus burden has been proposed as a mechanism to slow aneurysm expansion. In rat models, antiplatelet agents were shown to reduce AAA expansion.[79,80] However, no randomized control trials have shown direct correlation of reduction of AAA expansion with the use of antiplatelet therapy in humans. In summary, to date, there is no definitive evidence to suggest any specific medical management strategy slows the growth rate of AAAs.

INDICATIONS FOR INTERVENTION

In general, the size criterion for elective repair is 5.5 cm for men and 5 cm for women or a 12-month growth rate of equal to or greater than 10 mm in both sexes. Both the UK small aneurysm trial and the ADAM trial documented that surveillance of aneurysms between 4 and 5.5 cm is safe with compliant patients. However, in the ADAM trial, over 80% of patients with aneurysms between 5 and 5.4 cm underwent eventual repair. Additionally, over 60% of patients initially assigned to the surveillance groups in both trials eventually underwent repair. With 10-year follow-up in the UK small aneurysm trial, this percentage increased to 74%. Additional indications for elective or early intervention included saccular aneurysms, dissection of mural thrombus, or fracture of saccular calcification. It has been shown that elective repair of asymptomatic AAAs less than 5.5 cm in diameter provides no survival benefit as compared with surveillance and elective repair once the AAA has reached traditional size criteria.[81]

For those patients who are symptomatic or have suffered rupture, there is no specific size criterion for repair. For patients who can tolerate repair, whether endovascular or open, intervention should be offered. An algorithm for determining when to intervene is described (Fig. 70.5).

The difficulty in the overall consideration of operative intervention is that early intervention in certain patients may be beneficial, especially when operative risk is less than rupture risk and/or potential mortality due to rupture. Factors that impact aortic rupture risk include the initial maximal aneurysm diameter, rate of growth, and morphology. One should also consider elective operative mortality risk, life expectancy, and patient preference before proceeding with AAA repair.

A secondary consideration is the decision to pursue open versus endovascular intervention. It has been shown that long-term mortality is equivalent at approximately the 2-year mark whether open or endovascular repair is performed. However, endovascular intervention offers clearly reduced early morbidity and mortality, particularly in patients with significant comorbidities. Schermerhorn and colleagues argue that early intervention may be cost-effective in younger patients with larger aneurysm diameters.[82]

Risk Calculator

With increasing sophistication of outcomes research, including the establishment of high-quality prospective registries, risk calculators have been developed enabling more patient-specific determination of risk when operative intervention is under

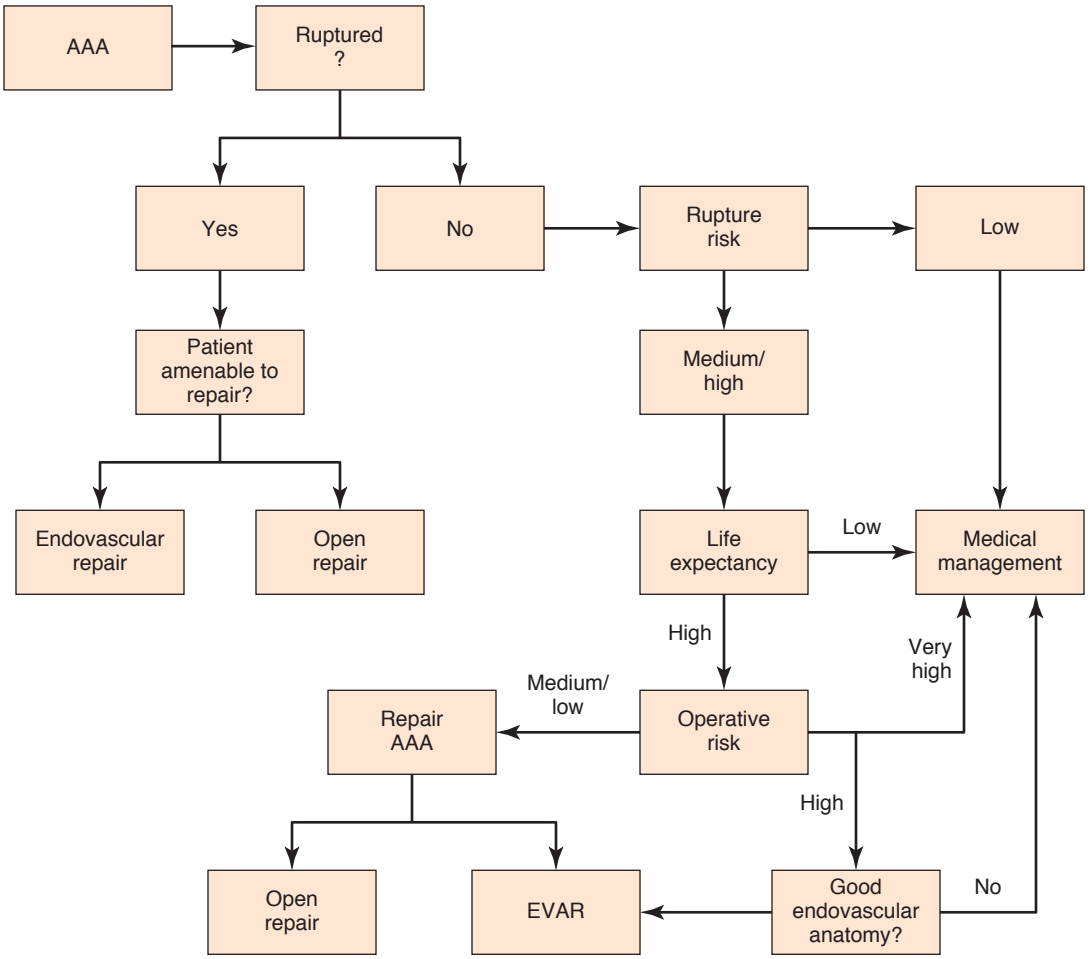

Figure 70.5 A simple algorithm for the management of patients with abdominal aortic aneurysms (AAAs). *EVAR*, Endovascular aneurysm repair.

consideration. The provision of more risk-specific information for patients with particular comorbidities is quickly becoming the standard of care, and it is recommended by the centers for Medicare and Medicaid as a discussion point during the informed consent process. Risk calculators are easily found on the Internet and are available in downloadable applications for a tablet or mobile phone. Berteges et al. reported the Vascular Study Group of New England (VSGNE) risk index specifically for patients undergoing carotid endarterectomy, lower extremity bypass, and endovascular or open repair of infrarenal AAAs.[83] As compared with previously used risk calculators, this one, explicitly derived for particular vascular interventions, was better at predicting the actual rates of postoperative cardiac events. As compared with previously used risk calculators, it was found that risk calculators that were not vascular-specific clearly underestimated the number of postoperative cardiac events in these patient cohorts.[84] The Society of Vascular Surgery provides online access to this risk calculator for intervention-specific events. For open AAA repair, the calculator considers the following patient and procedural variables: serum creatinine, the presence of chronic obstructive pulmonary disease, the anticipated level of distal anastomosis, planned proximal aortic clamp position, BMI, race, previous coronary artery bypass graft or percutaneous coronary intervention, results of patient's stress test within past 2 years, history of congestive heart failure, and age.

FUTURE DIRECTIONS

Endograft technology continues to evolve to improve outcomes and broaden current indications for use. Similarly, advances in our understanding of the molecular pathophysiology of aneurysm formation, growth, and rupture will drive the next round of advances in diagnosis and therapy. Better characterization of the serologic profile during aneurysm growth and particularly around the time of rupture may yield opportunities to develop biomarker screening for existing aneurysms and for evidence of active progression and impending rupture. As an example, future care of the AAA patient may involve measurement of circulating plasma levels of peptides associated with collagen and elastin degeneration during proteolysis of the extracellular matrix (ECM).[85]

Imaging interpretation and technology may also help with advancements in dealing with AAAs. At its most basic level, this may simply reflect the incorporation of observed characteristics of aneurysms into the interpretation of existing imaging

technology to provide the clinician parameters for consideration beyond simple maximal aneurysm diameter and gross morphology. Disruption of the ILT by fresh hemorrhage, yielding a "crescent sign" on CT or three-dimensional ultrasonographic imaging, may be used to suggest impending rupture. As calcification of the external media has been observed to be protective against growth, improved characterization of the degree and properties of observed calcification may also be used to inform imaging interpretation and individual patient risk. Better definition of the characteristics of aortic ILT and wall inflammation may also lead to the assessment of inflammatory cell activity using MRI, scintigraphy, or radionucleotide scans.

The most ambitious goal, however, remains the translation of the growing body of knowledge regarding the biologic mechanisms of aneurysm formation, growth, and rupture into effective medical therapy. Beneficiaries of these advances will include patients with small aneurysms as well as those with larger aneurysms who are medically ineligible for repair. Promising current targets include: 1) interruption of the inflammatory cascade leading to the degeneration of medial smooth muscle and ECM through MMPs 2, 8, and 9 as well as inflammatory cytokines, including TNFs and interleukins IL1β, IL-4, IL-6, and IL-8; 2) suppressing neoangiogenesis, which characterizes adventitial changes; and 3) minimizing the oxidative injury associated with ILT.

Lederle FA, Freischlag JA, Kyriakides TC, et al. Long-term comparison of endovascular and open repair of abdominal aortic aneurysm. *N Engl J Med*. 2012;367:1988–1997.

Key randomized trial of EVAR versus open AAA repair. No differences were seen in the overall death or reintervention rates between open repair and endovascular aneurysm repair in long-term follow-up in this large-scale randomized controlled trial.

Lederle FA, Johnson GR, Wilson SE, et al. Rupture rate of large abdominal aortic aneurysms in patients refusing or unfit for elective repair. *JAMA*. 2002;287:2968–2972.

The largest study to date of patients with "large" (>5.5 cm) aneurysms who refused or were unfit for elective repair. A high percentage had autopsy studies performed and most did not undergo surgery, thus demonstrating the natural history of these patients in a controlled environment.

Lederle FA, Wilson SE, Johnson GR, et al. Immediate repair compared with surveillance of small abdominal aortic aneurysms. *N Engl J Med*. 2002;346:1437–1444.

Classic U.S. randomized trial comparing open AAA repair and surveillance with selected repair; similar results (mostly in men) were demonstrated despite a lower mortality rate for open repair in this study.

Lindholt JS, Norman P. Screening for abdominal aortic aneurysm reduces overall mortality in men. A meta-analysis of the mid- and long-term effects of screening for abdominal aortic aneurysms. *Eur J Vasc Endovasc Surg*. 2008;36:167–171.

Largest accumulation of AAA screening study results yet published (>125,000 patients) that includes long-term follow-up from the screening studies; a significant reduction in aneurysm-related and all-cause long-term mortality was demonstrated.

Powell JT, Brown LC, Forbes JF, et al. Final 12-year follow-up of surgery versus surveillance in the UK Small Aneurysm Trial. *Br J Surg*. 2007;94:702–708.

Long-term follow-up on the seminal randomized trial comparing open AAA repair and surveillance with selected repair.

Powell JT, Sweeting MJ, Brown LC, Gotensparre SM, Fowkes FG, Thompson SG. Systematic review and meta-analysis of growth rates of small abdominal aortic aneurysms. *Br J Surg*. 2011;98:609–618.

Detailed literature review of studies discussing growth rates of small AAAs. More detailed estimates of aneurysm growth by initial aneurysm size were gained, along with determinants of growth rate.

Schermerhorn ML, O'Malley AJ, Jhaveri A, Cotterill P, Pomposelli F, Landon BE. Endovascular vs. open repair of abdominal aortic aneurysms in the Medicare population. *N Engl J Med*. 2008;358:464–474.

Largest comparison of "matched" open and endovascular AAA repair cases to date, with more than 22,000 patients in each group. This is the first study to quantify the secondary procedures and hospitalizations related to the open abdominal incision (bowel obstruction and hernia repair), not just aorta-related interventions. It also captures the rate of discharge to skilled nursing facilities.

Sweeting MJ, Thompson SG, Brown LC, Powell JT, RESCAN collaborators. Meta-analysis of individual patient data to examine factors affecting growth and rupture of small abdominal aortic aneurysms. *Br J Surg*. 2012;99(5):655–665.

Individual patient data meta-analysis of 15,000 patients over 18 trials of aneurysm surveillance versus early repair. The influence of covariables, including demographics, medical, and drug history on aneurysm growth and rupture rates were determined.

Thompson SG, Ashton HA, Gao L, Buxton MJ, Scott RA, on behalf of the Multicentre Aneurysm Screening Study (MASS) Group. Final follow-up of the Multicentre Aneurysm Screening Study (MASS) randomized trial of abdominal aortic aneurysm screening. *Br J Surg*. 2012;99:1649–1656.

Final results of the largest randomized trial on AAA screening, demonstrating a reduction in aneurysm related and all-cause mortality.

Open abdominal aortic aneurysm (AAA) repair, initially described in 1952 by Dubost et al., has undergone continuous evolution and refinement.[1] Current outcomes with elective open repair are excellent, with perioperative mortality rates between 1% and 7% depending on center volume and surgeon experience.[2-4] Notably, a contemporary meta-analysis of the randomized trials of endovascular aneurysm repair (EVAR) demonstrated a 3.3% 30-day mortality among the combined 1342 patients repaired via the open technique.[5] This is concordant with a 4% mortality reported for the highest volume centers in an administrative database study using the National Inpatient Sample (NIS),[2] although single-institution case series and carefully controlled registry studies have reported even better results.[3,6]

Since its introduction in the early 1990s, EVAR has dramatically transformed the management of AAA, with significant reductions in the number of open aneurysm repairs performed over time in both the Medicare database[7-10] and the NIS.[11] In

addition, high-quality randomized controlled studies have demonstrated better short- and medium-term outcomes, and equivalent long-term outcomes, with EVAR, as compared with open repair.[12-15] This has propelled EVAR to become the primary mode of therapy for the majority of patients with AAA, with open repair reserved for those with increasingly complex anatomies or coexisting disease processes that prohibit them from an endovascular repair.[16-18] Nonetheless, open AAA repair remains a cornerstone of vascular surgery.

INDICATION FOR OPEN REPAIR

Anatomy

In the current era of endovascular therapy, open repair tends to be reserved for patients who cannot undergo EVAR. Despite the advances in device design, there remain a number of anatomic constraints that mandate open repair (Fig. 71.1).[19] No aortic neck or a hostile aortic neck is the leading indication for open

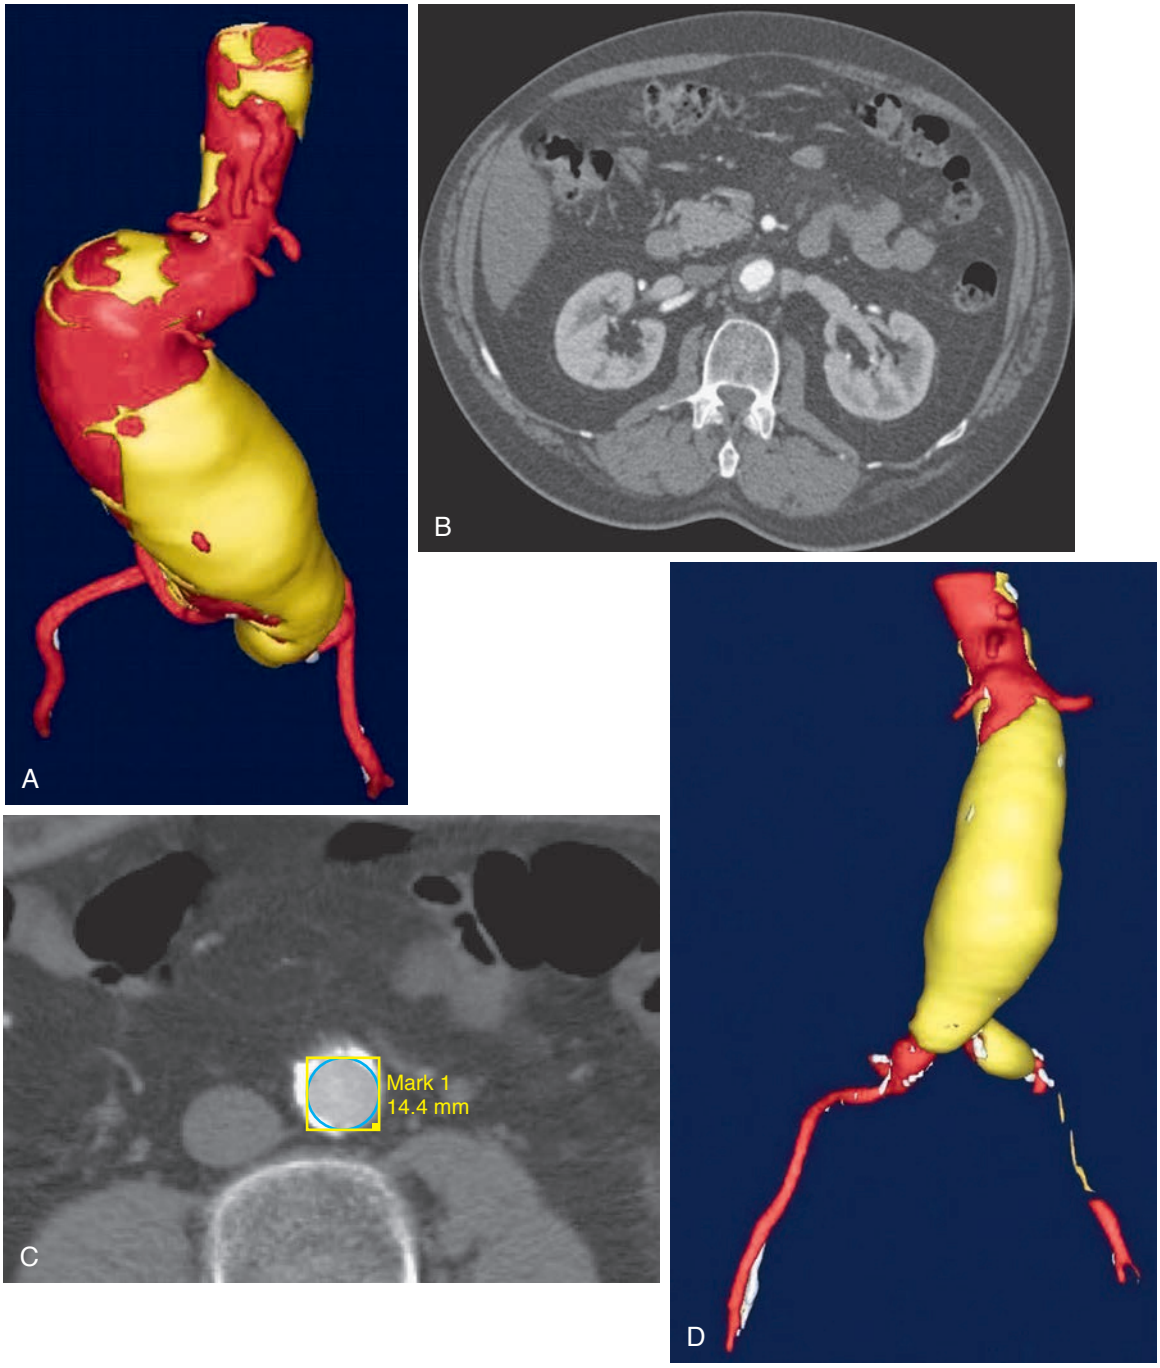

Figure 71.1 Axial images and three-dimensional computed tomographic angiography reconstructions demonstrating challenging aneurysm anatomy including a short, angled neck (A), circumferential thrombus (B), narrow calcified distal aorta (C), and bilateral common iliac artery aneurysms and left external iliac artery occlusion (D).

repair.[18] Proximal aortic necks that are short, angled, trapezoidal, have a high burden of thrombus, or are heavily calcified can compromise seal.[20-22] These patients are often better served with open repairs.

Anatomic constraints in the distal aorta and iliac arteries can also be preferentially treated with open aneurysm repair.[23] Likewise, iliac artery occlusive disease, especially chronic total occlusion, can mandate open repair for reasons pertaining to both access and treatment. Concomitant common or external iliac artery aneurysms may also represent indications for open repair, especially in situations in which internal iliac artery patency needs to be preserved, such as in claudicants and patients at risk for colonic, pelvic, and spinal cord ischemia (SCI).[24] None of these cases provide an absolute indication for open repair, especially with the introduction of newer devices such as branched endografts for the iliac arteries.

Endovascular Aneurysm Repair Conversion

Failure of a previous endograft due to migration or recalcitrant endoleak that is unable to be resolved via endovascular means requires open aneurysm repair. Due to the fibrosis and inflammation caused by the endograft, these operations can be significantly more complex than de novo AAA repair, and are associated with increased operative time, length of stay, and mortality.[25,26] Unless the EVAR explant is being performed for infectious indications, the endograft does not have to be completely removed, and in fact, it may be more expeditious to leave intact parts of the graft in situ. A recent series of 22 partial explants demonstrated no complications related to residual device components with 26 months of follow-up.[27]

Infection

Infection either of the native aorta or of a previous open or endovascular repair requires an open operation for definitive therapy. Endovascular salvage has been described, but this would be considered more of a palliative alternative or temporary bridge to open repair.[28,29] In cases of an infected prior aortic graft, excision of all prosthetic material and extra-anatomic reconstruction has long been the gold standard, but recent data suggest that the use of an aortic homograft[30] or rifampin-soaked Dacron may be equally efficacious in treating the infection.[31-33]

Additional Circumstances

A number of special circumstances can also influence the decision to proceed with open aneurysm repair. The presence of a horseshoe kidney with multiple renal and isthmus arteries originating from the aorta and iliac arteries[34] is best served with open repair so that these vessels will not be excluded.[35] Likewise, patients in which the patency of the inferior mesenteric artery (IMA) needs to be maintained, such as those with bilateral hypogastric artery occlusion, SMA stenosis/occlusion, or previous colectomy, may require open aneurysm repair as well.

PREOPERATIVE ASSESSMENT AND PLANNING

Careful patient selection and preparation is critical to obtaining excellent outcomes. Because of the physiologic derangements that occur as a result of the hemodynamic stress of an aortic cross-clamp, a detailed understanding of the patient's cardiac, pulmonary, and renal function is necessary to determine who is a candidate for open repair. In patients with a history of significant recent weight loss, nutritional parameters may be predictive of perioperative complications. Similarly, in patients with a history of liver disease and cirrhosis, appropriately tailored preoperative studies should be considered. Other subsets of patients require special consideration, such as those with a history of cerebrovascular or Parkinson disease. In these individuals with diminished physiologic reserve or compromised baseline functional status, it must be determined whether the patient's current and anticipated postoperative quality of life are sufficient to merit proceeding with an elective operation. This is especially pertinent in the very elderly, in which case postoperative complications may condemn the patient to long-term skilled nursing care and permanent loss of independent functional status.

Preoperative Imaging

Computed Tomography

Although CT angiography (CTA) with three-dimensional reconstructions, which allows for accurate anatomic measurements of a vessel's true cross-sectional diameter and center-line length (Fig. 71.2), is invaluable for EVAR,[36-39] it is also helpful for planning open repair. CTA visualizes aneurysm angulation, arterial tortuosity, arterial wall calcification, and intravascular thrombus (Fig. 71.3), which is useful for planning the best approach and clamp sites. A detailed view of the proximal aneurysm neck allows the involvement of the visceral aortic segment to be accurately determined (Fig. 71.4).[40,41] From this, the need for a suprarenal or supraceliac clamp site can be anticipated and potential clamp sites examined for the presence of heavy or circumferential calcification or thrombus. Concomitant occlusive disease of the visceral vessels and aortoiliac segment is also readily apparent on CTA, allowing decisions regarding the need for endarterectomy or complex reconstruction to be made preoperatively.[42-44]

CTA also provides valuable information about the venous and visceral anatomy that might alter the operative plan—the presence of a retroaortic or circumferential renal vein. Likewise, multiple renal arteries or a horseshoe kidney can affect both clamp site selection and arterial reconstruction. Appropriate visualization of the distal anatomy is also important. Concomitant stenotic, occlusive, or aneurysmal disease will influence the site of distal reconstruction, as well as the need for additional procedures. For example, additional graft limbs may be needed to preserve IMA or hypogastric flow. In addition, severe stenotic or occlusive disease can be bypassed at the time of the reconstruction.

Figure 71.2 Three-dimensional computed tomography reconstructions allow for accurate, inline measurement of aortic lengths and true cross-sectional diameter.

Finally, the rate of incidental findings on CTs obtained for AAA is not inconsequential,[45,46] and in certain circumstances, such as the diagnosis of an advanced malignancy, may take precedence over aneurysm repair.

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) may also be used for preoperative planning. It has been shown to be just as accurate as CT in the determination of aneurysm size and extent, as well as in the evaluation of concomitant occlusive disease.[47-49] In patients with inflammatory aneurysms, it may offer more information regarding the extent of the inflammatory process.[50] MRA, however, does not offer information on the extent of calcification and sometimes can overestimate stenotic disease. Our preference, and that of most institutions, is to use CT.

OPERATIVE TECHNIQUE

There are two widely practiced approaches to open aneurysm repair: transperitoneal and retroperitoneal. Various other methods (beyond the scope of this chapter) have been described, including minilaparotomy,[51-54] laparoscopic,[55-59] and robotic approaches (see Chapter 62).[60-62]

Selecting the Approach

Because the goal of any approach is to obtain adequate exposure of the affected aortic segment, both transabdominal and retroperitoneal approaches will be technically equivalent in many situations. Under these circumstances, selection of approach should be determined by surgeon preference and familiarity.

Some situations, however, would be best treated with one technique over another. The transperitoneal approach offers rapid access to the infrarenal aorta with little need for complex patient positioning and is ideal for use in emergencies. In addition, for surgeons unfamiliar with the retroperitoneal approach, the transperitoneal offers a more comfortable approach to the aorta. As compared with the retroperitoneal approach, it also offers better, but not exclusive, access to the right renal artery and the right internal and external iliac arteries, as well as the femoral arteries. It is, however, more difficult to expose the visceral aortic segment from this approach.

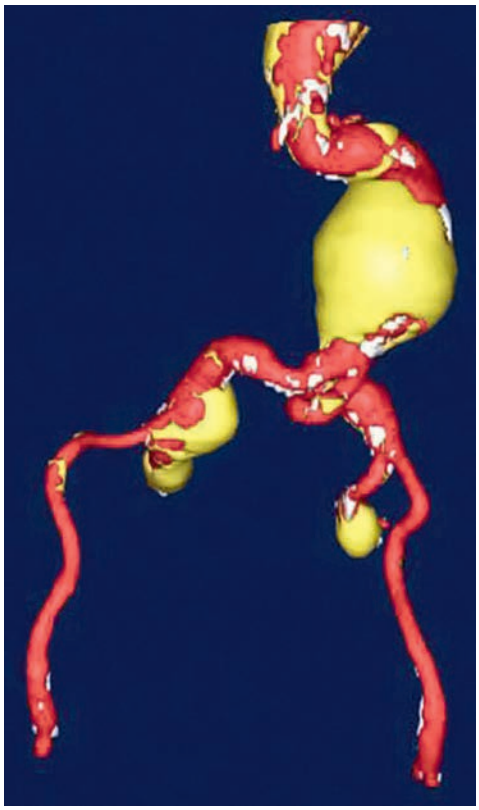

Figure 71.3 Three-dimensional computed tomography reconstruction showing an abdominal aortic aneurysm with tortuous proximal aorta and tortuous bilateral iliac artery aneurysms.

Figure 71.4 Axial computed tomographic angiography image showing visceral involvement in a type IV thoracoabdominal aortic aneurysm.

The retroperitoneal approach, usually via a left 10th interspace incision, allows for superior exposure of the visceral and supraceliac aorta as well as the left renal artery. This is useful in managing patients with pararenal aortic aneurysms and type IV thoracoabdominal aortic aneurysms. In addition, in patients who have undergone previous abdominal operations, it avoids the risk of "redo laparotomy" and eliminates the difficulties posed by intraabdominal adhesions. It may also offer advantages in obese patients by allowing the abdominal contents to fall away from the surgical field.[63,64] Although exposure of the right internal and external iliac artery can be more difficult from this approach, it can still be performed with appropriate careful dissection.

A number of both retrospective cohort and randomized trials have compared the outcomes of patients undergoing aneurysm repair using transperitoneal and retroperitoneal approaches. Depending on the study, retroperitoneal repair has been associated with significantly decreased postoperative fluid requirements, pulmonary edema, pneumonia, respiratory failure, postoperative ileus, shorter length of intensive care unit and overall hospital stays, shorter time to full recovery, and less costs.[64-67] Other studies have disputed this, showing equivalency between the two procedures regarding these variables.[63,68]

TRANSPERITONEAL REPAIR

Exposure (See Chapter 54)

The patient is positioned supine on the operating table with the arms abducted, and the abdomen is prepped and draped from the nipples to the knees. A midline incision is made. The omentum and transverse colon are retracted cephalad, and the small bowel is packed in the right hemiabdomen. A self-retaining retractor, such as the Bookwalter (Codman and Shurtleff, Inc., Raynham, Massachusetts) or Omni (Omni-Tract, St. Paul, Minnesota) retractor, greatly facilitates exposure and should be set up at this point.

To expose the aorta, the ligament of Treitz is divided, the third and fourth portions of the duodenum are reflected to the patient's right, and the periaortic lymphatic and connective tissue is ligated and divided (Fig. 71.5). Care must be taken to avoid injury to the inferior mesenteric vein; this structure can, however, be divided to facilitate exposure. The incision in the posterior peritoneum is then continued caudally in this plane to expose the entire infrarenal aorta. Although starting to the left of the aorta at the ligament of Treitz, the incision in the posterior peritoneum should course to the right of the aortic midline to prevent injury to the IMA, sigmoid mesentery, and autonomic nervous plexus at the bifurcation (Fig. 71.6). In cases in which a tube graft will be used and the distal anastomosis will be to the aorta itself, the dissection does not need to proceed beyond what is necessary to obtain distal control at the level of the bilateral proximal common iliac arteries.

Pararenal Aorta

A growing proportion of patients who require open aneurysm repairs have aneurysms with short or no infrarenal neck.[16] These juxtarenal aneurysms require the placement of a suprarenal clamp, which necessitates additional proximal aortic exposure. To do so, the posterior peritoneum is opened cephalad to the level of the renal veins. Note should be made as to location of the left renal vein on the preoperative CT scan. If it is anterior, as in most cases, it can be mobilized to gain more proximal

aortic exposure by dividing the gonadal, adrenal, and lumbar branches (Fig. 71.7A). Alternatively, it can be divided safely, albeit with an increased risk of postoperative renal insufficiency.[69-71] The decision to divide the left renal vein needs to be made before it is aggressively mobilized, because once it is divided, the gonadal, adrenal, and lumbar branches must be preserved in order to maintain adequate venous drainage; to facilitate this and maximize exposure, this should be done as close to the inferior vena cava as possible (see Fig. 71.7B). If a retroaortic or circumferential left renal vein is present, care must be taken during placement of the proximal clamp because the tips of the clamp can injure the vein.

Supraceliac Aorta

The supraceliac aorta is exposed by dividing the lesser omentum or gastrohepatic ligament. The aorta is identified by palpation, and the overlying fibers of the right crus of the diaphragm are divided with electrocautery. Mobilization of the left lobe of the liver by dividing the left triangular and coronary ligaments, as well as the falciform ligament, can assist with exposure but is often not necessary. In addition, the presence of a nasogastric tube helps identify the esophagus and thereby protect it from inadvertent injury. The esophagus is typically retracted to the left. The aorta can be dissected anteriorly down to the level of

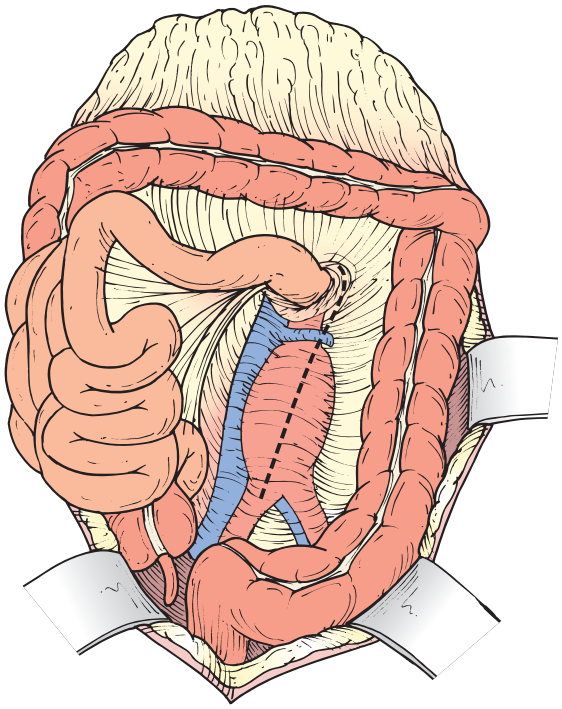

Figure 71.5 The aorta is exposed by incising the overlying posterior peritoneum.

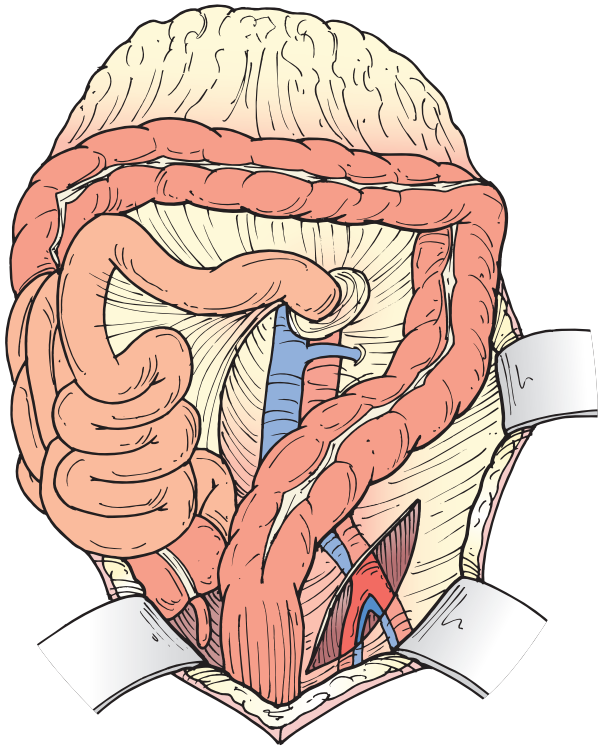

Figure 71.6 The left iliac artery can be accessed by mobilizing the sigmoid colon medially and incising the posterior peritoneum at its base.

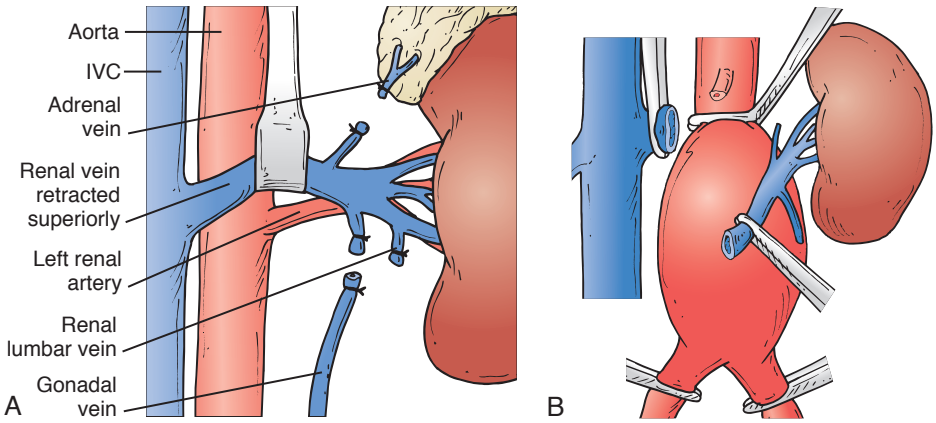

Figure 71.7 The renal vein can be mobilized by dividing it side branches (A) or simply divided close to the inferior vena cava (IVC) (B).

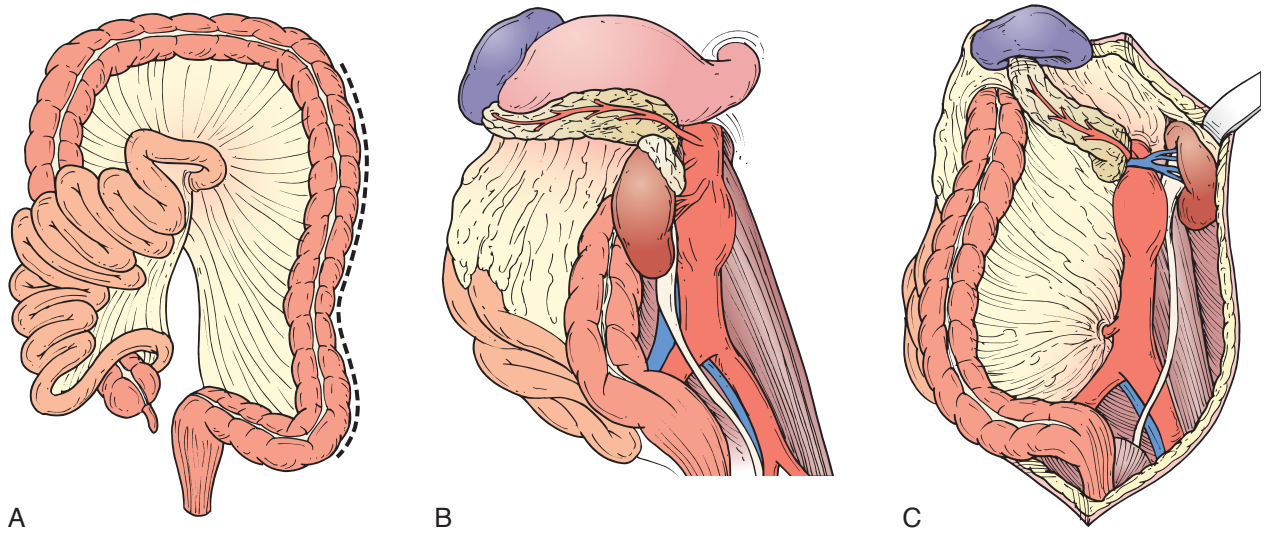

Figure 71.8 When using the transperitoneal approach, a left medial visceral rotation facilitates access to the visceral segment of the aorta. The peritoneum is incised along the line of Toldt (A) and the left colon, pancreas, and spleen are mobilized medially. The kidney can be mobilized en bloc (B) or left in the renal fossa (C).

the celiac axis, although care must be taken to avoid injury to the pancreas as one proceeds caudally.

Medial Visceral Rotation

Suprarenal aneurysms are best approached using a retroperitoneal exposure. Despite this, the complete visceral segment of the aorta can be accessed transperitoneally using a left medial visceral rotation (Fig. 71.8). The left colon is mobilized by incising the posterior peritoneum just lateral to the line of Toldt. This incision is then carried cephalad through the phrenicocolic ligament and then medially toward the aortic hiatus along the underside of the diaphragm. The plane separating the posterior aspect of Gerota's fascial and posterior abdominal wall is developed, allowing the colon, pancreas, spleen, and left kidney to be reflected medially. As the kidney is mobilized, the left renal lumbar vein should be identified and ligated to prevent avulsion. Alternatively, the kidney can be left in the renal fossa; this requires dividing the linorenal and linophrenic ligaments and developing a plane between the anterior surface of Gerota's fascia and the posterior surface of the colonic mesentery and pancreas (see Fig. 71.8C).

Arterial Reconstruction

Once the appropriate aortic segments are exposed, the proximal and distal clamp sites are identified. Encircling the vessels with Silastic vessel loops or cloth umbilical tape is not necessary and increases the risk of injury to posterior structures, especially the iliac veins. Only enough exposure to apply a clamp is needed. Care must be taken to avoid injuring or avulsing closely related venous structures. The patient is systemically heparinized, and the aorta and iliac arteries are clamped. Distal clamps are usually applied first to prevent any thrombus from embolizing to the legs during application of the proximal clamp. The aneurysm is opened via a longitudinal aortotomy, which transitions to a

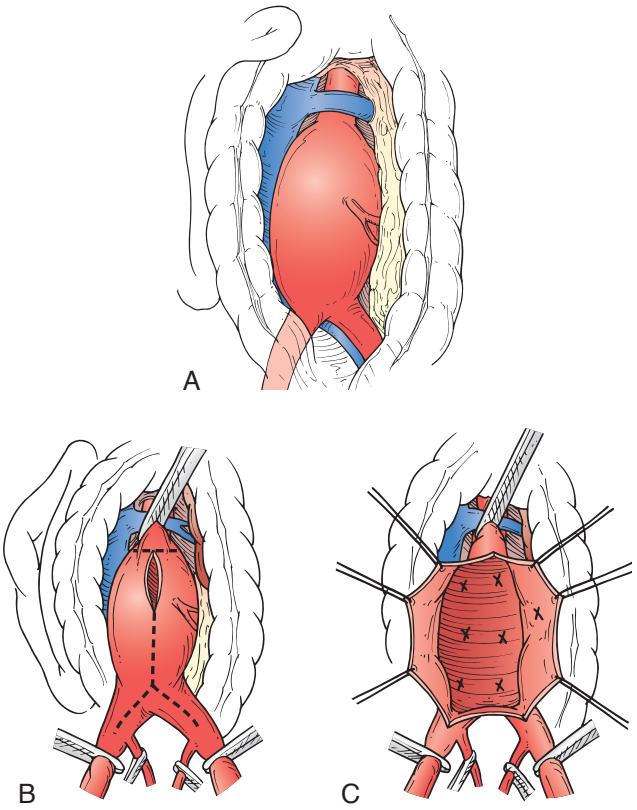

Figure 71.9 The aneurysm (A) is opened with a T-shaped (B) incision. Aortic retention sutures (C) can be used to help facilitate exposure.

T-shaped incision at the proximal and distal ends to allow for the graft anastomosis (Fig. 71.9). The proximal anastomotic site is cleared of thrombus and calcium, and an end-to-end anastomosis is performed using a running polypropylene suture. The use of aortic retention sutures or a self-retaining retractor

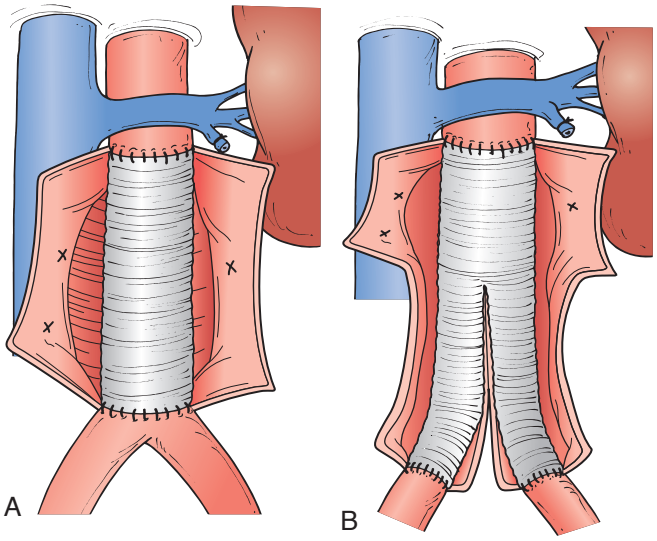

Figure 71.10 Completed repair with either a tube graft (A) or a bifurcated graft (B).

placed in the aneurysm sac helps facilitate exposure. Thrombus is then cleared from the remainder of the aneurysm sac, and back-bleeding lumbar vessels are controlled. The distal reconstruction is performed in a similar fashion (Fig. 71.10), allowing for forward flushing of the graft and back bleeding of the distal vessel before completing the anastomosis.

Closure

After hemostasis has been obtained, the aneurysm sac is closed over the graft using a running absorbable suture. The posterior peritoneum is likewise closed (Fig. 71.11). Both of these maneuvers help exclude the bowel from the retroperitoneal and prevent contact between the bowel and the graft. If the sac or retroperitoneum is unable to be approximated over the graft, the omentum can be brought down to cover the graft. It is critical to obtain separation of the graft from the bowels to prevent future aortoenteric fistulization. The intestines are then returned to their normal anatomic position, and the anterior abdominal wall closed according to surgeon preference.

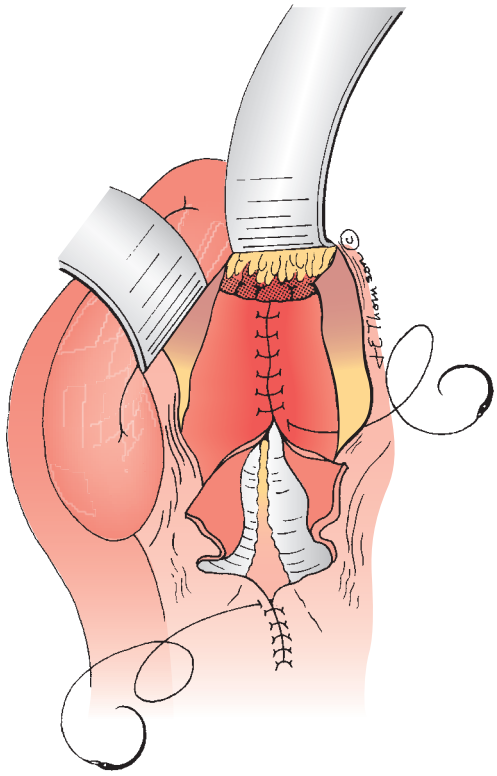

Figure 71.11 The aneurysm sac and posterior peritoneum are closed over the graft.

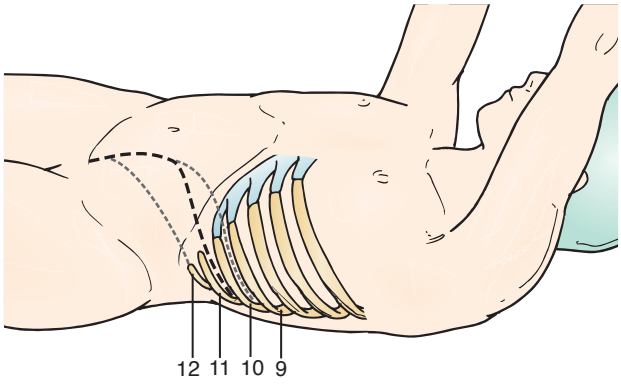

Figure 71.12 Incision *(heavy line)* for retroperitoneal aortic exposure. Alternate incisions are shown in *gray*.

RETROPERITONEAL REPAIR

Exposure

The patient is placed in right lateral decubitus position with the break in the table centered at the iliac crest. The table is maximally flexed and then leveled. A surgical beanbag positioner is used to help secure the patient in this position. Care must be taken to appropriately pad and protect the right axilla. The chest and abdomen and left groin are prepped and draped in the standard fashion. Access to the right groin can be obtained, if needed, by flexing the hips posteriorly.

The incision starts in the 10th intercostal space at the posterior axillary line; this can be varied depending on the proximal extent of the aneurysm (Fig. 71.12). It is carried onto the abdomen, where it runs lateral and parallel to the lateral boarder of the left rectus muscle and terminates below the umbilicus at a level determined by the distal extent of the intended arterial reconstruction. The skin and subcutaneous tissues are divided to expose the anterior fascia of the external oblique. The external oblique, internal oblique, and transversus abdominis muscles are sequentially opened over a short distance using a combination of blunt dissection and electrocautery. Care must be taken not to violate the peritoneum. The peritoneum is then blindly freed from the abdominal wall and diaphragm using careful blunt digital dissection. This permits the abdominal cavity to be opened to the level of the diaphragm. Exposure can be

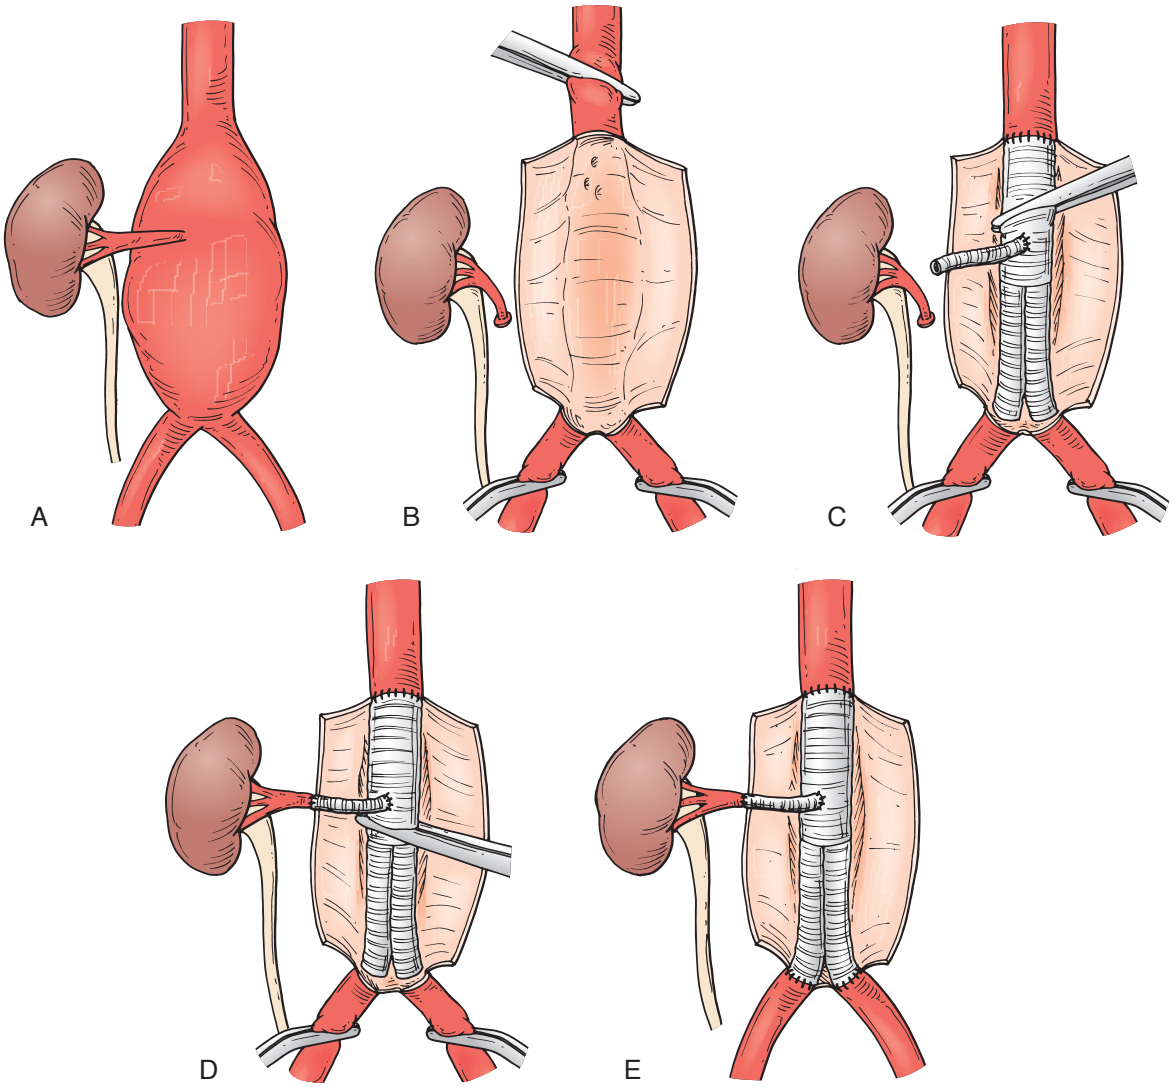

Figure 71.13 Beveled anastomosis with left renal bypass for a type IV thoracoabdominal aortic aneurysm. The aorta is clamped and opened with a T-shaped incision and the left renal artery is detached (A, B). The proximal anastomosis is beveled into the visceral segment and right renal artery, and the clamp is then advanced distal to the anastomosis (C). The left renal artery is bypassed with a presewn side arm from the graft (D). The distal anastomoses are completed and the clamp removed (E).

increased by entering the chest through the 10th intercostal space contiguous with the abdominal portion of the incision by dividing 2 to 3 cm of the diaphragm. The left psoas muscle is identified, and the peritoneal and retroperitoneal contents are swept anteromedially throughout the length of the wound, as well as off the inferior surface of the diaphragm. This exposes the entire intraabdominal aorta (Fig. 71.13A). At this stage, the left ureter should be identified and protected, because it runs anterior to the aorta and left common iliac artery. By staying on a plane directly anterior to the iliac arteries, the right ureter can also be identified and protected. A Bookwalter or Omni retractor can now be put in place to assist with exposure. If the patient has a posterior left renal vein, it may be advisable to not mobilize the kidney during the aortic exposure and to leave it in place in the retroperitoneum. Alternatively, it can be divided for exposure as long as the gonadal branch is preserved.

Supraceliac Aorta

To gain better access to the visceral segment of the aorta and obtain a supraceliac clamp site, the left crus of the diaphragm is divided. A suitable spot for clamping is identified, and the aorta is bluntly dissected along its anterior and posterior surfaces; care must be taken to avoid avulsing any lumbar arteries or veins that run posteriorly. Again, it is unnecessary to attempt to fully encircle the aorta or iliac arteries; this risks esophageal, caval, or iliac vein injury. The left renal artery is identified and dissected back to its origin so that it is not injured during the

opening of the aorta. Lumbar branches of the left renal vein are also identified, ligated, and divided to prevent avulsion.

Arterial Reconstruction

The use of a retroperitoneal incision is ideal for reconstruction of suprarenal and type IV thoracoabdominal aortic aneurysms, given the exposure it provides. After heparinization and supraceliac cross-clamping, the aneurysm is opened with a longitudinal aortotomy up to the level of normal proximal aorta, whereupon the aortotomy is transitioned into a T-shaped incision; it is important to have previously identified the origin of the left renal artery and to have divided the renal lumbar veins to avoid injuring these structures during this maneuver (see Fig. 71.13B). The left renal artery is freed from the aortic wall with a small cuff of surrounding aorta and retracted out of the immediate field.

Once the proximal extent of the aneurysm has been opened, the celiac, SMA, and right renal arteries are identified from the inside the aorta. Any significant stenosis detected on preoperative CTA, or at the time of operation, can be treated with either endarterectomy or a balloon-mounted stent deployed through the open aorta.[72] The proximal extent of the graft is beveled to incorporate the celiac, SMA, and right renal arteries, and the proximal anastomosis is completed using a running polypropylene suture (see Fig. 71.13C). The proximal graft is clamped, and the supraceliac cross-clamp is removed to allow perfusion of the viscera and right kidney (see Fig. 71.13D). The left kidney is now revascularized by bypass with a sidearm from the graft. If a bypass is to be performed, a hybrid stent graft can be fashioned as a sidearm from the main graft before aortic cross-clamping in order to reduce left renal ischemia time and to facilitate the anastomosis (Fig. 71.14). Once the anastomosis to the left renal artery is complete, the aortic cross-clamp can be shifted distally on the graft to allow for complete renal perfusion (see Fig. 71.13E). Minimizing ischemic time to this area is paramount; thus proper conduct of the operation and attention to technique is critical.

At this point the aneurysm sac is cleared of thrombus, and back-bleeding lumbar arteries are oversewn. By leaving the thrombus in situ until this point, visceral and renal ischemic time is reduced, because time is not wasted controlling bleeding with a supraceliac clamp in place. Moreover, the thrombus acts to obstruct the back-bleeding vessels and minimize blood loss. Distal reconstruction proceeds in a manner similar to that of the transabdominal approach.

Closure

After obtaining hemostasis, the self-retaining retractor system is removed and the peritoneal sac is returned to its normal anatomic configuration. Because the peritoneum has not been violated, the graft remains separate from the peritoneal contents, and the aneurysm sac does not need to be closed at the conclusion of the repair. Any rents in the peritoneum, however, should be closed; this can be accomplished with running absorbable suture. The flex is taken out of the operating table to remove tension on the wound during closure and the flank incision is closed in multiple layers. The ribs and diaphragm can be incorporated into the closure of the transversus abdominis and internal oblique muscles in a single layer of running absorbable suture. Great care must be taken to avoid inadvertent colonic injury during closure. The external oblique, with its associated fascia, is closed over this in an interrupted manner because it provides the strength for the closure.

ANATOMIC CONSIDERATIONS

A number of anatomic situations exist that can complicate open aneurysm repair and require additional planning to address. Fortunately, the vast majority of these should be detected on the preoperative CTA and plans can be made to address them in a proactive manner.

Management of the Inferior Mesenteric Artery

Note should be made on the preoperative CTA as to the patency of the IMA. If it is thrombosed, then it is of no further consideration. On the contrary, if there is significant SMA disease, bilateral hypogastric artery occlusions, a large IMA, or prior colectomy, IMA preservation may be indicated. This can be accomplished either by reimplantation of the IMA into the graft using a small cuff of surrounding aorta or in an end-to-end fashion from a sidearm attached to the body of the graft. This

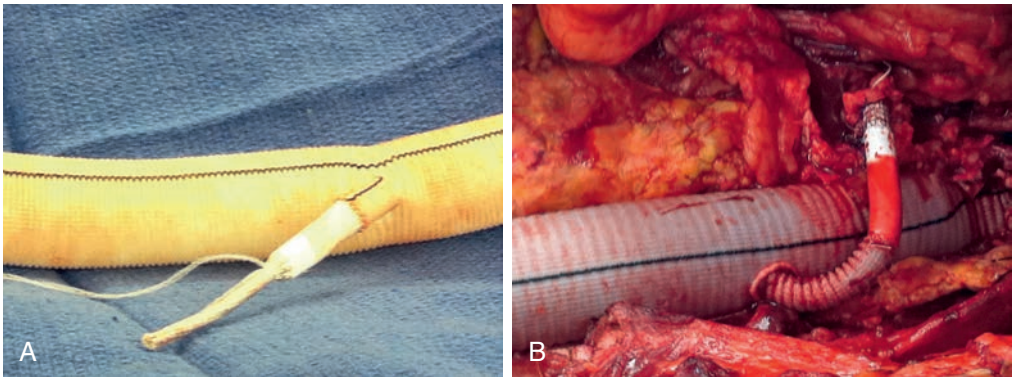

Figure 71.14 The left renal artery is revascularized with a hybrid stent graft sewn to sidearm from the aortic graft. Before (A) and after (B) graft anastomoses are performed.

is easily performed from both the transperitoneal and retroperitoneal approaches.

Renal Abnormalities

The presence of renal anomalies, such as a horseshoe kidney, pancake kidney, and crossed-fused renal ectopia, complicates open aneurysm repair. A renal perfusion scan can also be of assistance in this setting in helping to determine the functionality and contribution of not only each kidney but each portion of the respective kidneys. This is then helpful to determine what, if any, tissue can be sacrificed. Management is difficult because these situations pose technical challenges with respect to both exposure and revascularization, and longer aortic cross-clamp times have been reported.[73]

Venous Abnormalities

Based on surgical and radiologic studies, significant venous abnormalities of the renal veins and IVC are present in between 1% and 10% of the population, respectively.[74-77] The most common abnormalities include retroaortic left renal vein, circumaortic left renal vein, left-sided IVC, and duplicated IVC; accessory left renal veins and preaortic confluence of the iliac veins have also been described. These abnormalities can pose significant challenges with regard to aortic exposure and can complicate the operation.[77-79]

INTRAOPERATIVE MANAGEMENT

Management of Aortic Clamping

The dramatic effect of aortic cross-clamping on the patient's physiology must be managed in real time by the anesthesia team. Effort must be directed at maintaining adequate blood pressure and perfusion while avoiding excessive hypertension. Care must be taken to optimize preload and afterload to minimize the effects of cross-clamping on myocardial oxygen demand. Mean arterial pressure must also be reduced before application of the cross-clamp. This must all be done in a way that anticipates the ultimate need to remove the aortic cross-clamp and the ensuing hypotension. Accordingly, clear and direct communication between the surgeon and anesthesiologist is crucial around the time of the application and removal of the cross-clamp, so that the physiology can be managed appropriately. We typically give the anesthesiologist a prediction of the approximate duration of cross-clamping before beginning and then provide a several-minute warning before removal. A dedicated anesthesia team for these procedures likely results in the best outcomes.

Renal Protection

A number of agents have been purported to offer renal protection during aortic cross-clamping, including furosemide, mannitol, dopamine, and acetylcysteine; these benefits have not been borne out in clinical experience, and these interventions are not without risk and adverse effects.[80-83] Fenoldopam, a selective dopamine receptor antagonist, was thought to hold promise for renal protection based on its ability to augment renal blood flow in normotensive human volunteers,[84] as well as the results of two small studies on patients undergoing aortic surgery.[85,86] Unfortunately, a meta-analysis of the use of fenoldopam in cardiac surgery patients demonstrated that although it did reduce the rate of acute kidney injury, it had no effect on the need for renal replacement therapy.[87]

Renal perfusion with cold hyperosmolar crystalloid, histidine-tryptophan-ketoglutarate (HTK) solution, or saline with mannitol and methylprednisolone, resulting in renal hypothermia, has been reported by many groups to improve renal outcomes following the repair of juxtarenal aneurysms that require suprarenal aortic clamping and type IV thoracoabdominal aortic aneurysms.[88-93] However, this may be somewhat cumbersome to perform. In addition, establishing the perfusion circuit and performing the anastomosis around the perfusion cannulas can lead to increased overall ischemic time. It should be added, however, that other groups have obtained similarly excellent results without using intraoperative adjuncts and focusing on minimizing aortic cross-clamp time.[94,95] Ultimately, reducing ischemic times to the kidneys likely has the greatest beneficial effects on renal protection. Maneuvers such as beveling the proximal anastomosis to include the right renal artery and quickly reimplanting the left renal artery are useful in this regard.

POSTOPERATIVE COMPLICATIONS

Early Complications

Perioperative adverse events are not uncommon following open aneurysm repair.[6] Lifeline registry data of patients who underwent open repair of nonruptured infrarenal aortic aneurysms in the setting of randomized device trials demonstrated a 71% overall, 26% serious, and 11% major adverse event rates in the perioperative period. Moreover, data from single centers, the National Surgical Quality Improvement Program (NSQIP), and the Vascular Study Group of New England (VSGNE) suggest that as procedure complexity increases, the rate of overall complication does also.[96,97] It is clear that perioperative care has a direct effect on the incidence and outcome of these potentially devastating occurrences, and advances in intraoperative and postoperative care have been credited with improving aneurysm outcome over time.[63] In addition, the daily involvement of a critical care physician[98] and a high nurse-to-patient ratio[99] have been shown to significantly improve outcomes.

Myocardial Ischemia (See Chapter 42)

As previously described, aortic cross-clamping results in significant hemodynamic perturbations and creates increased demand on the heart. When combined with the baseline cardiac risk factors of patients undergoing aneurysm repair, this results in an increased rate of perioperative cardiac complications. With appropriate preoperative imaging, perioperative myocardial events can be reduced. Nevertheless, perioperative myocardial infarction still occurs in up to 10% of patients in the perioperative period.[100] The use of perioperative beta blockade for patients undergoing major noncardiac surgery has been shown to reduce

cardiovascular events and in-hospital mortality in both extremely large retrospective population studies[101] and in prospective randomized trials.[102,103] A smaller observational trial focused on patients undergoing AAA repair similarly showed that the administration of beta blockers was associated with significant reductions in in-hospital mortality.[104]

Respiratory Failure (See Chapter 43)

The decision to extubate the patient upon completion of the operation depends on the complexity of the procedure and the difficulty of the operation. In general, with more complex repairs that require higher proximal aortic control, leaving the patient intubated may be advisable. Patients often require ongoing fluid resuscitation for 12 to 36 hours because of the hemodynamic perturbations associated with proximal clamping. Once this is over and the patient has demonstrated hemodynamic stability with no evidence of ongoing bleeding, it is safe to proceed with extubation using standard criteria. Despite relative success in avoiding prolonged intubation, however, pulmonary complications still remain, with postoperative pneumonia occurring in up to 17% of patients.[100] Although very few patients progress to needing a tracheostomy, postoperative pulmonary complications of any form have been associated with reduced long-term survival.[105]

Renal Failure (See Chapter 44)

Patients undergoing open repair of AAAs are at significant risk of developing renal complications. Rates of postoperative renal insufficiency in the Medicare population approach 10%, albeit with only a 0.5% need for renal replacement therapy.[100] A meta-analysis of patients undergoing open elective pararenal aortic aneurysm repair demonstrated postoperative renal insufficiency in 15% to 20% of the patients, but dialysis-dependent renal failure in only 3.5%.[106] Close attention to volume status and the liberal use of intravenous fluids and colloid throughout the perioperative period are key in preventing recurrent episodes of renal ischemia and reversing the deleterious effects of aortic cross-clamping.

Colonic Ischemia

Ligation of the IMA, failure to revascularize the hypogastric arteries, preexisting iliofemoral occlusive disease, SMA stenosis, as well as atheroembolism, retractor injury, and previous colonic resection, can all contribute to colonic ischemia, which has a clinical incidence 0.2% to 6% following open aneurysm repair.[6,107-110] It is interesting to note that the rate of subclinical disease is much higher; surveillance studies following aortic surgery demonstrate rates of endoscopically evident disease approaching 13%, with histologically evident disease present in 30% of patients.[109,111,112]

The presence of early postoperative diarrhea, melena, hematochezia, or rectorrhagia mandates further interventions aimed at definitive diagnosis of the condition. In multiple large studies, the presence of bloody bowel movements is the primary presenting symptom.[108,109] Flexible sigmoidoscopy or colonoscopy can be done quickly and with little risk. In large series, intestinal ischemia is associated with a 25% to 55% mortality rate that can reach up to 90% when a bowel resection for infarction is required.[108,109] Accordingly, all patients should be aggressively resuscitated and started on broad-spectrum intravenous antibiotics targeting intestinal flora. Patients with disease limited to the mucosa, or limited to the mucosa and muscularis mucosae without evidence of systemic derangement, can be managed expectantly, whereas those with involvement of the muscularis mucosae and evidence of organ failure or those with full thickness ischemia require emergent exploratory laparotomy and bowel resection.[113] Ultimately, the extent of ischemia may be difficult to determine; in case of doubt, an exploratory laparotomy or laparoscopy may be the best way to make the diagnosis. A negative exploration is preferable to a missed full-thickness diagnosis and perforation.

Lower Extremity Ischemia

Patients undergoing open aneurysm repair are at increased risk for acute lower extremity ischemia. Distal perfusion should be checked before emerging from anesthesia and before leaving the operating room because the loss of lower extremity pulses or other evidence of limb ischemia in the immediate postoperative period suggests technical anastomotic complications, clamp injury, acute thrombosis, or acute embolic disease, all of which require intervention to resolve. Meticulous technique is important in performing the anastomosis, especially when sewing to diseased vessels. Care must be taken in selecting clamp sites to prevent atheroemboli or vessel injury. To prevent thrombotic complications, adequate systemic anticoagulation must be maintained and can be monitored using point-of-care measurement of the activated clotting time (ACT); heparin should be redosed accordingly. In addition, the graft itself should be clamped in a manner to minimize standing columns of blood in prosthetic surfaces, and all anastomoses should be adequately forward- and back-bled before completion.

Spinal Cord Ischemia

SCI following open AAA repair is an extremely rare event. Reported rates in the literature are generally less than 1%, even for suprarenal aortic aneurysm repairs,[96,105] but rates can be higher when patients undergoing extent IV (see Chapter 77) thoracoabdominal aortic aneurysm repair are included.[114-117] The extent of proximal coverage of the aorta appears to be the biggest risk factor; however, other considerations such as previous thoracic aortic procedures, aortic cross-clamp location and time, patency of the internal iliac arteries, and profound intraoperative or postoperative hypotension all likely play a role.[116,118]

Venous Thrombosis

Because of the use of systemic anticoagulation, lower extremity deep venous thrombosis (DVT) and pulmonary embolism (PE) are clinically rare events after aortic surgery[96,100,119]; in a recent study using NSQIP data from 2005 to 2009 that consisted of 3967 open AAA repairs, there was a 0.3% rate of

clinically diagnosed VTE at 30-days.[120] However, when routine surveillance with lower extremity duplex ultrasonography is performed, VTE can be detected at a rate of up to 8%, even in the setting of mechanical and chemical prophylaxis. The Society for Vascular Surgery guidelines in 2009 recommend prophylaxis consisting of intermittent pneumatic compression and early ambulation to all patients undergoing AAA repair, with the addition of chemoprophylaxis for those at high risk, including patients with prior VTE, BMI greater than 25, limited mobility, malignancy, or a hypercoagulable state.[121] In regard to PE, this complication is uncommon, occurring at a rate of 1.4%.[122]

OUTCOMES

Early Mortality

Historically in the 5% to 8% range, early mortality in large database, multi-institutional, and population-based studies now approaches 3% (Table 71.1).[67,100,120,123-141] Similar results of an overall mortality rate of 3.5% are obtained when examining the open arms of the major randomized controlled trials for EVAR (Table 71.2).[12,14,142,143] In fact, a meta-analysis of 30 peer-reviewed series, each with greater than 100 patients, also demonstrated an overall mortality of 3.2%.[144] Notably, this is in keeping with the reports of outcomes from large-volume centers of excellence.[105,145,146]

As endovascular devices have become more versatile and outcomes more durable, the aneurysms that remain for open repair have become increasingly complex. This has been manifest in an increasing percentage of patients who require suprarenal and supraceliac aortic cross-clamps and who have concomitant aortoiliac occlusive disease.[16,17,147] Despite the increased case complexity, the mortality rates within the series were unchanged, or in some cases even reduced, over the time studied, and in all cases outcomes were equal to or better than those reported earlier.

When the findings of major contemporary series of juxtarenal and suprarenal AAAs and extent IV thoracoabdominal aortic aneurysms are examined (Table 71.3),[90,92,95,105,114-117,148-152] it is

clear that their outcomes come close to those listed for infrarenal aortic aneurysm repair in Tables 71.1 and 71.2. Despite the fact that clamp position has been shown to affect overall outcomes in a number of studies,[152,153] it is clear from these series that excellent, durable results can be attained even with more complex aneurysm repairs. What is most interesting is that in multiple instances the same group achieved nearly equivalent outcomes with both pararenal aortic aneurysm repairs and type IV thoracoabdominal aortic aneurysms. Several studies have demonstrated superb outcomes with both complex pararenal[105] and type IV thoracoabdominal aortic aneurysm repair,[95] with perioperative (30-day) mortality rates of 4.4% and 5.6%, respectively, and 2.5% and 2.8%, respectively.[90] A recent paper using data from the VSGNE demonstrated a 30-day mortality of 3.6% for complicated AAA repair (pararenal and type IV thoracoabdominal aortic aneurysms) as compared with 1.2% for routine AAA repairs ($P = .002$) in a series of 443 elective cases.[97]

Postoperative Surveillance

Patients who undergo open aortic aneurysm repair should be followed closely after discharge until it is clear that they are free from procedure-related complications, at which point they can be transitioned to standard follow-up. The aorta should be imaged with at least duplex ultrasound to ensure that there is no progressive aortic dilation. In keeping with current Society for Vascular Surgery guidelines, patients should undergo surveillance imaging every 5 years[121]—more often if there is reason for clinical concern. It may be appropriate to obtain CT scans that include the chest, as well as the abdomen and pelvis, given the high rate of metachronous thoracic and iliac aneurysms in this population. In addition, close attention should be paid to the popliteal arteries on physical examination.

SPECIAL CIRCUMSTANCES

Open Conversion After Endovascular Aneurysm Repair

Open AAA repair for a failed endograft is a complex undertaking. Because of the suprarenal fixation present on many grafts, the aorta must be clamped in the supraceliac segment in these situations, even if the reconstruction is going to be infrarenally. Furthermore, the endograft can induce fibrosis and inflammation in the surrounding tissue, making the dissection quite difficult. If the graft is being explanted for infectious reasons, then all prosthetic material needs to be removed. Otherwise, some of the device parts can be left intact to make the procedure easier.[27] In some situations, the suprarenal stent can be left and the fabric divided just under it, allowing for a proximal anastomosis to include this and the aorta. Distally, if the limbs extend to

the external iliac arteries, they may be difficult to remove and leaving them in place is often better. In order to avoid clamping the limbs in the iliac arteries, we typically apply the proximal clamp, open the aneurysm, and then clamp the endograft main body to obtain distal control. The proximal anastomosis is then performed, and the limbs can either be sequentially removed with clamping of the iliac arteries or be sewn to the graft with balloon control or clamping of the more distal nonstented vessel. It is important to recognize that the lumbar branches and the IMA were never surgically occluded at the time of the original endovascular repair and may need to be oversewn.

Outcomes of EVAR conversion reflect the procedural complexity. Reported mortality rates for late conversion among contemporary series range from 0% to 22%.[154-157] In a study of 300 EVAR conversions and 7188 open repairs from the NSQIP, EVAR conversion was associated with significantly longer operative time (275 ± 124 vs. 232 ± 99, $P < .001$), increased rates of complications (58% vs. 47%, $P < .001$), and increased mortality (10% vs. 4.2%, $P < .001$), as compared with open repair.[26] A recent meta-review of the literature suggests that the overall mortality among 593 elective conversions across more than 26 centers was 3.2%,[158] and two of the more recent reports specifically stand out for both their size and outcomes.[25,159] Kelso et al. describe removing 44 endografts at a mean of 33 months following implantation.[159] The most common indication was endoleak with aneurysm growth. Of these patients, 78% had a suprarenal or supraceliac aortic cross-clamp, and 85% of the devices were completely removed. Overall mortality was 19%. Our group subsequently reported a series of 21 patients with nearly identical results.[25] Clamp times, estimated blood loss, and length of stay were all increased; however, no mortality occurred in our series.

Inflammatory Aneurysms

Inflammatory aneurysms are marked by a thickened aortic wall, fibrosis of the adjacent retroperitoneum, and dense adherence of adjacent structures to the aorta.[160] Although all aneurysms have some element of associated inflammation, this degree of local inflammatory response is rare. Inflammatory aneurysms account for 5% of all aortic aneurysms and are especially challenging to manage.[161] Multiple theories exist as to the etiology of inflammatory aneurysms, including an exaggerated variation of the normal inflammatory response, chronic subacute rupture, and a variant form of retroperitoneal fibrosis leading to the characteristic inflammatory rind.[162,163] Of note, stent grafting has been shown to promote the resolution of the perianeurysmal inflammatory response, similar to that of open repair.[164] This suggests that the aneurysm itself is driving the inflammatory process.

Indications for repair are based on standard criteria for aneurysm intervention. Although the inflammation is frequently limited to the infrarenal segment, the dense adherence of local structures, including ureters, duodenum, and small bowel, to the inflamed aneurysm frequently requires suprarenal or supraceliac aortic control to avoid injuring the viscera.[50,165-167] Utilization of the retroperitoneal approach helps minimize these injuries by reducing the need to dissect away adjacent structures to reach the aorta.[168,169] In fact, the aneurysm sac should be entered early after obtaining distant control of the aorta, and little to no attempt should be made to dissect away adjacent structures.[170] As a result, the aortic anatomy can often be identified from the inside of the aorta. The ureters are frequently involved in the inflammatory process as well, and the use of ureteral stents helps decompress the kidneys as well as protect the ureters during dissection.[165,166,170]

The use of prednisone has been shown to diminish the retroperitoneal fibrosis associated with inflammatory aneurysms.[171] Its use, however, is limited to those patients with ongoing inflammation following surgical treatment of the aneurysm.

Infected Abdominal Aortic Aneurysms

Infected AAAs are a rare occurrence, with a prevalence between 0.65% and 1.5% of all aortic aneurysms.[32,33,172] The most common etiologies include primary infection of the native aorta leading to rapid development of an infected aneurysm or infection of a preexisting aortic aneurysm by either local spread or as a result of bacteremia.[172,173] Staphylococcus, streptococcus, salmonella, and *Escherichia coli* together represent the vast majority of the pathogens, with a recent trend toward staphylococcal and salmonella infections having the greatest prevalence. Despite this, the increasing prevalence of immunocompromised hosts, as well as more sensitive culture methodologies, has broadened the spectrum of pathogens that have been isolated from infected aortic aneurysms, and it should be cautioned that any bacterial or fungal infection can result in an infected aortic aneurysm.[174]

Diagnosis is confirmed by a combination of patient history, laboratory investigations including blood cultures and measurement of inflammatory markers, and CT imaging. Classic imaging findings include periaortic soft tissue mass, stranding or fluid, as well as signs of destruction of surrounding tissues such as the kidney or vertebral column; in addition, infected aneurysms tended to be saccular with a lobulated morphology rather than fusiform.[175] Between 47% and 73% of patients have a contained or free rupture.[33,174,176,177]

Treatment consists of aggressive intravenous antibiotics targeted at the offending organism followed by prompt surgical repair, the key principle of which is the débridement of all infected tissue. Both extraanatomic bypass and in situ reconstructive techniques have been described, and most studies demonstrate equal short-term mortality.[33,172,176,177] More recently, endovascular techniques have been used as a bridge to definitive therapy or as destination therapy in patients unable to tolerate an open procedure.[178] Mortality rates for infected aortic aneurysms range from 5% to 36% in most series, although it is much higher among patients who present with rupture.[33,176,177,179] Uncontrolled sepsis has been identified as a common cause of postoperative death,[180] and the failure to control sepsis preoperatively has been shown to be a risk factor for early mortality.[181] The presence of aortic rupture, the extent of periaortic infection, and the virulence of the infecting organism have all been identified as additional risk factors for poor outcomes.[33,172]

Internal Iliac Artery Aneurysms 927
COST OF ENDOVASCULAR ANEURYSM REPAIR 927

Endovascular abdominal aortic aneurysm (AAA) repair was initially described by Volodos in 1986,[1] and later Juan Parodi published his experience with retrograde deployment through the femoral arteries of a stent-anchored, Dacron-prosthetic graft that would act to depressurize the aneurysm sac and thus reduce the risk of aneurysm rupture.[2] From there, the era of endovascular aneurysm repair (EVAR) was born. This chapter focuses on the outcomes of EVAR and their comparison with open surgical repair outcomes. The technique of EVAR is discussed in detail in Chapter 73.

GRAFT TYPES

The initial aortic endografts were constructed by suturing a balloon-expandable or self-expanding stent to a standard Dacron tube graft. These early grafts were tubular or "aorto-aortic" in design.[137] In 1993 the unibody bifurcated aorto-bi-iliac stent was developed[3] and the modular bifurcated design quickly followed.[4] Regulatory approval for the abdominal aortic stent-graft occurred in 1996 in Europe and subsequently in the United States in 1999. Although the timeline (Table 72.1) suggests

Abstract

This chapter provides an expansive overview of the endovascular treatment of aortic and iliac artery aneurysms. It reviews the literature comparing endovascular and open aneurysm repair, and provides an overview of current approved infrarenal aortic devices as well as approved and in trial iliac branch devices. Additional techniques including encroachment and snorkel/chimney management of the renal arteries are also discussed.

Randomized Studies (Start Date)	
1999	EVAR-1, EVAR-2, and DREAM
2001	OVER

EVAR, Endovascular aneurysm repair; *OVER*, open versus endovascular repair.

that the development and advancement of EVAR were part of a natural evolutionary process of technology, notable problems occurred along the way. The Guidant Ancure device (Indianapolis, Indiana), which was approved in 1999, was recalled in 2001 due to delivery system failures.[5] Follow-up of procedures using the Ancure device also revealed attachment site hook fractures and iliac limb stenoses and occlusions attributed to the graft limbs being unsupported by stents.[6,7] The lessons learned from the Ancure experience led to the development of subsequent stent-graft systems having fully supported main body and limbs.

The original AneuRx graft (Medtronic, Minneapolis, Minnesota), although well received because of its ease of deployment and smaller profile, was plagued with a higher migration rate.[8-10] Subsequent modifications and iterations have improved on early results, making the device less rigid and the fabric more robust. The Vanguard endograft (Boston Scientific, Natick, Massachusetts) was prone to fabric tears caused by fatigue erosion of the stents against the material, resulting in fabric perforation.[11] This observation appropriately influenced the design of future stent grafts and led to the secure suturing of stents to the fabric to prevent excessive motion over time. The initial Excluder graft (WL Gore, Flagstaff, Arizona) had a propensity for type IV endoleak due to the porosity of the fabric. Subsequent development of a low-porosity fabric resulted in an improvement in the rate of aneurysm sac shrinkage and marked reduction in the incidence of sac expansion due to endotension.[12] The Talent LPS graft exhibited stent spring fractures and longitudinal C-bar breaks. Chemical etching and medial placement of the longitudinal bar proved to prevent stent fatigue and reduced the overall failure rate.[13] Since it became commercially available, the Zenith stent graft has undergone few fundamental iterative changes, although it is now a more flexible design with delivery system enhancements. In fact, much of the long-term data regarding EVAR available to date come from studies with a large representation of Zenith stent grafts (DREAM, EVAR-1, EUROSTAR).

The modern version of stent-graft design is a bifurcated graft, most commonly using a modular system to allow for the most flexibility with regard to patient anatomy. Currently, six FDA-approved infrarenal endografts are commercially available for the treatment of infrarenal AAAs (Fig. 72.1 and Table 72.2). Most current stent-graft designs have favored suprarenal stents (Zenith-Cook Medical, Bloomington, Indiana; AFX-Endologix, Irvine, California; Endurant-Medtronic; Ovation-Trivascular, Santa Rosa, California) to inhibit downward migration and the development of type I endoleak and endograft failure. In addition, the Zenith, Endurant, Excluder, Aorfix (Lombard Medical Inc., Irvine, California) and Ovation stents have barbs to provide active, rather than passive, fixation. Ovation stents also have unique polymer-filled sealing rings to create an enhanced seal at the aortic neck and endolegs. The AFX device is the only one that touts passive fixation, whereby the flow divider of the stent-graft sits directly on the aortic bifurcation. The C3 delivery system for the Gore Excluder graft is a recent iteration of the device which allows for the ability to reposition the graft through the use of a constraining dial which allows for proximal trunk reconstraining and reopening, a feature that may be particularly beneficial in tortuous proximal necks. The Aorfix stent graft is the only FDA-approved device indicated for the treatment of angulated necks of up to 90 degrees. Recent technologic advances have focused on addressing suboptimal anatomy, in particular, of the infrarenal neck.

Percutaneous Technique

With the advent of smaller delivery systems, percutaneous technique has been used, decreasing the morbidity of the procedure even further. The most common vascular closure device used for percutaneous EVAR is the Perclose Proglide (Abbott, Abbott Park, Illinois) which consists of a pretied Prolene suture, and can accommodate a 5- to 8-French arteriotomy with one suture and an 8.5- to 21-French arteriotomy with two sutures (Fig. 72.2). For arteriotomies greater than 8 French in size, the "preclose technique" is required. The vast diameters

treatable with the Perclose Proglide make it a popular choice in performing percutaneous EVAR. The predictors for failure of the technique include small access vessel diameter and anterior wall calcification,[1] thus the role of ultrasound-guided access when contemplating the use of vascular closure devices is crucial. There is a learning curve with these devices, but given the high technical success rates observed in recent series,[2-5] as well as the decreased complication rate and hospital length of stay,[6] it is clear that given appropriate anatomy, percutaneous EVAR is a useful technique.

RANDOMIZED TRIALS OF ENDOVASCULAR ANEURYSM REPAIR VERSUS OPEN REPAIR

Perioperative Outcome

EVAR-1 was a randomized prospective U.K. study including 1082 patients that compared EVAR with open AAA repair in patients who were fit enough to undergo open surgical repair

TABLE 72.2 Device Characteristics of Current Stent Grafts

Device Name	Company	Configura-tion	Max Device Diameter	Minimum Device Diameter	Fabric	Metal	Active Fixation	Anatomic Fixation

from 1999 to 2003.[14] The 30-day mortality rate was reduced in the EVAR group (1.7% vs. 4.7%), although secondary interventions were more common in the EVAR group (9.8% vs. 5.8%). The DREAM trial was a multicenter randomized trial (enrolling from 2000 to 2003) that compared open repair with EVAR in 345 patients,[15] with a reduction in operative mortality in EVAR patients (1.2% vs. 4.6%) and a combined rate of operative and mortality (4.7% vs. 9.8%), with the majority of complications accounted for by pulmonary issues. The Open Versus Endovascular Repair (OVER) trial including 881 patients from 42 Veterans Affairs centers randomized to either EVAR or open repair[16] demonstrated that perioperative mortality was improved in the EVAR group (0.5% vs. 3.0%), yet no difference was seen in mortality at 2 years (7.0% vs. 9.8%). The Anevrisme de l'aorte abdominal: Chirurgie versus Endoprosthese trial compared EVAR with open surgical repair in low- to moderate-risk patients. In-hospital mortality and the incidence of postoperative complications were not statistically different. In addition, with a median follow-up of 3 years, no difference was observed in survival or the incidence of major events.[17]

Long-Term Outcome

A comparison between current stent grafts and those that are off the market reveals a striking difference regarding rates of migration, rupture, conversion, and re-intervention.[18,19] Survival analysis from EVAR-1 demonstrated no difference in all-cause mortality at 6 years, although only 24% of patients survived until the end of the study period. The initial survival benefit of EVAR was lost within 2 years of repair, secondary to a higher death rate from cardiovascular causes among those patients who had undergone EVAR.[20] The rate of graft-related complications and need for re-interventions was significant at 4 years, likely accounting for the higher aneurysm-related death rate in the EVAR group. The rates of aneurysm-related death converged at 6 years in these two groups. The 2-year follow-up study from the DREAM trial showed similar results with a reduction in aneurysm-related mortality in the EVAR group compared with the open surgery group (2.1% vs. 5.7%), which was not reflected in overall mortality.[21] Mortality from cardiovascular causes in the EVAR group again contributed to the equalization of survival between groups at 2 years. As expected, the need for re-intervention was higher in the EVAR group and was 3 times that of the open group in the first 9 months after randomization. At 6-years follow-up, secondary interventions were again higher in the EVAR group: 30% versus 19.1%. The cumulative 6-year survival in the two groups was similar, at 69.9% for the open group and 68.9% for the EVAR group.[22] The OVER trial 2-year results revealed that, although the perioperative advantage of EVAR was still realized at 3 years, survival was similar between groups beyond this time.[23]

Although the results from the EVAR-1, DREAM, and OVER trials rather conclusively demonstrate the improved perioperative morbidity and mortality profile of EVAR compared with open aortic aneurysm repair, concerns remain over the long-term durability and survival benefit of EVAR.[139] Although device modifications and improvements in design have led to a decrease in device failure, the 6-year follow-up data from the U.K. EVAR-1 trial indicated no differences in overall or aneurysm-related mortality compared with open repair in the long term. Furthermore, EVAR was associated with a higher rate of interventions and was costlier.[20] Data from large registries such as EUROSTAR have estimated a re-intervention rate of 5% per year and a continued rupture rate of 1% per year despite EVAR.[24,25] The success of EVAR is highly dependent on the patient's anatomic suitability for the procedure. Factors that determine anatomic suitability include neck diameter, neck length, and angulation. In EVAR-1, 54% of patients were anatomically suitable for EVAR, but this percentage ranged

from 6% to 100% across institutions. This wide variation in defining anatomic suitability was underscored in a U.S.-based study of 10,228 patients who underwent EVAR from 1999 and 2008 and had preoperative and postoperative CT assessment using the three-dimensional reconstruction company, M2s (Lebanon, NH).[7] Only 42% of patients met the most stringent criteria for instructions for use, whereas 69% met a more liberal definition of instructions for use. Most sobering, the 5-year rate of sac enlargement after EVAR was 41%. This paper showed the high rate with which EVAR technology was being applied to nonideal anatomy, as well as resultant continued sac enlargement after endovascular repair. Furthermore, long-term follow-up of EVAR patients has been inconsistent, a cause for concern given the not infrequent need for secondary interventions in the mid to long term. A study of 19,962 Medicare beneficiaries undergoing EVAR from 2001 to 2008 showed that 50% of patients were lost to annual imaging follow-up at 5 years after surgery.[8]

Population-Based Results

In general, institutional series results are reported by academic centers with a high level of expertise and controlled, prospective, multicenter studies reflect the beneficial effects of rigorous patient and investigator selection. Therefore statewide and nationwide audits may provide a more accurate clinical picture, although procedure-specific information may be sparse because the study is usually based on administrative data. Studies of this kind have confirmed the short-term advantages of EVAR over open AAA repair.[26,27] In an analysis of Medicare data from 2001 to 2004, in which one can assume that most of the repairs in this study were performed with AneuRx stent grafts because little else was available until 2003, the overall perioperative mortality rate was 1.2% for EVAR and 4.8% for propensity score–matched open surgical controls.[28] However, late survival was similar between the two groups, although the survival curves did not converge until after 3 years. By 4 years the EVAR group had more aneurysm ruptures, as well as a higher re-intervention rate. In contrast, a higher rate of laparotomy-associated complications was seen in the open repair group. This was further examined in a study of late survival with re-interventions and readmission after open and EVAR.[29] Re-intervention and readmissions were more frequent after EVAR than after open repair (7.56 vs. 6.96/100 person-years), but the majority of these re-interventions were minor endovascular interventions. Notably, rupture was five times more common after EVAR compared with open repair, but with a relatively low rate overall. In the open repair group, as expected, laparotomy-associated re-interventions were more common and were associated with a mortality rate of 12.2%. The study concluded that survival was negatively impacted by re-intervention or readmission after EVAR or open surgery, which contributed to the loss of survival benefit of EVAR over time. The late failures of EVAR are consistent with the known failure modes of the AneuRx stent graft.[30,31] In contrast, a more recent study of Medicare beneficiaries from 2003 to 2007 showed that open repair was associated with an increased risk of all-cause mortality and AAA-related mortality over a follow-up period of 5.7 years.[32] The initial increased 30-day mortality associated with open repair was sustained during the entire follow-up period.

Meta-Analysis

A large segment of the available data on EVAR, consisting of 161 papers and 278,862 patients, was examined in a recent meta-analysis.[33] The relatively high overall mortality rate (3.3%) in the combined series reflects the influence of poor early results. These authors used a technique of meta-regression to weigh the effects of different studies over time and assess temporal changes in outcome. The data show striking heterogeneity, some of which is attributable to the effects of changing technique and device design. Both mortality rate and endoleak rate showed steady improvement between 1992 and 2002. Based on the regression line, the perioperative mortality rate was estimated to have fallen to approximately 1.4% in 2002, which is very close to the rates seen in the Lifeline, EVAR-1, and DREAM studies discussed previously.

ENDOVASCULAR ANEURYSM REPAIR COMPARED WITH MEDICAL MANAGEMENT

The question of whether EVAR is better than medical management in high-risk patients was addressed by the EVAR-2 trial, in which 338 patients who were unfit for an open repair were randomized to either EVAR or medical management.[34] The aneurysm-related mortality and all-cause mortality rates were no different between groups. The 30-day mortality rate for EVAR was 9%, although 3.6% of these deaths were from rupture while awaiting EVAR, because the median time to intervention was 57 days. Furthermore, 25% of patients assigned to medical management eventually underwent EVAR either because of patient preference or surgeon preference, with a strikingly low mortality rate. Given the number of AAA ruptures in the EVAR group while awaiting surgery, as well as crossover of the medically treated patients to the treatment group, it is perhaps not surprising that no difference was seen in aneurysm-related or overall mortality between groups at 4 years. Despite its shortcomings, EVAR-2 correctly underscores the fact that very-high-risk patients may not benefit from AAA repair because they often die from other causes before a benefit can be realized. However, it appears that EVAR can be performed safely by experienced surgeons in carefully selected high-risk patients.

Other studies provide data on performing EVAR in high-risk patients.[35-37] Data from the Department of Veterans Affairs National Surgical Quality Improvement Program on high-risk veterans undergoing EVAR showed a 30-day mortality rate of 3.4% and a 1-year mortality rate of 9.5%, which was significantly reduced compared with open repair (5.2% and 12.4%, respectively).[37] A subset analysis of high-risk patients from five industry-sponsored FDA trials showed a perioperative mortality rate of 2.9%. Both studies had open surgical controls, which suggests that the relatively improved survival percentages may have been due to a "healthier" high-risk cohort. The Veterans

Affairs large aneurysm study, which was an observational study of surgically unfit patients, showed a 1-year rupture rate of 9.4% for aneurysms measuring 5.5 to 5.9 cm, 10.2% for aneurysms 6.0 to 6.9 cm, and 32.5% for aneurysms measuring 7.0 cm or greater.[38] Thus very large AAAs even in high-risk patients may benefit from EVAR, but often such AAAs are not anatomically suited for EVAR.

ENDOVASCULAR ANEURYSM REPAIR IN RUPTURED ABDOMINAL AORTIC ANEURYSMS

EVAR has been shown to be a successful, less morbid approach of ruptured aneurysms compared with open repair in select patients and in the setting of an appropriate endovascular infrastructure to accommodate emergent performance of the procedure. In an early single-institution study describing the use of a multidisciplinary protocol including involvement by emergency department physicians, anesthesiologists, and operating room staff, as well as radiology technicians, the authors reported a 95.2% technical success rate and a perioperative mortality rate of 18%, attributed to multisystem organ failure and abdominal compartment syndrome.[9] In a follow-up study from the same institution, EVAR patients had a significantly lower 30-day mortality compared with the open group (24.2% vs. 44.2%, $P < .005$) and an improved 5-year survival rate (37% vs. 26% $P < .005$).[10] However, these results were again balanced by the need for re-intervention in the EVAR group in up to 23% of cases. In another institutional study which used propensity score matching to compare EVAR versus open repair for ruptured AAAs, there was no difference in perioperative mortality (22% vs. 32%, $P = .40$) or 3-year survival rates (42% vs. 47%, $P = .66$), but there was a higher rate of tracheostomy, renal failure, and myocardial infarction in the open group.[11] In a Dutch study of patients with suspected aortic aneurysm rupture who were suitable for either endovascular or open repair, the intraoperative, 30-day and 6-month survival after EVAR was 4%, 20%, and 28% compared with 6%, 45%, and 54% in the open group, respectively. Thus, in patients with anatomy amenable for EVAR, there was a 25% perioperative mortality reduction with EVAR which persisted to 6 months of follow-up.[12] It is clear that in patients who are suitable candidates for EVAR and at institutions where endovascular stents of varying sizes are available for emergent use, as well as in the setting of having well-trained operating room staff, EVAR for ruptured aneurysms is associated with a high technical success rate and lower perioperative morbidity and mortality rate compared with open repair.

COMPARISON OF DIFFERENT STENT GRAFTS

There is a dearth of data to allow appropriate comparison among different EVAR devices, due to lack of large numbers and lack of long-term follow-up. From the EUROSTAR data,[36] the AneuRx and Talent stent grafts had the highest rates or migration, endoleak (types I and III), and conversion. The Zenith stent graft, although having the highest rate of aneurysm sac shrinkage and lowest rate of migration, had the highest rates of limb occlusion. The Excluder stent graft had the lowest rate of limb occlusion. There are limitations to the EUROSTAR Registry—including voluntary, not mandatory, enrollment—which likely introduce bias. The Lifeline Registry consists of data from patients collected under four multiinstitutional investigational device exemption clinical trials for FDA approval with mandatory 5-year follow-up.[39] Unfortunately, the only device-specific information was for the Ancure device, which is no longer commercially available. No data are available on Zenith stent grafts. Resch et al. devised a method to evaluate the amount of longitudinal traction required to disrupt endograft fixation to cadaveric aortas, with a sutured anastomosis used as a comparison.[40] Although a force of 150 newtons was needed to disrupt a surgical anastomosis, all endografts required much less traction for dislodgment. The Zenith required the most force to be exerted (24 N), followed by the Ancure (12.5 N), Vanguard (9.0 N), and Talent (4.5 N). A similar study by Malina et al. showed that barbs and hooks increased the fixation 10-fold, whereas radial force had no impact.[41] The migration rate appears to be lowest for stent grafts that offer proximal active fixation.

COMPLICATIONS OF ENDOVASCULAR ANEURYSM REPAIR

Endoleak

An endoleak is defined as persistent blood flow in the aneurysm sac following stent grafting. Endoleaks are categorized into five different types, which differ in etiology as well as treatment (Fig. 72.3).[42-48]

Type I

Type I endoleak is defined as persistent blood flow into the sac either from around the graft proximally (type IA) or distally (type IB). When recognized in the operating room, type I endoleaks are typically addressed by performing proximal device extension and/or bare metal stent deployment to buttress radial support in the neck, with or without renal artery snorkel/encroachment techniques to preserve renal artery blood flow.[49] The Aptus EndoStapling System (Heli-FX, Aortic Securement System, Sunnyvale, California), which uses screws to secure the stent graft to the aortic wall, may also be used to enhance the proximal seal. If the main body or trunk of the prior stent graft is too short for the deployment of a proximal extension, an aorto-uniiliac device may be used, necessitating a femoral-femoral artery bypass and embolization of the contralateral proximal iliac artery with an occlusion device. The patency rate of femoral to femoral artery bypass done with aorto-uniiliac stent grafting for treatment of aortic aneurysmal disease is high, with a primary patency at 54 months of 90.9% and assisted primary and secondary patency rates of 97.7% and

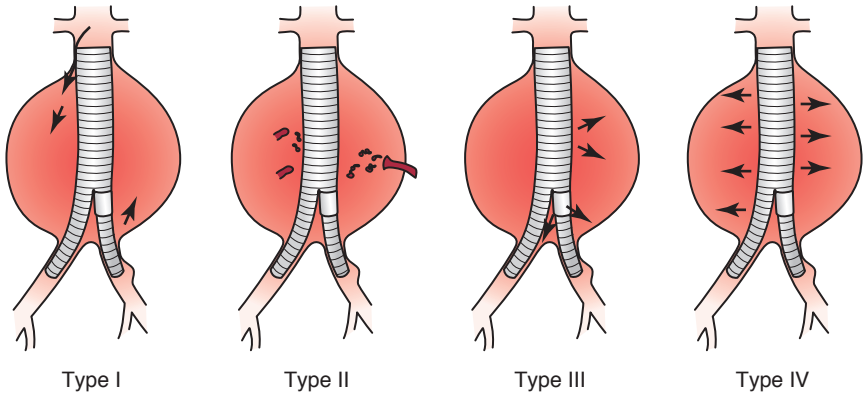

Figure 72.3 A type I endoleak (periprosthetic) occurs at the proximal or distal attachment zones (or at both). A type II endoleak is caused by retrograde flow from patent lumbar or inferior mesenteric arteries. A type III endoleak arises from a defect in the graft fabric, an inadequate seal, or disconnection of modular graft components. A type IV endoleak is due to graft fabric porosity, which often results in a generalized mild blush of contrast material within the aneurysm sac. (From White GH, May J, Waugh RC, et al. Type III and type IV endoleak: toward a complete definition of blood flow in the sac after endoluminal AAA repair. *J Endovasc Surg*. 1998;5:305-309.)

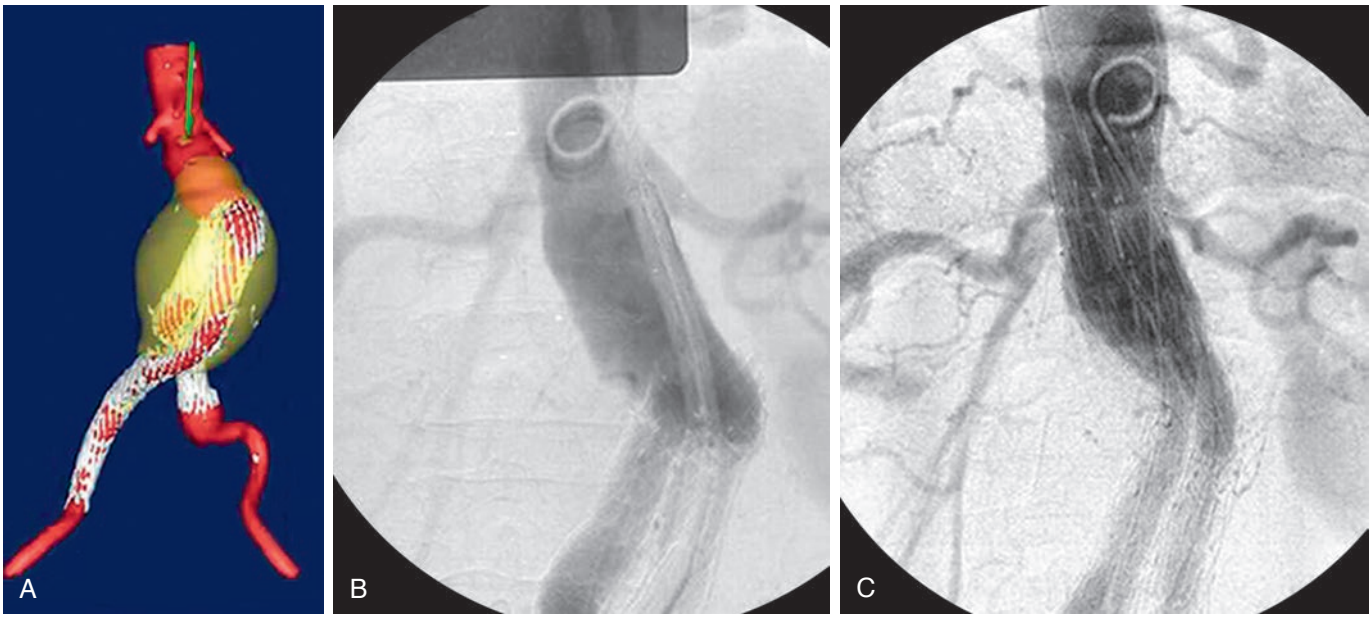

Figure 72.4 (A and B) Example of delayed type I endoleak secondary to graft migration. (C) Treatment consisted of proximal extension with a Zenith extender cuff.

100% at 66 months.[50] When type I endoleak is detected late, it is typically secondary to caudad migration of the stent graft or continued dilatation of the neck. A proximal extension may be deployed to achieve a proximal seal (Fig. 72.4). If type I endoleak continues after proximal stent-graft extension or bare metal stent placement, embolization with glue and or coils has been shown to be a useful adjunct in treating persistent type I endoleak in a small series.[51] A fenestrated graft may also be used to extend the seal zone to the juxtarenal and suprarenal aorta (see Chapter 80). Another described maneuver to treat proximal type I endoleak includes the aortic wrap method with a 12-mm Hemashield patch secured around the aortic neck.[52] Distal common iliac artery dilatation with type IB endoleak is retreated with hypogastric artery occlusion and extension to the external iliac artery or by use of a branched iliac device (Zenith or Gore). If the previously described maneuvers are not successful in fixing the endoleak, operative explant of the stent graft is necessary because of the high risk of rupture associated with type I endoleak.

Type II

Type II endoleak is defined as persistent sac filling from back-bleeding side branches (i.e., the inferior mesenteric artery, lumbar arteries, or middle sacral artery). Postoperative CT scans show type II endoleak in 10% to 20% of patients following EVAR.[42-44,53] In comparison with type I and type III endoleaks, type II endoleaks have a relatively benign course, with as many as 80% resolving spontaneously within 6 to 12 months of

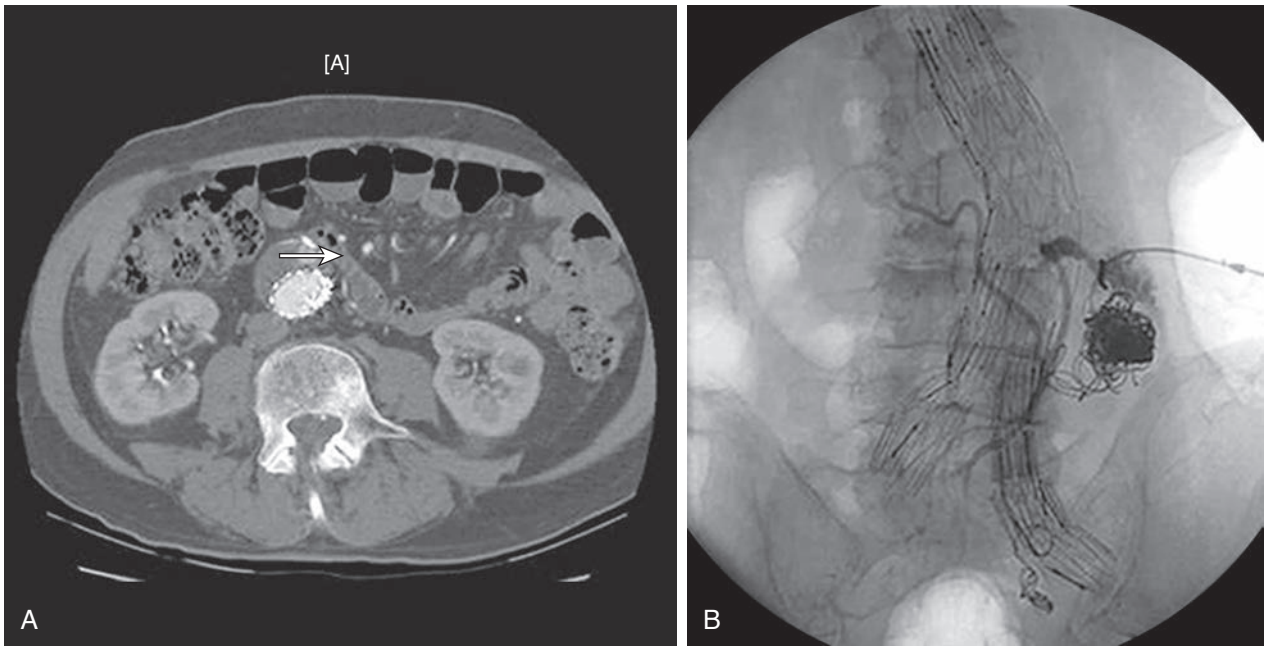

Figure 72.5 (A) A type II endoleak is visible on computed tomographic angiography. (B) A translumbar approach was used to deliver coils into the origin of the inferior mesenteric artery.

stent-graft repair.[18] Furthermore, the risk of aneurysm rupture due to a type II endoleak is small. Multivariate analysis of the EUROSTAR data showed no association between type II endoleak and risk of aneurysm rupture or need for surgical conversion.[44] A recent meta-analysis likewise demonstrated the rarity of aneurysm rupture with isolated type II endoleak.[54] Therefore typically type II endoleaks are not treated unless aneurysm sac enlargement is documented. Persistent type II endoleaks are usually associated with a large endoleak cavity,[55] flow between inflow and outflow arteries,[56] and large patent inferior mesenteric and lumbar arteries.[57] Embolization can be performed using coils or N-butyl cyanoacrylate glue. The transarterial approach can be undertaken to embolize the inferior mesenteric artery through the superior mesenteric artery via the marginal artery of Drummond. Another technique involves catheterizing the sac via the femoral artery by advancing the wire and catheter in between the iliac limb and the iliac artery into the AAA.[58] The translumbar approach uses direct aneurysm sac puncture technique (Fig. 72.5). Regardless of the approach, type II endoleaks physiologically behave like AV malformations, and embolization of the nidus of the endoleak, including the inflow and outflow vessels, is the optimal approach. Retroperitoneal endoscopic ligation of the lumbar arteries has also been described.[59] If the previous interventions fail to be successful, operative explant or direct ligation of the backbleeding vessel via sacotomy is required.

Type III

A type III endoleak results from fabric erosion or a leak between stent-graft components. Only modular grafts are at risk for component separation, but all devices are at risk for graft failure. Rates of type III endoleak range from 0% to 1.5%.[44,60] Type III endoleak from fabric erosion is effectively treated with stent-graft relining or bridging of components to effectively seal the defect (Fig. 72.6). Component separation is likewise treated with relining. In cases in which the device pieces are particularly separated in space due to excessive tortuosity, obtaining wire access through both components may be challenging, and transbrachial access with a snare may be useful in this situation. Plain radiographs are often more sensitive for detecting impending component separation because they offer a more global overview of the framework of the stent graft. While in the operating room, arteriography with the pigtail catheter in the main body of the stent graft and below the proximal fixation site can help to distinguish a type I from a type III endoleak.

Type IV

Type IV endoleaks are related to porosity of the graft fabric, occur less frequently with current-generation stent grafts, and are noted within 30 days of graft implantation. They usually resolve after graft interstices thrombose. No treatment is usually required because they are short-lived and resolve on their own. However, high graft porosity, as demonstrated by the earlier-generation Excluder graft, can lead to sac growth in the absence of demonstrable endoleak.[12]

Type V

Type V endoleak, or "endotension," is defined as elevated sac aneurysm pressure without a demonstrable endoleak. It is generally believed that the etiology is an undetected endoleak or transmission of systemic pressure through thrombus. Endotension is typically detected as continued sac enlargement on CT scan but can also be detected by direct aneurysm sac pressure sensors (Cardiomems, Atlanta, Georgia). Relining with proximal and/or distal extension may be initially performed. If this is

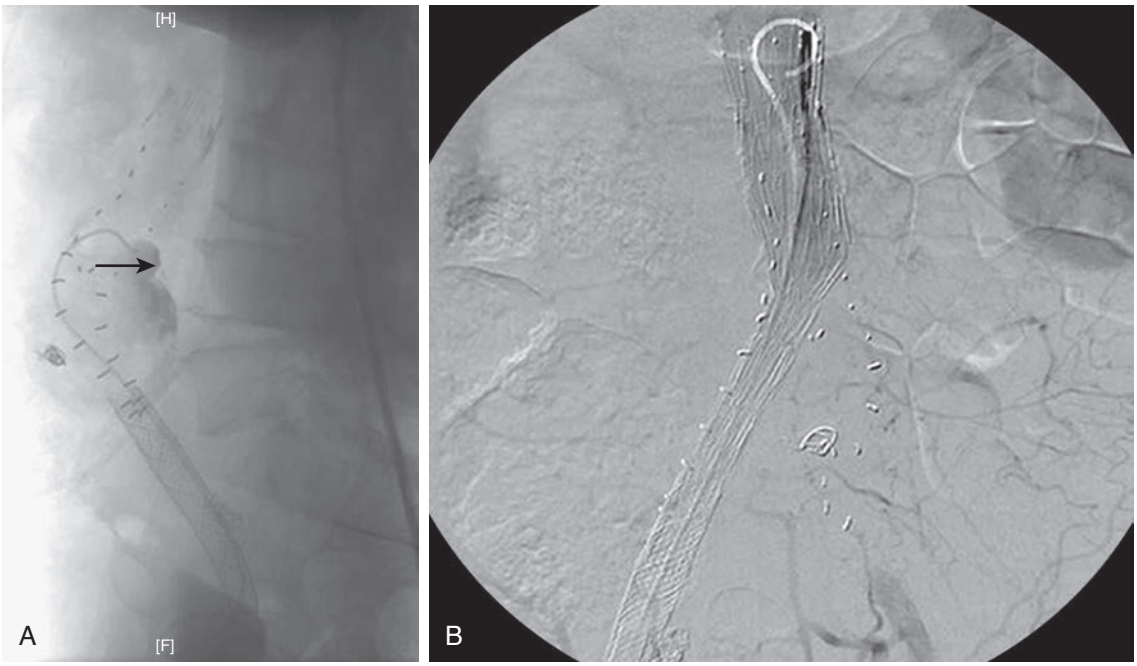

Figure 72.6 (A) A patient who had undergone an endovascular aneurysm repair 4 years previously with the Ancure device. His left limb was chronically occluded, which was causing claudication symptoms. Computed tomography scan additionally revealed continued aneurysm sac enlargement. A lateral projection arteriogram demonstrated erosion of the stent graft in the posterior portion of its main body *(arrow)*. (B) Aortouniiliac stent graft was deployed to reline the original repair followed by femoral-to-femoral artery bypass to revascularize the contralateral limb.

not successful, operative explant is necessary in the setting of continued AAA enlargement.

Endoleak Detection

Contrast-enhanced CT scan is the "gold standard" for detection of endoleaks unenhanced, early, and delayed phases. The unenhanced scan shows mural calcium, which can be distinguished from contrast on subsequent series. Types I and III endoleaks are detected on arterial phase images, whereas type II endoleaks are detected on delayed phase images. The location of the endoleak may give an indicator as to its origin. For example, a ventrally oriented leak is likely to be emanating from the inferior mesenteric artery, whereas a dorsally oriented endoleak is more likely to supplied by the iliolumbar arteries.[46] If the endoleak is not demonstrated on three-dimensionally reconstructed CT images, arteriography is warranted. Alternative imaging modalities include magnetic resonance imaging (MRI)[61,62] and duplex ultrasound.[63-65] MRI is an expensive imaging modality, and caution must be used with stainless-steel devices such as the Cook Zenith stent grafts.[66] In addition, the earlier proposed benefit of use in patients with renal insufficiency has been overturned in light of the increased incidence of nephrogenic systemic fibrosis with gadolinium exposure in patients with a glomerular filtration rate less than 30.[67] Duplex ultrasound does not require contrast administration and is not associated with radiation exposure, but its success depends greatly on the technologist and it can be challenged by patient factors such as morbid obesity or presence of bowel gas. A recent meta-analysis revealed a pooled sensitivity of 0.83 and a pooled specificity of 1.00 for duplex ultrasound detection of type I and type III endoleaks.[68] Data from a relatively large study revealed that, although duplex ultrasound yielded only a sensitivity of 67% compared with CT scan, no type I endoleaks or endoleaks requiring intervention were missed.[64]

Migration

Migration refers to caudal movement of the stent graft, which may lead to loss of proximal fixation and result in type IA endoleak. Cephalad migration of iliac limbs occurs less frequently, and rarely a stent graft can migrate proximally to encroach on the renal arteries. The tendency toward caudal migration increases with angulation of the neck,[69] decreased neck length, neck thrombus, and large diameter of the neck.[70] In the multicenter AneuRx trial, 8.4% patients experienced migration of their stent grafts, with initial low deployment of the device and short fixation length found to be significant predictors.[71] Postprocedural causes for stent-graft migration include aortic neck dilatation, sac shrinkage with concomitant sac shortening, and displacement of the stent graft from external compression.[52,72,73] The most important planning strategy is adherence to the instructions for use, as much as possible. Preprocedurally, a proximal neck fixation length of 15 mm is typically recommended, although some data suggest that as little as 10 mm may be effective in providing a seal, at least in the short term.[74,75] In addition, avoiding angulation greater than 60 degrees between the infrarenal neck and the longitudinal axis of the aortic aneurysm is associated with less migration. In a particularly angulated

patient, a more flexible stent graft should be chosen. The Aorfix stent graft (Lombard Medical Inc.) is the only stent graft approved for neck angulation of up to 90 degrees. In a flow model study comparing the Aorfix stent graft with other manufactured stent grafts of less flexible design, the endoleak rate in angulated necks was lower in the Aorfix-treated patients.[76] Midterm results from a European multicenter study on the Aorfix also revealed acceptable results, although longer-term follow-up is needed.[77]

To avoid migration in patients with short and angulated necks, several manufacturers have modified their original devices to make them more flexible. In addition, the Zenith and the Excluder also offer active fixation with the use of barbs, which are an integral part of the device and become embedded in the aortic wall. The AFX stent graft (Endologix) provides passive fixation via its "anatomic" seating on the aortic bifurcation. It is designed to allow for aortic extensions to be added proximally, which is ideal in the presence of a highly angulated neck. The Aorfix stent graft has proximal clips for active fixation of the device to the aortic wall. Its fish-mouth design also enhances the length of seal available at the neck. In addition, because of its unique ring stent design, it is very flexible and resistant to kink. The Aptus EndoStapling System helps to fix the proximal aspect of the main body to the aortic wall. The Anaconda (Vascutek, TERUMO Cardiovascular Systems Corp, Ann Arbor, Michigan) is another device undergoing clinical trials in the United States. In addition to its unique flexibility, the Anaconda allows for repositioning after graft deployment, allowing for optimum graft placement.[78]

Graft Limb Occlusion

Stent-graft limb occlusion occurs after 3% to 7% of procedures over a 9-month to 4-year period,[79,80] usually within the first 6 months following EVAR; it is more frequent in patients who have aortoiliac occlusive disease, a small distal aorta (<14 mm), or tortuous iliacs or in those who require external iliac artery landing. Earlier-generation stent grafts with unsupported limbs were at greatest risk for limb kinking.[6,81,82,140] However, newer stent grafts are protected from graft limb kinking by more limb support. In a review of 460 patients, current-generation stent grafts were associated with a graft limb occlusion rate of 4.3% compared with 18.7% in first-generation devices.[80] Data on the Endurant graft revealed a graft limb occlusion rate of 4.0% at 1.7 years.[83] More recent data comparing limb occlusion in patients undergoing elective EVAR with the standard Zenith flex stent graft versus the low profile stent graft showed that despite more challenging iliac artery anatomy in the low profile group, the 24-month rates of freedom from limb occlusion were no different (92% vs. 95% respectively, $P = .293$). During the conduct of the operation, it is important at the completion of the endovascular stent-graft repair to remove stiff wires before performing the completion arteriogram. This provides the ability to detect any occult kinks that may be straightened by the presence of a stiff wire.[81] Most patients with limb occlusion present with either buttock, thigh, and/or calf claudication; rest pain is infrequently encountered.[80] Usually the limb can be recanalized with either thrombolysis or surgical thrombectomy techniques, with adjunctive iliac stenting as needed. When a kink is identified and treated with a stent, patency rates are quite high. Arteriography with oblique orientation can be helpful in providing views to identify the problem. In addition, intravascular ultrasound (IVUS) and measurement of pullback pressures may help identify graft infolding, which may not be appreciated on arteriography.[84] In those patients in whom the limb cannot be reopened, femoral-femoral bypass or axillofemoral bypass is performed to revascularize the affected leg.

Renal Artery Occlusion

Renal artery occlusion occurs either from inadvertent stent-graft coverage of the renal artery origins or from embolization. Stent-graft coverage most often occurs procedurally; delayed upward migration of the stent graft after EVAR is uncommon.[85] During the procedure, under systemic heparinization, graft impingement on the renal artery orifice may not be readily apparent. Often the graft fabric of stent grafts extends 2 mm above the radiopaque markers (e.g., Zenith); thus the radiopaque stent struts must be placed to ensure that the fabric does not cover the renal artery origin. Appropriate positioning of the C-arm to avoid parallax and to ensure that the origin of the renal artery is appreciated is paramount. When detected in the operating room, rescue renal stenting can be attempted via the femoral or brachial approach to preserve renal artery flow. When detected late, open hepatorenal or splenorenal bypass may be required.[86] In a single-institution study investigating suprarenal versus infrarenal fixation, suprarenal fixation did not cause a decrease in renal function or increase the need for dialysis.[87] Embolization to the renal arteries can be a cause of early or delayed renal insufficiency. This is especially true if thrombus is present in the area of aortic fixation. A recent study showed that the presence of thrombus in the neck in combination with suprarenal fixation was associated with an increase in thromboembolic complications.[88]

Neck Dilatation

The juxtarenal portion of the aorta is not as prone to dilatation as is the infrarenal aorta, but this region can dilate following EVAR,[89] resulting in migration and/or type I endoleak and risk of rupture.[9] In a study of 230 patients, the predictors for neck dilatation were large AAA diameter, large aortic neck size, and circumferential neck thrombus.[90] It is interesting to note that no difference was found between stent grafts with infrarenal or suprarenal attachment. Indeed, a study evaluating the neck following endovascular and open repair found similar increases in neck diameter over time, suggesting that the dilatation is a sign of progression of disease rather than the radial force of a stent graft that is larger than the aortic neck.[91] However, generous oversizing of the stent graft should be avoided because greater than 30% oversizing with the Zenith stent graft was associated with a higher migration and aneurysm expansion risk.[92] Excessive device oversizing also contributed to neck dilatation with the AneuRx graft.[93]

Stent-Graft Infection

Infection of the aortic stent graft is a rare event, with small case series reporting an incidence of 0.2% to 0.7%.[94] Development of aorto-enteric fistula has also been described. In the largest case series to date, nine patients presented with infected EVAR at a tertiary referral center.[95] All patients underwent complete explants of the stent graft—five patients with preemptive extra-anatomic revascularization (axillary-femoral to femoral artery bypass), the other four patients by in-situ reconstruction with Rifampin-soaked polyester. Seven of the patients survived to discharge, and the mean follow-up of the surviving patients was 11 months. In this series the presence of a concomitant aortoenteric fistula was particularly virulent. Two of the three patients with aortoenteric fistula died before discharge. Although stent-graft infection is generally considered a highly morbid condition with mortality rates estimated at 36%,[96] the findings from this study suggest that explantation of infected grafts can be performed with an acceptable mortality rate. Additional data suggest that conservative management may be possible. Data from a retrospective study of TEVAR and EVAR graft infections showed an overall mortality of 25% but no difference in outcome in those patients treated with antibiotics alone versus those who underwent surgical explantation. Although the numbers are small and the authors acknowledge the possibility of a type II error, this study does suggest that a subset of patients may be best treated with antibiotic therapy alone.[97] Indeed, the patients treated conservatively either had no microorganisms isolated or predominantly *Staphylococcus* and *Streptococcus* species grown in their blood cultures.

Pelvic Ischemia

Pelvic ischemia can manifest itself as buttock claudication, buttock necrosis, spinal cord ischemia, colorectal ischemia, and erectile dysfunction.[98-100] The incidence after EVAR varies in the literature, but pelvic ischemia occurs frequently, and the complications should be discussed with the patient during the consenting process. It typically occurs as a consequence of occlusion of one or both internal iliac arteries in the presence of a common iliac or internal artery aneurysm. In a study that also included data from 18 papers detailing internal iliac artery embolization before EVAR, buttock claudication occurred in 55% of patients overall, with 52% occurring in unilateral embolization and 63% occurring in bilateral embolizations.[99] Staging the bilateral internal iliac artery embolizations by at least 1 week appears to decrease the risk of ischemic complications.[13–15] Erectile dysfunction occurred in 17% overall, with 17% occurring after unilateral and 24% occurring after bilateral embolizations. Other studies similarly found that bilateral embolization was associated with an increase in pelvic ischemic complications.[100] Furthermore, when bilateral profunda femoral arteries are diseased, these complications tend to be most severe. Although relatively common initially, buttock claudication appears to improve in most patients. In a study in which bilateral internal iliac arteries were occluded, buttock claudication occurred in 31% of patients but persisted beyond 1 year in only one-third of those patients.[101] In addition, multiple studies have shown that embolization of the internal iliac artery proximal to its bifurcation is associated with a lower incidence of buttock claudication than if more distal branches are occluded, because this allows more pelvic collateral flow via internal iliac branches.[101,102] Colonic ischemia is relatively rare following internal iliac artery embolization and EVAR, with an incidence of 1.7% in one series.[103] Spinal cord ischemia is also a rare complication following internal iliac artery occlusion and EVAR. In a small series that examined the incidence of complications following bilateral internal iliac artery embolization before EVAR, the incidence was 3% and was characterized as paraparesis.[101]

Stent-Graft Fatigue

The aortic stent graft is under constant mechanical stress during the cardiac cycle, which can cause fracture of barbs and stent struts. With the exception of the original Zenith stent (stainless steel), most stent grafts are composed of nitinol, which is an ideal material given its flexibility and conformability. However, nitinol can be associated with surface irregularities, which serve as foci for stress and strain and can predispose to wire fracture. This problem has been lessened with electropolishing chemical etching techniques. Strut and stent fractures have been reported in multiple older-generation devices, including the Ancure,[104,138] Vanguard,[105] and Lifepath.[106] Strut failure, barb separation, and stent breakage have also been described with current-generation devices.[107,108] Not all stent failures require intervention; enough redundancy exists in the number of barbs and stents per ring that all stents do not need to be intact for appropriate fixation and support to occur. Barb separation or disruption associated with migration and endoleak formation or stent fracture associated with graft disruption must be treated as outlined earlier for type I endoleak and type III endoleak, respectively.

FOLLOW-UP

Postoperative follow-up is important for ensuring continued success of EVAR. Postoperative surveillance allows the detection of endoleaks, aneurysm sac expansion, stent fracture, limb kinking, and material fatigue.

Computed Tomography Scans and Ultrasound

Initial protocols were adopted from early FDA-sponsored pivotal trials, which recommended CT scans at 1-, 6-, and 12-month intervals and annually thereafter.[109] The frequent use of CT scanning has raised concerns related to the added cost of these studies, as well as cumulative radiation exposure[110,111] and use of nephrotoxic agents. Although ultrasound/duplex avoids radiation exposure and the use of contrast, concerns have been raised in the past regarding its variable sensitivity in detecting endoleaks.[65] The utility of ultrasound is also limited in obese patients or those presenting with substantial bowel gas. Based on recent reports, some investigators have proposed that follow-up with duplex as the sole imaging modality is appropriate, provided no endoleak or sac enlargement is documented on

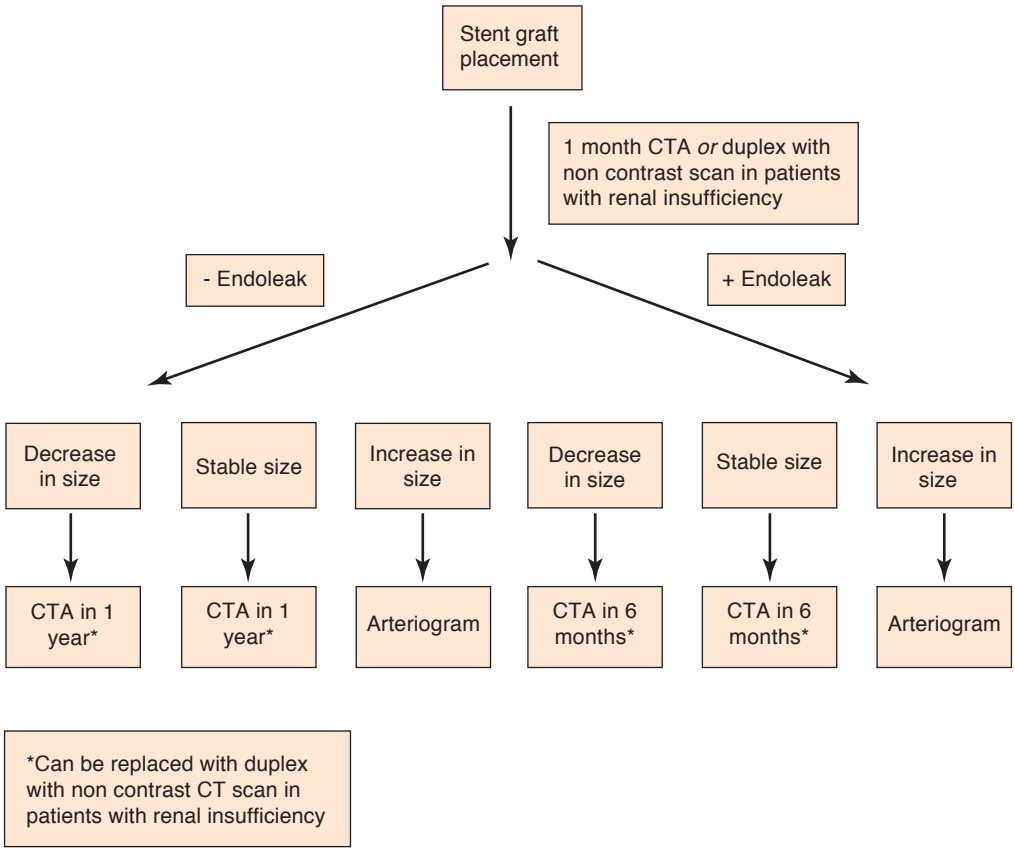

Figure 72.7 Surveillance strategy following endovascular aneurysm repair. *CTA*, Computed tomographic angiography.

the first annual CT scan.[112] A significant increase in sac size or a newly diagnosed endoleak would then prompt CT imaging.[113] Omitting the 6-month scan has also been recommended, if CT imaging at 1 month does not identify an endoleak.[112,114] These protocols have been shown to be safe, with minimal risk of clinical adverse event.[115] The Society for Vascular Surgery practice guidelines currently recommend contrast-enhanced CT scanning at 1 and 12 months during the first year after EVAR.[109] Detection of an endoleak at 1 month would prompt another CT scan at 6 months to evaluate the need for intervention. If neither endoleak nor aneurysm expansion is detected during the first year after EVAR, subsequent duplex follow-up may be a reasonable alternative. In patients with renal insufficiency, duplex ultrasound in combination with a noncontrast CT scan is an alternative surveillance strategy (Fig. 72.7). Although the risk of endoleak declines with each negative surveillance CT scan, new endoleaks have been identified as late as 7 years following EVAR,[116] underscoring the importance of lifelong surveillance.

Sac Pressure Measurement

Sac pressure measurement has also been recommended as an alternative method to image-based follow-up.[117,118] One such device, CardioMEMS (Cardiomems Inc.) uses a $30 \times 5 \times 1.5$ mm sensor that contains no battery and is powered externally with radiofrequency energy. This wireless implantable pressure-sensing device is placed in the aneurysm sac at the time of EVAR. The pressure measurements obtained from these sensors have been shown to correlate well with transcatheter pressure measurements from the sac, with a sensitivity of 0.94 and a specificity of 0.80 for detecting type I or III endoleaks.[118] Sac pressures have been shown to decrease in shrinking aneurysms and in patients who have undergone successful coil embolization of type II endoleaks.[119]

Re-intervention Rates

The long-term (>20-year) outcome of stent grafts has not yet been established, and multiple reports of the midterm results of EVAR using various devices cite a not insignificant need for secondary intervention. From the EVAR-1 and EVAR-2 trials the secondary intervention rates were 7.0% for the Zenith and 9.4% for the Talent grafts at approximately 4 years of follow-up.[120] In the 5-year follow-up study of patients who underwent Zenith stent-graft repair as part of the pivotal trial, the cumulative risk of conversion, limb occlusion, migration greater than 10 mm, or component separation was 3% or less at 5 years. The cumulative risk of late endoleak was 12% to 15%, accounting for most of secondary interventions and underscoring the importance of continued surveillance long term.[121] The effect of re-interventions and readmissions following EVAR versus open aneurysm repair was also examined in Medicare beneficiaries (Fig. 72.8).[29] Survival was found to be negatively

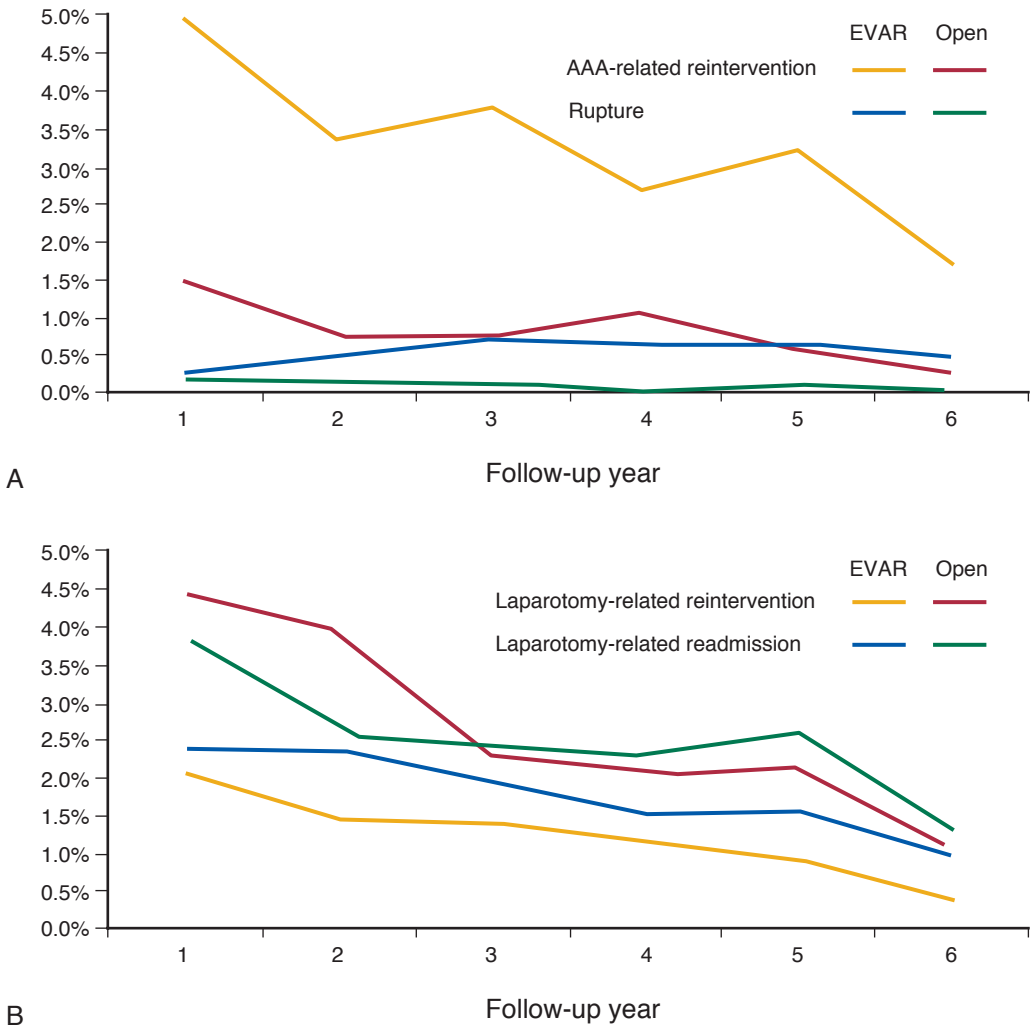

Figure 72.8 Re-interventions for Medicare beneficiaries undergoing endovascular aneurysm repair (EVAR) or open repair. (A) Abdominal aortic aneurysm (AAA)-related re-interventions and AAA rupture. (B) Laparotomy-related re-interventions and readmissions. (From Giles KA, Landon BE, Cotterill P, et al. Thirty-day mortality and late survival with reinterventions and readmissions after open and endovascular aortic aneurysm repair in Medicare beneficiaries. *Vasc Surg*. 2011;53(1):6-12, 13.)

affected by readmission or re-intervention in both groups. However, the majority of secondary interventions were minor in nature, with a relatively low 30-day mortality. In contrast, laparotomy-related re-interventions were more common in the open repair group and were associated with a relatively high mortality. The authors point out that, although the cumulative effect of re-interventions and higher rate of rupture following EVAR contribute to the equalization of survival benefit, the surviving patients in the EVAR group are likely sicker than those in the open repair arm.

ENDOVASCULAR REPAIR OF THE JUXTARENAL AORTA

For some patients with a proximal infrarenal neck length less than 10 to 15 mm (the traditional desired neck length for EVAR), partial renal artery coverage with adjunctive renal artery stenting can be performed.[49]

Encroachment Technique

This technique is used when partial renal artery coverage is needed to achieve a seal (Fig. 72.9A). The aortic stent graft is deployed in the usual fashion, with careful attention paid to the relationship between the top of the stent-graft fabric and the lowest renal artery. The optimal degree of angulation and rotation for visualizing the takeoff of the renal artery is then determined. Catheter and wire access of the renal artery can usually be obtained transfemorally. If a device with a suprarenal stent is used, care is taken to access the base of the triangular stent rather than in between the triangular stents. The authors use a combination of a Rosen wire (Cook Medical) and a guide catheter system to serve as a platform for performing

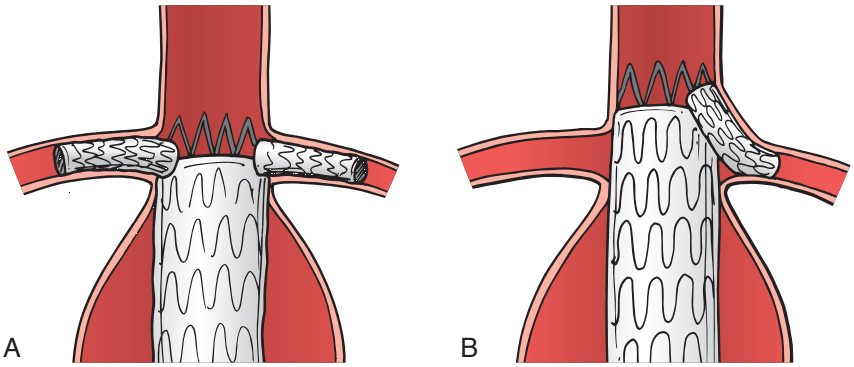

Figure 72.9 (A) The encroachment bilateral renal stenting technique. (B) The snorkel technique. (From Chaikof E, Cambria R. *Atlas of Vascular Surgery and Endovascular Therapy.* Philadelphia: Elsevier; 2012.)

the renal stent. Balloon-expandable stents are favored in this location because the increased radial force is essential to push the superior margin of the stent graft inferiorly to preserve renal artery flow.

Snorkel Technique

This technique is used when complete coverage of the renal artery origin is required to achieve a seal (see Fig. 72.9B). Transbrachial access is key because the snorkel maneuver is often used when more extensive coverage of the renal artery is required, and the stent is required to run alongside the stent graft before entering the orifice of the artery. The authors use a combination of a Rosen wire and a long Destination sheath (Terumo, Somerset, New Jersey) as our platform. The renal stent comes to lie entirely outside the aortic stent graft, parallel to it, until it enters the renal artery orifice. A covered stent is preferred for this purpose. The length of the renal stent is usually longer because of the distance along the aortic stent graft, which needs to be traversed before reaching the origin of the renal artery. It is important to maintain balloon support of the renal stent while ballooning the aortic graft, because compression of the stent can occur with this maneuver.

Results

Using either the encroachment or snorkel technique, a case series showed that sealing of the aneurysm was possible (no type I endoleak at 1-month follow-up) with a primary assisted patency of renal artery stents of 100% at a median follow-up of 12.5 months.[49] Another case series examined the efficacy of snorkel for repair of juxtarenal aneurysms.[122] In this study, 56 snorkel stents were placed in the renals alone or in the renals in combination with the mesenteric vessels. Technical success was 98.2% for snorkel placement, with 98.2% patency over a mean follow-up of 10.7 months. The 30-day mortality rate was 7.1%, with a 25% early endoleak rate, which was distributed among types I, II, and III. Another meta-analysis summarized the results from 15 case series of snorkel or chimney grafts in which 77.4% of patients underwent a concomitant EVAR.[123] Primary technical success was achieved in all patients, but a 14.0% type I endoleak rate occurred, over half of which required treatment. The primary patency was 97.8% at a mean follow-up of 9 months, and the 30-day in-hospital mortality rate was 4.3%.

ENDOVASCULAR REPAIR OF COMMON ILIAC AND INTERNAL ILIAC ARTERY ANEURYSMS

Common Iliac Artery Aneurysms

Current stent-graft technology allows treatment of iliac artery aneurysms with a seal zone diameter of up to 25 mm at the common iliac artery bifurcation.[124,125] The largest iliac limb diameter is 28 mm, provided by the Endurant endograft (Medtronic Inc.). When the diameter of the seal zone is greater than 25 mm or the aneurysmal disease extends into the external iliac artery, the endograft can be extended into the external iliac artery, with coil embolization or plug occlusion (Amplatzer vascular plug, St. Jude Medical, Inc., St. Paul, Minnesota) of the proximal internal iliac artery to prevent a type II endoleak.[126] To preserve internal iliac artery flow, an external to internal iliac artery bypass can be performed with proximal ligation of the internal iliac artery to effectively "move" the iliac bifurcation more distally. In one series of 22 patients, all bypasses remained patent at a mean follow-up of 15 months, with only mild buttock claudication occurring in two patients ipsilateral to the site of coil embolization.[127] Another series showed similar excellent internal iliac bypass patency rates of 91%, as well as freedom from ischemic symptoms.[128] Using the iliac-branched device (IBD) designed by Cook (Cook Medical) (Fig. 72.10A-C and 72.11), in a single-institution study of 46 patients, IBD side-branch patency was 87% at 5 years.[129] In another series with 100 patients, internal iliac artery patency was 91.4% at 5 years.[130] However, initial results from the trial in the United States revealed a stent fracture in the connecting stent, causing a type III endoleak, which has been treated with relining. The recently FDA-approved Gore Excluder Iliac Branch Prosthesis in the United States has the potential to achieve a more stable seal in those with ectatic iliac arteries, as well as preservation of important pelvic collaterals to decrease the likelihood of buttock claudication as well as reduce the complications of spinal cord ischemia should further aortic repair be required (Fig. 72.12). In a study of 10 patients evaluating the safety and

short-term efficacy of this device in the treatment of iliac artery aneurysms, there was a 100% technical success rate, with 100% branch patency at 1 month and 90% branch patency at 6 months (see Chapter 75).[16]

Internal Iliac Artery Aneurysms

Internal iliac artery aneurysms are typically managed with endovascular coiling/plug occlusion with stent-graft coverage of the origin, although an iliac branch device solution could be considered if anatomy is suitable. If the proximal landing zone is compromised, a chimney/snorkel can be deployed extending into either the common or external iliac artery,[131] or the "sandwich technique" may be used (Fig. 72.13).[141] A hybrid technique has also been described. An aorto-uniiliac endograft with a femoral-to-femoral artery bypass can be performed with a covered stent deployed from the contralateral external to the internal iliac artery in a "reverse U" fashion (Fig. 72.14).[132]

COST OF ENDOVASCULAR ANEURYSM REPAIR

The in-hospital cost of EVAR is approximately $20,000 in the United States.[133] In an Australian study comparing the cost of endovascular with open repair, operative costs were significantly higher in the endovascular group and were attributed entirely to the cost of the endograft. In addition, although overall length of stay and ICU stay were shorter in the endovascular group, total hospital costs were still greater in the EVAR group.[134] Because of the need for continued surveillance, the average cost for follow-up (median was 1 year) was also significantly greater in the EVAR group, which increased over time. The data from the EVAR-1 study likewise showed that EVAR was more costly than open repair.[135] In a study investigating the cost of long-term surveillance and secondary procedures, the cumulative cost at 5 years was $11,351.[133] The cost was significantly higher if the

(C) Cannulate the ipsilateral IIA using left brachial access. (D) Deploy the covered stent inside the nondiseased IIA with 5-cm overlapping into the iliac limb extension. (E) Position the iliac limb extension with the proximal end distal to the IIA stent. (E) Deploy the iliac limb extension and then the internal iliac artery stent. (G) For bilateral sandwich repair, deploy the contralateral iliac limb stent graft, then cannulate the remaining IIA, using left brachial access. (H) Deploy the iliac limb extension followed by the internal iliac artery stent. (From Lobato AC, Camacho-Lobato L. The sandwich technique to treat complex aortoiliac or isolated iliac aneurysms: results of midterm follow-up. *J Vasc Surg*. 2013;57:28S.)

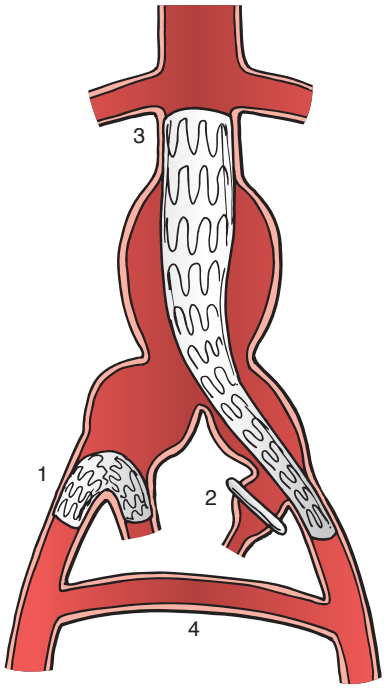

Figure 72.14 Diagram of external-to-internal iliac artery stent *(1)* and contralateral internal iliac artery occlusion *(2)*. Aortouniiliac device *(3)* and femoral-femoral artery bypass *(4)*. (From Ghosh J, Murray D, Paravastu S, et al. Contemporary management of aorto-iliac aneurysms in the endovascular era. *Eur J Vasc Endovasc Surg*. 2009;37:184.)

patient required a secondary intervention ($31,696 compared with $3668). The 5-year cost for patients with endoleak was $26,739 compared with $5706 for those without endoleak. In the OVER trial,[136] although the operative costs were significantly higher in the EVAR group, the shortened length of stay led to a decreased overall hospital cost for EVAR ($37,068 vs. $42,970). However, by 2 years, this difference in cost was no longer statistically significant. In addition, the probability of EVAR being less costly and more effective was 71% for life-years and 51% for quality-adjusted life years (QALYs). Recently, a cost-utility model based on a meta-analysis of patients treated with EVAR or open repair of ruptured aneurysms was performed. EVAR was less costly compared with open repair ($26,133 vs. $28, 395).[17] The mean QALY was higher for EVAR compared with open repair (3.09 vs. 2.49). EVAR was thus cost effective compared with open repair at a threshold of $30,000 to $45,000/QALY.

Abstract

Endovascular aortic aneurysm repair is currently the mainstay of treatment for the elective repair of anatomically suitable aortic aneurysms. Appropriate repair requires in depth knowledge of the types of stent-grafts available, including their configurations, sizes, methods of "sealing" and physical properties. Successful treatment also requires precise preoperative measuring techniques, as well as extensive knowledge of vascular access techniques, stent graft deployment techniques and troubleshooting, the appropriate use of adjunctive procedures when warranted, and the management of intraoperative troublshooting and complications, including endoleaks. These areas are reviewed in the current chapter.

endoleaks

CHARACTERISTICS OF ABDOMINAL AORTIC STENT GRAFTS

Current commercially available systems have a wide variety of configurations that can treat the majority of infrarenal aortoiliac aneurysms. Various options exist for stent-graft fixation, sealing, patency, sizing, and durable exclusion of aortic aneurysms. Radiopacity, deployment precision, ease of use, and sheath size and flexibility are additionally important characteristics. Current commercially available infrarenal endografts and their respective U.S. Food and Drug Administration (FDA) approval dates can be seen in Table 73.1.

Fixation

An essential feature of all stent grafts is a method of fixation to inhibit distal migration from the seal zone after deployment. Aortic blood flow delivers constant caudad force against the proximal end of a stent-graft. In tortuous anatomy, augmented vector forces increase the risk of component separation and even cranial migration of the distal components. Aortic remodeling after endovascular aneurysm repair (EVAR) can also result in morphologic changes and cause stent graft component separation. These factors increase endograft susceptibility to distal migration, kinking, and limb thrombosis over time.

Positive Fixation, Column Support, and Friction

Multiple endograft features are designed to prevent graft migration and consequent complications. *Positive fixation* describes the use of metal hooks, barbs, anchors, or supplemental staples to attach the graft to the aortic wall and prevent migration. In endografts with stents that run the full length of the device, *column support* helps maintain the position of the cranial end of the device in place by straddling the aortic bifurcation for buttressed stability. The outward radial force of the stents themselves creates *friction* with the vessel wall that can reduce migration. However, increased risks of long-term migration in earlier devices without active fixation (AneuRx) have led to near universal incorporation of active fixation in current endograft designs. Some devices have polyester fuzz or other prosthetic material that induces a fibrotic reaction in the aortic neck that aids in graft fixation, and several devices include a combination of these characteristics.

TABLE 73.1 Current Commercially-Available FDA-Approved Infrarenal Aortic Stent Graft Devices

Device	Manufacturer	FDA Approval Date	Implants Worldwide (Approx.)
Excluder	Gore	2002	250,000
Zenith Flex	Cook Medical	2003	150,000
Endurant	Medtronic	2010	200,000
AFX	Endologix	2011	80,000

Infrarenal Versus Suprarenal Fixation

Infrarenal fixation describes active sealing at the proximal most aspect of the endograft in the infrarenal aortic neck. Endografts with suprarenal fixation employ a bare-metal stent that is separated from the sealing component of the infrarenal neck portion of the stent-graft, extending the fixation component into the pararenal and suprarenal aorta. The suprarenal aortic neck is typically more resistant to late dilation, and long-term fixation with this suprarenal fixation may be improved. If open conversion and complete graft explantation become necessary, removal of endografts with suprarenal fixation requires a comparatively more complex surgical approach.

Sealing

Almost any endograft will seal in an aortic aneurysm with an ideal straight, cylindrical, 15-mm-long neck without thrombus or calcification. Seal zone adjuncts include covered flares that expand beyond the nominal diameter of the main graft, polyester fuzz, sealing cuffs, and off-label stent utilization. The basic stent pattern of the seal zone of the device has a large impact on both sealing and conformability, which are critical factors for treating angulated necks. The scallop depth of the graft material at the cranial margin of the device also determines the effective required seal zone of the device.

Iliac Limbs

The unsupported limbs of early EVAR devices were often plagued by limb occlusion, which prompted frequent off-label use of stents within the originally unsupported limbs. Late fabric erosion with subsequent type III endoleak and aneurysm enlargement or rupture is one complication of this approach that illustrates a late pitfall of off-label use without adequate evidence of safety and effectiveness. Although most current fully supported endograft limbs provide excellent long-term patency, there is sufficient space between stents or stent rings in some devices to allow potential limb kinking, compression, and occlusion. Concomitant iliac arterial injury during EVAR, heavy circumferential distal aortic or iliac calcification, severe iliac tortuosity, and excessive graft limb oversizing are additional factors that may lead to limb occlusion.

Sizing

EVAR stent-grafts come in a wide range of aortic diameters, iliac limb diameters, and graft lengths that are labeled for varying arterial diameters and angulations. The complexity of case planning varies with each system because of differences in sizing windows, techniques, tapering zones, and usable seal zones.

Graft Material

The polyester or polytetrafluoroethylene (PTFE) graft material is similar to that used for open surgical repair. In contrast to open grafts, which become incorporated in fibrous retroperitoneal tissue, stent-grafts are suspended in the thrombus and may develop transudates or microfenestrations that do not close. The graft material may abrade with constant wear against metallic stent components or may be subject to weave deformation by attachment sutures. Sutures themselves may wear or break, causing subsequent increased abrasion. Some stent-grafts are sutured only at the ends of the stent, whereas others use a composite bonding process without sutures.

Radiopacity

Stent components are visible with high-quality fluoroscopic equipment, but some EVAR procedures are performed with portable C-arms, and visualization in these conditions may be difficult in heavy patients. Delivery systems and stent-grafts have additional radiopaque markers to facilitate rotational orientation, deployment, and gate cannulation. Such markers vary with each graft, and not all are positioned in the same position with respect to the graft's fabric edge, which is not itself radiopaque. Some markers are circumferential, whereas others are positioned intermittently around the circumference of the device.

Deployment Precision and Ease of Use

Deployment components vary in flexibility, trackability, valve function, outer diameter of the ipsilateral and contralateral sheaths, number of times that a large sheath must be inserted, and deployment precision. The labeling, torque responsiveness, need for exchange-length wires, difficulty in cannulation of a contralateral gate or snaring a contralateral wire, and other attributes all contribute to the relative complexity of the deployment sequence with each respective graft. Ease of use is thus only one aspect of a deployment system's performance.

Graft Selection and Primary Device Characteristics

Detailed knowledge of sizing, deployment techniques, failure modes, expected outcomes, and reintervention techniques is essential to provide a durable endovascular result. There are a few anatomic situations in which one particular device may be preferred, although even in these situations a surgeon with mastery of a single specific device could probably make that device work for even challenging cases (Fig. 73.1). Difficult iliac anatomy can often be treated with smaller systems or those featuring deployment systems with a higher degree of flexibility and trackability. Short lengths from the lowest renal artery to the aortic bifurcation can be better treated with some devices. Severely angulated, short aortic necks are not well treated with any approved system except the Aorfix, but more flexible investigational devices and off-label aortic stents can potentially overcome challenging proximal necks. Less angulated short necks may be addressed with branched or fenestrated devices or snorkel or chimney adjuncts (see Chapter 80).

Endograft Configurations

Bifurcated endografts are currently utilized in greater than 95% of EVAR cases. These are either modular (Endurant, Excluder, Trivascular, Zenith, Aorfix) or unibody (AFX—Endologix). In the infrarenal position, tube endografts are now utilized only for focal saccular aneurysms or penetrating ulcers that have sufficient normal distal aorta for a dependable seal. While there are no commercially available devices for this indication, off-label use of "stacked" aortic cuffs, larger iliac components, or small diameter thoracic extensions can be utilized for this purpose. Aorto-uni-iliac endografts (ReNu, Endurant) can be utilized in conjunction with a contralateral iliac occlusion device and a femoral-femoral bypass. The relative indications for use of this configuration are listed in Box 73.1. Branched and fenestrated endografts and chimney or snorkel grafts can be utilized in juxta/pararenal aneurysms and TAAA, where there is inadequate normal aorta to achieve a durable seal adjacent to a critical side branch.

Preoperative Sizing and Planning

Precise sizing and preoperative planning are essential for successful initial and long-term outcome after EVAR.

Preoperative Imaging

Computed Tomography Arteriography

Computed tomography arteriography (CTA) is the cornerstone of preoperative imaging for EVAR. The maximum recommended slice diameter is 2.5 mm for standard devices, while sizing for fenestrated or branched devices requires ≤1 mm cuts. Intravenous contrast should be routine unless the patient has severe renal insufficiency. The axial, coronal, sagittal, and three-dimensional (3D) reconstructions (Fig. 73.2A) should all be reviewed. Postprocessing software allows further image interrogation by generating centerline reconstructions, which aid in precise length and diameter measurements. Access to dedicated workstations that allow postprocessing and manipulation of images is ideal. Alternatively, such image processing is available by third parties. Standard digital subtraction arteriography (DSA) has little utility in the preoperative evaluation for EVAR and should not be routinely employed.

Patients with significant renal insufficiency present challenges in preoperative imaging prior to EVAR. Frequently, noncontrast computed tomography (CT) scanning provides enough anatomic information to proceed with standard EVAR. Diameter and length measurements can be made from such a study, and if the anatomy appears uncomplicated and there is no clinical suspicion of associated occlusive disease, it may be reasonable to proceed. Potentially important anatomic information can be missed, however, including: (1) the presence of laminated thrombus in the aortic neck, (2) patency of important side branches such as the hypogastric arteries, and (3) potential occlusive disease in the common or external iliac arteries.

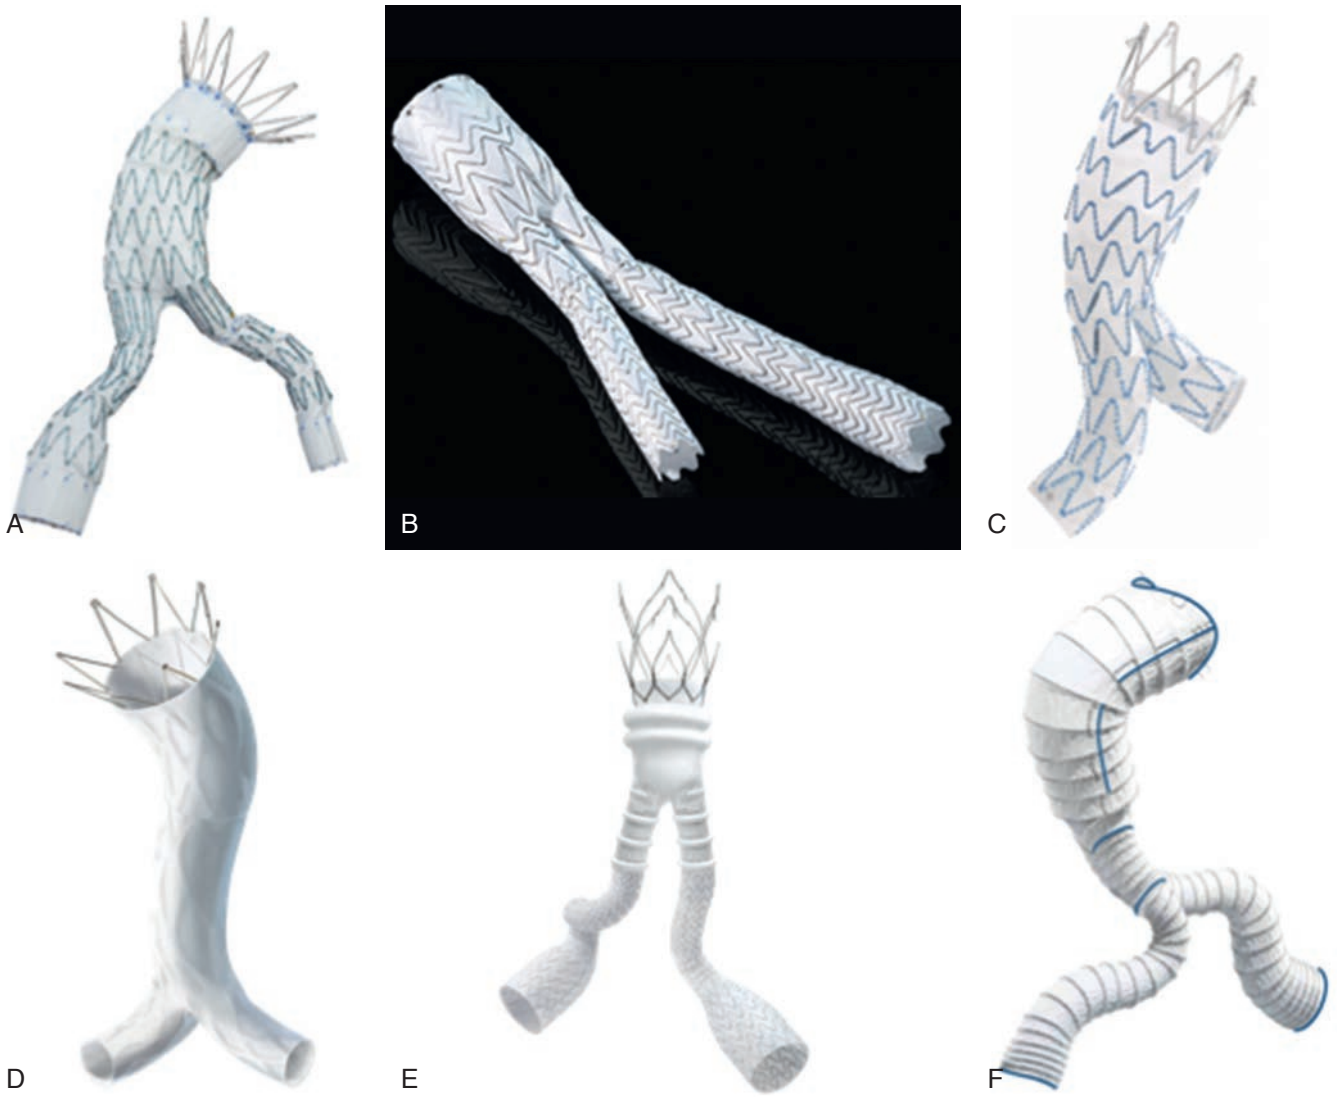

Figure 73.1 Commercially Available Endografts. A, Cook Zenith Flex; B, Gore Excluder; C, Medtronic Endurant IIs; D, Endologix AFX; E, Trivascular Ovation; F, Lombard Aorfix.

BOX 73.1 Relative Indications for Aorto-Uni-Iliac Endograft Configuration

- Very small (<15 mm) terminal aorta (which would not accommodate a bifurcated device)
- Severe unilateral iliac occlusive disease
- Secondary treatment of migration of a short-body endograft

Significant calcification in the iliac arteries, particularly the external iliacs, should make the operator suspicious that associated occlusive disease may be present.

Alternative Imaging

In the patient with severe renal insufficiency who needs further delineation of pertinent anatomy prior to EVAR, intravascular ultrasound (IVUS) can be used to size the aortic and iliac seal zones, evaluate for potential aortic neck eccentric thrombus, and interrogate the external iliacs for potential occlusive disease. Direct angiographic imaging can be obtained using CO_2 as the contrast agent with relatively good visualization.

Endograft Sizing

Aortic Neck Diameter

Measurement of the aortic neck diameter should be taken proximally at the level of the lowest renal artery and extend 15 mm caudal in 5 mm increments. These measurements should be made from the *minor axis* of axial cuts, or ideally from reformatted slices that allow a plane perpendicular to the centerline. The key here is not to overestimate diameter based on oblique CTA cuts of the tortuous aortic neck. Using electronic calipers, these measurements are generally made from adventitia to adventitia to size the aortic neck for most devices. Intima-to-intima measurements were used in the U.S. pivotal studies of the Excluder endograft (W.L. Gore) and are recommended for use with this device.

Endografts should be oversized 10% to 20% in comparison to the aortic neck. In practical terms, this usually translates

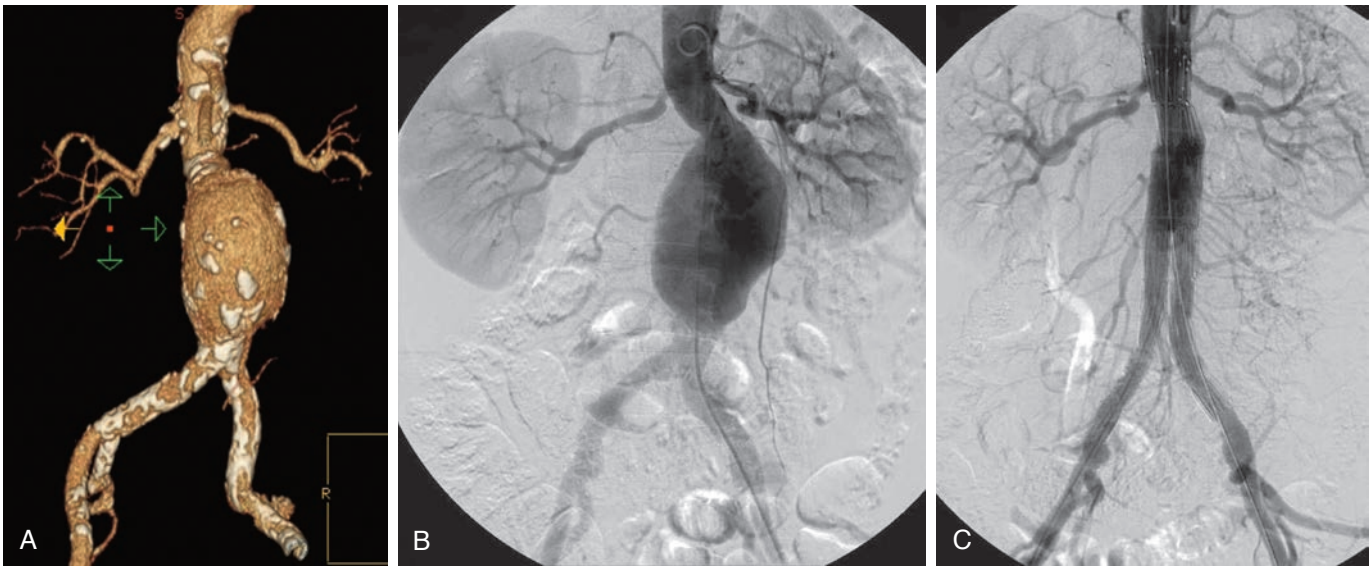

Figure 73.2 (A) Computed tomographic angiography reconstruction of a 6.3-cm abdominal aortic aneurysm (AAA). (B) Angiogram demonstrating the same AAA. (C) Immediate postendovascular aneurysm repair angiogram demonstrating exclusion of the AAA without endoleak.

TABLE 73.2 Specific Notable Characteristics of Current Commercially-Available Infrarenal Aortic Stent Graft Devices, Including Their Graft and Stent Material Design, the Sizes of Aneurysms Appropriate for Treatment With Each Respective Device, The Delivery System Profile, Proximal Fixation Level, and Other Unique Features.

Device	Graft Material	Stent Material	Treatable Aortic Neck Range (mm)	Treatable Iliac Artery Range (mm)	Delivery System Profile Main Body/ Limb (Fr)	Proximal Fixation	Unique Features
Excluder	ePTFE	Nitinol	19-29	8-25	16-20/12-15	Infrarenal	Repositionable proximal delivery system allows multiple attempts to achieve accurate proximal landing
Zenith Flex	Woven Polyester	Stainless Steel	18-32	7.5-20	21/14-16	Suprarenal	Partial proximal repositioning; shortened z-stents of main body and limbs inhibit migration and kinking
Endurant II	Woven Polyester	Nitinol	19-32	8-25	18/14-16	Suprarenal	Three piece system allows flexible *in situ* length sizing, approved to treat 10 mm proximal neck length
AFX	ePTFE	Cobalt Chromium Alloy	18-32	10-23	19/9	Infrarenal or Suprarenal	Unibody component provides anatomic fixation on aortic bifurcation

ePTFE, Expanded polytetrafluoroethylene.

into an endograft diameter that is 3 to 4 mm larger than the aortic neck. Currently, EVAR devices range from diameters of 18 to 36 mm and can accommodate aortic diameters of 16 to 32 mm (Table 73.2).

If there is not full apposition of the endograft to the aortic wall, the risk of a type IA endoleak is substantial. The risks of excessive oversizing are less obvious, however. Bench testing has demonstrated that oversizing greater than 20% creates pleats in the fabric (Fig. 73.3). This pleating of the fabric may contribute to an increased risk of a type IA endoleak and decreased fixation regardless of the endograft used.

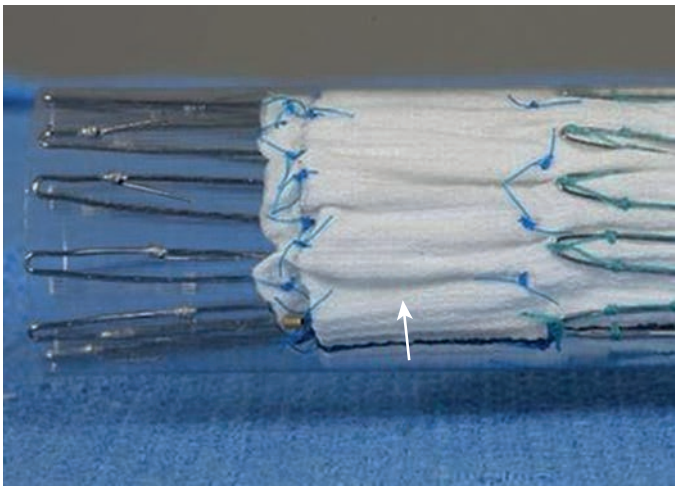

Figure 73.3 Oversizing causes pleating of the fabric *(arrow)*. This is a 28-mm Zenith endograft in a 22-mm tube (27% oversize). Such pleating increases the risk of type I endoleak and migration.

Sizing the Conical Aortic Neck

Patients with conical necks, meaning those with more than a 2 to 3 mm change in neck diameter over the first 15 mm length of aortic neck length, pose an interesting sizing conundrum. In a patient with an aortic neck diameter of 20 mm at the renal arteries that dilates to 24 mm at a position 15 mm caudal, sizing to the larger diameter would suggest the use of a 28 mm endograft. However, this would correspond to a proximal oversizing of 40%. Conversely, sizing to the smaller diameter, such as a 24 mm endograft in a 20 mm neck, would result in inadequate oversizing in a larger area caudally. In these situations, it is prudent to "split the difference," so as to give at least a minimum 10% oversizing in the larger segment and a less than 30% oversizing in the smaller segment. If the degree of size mismatch does not allow such sizing, for example in a situation where there is more than a 3 to 4 mm conical change in first 15 mm of neck, EVAR is not advisable.

Length Measurements

Accurate length measurement between proximal and distal landing zones is critical in selecting the correct endograft components. For EVAR cases, counting the axial cuts is accurate when calculating the distance between the lowest renal artery and the aortic bifurcation in the absence of significant tortuosity or aortic neck angulation. Axial measurements will underestimate the length between the aortic bifurcation and the hypogastric arteries, especially with tortuous vessels. Conversely, length measurements based on centerline calculations with EVAR will occasionally *over*estimate the true length needed.

Situations that typically require longer iliac limbs than the measurements suggest including the presence of extreme iliac tortuosity, when utilizing "balleting" of iliac limbs (Endurant and Excluder, Fig. 73.4) and when extension of the limbs to the external iliac arteries is necessary. In these anatomic circumstances, it is wise to choose a longer length, when in doubt.

Figure 73.4 "Balleting" of iliac limbs. This technique can facilitate cannulation of the contralateral gate of short-bodied modular endografts. A longer iliac limb is frequently required.

Modular devices with variable body lengths, such as the Cook Zenith system, give additional flexibility in sizing by allowing adjustment of the amount of overlap between the components. With this device, the contralateral iliac gate is ideally positioned 1 to 2 cm from the aortic bifurcation. Unlike the iliac components, when there is doubt about the correct main body length, the shorter length should generally be chosen. Other scenarios that would call for a shorter body length include patients with a narrow (<20 mm) distal aortic neck or those with an eccentric calcific "reef" in the terminal aorta. In these instances, after opening the ipsilateral limb, there may be inadequate room for the contralateral gate to open, making cannulation difficult. Of note, the Medtronic Endurant IIs, approved by the FDA in 2014, aims to address and simplify the main body and limb length issues. This stent graft features the shortest available ipsilateral and contralateral main body covered length at 103 and 80 mm, respectively. All main body limb diameters are fixed, allowing any limb to be used on either side. Limb length can therefore be determined during the procedure.

Iliac Diameters

Limbs for the iliac arteries should be sized 10% to 20% greater than their respective minor axis diameter. For non-ectatic iliac arteries, this generally translates into an iliac limb diameter 1 to 3 mm larger than the native vessel. Particular care should

be made to correctly size the iliac limb if extension to the external iliac is required. Excessive oversizing in this scenario may increase the risk of limb thrombosis. When extending to the external iliac artery, the limb should ideally land proximal to or greater than 15 mm distal to points of major angulation in order to avoid kinking and possible limb thrombosis. At least 2 to 3 cm length of distal seal is recommended in patients with large or tortuous common iliac aneurysms that may undergo significant conformational changes as the aneurysm remodels.

Patient Selection

The major anatomic factor in predicting suitability for EVAR is the character of the aortic neck, including the length, diameter, angulation, and shape of the neck. The instructions for use (IFU) of most current devices suggest a minimum neck length of 10 to 5 mm and angulation of less than 45 to 60 degrees. An exception to the limitations on neck angulation is found with the Aorfix device (Lombard), which is FDA approved for aortic neck angles ≤90 degrees. Considering proper oversizing and available endograft sizes, aortic neck diameters up to 32 mm can be accommodated. The shape of the neck is also important in both immediate and long-term success.

The ideal native anatomic configuration is a parallel aortic neck without eccentric laminated thrombus or heavy calcification. Patients with irregularly shaped necks will have a greater risk of inadequate seal and subsequent endoleak. In addition to patients with conical and reverse conical necks, the occasional patient will have a localized posterior bulge in the neck, the so-called double-bubble, which can compromise the seal zone.

While a patient with a single adverse aortic anatomic variable can frequently be treated effectively, those patients who have aortic necks with multiple compromising anatomic features are more problematic. Although highly angulated necks are associated with inferior outcomes, if the neck length is greater than 2 cm and the shape is parallel, the patient may be a reasonable EVAR candidate. Patients with neck lengths of 10 to 15 mm can frequently attain a good initial outcome in the absence of other anatomic compromise. However, the risk of late neck degeneration and a subsequent type IA endoleak may be increased, particularly in the setting of a larger aortic neck diameter or significant angulation. All devices will have compromised outcomes if the anatomic constraints are profoundly exceeded. Patients with aortic necks less than 10 mm in length should be considered for open surgical repair, fenestrated EVAR, or EVAR with adjunctive endovascular techniques.

ANESTHESIA, ACCESS, AND IMAGING

Anesthesia

The choice of anesthetic technique can be tailored to the patient's comorbidities and body habitus. In all situations, it is ideal to control the patient's respirations, either by vocal instruction or by control with the ventilator. Although general anesthesia is used commonly with percutaneous access, the use of local infiltration and intravenous sedation is possible and may be preferred in some clinical scenarios such as rupture. When utilizing open vascular access, a regional (spinal or epidural) or general anesthetic is favored by most operators. In a patient who may need an ilio-femoral conduit, general anesthesia is clearly the appropriate choice.

Vascular Access

Access to the femoral vessels can be achieved in an open surgical or percutaneous fashion.

Percutaneous Access

The popularity of percutaneous access for EVAR and thoracic endovascular aortic repair (TEVAR) has increased over the last 10 years. A recent systematic review of percutaneous access for EVAR cites the potential for a shorter procedure time, less postoperative pain, and a lowered risk of wound complications. A 2016 meta-analysis of three randomized controlled trials and 18 observational studies reported that percutaneous access for EVAR was associated with a significantly lower frequency of groin infection and lymphocele, and with a shorter procedure time and hospital length of stay compared with open surgical access. In addition, percutaneous access did not increase the risk of hematoma, pseudoaneurysm, or arterial thrombosis or dissection. Disadvantages of percutaneous access for EVAR include increased hospital cost and the occasional need for urgent conversion to open repair, which can be quite cumbersome. Percutaneous access is possible for sheath sizes up to 24 Fr. The reported success rates for percutaneous closure of ≥18 to 20 Fr sheath is 78% to 95%, increasing to 95% to 99% with sheaths 12 to 16 Fr. Of note, a substantial learning curve for the percutaneous technique has been observed. Given the 5% to 10% rate of failure in closure of larger arteriotomies with percutaneous access, the immediate availability of surgical expertise for operative exploration is essential. Box 73.2 lists the relative contraindications for this procedure. Preoperative imaging should be closely scrutinized for anatomic information regarding the common femoral artery, including its diameter, associated occlusive disease, particularly anterior calcification, and the location of the femoral bifurcation relative to the femoral head and inguinal ligament.

The percutaneous technique employs off-label use of suture-mediated closure devices in a "preclose" fashion. The common femoral artery is ideally accessed 1 to 2 cm proximal to its bifurcation but below the inguinal ligament. Some operators

BOX 73.2 Relative Contraindications to Percutaneous Access for Endovascular Aneurysm Repair

- Severely scarred groin
- High femoral bifurcation
- Need for frequent introducer sheath changes
- Significant proximal iliac occlusive disease
- Small iliofemoral arteries
- Anterior calcific femoral disease

routinely employ a micropuncture set with a 21-gauge needle and 3 Fr introducer rather than a standard 18-gauge needle. Routine use of ultrasound guidance in the transverse plane is highly recommended to increase the accuracy of arterial access. Verification of appropriate wire entry location should be routine. This is done through a small retrograde arteriogram with the appropriate ipsilateral oblique angulation of the image intensifier to better define the SFA and profunda femoris origins.

A 0.035-inch guidewire is then advanced into the aorta and a 6- or 7-Fr sheath placed. A 10- to 15-mm incision in the skin is made around the sheath. The sheath is then removed, and the wire track is aggressively dilated with a hemostat, down to the level of the artery. This is an important step to ensure that the Proglide knots will not "catch" on subcutaneous tissue and prevent hemostasis at the end of the procedure. The "preclose" technique may be performed with either a single 10 Fr Prostar or with two 6 Fr Proglide (Abbott Vascular) devices. Utilizing the Proglide devices, the first device is deployed with a 30-degree medial rotation. Maintaining wire access, the second device is deployed with a 30-degree lateral rotation. These devices place a single monofilament suture proximal and distal to the puncture site. The sutures are exteriorized and then tagged for later use when the delivery device is removed. An 8- to 10-Fr sheath is then replaced for hemostasis. Alternatively, a single 10 Fr Prostar device may be used. Some operators have suggested the routine use of serial "coons" dilators to predilate the tract and the arteriotomy after the preclose sutures have been placed but prior to delivery of the sheath for endograft delivery. This maneuver may decrease the chance of the "lip" of the dilator/sheath interface catching on the subcutaneous tissue or the arteriotomy itself.

After completion of the EVAR, the delivery sheath is removed while retaining guidewire access. Prior to sheath removal, the sutures are irrigated with heparinized saline to remove any clotted blood. We have also found that gentle traction of the blue suture prior to using the knot pusher will help "seat" the knot closer to the vessel. Hemostasis is maintained with manual compression until the preformed knots (Proglide) are cinched down with the knot-pusher. After hemostasis is confirmed, the guidewire is removed, and manual compression is reapplied. Reversal of the heparin with protamine is suggested at this time. If there is pulsatile bleeding after the two Proglide sutures are tied, a third Proglide can be placed over the existing wire and deployed. If there is continued pulsatile bleeding, an open surgical repair should be performed. Replacement of an appropriate sized dilator over the existing wire facilitates this exposure by providing a nonhemorrhagic field.

Open Surgical Access

With open access, either a vertical or oblique skin incision can be utilized. The advantages of a vertical incision include the ease of gaining additional exposure of the iliac and femoral vessels. Postoperative wound problems can be minimized by keeping the incision above the femoral crease, which is possible in most patients. The oblique skin exposure is favored by many operators because wound problems may be less frequent. This technique of open exposure may be particularly useful in the morbidly obese patient. If the angle into the femoral vessel is too acute, a small counterincision can be made inferior to the skin incision to facilitate sheath insertion.

Iliac Occlusive Disease

The iliac vessels should be carefully studied preoperatively with CTA so any potential difficulties in access can be anticipated. Focal iliac occlusive disease can be treated with balloon angioplasty immediately prior to endograft insertion. Bare metal stents should not be placed initially, however, as the large sheath for the endograft would need to be advanced through them, increasing the possibility of stent migration or arterial injury. If an iliac lesion warrants stent placement and is not covered by the distal extent of the endograft, the additional stent can be placed at the completion of the EVAR.

Hydrophilic "coons" dilators can be effective in dilating longer segments of occlusive disease, and may also alert the operator to potential issues with device tracking. These dilators should only be placed over very stiff wires to avoid wire kinking and arterial trauma. However, sometimes a larger sheath can be negotiated into the aorta with significant pressure, only to have catastrophic bleeding from iliac disruption upon removal of the sheath or with repeated exchanges. In addition, maintenance of wire access across a diseased, narrowed, or angulated segment during device and sheath removal is essential to allow potential endovascular salvage of life-threatening arterial injury. Confirmatory angiography after device or sheath removal is recommended.

There are other potential endovascular approaches to obtaining access in the setting of small iliac arteries. It is possible to create an "internal endoconduit" by placing a covered stent in the external iliac vessel, which is then aggressively angioplastied to the required diameter of 9 to 12 mm. The covered stent will protect against the extensive dissection and/or free rupture of the native vessel which can be caused by aggressive angioplasty. Clearly, there must be a sufficient proximal and distal seal zone for the covered stent. From a practical point of view, however, such ideal landing zones are not routinely present. Prudent patient selection is critical. While these techniques have been anecdotally reported with successful outcomes, larger series are needed to establish the safety of these adjunct access procedures prior to broader utilization. Recently a balloon-expandable sheath has become available to help in accessing smaller iliac arteries (SoloPath, Onset Medical Corp, Irvine, California). This sheath is delivered in an 11.5 to 15 Fr size and then dilated by an integrated balloon to sizes from 17 to 24 Fr.

Iliac Conduit Placement

The potential use of a surgically placed conduit should be in the "toolbox" of all operators performing endovascular aortic aneurysm repair. The need for a conduit is currently unusual, particularly with the introduction of lower profile devices. Nevertheless, patients with diffused calcified and very small external iliac arteries need a conduit in many circumstances. If the operator is concerned about access in this situation, serious consideration should be given to performing a surgical conduit without even trying to access the iliac artery. Visual inspection of the common femoral and terminal external iliac artery with open exposure can aid decision making in equivocal cases.

An iliac conduit is performed through a right or left low retroperitoneal incision. We favor a standard end to side anastomosis at the level of the distal common iliac artery. A 10-mm prosthetic conduit (Dacron or PTFE) will accommodate the largest needed sheath. The conduit should be tunneled under the inguinal ligament through a femoral counterincision. The distal end of the conduit is then clamped to the drapes and accessed in the usual fashion. After the EVAR is completed, most operators elect to anastomose the distal end of the conduit to the common femoral artery in an end-to-side fashion. Alternately, the conduit can be removed, leaving a small "stump" on the common iliac artery.

Imaging

Equipment

High-quality fluoroscopy and angiographic equipment is essential to successful EVAR. A contemporary fixed-imaging unit as part of a "hybrid" odds ratio (OR) room is increasingly utilized in many institutions. The performance of fenestrated or branched EVAR mandates this level of imaging. Portable C-arm fluoroscopy with a modern unit is acceptable for standard EVAR but cannot provide the versatility and imaging capabilities of fixed units.

Gantry Positioning

The precision of proximal endograft deployment with EVAR is considerably enhanced by adjusting the gantry of the fluoroscope to be perpendicular to the axis of the aortic neck. A large percentage of infrarenal aortic necks have a modest amount of anterior angulation, which should be adjusted for by adding an appropriate amount of cranial tilt to the fluoroscopy unit. The amount needed can be estimated by the preoperative CTA. The majority of infrarenal aortic necks have 5 to 15 degrees of cranial angulation, but this increase to as much as 30 to 40 degrees in highly angulated necks. Adjusting the left/right obliquity is also helpful in precisely locating the origin of the lowest renal artery. The left renal artery typically comes off the aorta slightly posterior to the centerline, while the right renal most commonly originates somewhat anterior to the centerline. An appropriate amount of left anterior oblique (LAO) will give the proper orientation to the renal arteries in most cases. Frequently, this translates to approximately 10 to 20 degrees of LAO. These adjustments are particularly important in patients with short or angulated aortic necks.

EVAR DEPLOYMENT

Wire Placement

After bilateral open or percutaneous femoral access is achieved, a floppy J-wire should be placed in the proximal thoracic aorta and exchanged over a catheter for a stiff guidewire (Lunderquist, Amplatz Super Stiff, or Meier). Failure to routinely visualize the location of these stiff wires in the aortic arch increases the risk of inadvertent cannulation of an arch vessel, aortic or branch vessel trauma, plaque disruption and stroke. After the stiff wire is placed, the distal end of the wire should be marked on the operative drape so that a stable position is ensured throughout the procedure. Through the contralateral femoral access, a pigtail catheter is then placed just above the renal arteries, which is usually between the L1 and L2 vertebral bodies. If there is concern about iliac occlusive disease, an angiogram should be taken at the aortic bifurcation and the occlusive disease treated as detailed previously. If there is uncertainty regarding the correct main body length to select, an aortogram with a 1 cm graded marker catheter can be performed to confirm the distance between the lowest renal artery and the ipsilateral hypogastric artery origin. Otherwise, arteriography should not be performed until the undeployed main component is advanced into the pararenal aorta. Particularly in patients with significant iliac or aortic neck tortuosity, placement of the undeployed endograft in the pararenal aorta may alter the relative position of the renal arteries as the aorta accommodates to the hardware over a stiff wire, making preinsertion arteriography inaccurate.

Delivery of the Main Device

The contralateral gate or limb of the main device should be appropriately oriented by fluoroscopic evaluation prior to insertion. This orientation should be rechecked as the device is being advanced and during any rotational adjustments made while the device is advancing to eliminate friction associated iliac injury. In addition, attempts to rotate the device statically may not translate to the entire device, particularly in tortuous or small iliac arteries. Failure to follow these principles can cause a relative twist and misdeployment of the endograft

If the endograft is not advancing smoothly, the first step is to change to an extra stiff guidewire such as a Lunderquist. Using this wire and current trackable endografts, it is uncommon to fail to deliver the endograft to the desired location. Rarely, external manipulation of the distal aortoiliac segment may be beneficial. An assistant stabilizes the aorta from the contralateral side of main device placement by placing a hand on the lateral edge of the aneurysm, thus helping reduce any additional induced tortuosity created by advancement of the endograft. Finally, one should reconfirm that unexpected occlusive disease is not contributing to the inability to advance the endograft. If these maneuvers are not successful, use of a "buddy wire" should be considered. A second extra stiff wire can be placed through the iliac helping to further straighten the tortuous segment.

Proximal Endograft Deployment

After the main device is placed in the pararenal aorta and the contralateral gate/limb position is satisfactory, the gantry position of the fluoroscopy unit is adjusted with the appropriate amount of cranial and oblique angulation as detailed previously. A magnified view should be utilized, with the lowest renal artery in the center of the screen and proximal graft marker position verified to minimize parallax errors. Using a power contrast injector, a short-burst injection using a high rate to small volume ratio will allow good visualization of the renal arteries with a small amount of contrast. A 20 cc/s injection rate with a total of 7 to 15 cc of contrast is usually sufficient, depending on the equipment and patient's body habitus. It is essential to visualize

both renal arteries. If the lowest renal artery is not close to the center of the image, the table or fluoroscopy unit should be adjusted, and the image repeated.

With devices that are designed for a slow step-wise deployment (Endurant, Excluder, Zenith), initial deployment should begin approximately 1 cm above the intended target position. The endograft should then slowly be pulled down until the proximal extent of the device fabric sits immediately below the lowest renal artery. After the initial proximal deployment, the gantry position may be adjusted further to ensure a perfectly perpendicular alignment with the aortic neck. The anterior and posterior aspects of the endograft should appear superimposed if the gantry position is parallel to the aortic neck. If they do not, the degree of cranial tilt can be adjusted, and the arteriogram repeated. The goal is to place the endograft within 2 mm of the caudal edge of the lowest renal artery orifice. Maximal overlap of the graft within the aortic neck will increase the seal zone and reduce the likelihood of a type IA endoleak and late migration.

After the proximal landing zone of the endograft is established, deployment of the endograft continues until the contralateral gate is deployed. Many operators will then recheck the position of the endograft relative to the renal arteries at this time. Deployment of a bare suprarenal stent is now generally performed with devices that have this feature. After deployment of the bare suprarenal stent, no further movement of the main device is possible. An exception to this principle is found with the C3 Excluder endograft (W.L. Gore), which has no suprarenal stent and can be reconstrained and repositioned if the initial position is not ideal.

Accessory Renal Artery Management

In patients with normal renal function, it is generally safe to cover such an accessory renal artery with the endograft. Embolization of the vessel prior to coverage is not generally performed. Patients with significantly impaired renal function pose a more difficult situation. Further reduction in a patient's renal function by coverage of an accessory renal artery is far from ideal. However, alternate approaches, including a fenestrated endograft or open surgical repair, have markedly elevated morbidity and mortality in the patient with significant renal insufficiency.

Contralateral Gate Cannulation

For modular devices, the next step is cannulation of the contralateral iliac gate. This step is obviated if a unibody device such as the AFX Endologix is utilized. Retrograde cannulation of the gate should be possible in greater than 95% of cases. Several "pearls" will facilitate this maneuver. Perhaps the most important step is planning appropriate gate orientation for favorable cannulation. Deployment of the gate in a slightly anterolateral position will usually compliment the angle of the iliacs and allow straightforward access. With short body devices such as the Endurant and Excluder, it is sometimes easier rotate the contralateral gate ipsilateral to the main limb, thus crossing or "balleting" the limbs. This maneuver is particularly helpful if the angle of the proximal common iliac artery is splayed laterally, there is a large aortic sac, or the anterior-posterior diameter of the aortic bifurcation is significantly less than the left-right diameter. With a long body device such as Zenith, the contralateral gate should be within 1 to 2 cm of the iliac artery, and thus balleting the iliac limbs is inadvisable. In cases where one common iliac has significantly more lateral angulation than the other, placing the main device in the *more* tortuous side will facilitate the contralateral gate cannulation.

Several maneuvers will speed cannulation of the gate:

1. After retrieving the pigtail or other angiographic catheter, avoid pulling the wire back into the iliac artery. If there is severe tortuosity or a narrow distal aortic neck it can occasionally be challenging to regain access to the aneurysm sac.
2. Choose a steerable angled wire such as an angled Glidewire and an appropriately angled catheter such as a DAV/Bernstein or Vanchie 4.
3. Position the contralateral sheath (8 Fr × 25 cm or similar) at the bifurcation just proximal to the respective common iliac orifice for increased catheter support.
4. Oblique the fluoroscopic views to maximally "open" the gate. Using both the catheter and wire to steer, attempt to place the wire into the gate. If the wire first appears to be in the appropriate orientation with the gate but ultimately is not, then the operator knows that the wire is either anterior or posterior. In such a case, by changing the obliquity of the fluoroscopic image with the wire in place, it will then become clear whether anterior or posterior deflection is needed. If the wire is seen to transiently engage the gate fabric but not cannulate successfully, subtle, controlled movements of the catheter tip to slightly change the angle of the wire should follow until the gate is accessed. Occasionally a different-shaped catheter will facilitate cannulation.

Confirmation of proper gate cannulation is essential and can be done with angiography or by spinning the pigtail catheter in the area of the aortic neck. Some operators utilize a 12- or 14-mm balloon inflated in the gate while the gantry is rotated to confirm appropriate positioning. Failure to routinely confirm the wire position can result in deployment of the limb outside of the gate.

Rarely the contralateral gate cannot be cannulated in a retrograde fashion despite utilization of the above maneuvers. Failure to cannulate is usually the result of the gate not opening adequately because of a small (<20 mm) distal aortic neck, an eccentric calcific distal aortic "reef" (long body devices) or extreme tortuosity (short body devices). In such situations, the gate should be cannulated in an antegrade fashion, usually via brachial access. Once a wire is negotiated through the gate in an antegrade fashion from above, it is snared in the respective iliac artery and withdrawn through the corresponding femoral access sheath. Then, over a catheter, the wire can be exchanged for typical retrograde deployment. An alternate method of antegrade cannulation is to approach the gate by going "up-and-over" the flow divider with an appropriately shaped catheter, such as a Simmons 1, or SOS. However, our experience has been that the anatomic issues that made retrograde cannulation impossible also make this approach problematic and frequently unsuccessful. Recently

available steerable sheaths do provide better support and can allow for easier "up and over" antegrade catheterization.

If all attempts at gate cannulation are unsuccessful, the final bailout technique is conversion of the bifurcated device into an aorto-uni-iliac configuration. This maneuver should be needed in less than 1% of cases. With the Zenith device, this is accomplished with a specifically made converter endograft that is deployed within the main body, excluding the contralateral gate. A similar configuration can be accomplished with other modular devices by either the use of stacked aortic/iliac cuffs, an aortounibody graft, or deploying a second main body device within the existing main body device with the contralateral gate oriented 180 degrees opposite the existing contralateral gate. After conversion to such a configuration, an occluder must be placed in the contralateral common iliac artery, and limb perfusion reestablished with a femoral-femoral bypass.

Limb Deployment

Once contralateral gate cannulation is confirmed, the distal landing zone in the iliac artery is established with a retrograde arteriogram shot through the previously placed iliac sheath. The image intensifier should be positioned with complimentary, contralateral obliquity to best visualize the takeoff of the respective hypogastric artery; this is typically 20 degrees LAO for the right iliac and RAO for the left iliac. Appropriate angulation should be determined during evaluation of the preoperative images and reconstructions. If the required length of the limb is in question, a marker catheter can be placed over the wire. Ideally, more iliac overlap is preferred over less. The absolute minimum overlap into the iliac artery (common or external) is 2 cm in a patient with nontortuous vessels and a less than 6 cm AAA. Patients with larger AAA and/or tortuous anatomy should receive longer iliac coverage, if possible. These patients may have greater conformational changes as the AAA sac thromboses and shrinks in the postoperative period, putting increased axial strain on the device components. This scenario can produce migration of the iliac limb with a subsequent type IB endoleak, graft kinking, and limb thrombosis, or component separation.

In patients with extremely tortuous iliac arteries, landing the distal end of the device within 1 centimeter of an acute angle should be avoided. Any kinking or stenosis of the endograft limbs should be aggressively angioplastied, usually with a compliant balloon (Coda, Reliant). If any significant residual stenosis persists, one should consider the placement of a self-expanding stent within the endograft. Occasionally a narrow distal aortic neck compresses both iliac limbs. Use of simultaneous, conventional, noncompliant angioplasty balloons will usually resolve this issue. If there is significant recoil, the use of bilateral balloon-expandable stents in this location should be considered.

A compliant molding balloon (Coda, Reliant, P50) may be utilized at the aortic neck, iliac gates, and distal iliac limb to optimize seal (Fig. 73.5). It is important not to overinflate this balloon outside the proximal or distal aspect of the endograft. Rupture of the pararenal aorta and iliac arteries has been reported after overly aggressive inflation of these compliant balloons.

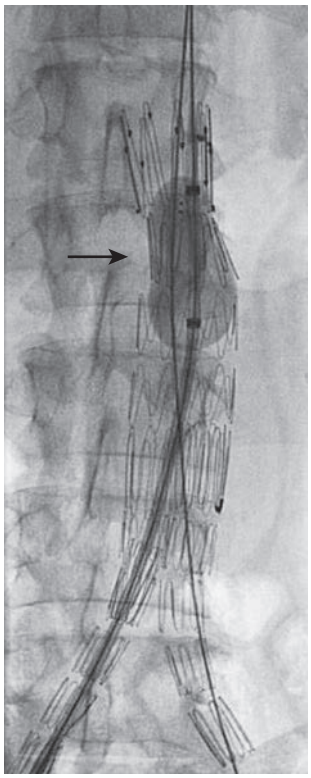

Figure 73.5 Use of a compliant molding balloon (Coda) on the aortic neck to optimize the seal *(arrow)*.

Completion Arteriography

After endograft placement is completed, a completion arteriogram is performed through an angiographic catheter placed in the pararenal aorta (see Fig. 73.2C). Use of a power injector with an injection rate of 15 cc/s and a total contrast volume of 30 cc is recommended. Because the large sheath size of devices will frequently reduce iliac flow, these should be routinely aspirated with 20 cc syringes during the injection. Image acquisition should continue for a minimum of 5 sec after the contrast in the iliac arteries has washed out to allow visualization of late type II endoleaks. The completion arteriogram should be systematically and carefully studied in the following manner:

1. Confirm patency of the renal and hypogastric arteries.
2. Assess the precision of the proximal and distal endograft landing zone apposition. The proximal extent of the endograft should be ideally within 2 mm of the lowest renal artery. If this distance is considerably greater, and the residual seal zone is less than 10 to 15 mm, placement of an aortic cuff should be considered, even in the absence of a type IA endoleak. Likewise, iliac extensions should be placed if there is inadequate overlap with the iliac artery or if a type IB endoleak persists after balloon dilation.
3. Evaluate for unsuspected occlusive external iliac disease. If significant tortuosity in the iliac vessels exists, the stiff wires in place for the endograft deployment should be exchanged for flexible wires prior to the final arteriogram. Stiff wires will occasionally cause the tortuous iliac artery to "accordion," giving the radiographic appearance of severe stenosis

(Fig. 73.6). These pseudo-lesions will disappear with removal of the stiff wire. True occlusive lesions should be treated accordingly.

4. Assess for endoleak.

EVAR TROUBLESHOOTING

Type I and III Endoleaks

Every effort should be made to definitively treat any initial type I or III endoleak prior to leaving the endovascular suite. Type II endoleaks should be observed, as the large majority will spontaneously resolve without intervention. In general, the early appearance of endoleak after contrast injection almost always signifies a type I or III endoleak, whereas late-appearing endoleaks are more commonly type II. However, even late contrast seen in the sac adjacent to the proximal or distal seal zones is worrisome for a type I endoleak and should be aggressively interrogated. Additional magnified views with differing obliquities may be helpful in establishing the presumptive type of endoleak.

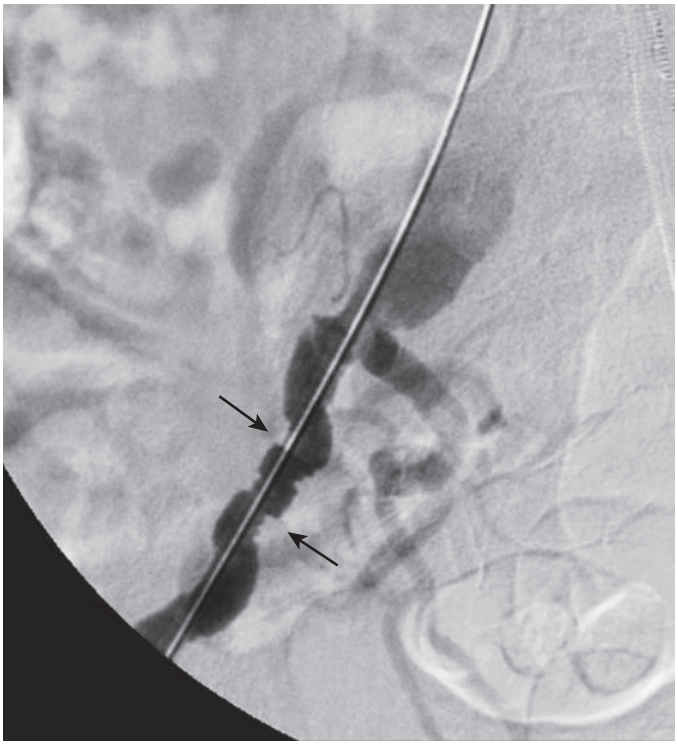

Figure 73.6 "Pseudolesion" of the external iliac artery *(arrows)*. This is caused by placement of a super-stiff wire in a tortuous vessel, causing it to "accordion" around the wire. Removal of the stiff wire corrects the stenosis without adjunctive measures.

Aortic Cuffs

Initial type IA endoleak treatment is predicated on the proximity of the endograft to the lowest renal artery. If this distance is less than 3 mm, the seal zone should be angioplastied with a compliant molding balloon. If the distance is greater than 5 mm, placement of a proximal aortic cuff followed by compliant balloon angioplasty should be performed.

Giant Palmaz Stent Placement

If a type IA endoleak persists despite the above maneuvers, placement of a giant Palmaz stent should be considered (Fig. 73.7). A 4010 or 5010 Palmaz stent is hand mounted on an appropriately sized valvuloplasty balloon (Braun Z-Med) in a slightly asymmetric fashion such that more of the proximal extent of the balloon will inflate first. The existing main body delivery sheath, or comparable sized sheath, is then advanced beyond the intended deployment zone. The Palmaz stent is then carefully delivered through the sheath with continuous fluoroscopic observation to confirm the position of stent on the balloon. One should be aware that the stent will foreshorten significantly as it is expanded. While it is 5 cm in length at 10 mm of expansion, it shortens to approximately 3.8 at 28 mm of expansion. To prevent the stent from "watermelon seeding" and potentially misdeploying during balloon inflation, the distal two-thirds of the stent is constrained in the delivery sheath while the initial balloon deployment is performed (Fig. 73.8). Because the stent is slightly asymmetrically mounted, no movement should occur. After the proximal portion of the stent is expanded, the sheath in carefully retracted and the remainder of the stent is deployed. In most cases, use of a compliant molding balloon is needed

Figure 73.7 (A) Short aortic neck immediately before endovascular aneurysm repair. (B) Type IA endoleak *(arrow)* after initial endograft placement and molding balloon angioplasty. (C) Resolution of the type IA endoleak after placement of a 5010 "giant" Palmaz stent (*arrows*, proximal and distal extent).

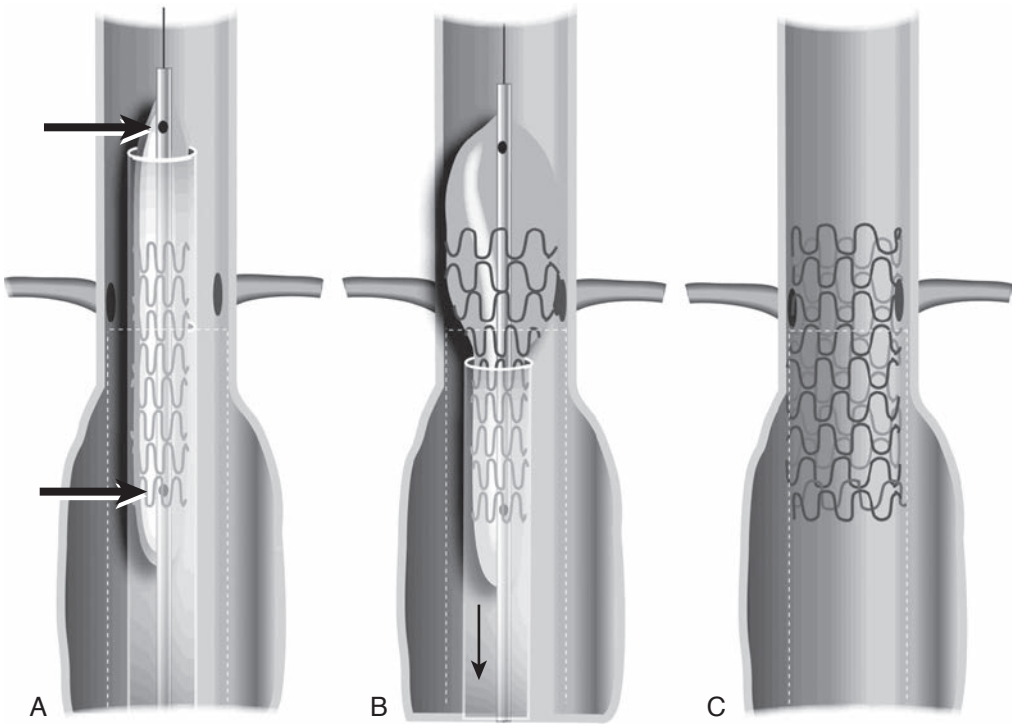

Figure 73.8 Sequence of the modified deployment technique of a "giant" Palmaz stent in the perirenal aorta for repair of a type IA endoleak. The *white dotted lines* represent the previously placed endograft for endovascular aneurysm repair. Details of the endograft have been omitted to enhance the clarity of the giant Palmaz stent device. (A) The stent (Palmaz 3010, 4010, or 5010) is hand-crimped off-center on a valvuloplasty balloon *(arrows)*. The balloon-mounted stent is then positioned at the intended area of deployment through the sheath under fluoroscopic guidance. (B) The sheath is partially retracted, and the balloon is inflated, deploying the proximal (cranial) portion of the stent. The off-center mounting of the stent ensures that it will not "watermelon-seed" craniad; the sheath prevents caudad displacement. (C) Fully deployed stent. (Redrawn from Kim JM, et al. A technique for increased accuracy in the placement of giant Palmaz stents for treatment of type I endoleaks following EVAR. *J Vasc Surg.* 2008; 48:755-777.)

after removal of the valvuloplasty balloon to optimize apposition of the Palmaz stent to the endograft.

Endo-Anchors

Another option for treatment of a type IA endoleak is the use of a device that "staples" or "anchors" the stent graft to the aortic neck to achieve better apposition. There are several devices currently on or coming to the market, led by the Heli-FX EndoAnchor system (Aptus Endosystems), which received FDA approval in 2011. It consists of two devices used in concert: a16-F outer-diameter deflectable sheath, the Heli-FX Guide, and an electromechanical, motorized delivery device, the Heli- FX Applier, which implants the actual EndoAnchor. The anchor itself is a metallic alloy, helical screw implant with an atraumatic tip that is 4.5 mm in length, 3 mm in diameter, and made of a round wire that measures 0.5 mm in diameter. A minimum of four anchors are recommended for aortic necks up to 29 mm in diameter, and at least six anchors are required for larger necks. A tapered point and "crossbar" allow penetration through calcified tissue but prevent penetration through the adventitia of the aortic wall.

Type IB endoleaks should be initially treated with repeat angioplasty at the distal seal zone. If this is not successful, extension of the limb with an appropriately sized cuff of limb should be performed. Type III endoleaks should almost always resolve with angioplasty, assuming the correct amount of overlap was achieved, and the limb was sized appropriately. If the overlap between components is not adequate, one should place a bridging iliac component.

Renal Artery

Inadvertent partial or complete coverage of a renal artery by the endograft should be a rare occurrence, but knowledge of "bailout" strategies can prove invaluable. It may be possible to caudally displace the endograft by pulling on a wire that has been placed over the flow divider, snared, and brought out the contralateral femoral artery sheath. Alternately, a large compliant balloon can be inflated just above the flow divider and caudal pressure applied. These maneuvers should be utilized with extreme caution to avoid aortic injury. Placement of a balloon-expandable stent in the respective renal artery can restore flow in most cases, and this is the preferred treatment strategy. Depending on the percentage of renal ostium covered and the amount of caudal angulation of the renal artery, a brachial approach can facilitate this maneuver, especially if suprarenal endograft fixation was utilized. If none of these endovascular options is successful, extraanatomic bypass via an iliorenal or

hepatorenal approach is possible. As a last resort, acute open conversion could be considered.

The management of the incidentally discovered renal artery stenosis should follow the same indications as that of isolated renal artery disease. Generally it is best to treat the renal artery stenosis after EVAR. This sequential treatment may be done at the same setting or in a staged manner. The rationale for this approach is that theoretical dislodgement or crushing of the renal stent could occur during manipulation and deployment of the aortic endograft. These concerns are more pronounced when using devices that are commonly deployed slightly above the renal arteries and then moved caudally into their final positions (Endurant, Zenith). An exception to this rule is the patient with either severe renal insufficiency due to renal artery stenosis or severe hypertension that increases the perioperative risk of EVAR. In such circumstances, staged treatment of the renal artery stenosis prior to EVAR is indicated.

Iliac Artery

External Iliac Extensions

Ectatic common iliac arteries up to 2 cm in diameter are suitable landing zones for the iliac limbs of an aortic endograft. However, common iliac arteries greater than 2 cm generally necessitate extension of the endograft to the external iliac artery to ensure adequate distal sealing. When extending to the external iliac artery, one should be particularly mindful of excessive oversizing, as this can predispose to limb thrombosis or type IB endoleak. There is frequently significant iliac tortuosity in these cases, which makes accurate length measurement difficult.

Hypogastric Artery

Embolization

The most frequently utilized approach is embolization of the proximal hypogastric artery to eliminate the possibility of a type II endoleak (see Chapter 72). Coverage of the hypogastric artery without embolization has been described and may be an appropriate choice in some situations. Although rare, the theoretical limitation of such a strategy is a persistent type II endoleak from the internal iliac artery that contributes to aneurysm growth.

Preservation

Preservation of flow to the hypogastric artery can be achieved either with the use of a branched endograft, the placement of a covered stent from the hypogastric artery into the ipsilateral external artery combined with a contralateral aorto-uni-iliac endograft and a femoral-femoral bypass, or a short open bypass or transposition from the external artery (see Chapter 72).

Management of Late Type II Endoleaks

Indication

Type II endoleaks associated with AAA sac growth of ≥5 mm should generally be treated. However, there is no level 1 or 2 evidence supporting a specific threshold for intervention of type II endoleaks. Embolization of the inferior mesenteric artery (IMA) prior to EVAR has been performed in an attempt to decrease late endoleak, but these interventions have not demonstrated aggregate late benefit.

Diagnosis

A high quality thin-cut CTA can reveal the source(s) of type II endoleak in many cases. Frequently, continuity between patent lumbar vessels and/or the IMA and the AAA sac is evident with contrast opacification. However, detailed angiography is generally recommended to confirm the etiology of the endoleak prior to treatment. In addition, the possibility of occult type I or type III endoleaks as the etiology for sac expansion should be eliminated. In a recent series of treatment for type II endoleak, more than 20% of patients were found to have an occult type I or III endoleak. After the proximal and distal seal zones and component connections are interrogated, selective arteriography of the superior mesenteric artery (SMA) and hypogastric arteries may be needed to identify the source of the type II endoleak.

Treatment

Box 73.3 lists the various options for treatment of type II endoleaks. A central tenet to successful treatment of type II endoleaks is occlusion of the offending branch vessel as centrally as possible—ideally at its takeoff from the aneurysm sac. Embolization of a more peripheral feeding branch has a high failure rate, as new collateral pathways frequently maintain flow into the IMA or relevant lumbar vessel.

Endoleaks from the IMA are most commonly managed by transarterial coil embolization. This is performed by accessing the middle colic artery via the SMA, providing retrograde access to the proximal IMA through the arc of Riolan or marginal mesenteric artery. A hydrophilic 0.014 wire and 3 Fr supporting microcatheter should be advanced to the ostial IMA, and microcoils deployed in the first ~1 cm of the vessel to avoid flow disruption to the middle sacral artery and other colorectal collaterals.

Alternatively, direct antegrade access to the IMA can be achieved from within the aneurysm sac by several methods. Occasionally it is possible to obtain access to the sac by placing a hydrophilic wire in retrograde fashion between the endograft limb and the native iliac artery, giving direct transarterial access. Translumbar puncture of the AAA sac (frequently using CT or

IMA, Inferior mesenteric artery.

fluoroscopic guidance) is the most popular route for antegrade access to branch vessels. Finally, transcaval access to the AAA sac has been described.

Endoleaks from patent lumbar vessels can be treated with transarterial coil embolization, typically via hypogastric artery branches, using a microcatheter system. However, it is sometimes difficult to advance the microcatheter to the ostium of the lumbar vessel because of native vessel tortuosity. Translumbar access to the AAA sac for embolization with glue or coils facilitates this process and is favored by some operators for the treatment of lumbar endoleaks. The use of glue from this approach may allow simultaneous occlusion of multiple branch vessels. Endovascular treatment of type II endoleaks has a relatively high failure rate, with a 20% need for reintervention and a freedom from AAA sac growth of only 43% at 5 years.

Finally, open approaches to treatment of type II endoleaks are possible, but usually reserved for repeated endovascular failure and concomitant sac growth. The IMA can be ligated laparoscopically; because proximal control of the vessel is required with this approach, advanced laparoscopic skills are needed. Direct ligation of lumbar vessels via a laparotomy is possible, but seldom utilized.

Rupture of an abdominal aortic aneurysm (RAAA) remains a lethal condition despite advances in all aspects of care.[1,2] RAAA repair has a 5-fold to 10-fold higher mortality[3] compared with elective repair.[4] Despite advances in perioperative management and service centralization, open RAAA survival rates have only marginally improved. A shift to REVAR techniques has improved outcomes, with reductions in mortality noted in population and randomized data.[4-12] A major decline in RAAA incidence is evident in the United States and Europe.[9,13-15]

TERMINOLOGY AND HISTORY

Definitions

RAAA is an abdominal aortic aneurysm (AAA) with extraluminal blood on computed tomography (CT) or noted clinically at the time of surgery. A contained rupture refers to blood outside the aneurysm sac confined to the retroperitoneal space. A free rupture refers to bleeding directly into the peritoneal cavity. A symptomatic, nonruptured AAA is one with back pain or tenderness over the aorta on deep palpation but with an intact aneurysm on CT and at surgery. The pain is thought to be secondary to acute expansion of the wall, intramural hemorrhage, wall degeneration, or bleeding into the thrombus and is considered a prelude to rupture. Symptomatic aneurysms are not associated with hypotension; however, the prognosis is much better than that of RAAAs (but worse than after elective repair).[16] Symptomatic aneurysms require rapid diagnosis and urgent management to prevent rupture; however, inclusion within RAAAs data can artificially improve outcome data.[17]

History of Ruptured Abdominal Aortic Aneurysm Repair

The first successful reconstruction for RAAA was by Henry Bahnson with a homograft in 1953.[18] By 1954 Cooley and DeBakey had treated six RAAA patients, with a 50% survival rate.[19] Just as elective open aneurysm reconstruction was rapidly applied to ruptures, so too was endovascular aneurysm repair (EVAR), with Hopkinson reporting the first REVAR in England in 1994.[20]

EPIDEMIOLOGY

Declining Incidence

The true incidences of RAAA have historically been difficult to quantify. In the 1950s a diagnosis of RAAA was made on clinical grounds (or at autopsy), without CT or other abdominal imaging, and missed those who died out of hospital, because deaths were attributed to another cause. The incidence of RAAA was thought to be increasing based on a Swedish population study in which the incidence almost doubled between 1971 and 2004.[21] The incidence of RAAA in men increased threefold despite more elective repairs.[22] In 2011 a decline in the incidence of ruptured (and intact) AAA began to be reported in most Western populations. In Australian men the number of deaths from RAAAs fell by 38% between 1999 and 2006[23]; in New Zealand the decline was 53%.[24] A review of population-based mortality in England and Wales from 1979 to 2009 showed a steady increase in deaths from RAAAs, especially in men, until 1996, then deaths declined.[3] In Medicare beneficiaries from 1995 to 2008, AAA-related deaths halved, with the greatest decline seen in patients older than 80 years.[14] Data from the Centers for Disease Control and Prevention reported that in 1999–2014 deaths from RAAA dropped across all ages and in both sexes (Fig. 74.1). RAAA deaths have declined by 33% for men and women together.[25] Deaths are more frequent in men compared with women and the peak age for females was older than for men. Confounding information from a detailed prospective analysis of acute AAA in Oxfordshire, United Kingdom demonstrated the rates of symptomatic and ruptured AAA were 30% to 40% higher than the local and national coding data, but the rates have fallen in the younger age groups over the past 2 decades.[26]

Population screening has been shown to reduce AAA-related deaths,[27] but the decline in mortality due to RAAA began before widespread population screening. EVAR may have led to more elective AAA repairs in older and less fit patients, thereby reducing the at-risk population for RAAA.[28] The biggest reduction in absolute numbers of RAAA has come from a decline in the prevalence of intact AAA identified in the Swedish (1.7%[29]) and UK screening programs, where the detection rate is only 1.7%, less than the 4% detection rate expected.[30] This has been attributed to decreased levels of smoking and improved control of cardiovascular risk factors.[26,28,31,32]

Overall Mortality of Ruptured Abdominal Aortic Aneurysm Repair

Two population-based series of RAAA mortality rates were 89% and 86% for RAAAs.[6,33] In 2006 a population-based Swedish study[21] with a high autopsy rate reported that the early mortality rate (death in the community or during hospitalization) was 74% and that in 2004, only 48% underwent repair.

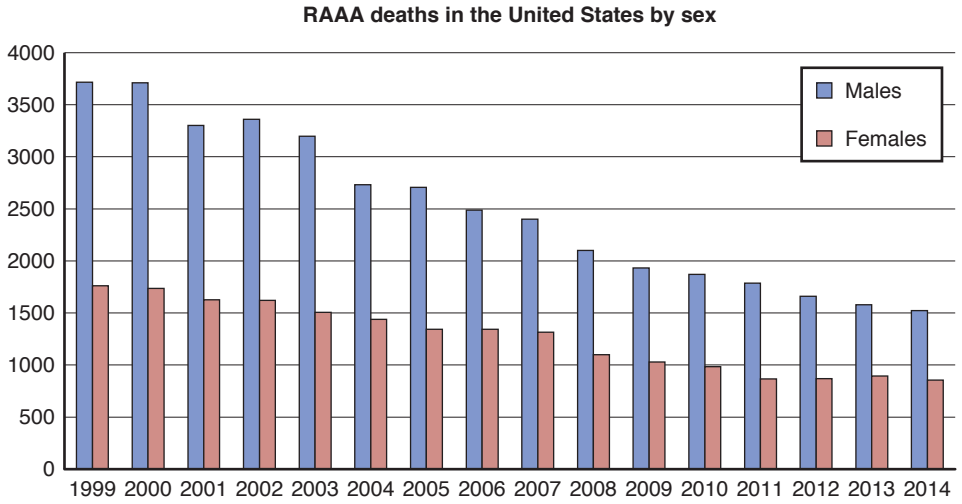

Figure 74.1 Ruptured abdominal aortic aneurysm *(RAAA)* death rates per 100,000 population between 1999 and 2014 in United States for men and women between the ages of 55 and 94 years. (From Centers for Disease Control and Prevention, National Center for Health Statistics: Compressed Mortality File 1999-2009. CDC WONDER online database, compiled from Compressed Mortality File 1999-2009, Series 20, No. 2O, 2012. http://wonder.cdc.gov/cmf-icd10.html.)

The Danish national registry (1994–2008) noted operative mortality decreased from 51% to 42%, attributed to centralization of services and better prehospital care. Data from the Vascunet (from nine national and regional registries) of outcomes for RAAA repairs in 7040 patients noted a mortality rate of 31.6%, with the rate declining by 4.2% between 2005 and 2009 attributed to EVAR.[34] Comparison of English and American databases from 2005 to 2010 noted that intervention for RAAA was offered to 80% in the United States (21% EVAR) versus only 58% in England (8.5% EVAR). Postintervention mortality was similar at 41.6% and 41.8%, respectively.[10]

The high postoperative mortality rates after aortic rupture are related to a high incidence of myocardial infarction, colon ischemia, renal failure, and multiple organ failure (MOF). The synergistic effect of the total body ischemia caused by hemorrhagic shock and the lower torso ischemia that occurs during repair, followed by reperfusion secondary to resuscitation and aortic unclamping, has been proposed to explain the high incidence of MOF and mortality after repair is supported by data from both animal and human clinical studies.[35,36] EVAR for RAAAs may reduce the ischemic insult by minimizing lower torso ischemia induced by aortic clamping. RAAAs anatomically suitable for EVAR have the lowest mortality and complication rates.[37,38]

PATHOPHYSIOLOGY OF AORTIC RUPTURE

Aneurysm rupture represents failure of the aortic wall to bear the load or tension of the blood pressure. In-vitro testing has demonstrated that the aneurysmal aortic wall is weaker than the normal structure: aneurysmal aortic wall 65 N/cm^2 versus 121 N/cm^2 for normal aortic wall.[39,40] Laplace's law (tension is proportional to radius times pressure) relates wall tension to pressure and emphasizes the importance of aneurysm size but does not account for complex geometry of individual AAAs.

Abdominal Aortic Aneurysm Shape and Finite Element Analysis

Finite element analysis has been applied to AAAs to estimate regional variations in peak wall stress (PWS) for many small segments of the entire aortic wall using CT scan data and provides a visual representation of PWS variability. Early 3D representations of PWS noted that the posterior wall of the aorta had higher values corresponding to sites where clinical observations and autopsy studies document the rupture sites.[41,42] Initial studies assumed that AAAs had uniform wall thickness and material isotropy (uniform strength in all orientations), but studies[42-45] show there are localized "hot spots" of matrix metalloproteinase (MMP) activity that could cause focal weakening of the aneurysm and rupture at relatively low levels of intraluminal pressure. Newer models include growth and remodeling theory that allows evolving wall thickness, stiffness, regional heterogeneity, and fluid-structure interactions within the aneurysm sac to be analyzed.[46,47] A study of CT scans of patients who subsequently ruptured compared with diameter-matched controls, ruptures had higher peak wall rupture risk (PWRR) at equivalent diameters but no difference in PWS or intraluminal thrombus volume (Fig. 74.2). These findings provide some justification for prediction of individual risk of AAA rupture from conventional CT.[48]

Role of Aortic Thrombus

In 1965 Martin surmised that as an aneurysm develops, it becomes lined with thrombus, which weakens it by interfering with nutrition of that wall segment.[49] Schurink et al.[50] confirmed that intraluminal thrombus does not reduce pressure near the

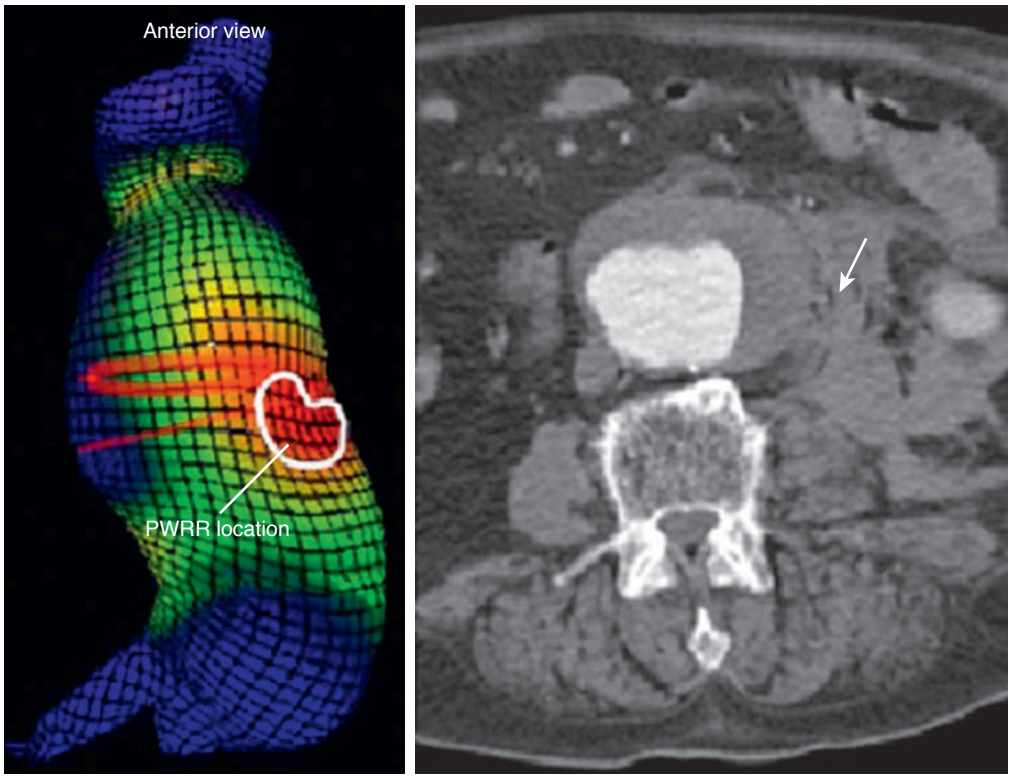

Figure 74.2 Peak wall rupture risk *(PWRR)* predicts subsequent indefinite rupture site. Finite element analysis (FEA, *left*) of patient 5 indicates PWRR location on the left lateral region within the aneurysm wall. Rupture occurred (image on the *right*) 154 days after FEA computation, and a left lateral periaortic hematoma *(white arrow)* was detected.

aneurysm wall, using a pressure transducer during open AAA repair. Vorp et al.[51] noted localized hypoxia in regions of thicker thrombus leading to localized wall neovascularization, inflammation, and regional wall thinning. Hypoxia also affects the function of vascular smooth muscle cells, causing them to secrete more collagenase than in normoxic conditions, with less elastin and collagen production.

An autopsy study of patients who died of infrarenal RAAAs noted that 80% of ruptures occurred at the site of mural thrombus.[52] CT studies of patients admitted with rupture showed that most occurred through the thrombus or at its edge. Others argue that ruptures are caused by fissures in the intraluminal thrombus, due to proteolytic enzymes on the luminal surface of the clot.[53] A Dutch report[54] in 2013, although accepting a role for fissure formation, confirmed that intraluminal thrombus thickness was associated with vascular smooth muscle cell apoptosis (or cell death), elastin degradation, and high levels of matrix metalloproteinase 2 and correlated with aneurysm rupture. PET-CT with ^{18}F-fluorodeoxyglucose has not be predictive of rupture.[9,55]

CLINICAL FEATURES

Signs and Symptoms

The classic presentation of RAAA includes the triad of acute-onset abdominal/back pain, hypotension, and a pulsatile abdominal mass. Severe and unremitting back pain is caused by rupture of the aneurysm into the retroperitoneal lumbar space. The pain may radiate to the back, testes, inguinal canal, or rectum and possibly hip due to psoas irritation. On examination, the patient is frequently pale, diaphoretic, and hypotensive with a tender, pulsatile abdominal mass. Flank ecchymosis is a late sign.

Differential Diagnosis

In patients older than 50 years with hypotension and/or syncope, consideration of RAAA is critical. The differential diagnosis may include renal colic, diverticulitis, pancreatitis, gastrointestinal hemorrhage, myocardial infarction, and perforated ulcer. Although the signs and symptoms of RAAA can be clear-cut, recognition in the early stages can be difficult. Presentation can range from sudden onset with hypotension and collapse to slowly increasing pain over a few days as the AAA wall has gradually stretched and then torn. In this age group, chronic back problems are common; there may be a tendency to ascribe symptoms to exacerbation of long-standing back problems.

Among those subsequently diagnosed with an RAAA, only 23% had a definitive and immediate diagnosis of RAAA made by the first examining physician.[56,57] The rate of incorrect diagnosis ranges from 16% to 60%.[58] The most common misdiagnoses were renal colic, perforated viscus, diverticulitis, gastrointestinal hemorrhage, and ischemic bowel. The initial manifestation of renal colic occurs infrequently in patients older than 60 years. The classic triad was present in only 9% of the

misdiagnosed group compared with 34% of the correctly diagnosed group. The presence of a pulsatile mass was identified in 72% of those correctly diagnosed but in only 26% of the misdiagnosed patients. Furthermore, the use of ultrasound in older studies was reported as being consistent with rupture in only 51% of cases.[59]

Rare presentations include rupture into an adjacent structure, such as an acute gastrointestinal bleed due to a primary aortoduodenal fistula or an aortocaval fistula that presents as a pulsatile abdominal mass, loud machinery-like bruit, or thrill with elevated jugular venous pressure associated with new-onset acute congestive heart failure.

Diagnostic Evaluation

Plain Radiographs

Although the use of plain radiography is currently rare, a retrospective review of plain films of patients with RAAAs showed evidence of the diagnosis on 90% of the films.[60] Enlargement of a calcified aortic wall beyond normal limits was seen in 65%, and loss of a psoas shadow from retroperitoneal hemorrhage was identified in 75%.

Ultrasound

Bedside ultrasound in the emergency department by trained emergency physicians has led to its use in cases of suspected RAAA. FAST (focused assessment with sonography in trauma) ultrasound protocols can rapidly identify fluid collections and direct further trauma care.[59,61] When ultrasound is used in patients with back pain, abdominal pain, or other indication of AAA, it can identify aortic aneurysms with high sensitivity, specificity, and positive and negative predictive values.[62,63] No large prospective studies have been conducted, although with appropriate training the use of ultrasound to quickly assess patients for the presence of AAA is likely beneficial as it directs rapid investigation and therapy. It is not sufficiently accurate to exclude rupture.[62,64]

Computed Tomography

The most accurate method for diagnosis of RAAA is CT, which also provides important associated information. A non–contrast-enhanced CT scan can identify retroperitoneal hemorrhage associated with RAAA and important anatomic information (Fig. 74.3A and B). However, CT scanning with contrast enhancement is ideal to plan RAAA either open surgical repair (OSR) or EVAR. Proper timing of contrast injection reduces the volume required, lessening its renal impact. Patients leaving the ER department for CT if RAAA is in the differential should be accompanied and monitored for acute deterioration.

If evidence of retroperitoneal blood with an AAA is used as the "gold standard" for diagnosis of RAAA on CT, it is 77% sensitive and 100% specific in a retrospective series.[65] Its positive predictive value was 100%, and its negative predictive value was 89%.[66] The level of agreement of the diagnosis of RAAA based on CT scanning was only moderate in five observers, whereas agreement on suitability for EVAR was only fair in vascular surgeons and radiologists experienced in EVAR from the Amsterdam Acute Aneurysm study.[67] Intraobserver agreement on rupture and suitability for EVAR was higher than interobserver agreement.

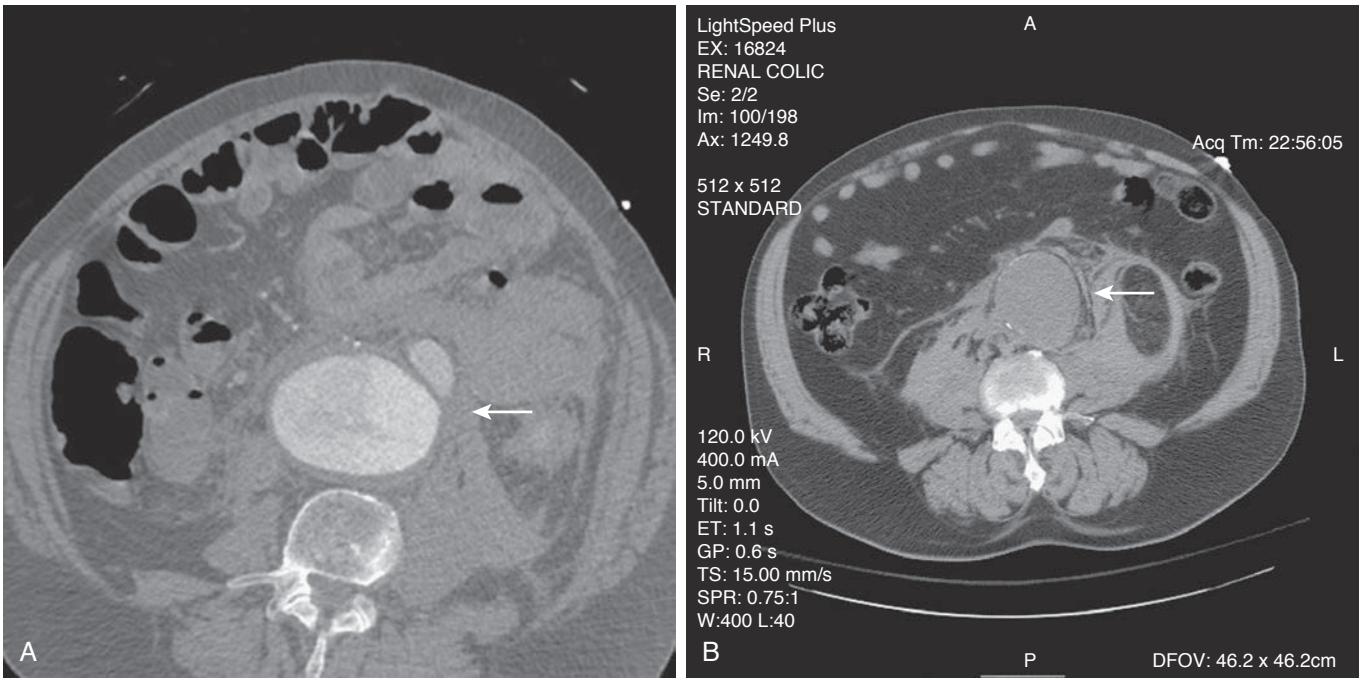

Figure 74.3 (A) Frank rupture of an infrarenal abdominal aortic aneurysm with contained extravasation *(arrow)*. (B) Computed tomography scan of a ruptured abdominal aortic aneurysm. Note the pattern of stranding of blood into the tissues *(arrow)*. No contrast material was used, and the scan was performed for the diagnosis of renal colic.

Is There Time for a Computed Tomography Scan in Ruptured Abdominal Aortic Aneurysm?

Prospective and retrospective studies have examined the delay between the initial manifestation of RAAA and the time to death to determine whether sufficient time exists to perform a CT scan and to evaluate patients' suitability for EVAR. The time to death for conservatively managed patients (due to age or comorbidities) from onset of symptoms to death was a median of 16 hours.[68] Only 13% died within 2 hours of hospital admission, suggesting that sufficient time exists for most patients to undergo CT scanning and evaluation for EVAR. A small number of patients in both the UK RAAA randomized trial (Immediate Management of the Patient with Rupture: Open Versus Endovascular Repair [IMPROVE]) and the Amsterdam Acute Aneurysm study were too unstable for CT scanning and required immediate transfer to the operating room.[69] Prospective data from the IMPROVE trial demonstrated that 90% to 97% of patients had a CT scan prior to intervention and the time to arrival at the operating room was 25 minutes shorter in the EVAR group versus OSR despite the requirement for a contrast-enhanced CT scan.[70] Thus, for the majority of patients who are stable on arrival at a center where definitive care will be carried out, a prompt CT scan does not adversely affect mortality.[68,71] A protocol for priority management of RAAA may significantly shorten the time to definitive therapy despite the CT scan requirement.[72,73]

INITIAL MANAGEMENT STRATEGIES

Patient Triage and Transfer to Appropriate Institutions

RAAA is a surgical emergency, and when the diagnosis is being considered, immediate vascular surgery consultation is critical. Rural hospitals without vascular surgery expertise tend to face a higher burden of RAAA patients and more commonly do not offer any intervention.[74,75] Patient transfer increases the time of arrival from the initial hospital to the operating room, although most studies demonstrate that patients who are transferred do not have a higher mortality but in fact have lower mortality as noted in the US National Inpatient data.[72,74] Furthermore, high-volume regional centers, teaching centers, and high bed capacity hospitals have significantly lower mortality for RAAA patients.[10,74,76]

Permissive Hypotension

Preoperative resuscitation of RAAA patients with hypotension must be judicious.[70,77-81] Large volumes of intravenous fluids raise blood pressure, causing further hemorrhage by overcoming the tamponade, result in hemodilution, coagulopathy, hypothermia, and acidosis, and further deterioration.[82] Protocols that restrict aggressive fluid resuscitation in hypotensive trauma patients with hemorrhagic shock improve survival so that permissive hypotension for RAAA patients is recommended. Fluid resuscitation should be sufficient to maintain consciousness, minimize organ ischemia, prevent ST depression, and maintain a systolic pressures of 70 to 80 mm Hg, although some have suggested lower BP targets.[78,83] Contemporary algorithms for management of RAAA patients include permissive hypotensive resuscitation.[82] Aggressive volume resuscitation before proximal aortic control is a predictor of increased postoperative mortality.[77,80] The IMPROVE trial demonstrated that those with the lowest BP had the highest mortality and increasing SBP to greater than 70 mm Hg was beneficial.[70] Observational studies also suggest that increased fluid administration prior to aortic control increased mortality.[83] Implementation of a controlled hypotension strategy in a regional ambulance service for patients with hypotension, in which only 27% had a final diagnosis of RAAA, demonstrated the overall risk of harm was low.[77] Evidence regarding resuscitation with blood versus crystalloids is limited; if blood is available, it should accompany the patient during transfer and can be given to maintain consciousness.

Protocol-Based Approach

EVAR for RAAA now requires a preoperative contrast CT scan (Fig. 74.4). EVAR obstacles are anatomic suitability, availability of staff and equipment at all hours, feasibility of treating hemodynamically stable and unstable patients, and ability of the care team to manage unexpected scenarios under emergent circumstances. One key factor is awareness among the emergency department staff of the diagnosis of RAAA and early notification of the on-call vascular surgeon/team.[73,84,85] A fine cut, low contrast volume CT scan to assess neck diameter, angulation, and iliac size is of critical importance.[85] Hemodynamically unstable patients can be directly transferred to the operating room without a preoperative CT scan for balloon control with either an EVAR or conversion to OSR as needed.[84] The initial emergency room evaluation must include a blood crossmatch.

Anatomic Suitability of Ruptured Abdominal Aortic Aneurysms for Endovascular Aneurysm Repair

The proportion of RAAA patients suitable for EVAR varied from 47% to 67% in two meta-analyses.[86,87] RAAAs have larger infrarenal aortic diameters and shorter neck lengths, which impact the percentage suitable for EVAR.[88,89] The success of EVAR on RAAA outcomes has been examined in patients with favorable versus unfavorable aortic neck morphology.[86,87,90,91] Data from the IMPROVE trial demonstrated that shorter neck lengths were associated with higher mortality in both open and EVAR patients.[92] For every 15-mm increase in neck length the mortality dropped by approximately 20%. A longer neck in RAAA facilitated both open (with an easier clamp site) and EVAR (improved proximal seal). The relationship between neck length and outcome may be a key variable that explains the discrepancy in RAAA outcomes between population-based data and randomized trials.[92]

(From Mehta M. Endovascular aneurysm repair for ruptured abdominal aortic aneurysm: the Albany Vascular Group approach. *J Vasc Surg*. 2010;52:1706–1712.)

Operative Preparation and Setup

The operating room should be equipped for EVAR and OSR. Anesthesia, nursing, and technical personnel can simultaneously and rapidly prepare the patient for intervention. Large-bore access, insertion of an arterial line, and placement of a Foley catheter can be done simultaneously. The patient is prepared and draped (including one brachial artery site) awake for both EVAR and open conversion. Local anesthesia can be infiltrated and ultrasound used to obtain percutaneous access for balloon control, then EVAR or open repair can proceed with agents designed to have minimal effect on blood pressure.

OPERATIVE STRATEGIES: ENDOVASCULAR REPAIR

EVAR has become the preferred method of therapy for RAAA repair for those with suitable anatomy.[93] At institutions with infrastructure for both EVAR and OSR for RAAA, by 2012 most RAAA patients (>70%) undergo EVAR in the United States.[8] OSR is generally reserved for those who are anatomically unsuitable for EVAR, for institutions that do not have the infrastructure to provide emergent EVAR, or when EVAR fails to seal the AAA.

Initial Management Technique

Arterial Access and Aortic Occlusion Balloon

After local anesthesia percutaneous access (preferred) or femoral artery cutdown (if required) is performed, ipsilateral access is obtained with exchange to place a stiff wire for device delivery. A large sheath (12F-16F × 45-cm length) in the ipsilateral femoral artery is placed over the stiff wire and advanced above the renal vessels, a compliant aortic occlusion balloon is deployed in hemodynamically unstable patients, into the supraceliac abdominal aorta under fluoroscopic guidance, and partially or fully inflated as needed (Fig. 74.5).[84,94,95] A retrospective review of a single-center experience of unstable RAAAs comparing open conventional cross-clamp and balloon occlusion demonstrated that balloon occlusion reduced intraoperative mortality to 19% from 34%; however, 30-day and in-hospital mortality rates were not significantly different (69% vs. 77%).[96]

Choice of Anesthesia and Approach

A key benefit of local anesthesia with conscious sedation is maintenance of "sympathetic tone" in the hemodynamically compromised patients. In hemodynamically unstable patients with weak or absent femoral pulses, this can be difficult and should be aided by ultrasound-guided femoral access and a micropuncture technique. The advantages of local anesthesia

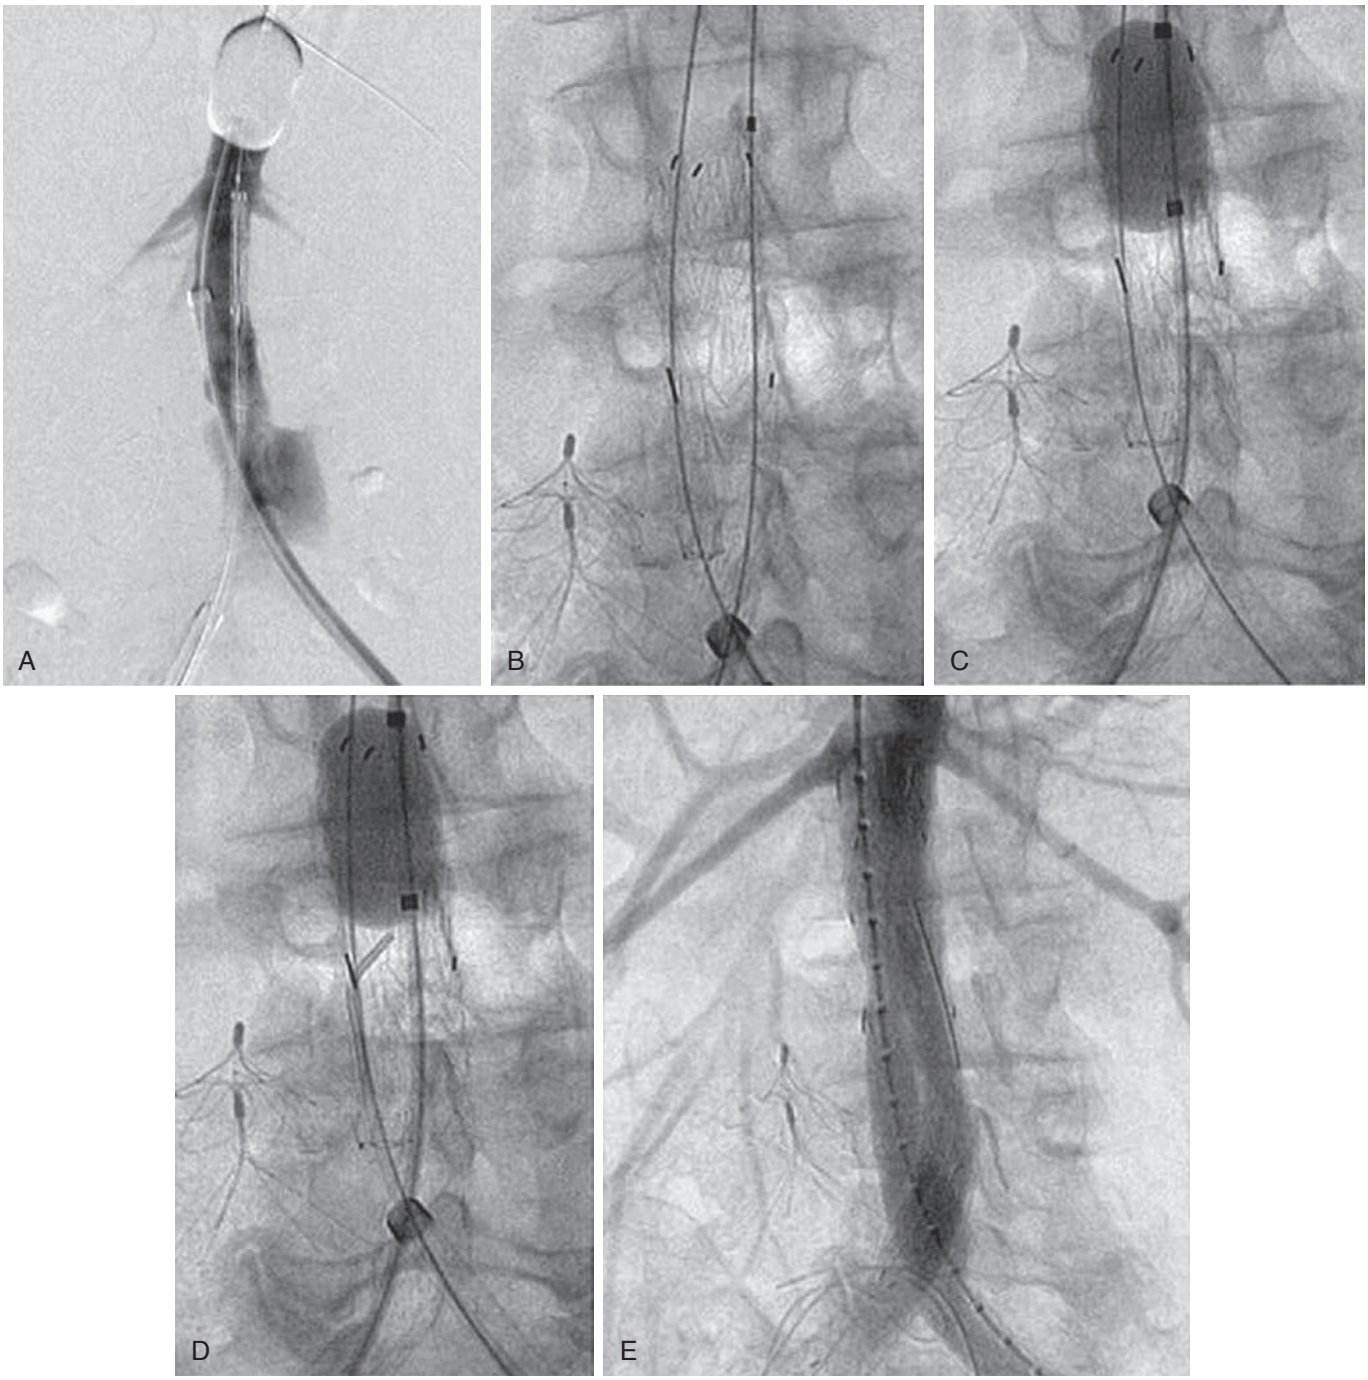

Figure 74.5 Managing the Aortic Occlusion Balloon During Stent-Graft Deployment. (A) The inflated suprarenal aortic occlusion balloon is advanced through the left femoral approach, the stent-graft main body is advanced through the right femoral approach, and arteriography is performed through the left femoral sheath supporting the occlusion balloon. (B) The aortic occlusion balloon is deflated and retracted from the aortic neck, and the stent-graft main body is subsequently deployed. This avoids trapping of the compliant aortic occlusion balloon between the aortic neck and the stent-graft. (C) In hemodynamically unstable patients the occlusion balloon can be redirected into the aortic neck from the side ipsilateral to the stent-graft main body and reinflated at the infrarenal aortic neck within the stent-graft main body before contralateral gate cannulation. (D) After the occlusion balloon is reinflated in the stent-graft main body in hemodynamically unstable patients, the contralateral stent-graft gate can be cannulated, and contralateral stent-graft extensions are placed as needed. (E) After contralateral iliac extension and ruptured abdominal aortic aneurysm exclusion, the occlusion balloon can be removed, as shown in the completion arteriogram. (Mehta M. Endovascular aneurysm repair for ruptured abdominal aortic aneurysm: the Albany Vascular Group approach. *J Vasc Surg*. 2010;52:1706–1712.)

must be balanced by the potential difficulties with the incoherent and uncooperative patients.[73,70] In hemodynamically unstable patients, starting the procedure under local anesthesia, then conversion to general anesthesia after RAAA exclusion, can be required for sheath removal and femoral repair.[97] Local anesthesia for EVAR in the IMPROVE trial greatly reduced the 30-day mortality compared with general anesthesia (adjusted OR of 0.27).[70]

Bifurcated Versus Aorto-Uni-Iliac Stent-Grafts for Ruptured Abdominal Aortic Aneurysm

Choice of stent-graft is determined by the patient's aorto-iliac morphology. An aorto-uni-iliac stent-graft for RAAA can be an advantage if there is inability to access the contralateral gate expeditiously or significant unilateral occlusive disease or tortuosity. Use of aorto-uni-iliac devices for EVAR of RAAA has similar outcomes to bifurcated stent-grafts.[98,99] Maintaining pelvic perfusion with at least one internal iliac artery patent is advantageous.

Conversion to Open Surgical Repair

When OSR or conversion is needed, the aortic occlusion balloon is invaluable to maintain hemodynamic stability. During laparotomy, it is crucial to maintain the position of the aortic occlusion balloon and its delivery sheath to prevent prolapse into the AAA. For conversion after stent-graft deployment, a tailored approach is suggested. For a IA leak, the suprarenal stent can be left in place to avoid aortic tearing. For IB endoleaks, sewing an interposition graft to an endograft body is possible.

OPERATIVE STRATEGIES: OPEN SURGICAL REPAIR

Transperitoneal Approach

This widely advocated approach allows safe, rapid, and effective proximal aortic control at the supraceliac, suprarenal, or infrarenal aorta and distal control of the iliac or even femoral vessels (see Chapter 54).[78,100] The supraceliac aorta can be exposed as shown in Fig. 74.6. Supraceliac clamping is preferred compared with the aortic compression devices, which provide only incomplete and imperfect control. After supraceliac clamping, the infrarenal aortic neck is dissected and the clamp may be repositioned to the infrarenal aortic neck before or after the proximal anastomosis is completed, trying to minimize visceral ischemic time. Supraceliac clamping induces ischemic injuries to the liver, bowel, and kidneys, which, in addition to the injury induced by hemorrhagic shock, may contribute to the development of postoperative MOF.[35,101] Supraceliac unclamping requires coordination with the anesthesia team to avoid sudden hypotension. Supraceliac control is beneficial for uncontrolled hemorrhage when immediate aortic control is needed, and it helps to avoid the renal and inferior mesenteric vein injuries that occur with blind retroperitoneal dissection in the face of large bleeding retroperitoneal hematoma.

For RAAA with clear evidence of suprarenal extension identified on CT, a thoracoabdominal incision allows rapid access to the aorta just above the diaphragm. A medial visceral rotation is then carried out to expose the visceral aorta, and standard elective techniques are used to reconstruct the visceral vessels and the aorta.

Retroperitoneal Approach

This approach is suggested to expedite supraceliac exposure and control and is safe when performed by those fascicle with its elective use.[102,103] It is particularly useful in patients with challenging body habitus or hostile abdominal situations.

Operative Technique

After proximal control is achieved in open repair, allowing the anesthesia team time for resuscitation, before the blood loss associated with aneurysm sac opening occurs. Controlling the IMA and iliacs can limit this. Once the aneurysm is opened, balloon iliac occlusion, if required, and lumbar suture ligation are rapidly accomplished. With supraceliac aortic control, bleeding from the proximal visceral arteries will require continuous suction during construction of the proximal anastomosis, preferably with a cell saver. Systemic heparin is generally avoided during RAAA repair, although it can be administered in a lower than usual dose just prior to clamp application. Alternatively, heparinized saline can be administered directly into the iliac arteries through occlusion balloons in an attempt to reduce distal thrombosis. Aggressive retrograde flushing of the iliac artery before distal anastomosis completion to remove any soft clot, particularly in nonheparinized patients, is important. Aortic repair is most rapidly accomplished with a tube graft. If bifurcated grafts are required, the easier of the two iliac (or femoral in ABF grafts) anastomoses is repaired first to reduce lower torso ischemic time. Maintaining perfusion of one internal iliac artery is optimal to reduce pelvic and colon ischemia.

Aortocaval Fistula

Continuous venous bleeding into the aortic open aneurysm sac after proximal and distal control have been achieved suggests an aortocaval fistula. Direct digital pressure or the use of sponge sticks above and below the fistula is recommended. Suture of the fistula from within the aneurysm is recommended to avoid further additional venous injury, with care to avoid an air or aortic debris embolus during the repair.

Autotransfusion

The use of red cell salvage with a cell saver device has proven beneficial in reducing mortality in RAAA patients undergoing OSR.[104] Red cell salvage reduces blood transfusions, morbidity, and mortality.[105] A retrospective review demonstrated that a ratio of autotransfusion/PRBC of greater than or equal to 1 was associated with lower mortality for open repair; however, liberal use of fresh frozen plasma did not decrease mortality.[106]

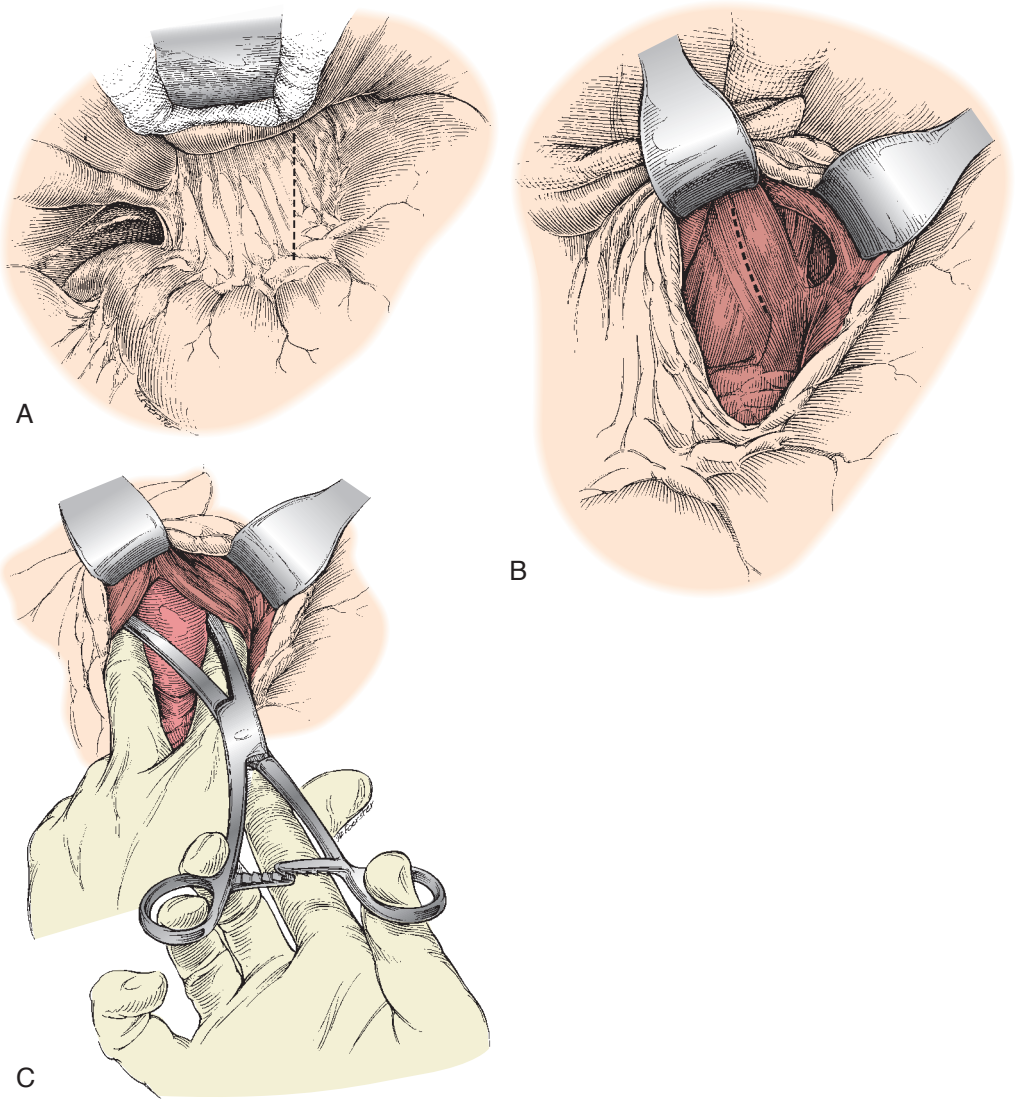

Figure 74.6 Exposure of the Supraceliac Aorta. (A and B) Initially, the lesser sac needs to be opened to allow opening of the diaphragmatic crura. (C) Blunt dissection of the aorta then allows a clamp to be placed over the two fingers that are exposing the aorta. (From Rutherford RB. *Atlas of Vascular Surgery: Basic Techniques and Exposures.* Philadelphia: WB Saunders; 1993:188–189.)

Hypothermia

Hypothermia increases surgical bleeding, wound infections, and cardiac events and is significantly associated with RAAA mortality.[104,107] Current recommendations for hypothermic patients include the use of warmed anesthetic gases, intravenous fluids, and the use of forced-air warming devices.

Anatomic Abnormalities

Variant arterial, venous and renal anatomy can greatly complicate OSR of RAAA; however, the preoperative CT scan can identify these abnormalities and allow planning. Arterial and venous injuries increase the mortality rate in RAAA repairs. Intraoperative finding of an inflammatory aneurysm may require suprarenal or supra celiac control with repair from within the aneurysm without duodenal dissection.

Venous Abnormalities

The most common venous abnormalities encountered include a retroaortic renal vein (1%-3%), circumaortic renal vein (0.5%-1.5%), left-sided vena cava (0.15%-0.5%), and duplicated inferior vena cava (0.4%-3%).[108] Retroaortic renal vein injury can be managed by more proximal clamp application, division of the aorta with anterior aortic retraction, and vein ligation. A left-sided vena cava or duplicated inferior vena cava that crosses in front of the aorta at the level of the renal vein can complicate proximal aortic clamp application. If elevation and mobilization fail to allow sufficient access for repair, temporary division and reanastomosis may be required.

Renal Abnormalities

A horseshoe kidney discovered on preoperative CT scanning prior to RAAA repair can present technical challenges for both

EVAR and OSR. Adjunctive measures for renal protection may include systemic mannitol (3-5 mL/kg), renal cooling, and arterial revascularization using an island with the arterial supply.[109]

Abdominal Closure

Primary abdominal closure is most common. In 25% to 30% of patients the abdomen cannot be closed primarily without significant tension secondary to swollen bowel, tissue edema, and retroperitoneal hematoma.[110] Patients who have severe preoperative anemia, prolonged shock, preoperative cardiac arrest, massive resuscitation, profound hypothermia, and severe acidosis may benefit from closure with mesh sewn to the fascia. Early mesh closure prevents abdominal compartment syndrome (ACS) and appears to reduce the incidence of MOF and may reduce mortality in comparison with patients who eventually returned to the operating room for decompressive laparotomy and delayed mesh closure.[110] Vacuum-assisted closure systems are available but have not been proven in RAAA patients but offer advantages in terms of high abdominal closure rates with a low incidence of complications in selected patients.[110,111]

COMPLICATIONS OF RUPTURED ABDOMINAL AORTIC ANEURYSM REPAIR

Local Complications

After OSR and EVAR, postoperative bleeding related to coagulopathy occurs in 12% to 14% of patients.[112] Limb ischemia can be related to in-situ graft limb thrombosis or distal thromboembolism. EVAR complications include access site bleeding and thrombosis ranging from 7% to 10%.[8]

Colonic Ischemia

Colonic ischemia is a potential lethal consequence of any AAA repair. Prospective sigmoidoscopy studies noted an ischemic colitis incidence of 38% after OSR and 23% after EVAR of RAAA ranging from patchy mucosal necrosis (grade I), to mucosal and muscularis involvement (grade II), to transmural necrosis, gangrene, and perforation (grade III).[113-115] If colonic ischemia is suspected during the postoperative period, sigmoidoscopy or colonoscopy to visualize the area is diagnostic. A prospective analysis of RAAA patients who survived 24 hours demonstrated a 26% incidence of grades I and II ischemia and 10% grade III changes.[113] Only 11% of grade I or grade II changes progressed to grade III in 48 hours. Grade III changes have extensive sigmoid and rectal necrosis and a mortality rate of 55% despite aggressive surgical management. Factors determining the degree of colonic ischemia after RAAA repair include the degree and duration of hypotension, patency of the inferior mesenteric artery, and collateral supply between the superior mesenteric, inferior mesenteric, and internal iliac arteries. At the conclusion of OSR, careful bowel examination with Doppler evaluation of the mesenteric vessels should be routinely performed and reimplantation of the inferior mesenteric artery considered. The incidence of ischemic colitis differs with the type of repair: 4% for tube grafts, 2.7% for aorto-iliac grafts versus 22% for an aortobifemoral graft. Colonic ischemia is also prevalent after EVAR of RAAA. After EVAR, prospective flexible sigmoidoscopy done 24 hours postoperatively noted a 22% incidence of ischemic changes, with 5% having segmental necrosis.[114,115] No blood test parameter was sufficiently discriminative to assist reliably in the diagnosis of colonic ischemia so that a high index of suspicion and routine sigmoidoscopy for all RAAA patients has been suggested.[115]

Assessment for Abdominal Compartment Syndrome

RAAA repair is a common cause of ACS. ACS is defined as an acute and rapid elevation in intraabdominal pressure of more than 20 mm Hg that is associated with cardiovascular, pulmonary, renal, and splanchnic organ dysfunction. Postoperative oozing and tissue edema contribute to the increase intraabdominal pressure. Clinical findings include a tense distended abdomen, progressive respiratory failure (elevated peak inspiratory pressures, decreased tidal volume, and elevated PCO_2), diminished cardiac output, and oliguria.[116,117] Intraabdominal hypertension is graded on the basis of bladder pressures.[117] Decompression laparotomy is recommended for intraabdominal hypertension greater than 25 mm Hg (grade III and grade IV).[116,117] Bladder pressure is measured with 50 to 100 mL of instilled bladder fluid and zeroed at the pubic symphysis.

ACS after EVAR of RAAA increases mortality and is associated with use of an aortic occlusion balloon, massive blood transfusions, coagulopathy, and hemodynamic instability.[117-119] A meta-analysis of ACS in RAAA demonstrated an incidence of 8% for all RAAAs and 21% after EVAR with a suggested management algorithm (Fig. 74.7).[120] ACS requires prompt recognition and decompression laparotomy. Proactive abdominal decompression by percutaneous intra peritoneal blood removal or retroperitoneal hematoma evacuation after EVAR of RAAA has been successful.[119]

Spinal Ischemia

Paraplegia and paraparesis are rare complications after RAAA repair with a risk for OSR of 1.2% compared with 0.5% to 11.5% for EVAR.[121,122] Factors associated with spinal cord ischemic complications include interruption of the pelvic blood supply, prolonged aortic cross-clamping, preoperative and intraoperative hypotension, and embolization. Early recognition with CSF drainage and pelvic revascularization are the main therapies.

Systemic Complications

Cardiac Complications (See Chapter 42)

Myocardial infarction, arrhythmias, cardiac arrest, and congestive heart failure increase mortality after RAAA.[112] Myocardial infarction develops secondary to the increased demand placed on the heart in the setting of preexisting coronary artery disease. Preexisting coronary artery disease has been shown to increase

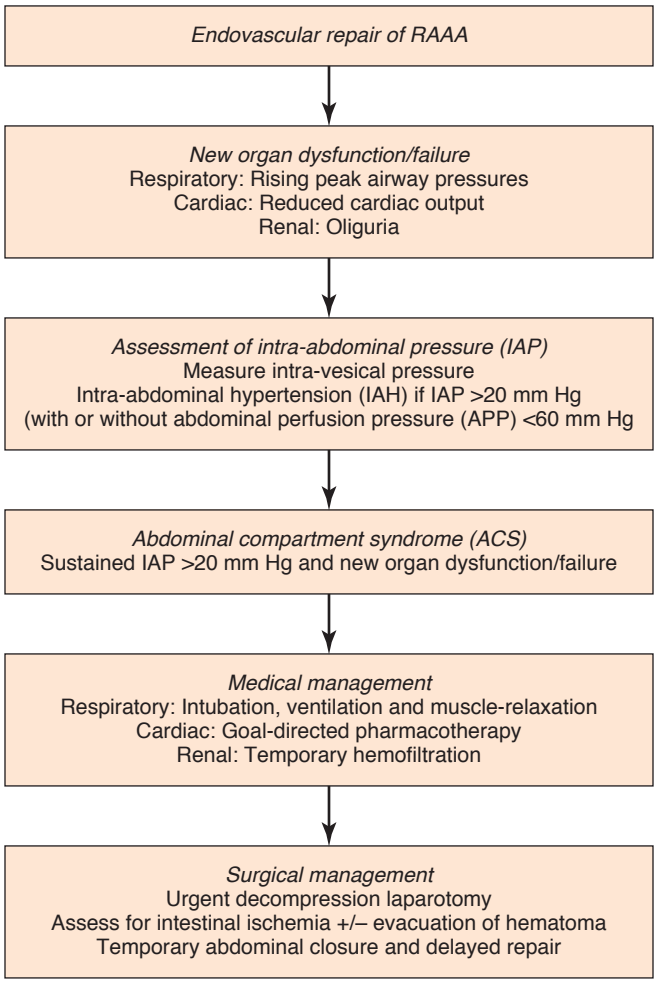

Figure 74.7 Algorithm for escalation of management of abdominal compartment syndrome (ACS) after endovascular repair of ruptured abdominal aortic aneurysms (RAAAs). (From Karkos CD, et al. A systematic review and meta-analysis of abdominal compartment syndrome after endovascular repair of ruptured abdominal aortic aneurysms. *J Vasc Surg.* 2014;59(3):829–842.)

the risk for MI and death after OSR of RAAA but not after EVAR.[8] Cardiac arrest occurs in up to 20% of patients, with a mortality of 81% to 100%. Myocardial infarction develops in 15% to 20% of patients, with a mortality rate of 17% to 66%; arrhythmias and congestive heart failure develop in nearly 20% of patients, with a mortality approaching 40%.[8,37,112] EVAR for RAAA has not been demonstrated to reduce the number of cardiac complications.[37] Postoperative measurement of cardiac-specific troponin has been shown to be elevated in up to 55% of RAAA patients. An elevated troponin and EKG changes were associated with significantly higher rates of CHF, cardiogenic shock, and in-hospital mortality (56.3% vs. 29.3%).[123] Elevation of troponin alone irrespective of the EKG changes was associated with an elevated mortality rate of 40.3% versus 14.1%.

Respiratory Failure (See Chapter 43)

Respiratory failure, pneumonia, and pulmonary complications develop in 36% to 41% of patients after OSR of RAAA and are predicted by preexisting chronic obstructive pulmonary disease (COPD).[37,124] Administration of large volumes of fluid and blood products, long cross-clamp times and COPD predisposes to the development of respiratory failure. Pneumonia, respiratory complications, and the need for tracheostomy are significantly lower after EVAR compared with OSR (28.5% vs. 35.9%, 4.6% vs. 9.9%, respectively; $P < .001$ for both).[37,124] Lung dysfunction is significantly reduced by EVAR.

Renal Dysfunction (See Chapter 44)

Renal dysfunction after RAAA predicts mortality.[37,112] Although the incidence of renal dysfunction after elective AAA repair is low, RAAA patients have an incidence of 26% to 45%.[37] In RAAA patients who require dialysis (incidence 11%-40%), the mortality rate is between 76% and 89%.[112,125] Renal dysfunction has been found to be increased in those with suprarenal cross-clamping, longer duration of cross-clamping, preexisting renal insufficiency, shock, and increased age.[124-127] The US National Inpatient Sample (NIS) noted significantly less acute renal failure (ARF) for EVAR (12.1%) compared with 19.6% in OSR.[74] In Medicare patients, EVAR was associated with 33.4% incidence of ARF despite contrast administration versus 45.4% for OSR.

Liver Failure

Hepatic failure is a late event after RAAA and described as hypoxic hepatic injury.[128] Increased metabolic demands, hematoma reabsorption, and unrecognized preexisting hepatic dysfunction are risk factors and are associated with pulmonary, cardiac, and gastrointestinal dysfunction with a mortality rate of 83%.[128,129]

Multisystem Organ Failure

The development of MOF depends upon the magnitude, number, and timing of inflammatory insults. Clinical RAAA data suggest that suprarenal clamp location, duration of clamping, and development of ACS are associated with higher rates of MOF and death.[118,126] The incidence of MOF was noted to be 3.8% after elective AAA repair, 38% after urgent AAA repair, and 64% after OSR of RAAA.[127] MOF after RAAA repair occurs more frequently after OSR than after EVAR and has mortality rates of 64% to 93%.[101,129,130]

The two-hit hypothesis of RAAA (hemorrhagic shock and ischemia secondary to temporary aortic clamping) initiating MOF may account for the persistently elevated mortality in the patients undergoing RAAA repair.[36,131-133] In a model of RAAA, individual insults of hemorrhagic shock alone or aortic clamping alone were insufficient to result in the development of systemic organ injury. However, combining the insults resulted in a synergistic effect with systemic organ injury that resembled MOF.[131-133] Hemorrhagic shock causes cardiac contractile dysfunction after resuscitation which further reduces tissue perfusion.[134] RAAA patients have neutrophils that are primed to respond to ex-vivo stimulation on arrival to the ER and with further significant elevations in neutrophil oxidative burst postoperatively.[135] A significant relationship between the level of neutrophil oxidative bursts and the level of tissue oxidative

injury products was identified. Both laboratory model and human subject data suggest that RAAA is a two-hit model of injury which may explain why the mortality after RAAA repair has failed to drop dramatically despite advances in perioperative management.

OUTCOMES OF RUPTURED ABDOMINAL AORTIC ANEURYSM REPAIR

Results of RAAA repair by OSR and EVAR are published from single-center series, national registries, randomized trials, and a meta-analysis of the randomized trials.[136-155] Major differences in outcomes exist between large registry data and the randomized trials. Large data sets (US National Discharge database, the NIS, and the US Medicare database) demonstrate a significant in-hospital and/or 30-day mortality benefit of EVAR over open repair, between 13% and 14%.[10,37,74] A major bias that cannot be addressed in observational data sets is that those with longer necks and anatomy suitable for EVAR are more likely to undergo EVAR. Those with shorter, angulated necks and unfavorable EVAR anatomy are relegated to OSR, which are technically more challenging to repair, likely adding to the mortality rate. The randomized trials had different randomization strategies, criteria, and outcome measures. The Amsterdam Trial (AJAX) randomized patients after a CT scan that demonstrated a rupture and patients eligible for either therapy.[146] The ECAR (French) randomized RAAA patients after a CT scan confirming both rupture and anatomy suitable for EVAR and a systolic BP of greater than 80 mm Hg.[124] IMPROVE randomized the largest number of patients (with more women) with a clinical diagnosis of RAAA, before a CT scan; thus not all patients had a RAAA and not all randomized to the EVAR cohort had suitable anatomy for EVAR, leading to crossovers.[147]

Observational Ruptured Abdominal Aortic Aneurysm Study Outcomes

US Medicare data of repaired RAAAs between 2001 and 2008 were propensity matched for baseline demographics, coexisting conditions, admission source, and hospital volume of RAAA repair to assess short- and long-term mortality, complications, and re-interventions, but differences in hemodynamic stability and anatomic suitability for EVAR are not accounted for in this comparison of EVAR and OSR outcomes.[37] EVAR mortality of 33.8% versus 47.7% for OSR, and all ages derived significant benefit. Complications were lower in the EVAR group, including pneumonia, ARF, respiratory failure but not MI, venous thromboembolism, or the incidence of hemodialysis. Surgical complications were significantly lower with EVAR except wound hematomas, LOS was 7 versus 14 days for survivors and discharge to home was 22% higher for EVAR. A significant long-term benefit for EVAR was seen in all ages which persisted for more than 4 years. Laparotomy-related complications were less after EVAR, but EVARs did have higher open surgical and endovascular AAA-related re-interventions. The important trends over the study period were: increased EVAR use 6% to 31%; EVAR mortality dropped from 46% to 27%; OSR mortality dropped from 44.7% to 40%; and the percentage of unrepaired RAAAs declined.

The NIS RAAA data (21,206 patients: 2005–2009) noted that EVAR was performed with higher percentages in teaching versus urban versus rural hospitals and nonoperative therapy was highest in rural hospitals.[74] After age 80, the rate of OSR dropped and the rate of no therapy increased. EVAR patients were older, with more CHF, CAD, DM, and renal disease. Univariate and multivariate analysis showed they were less likely to die (OR = 0.54) and had fewer postoperative complications with an EVAR repair (OR = 0.51).

A retrospective RAAA analysis (2005–2010) compared the UK Hospital Episode Statistics of 11,799 cases with 23,828 cases from the NIS. The percentage undergoing any type of repair was 58.4% in the United Kingdom versus 80.4% in the United States, OSR percentage was higher in the United Kingdom 91.5% versus 79.1%, but in the United Kingdom open repair mortality rates were significantly lower; however, EVAR mortality rates were significantly better in the United States. The postintervention mortality was not different (41.8% vs. 41.7%). UK survivors had longer LOS but were more commonly discharged to usual residence, whereas in the United States discharge to a skilled nursing facility was most common. In both countries the overall mortality, postintervention mortality, and rates of mortality after open and EVAR were significantly lower in teaching hospitals versus nonteaching hospitals. After adjustment for age, sex, comorbidity, and hospital size the predictors of mortality were weekend admission versus weekday, interhospital transfer, and treatment outside a teaching institution. In the United Kingdom after risk adjustment, noncorrective therapy was more common on a weekend or when treatment was delivered outside a teaching hospital. US predictors of mortality were weekend admission and treatment outside a teaching hospital. Significant difference in the incidence of noncorrective therapy accounts for the major differences in overall outcomes, although the significant outcome differences between weekday versus weekend therapy need to be addressed. The treatment and outcome differences based on hospital size and teaching status have important implications for improving population-based mortality for RAAA patients.

Randomized Ruptured Abdominal Aortic Aneurysm Trials

A pilot prospective randomized trial that evaluated 103 patients identified 32 who were stable enough to be randomized and CT scanned and were also fit for OSR between 2002 and 2004.[72] The mortality of EVAR and OSR were both 53%. However, it demonstrated the feasibility of randomized trials for RAAA.

The Amsterdam multicenter randomized RAAA trial (AJAX) evaluated mortality and severe complications as its primary endpoints between 2004 and 2011.[146] Of the 520 patients enrolled, 395 (76%) were evaluated by CT scan, 240 (61%) were excluded due to unfavorable EVAR anatomy, and 39 (10%)

were excluded due to unfit for open, logistics, severe hemodynamic instability after CTA, and surgical refusal. The remaining 116 (22%) patients deemed EVAR suitable by CT and clinically suitable for OSR were randomized to EVAR (57) or OSR (59). EVAR mortality was 21% versus OSR mortality of 25%. Death and severe complications at 30 days occurred in 42% of EVAR versus 47% after OSR of RAAA ($P > .05$), with OSR mortality much lower than expected. Renal insufficiency was significantly reduced after EVAR.

The IMPROVE trial randomized patients with a clinically diagnosed RAAAs prior to a CT scan.[147] The pragmatic design meant that, in each group, some symptomatic AAAs were randomized, some patients did not undergo repair and treatment crossovers occurred. Analysis was done on an intention-to-treat basis comparing endovascular-first to open surgical–first strategies. The 30-day mortality was 35.4% in EVAR versus 37.4% for OSR. Women had a significant mortality benefit from EVAR (37% to 57%; $P = .02$). The average aneurysm size was greater than 8 cm, and core lab review of all CT scans suggested 64% of RAAAs were suitable for EVAR. Older patients and those with a Hardman index of two or more did better with EVAR versus OSR, although these did not reach statistical significance. All of those who had EVAR from both treatment assignment groups had a 30-day mortality of 25% versus 38% for those who had OSR. Important secondary outcomes included shorter ICU stay for the EVAR group and higher rate of discharge to directly to home 94% versus 77% OSR; however, overall costs were not different at 30 days.

ECAR (Endovasculaire vs. Chirurgie dans les Anévrysmes Rompus) randomized hemodynamically stable RAAA patients, eligible for both therapies with a proven RAAA.[124] The 30-day and 1-year mortalities were not different (30% EVAR vs. 35% OSR at 1 year). EVAR benefits were lower total respiratory support time, reduced pulmonary complications, total blood transfusions, and duration of ICU stay.

Meta-Analysis of Ruptured Abdominal Aortic Aneurysm Randomized Trials

The pooled mortality in the three randomized trials demonstrated a nonsignificant mortality difference at 1 year of 38.5% for EVAR versus 42.8% for open repair. Data for re-interventions could not be subject to meta-analysis.[155] When the analysis was redone including only those anatomically suitable for EVAR from the IMPROVE trial, the results were unchanged. The benefits of EVAR were shorter LOS, fewer pulmonary and renal complications, and lower costs. There was a significant mortality benefit for women from EVAR.[11]

Why have randomized trials failed to demonstrate the mortality benefits seen in large observational studies?[156] First, observational studies of discharge databases frequently do not contain hemodynamic stability data or neck length. A meta-analysis of more than 80,000 patients demonstrated that EVAR had better outcomes compared with OSR in RAAA. However, when hemodynamic stability was accounted for, the results of OSR and EVAR were equivalent.[157] Second, a reanalysis of neck length of RAAAs demonstrated that aneurysm neck length was inversely associated with mortality.[70]

IMPROVE at 3 Years

At 3 years the EVAR strategy in IMPROVE was clearly superior, EVAR mortality was 42% versus OSR 54%.[93] Average LOS was 14.4 days for EVAR versus 20.5 days for OSR, with more EVARs cases discharged directly to home.[11] EVAR was the more cost-effective strategy and delivers more QALYs. IMPROVE data demonstrated that aneurysm neck length was inversely associated with overall mortality for both EVAR and for open repair and there was a significant relationship between lowest recorded BP and survival; every 10-mm Hg increase in systolic BP improved survival odds by 13%.[70] Use of local anesthesia for EVAR had a fourfold adjusted survival benefit.

Preoperative Predictors of Mortality

Many RAAA scoring systems assess preoperative variables to predict postoperative outcomes before repair, including the Hardman index, Glasgow Aneurysm Score, V- and RAAA-POSSUM, Edinburgh Ruptured Aneurysm Score, Vancouver score, the VSGNE RAAA risk score, and Neural network scores.[158-160] None definitively predicts outcomes with sufficient accuracy to deny RAAA repair. Variables associated with a reduction in survival after OSR of RAAA include loss of consciousness, preoperative cardiac arrest, preexisting congestive heart failure, preexisting renal insufficiency, advanced age, female gender, nonwhite race, and high APACHE II score.[a] Variables most commonly associated with death after RAAA include hypotension, advanced age, ischemic heart disease, cardiac arrest, low hemoglobin level, and preexisting renal insufficiency.[158] Women with RAAA tend to be 2 to 3 years older, have smaller AAA size, are offered repair less frequently, and have a higher mortality.[8,168,169] The VSGNE RAAA score identified the following independent predictors of death: age 76 years or older, (OR = 5.3), preoperative cardiac arrest (OR = 4.3), loss of consciousness (OR = 2.6), and suprarenal clamp (OR = 2.4).[163] The potential advantage of artificial neural network calculations to assist in predicting RAAA mortality could be the ability to combine age with other categorical risk factors not assigned a specific weight and the flexibility of the model to evolve as additional information is added.[161] This AI approach offers promise for real time estimates of mortality.

Postoperative Estimates of Survival

At the conclusion of RAAA repair, the surgeon can review the key variables to give the family an estimate of the expected outcome. Table 74.1 combines the preoperative and intraoperative variables that were significant in a prospective analysis of early survival using a logistic regression model based on prospective data of OSR for RAAA patients.[112] Predictive variables (univariate analysis) associated with increased mortality were preinduction systolic BP, preoperative serum creatinine, intraoperative urine output, site of the cross-clamp, and duration of cross-clamping. Intraoperative variables included the site of the aortic clamp, the volume of blood administered, and the intraoperative urine output. When all preoperative, intraoperative, and postoperative

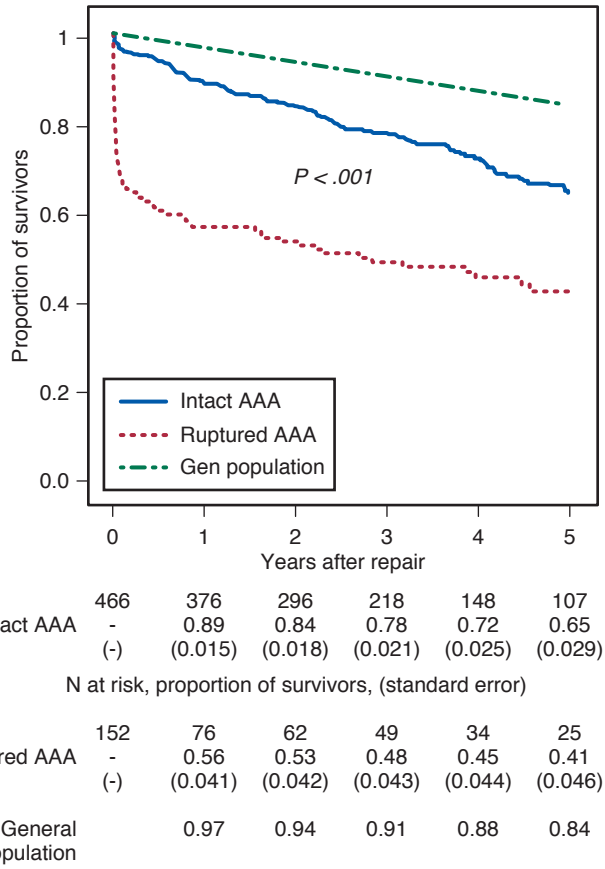

Figure 74.8 Kaplan-Meier survival estimates after abdominal aortic aneurysms (AAA) repair compared with an age-and-gender matched general population.

variables were included, early survival was predicted by site of the aortic cross-clamp and occurrence of myocardial infarction, respiratory failure, kidney damage, and coagulopathy. Dialysis has a dramatic impact on survival, even when no other complications are present. The development of two complications also has a dramatic impact on mortality, especially if one is a rise in creatinine concentration or dialysis requirement.

Predictors of Late Survival

Three studies assessed late survival after OSR of an RAAA compared with elective OSR: US Veterans Affairs (VA) data, the Mayo Clinic, and the Canadian aneurysm study.[112,167,170] The 5-year RAAA survival data were remarkable similar for those alive 30 days postoperatively: Canadian aneurysm study data was RAAA 53% versus 71% elective; US VA data 5-year survival rate was 54% RAAA versus 69% elective[170]; and Mayo Clinic study was RAAA 64% and 74% elective AAA repair.[167] Variables associated with late mortality were lower intraoperative urine output, respiratory failure, and myocardial infarction. The VA study also identified increasing age, illness severity, patient complexity, rupture, and aortic graft complications as being independently associated with late mortality.[170] Long-term survival has been assessed in the United States, United Kingdom, Sweden, and the Netherlands at 5 years and ranges between 38.6% in the United Kingdom and 50% in the United States.[162,164,171] There are significant differences between countries in 5-year survival for RAAA patients which is related to the early 30- to 90-day mortality. The most common causes of long-term mortality were cardiovascular death (35% of cases) and cancer (29%, lung cancer most common followed by GI cancer). The early mortality of the rupture accounts for the largest drop in the RAAA patient's survival (Fig. 74.8).[164]

RAAA long-term outcomes from VQI noted an increasing usage of EVAR in the cohort over time, and the unadjusted in-hospital mortality was 23% for EVAR versus 35% for OSR.[162] After adjusting for confounding variables, EVAR did not independently demonstrate a lower 1- or 5-year mortality rate; however, in a US Medicare cohort, EVAR was associated with improved survival (Fig. 74.9).[37] Primary predictors of 1- and 5-year mortality were patient comorbidities (home oxygen, dialysis, cerebrovascular disease, and ejection fraction <50%) and the indices of shock on admission (SBP <90, loss of consciousness, cardiac arrest).[162]

Late Re-Interventions

In the IMPROVE trial at 3 years a 28% re-intervention rate was noted in each group related to the aneurysm, and most of which occurred in the initial 3 months postoperatively.

Rupture After Endovascular Aneurysm Repair

None of the currently available stent-grafts is completely effective in preventing aneurysm rupture after EVAR.[154] A meta-analysis of late re-intervention for repeat RAAA following EVAR for RAAA demonstrated that the rate is similar to elective EVAR:

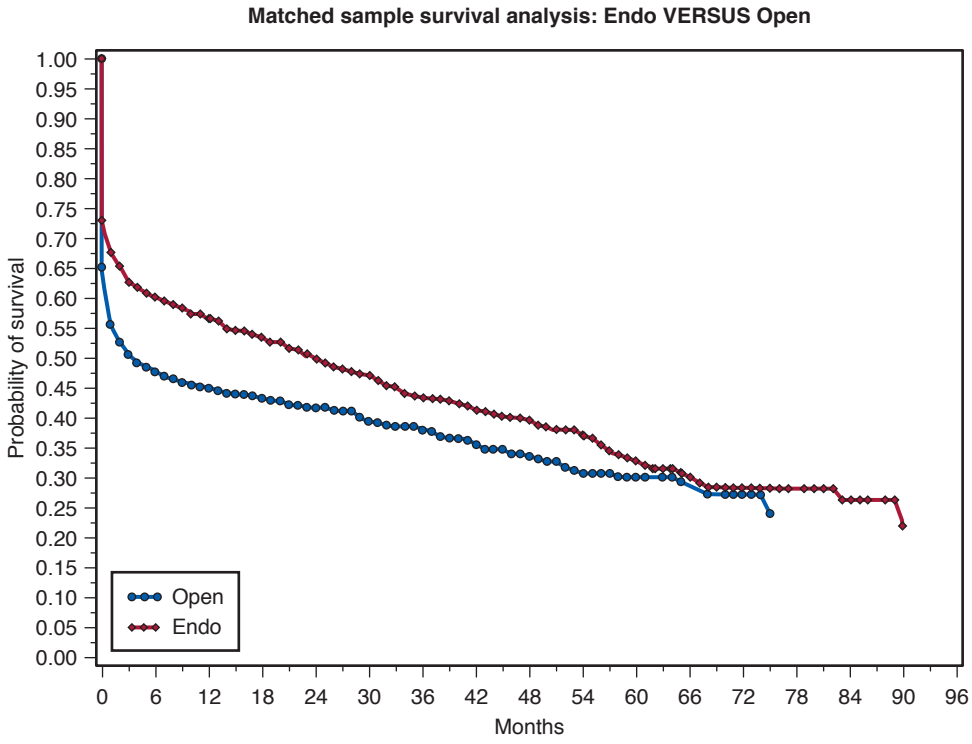

Figure 74.9 Probability of survival in propensity-matched data from Medicare beneficiaries age 67 or older admitted with a primary discharge diagnosis of ruptured abdominal aortic aneurysm between 2001 and 2008. (From Raghavan ML, Vorp DA, Federle MP, et al. Wall stress distribution on three-dimensionally reconstructed models of human abdominal aortic aneurysm. *J Vasc Surg.* 2000;31:760–769.)

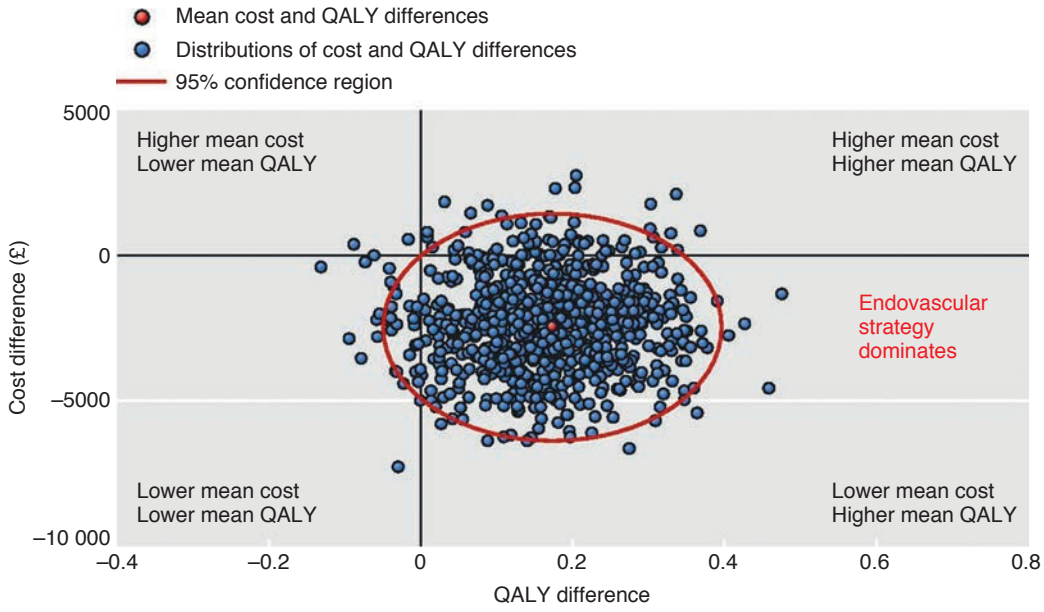

Figure 74.10 Uncertainty in mean cost (£) and quality-adjusted life year (QALY) differences and their joint distribution for endovascular strategy versus open repair for all 613 patients.

1.4% at 28 months and most common etiology is a type 1 endoleak.[155] Of those who ruptured after EVAR, 46.8% underwent intervention to treat the endoleak. Careful follow-up of RAAA EVAR patients is required, especially those who have had intervention for endoleaks.[172]

QUALITY OF LIFE

Quality of life (QoL) after RAAA repair has been assessed with several different instruments.[157,173,174] The overall SF-36 scores compared favorably with those of the age- and sex-matched general population. Hospital survivors had 8.5 quality-adjusted life years, but physical functioning was significantly lower in RAAA repair survivors than in age- and sex-adjusted population controls. Major postoperative complications did not reduce the QoL in RAAA survivors. IMPROVE prospectively measured differences in QoL between EVAR and OSR survivors at 3 and 12 months. Mean utility scores were significantly higher for the EVAR group at 3 months but were not significant at 1 year. When mean cost was plotted versus quality-adjusted life year differences, EVAR for RAAA delivered the best quality for the lowest costs (Fig. 74.10). The more rapid recovery from EVAR

was likely reflected in these early differences which dissipated over time. Therefore an aggressive approach to RAAA repair is justified as patients derive significant survival with good QoL following successful repair.

75 CHAPTER

Isolated Iliac Artery Aneurysms and Their Management

ANDY M. LEE and RONALD L. DALMAN

INTRODUCTION 961
PATHOGENESIS 961
NATURAL HISTORY 962
PRESENTATION 962
DIAGNOSIS 963
MANAGEMENT 963
Operative Approaches and Techniques 963
Endovascular Repair of Common Iliac Artery Aneurysms 964
Endovascular Repair of Internal Iliac Artery Aneurysms 966
CONCLUSIONS 968

INTRODUCTION

Iliac artery aneurysms (IAAs) commonly occur concurrently with other more proximal arterial aneurysms. As a distinct entity, IAAs were initially described by Valentine Mott in 1827, and later by Halstead in 1912.[1-3] In contrast to generalized aortoiliac aneurysms, isolated iliac aneurysms are much less frequently recognized, and are prevalent in ≤ 2% of the general population.[4,5] Aneurysmal degeneration typically involves the common iliac (70%-90%) and internal iliac (10%-30%) arteries, or both of these segments contiguously; external iliac artery (EIA) involvement is extremely rare.[1,6] Bilateral common IAAs are present in at least 50% of affected patients.[7]

Iliac arteries are defined as aneurysmal when their diameter is 1.5 times greater than the "normal" or expected diameter. On physical examination, isolated asymptomatic iliac aneurysms are difficult to identify, mainly due to their anatomical location deep within the pelvis. Most commonly, IAAs are identified during abdominal aortic aneurysm (AAA) screening studies, or recognized as incidental findings on abdominal and pelvic computed tomography (CT) imaging obtained for other purposes. When they do become symptomatic and rupture; however, isolated IAAs are associated with a high rate of mortality, frequently due to late or missed diagnosis.[4,6] Moreover, emergent open IAA repair in the setting of rupture portends relatively high morbidity and mortality rates due to uncontrolled hemorrhage. Iliac aneurysms carry the potential for severe complications if not managed appropriately.

The type of operative repair depends largely on patient anatomy, clinical stability, and the presence and severity of concomitant AAAs. Like the experience with AAA repair, isolated IAA management has evolved toward an endovascular first approach over the past decade. The availability of dedicated iliac devices, including multiple branching or "bell-bottom" stents, has steadily improved the feasibility, ease, and durability of endovascular repair.

PATHOGENESIS

The mechanisms relevant to IAA formation are multifactorial and involve an altered balance between proteolytic degradation of the extracellular matrix, mechanical integrity, inflammation, and an impaired arterial remodeling process, in the setting of specific at-risk genetic polymorphisms and environmental exposures (see Chapter 70).[8,9] Ferreira and colleagues demonstrated that hypertension and cigarette smoking were prevalent in patients with iliac aneurysms.[10] Other less common etiologies include previous trauma, iatrogenic injury, arteritis, connective

tissue disorders, and infections. Historically, syphilis and tuberculosis were frequently associated with mycotic IAAs, but *Salmonella, Staphylococcus, Klebsiella,* and *Candida* species are more commonly reported today.[2,7,11,12]

It remains unclear as to why the anatomical distribution of IAA tends to involve only the common and internal iliac segments, as opposed to the EIA. A developmental etiology has been proposed. Developmental factors encountered during embryogenesis involve signaling pathways that influence the fate of cell lineages and response to factors implicated in aneurysm formation. It has been demonstrated that different parts of the normal and aneurysmal adult aorta appear to have distinct DNA expression profiles, which may explain the site specificity and prevalence of various aneurysm phenotypes.[12,13] This genetic heterogeneity of endothelial and smooth muscle cells, in conjunction with systemic and physiologic exposures, alter the structural integrity of a vessel to enable aneurysmal degeneration. Tilson[14] and others have speculated that the EIA is resistant to aneurysm formation because of the distinct embryonic lineage of its vascular smooth muscle cells as compared to the aneurysm-prone common and internal iliac arteries.[12,14] Immunobiological characteristics suggest phenotypical differences between the internal and external iliac arteries, emphasizing the concept that normal and disordered embryogenesis can influence the propensity of an artery to aneurysmal disease.[12,14,15]

NATURAL HISTORY

There is a paucity of level I evidence available regarding the true prevalence, natural history, and rupture potential of IAAs.[9] Retrospective surgical case series provide most of the basis of our understanding of this condition. In a series of 715 common IAAs in 558 patients, 65% had bilateral IAAs.[16] Another series of 198 patients undergoing repair of 323 IAAs had a demographic profile similar to the previous study.[17] In both series, the rate of diameter enlargement for IAAs under surveillance varied based on the baseline diameter present at the time of diagnosis; for IAA ≤ 3 cm, expansion rates averaged 0.05 to 0.15 cm/year, whereas aneurysms greater than 3 cm enlarged 0.26 to 0.29 cm per year; no differences in growth rates were noted between isolated IAAs and those present in patients with concomitant AAA.[11,17]

IAAs are reportedly associated with a high propensity for rupture. Although asymptomatic initially, they are difficult to recognize on physical examination, enlarge slowly over time, and are often first identified at the time of rupture.[18] According to Bacharach and associates, as many as 33% of IAAs have ruptured at the time of initial presentation, an event associated with significant mortality.[11] The mortality from emergent repair for rupture in reports from the last 20 years is approximately 28% (range from 0% to 60%) as compared to a reported 5% mortality for elective IAA repair (range from 0% to 50%).[9] The mean size of ruptured IAAs varies in reports from 6 to 6.8 cm.[19]

Kato and associates reported 11 cases of unusual isolated external iliac artery aneurysms (EIAAs). According to their review, there were four (36%) ruptured EIAAs and one (9%) symptomatic EIAA associated with peripheral embolization. All ruptured EIAAs were greater than 4 cm in diameter.[20]

Dix and associates performed a literature review of internal iliac artery aneurysms (IIAAs) and identified 94 cases; the initial presentation was associated with rupture in 40%. Mortality in this group was 31%, with a median aneurysm size at presentation of 7.7 cm (range, 2-13 cm). [21] From a recent retrospective study across 28 vascular centers, Laine and associates[22] reviewed 63 IIAA patients who were all surgically treated. Regarding anatomical distribution, isolated IIAAs were uncommon (30%); they were more typically present concurrent with aortic and/or common iliac aneurysms. Only one IIAA rupture occurred at less than 3 cm in diameter, and four occurred at less than 4 cm (6.3% of all ruptures). Patients were treated with both open (73%) and endovascular techniques (27%); the outcomes include a 30-day postoperative mortality of 12.7% and a 1-year Kaplan-Meier survival estimate of 74.5% (standard error, 5.7%).[22] Overall, literature on isolated IIAAs remain sporadic and consist largely of case reports.

Thus, natural history studies suggest that IAAs smaller than 3.8 cm to 4 cm in diameter are not frequently associated with rupture,[21,22] supporting a generally accepted threshold of 3 cm to 3.5 cm for elective repair of asymptomatic IAAs (indications may vary between common iliac and IIAAs). These recommendations vary based on anatomical location and complexity, rate of enlargement, presence of symptoms, and concomitant comorbid conditions. Symptomatic IAAs should be expeditiously repaired upon presentation at any diameter.

PRESENTATION

The size and location of the aneurysm may foretell the clinical presentation of the IAA. Their anatomic location and proximity to adjacent pelvic structures including bowel, bladder, the urinary collecting system, nerve roots, and pelvic veins can obscure the diagnosis in the absence of a perceptible mass.[1] Vague lower abdominal pain often results from compression or impingement of these neighboring structures. Patients may also complain of intermittent claudication or lower extremity pain secondary to embolic arterial occlusion, lower extremity paresis, sciatic neuralgia, lumbosacral pain, ureteral obstruction, tenesmus, or even constipation.[11]

Sudden abdominal, groin, or flank pain associated with hemorrhagic shock likely indicates rupture. Although IAA rupture may initially be contained in the retroperitoneum, uncontrolled exsanguination typically leads to irreversible shock. Delays in diagnosis contribute significantly to reported mortality, with or without emergent intervention.

In rare instances, an IAA can elicit thromboembolic symptoms and peripheral arterial insufficiency. In the era preceding the current nearly ubiquitous use of cross-sectional imaging in the assessment of vascular compromise, Richardson and associates noted that IAAs were often recognized only after observed ipsilateral limb ischemic changes precipitated the need for angiographic evaluation.[1] In a reported observational cohort study, Nachbur and associates retrospectively identified four cases where intermittent claudication was a result of thrombotic

stenosis or occlusion caused by an iliac aneurysm.[23] Distal embolization was the clinical presentation of IAA disease in one patient (9%) of 16 symptomatic aneurysm IAA patients identified in a single institution over 6 years.[10]

DIAGNOSIS

As noted previously, physical examination frequently fails to identify even large IAAs.[18] Imaging modalities provide needed sensitivity and specificity for both diagnosis and anatomical information crucial to surgical planning. Ultrasound represents the primary diagnostic and screening tool, especially in asymptomatic patients. Limitations involve user variability and presence of other organs and structures. CT and magnetic resonance (MR) angiography imaging provide far more extensive detail of aortoiliac anatomy, and improve diagnostic accuracy in challenging circumstances.[24] However, the expense and risks of these techniques should be factored into the overall approach to the individual patient.[9]

Precise operative planning requires high-resolution, high-fidelity imaging, and in most circumstances, CT arteriography is optimal for this purpose. Using a combination of axial imaging and 3-D postprocessing, evaluation includes locations, diameters, and length of proximal and distal landing zones for endovascular grafting, information regarding iliac artery tortuosity and angulation, the presence and severity of associated occlusive disease, ipsilateral and contralateral internal iliac artery patency, the status of the ipsilateral deep femoral artery, and concomitant abdominal or thoracic aortic pathology.[25]

MANAGEMENT

Iliac aneurysms are targeted for repair as they enlarge or become symptomatic. Based on retrospective reviews and consensus statements, current recommendations favor elective repair for asymptomatic IAAs ≥ 3.5 cm in diameter in healthy patients.[9] Early and extensive application of CT imaging in the assessment of patients with abdominal pain has substantially reduced the historically high morbidity associated with delays in diagnosis of ruptured IAAs, but rupture of previously unrecognized IAA still occurs, often presenting serious surgical management challenges.[21]

Asymptomatic IAAs less than 3 cm in diameter are best managed with serial surveillance imaging studies. In fact, general abdominal ultrasound screening for aortoiliac aneurysms is recommended by the US Preventive Services Task Force (USPSTF) for men aged 65 to 74 years who have ever smoked.[24,26] The strong association between smoking and aortic aneurysm was described by Hammond and Horn in 1958.[25,27] A systematic review that included this and other large studies relating smoking behavior to subsequent mortality showed that the relationship between smoking and aortic aneurysm was several times stronger than the relationship between smoking and occlusive vascular disease.[25,27,28] Notably, other documented characteristics have been shown to influence AAA and IAA growth or rupture rates: smokers and nondiabetics have higher growth rates, and smoking, older age, and higher blood pressure increase rupture risk.[26-28] In general, smoking cessation may reduce the rate of aneurysm expansion, as has been demonstrated in early AAA disease.[26] Depending on concomitant patient medical comorbidities, a conservative approach to some IAAs may be most appropriate for even symptomatic patients.[29] Santilli and associates correlated IAA expansion rates with baseline diameter; aneurysms less than 3 cm in diameter expanded at 1 mm annually, whereas IAAs between 3 cm and 4 cm in diameter expanded 2.6 mm/year.[17] Interestingly, these rates were similar across all types of IAA, whether isolated or multiple.

Operative Approaches and Techniques

Due to the relatively inaccessible location of iliac aneurysms (situated deep in the pelvis), the presence of densely adherent pelvic veins, and the frequent cooccurrence of calcific occlusive disease, conventional surgical repair is challenging and fraught with risk of significant hemorrhage.[30] Using standard open operative techniques, modern retractor systems, and patience; however, repair of isolated iliac aneurysms provides excellent long-term results and is generally well tolerated by good-risk patients.

The primary goal of surgical intervention is to maintain distal perfusion while preventing further aneurysmal degeneration and rupture.[18] The iliac artery may be best approached from a midline, retroperitoneal, or transplant-type incision, depending on the extent of the aneurysm, the presence of unilateral or bilateral disease, and surgeon preference and experience. In general, large aneurysms that produce compressive symptoms require adequate exposure to effectively open and repair the aneurysm via standard endoaneurysmorrhaphy techniques. If an adequate portion of proximal common iliac artery is nonaneurysmal, common IAAs can be replaced with a prosthetic interposition graft. When the entire common iliac artery is aneurysmal, however, control must obtained on the aorta itself and the proximal graft needs to be anastomosed directly to the aorta; this usually requires transperitoneal or full retroperitoneal exposure (see Chapters 54 and 71).

The quality of the artery will dictate the amount of exposure required for proximal vascular control. In terms of the distal extent, the graft can almost always be sewn to the bifurcation of the external and internal iliac arteries, thus preserving pelvic flow. In rare circumstances, with significant splaying of the external and internal iliac arteries or aneurysmal extension into the internal iliac artery, the distal extent of the graft must be sewn to more normal, distal arteries.

Direct open repair of the common iliac artery also maintains collateral flow to the pelvis via the lumbar arteries and the inferior mesenteric artery, thus reducing the risk of postoperative colonic or pelvic ischemia.[31] As in the case of open AAA repair, resection of the aneurysm sac is not advised, because this increases the risk of bleeding and injury to adjacent adherent structures such as the iliac veins and the inferior vena cava. Preoperative placement of ureteral stents can reduce the risk of ureteral injury, particularly in advanced and inflammatory aneurysms.

Maintenance of antegrade internal iliac artery flow is essential for optimal outcomes, particularly in younger patients or those

with contralateral internal iliac artery compromise or occlusion. Loss of internal iliac artery perfusion can lead to buttock claudication, impotence, and more rarely, colonic ischemia, gluteal necrosis, and spinal cord ischemia.[32-37] In situations when both internal iliac arteries are affected, or if both internal iliac arteries are aneurysmal, it is advisable to use bypass grafting of at least one internal iliac artery to preserve antegrade flow.[7] In their clinical experience with open repair of 715 iliac aneurysms in 438 patients, Huang and associates advised reimplantation of the inferior mesenteric artery to the aortic graft if both internal iliac arteries were occluded; however, even adherence to that algorithm resulted in ischemic colitis in two patients.[16] When aneurysmal disease is limited to a single common iliac artery, the ipsilateral internal iliac may be ligated without significant ischemic consequences. This strategy has other limitations, however, including a relatively high likelihood of progressive enlargement of residual IIAAs distal to the ligature site. These may continue to be pressurized by retrograde branch artery flow, resulting in progressive enlargement, compressive symptoms, and a continued risk for late rupture.[38-40]

Ultimately, iliac artery aneurysmorrhaphy, in experienced hands, provides a durable repair with excellent outcomes. Mortality rates for elective procedures range from 0% to 5%, depending on the comorbidity profile and anatomic considerations.[9,16,41,42] The overall incidence of perioperative complications ranges up to 22% including lower extremity ischemia from distal embolization or stenosis; visceral and pelvic wall ischemia from disruption of hypogastric flow; aneurysm reperfusion and rupture; arterioenteric fistula formation; graft infection; and ureteral, neural, and venous injuries.[1,9,28] Both early and late graft-specific complications are rare, and primary patency at 5 years approaches 100%.[16,42]

Endovascular Repair of Common Iliac Artery Aneurysms

Treatment of concomitant aortoiliac aneurysmal disease has been preferentially endovascular since the advent of later-generation bifurcated AAA grafts.[43] Continued advancement of these technologies has shifted isolated IAA management to an endovascular-first approach as well. Endovascular IAA management reduces length of hospitalization, operative blood loss, the need for invasive monitoring and intensive care unit care postoperatively, and perioperative complications.[44] In a study of 33,161 patients with isolated IAA, derived from the National Inpatient Sample Database from 1988 to 2011, Buck and colleagues observed that the total number of aneurysm repairs increased from 28 to 71 per 10 million US population following the introduction of endovascular AAA and IAA treatment methodologies ($P < .001$).[45] This analysis demonstrated that the number of annual endovascular iliac aneurysm repairs surpassed the number of open repairs in 2003. Moreover, death from rupture or repair of isolated IAAs decreased from 4.4 to 2.3 per 10 million US population ($P < .001$) over a similar time period, although technical issues alone do not likely completely account for this improvement (see Chapter 72 and Chapter 73).[24]

The primary goal of endovascular intervention is similar to that of open repair: exclude the aneurysm sac from the circulation, thereby minimizing risk for further expansion and rupture. Anatomic considerations that influence endovascular treatment strategies include: (1) the presence and quality of proximal and distal landing zones (e.g., location and length of nonaneurysmal inflow and outflow arteries), (2) the presence of concomitant internal iliac artery involvement, (3) the presence of bilateral or unilateral iliac disease, and (4) the presence or absence of concomitant aortic aneurysm.[19] Melas and colleagues proposed a revised common IAA classification system based on the proximal and distal extent of the lesion, providing a framework for treatment selection.[46,47] Anatomic considerations are paramount in endovascular management considerations (Table 75.1).

Using standard techniques and devices, endovascular repair of isolated common IAAs requires approximately 2 cm of proximal and distal landing zone (Fig. 75.1). Lack of a proximal landing zone necessitates extension into the abdominal aorta to achieve seal. In this situation, depending on the extent of aneurysmal involvement, a bifurcated aortic endograft is generally the most appropriate choice. Current "on label" applications allow for endovascular management of common iliac bifurcation disease up to 25 mm in diameter, including the use of flared or bell-bottom iliac limbs. Although an initial seal may be obtained with these devices, durability may be suspect based on the inherently diseased nature of the landing zones. Agu and associates identified late aneurysmal degeneration at the distal iliac landing zone following endovascular repair in 2.4% of patients with up to 9 years of follow-up.[48] Similarly, in a retrospective review,[49] bell-bottom iliac limbs placed concomitantly with AAA endografts were associated with subsequent dilation of common IAAs in 35.3% of cases; endoleak and reoperation rates were 17.6% and 15.7%, respectively. Over a 4-year period, the average increase in arterial dilation was 16% in the first year, 29% in the second year, 57% in the third year, and 95% from the fourth year.[49] Although simple to use and generally considered to be a safe alternative to preserve pelvic blood flow, long-term outcomes for the durability of this method remain questionable.[50]

When the distal seal zone diameter is greater than 25 mm, or aneurysmal degeneration extends into the proximal internal iliac artery, the seal zone may be extended into the EIA; coil embolization or plug occlusion (Amplatzer vascular plug, St. Jude Medical, Inc., St. Paul, Minnesota) of the proximal internal iliac artery is generally employed to prevent retrograde flow into the common iliac aneurysm.[51] Because coil embolization of the internal iliac artery can be technically challenging, these adjuncts may be associated with increased operative time, contrast use, radiation time, and cost.[52]

As an alternative, straightforward stent graft coverage of the internal iliac artery orifice without embolization can extend the distal sealing zone of the repair without significant complications. Papazoglou et al.[52] reported on their series of 137 patients undergoing endovascular aneurysm repair. Patients were treated with simple stent graft coverage across the internal iliac artery ($n = 112$) or stented with concomitant internal iliac artery coil embolization ($n = 25$). Overall, there was no difference in

TABLE 75.1 Classification Scheme for Endovascular Treatment of Isolated Iliac Artery Aneurysms

Aneurysm Type	LANDING ZONES		Internal Iliac Artery Configuration	Endovascular Techniques
	Proximal	Distal		
A	CIA	CIA		Direct aneurysm exclusion with covered stents within proximal and distal fixation zones (balloon-expandable or self-expandable)
B1	CIA	IIA	IIA diameter < 15 mm	**Anatomical with IIA preservation** Iliac side-branch device **Extraanatomical with IIA preservation** 1. Placement of AUI in contralateral nonaneurysmal CIA with a femorofemoral bypass and endograft deployment from ipsilateral EIA to ipsilateral IIA 2. Placement of bifurcated endograft with ipsilateral extension to EIA, ipsilateral retroperitoneal open surgical ligation of IIA, bypass grafting from ipsilateral distal EIA to the ipsilateral IIA 3. Placement of bifurcated endograft with an ipsilateral iliac limb extension toward the ipsilateral IIA and adjunctive femorofemoral bypass and distal EIA ligation **Sacrificing IIA** Exclusion with coverage or embolization of IIA and placement of covered stent across CIA aneurysm to EIA
	CIA	IIA	At least 20 mm of nonaneurysmal tissue within IIA	
B2			Aneurysm extends into IIA IIA diameter < 15 mm Insufficient length of IIA (< 20 mm)	
C	Aorta	CIA		**Anatomic with IIA preservation** Placement of bifurcated endograft with the ipsilateral iliac limb extending to the distal CIA landing zone **Extraanatomic with IIA preservation** 1. Placement of AUI into contralateral nonaneurysmal CIA with femorofemoral bypass and endograft extending from the ipsilateral EIA to the ipsilateral IIA 2. Placement of AUI into contralateral nonaneurysmal CIA with femorofemoral bypass and occlusion of distal CIA before bifurcation
D1	Aorta	IIA	IIA diameter < 15 mm	**Anatomic with IIA preservation** 1. Iliac side-branch device 2. Double barrel graft technique using a bifurcated device **Extraanatomical with IIA preservation** 1. Placement of AUI into contralateral nonaneurysmal CIA with femorofemoral bypass and endograft extending from ipsilateral EIA to the ipsilateral IIA 2. Placement of bifurcated endograft with an ipsilateral iliac limb extension toward the ipsilateral IIA and adjunctive femorofemoral bypass and distal EIA ligation **Sacrificing IIA** 1. Exclusion of aneurysm with placement of bifurcated endograft with ipsilateral extension to the ipsilateral EIA and ipsilateral IIA embolization
D2	Aorta	IIA	At least 20 mm of nonaneurysmal tissue within IIA Aneurysm extends into IIA IIA diameter < 15 mm Insufficient length of IIA (< 20 mm)	

"Landing Zone: Aorta" signifies no proximal landing zone of 1.5 cm in the common iliac artery, i.e., the CIA aneurysm extends to or within 1.5 cm of the aortic bifurcation

AUI, Aortouniiliac endograft; *CIA*, common iliac artery; *EIA*, external iliac artery; *IIA*, internal iliac artery.

Modified from Melas N, Saratzis A, Dixon H, et al. Isolated common iliac artery aneurysms: a revised classification to assist endovascular repair. *J Endovasc Ther*. 2011;18(5):697–715 and Uberoi R, Tsetis D, Shrivastava V, et al. Standard of practice for the interventional management of isolated iliac artery aneurysms. Subcommittee on Reporting Standards for Arterial Aneurysms of The Society for Vascular Surgery. *Cardiovasc Intervent Radiol*. 2011;34(1):3–13.

incidence of postoperative buttock claudication between the two groups (13.4% for stenting alone, 12% for stenting with coil embolization, $P = .852$). In fact, after 4 years, there were no differences in cumulative survival or the rates of secondary interventions between the two groups. In another similar series of 32 patients, Stokmans et al.[53] reported that endovascular coverage of the internal iliac artery did not result in severe symptoms of pelvic ischemia and had a low rate of secondary reinterventions. The incidence of buttock claudication (22.6%) was within the range reported in previous studies on sole internal iliac artery coverage, and compared favorably to the incidence reported in the majority of studies on coil embolization.[53] Covering the internal iliac artery without coil embolization may thus provide a safe alternative approach for some patients. However, failure to adequately seal the internal iliac artery in the process of common iliac artery endografting may lead to long-term procedural failure secondary to persistent retrograde endoleak arising from the patent internal iliac artery. Furthermore, once the internal iliac artery origin is covered, future percutaneous access is likely precluded, requiring open conversion or CT-guided transpsoas access directly to the internal iliac artery for later definitive management of aneurysm expansion.

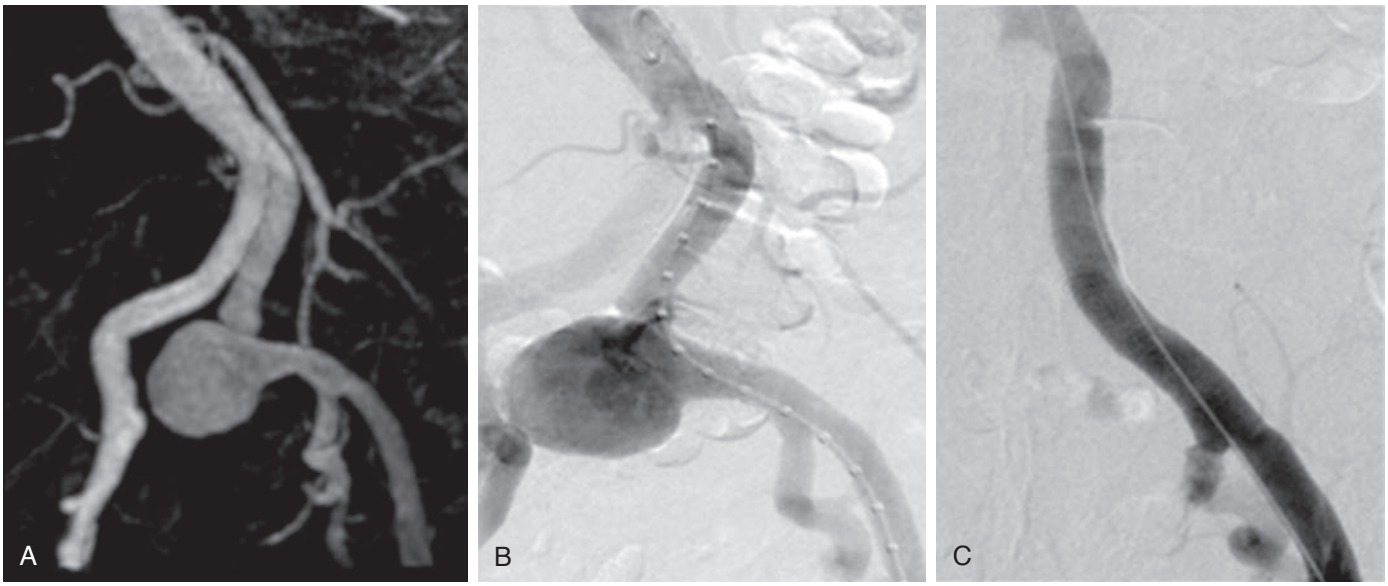

Figure 75.1 (A) Magnetic resonance imaging (MRI) of isolated 3.8 cm × 3.5 cm left common iliac aneurysm that was incidentally discovered. (B) Endovascular repair with sizing catheter placed ipsilateral. Angiogram demonstrating proximal and distal landing zones and iliac bifurcation. (C) Approximately two covered stents deployed to seal and exclude aneurysm while preserving internal iliac artery.

In patients with contralateral internal iliac artery occlusion or bilateral common IAAs, or those who are otherwise perceived to be at high risk for spinal cord ischemia, it is essential to preserve internal iliac artery flow. Typically, few patients experience prolonged or permanently debilitating symptoms following unilateral occlusion, and if bilateral internal iliac artery occlusion is deemed necessary, staged intervention to allow collateral flow development and close patient monitoring to detect symptom development is warranted. As an alternative to uni- or bilateral internal iliac artery occlusion, an external-to-internal iliac artery bypass may be performed in conjunction with proximal internal iliac artery ligation to effectively "move" the iliac bifurcation more distally. Iliopoulos and colleagues examined the collateral arterial supply to the hypogastric arterial bed.[54] Using staged, sequential internal and external iliac artery occlusion techniques while measuring corresponding stump pressures, Iliopoulos et al. demonstrated that the ipsilateral external iliac and femoral arterial systems actually provide more collateral internal iliac artery flow than does the contralateral internal iliac artery system. These findings emphasize the importance of maximizing ipsilateral external iliac and femoral arterial inflow to compensate for an ipsilateral internal iliac artery occlusion and to minimize the risks for resulting pelvic ischemia. In one series of 22 patients, Hosaka and associates assessed the impact of performing endovascular aortoiliac stent-grafting with concomitant unilateral internal iliac artery embolization and contralateral external-to-internal iliac artery bypass grafting, with both endograft limbs extended into the EIAs for distal seal.[55] After following their patients for approximately 15.7 ± 7.8 months, all bypasses (100%) remained patent without graft-related complications. Although there were no cases of sac enlargement or development of type I endoleaks, persistent mild buttock claudication occurred in two patients (9%) ipsilateral to the site of coil embolization.[55] Another series showed similar excellent internal iliac bypass patency rates of 91% and freedom from ischemic symptoms at 36 months.[56] It is important to avoid embolization of the distal hypogastric branches to further decrease the risk of pelvic ischemic complications.

Endovascular Repair of Internal Iliac Artery Aneurysms

Because of the multiple branches emanating from the internal iliac artery, preservation of flow in the presence of an IIAA is challenging. Maintaining pelvic perfusion helps to avoid any potential ischemic complications of internal iliac artery occlusion, including buttock claudication; vasculogenic impotence; and perineal, vesicular, colonic, rectal, or spinal cord ischemia.[57] In a series of 103 patients, Yano and associates[58] elaborately quantified the clinical presentation of pelvic ischemia after intentional internal iliac artery occlusion during endovascular aortoiliac aneurysm repair. The authors developed the following criteria based on the severity of clinical symptoms: class 0, no symptoms; class I, nonlimiting claudication with exercise; class II, new onset impotence, with or without moderate to severe buttock pain, leading to physical limitation with exercise; class III, buttock rest pain, colonic ischemia, or both. From their results, following internal iliac artery occlusion, pelvic symptoms developed in 22 patients (21%) with 12 patients categorized in class I, 9 patients in class II, and 1 patient in class III. Furthermore, the authors commented on two unique preoperative angiographic findings that they identified in 16 patients (16%) who ultimately developed chronic pelvic claudication: (1) stenosis of the remaining internal iliac artery origin greater than 70% with nonopacification of more than three of the six typical internal iliac artery branches (63%); and (2) small-caliber,

diseased or absent medial and lateral femoral circumflex arteries ipsilateral to the side of the internal iliac artery occlusion (25%).[58] These findings emphasize the importance of preoperative evaluation of the pelvic circulation to aid in the safe planning of internal iliac artery embolization and identification of the need for revascularization procedures.

In general, direct stent graft repair is possible provided proximal and distal landing zones are present within the aneurysmal internal iliac artery. This may require landing the stent in the largest distal branch available following coil embolization of smaller branches feeding into the aneurysm sac. If the proximal landing zone is compromised, a "chimney" type graft can extend into the common or EIA,[59] or the "sandwich" technique may be employed.[60] In the latter technique, the covered self-expanding stent within the internal iliac artery lies side by side with the iliac limb extender within the common iliac limb. This technique is the most successful and durable endovascular option to preserve internal iliac artery flow because it involves stenting into normal-sized arteries while excluding flow to the aneurysm itself. Alternatively, Wu and associates described the crossover chimney technique, which consists of delivering the chimney graft across the aortic bifurcation outside the bifurcated stent graft to provide retrograde flow to the internal iliac artery in endovascular repair of iliac or aortoiliac aneurysms.[61,62] Their midterm results were promising, with 100% initial technical success of internal iliac preservation without intraoperative endoleak. The crossover graft primary patency was 92.8% over a mean of 14.3 months (range 6-21 months).[61] Another hybrid approach employs an aortouniiliac endograft with femoral-to-femoral artery bypass along with a covered stent that is deployed retrograde from the "target" (distal) EIA into the ipsilateral internal iliac artery in a reverse U-shaped configuration (see Fig. 72.14).[63] Experience has demonstrated, however, that it is difficult to maintain position and patency in the "U" endograft, which tends to dislodge or kink over time. Due to these durability concerns, and the need for adjunctive open femoral-femoral bypass, this procedure has not gained widespread acceptance.

The W.L. Gore & Associates, Inc. (Flagstaff, Arizona) Gore Excluder Iliac Branch Endoprosthesis (IBE) device recently gained Food and Drug Administration approval in the United States. As of 2017, this is the only device with an on-label indication for endovascular management of common iliac aneurysms. The IBE device is composed of an iliac branch and a precannulated internal iliac component. At 16 French, the delivery system allows for repositioning and cannulation of the internal iliac vessels without need for brachial or axillary access. In their retrospective case series of 10 patients, Millon and associates[64] described a technical success of 100% in deployment of all components, and no intraoperative adverse events or endoleaks. They followed their patients up to 6 months and reported one internal iliac component occlusion. In a larger series spanning multiple centers using the IBE, Ellozy and associates[65] demonstrated 95.1% internal iliac limb patency, 95.2% technical success, and no type I or type II endoleaks or device migration at 6-month follow-up. Moreover, data from the IBE 12-04 US pivotal trial (28 centers) and Global Registry for Endovascular Aortic Treatment (GREAT registry, 14 centers) revealed 100% freedom from new buttock claudication symptoms at 6 months.[65] Across all centers, use of the device was associated with 90% iliac branch patency over 2 years. Although gaining favorable usage, further long-term results are needed to fully evaluate the longer-term durability of this and other similar devices.

Purpose-specific iliac branch devices (IBD) designed by Cook (Cook Medical, Bloomington, Indiana) have been implanted in patients outside of the United States since 2006 (see Fig. 72.1A–F). The delivery system for this device comes with a preloaded curved catheter, which simplifies cannulation of the internal iliac artery from the contralateral groin. The IBD is positioned over a stiff wire in typical fashion. Wire passage through the curved catheter is snared from the contralateral femoral artery. Following stiff wire exchange and partial deployment of the IBD, a sheath is then introduced from the contralateral femoral artery into the internal iliac artery branch. A covered bridging stent is then deployed after fully unsheathing the IBD (see Fig. 72.11). Depending on the anatomy, the standard bifurcated iliac stent configuration comes with a modular side-arm branch that can be short (~14 mm) and straight, or helical and elongated, to provide a longer sealing zone. The application of this device preserves internal iliac arterial flow and can also be used for complicated cases of concomitant common and internal IAAs.

In a case series study of 27 patients, Chowdhury and his associates demonstrated that these procedures achieved a primary patency rate of 100%, a cumulative patency rate of 94.1%, and a 12-month patient mortality rate of 3.7% with low rates of reintervention and no device-related adverse complications.[66] From a single institution study of 46 patients, Cook IBD side-branch patency was 87% at 5 years.[67] In another series with 100 patients, internal iliac artery patency was 91.4% at 5 years, and cumulative IBD side-branch patency was 87% at 60 months with 11% hypogastric side-branch occlusions occurring within the first year.[68] Extracting data from nine series reporting the use of the Cook IBD in 196 patients, Karthikesalingam et al.[69] noted that early technical success was between 85% and 100%. The review also revealed a collective 12% postoperative IBD limb occlusion rate; half of the patients with IBD limb occlusion developed buttock claudication. The reported rate of combined type I or III endoleak was only 1.5%, and the reintervention rate across all series was 6%.

More recently Simonte et al.[70] reported their long-term experience with the Cook IBD used in 149 patients over a 10-year period. Initial technical success was 97.5%; however perioperative procedure failure occurred in seven patients, four during surgery and three within 30 days of the index procedure. In follow-up, freedom from IBD reintervention was 91.8% at 9 years and hypogastric patency was 90.4% at 10 years. Interestingly, the presence of ipsilateral hypogastric aneurysm ($P = .031$) and initial IBD use during the early "learning curve" period of the study ($P = .006$) were predictive of early failure on multivariate analysis.[70] Having the distal seal landing zone in the hypogastric artery was also predictive of endoleak in a reported series from the Cleveland Clinic. Reporting on 138 IBDs used in 130 patients, estimated patency at 5 years was

81.8% and freedom from IBD-related endoleak was 96% at 5 years; all endoleaks were due to loss of the distal sealing in the hypogastric artery.[71] Finally, in their 5-year experience, Parlani and associates[68] also demonstrated that the presence of a hypogastric aneurysm was the only significant predictor of reintervention, with a hazard ratio of 5.9 (95% confidence interval 1.57–22.08; $P = .008$). Based upon their reported experience, the authors now tend to avoid short distal necks, with more extensive distal landing into the gluteal artery in case of extensive hypogastric aneurysmal involvement.[68,70]

Although designed to be user friendly, both the Gore IBE and Cook IBD prostheses are less adaptable to complex anatomy, thus limiting their wider applicability especially when adhering to the instructions for use (IFU). Based on the current criteria for IBD use, up to 52% of patients may not be suitable for these devices.[72] Pearce and associates[73] conducted a study from two centers and noted that by strictly complying with the manufacturer's IFU, only 35% (35/99) of patients with IAAs treated over the past decade at those institutions would have been suitable for treatment with the IBD or IBE device while remaining strictly within the IFU. In their analysis, only 18.2% and 25.3% of patients fit the stringent inclusion criteria for the Cook and Gore iliac branch devices, respectively.[73] The most common reason for exclusion for either device is the diameter of the internal iliac artery precluding an appropriate landing zone.

In a single-center study, Della Schiava and associates[74] compared the in vivo anatomical conformability of the branched stent grafts (13 Gore IBE vs. 9 Cook IBD) when used in aortoiliac aneurysm repair. Because the branched stent grafts rely on both the external and internal iliac axes, they are subjected to high tortuosity constraints that generate stiffness along the axes of repair, resulting in gradual shortening of the covered lengths.[74] This applied stress, in a setting of marked iliac tortuosity, can potentiate type Ib endoleaks, graft limb plication, and limb thromboses.[74-77] After applying centerline software to compute and compare the index of tortuosity along the iliac axis, the authors noted that the IBD stent graft more significantly modified the length and tortuosity of the iliac axis following implantation. The implantation of an IBD causes a shortening of the total iliac length of 20.56 mm on average versus only 9.77 mm for IBE stent grafts ($P \leq .02$).[74] The postoperative lengths along the internal iliac axis were not affected by either stent. Within anatomical constraints, this finding appears to favor the use of the more conformable Gore IBE in cases of severe iliac tortuosity to minimize postoperative complications associated with stent malposition (type 1b or 3 endoleaks) or branch occlusion (pelvic ischemia). Although the early results associated with both these devices are promising, additional information regarding long-term outcomes are still required.

CONCLUSIONS

Isolated iliac aneurysms are uncommon lesions, usually recognized incidentally during imaging procedures indicated for other reasons. Symptomatic or large iliac aneurysms greater than 3 cm in diameter can be electively repaired safely with open or endovascular techniques. Surgical objectives are to repair and exclude the aneurysm with reconstruction or preservation of the internal iliac artery to minimize pelvic ischemia. Endovascular repair, with its associated reduced incidence of in-hospital morbidity and mortality along with reduced length of stay, has gained favor over open repair as the initial approach of choice for patients with suitable anatomy. Successful endovascular repair is highly dependent on precise, preoperative high-resolution cross-sectional imaging for detailed case planning.

Short- and midterm outcomes for complete endovascular repair using new stent graft devices that maintain flow to both the external and internal iliac artery are promising, with acceptable initial technical success rates and durability as compared to techniques involving unilateral or bilateral internal iliac artery occlusion. Nevertheless, in situations where internal iliac artery patency is essential and a complex anatomy is not amenable to these devices, open surgical repair may be the preferred modality. Knowledge of all current devices and techniques allows for predictably excellent outcomes for almost any patient, regardless of anatomic limitations, when these are applied in a creative and innovative fashion.

INTRODUCTION

Aortic diseases, including aortic aneurysms, are the 12th leading cause of death in the United States.[1] Although abdominal aortic aneurysms (AAAs) and ascending aortic aneurysms are more common, descending thoracic aortic aneurysms (TAAs) and thoracoabdominal aortic aneurysms (TAAAs) are not rare, with an estimated incidence of 5.9 cases per 100,000 person-years.[2] A study by Clouse and others suggests that the incidence is increasing.[3] During the last 5 years, the mortality for nonruptured and ruptured TAAs in the US population aged 55 and older ranges from only 0.1 to 2.8 and 0.2 to 3.2 per 100,000, respectively, and increases with age. TAA repair is associated with a high morbidity and mortality. Although aortic aneurysms may affect the ascending aorta and aortic arch, the focus of this chapter is on descending TAAs and TAAAs, which can occur from the left subclavian artery to the aortic bifurcation.

Thoracic aortic pathology is very complex and may be related to a variety of histopathologic conditions. Most TAAs and TAAAs are secondary to either medial degeneration or aortic dissection. Medial degeneration is characterized by disruption and loss of elastic fibers and increased deposition of proteoglycans. Many other thoracic aortic pathologies, including the acute aortic syndromes (aortic dissection, intramural hematoma, and penetrating aortic ulcers) and various forms of vasculitis (giant cell arteritis, Takayasu arteritis, and Behçet disease), can induce TAAAs. Although isolated abdominal aortic aneurysms were once called atherosclerotic, TAAs associated with frank atherosclerosis are much rarer. Other histopathologies associated with the thoracic aorta include coarctations, various brachiocephalic anomalies (e.g., aberrant right subclavian arteries), and tumors. Disastrous complications of TAA include pulmonary and enteric fistulas.

This chapter is intended to provide an overview of thoracic aortic disease in order to help these patients' caregivers make the decisions involved in dealing with these pathologies. Importantly, guidelines for the diagnosis and management of patients with thoracic aortic disease have recently been published,[4] and contemporary reviews on the management of TAA and TAAA are also available.[5-7]

THE THORACIC AORTA: ANATOMY AND EPIDEMIOLOGY OF TAA AND TAAA

Although the techniques of open and endovascular TAA and TAAA repair are discussed in more detail in Chapters 77-80, this chapter provides a description of the normal anatomy, as well the many and varied pathologies that are associated with TAA.

Definition

TAAAs are localized dilatations in the thoracic and abdominal aorta secondary to weakening and subsequent expansion of the aortic wall. A TAAA by definition is a dilatation at least 1.5 times its normal value.[8] It is critically important to define these anatomic aortic sizes (Table 76.1) to help identify pathologic aortic growth, because TAAA diameter is the strongest predictor of rupture, with a reported mean aortic diameter of ruptured TAAAs of 6.1 cm.[9] When all aneurysms of the thoracic aorta are considered, those of the ascending aorta are the most common (40%), followed by those of the descending thoracic aorta (35%), aortic arch (15%), and thoracoabdominal aorta (10%).[10]

Normal and Pathologic Aortic Size

The normal thoracic aortic is divided into four parts: the aortic root, the ascending aorta, the aortic arch, and the descending thoracic aorta.[4] The normal thoracic aortic wall is composed of three layers, similar to all blood vessels, which include the intima, media, and adventitia. The aorta normally enlarges as it progresses from the aortic root to the terminal aorta.[10] In addition, gender, age, and body surface area influence aortic diameter (Table 76.2). Even after adjusting for age and body surface area, mean aortic size is significantly smaller, usually 2 to 3 mm, in women than in men.[11-14] Body surface area is reported to be a better predictor of aortic diameter than height or weight.[14] The annual increase in TAAA cross-sectional diameter is highly variable, with reported increases of 1.9 to 3.4 mm/year.[15] Importantly, the growth rates of TAAAs are not predictable or linear. However, there is consensus that TAAAs, similar to

TABLE 76.1 Normal Aortic Diameter and Length by Segment, as Well as Percentage of Aortic Aneurysm Total Represented by Each Aortic Segment[2,9]

Aortic Segment	Mean Aortic Diameter (cm)	Mean Aortic Length (cm)	Percentage of Aneurysms
Ascending	3	5	40
Aortic arch	2.5-3.5	4	15
Descending thoracic	2.0-2.3	NR	35
Thoracoabdominal	1.7-2.6[a]	NR	10

NR, Not reported.
[a]Average 2 mm larger in males than in females.

TABLE 76.2 Normal Adult Thoracic Aortic Diameters by Gender[4]

Aortic Segment and Gender	Range of Reported Mean (cm)	Modality of Assessment
Mid-descending (female)	2.45-2.64	CT
Mid-descending (male)	2.39-2.98	CT
Diaphragmatic (female)	2.40-2.44	CT
Diaphragmatic (male)	2.43-2.68	CT

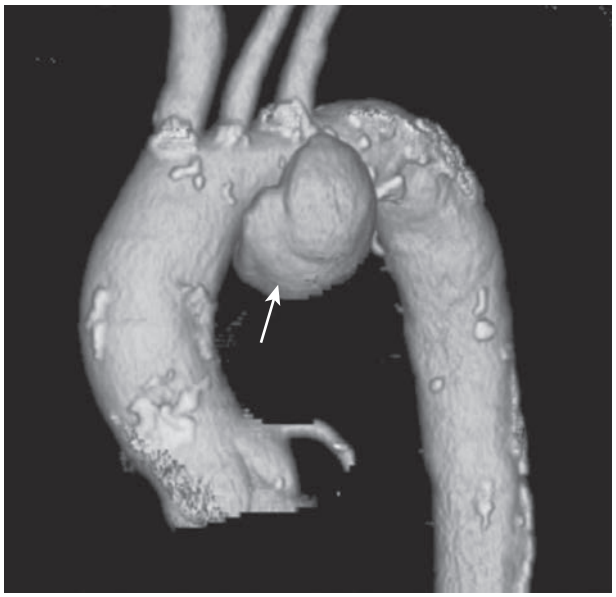

Figure 76.1 Saccular, mycotic thoracoabdominal aortic aneurysm. The patient had bacteremia and was found to have a distal aortic arch/proximal descending thoracic aortic saccular aneurysm *(arrow)*.

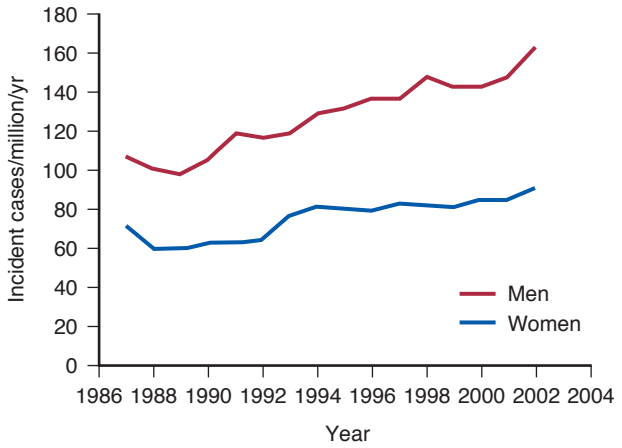

Figure 76.2 Increasing incidence of thoracoabdominal aortic aneurysms and dissection in the Swedish population (men and women), 1987 to 2002 (cases per million). (Used with permission from Olsson C, Thelin S, Stahle E, et al. Thoracic aortic aneurysm and dissection: increasing prevalence and improved outcomes reported in a nationwide population-based study of more than 14,000 cases from 1987 to 2002. *Circulation*. 2006;114:2611–2618.)

AAAs, have growth rates that accelerate as they enlarge.[16] For example, TAAAs larger than 5 cm expand at a rate of 0.79 cm/year, whereas TAAAs less than 5 cm experience growth rates of 0.17 cm/year.[15] Dapunt and associates have documented that patients with ruptured TAAAs experienced growth rates of 0.7 cm/year.[9] Additionally, the distal aorta manifests more rapid growth than the more proximal segments.[15]

The terms *saccular* and *fusiform* should also be defined for TAAAs, because the morphology of an aneurysm will often dictate treatment options as well as pointing to specific causes (i.e., mycotic aneurysms are often saccular and at high risk for rupture).[17] Most TAAAs are fusiform aneurysms, which involve a chronic uniform dilatation involving the whole circumference of the aorta. In contrast, saccular aneurysms often represent an eccentric dilatation of the aorta (Fig. 76.1). The size at which eccentric saccular aneurysms should be repaired has not been well studied; however, most would concur that a lower threshold is an acceptable indication for repair.

Incidence/Prevalence

Clouse and coauthors have documented that the incidence of TAAAs in the United States is 10.4 cases per 100,000.[3] Olsson examined the prevalence of TAAA in a large contemporary population. All subjects with thoracic aortic dissections or aneurysms from 1987 to 2002 were identified in the Swedish National Healthcare Registry. Of 14,229 individuals with thoracic aortic disease, the diagnosis was made in 11,039 (78%) before death. The incidence of thoracic aortic disease rose by 52% in men and 28% in women to reach 16.3 and 9.1 per 100,000 per year, respectively. The authors concluded that the prevalence and incidence of thoracic aortic disease were higher than previously reported and were increasing (Fig. 76.2).[18] The increasing prevalence of TAAAs has been attributed to a number of factors, including improved imaging techniques, an aging population, and increased patient and physician awareness.[19]

Population Affected

TAAAs are primarily a disease of the elderly. The average age of patients with TAAAs is 65 years, with a male-female ratio of 1.7 : 1[2]; in contrast, in patients with AAAs whose mean age is 75 years, the male-female ratio is 6 : 1.[20] TAAAs clearly have a genetic component, since more than 20% of patients will have a first-degree relative affected by aneurysm disease.[21-23]

Risk Factors for Disease and Rupture

Many risk factors that are common in patients with AAAs, including hypertension, smoking, and atherosclerosis in other arteries, are also common in patients with TAAAs.[2,24-26] Systemic hypertension—in particular elevated diastolic blood pressure greater than 100 mm Hg—has been associated with aortic growth and rupture.[9,27] Although TAAAs are most often described as degenerative, up to 20% are the sequelae of chronic aortic dissection.[28]

Although patients with chronic dissection do not seem to be at risk of more rapid aneurysm expansion than those with purely degenerative aneurysms,[15] dilatation of the outer wall of the false lumen necessitates late aortic repair in up to 40% of patients irrespective of initial medical or surgical treatment of the dissection.[28] Durham and colleagues reviewed their experience of 200 patients serially followed by axial imaging after acute uncomplicated type B dissection. They found that at a mean time to intervention of 27 months, 28% of patients required aortic reconstruction for aneurysm degeneration, typically open TAAA repair. The only factor predictive of aortic growth was an initial aortic diameter greater than 3.5 cm, while

false lumen thrombosis prior to discharge was protective against aortic growth.[29] Given that nearly all of the operated patients ultimately underwent open TAAA, early intervention with thoracic endovascular aortic repair (TEVAR) to cover the entry tear in selected high-risk patients may induce positive aortic remodeling and avoid the morbidity associated with open aortic reconstruction. This should be an area of inquiry for future investigations.

Multiple genetic syndromes, including, most commonly, Marfan syndrome, have been associated with TAAs and dissections. The vascular manifestations of Marfan syndrome invariably involve aortic root dilation, progressive root and ascending aortic aneurysmal degeneration, and potentially aortic dissection of variable extent.[30] The extent of dissection predicts the need of future intervention on the distal aorta, but there is no consensus on appropriate management of the aortic arch.[31] Reoperation is common in Marfan syndrome, it has occurred in 20% of patients at a mean of 5 years from the index operation, with most of these requiring multiple reoperations.[32]

Familial aggregation studies have shown that between 11% and 19% of patients referred for TAA or dissection repair have a first-degree relative with a TAA or dissection.[21,24,25] Patients with a strong family history of TAA tend to present at a younger age than those without a positive history, yet at an older age than those with connective tissue disease. This disease appears to be inherited in an autosomal dominant fashion with variable expression.[33] Mapping studies have shown that there is significant genetic heterogeneity in these patients with familial thoracic aortic aneurysm and dissection (TAAD). Causative genes for TAAD2 (due to TGFBR2 mutation), 16p (due to MYH11 gene), and TAAD4 (due to ACTA2 gene) have been identified, suggesting that mutations to the basic aortic wall building blocks of actin and myosin are responsible for these syndromes.[23,34,35]

Even among patients with Marfan syndrome, in whom mutations in fibrillin-1 (*FBN1*) are the culprit genetic defects, the pathogenesis is more complicated than previously thought. Homology between *FBN1* and transforming growth factor beta (TGF-β) binding proteins and the insufficiency of impaired elastogenesis alone to provoke aneurysmal aortic degeneration suggest a complex interplay between multiple factors and perhaps a central role for TGF-β signally.[36] Further studies have suggested that rare copy-number variants disrupt genes responsible for smooth muscle cell adhesion and contraction in patients with both sporadic and familial TAA disease.[37] The genetic implications of TAAs and dissections are the subject of many contemporary reviews.[36,38,39]

Because most patients with TAAAs are asymptomatic, treatment is aimed at preventing rupture. Natural history studies of TAAAs are rarer than those of isolated infrarenal AAAs, likely related to their much less frequent occurrence. In addition, studies on TAAAs often include patients with both acute and chronic aortic dissection, which serves to complicate natural history analyses. Initial studies from the 1970s by Pressler and McNamara documented that approximately 40% of patients who did not undergo surgical repair died of TAAA rupture, whereas 32% died of other cardiovascular diseases. Mean survival was less than 3 years. During the extended period of observation, more than 90% of patients sustained aortic rupture, with 68% of ruptures occurring more than 1 month after the diagnosis.[40,41]

The 5-year survival rate for patients with 6.0-cm TAAAs is 54%, with a risk for rupture of 3.7%/year and a risk for death of 12%/year. Median survival in patients with untreated TAAAs, at only 3.3 years, is poor.[42] In a natural history study by Crawford and DeNatale of patients who were not candidates for surgery, the survival rate was just 24% at 2 years, with over half the deaths related to aneurysm rupture. Chronic obstructive pulmonary disease (COPD) was noted in 80% of the subgroup with rupture.[43] Similar studies in patients with small infrarenal AAAs have confirmed COPD as a significant risk factor for rupture.[44] Cambria and others followed a series of 57 patients with TAAAs who were not considered operative candidates. In addition to COPD, the authors found an association ($P = .06$) between rupture and chronic renal failure.[45] In a study by Griepp and colleagues, 165 patients with TAAAs were monitored after being assigned nonoperative status. Twenty percent of patients eventually suffered rupture. Important risk factors for rupture included older age, COPD, uncharacteristic continued pain, and aortic diameter. Patients with aortic dissection ruptured at smaller aortic diameters than did those with degenerative aneurysms.[46]

Maximal aortic dimension has emerged as the most reliable predictor of future aortic dissection or rupture. Those with aortic diameters less than 50 mm experienced estimated annual event rates (rupture or dissection) of less than 1%, as compared with 2.7% to 8.1% and 37.5% to 62.5% among those maximal diameters of 50 to 60 and greater than 60 mm, respectively.[47] Dapunt and coworkers documented that TAAAs greater than 8 cm have an 80% risk for rupture within 1 year of diagnosis.[9] However, the size at which TAAAs rupture is unpredictable. Similar to AAAs, it appears that aneurysm growth rates play a role. The average expansion rate of a TAAA is approximately 0.10 to 0.42 cm/year.[42,48-50] Coady and associates suggested that expansion by more than 1 cm/year signals impending rupture.[48] Juvonen and colleagues examined 114 patients with TAAAs in detail.[51] Multivariate analysis suggested that increasing age, pain (even atypical), COPD, descending thoracic aortic diameter, and abdominal aortic diameter were predictive of rupture (Table 76.3).

TABLE 76.3 Risk Factors for Thoracoabdominal Aortic Aneurysm Rupture[51]

Risk Factor	Odds Ratio	*P*-Value
Age	2.6[a]	0.02
Pain	2.3	0.04
COPD	3.6	0.004
Descending aortic diameter	1.9[b]	0.003
Abdominal aortic diameter	1.5	0.05

[a]Per decade of age.
[b]Per centimeter of diameter increase.
COPD, chronic obstructive pulmonary disease.

PATHOGENESIS

The development of a TAAA is a multifactorial event that involves a complex interaction of genetic factors, cellular imbalance, and altered hemodynamic factors.[52] The increased incidence of TAAAs in patients with Marfan syndrome and other connective tissue disorders inherited in a Mendelian manner, as well as the familial inheritance of nonsyndromic TAADs typically inherited in an autosomal dominant fashion with marked variability in the age of onset and decreased penetrance, suggests a varying genetic role along different segments of the aorta.[23,33-35] As alluded to previously, even in Marfan syndrome, the mechanisms behind aortic aneurysm degeneration are more complex than previously appreciated. More recent studies have suggested that genetic variation in extracellular matrix (ECM) actin and myosin may contribute to the development of TAAAs.[53,54] Wang and coauthors examined genetic signatures in the peripheral blood of patients with TAAAs (n = 58) and control patients (n = 36). This study documented a number of gene families that were different between the two groups, including those involved in the cell cycle, DNA metabolism, glycolysis, interferon-γ signaling, and transcription factors. The authors concluded that analysis of peripheral blood to determine expression signatures may help to identify patients with TAAAs with high accuracy.[55]

TAAA formation, therefore, is a complicated, dynamic process involving both extracellular and cellular processes, similar to other aneurysms (see Chapter 69). Once initiated through a combination of the aforementioned factors, inflammation and pathologic remodeling of the ECM occur. A large body of evidence suggests that ECM degradation by matrix metalloproteinases (MMPs) exceeds matrix production and repair during aneurysm formation. It is important to emphasize that there are significant differences in the composition of the aortic wall as one progresses from the ascending aorta to the iliac bifurcation. Andreotti and colleagues documented that the ascending aorta has a greater concentration of elastin and is therefore more compliant than the descending aorta. This alteration in elastin concentration leads to a progressive decrease in the elastin-collagen ratio as the aorta progresses from the ascending aorta to the abdominal aorta.[56] The media also becomes thinner as one progresses from proximal to distal along the aorta.[57]

A number of recent studies have documented the overexpression and increased activity of various ECM proteinases, specifically the MMPs, in human TAAAs.[58] These proteolytic enzymes, which have been more extensively studied in AAAs, are clearly critical as well during the formation of TAAAs. Sinha and coworkers documented asymmetric production of MMP9 in the expanding human TAAA wall, which correlated with increased numbers of macrophages.[59] In contrast, MMP2 was documented to be increased in the wall of the TAAA that was preserved, in particular, at the point where smooth muscle cells were more abundant and the wall was preserved. Ikonomidis and associates studied the role of MMPs in a murine model of TAAAs.[58] These authors documented that MMP9 gene deletion attenuated TAA formation despite increases in MMP2 activity. They concluded that interactions between MMP9 and MMP2 are necessary to facilitate TAAA progression. Recent studies by Ikonomidis and others have documented altered membrane type-1 matrix metalloproteinase and tissue inhibitor of metalloproteinase2 (TIMP2 an inhibitor of MMPs), in the murine TAA model.[60] Further studies by Johnston, Pope and others have also suggested a critical role for IL-1β and IL-6 in TAA based on animal studies.[61,62]

Aortic Wall Histology

The histology of TAAAs is most closely associated with medial degeneration, formerly known as cystic medial necrosis (Fig. 76.3). Medial degeneration is characterized by fragmentation and loss of elastic fibers, loss of smooth muscle cells, and collections of interstitial collagenous tissue, basophilic ground substance, and proteoglycans.[63,64] Although medial degeneration is considered part of the normal aging process, it is accelerated by certain clinical conditions such as hypertension and atherosclerosis.[65] Given the relatively widespread process along the thoracic aorta, medial degeneration is most closely associated with the development of fusiform aneurysms. Genetic abnormalities, such as Marfan syndrome, also accelerate aortic medial degeneration.[66] Although TAAAs were originally described as noninflammatory, recent studies have shown that infiltration of leukocytes contributes to the formation and development of TAAAs. The significant difference in the epidemiology and histology of TAAAs and AAAs suggests distinct causes.

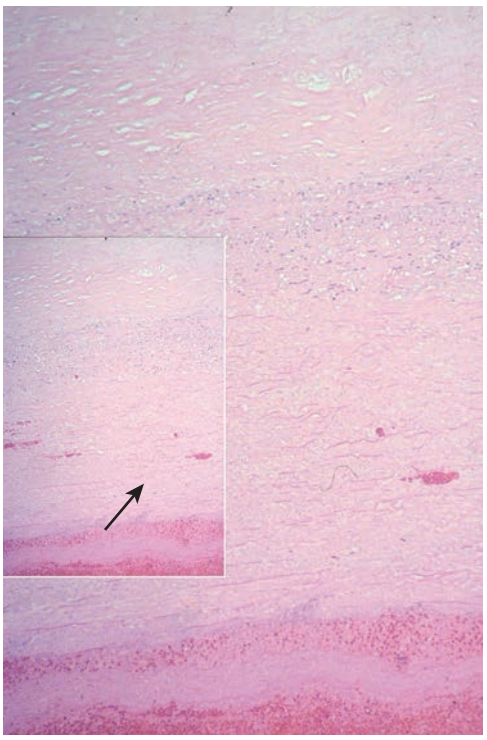

Figure 76.3 Documentation of medial degeneration and fragmented elastin (see *insert*, *arrow*) by histology (hematoxylin and eosin, 100×) of an aortic section in a patient with a thoracoabdominal aortic aneurysm. (Courtesy of Dr. David Williams.)

ETIOLOGY

Eighty percent of TAAAs are secondary to medial degeneration, with approximately 15% to 20% caused by aortic dissection (Table 76.4) (see Chapter 81). Patients with TAAAs secondary to aortic dissection are typically younger and involve more extensive aortic segments than do degenerative aneurysms.[67] The aorta in patients with Marfan syndrome is particularly prone to aortic dissection and subsequent TAAA formation.[68] Both systemic autoimmune disorders, such as Takayasu arteritis, and chronic nonspecific aortitis can destroy the aortic media with progressive aneurysm formation. Aneurysms associated with arteritis are more commonly seen in women than are degenerative aneurysms. Aneurysms of the upper thoracic aorta can also be secondary to congenital aortic coarctations, either in unrepaired coarctations or after repair.[69-71]

TAAAs may also form secondary to infection. Although saccular aneurysms have been described as mycotic, these aneurysms are most often bacterial and occur because of hematogenous spread of emboli laden with bacteria. Infected TAAAs usually arise as a result of seeding of atherosclerotic plaque in the aorta, the development of a focal inflammatory process in the aortic wall, and ultimately the formation of a false aneurysm. Infected TAAAs present many challenging dilemmas. The goal of therapy is to debulk the infection and restore arterial continuity. For years this has involved in situ repair with its attendant lifetime risk of reinfection. Recent reports of treatment of infected TAAAs with endovascular prostheses are beginning to accumulate.[73,74] The endovascular approach can be utilized as either definitive management or as a bridge to stabilize an ill patient to eventual open operation. An endovascular approach, if durable, may definitively circumvent the challenges posed by open aortic reconstruction in an infected field (Fig. 76.4).

TABLE 76.4 Etiology of Thoracoabdominal Aortic Aneurysms and the Relative Percentage Contributing to Disease[72]

- Degenerative (associated with atherosclerosis) (80%)
- Dissections (15%-20%)
- Connective tissue disorders (Marfan syndrome, Ehlers-Danlos syndrome, Loeys-Dietz syndrome)
- Infection (2%)
- Mycotic aneurysms (*Salmonella, Haemophilus influenzae, Staphylococcus* sp.)
- Syphilis
- Tuberculosis
- Aortitis (2%)
- Takayasu disease
- Nonspecific variety of giant cell aortitis
- Rheumatoid aortitis
- Ankylosing spondylitis
- Reiter syndrome
- Relapsing polychondritis
- Postoperative pseudoaneurysms (<1%)
- Associated with unrepaired and repaired aortic coarctations
- Traumatic (<1%)

ANATOMIC CLASSIFICATION

Evaluation of a patient with a TAAA, as well as the technical performance of either open or endovascular repair, is closely

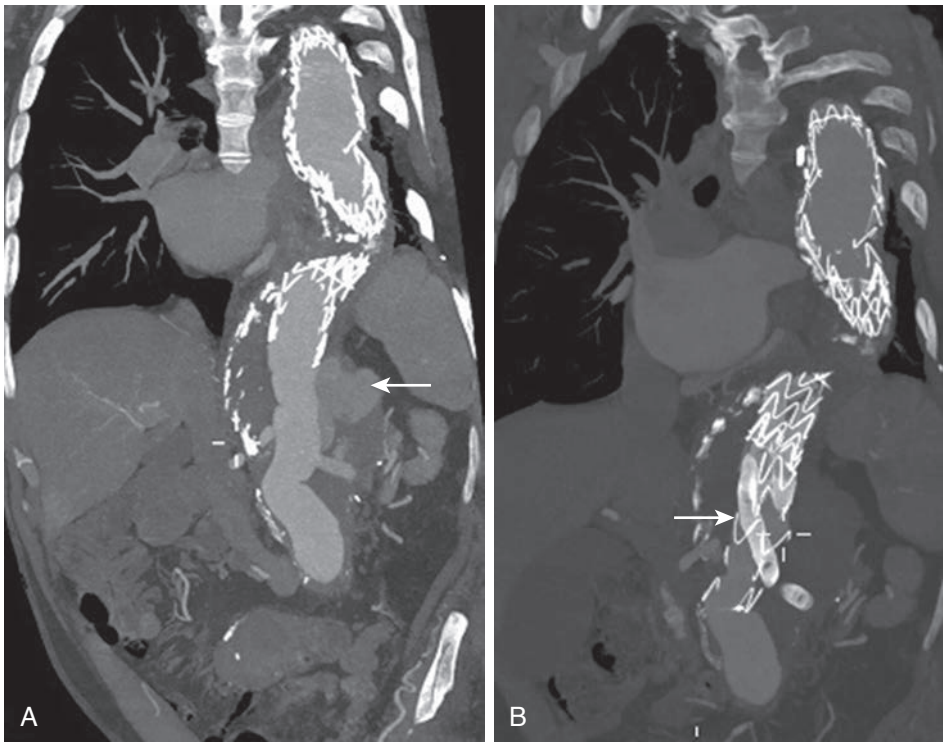

Figure 76.4 Patient with Marfan syndrome—who had previously undergone open thoracic aortic aneurysm repair, open thoracoabdominal aneurysm repair through redo thoracoabdominal approach, and thoracic endovascular aortic aneurysm repair—who presented with para-anastomotic pseudoaneurysm (A, *arrow*) and was successfully treated with a snorkeled exclusion of his pseudoaneurysm (B, *arrow marks* the celiac trunk snorkel).

aligned with the Crawford classification (Fig. 76.5).[72,75-77] Classification of TAAAs also has important therapeutic implications for the operation to be performed as well as the risk for specific complications. Type I TAAAs account for approximately 25% of all TAAAs. They involve the entire descending thoracic aorta and extend only to the upper abdominal aorta. Type II TAAAs (approximately 30% of TAAAs) involve the entire descending thoracic aorta and most of or the entire abdominal aorta (Fig. 76.6A). Type III TAAAs (<25%) involve variable lengths of the descending thoracic aorta and extend into the abdominal aorta (see Fig. 76.6B). Type IV TAAAs (<25%) are limited to the abdominal aorta, including the visceral and renal arteries.

CLINICAL FINDINGS

History and Physical Examination

Most patients with TAAAs have no symptoms attributable to their disease at the time of diagnosis.[26,41,72] The diagnosis is therefore often made when evaluating the patient for unrelated

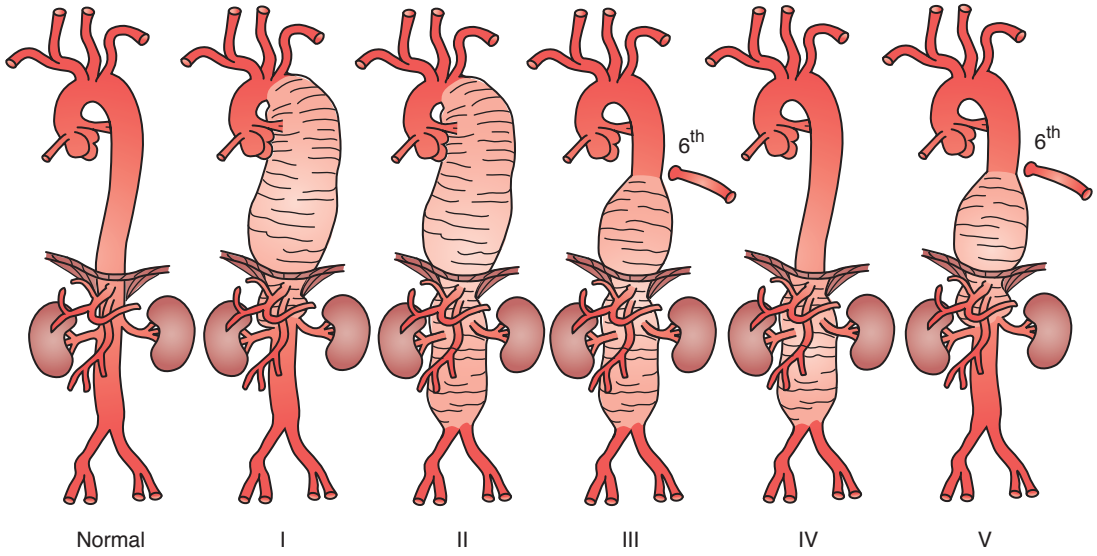

Figure 76.5 Crawford classification of thoracoabdominal aortic aneurysms. Type I, distal to the left subclavian artery to above the renal arteries. Type II, distal to the left subclavian artery to below the renal arteries. Type III, from the sixth intercostal space to the renal arteries. Type IV, entire abdominal aorta. Type V, below the sixth intercostal space to just above the renal arteries.

TABLE 76.5 Recommendations for Physical Examination of the Patient Presenting With Thoracic Aortic Aneurysm

Class/Level of Evidence	Recommendation
I/C	Perform a focused physical examination evaluating • Perfusion differentials in the upper and lower extremities • Evidence of visceral ischemia • Focal neurologic deficits • Murmur of aortic regurgitation • Evaluation for bruits • Findings compatible with possible cardiac tamponade

conditions. Although most patients with TAAAs are asymptomatic, Panneton and Hollier documented that 57% of patients with degenerative TAAAs will have symptoms before rupture.[72] The recent American Heart Association (AHA) guideline for thoracic aortic disease includes recommendations regarding the history and physical examination for the general approach to the patient with suspected thoracic aortic disease (Table 76.5).[4] The authors have suggested based on Class I, Level C evidence, that "the clinician should perform a focused physical examination, including a careful and complete search for arterial perfusion differentials in both upper and lower extremities, evidence of visceral ischemia, focal neurologic deficits, a murmur of aortic regurgitation, bruits, and findings compatible with possible cardiac tamponade."[78-80]

The most common initial symptom in patients with TAAAs is vague pain, which can occur in the chest, back, flank, or abdomen. The differential diagnosis in a patient with a symptomatic TAAA therefore includes angina, aortic dissection, and degenerative disease of the spine. The chronic pain associated with TAAAs may easily be dismissed in patients with TAAAs before the diagnosis of a TAAA has been made. Typical of most aneurysms that are enlarging, pain may increase in severity dramatically. Juvonen and coworkers suggested that the back pain associated with a TAAA can indeed be chronic and have a different pattern and implication than noted with AAAs, in which the back pain is more often acute and suggests impending rupture.[51]

Symptoms may also occur in patients with TAAAs from compression of the thoracic aorta by structures in the thoracic cavity. Hoarseness can develop in patients with TAAAs as a result of stretching or compression of the left recurrent laryngeal nerve (Fig. 76.7). Tracheal deviation, persistent cough, or other respiratory symptoms may also be present.[40,81] Dysphagia is an uncommon, nonspecific complaint due to compression of the aneurysm by the esophagus.[82] Sudden and catastrophic hemoptysis or hematemesis may occur as a result of erosion of the TAAA into the bronchial and pulmonary space or the esophagus, respectively.

Patients with TAAAs may rarely have neurologic deficits, including paraplegia. This is much more common in those with

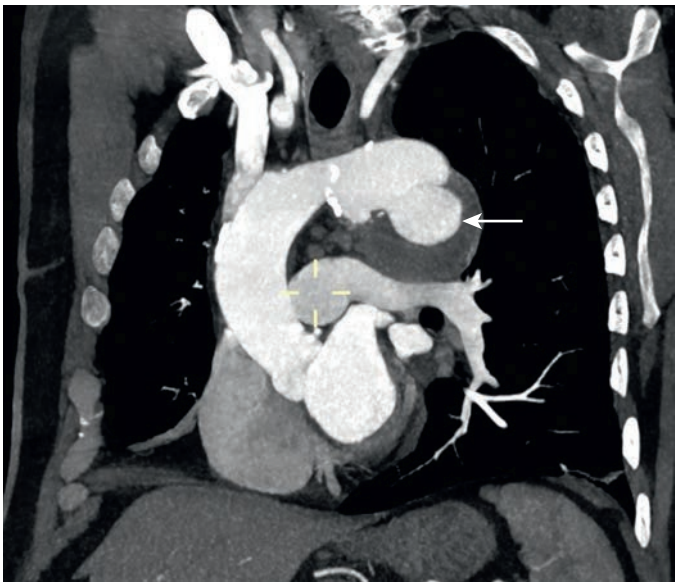

Figure 76.7 Patient who presented with new-onset hoarseness and voice weakness following previous endovascular abdominal aortic aneurysm repair. The patient was found to have a saccular thoracic aortic aneurysm *(arrow)*, ultimately requiring arch reconstruction with elephant trunk and subsequent thoracic endovascular aneurysm repair.

aortic dissection. Embolization to the visceral and renal arteries and arteries of the lower extremities has been reported.[83] Patients with an abdominal component of their aneurysm may have gastrointestinal hemorrhage, aortoenteric fistulas, or a functional obstruction of the small bowel secondary to compression of the duodenum. Most patients with symptoms have TAAAs that have attained a diameter greater than 5 cm.

On examination of a patient with TAAA there are generally no obvious physical findings in the chest area unless tracheal deviation is present.[84] Patients with an abdominal component of their TAAA may have a pulsatile abdominal mass similar to that seen in patients with pure AAAs. It is important to note that no controlled or blinded study has been performed that reproducibly stratifies patients with TAAAs into groups that predict poor outcomes.[4] The critical issue is to identify those patients who are acutely ill from their thoracic aortic disease and to triage them accordingly.

Synchronous Aneurysm Risk

Studies examining the natural history of patients with TAAAs indicate that between 20% and 30% will also have an AAA.[40,85] In a series of 1500 patients, Crawford and Cohen documented that 13% harbored aneurysms in other segments.[86] This appears to be true when examining patients who undergo TAAA repair as well, where as many as a third of patients will have undergone previous aortic repair.[87] Most commonly patients with TAAAs have undergone previous infrarenal AAA repair. Synchronous proximal ascending and arch aneurysms are noted in 6% to 13% of patients with TAAAs.[72] Even after repair, at least 10% of patients with TAAAs will require subsequent aneurysm repair in noncontiguous aortic segments.[88] Patients with Marfan

syndrome appear to be at high risk for this type of manifestation. Among patients with Marfan syndrome who had undergone cardiac surgery—over an average of 5 years following initial operation—20% required reoperation, with 37% of reoperations performed on the thoracic or thoracoabdominal aorta.[32] In Marfan patients presenting with type A dissection, 27% eventually required reoperation on the thoracoabdominal aorta, and this was three times more common in DeBakey I compared with DeBakey II dissections.[31] As discussed in subsequent chapters, there is clearly an increasing trend toward treating complex arch aneurysms and TAAAs with sequential open and endovascular therapies.[89-91]

DIAGNOSTIC EVALUATION

Imaging

Accurate and precise determination of the anatomy of a patient with a TAAA is mandatory in determining both the need for and the details of operative repair as well as the prescribed follow-up in patients with TAAAs who have not reached a diameter threshold for repair. Recommendations for aortic imaging techniques to determine the presence of progression of thoracic aortic disease have been modified and summarized (Table 76.6). Cross-sectional imaging, mainly by computed tomography (CT), is the primary method to visualize the thoracic and abdominal aorta for determining aneurysm diameter and extent. Because most TAAAs are small when discovered, serial imaging is required; however, level A and B evidence regarding the timing of surveillance is lacking. Serial imaging is typically performed at 6- to 12-month intervals, but it varies depending on the initial diameter and extent of the aneurysm.

Chest X-Ray

A chest radiograph (Fig. 76.8) or plain films of the abdomen in patients with TAAA may suggest an enlarged thoracic aorta secondary to a calcified aortic wall. Indirect findings suggestive of TAAA on chest radiography include a widened mediastinum, enlargement of the aortic knob, tracheal deviation, or left main stem bronchus displacement. Although chest x-rays are part of the routine preoperative workup of every patient considered for TAAA repair, they are inadequate to definitely exclude the presence or absence of thoracic aortic disease. A study of data pooled from 10 studies suggests that the predictive sensitivity of a widened mediastinum or an abnormal aortic contour associated with thoracic aortic disease is 64% and 71%, respectively.[92] In contrast, a prospective study of over 200 patients with thoracic aortic pathology documented a specificity of 86% for chest x-ray.[93]

Computed Tomography

Multidetector CT (MDCT) scanning with three-dimensional reconstruction capability is now the "gold standard" for evaluating the aorta in patients with TAAAs, rendering a diagnosis and establishing the extent and maximal dimensions of the aneurysm. New-generation MDCT scans have been shown to

TABLE 76.6 Recommendation for Aortic Imaging to Determine the Presence and Progression of Descending Thoracic Aortic Disease[4]

Class/Level of Evidence	Recommendation
I/C	Measurements of aortic diameter should be taken at reproducible landmarks, perpendicular to the axis of blood flow, and report in clear and consistent format. For measurements taken by CTA or MRA, the external diameter should be measured perpendicular to the axis of blood flow. Abnormalities of aortic morphology should be recognized and reported separately even when aortic diameters are within normal limits. The finding of aortic dissection, aneurysm, or trauma with or without aortic rupture should be immediately communicated to the referring physician. Techniques to minimize episodic and cumulative radiation exposure should be utilized whenever possible.
IIa/C	If clinical information is available, it can be useful to relate aortic diameter to the patient's age and body size.

CTA, computed tomography angiography; *MRA*, magnetic resonance angiography.

have sensitivities and specificities of well over 95%.[94-97] Post-acquisition image processing can generate sagittal, coronal, and oblique images as well as three-dimensional renderings that can be used to determine whether a patient is a candidate for a stent or graft.[98] A general assessment of other organs in the chest, abdomen, and pelvis is also obtained with MDCT, which allows the detection of other pathology, including cancer, that might affect patient management and surgical planning.[99,100] In patients with renal insufficiency, MDCT without iodinated contrast agents can be useful to determine TAAA size or extent but will not provide accurate data regarding the atherosclerotic burden of branch vessels or the presence of a dissection. It is our general impression, supported by the medical literature, that given the standard use of small boluses of low-osmolar contrast material in performing CT angiography (CTA), contrast-related acute renal failure after CTA is, in fact, rare and, when it does occur, mild.[101]

CTA also importantly allows other essential information to be obtained, as from the assessment of occlusive disease in branch vessels including the vertebral, subclavian, and hypogastric arteries, all essential contributors to the spinal collateral network. In addition, CTA documents the patency of important intercostal arteries that might be reimplanted into the aortic graft if extensive open TAAA repair is being considered. CTA further documents the presence of thrombus, inflammatory changes, dissection, and retroperitoneal blood suggestive of a ruptured aneurysm. The relative advantages of CT scanning over magnetic resonance imaging (MRI) include its better spatial resolution, reduced cost, rapidity of acquisition (thereby decreasing patient claustrophobia, anxiety, and image motion artifact), applicability to patients with previously implanted ferromagnetic devices, and wide availability.

A word of caution is needed regarding CTA and the timing of TAAA repair. Because of the nephrotoxicity of iodinated contrast agents, in the elective surgery and endovascular therapy setting, repair is best delayed for at least 24 hours after CTA, especially in patients with chronic renal insufficiency. The administration of *N*-acetylcysteine and intravenous hydration are current strategies used to limit contrast-induced nephropathy.[102,103] If the latter complication does occur, elective repairs should be delayed until renal function returns to baseline.

Magnetic Resonance Imaging and Magnetic Resonance Angiography

MRI/MR angiography (MRA) can be considered when evaluating patients with TAAAs, especially those with renal insufficiency, because it avoids the use of iodinated contrast material (Fig. 76.9). MRA has also been used to map the spinal cord circulation before TAAA repair.[104,105] Although MRI is believed to provide better contrast resolution, its spatial resolution is poorer than that of MDCT. Initially there was enthusiastic support for using MRI/MRA to identify the patency of visceral and renal vessels in patients with TAAAs.[106] However, recent concerns over the use of gadolinium in patients with renal insufficiency has made the use of MRA less attractive in those with aortic aneurysms.[107] MRI/MRA is also technically limited in that thrombus and calcium are not prominently displayed. In addition, the increased time required to acquire the images, the associated claustrophobia, the increased cost, and interference from metallic implants make MRA of limited use in the diagnostic evaluation of TAAAs.

Arteriography

Although in the past aortography was routinely performed as part of the preoperative evaluation of patients with TAAAs to define the extent and location of the aneurysm, angiography is currently considered obsolete except for special situations, such as attempting to map the spinal cord circulation. Williams and coworkers used angiography to identify the spinal artery of Adamkiewicz, or the great radicular artery. By knowing in

advance of TAAA repair which intercostal artery was providing this important branch, they sought to enable prompt and focused revascularization while also preventing paraplegia.[108] Indications for angiography also include the evaluation of branch anatomy in a patient with a TAAA and occlusive disease in the cerebrovascular, visceral, renal, or iliac beds when it is important to limit the use of iodinated contrast material in patients with chronic renal failure. Selective angiography using dilute contrast or CO_2 might also be used to treat patients with occlusive disease before TAAA repair, even though few specific studies documenting this approach have been performed.

Laboratory Testing

At present, there are no available biomarkers to suggest the presence of a TAAA. Initial research in patients with acute aortic dissections has focused on a number of proteins, including lipoprotein (a), S-100B, and calponin.[109-111] Touat and others have suggested that platelet activation and thrombin generation occur in patients with large dilated ascending aortic aneurysms, particularly in areas of mucoid degeneration.[112] Recent reviews suggest that although there are currently no clinical serologic screening tests for TAAA, there are multiple promising targets for investigation.[113,114] One recent study examined plasma and aortic tissue markers in patients with and without bicuspid aortic valves undergoing aortic valve or ascending aortic repair. The investigators demonstrated differential expression of microRNA and MMP subtypes between those patients with bicuspid and tricuspid aortic valves. This suggests that familial and degenerative aortic disease may be distinguished by a relatively simple blood test, although these tests are not yet clinically available.[115] Standard laboratory testing, including a complete blood count with platelets, coagulation studies, and determination of blood urea nitrogen and creatinine levels, is routine before TAAA repair. Reports have suggested that the rare patient with a TAAA may have low-grade disseminated intravascular coagulation based on consumptive coagulopathy from the aneurysm.[116]

MEDICAL THERAPY

It is important to acknowledge that there is no level A or B evidence comparing modern medical therapy (aspirin, beta blocker, statin, angiotensin-converting enzyme inhibitor [ACE-I] or angiotensin receptor blocker [ARB], smoking cessation medications) with open or endovascular TAAA repair. In addition, most of the literature on which we base our medical management of patients with TAAAs is extrapolated from literature on patients with ascending aortic aneurysms or aortic dissections.[117-120] In general, nonoperative management consists of strict blood pressure control with beta blockade and an ACE-I or ARB, cessation of smoking, and periodic imaging to monitor the size of the TAAA. There are guidelines that are helpful in the management and preoperative preparation of patients with AAAs but not specifically for patients with TAAAs. In addition, reports focused on medical therapies to limit or slow the growth of TAAAs are few. The AHA Guidelines suggest that "stringent control of hypertension, lipid profile optimization, smoking cessation, and other atherosclerotic risk-reductions should be instituted for small aneurysms not requiring surgery, as well as for patients who are not considered to be surgical or stent graft candidates."[4] The medical management of TAAA has recently been reviewed and is further detailed in the following text.[121,122]

Antihypertensive Medication

Recent guidelines suggest that antihypertensive therapy should be administered to patients with TAAAs; it should be titrated to a goal blood pressure of 140/90 in patients without diabetes and 130/80 in patients with diabetes or chronic renal failure.[4] It has been recommended that, unless contraindicated, patients with Marfan syndrome and aortic aneurysms be given beta blockers to reduce the rate of aortic dilatation. A Class IIa recommendation has been made that in those with TAAs, blood pressure should be reduced with beta blockers, an ACE-I, or anARB to the lowest point the patient can tolerate without adverse effects.

Beta Blockers

Wheat and Palmer are credited with documenting that decreasing the force of myocardial contraction (dP/dt) slows aortic growth and may prevent TAAA rupture secondary to aortic dissection; however, it does not apply to degenerative TAAAs.[123] This observation is the basis for prescribing β-adrenergic blocking agents as first-line antihypertensive therapy for patients with TAAAs. Shores and colleagues used propranolol over a 10-year period and showed a significant reduction in growth of the aortic root, aortic events, and mortality in patients with Marfan syndrome.[124] Results in animal models of AAA have not translated into beneficial effects of slowing AAA growth in humans.[125,126] It is therefore not clear that beta blockers retard aortic growth in patients with degenerative TAAAs. Nevertheless, the safety and efficacy of beta blockers in preventing death secondary to myocardial infarction are well documented; therefore they should be prescribed, or, if already prescribed, continued in the perioperative setting.

Angiotensin-Converting Enzyme Inhibitors or Receptor Blockers

There is increasing evidence that oxidative stress plays an important role in the development of degenerative TAAs. Ejiri and associates documented a role for the renin-angiotensin system in the pathogenesis of TAAAs. Human thoracic aneurysmal ($n = 40$) and nonaneurysmal (control, $n = 39$) aortic sections were examined, and the results documented markedly increased in situ production of reactive oxygen species throughout the TAAA wall. Multiple regression analysis revealed that medical treatment with angiotensin II type 1 receptor blockers suppressed expression of reactive oxygen species in TAAA.[127] A study by Moltzer and others specifically focusing on TAAs also suggests that angiotensin II type 1 (AT_1) receptor blockers, and not ACE or renin inhibitors, should be preferred treatment for patients with TAAs.[128] Multiple lines of evidence now suggest that the mechanism of action of ACE-I, and particularly the ARB losartan, on the attenuation of aneurysm growth is

modulation of TGF-β–mediated signaling.[121,122] It remains to be seen whether this is an ARB class effect or if one particular ARB is more effective than others at preventing aneurysm growth.

It should be noted that the evidence for the use of ARB in preventing aneurysm growth is strongest among patients with Marfan syndrome. However, this finding should not be surprising given the new evidence, discussed previously, of the pivotal role of TGF-β signaling in the pathogenesis of that disease. But even in this patient population, the data are somewhat contradictory. In a large randomized trial comparing losartan to atenolol (considered standard therapy), Lacro and colleagues demonstrated no difference in efficacy between the two drugs in preventing aortic root dilatation among young Marfan patients.[129] Similarly, a smaller randomized study comparing losartan to atenolol in group of patients with a broader age range found no difference in aortic root dilatation or adverse aortic events.[130] Yang et al. demonstrated the ability of losartan, in combination with the MMP inhibitor doxycycline, to normalize MMP and TGF-β expression profiles and thereby maintain aortic structural integrity and decrease aortic degeneration in a mouse model of Marfan syndrome.[131] In a study comprising nearly 600 Marfan patients, den Hartog and colleagues demonstrated that ARB use is associated with a 70% reduction in the incidence of subsequent type B aortic dissection compared with patients not taking ARB. Given our understanding of TAAA development following aortic dissection, this study suggests that ARBs have the potential to alter, at least in Marfan patients, the natural history of the disease.[132]

Statins

A well-studied class of drugs with important cholesterol-lowering properties is the 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors. HMG-CoA reductase inhibitors, also known as statins, in addition to lowering cholesterol, also have pleiotropic effects that inhibit inflammation.[133,134] Specific to TAAAs, recent studies in human TAAAs have shown a role for p22phox-based reduced nicotinamide adenine dinucleotide/reduced nicotinamide adenine dinucleotide phosphate (NADH/NADPH) oxidase in the pathogenesis of TAAAs. This study suggests that statins might have inhibitory effects on the formation of TAAAs via the suppression of NADH/NADPH oxidase.[127]

Although data examining TAAA growth in humans are limited, Schouten and associates documented that statins inhibit the growth of AAAs.[135] A recent propensity score matched retrospective review investigated the effect of statins on patients with dilated ascending aortas. The investigators found a significant decrease in further aortic degeneration as well as a composite of death, dissection, rupture, and need for repair among patients receiving statins.[136] As mentioned earlier, the structural anatomy and the pathophysiology of aortic degeneration in different aortic segments varies. Extrapolating the benefit of statins to other thoracic aortic pathology is thus speculative. Another retrospective review of patients with aortic aneurysms stratified by statin use demonstrated a reduction in rates of aneurysm-related events (dissection, rupture, or death) and need for operation among patients taking compared to those not taking statins.[137] Other investigators have suggested that statins are effective in lowering mortality after endovascular AAA repair but not after TAAA repair.[138] These authors concluded that this variable response to statins, again, indirectly supports the concept of a distinct pathogenesis of AAAs and TAAAs. Nonetheless, most patients with TAAAs have other indications for statin therapy.

Smoking Cessation

Patients who smoke or who have COPD are at increased risk for the development of TAAAs. TAAAs also grow faster and rupture more often in smokers.[9,51] Cannon and Read suggested that this was secondary to increased elastolytic activity.[139] Based on the AAA literature, few would argue that patients who smoke are at risk for the development of TAAAs.[140,141] These studies suggest that active pursuit of cessation of cigarette smoking is an important adjunct in those under observation with a TAAA. Yet, similar to statin usage, no randomized or prospective trials have ever shown that smoking cessation will slow thoracic aortic growth.

SELECTION OF TREATMENT

The decision as to when to operate on a patient with a TAAA involves assessment of the likelihood of aortic rupture versus the operative risk of the individual patient.[142] It is unclear at present what the impact of thoracic endovascular aortic repair (TEVAR) will be, with its attendant lower short-term mortality and morbidity, on decision making regarding what aortic diameter should serve as a threshold for TAAA repair. Two major factors, the patient's physiologic reserve and vascular anatomy, play a significant role in determining whether a patient is best suited for open repair or an endovascular approach.[143] Recent guidelines specifically tailored for when and how to repair TAA and TAAA have been issued (Table 76.7).[4]

Size Criteria

Size criteria for TAAA repair are not as clearly defined as for infrarenal AAAs because there are no level A or B scientific data regarding the timing of operative intervention.[144,145] This issue is further complicated by the observation that degenerative TAAAs are often not uniform in size and involve aortic segments of varying diameters and morphology. In addition, it is important to recognize the impact of body size on aortic size. Adjustment for body surface area or height must be incorporated into decision making about the threshold for repair and risk for rupture.[146] For the average older man (1.7-1.8 m in height), the normal proximal descending aorta is 2.8 cm, the mid-descending aorta is 2.7 cm, and the distal descending aorta is 2.6 cm. The authors suggested that the accepted size indications for TAAA repair, independent of etiology, might be a diameter of 5.2 to 5.6 cm or twice the diameter of the normal contiguous aorta, depending on the aortic segment being repaired. Algorithms suggest that

TABLE 76.7 Recommendation for Thoracic and Thoracoabdominal Aortic Aneurysm Repair[4]

Class/Level of Evidence	Recommendation
I/B	For patients with chronic dissection, particularly if associated with a connective tissue disorder but without significant comorbid disease and a descending thoracic aortic diameter exceeding 5.5 cm, open repair is recommended. For patients with degenerative or traumatic aneurysms of the descending thoracic aorta exceeding 5.5 cm, saccular aneurysms, or postoperative pseudoaneurysms, endovascular stent grafting should strongly considered when feasible. For patients with thoracoabdominal aneurysm and with end-organ ischemia or significant stenosis from atherosclerotic visceral artery disease an additional revascularization procedure is recommended.
I/C	For patients with thoracoabdominal aneurysms in whom endovascular stent graft options are limited and surgical morbidity is elevated, elective surgery is recommended if the aortic diameter exceeds 6.0 cm, or less if a connective tissue disorder, such as Marfan or Loeys-Dietz is present.

0.6 cm can be added to or subtracted from these figures for individuals taller than 1.8 or shorter than 1.5 m.[75,147] Others have suggested that repair of TAAAs should be considered in patients with aortas twice the size of a normal continuous segment or approximately 6 cm in diameter.[84]

Based on natural history studies documenting an extremely high risk for rupture and death if a TAAA is left untreated, all patients with TAAAs should be considered for repair.[40,46,148] The natural history of ruptured TAAAs was first studied extensively by Crawford and colleagues.[149] In a series of more than 100 ruptured TAAAs, the authors noted that 80% of ruptures occurred in patients with aneurysms that were less than 10 cm in diameter. The presence of an aortic dissection portended rupture at smaller diameters, with a reported 13% of ruptures occurring in aneurysms smaller than 6 cm. Rupture occurred in the thoracic and abdominal cavity with approximately equal frequency. They concluded by suggesting that because elective surgery was associated with a 92% survival rate, TAAA repair should be considered before rupture when aneurysms are 5 cm or larger in good-risk patients, in patients with symptomatic aneurysms, and in most patients with larger aneurysms.

In a large Scandinavian autopsy series, Juvonen and colleagues suggested that 6 cm should be the threshold for open TAAA repair.[51] More recently, Elefteriades suggested that the size criteria for surgical TAAA intervention should be greater than 6.5 cm. The author believe that this threshold should be lowered for patients with connective tissue disorders, in whom repair should be offered when the aneurysm attains a diameter of 6.0 cm.[150] A positive family history for aortic rupture or dissection might also serve to lower the threshold for repair. Coady and coauthors suggested that in asymptomatic TAAA patients who are monitored longitudinally, there are "hinge points" that demarcate highly dangerous aortic thresholds.[48] For the descending thoracic aorta, the hinge point is 7 cm, where a 43% risk for rupture is encountered. This suggests a "conservative" criterion of 6.5 cm for surgical intervention in TAAAs.

Because multiple studies have suggested increased mortality and morbidity—particularly spinal cord ischemia (SCI)—for types I, II and III TAAAs, perhaps a higher threshold for repair (6 cm) should be used in these patients. In contrast, patients with less extensive aneurysms, such as type IV TAAAs, might be better served to undergo repair at a diameter of 5.5 cm. Although patients with symptoms should undergo TAAA repair even if their aneurysm has not attained a certain threshold size, the threshold for repair should be tailored to the individual surgeon and institutional results. In our practice, for most patients we utilize a threshold for repair of 6 cm, and this threshold has not changed with the advent of TEVAR.

PREOPERATIVE EVALUATION

The physiologic stress on a patient undergoing open TAAA repair is unparalleled, and it is to be emphasized that the preoperative evaluation detailed herein will probably differ substantially as a function of the mode of operative repair. The initial evaluation of a patient with a TAAA begins with a thorough history and physical examination focusing on the patient's cardiac, pulmonary, and renal function. Imaging studies are reviewed to determine the operative plan. Standard preoperative laboratory testing, electrocardiography (ECG), and chest radiography should be performed. Guidelines for perioperative evaluation prior to repair of open surgical and endovascular thoracic aortic repairs have been created (Table 76.8).[4] Patterson and colleagues developed an externally validated risk-stratification model for patients undergoing elective TEVAR comprising six easily obtainable variables (Table 76.9). The authors stress that while the decision to offer repair to a particular patient must be individualized, the risk model can lead to a more informed discussion with the patient.[151]

Cardiac

The presence of coronary artery disease varies based on the aortic pathology being treated. Because the typical patient undergoing TAAA repair is elderly, compared with a patient with a connective tissue disorder with a dissection, impaired myocardial function and the presence of atherosclerotic disease of the coronary arteries are common in patients undergoing aneurysm repair.[153,154] In landmark studies in patients before undergoing AAA repair, Hertzer and colleagues documented that 42% had significant coronary artery disease in the setting of ischemic cardiac symptoms. Importantly, 19% of the patients who were symptom-free also had significant coronary artery disease. Given the high prevalence of coronary artery disease combined with the stress of this operation, cardiac disease is

TABLE 76.8 Recommendations for Preoperative Evaluation for Patients Undergoing TAA Repair[4]

Class/Level of Evidence	Recommendation
I/C	In preparation for surgery, imaging studies adequate to establish the extent of disease and the potential limits of the planned procedure are recommended. Patients with thoracic aortic disease requiring a surgical or catheter-based intervention who have symptoms or other findings of myocardial ischemia should undergo additional studies to determine the presence of significant coronary artery disease (CAD). Patients with unstable coronary syndromes and significant CAD should undergo revascularization prior to or at the time of thoracic aortic surgery or endovascular intervention with percutaneous coronary intervention or concomitant coronary artery bypass surgery.
IIa/C	Additional testing is reasonable to quantify the patient's comorbid states and develop a risk profile. These may include pulmonary function tests, cardiac catheterization, aortography, 24-hour Holter monitoring, noninvasive carotid screening, brain imaging, and neurocognitive testing.
IIb/B	For patients who are to undergo surgery or endovascular intervention for descending thoracic aneurysm and who have clinically stable but significant (flow limiting) CAD, the benefits of coronary revascularization are not well established.

TABLE 76.9 Risk Factors Predictive of Perioperative Mortality Following Thoracic Endovascular Aneurysm Repair[152]

Risk Factor	Hazards Ratio	*P* Value
Age	1.04[a]	<0.001
Renal insufficiency	1.68	0.002
History of stroke	1.58	0.011
Placement of >2 devices	1.46	0.018
Maximal aneurysm diameter	1.02[b]	0.01

[a]Per year of age.
[b]Per millimeter of diameter increase.
All-cause mortality score = 0.0398 × (age) + 0.516 × (renal insufficiency) + 0.46 × (previous history of cerebrovascular disease) + 0.352 × (prior tobacco use) + 0.376 × (number of devices > 2) + 0.016 × (maximum aneurysm diameter).
Categorical variable expressed as "1" if present, "0" if absent.

the leading cause of mortality after open TAAA repair,[72,76] including 49% of early deaths and one third of late deaths. Therefore, before TAAA repair, all patients should undergo extensive evaluation of their coronary arteries and heart valves.

The preoperative ECG in a hypertensive patient with a degenerative TAAA may suggest left ventricular hypertrophy. There may also be evidence of ischemic heart disease. Although noninvasive stress testing can often predict areas of reversible ischemia and may be useful in an asymptomatic patient, the use of coronary angiography in patients with suspected atherosclerotic coronary disease (e.g., angina, low ejection fraction, previous coronary artery bypass grafting [CABG]) may be indicated (see Chapter 42).

In the elective setting, coronary artery revascularization may be indicated. If the patient undergoes coronary stenting, clopidogrel is used for a minimum of 6 weeks, which will delay TAAA repair. The use of drug-eluting coronary stents typically requires lifelong clopidogrel use. In addition, if the patient is to undergo CABG, use of the left internal mammary artery is discouraged, primarily because it serves as an important collateral to the spinal cord as well as the chest wall.

Echocardiography, most often transesophageal echocardiography (TEE), is helpful in demonstrating left ventricular function and concomitant valvular abnormalities. TEE is also useful in evaluating the ascending and descending thoracic aorta. There are many advantages to TEE over other modalities, including the ability to perform it in the emergency room or operating room. It can also be safely used in patients with renal insufficiency to assess ascending and descending thoracic aortic size as well as the presence of dissection. However, TEE may not be widely available in the emergency setting and is operator-dependent.

Recent authoritative guidelines reflect the uncertain value of extensive preoperative cardiac evaluation in patients undergoing TEVAR in the presence of stable coronary disease, even if this workup prompts percutaneous or surgical cardiac revascularization. Bub and colleagues reviewed their experience involving 395 high-risk patients undergoing complex endovascular thoracoabdominal and juxtarenal aneurysm repairs. Overall, 7% of patients suffered a myocardial infarction, and 30-day cardiac-related mortality was only 2%. Of the total, 73% and 65% of patients underwent preoperative stress testing and echocardiography, respectively. Among the 85% of patients who had a negative stress test, 6% suffered a postoperative myocardial infarction, similar to the 7% of those with a positive test. The majority of the patients with positive stress tests were managed either medically after cardiac catheterization or were cleared by their cardiologists with no further testing. Only 30% of patients ultimately underwent percutaneous coronary intervention, and one quarter of them suffered a postoperative myocardial infarction.[155]

Another similar study stratified perioperative cardiac outcomes following TEVAR by extent of cardiac evaluation. Of 352 stable patients, 95% underwent only resting ECG or TTE and then proceeded to operation. Only 5% required additional cardiology evaluation and 1% underwent coronary angiography or revascularization. Those patients with more risk factors were more likely to undergo a more extensive workup. In this population,

only 2.4% of patients suffered a postoperative myocardial infarction, all in patients evaluated solely with ECG or TTE; this was a relationship found not to be statistically significant.[156] Taken together, these studies call into question the utility of routine extensive preoperative cardiac evaluation even among high-risk patients undergoing endovascular repair.

Pulmonary

Pulmonary complications after open TAAA repair are common, with the incidence of COPD estimated to be between 30% and 40%. COPD is also associated with increased perioperative mortality after TAAA repair.[76,157] Pulmonary function tests and arterial blood gas analysis are performed routinely. Preoperative maneuvers to improve pulmonary function before TAAA repair include immediate cessation of smoking, use of appropriate bronchodilators, and rarely the administration of preoperative steroids when an acute exacerbation of reactive airway disease occurs. Patients can also be placed on an exercise program to improve lung capacity and be required to lose weight if obesity accompanies their lung disease. In a study of patients with COPD undergoing elective open AAA repair, fewer prescribed inhalers, lower hematocrit, renal insufficiency, and coronary artery disease were associated with unfavorable outcomes.[158] Preservation of the left recurrent laryngeal and phrenic nerves is an important adjunct to decrease the incidence of pulmonary complications in these patients.

Renal

Review of a large series of patients undergoing open TAAA repair suggested that the rate of renal failure postoperatively ranges from 5% to 40%, with an attendant mortality rate as high as 70%.[159-162] Acute renal failure also predicts increased nonrenal complications postoperatively, including respiratory failure. Second only to aortic rupture, chronic renal insufficiency is the strongest predictor of perioperative acute renal failure and mortality after TAAA repair (Fig. 76.10).[152,163] Therefore evaluation of renal function before TAAA repair, whether open or endovascular, is imperative.[152] A full 15% of patients with TAAAs will have some degree of chronic renal insufficiency as defined by a creatinine level of 1.8 mg/dL (159 µmol/L) or greater.[24]

Preoperative renal insufficiency is such a strong predictor of poor outcome after type II to type V TAAA repair that it has been suggested to be a relative contraindication to proceed with repair. Huynh and coworkers documented that calculation of the glomerular filtration rate is a better predictor of outcome after TAAA repair than serum creatinine.[164] Cross-sectional imaging will aid the surgeon in evaluating diminutive kidney size and the often associated renovascular atherosclerotic disease. If physiologic testing is required, duplex ultrasonography will provide information regarding the severity of ostial atherosclerotic disease, based on velocities, as well as parenchymal function, based on resistive indices. In performing TAAA repair in patients with renal failure, it is imperative that severe renal artery occlusive disease be treated intraoperatively by endarterectomy, stenting, or bypass grafting with the expectation that renal function will not worsen.[165,166] Stenting before TAAA repair to theoretically improve renal function has been reported.[167]

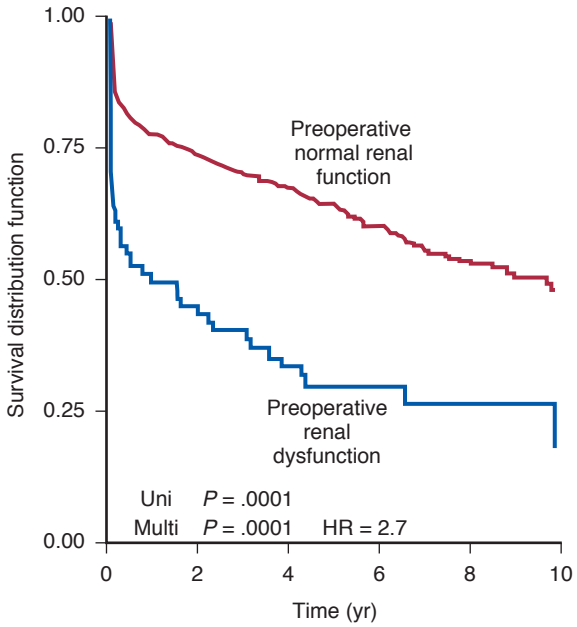

Figure 76.10 Ten-year actuarial survival for patients undergoing thoracoabdominal aortic aneurysm repair with and without preoperative renal failure. *HR,* Hazard ratio.

Preoperative intravenous hydration, as well as avoidance of nephrotoxic agents such as iodinated contrast material, is indicated. Although national trends have moved away from admitting patients preoperatively to the hospital, this group of patients, especially if their visceral arteries are to be bypassed, should probably still be admitted to the hospital and undergo both bowel preparation and intravenous hydration. The rationale for this strategy is reduction in the risk for bacterial translocation, especially in the setting of visceral ischemia during placement of a synthetic graft at the time of TAAA repair.[168]

Functional Status

The preoperative functional status of patients undergoing TAAA is critical in evaluating risk. Hua and coworkers, using the National Surgical Quality Improvement Program database in patients undergoing AAA repair, suggest that "poor functional status" predicts mortality.[169] Although TAAA repair has been shown to improve survival, Zierer and coauthors, in a recent report, examined the late functional status and quality of life of asymptomatic patients undergoing elective repair.[170] Over a 5-year period, 110 asymptomatic patients underwent elective thoracic aortic replacement for ascending, descending, or thoracoabdominal aneurysms. Functional status, physical and psychological quality of life, and survival were assessed. The results documented that return to normal activity levels was independent of age and procedure. At a mean of 35 months, psychological quality of life was similar between the various surgical groups, but physical quality of life was lower after

thoracoabdominal than after ascending or descending aneurysm repair (P <.02). Importantly, age did not affect physical quality of life, and, interestingly, older patients had improved psychological quality of life. The overall survival rate was 70% at 4 years and was lower for thoracoabdominal than for ascending or descending aneurysms (P <.002). The authors suggested that advanced age does not impair return to normal functional status and that patients with asymptomatic thoracic aneurysms thus should not be denied elective replacement based on age alone, because functional recovery is not significantly impaired.[171]

Patients considered for TAA repair are often old and frail, with multiple medical comorbidities. In these circumstances, there may be reluctance to offer repair with the expectation that the elderly patient is unlikely to accrue much benefit from intervention. Rango and colleagues reviewed their TEVAR experience in treating patients with aortic pathology isolated to the descending thoracic aorta and found that although, overall, patients aged 75 years and older were at four times the mortality risk of younger patients, most of the mortality difference stemmed from the fact that aged patients underwent surgery in the setting of an emergency or rupture. Elective outcomes were similar among older and younger patients. Furthermore, older patients survived on average 54 months after their repairs, with 57% and 84% 3-year overall and aneurysm-related survival. As noted in the study by Zierer et al., the authors argue that elective treatment should not be withheld based on age criteria alone and, in fact, elderly patients might be better served by aggressive elective intervention as opposed to emergency intervention for rupture.[172]

Although most of these studies have focused on perioperative functional status, Rigberg and colleagues documented that late (1-year) survival was poor after open TAAA repair and decreased with patient age.[173] Another study by Crawford and coworkers also investigated late (5-year) functional status after open TAAA repair. These authors concluded that permanent loss of functional capacity occurs only rarely in survivors of TAAA repair, but they also noted the difficulty in obtaining appropriate controls for studies such as this.[174]

Addressing quality-of-life issues between open aortic repair and TEVAR, Dick and associates performed a post hoc analysis of a prospectively collected (between January 2001 and December 2005) consecutive series of 136 patients with surgical diseases of the descending aorta. Endpoints included perioperative and late mortality rates as well as long-term quality of life as assessed by the Short Form Health Survey and Hospital Anxiety and Depression Score questionnaires. The study documented no differences in perioperative mortality rates (9% for open repair versus 8% for TEVAR, P = .254). Cumulative long-term mortality rates were similar in both cohorts. Overall quality-of-life scores were 93 (63-110) for open repair and 83 (60-112) for TEVAR and were not significantly different. Anxiety and depression scores were not increased after open surgery. The authors suggest that both TEVAR and open aortic repair provide excellent long-term results in the treatment of thoracic aortic disease and thus provide little aid in helping us counsel patients on which type of repair they should seek.[171]

OTHER PATHOLOGIES ASSOCIATED WITH THE THORACIC AORTA

Aberrant Right Subclavian Artery

Although multiple and various brachiocephalic congenital abnormalities have been described, the most common variant is an aberrant right subclavian artery. This anomaly is associated with the right subclavian artery taking a course posterior to the esophagus. As many as 80% of individuals with this anomaly will develop dysphagia (*dysphagia lusoria*) as the artery grows larger with the patient's growth.[4] The artery itself, as it enlarges, develops a Kommerell diverticulum. This artery will often become aneurysmal and is associated with thoracic aortic dissections and aneurysms. Although initial treatment of this condition was surgical resection of the proximal right subclavian artery and replacement of it and the abnormal section of the descending thoracic aorta with a graft, reports describe a hybrid approach in managing the aberrant right subclavian, where a bypass from the right common carotid artery to the distal right subclavian artery is performed with ligation of the right subclavian artery proximal to the vertebral artery. This is followed by stent grafting of the abnormal descending thoracic aorta.[175] It must be added that it is imperative that prior to covering the origin of the right subclavian artery, coil embolization of side branches off the aberrant subclavian artery be performed. Often, to achieve proximal seal, the origin of the left subclavian artery must also be excluded, which then requires left carotid subclavian bypass or transposition.

Coarctation of the Aorta

Coarctation of the aorta is relatively common congenital abnormality occurring in approximately 40 to 50 of 100,000 live births.[4] On physical examination, patients may have a disparate exam between their upper extremity and lower extremity pulses. Although this finding is most often managed soon after birth or in childhood by nonvascular surgeons, some patients may present later with resultant heart failure, refractory hypertension, or diminished pulses. It is important to diagnose and treat this pathology because, if left untreated, it is uniformly fatal. Surgical options depend on the location of the coarctation, but coarctation discovered in the thoracoabdominal aorta is typically managed by patch aortoplasty or thoracoabdominal bypass.[176,177] Congenital stenoses of the renal and mesenteric arteries are also commonly seen in these patients and can be managed concurrently in the same surgical setting.[178-180]

Vascular surgeons may be called on to help manage previously repaired coarctations in the descending aorta that present later in life with patch pseudoaneurysms. The use of both uncovered and covered stents have been described and appear to be effective. A recent review by the Cochrane Group concludes that there is insufficient evidence with regard to the best treatment for coarctation of the thoracic aorta. The authors suggested a randomized, controlled trial was needed.[181]

The surgical repair of descending thoracic aorta (DTA) and especially thoracoabdominal aortic aneurysms (TAAA) remains one of the major challenges in vascular surgery because of the technical demands of the surgery, which may require reattaching brachiocephalic, visceral, renal, and intercostal arteries (ICA) to a synthetic graft or aortic homograft, as well as the physiologic stress of the surgery, which can result in stroke, renal failure, cardiac or pulmonary failure, and paraplegia leading to significant disability, decline in quality of life, and death. The first successes in treating thoracic aortic disease were by Crawford, Gross, and Etheridge. The difficulty of thoracic aortic surgery was documented early in aortic surgical history by Adams' 1954 landmark paper on paraplegia causation and risk in thoracic aortic surgery, where he described the anatomy of spinal cord blood flow and the high mortality and paralysis risk of 25% in attempts at just thoracic aortic repair. Ten years later, DeBakey reported 50% mortality in his first small series of TAAA repair.[1,2]

The modern era of surgical treatment of TAAA began with E. Stanley Crawford, who in his first published series in 1974, reported significant reductions in mortality and paraplegia rates accomplished without assisted circulation (AC-cardiopulmonary bypass).[3] With his lifetime experience of over 1500 TAAA, achieving an overall mortality of 8% and paralysis risk of 16%, Stanley Crawford set the standard for a generation of surgeons.[4]

Despite improved outcomes reported from major centers in the modern era with mortality and paraplegia rates <7% in elective operations,[5] high mortality and morbidity continue to occur as demonstrated in two administrative database studies that documented 20% or higher elective mortality and equally high paraplegia rates in smaller lower volume centers attempting treatment of these challenging complex aneurysms.[6,7] In this chapter, we explore how the different pathologies encountered affect surgical approach and treatment indications, the mechanics

Abstract

The fundamental principles of open thoracoabdominal aneurysm repair have remained remarkably stable with controlled hypothermia, spinal fluid drainage and optimized mean arterial pressure and cardiac function as the primary interventions to minimize paraplegia risk from surgical repair regardless of the technique of repair. These interventions along with neurochemical protection and the addition of staging of repair of the most extensive aneurysms when possible have reduced paralysis risk by 85% to 90% when applied stringently and reduced mortality by 50%. With the advent of thoracic endovascular repair, staging in patients with aortic aneurysm and dissection requires newer anastomotic techniques to sew surgical aortic grafts to endografts, making it possible to convert a more difficult Crawford type 2 repair to a type 3 or 4 repair, which is less stressful on the elderly patient; and the combined treatment options has significantly changed the way surgeons approach open repair. However, open thoracoabdominal aneurysm repair remains a very complex and high-risk surgery that requires equally experienced anesthesia, surgical, and intensive care teams working in concert to optimize probability of successful treatment.

hybrid aneurysm repair

of repair, and how experienced centers have been able to reduce morbidity and mortality of open surgical repair. To understand paraplegia and mortality risk more comprehensively, we explore how observed/expected (O/E) ratios are calculated for paraplegia from a predictive model that was previously published using clinical factors (extent of aortic replacement and clinical acuity and dissection) to compensate for differing populations in clinical reports.[8] Data from our own experience from treating over 1000 patients and a database of over 15,000 patients from published reports are also described.

PATHOLOGY

Aneurysm causation and pathologic classification are discussed in Chapter 76. It is important, however, for the surgeon to understand the pathology involved in an individual patient, because it can affect technical considerations in thoracoabdominal aneurysm repair.

DEGENERATIVE

Degenerative aneurysms are the most common TAAA, usually occurring in older patients who have atherosclerosis and smoked. The pathogenesis is complex and associated with the inflammation of atherosclerosis and the individual's response to injury through matrix metalloproteinases and collagen remodeling of the aorta.[9–14] Degenerative aneurysms are more likely calcified to varying degrees and may have a damaged and poorly functioning intimal surface covered with debris from plaque and old thrombus, as well as plaque stenosis or occlusion of branch vessels, which makes repair and revascularization more difficult. These older atherosclerotic patients may also have significant cardiac, pulmonary, and renal comorbidities, as well as the infirmities of advanced age, significantly increasing treatment risk. Although not common, the inflammatory response in degenerative aneurysms can be so severe that they fall into a category called "inflammatory aneurysms" in which the periaortic structures, such as branch vessels, ureters, bowels, or mediastinal structures are encased in a dense retroperitoneal fibrosis that makes surgery especially difficult.[15,16]

INHERITABLE

The known heritable pathologies such as Marfan, Ehlers-Danlos, and Loeys-Deitz syndromes[17–20] are defined by known genetic mutations that create abnormalities in elastin and collagen and TGF Beta receptors that weaken the aortic wall leading to aortic aneurysms and dissections that usually occur in younger patients. It is also increasingly apparent that similar mutations account for familial aneurysms and other noncategorized patients predisposed to aneurysms and aortic dissection (Fig. 77.1).[21–25] The quality of the aortic tissue the surgeon is required to work with may vary within a group depending on the severity of the structural defect and differences between pathologic groups with Ehlers-Danlos and Loeys-Deitz patients having more fragile aortas than Marfan patients.[26,27] These differences may require different surgical techniques with less traumatic vascular clamps, using hypothermic circulatory arrest (HCA) to avoid clamping, or the use of aortic wall reinforcement with felt pledgets or strips to secure the suture line because of tissue fragility. In some patients, for example, some severe types of Ehlers-Danlos syndrome, surgical repair may not be a viable option (see Chapter 10).[28,29]

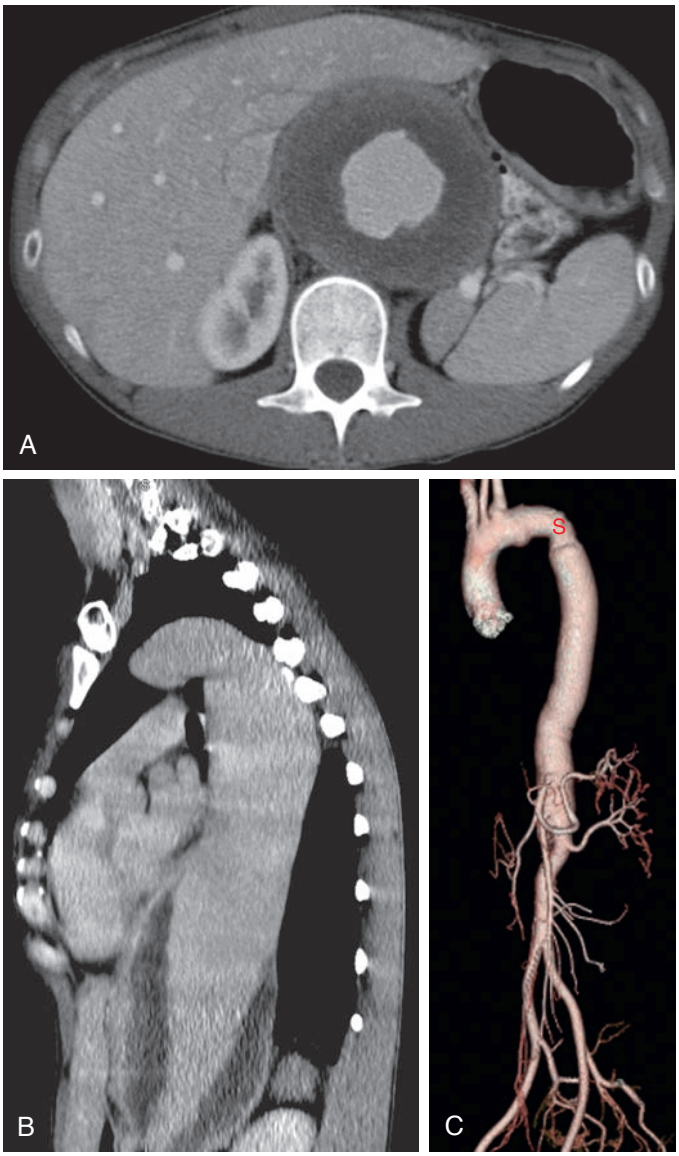

Figure 77.1 (A and B) A very large thoracoabdominal aneurysm in a 32-year-old woman (5′4″, 110 lbs) with no family history or stigmata of Marfan, Loeys-Deitz, or Ehlers-Danlos syndromes and no elevated inflammatory markers. Presented with vague chest pain and fatigue. At repair (C) the proximal neck was wrapped with a Dacron sleeve to prevent future expansion. Patients like this are undefined genetically but obviously have some molecular defect, which more than likely will be defined within the next decade from research efforts such as the National Registry of Genetically Triggered Thoracic Aortic Aneurysms and Cardiovascular Conditions (GenTAC).

TRAUMA, MYCOTIC, VASCULITIS

Clinical presentation also poses significant challenges for the surgeon as in trauma with multiple injuries or mycotic aortitis

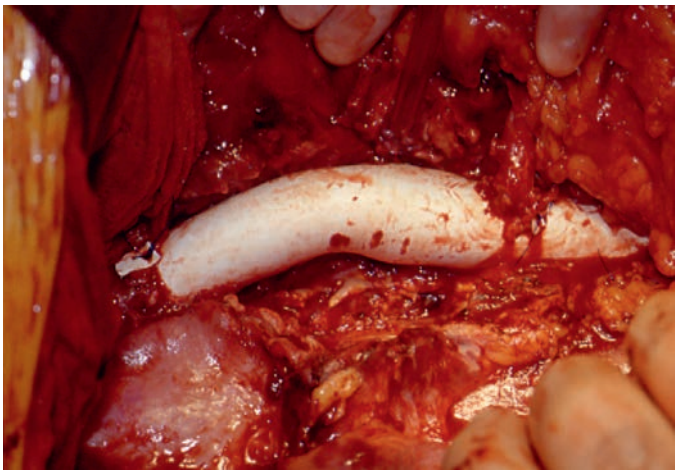

Figure 77.2 The fundamental principle in mycotic thoracoabdominal aneurysm is radical debridement of all infected aortic and periaortic tissue as seen here in a patient who developed a mycotic thoracoabdominal aneurysm from an *Escherichia coli* urinary tract infection and required debridement of the distal third of the thoracic and all the abdominal aorta with in situ aortic reconstruction using a Teflon graft.

where treatment requires radical aortic and periaortic debridement with *in situ* repair (Fig. 77.2) or aortic oversewing with extra-anatomic bypass in desperate situations.[30]

Thoracoabdominal aneurysm associated with the vasculitis of rheumatoid diseases (ankylosing spondylitis)[31–33] or the vasculitis of Takayasu disease, lupus erythematosus, or giant cell arteritis, which although uncommon, they may have associated branch vessel occlusive disease and cardiac and pulmonary involvement that can complicate repair.[34–36]

ANATOMIC CLASSIFICATION

Aneurysms of the thoracoabdominal aorta are classified anatomically (see Chapter 76) primarily by extent of aortic involvement, which is associated with the surgical complexity of repair. Crawford type 2 have the greatest paralysis risk followed by Crawford types 1, 3, 4, and thoracic aortic aneurysms (TAA), which are confined to the distal arch and DTA and have the lowest paralysis risk from surgery.[37]

Aortic dissections have a different classification based on origin and extent of the dissection and the need for immediate surgery (Stanford A) and those historically treated medically with antihypertensives which originate in the distal arch or more commonly in the DTA at or near the ligamentum arteriosum and left subclavian artery (Stanford B) (see Chapter 76). These classifications capture most but not all of the variation seen clinically and in general indicate increased risk of stroke and paralysis associated with repair.[38–40]

INDICATIONS FOR SURGICAL TREATMENT

The primary indication for treatment of aortic aneurysms is rupture risk, which is generally considered to correlate with aortic diameter in accordance with Laplace's law. A larger aneurysm and thinner wall increases the likelihood of rupture, which usually results in death. Some TAAA become very large (>10 cm) before rupture and invariably have thick walls that allow such unusual size before structural failure occurs. However, there is considerable variation in TAAA diameter at the time of rupture or other acute event (dissection, plaque hemorrhage), which in our experience averages 8.2 ± 2.8 cm (median 7.4 cm) with only 13% of all ruptures occurring below 6 cm and rarely below 5.5 cm.

Griepp, Elefteriades, and others have performed extensive research on the natural history of thoracic aneurysms.[41–47] These natural history studies indicate that beside diameter and pain, age, the presence of chronic obstructive pulmonary disease (COPD) or renal insufficiency, the extent of the aneurysm, and the expansion rate of the aneurysm are independent risk factors for rupture.[48–55] The growth rate for DTA (0.42 cm per year) found by Hirose was the same as the growth rate for AAA found in the ADAM trial.[56,57]

The dilemma in TAAA repair, because of the significantly greater surgical risk than infrarenal AAA repair, is if and then when to treat. Most aortic surgeons put the threshold for risk benefit at about 6 cm from natural history information weighed against surgical risk and long-term survival.[42,46,48,58–61] It is known from these observational studies that 40% to 50% of patients die of other causes before rupture, making the decision for aneurysm treatment much more complex than just natural history, physics, and molecular biology. Furthermore, individual patients have differing treatment and rupture risks related to pathology, age, comorbidities, and personal preference.

Other indications, such as occlusive or aneurysmal disease of branch vessels (mesenteric or renal ischemia, brachiocephalic, visceral, or iliac aneurysms), may lead to treatment of smaller TAAAs. Similarly, acute events of aortic plaque rupture, mycotic aortitis, trauma, renal failure from obstructive uropathy in inflammatory aneurysms, or malperfusion in acute dissection may require aortic repair or bypass with little aneurysmal dilatation. Some patients have significant aneurysm enlargement in the ascending aorta and arch in addition to the thoracoabdominal aorta that requires staged repair, which presents unique technical challenges. In addition to all these factors, new dilemmas are created because of new and advancing endovascular technologies that may require surgical rescue because of failure or surgery to treat aneurysm progression above or below previously placed endografts. The surgeon may also decide to stage or combine open and endograft repair for ascending arch and descending aneurysm repair (see Chapters 78-80).

PATIENT EVALUATION

The decision to treat begins with and is clarified by evaluation of cardiac, pulmonary, renal, and overall vitality factors to establish patient fitness for elective surgery (see Chapter 32). This evaluation is expensive and time consuming for patients and families, but it is important when discussing operative risk.

IMAGING

Aortic and branch vessel imaging primarily with magnetic resonance imaging (MRI) and computed axial tomographic angiography (CTA) is important for identifying extent of pathology for preoperative planning (see Chapters 27 and 28). The improved resolution and quality of imaging that has occurred over the last 15 years allows identification of patent ICA of interest, detailed understanding of complex dissection anatomy, and plaque morphology. A newer and exciting imaging technique is four-dimensional MRA. With this MRI technique, detailed anatomy and flow dynamics such as velocities, flow rates, wall stress, and pressure gradients can be measured noninvasively, which increases our clinical understanding of the effects of treatment, as well as the complex flow and stress dynamics in aneurysms and aortic dissection.[62–64]

INFORMED CONSENT

Informed consent for complex high-risk surgeries for life-threatening diseases is a difficult and nuanced process that should give the patient a realistic understanding of what you face as the surgeon and what they face as the patient, which must include the worst case scenario along with the best if the patient is to make a decision consistent with his goals in treatment.[65–67] Especially because of the risks of paraplegia, stroke, and renal failure in addition to possible ventilator dependence in marginal patients facing DTA or TAAA surgery, the consent conversation has to be a realistic discussion of probability and uncertainty surrounding surgery and what life will be like if the surgical effort fails to return the patient to his preoperative functional status. The older the patient the more selective both surgeon and patient should be about treatment.

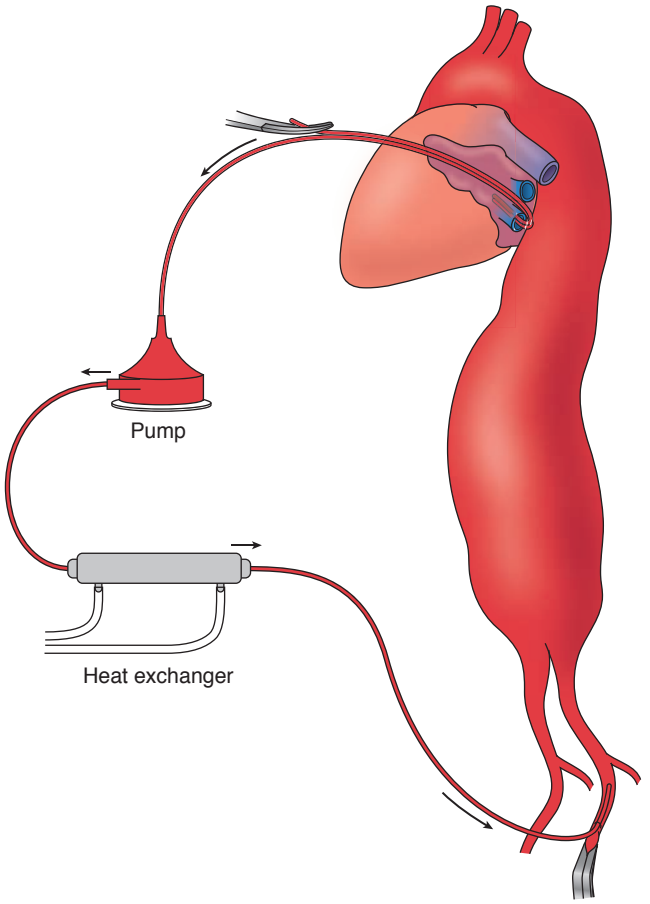

Figure 77.3 Left heart bypass is the most commonly used technique of assisted circulation and is dependent on the lungs for oxygenation and the heart as the primary pump. The circuit is from the left atrium via direct cannulation or through the pulmonary vein to a centrifugal pump back into the arterial circulation (the femoral artery most commonly).

SURGICAL REPAIR

Once the decision for surgery has been made, the surgeon and anesthesiologist must develop and execute the plan for repair. That plan depends on anatomy and pathology that can vary greatly between patients, requiring the surgeon and anesthesiologist to adapt. In addition to patient variation, surgeons may favor different surgical approaches ranging from simple cross clamp (Crawford technique) with adjunctive measures to protect the kidneys and spinal cord, assisted circulation-AC (atrial femoral or femoral femoral bypass), or HCA.

Extracorporeal Circulation

AC is usually atrial-femoral (partial heart bypass) with oxygenated blood coming from a left atrial or left pulmonary vein cannula to a centrifugal pump that feeds a femoral artery cannula that can retrograde perfuse the pelvic and visceral arteries during proximal repair (Fig. 77.3). The bypass flow rate is adjustable, so proximal and distal arterial perfusion pressures can be maintained and is an effective technique to off load the heart, reducing cardiac strain with very proximal aortic clamping. This technique is dependent on the heart and lungs for oxygenation and cerebral circulation but does not require full systemic heparinization. HCA requires complete cardiopulmonary bypass with arterial perfusion cannulas in the femoral artery or ascending aorta and venous return through a femoral vein cannula that usually extends to the right atrial level and superior vena cava and is placed with guidewire and transesophageal echocardiography to confirm location. A left ventricular sump drain is required to prevent cardiac dilatation and pulmonary congestion during cardiopulmonary bypass. Patients are cooled to 16 to 18°C, and then circulation is arrested during the proximal anastomosis after which cerebral perfusion is resumed through a side arm on the aortic graft while the remaining aorta is reconstructed. HCA is a complex procedure because of longer pump runs and coagulopathy with bleeding made worse by the large surface area of a thoracoabdominal incision. Profound hypothermia provides excellent organ protection during aortic reconstruction; however, because of its complexity, this technique is used the least.

Other Perfusion Techniques

Distal aortic perfusion and selective perfusion of the mesenteric arteries can be achieved without pump devices. The Gott shunt

and external axillofemoral artery bypass have been used as a passive bypass circuit for repair of DTA and TAAA.[68,69] Cambria describes an in-line mesenteric shunt technique that restores pulsatile flow to the mesenteric circulation within 25 minutes, even in the absence of distal aortic perfusion. This technique is used in combination with renal artery perfusion with 4°C renal preservation solution.[70] Cambria, however, has abandoned epidural cooling because of poor results. Each technique has advantages and disadvantages.

Our approach is to simplify the surgery as much as possible but vary the surgical technique depending on anatomy and pathology. Therefore, most of the time we use Crawford's technique of simple cross clamping with adjuncts (hypothermia, spinal fluid drainage, steroids, endorphin receptor antagonists, and optimizing perfusion pressure and cardiac function) that Crawford did not use to protect the spinal cord, kidneys, and other organs.[71] When anatomy dictates (no place to proximally clamp the aorta or occasionally in acute dissection) we use HCA. Our surgical approach is based on experimental studies of the effects of aortic occlusion and preservation of spinal cord, renal, and other organ function. This chapter demonstrates experimentally how validated protective adjuncts work regardless of surgical technique and that equal results can be obtained with all techniques if experimentally demonstrated protective principles are followed.

ANESTHESIA

The anesthesia for TAAA repair is complex, requiring multisystem monitoring and control. Arterial lines in the upper (radial artery) and lower (femoral artery) extremities, pulmonary artery catheter for monitoring cardiodynamics (cardiac index [CI], central venous pressure, pulmonary artery pressures), and transesophageal echo to evaluate ventricular function and valve function are used to optimize mean arterial pressure and cardiac function. Electroencephalogram (EEG) monitors central nervous system activity because barbiturates are used to reduce oxygen demand[72] prior to and during aortic occlusion. Blood and nasopharyngeal temperature are monitored, because these correlate with spinal fluid and brain temperature. Coagulation parameters, blood chemistries, and arterial blood gases are closely monitored throughout surgery. A 16 French Medtronic lumbar spinal drain is fluoroscopically placed in most patients to monitor and control spinal fluid pressure (SFP) by draining spinal fluid to improve spinal cord blood flow during aortic occlusion.[73] The anesthesiologist uses vasoactive medications to control arterial pressure and maximize cardiac function. Arterial dilators such as nitroprusside and hydralazine are avoided because of their experimentally demonstrated stealing effect on spinal cord blood flow.[74] Infusing sodium bicarbonate (0.05 meq/kg per min) while the aorta is occluded above the renal arteries prevents systemic acidemia. Our group administers methylprednisolone after induction and naloxone (1 μg/kg per hour) is infused during and after the procedure.[75,76] Mannitol is given before and during aortic occlusion and after renal reperfusion. When one lung ventilation is required in extensive proximal aortic replacement, we use an Arndt endobronchial blocker, bronchoscopically placed using a guidewire,[77] which we think is easier and safer than a double lumen endotracheal tube. This technique provides excellent lung isolation without the need to change endotracheal tubes at the end of surgery. Moderate systemic hypothermia (31-34°C) is used to prolong spinal cord and organ ischemic tolerance. Aggressive blood component replacement is important to prevent coagulopathy.

During the surgical exposure, the anesthesiologist cools the patient (34°C or lower) with a cold operating room and intravenous (IV) fluids. As the time for aortic clamping approaches, our anesthesiologists drain enough spinal fluid to achieve a SFP less than 6 mm Hg during aortic occlusion. Timing this requires close communication between the surgeon and anesthesiologist. If assisted circulation (cardiopulmonary bypass, circulatory arrest, or atrial femoral bypass) is used, we complete the exposure dissection before cannulation and heparinization to minimize bleeding. These assisted circulation patients require additional exposure, depending on surgeon preference for cannulation of the femoral artery and vein, left ventricle apex, ascending aorta, left atrium, or pulmonary veins

During surgical reconstruction, the anesthesiologist assures the patient is volume resuscitated with blood reclaimed from the high-speed cell saver, red blood cells, and fresh frozen plasma to replace coagulation factors from blood loss. The anesthesiologist's goal is to optimize tissue oxygen delivery, intravascular volume, cardiac function, and arterial perfusion pressure (MAP >90 mm Hg), in addition to keeping the SFP low without draining excessive fluid. Unless the anesthesiologist is aggressive and proactive in managing cardiac function, fluid resuscitation, and preventing coagulopathy, hypovolemia, and hypotension, the patient will have increased risk of coagulopathy, paraplegia, renal failure, cardiac ischemia, and death. The anesthesiologist is as important as the surgeon in the success of these complicated aortic reconstructions.

When surgery is done using assisted circulation, the anesthetic management must adjust primarily to prevent the proximal relative hypotension associated with left heart bypass that puts the spinal cord at increased risk because of reduced perfusion pressure to the collateral circulation. This negative effect is exacerbated if hypothermia is not used. To maintain proximal and distal MAP greater than 90 mm Hg while on partial bypass requires aggressive volume replacement, inotropes, and vasopressors. This is even true in hypothermic arrest where the very potent spinal cord protective effects of profound hypothermia can be undone during rewarming if a low MAP is allowed and the patient is made normothermic.

PATIENT POSITIONING

For a thoracoabdominal incision, the patient is positioned in a lateral decubitus position with the left side up. The shoulders are usually vertical, but the pelvis is tilted so the left femoral artery and vein can be easily accessed for aortofemoral bypass, arterial line, or cannulation if left heart bypass is planned. Extreme pelvic tilting can expose the right groin for access to those vessels (Fig. 77.4A). We use an Olympic Vac-Pak patient

positioner (beanbag) with inner gel pad to secure the patient in this position.

SURGICAL EXPOSURE

The level of the incision is determined by what portion of the aorta is to be replaced (see Fig. 77.4B; Chapter 53). An aneurysm confined to the DTA may only require a thoracotomy in the 4th, 5th, 6th, or 7th intercostal space depending on the extent of aortic involvement. A Crawford type 3 or 4 replacement allows extraperitoneal exposure via the 8th or 9th intercostal space, but a Crawford type 1 or 2 requires incision at the 5th or 6th intercostal space with intraabdominal exposure with the spleen, colon, and left kidney mobilized medially off the retroperitoneal space. Posterior "shingling" of the ribs is usually done with the higher costal incisions to minimize rib fracture with the rib spreader (see Figs. 77.4C, D and 77.5A). In such cases, the diaphragm is incised through the aortic hiatus, which allows compete exposure of the descending thoracic and abdominal aorta with its visceral branches, and the iliac arteries if necessary (see Figs. 77.5B, C and 77.6A, C). Some surgeons spare the central diaphragm and some use two incisions, a higher thoracotomy and a lower thoracoabdominal extraperitoneal incision, believing that this reduces pulmonary morbidity, but this approach obscures the anatomy making surgical repair more difficult with only a modest decrease in prolonged ventilation (36% vs. 48%) without any demonstrable decrease in mortality.[78]

If the patient has had previous aortic or thoracic surgery, the exposure can be more difficult because of periaortic scaring, inflammation, and adhesions, especially lung adhesions to the parietal pleura, which can be very tedious to take down and can result in lung injury with bleeding or air leaks. We usually dissect and expose the celiac, superior mesenteric, and left renal arteries, but if the aneurysm is very large or is inflammatory, the mesenteric exposure may be too difficult and is avoided. In the case of associated mesenteric ischemia, the superior

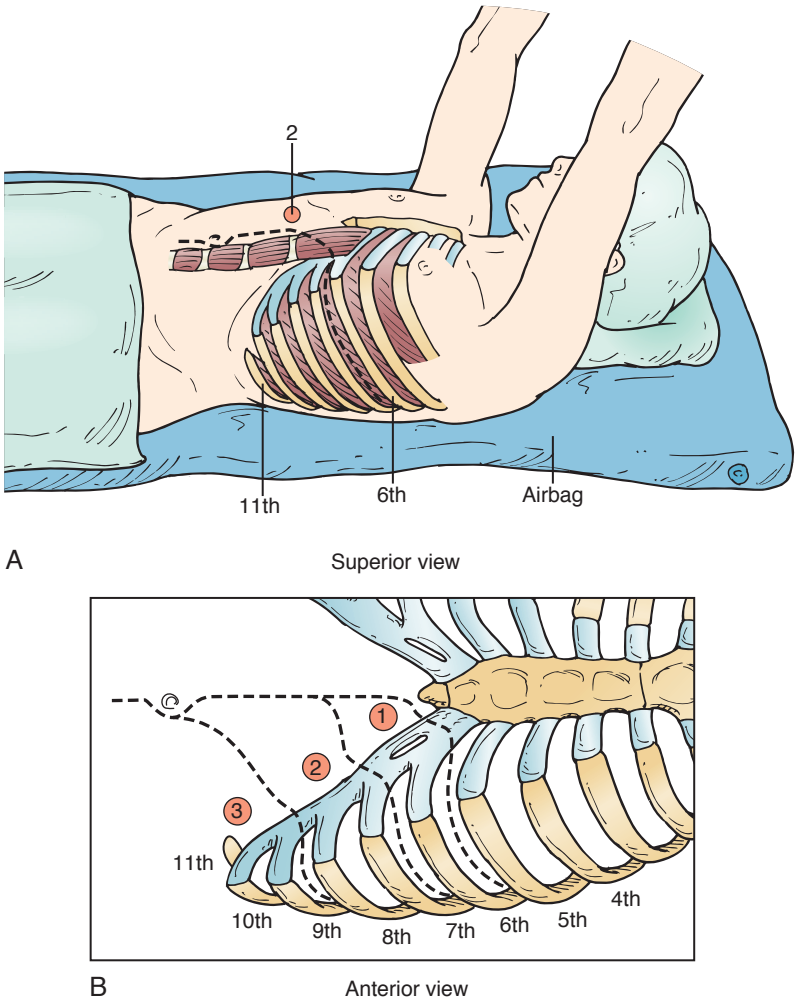

Figure 77.4 (A and B) The lower the interspace of the incision the lower the risk of pulmonary complications so the lowest incision is chosen that allows aortic repair. Aneurysms at the arch level usually require a 5th interspace incision, whereas type 3 and 4 aneurysms can be repaired with an incision in the 8th or 9th interspace, with extraperitoneal exposure. In older patients and in patients with elevated body mass index, in addition to cutting the costochondral junction, the ribs are cut posteriorly to create a controlled cut instead of a fracture.

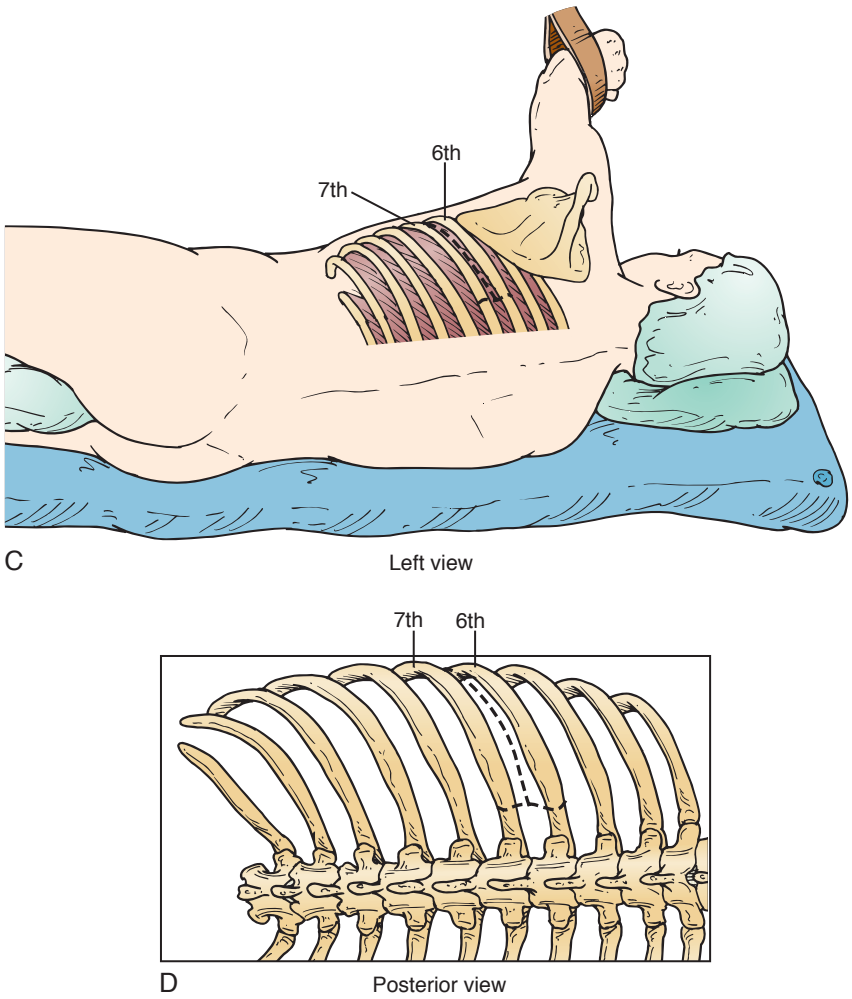

Figure 77.4, cont'd **(C and D)** As much of the latissimus dorsi and serratus anterior is preserved as possible by incising them lower than the interspace to be opened.

mesenteric artery (SMA) can be exposed more completely if necessary by dissecting anterior to the kidney between the peritoneal sac and Gerota's fascia. Occasionally, the left renal vein is retro-aortic, requiring the surgeon to work around it and/or divide it for re-anastomosis after aneurysm repair (see Fig. 77.6B).

The extent of exposure of the arch vessels depends on where the proximal aortic clamp is placed and requires avoidance of injury to the phrenic nerve and the vagus, and its recurrent branch because injury to these nerves increases the risk of pulmonary complications. Patients should be informed preoperatively about recurrent nerve injury and the resulting vocal cord dysfunction, which cannot always be avoided and occurs in about 10% of patients where the proximal anastomosis is at or proximal to the left subclavian artery. Also at this level, the ligamentum arteriosum is usually divided for more complete arch exposure. Occasionally in emergencies with a large mediastinal or arch hematoma or in the case of a very large proximal aorta, the pericardium is opened to obtain easier access to the proximal arch for aortic control. Patients with aneurysms from chronic dissections or with anomalous arch anatomy present special challenges and operative planning. The patient in Fig. 77.7A is an example of difficult arch anatomy because of an aneurysmal aberrant right subclavian artery in a dissected arch. Only after a right carotid subclavian transposition, which was staged a month before his TAAA repair, could the arch be safely crossclamped and the aneurysm be repaired (see Fig. 77.7B).

The left iliac artery is easily seen and exposed, but the right may require dividing the inferior mesenteric artery (IMA) at its origin to mobilize the distal aorta for better access to the right iliac artery. If the IMA is patent and large, it may be important for colonic perfusion and require reattachment, although this is uncommon. The ureters, especially the left, are vulnerable to injury in inflammatory aortas or redo surgery and in such cases, ureteral stents can be placed prior to surgery so the ureters can be identified more easily. It is important to take the time to get complete enough anatomic exposure in anticipation of problems that might develop (such as a need for a more proximal clamp or more distal exposure) so that if the need arises, further dissection is not necessary after aortic occlusion.

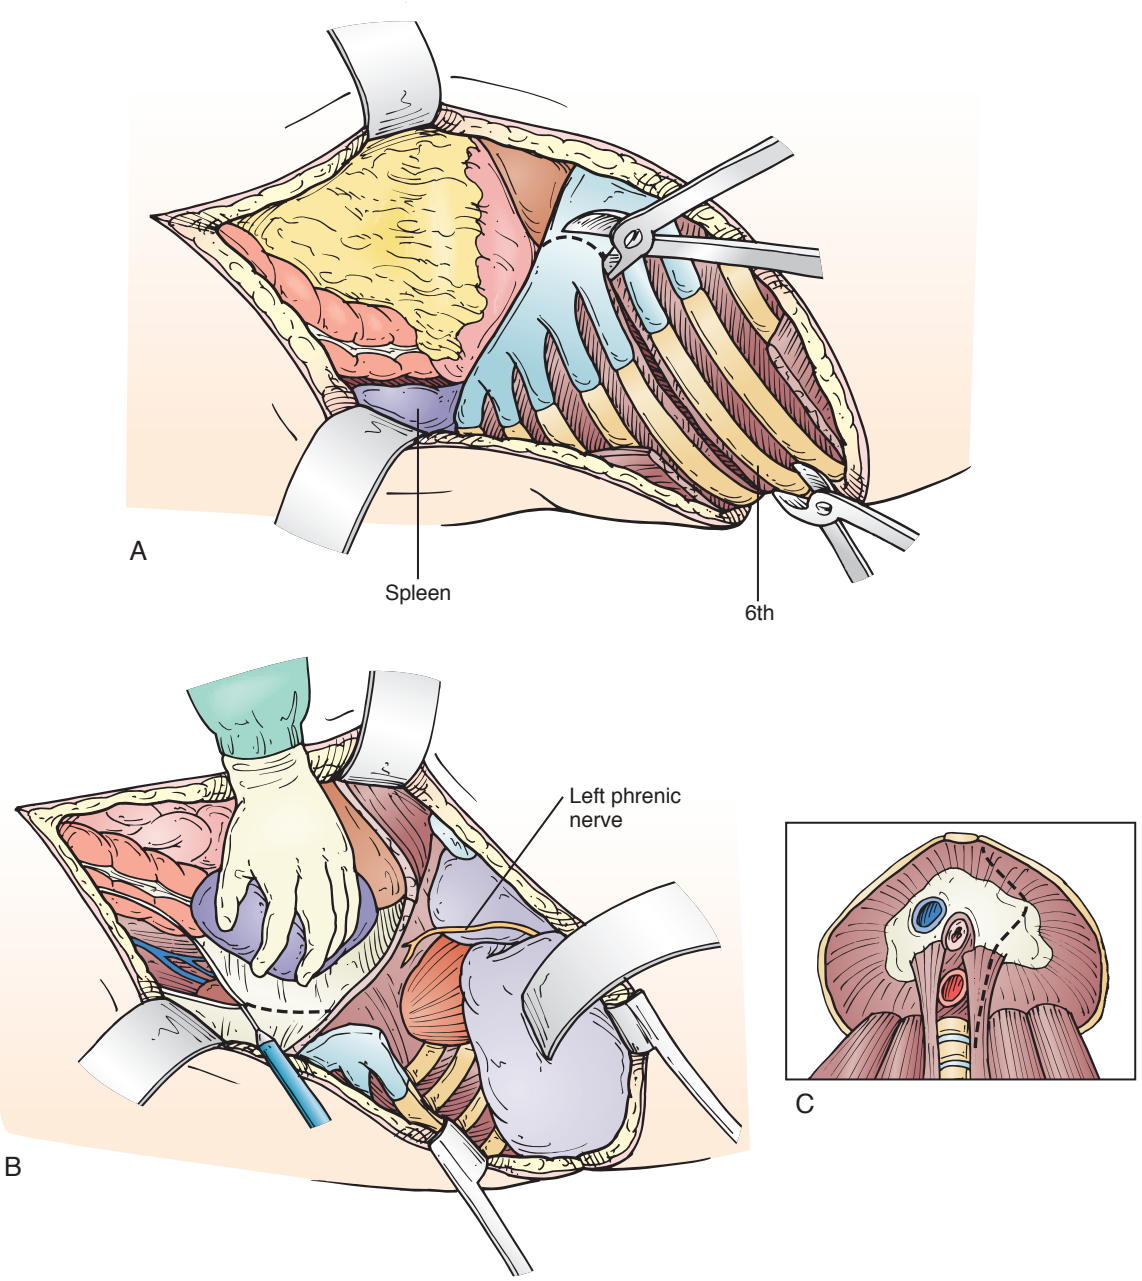

Figure 77.5 **(A-C)** After incising the diaphragm down to the peritoneal reflection, the spleen, pancreas, colon, and left kidney are mobilized off the retroperitoneum. It is important to not dissect into the psoas fascia but open Gerota's fascia posteriorly closer to the midline so the retroperitoneal periaortic space can be easily seen and exposed. Occasionally, dissection is also anterior to the left kidney to gain access to more of the superior mesenteric artery.

ANEURYSM REPAIR

Initial Clamping

With the simple crossclamp surgical technique, heparin flush (1000 units/L) is used on the field. Systemic heparin is used if patients have previous aortic grafts or if clamping is proximal to the subclavian or carotid arteries and then the dose is small (3000-5000 units). In patients with AC (partial bypass) heparin requirements are reduced, and ACTs are monitored. With complete heart bypass (hypothermic arrest) total systemic heparinization is required (400 units/kg).

Once the exposure is complete and the systolic pressure is <100 mm Hg, temperature <34°C, SFP <6 mm Hg and barbiturate burst suppression is initiated, the aorta is crossclamped and the aneurysm is opened for repair. Mean arterial pressure is kept at greater than 100 mm Hg while the aorta is clamped. If there are many open ICA and/or assisted circulation is used, a distal or distal sequential clamp technique is used to avoid what can be exsanguinating back bleeding from open intercostal and lumbar arteries. In aneurysms of just the DTA, we usually do not re-attach ICA; but in TAAA patients before or after opening the aneurysm, the ICA chosen for reimplantation by preoperative MRA and/or patency and location at surgery are temporarily

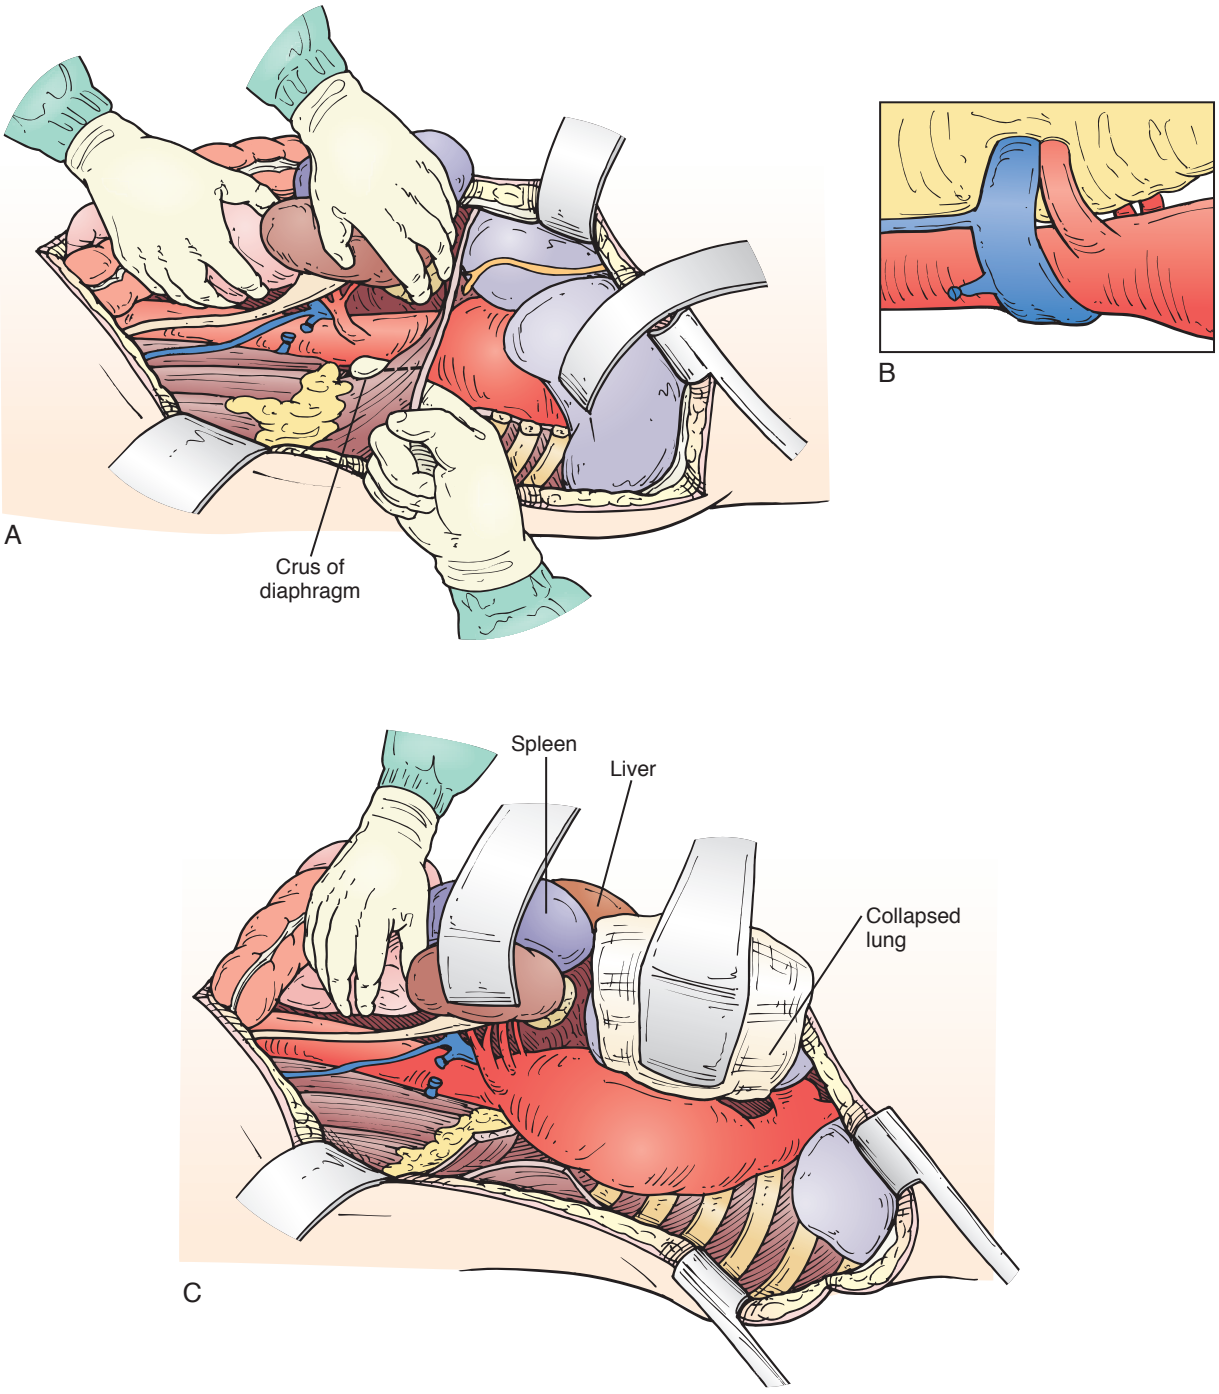

Figure 77.6 **(A)** After mobilizing renal and visceral structures off the retroperitoneal space, the diaphragm is incised through the aortic hiatus, the inferior pulmonary ligament is divided with cautery, and the periaortic lymph tissue is divided exposing the thoracoabdominal aorta. **(C)** We usually dissect the first few centimeters of the left renal and visceral arteries. Occasionally, a retroperitoneal left renal vein is encountered **(B)** which we preserve by dividing between two straight DeBakey vascular clamps and then sewing it back together after the arterial reconstruction is done.

occluded using micro bulldog clamps (usually 2-4 arteries between T8 and L2), and the remaining intercostal and lumbar vessels are quickly oversewn to minimize blood loss and maximize collateral perfusion pressure. Similarly, Fogarty balloon catheters are used to occlude the visceral and renal arteries. At this point, the renal artery orifices are exposed, and each kidney is cooled with 300 to 400 mL of cold (4°C) renal perfusion solution (12.5 g of mannitol and 1000 units of heparin/L of lactated Ringers). This gives hypothermic renal protection and further lowers the body temperature to 31 to 32°C to enhance spinal cord and end organ ischemic tolerance. This sudden volume infusion increases SFP, which may require more drainage to keep the SFP low.

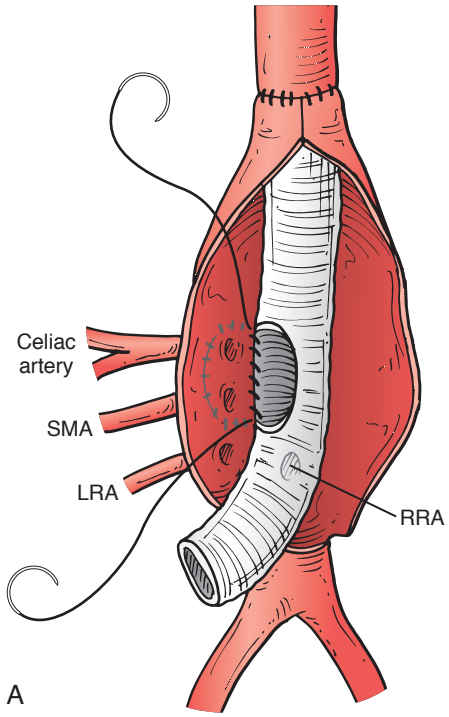
Figure 77.7 Marfan patient with an 8-cm Crawford type 2 aneurysm from a chronic dissection from an acute type A dissection presents additional challenges because of an aneurysmal aberrant right subclavian artery shown from the posterior view (A). Right carotid subclavian transposition was done prior to TAAA repair to fix the subclavian aneurysm and secure the arch for crossclamp and TAAA repair (B). Even though the dissection runs through the arch, it is not aneurysmal and is suitable for clamping and suturing a graft with felt reinforcement.

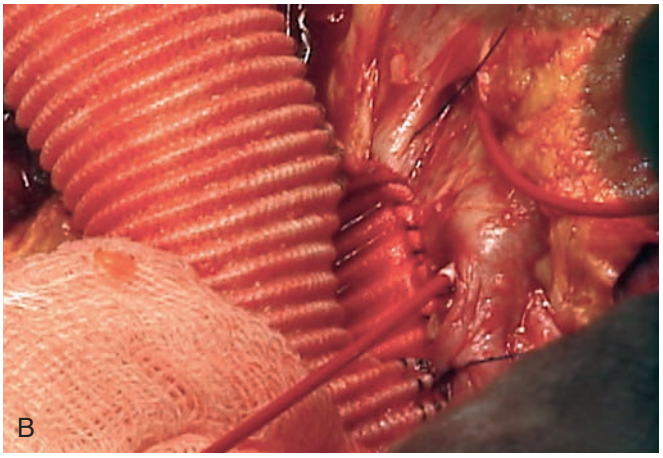
Proximal Anastomosis

After completing this portion of the operation, the proximal graft aortic anastomosis is performed using 2-0 Prolene on a large CT1 needle most of the time. Depending on the tissue integrity (dissection, calcium requiring aortic endarterectomy, or just a fragile thin aortic wall), a finer suture or needle (3-0 suture or SH needle) and/or felt strips or pledgets may be used to reinforce the anastomosis. An important technical point is that all anastomosis should be done so the aorta is not repeatedly crossclamped to repair leaks. This requires a little more time but makes for a faster less traumatic anastomosis. After completing the proximal anastomosis, the patient is put in Trendelenburg, and the anastomotic integrity is tested by placing a vascular clamp on the graft after flushing (to remove air and thrombus that can cause a stroke via the arch vessels) and removing the proximal clamp. If there is a leak requiring attention, we will usually repair this with a pledgeted stitch without reclamping the aorta.

Visceral-Renal Reattachment

The next stage of the repair is visceral and renal artery reattachment, which is usually done with a Carrel patch directly to the aortic graft (Fig. 77.8A-C). The patch configuration is





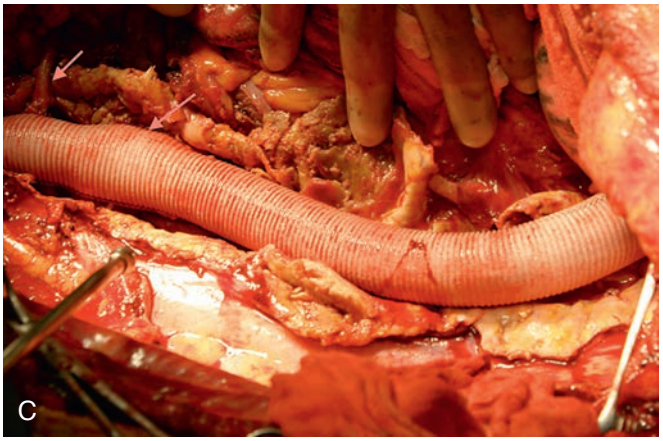


Figure 77.8 (A) When attaching visceral and renal arteries to the graft, it is important to keep the Carrel patch as narrow (small) as possible so patch aneurysms do not form. Spacing between the vessels determines patch configuration, and if the vessels are too far apart, they are attached individually. (B) Photo of sewing a visceral patch comprising the celiac and SMA with their balloon catheters in place. These are removed after establishing blood flow to that portion of the aorta. (C) is the completed graft within the aneurysm sac with arrows to the visceral patch and left renal artery. *LRA,* Left renal artery; *RRA,* right renal artery; *SMA,* superior mesenteric artery.

determined by the spacing of the vessels and the most common configuration is the celiac, SMA, and right renal in one patch and the left renal artery attached separately. Another common grouping is the celiac and SMA in one patch and both renal arteries attached separately. The Carrel patch is kept as narrow as possible to avoid patch aneurysms, but if the vessels are spaced too far apart, they are attached individually to avoid a large visceral patch that is prone to aneurysm dilatation over time. There is a tendency by inexperienced surgeons to sew all the visceral vessels on one patch or create a too large proximal bevel and this more often than not leads to problems later.[79] In our experience, by using the above principles for visceral patch reconstruction, we avoid patch aneurysms. However, individual bypass grafts to the visceral arteries is another strategy that has been advocated with the Coselli branched graft specifically designed for this,[80] especially in patients with connective tissue disorders such as Marfan syndrome, because patch aneurysms are more prevalent in patients with connective tissue disease. In about a third of patients, an endarterectomy of some or all the renal and visceral vessels is required (Fig. 77.9A, B) because of calcified plaque with or without stenosis. If the renal or visceral artery has been previously stented, the stent is usually removed with the endarterectomy plaque. Some surgeons prefer bypass or direct stenting rather than endarterectomy because of possible flap dissection beyond the endarterectomy endpoint, which can require additional exposure and artery repair to avoid occlusion. However, the superior long-term patency of a properly endarterectomized artery is why we prefer endarterectomy. A bypass to a renal or visceral vessel may be necessary, however, if the endarterectomy fails or if the artery is aneurysmal or too distant from the graft surface for easy no tension reattachment. In patients with dissections, the dissection flap may extend some distance into a visceral or renal artery, which can create a possible flap occlusion with re-attachment. In most cases, the flap can be excised to create a common channel for re-attachment, but stenting the true lumen directly has also been proposed as an effective technique.[81]

After completing the visceral and renal reattachment, the patient again is put in the Trendelenburg position with flushing of the graft and then reestablishing blood flow to the visceral and renal arteries (by removing the Fogarty occlusion balloons). Intravenous Indigo Carmine is then given to document when urine is produced after renal reperfusion. The visceral and renal flow is evaluated with vessel palpation and a handheld Doppler to confirm normal blood flow. If there is a concern regarding patency, intraoperative duplex is used to interrogate the arteries in question. In our experience, the average time for the proximal anastomosis and reestablishing renal blood flow is 47 minutes, but it is not unusual to exceed one hour. If renal ischemia time is longer, the kidneys are flushed again with the cold renal perfusion solution.

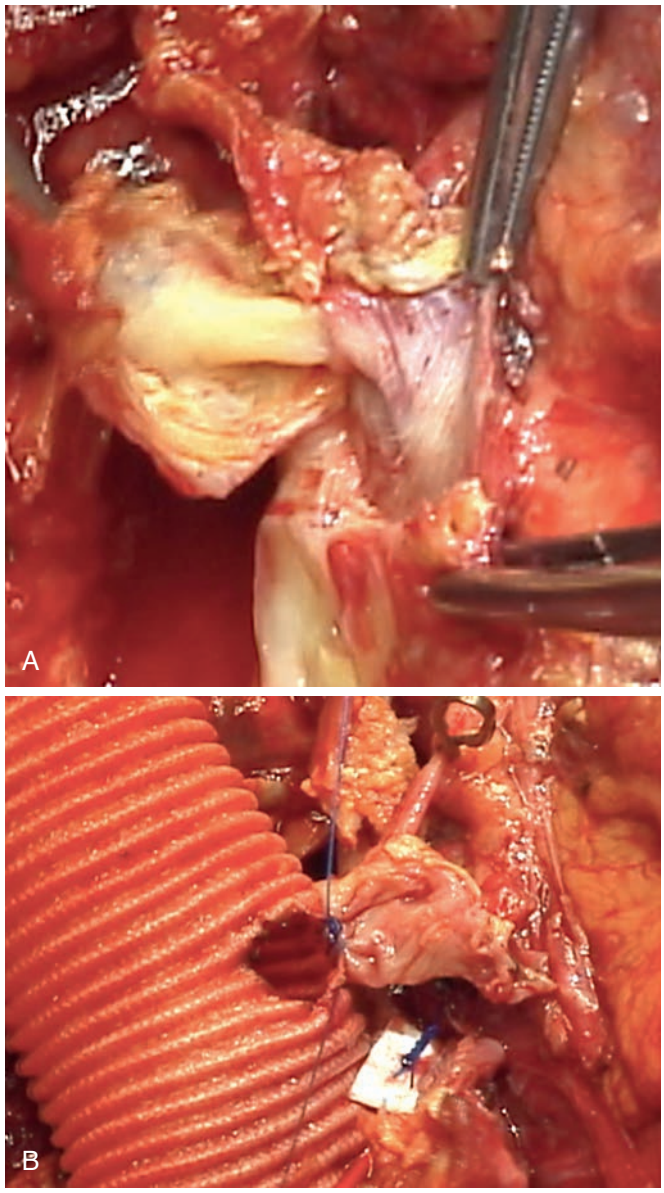

Figure 77.9 Approximately 35% of patients require a visceral and/or renal endarterectomy because of occlusive disease or a very calcified aorta or vessel orifice. This is a sequence of renal endarterectomy (A), which is attached directly to aortic graft (B).

Distal Anastomosis

After completing the visceral reattachment, the aortic graft is sutured to the distal aorta, usually at the iliac bifurcation, and after confirming there is no thrombus by back bleeding the iliac arteries and flushing the graft, the anastomosis is completed and blood flow opened to the iliac arteries. If the iliac arteries are aneurysmal and need repair, a bifurcated aortic graft is sutured to the proximal graft and the distal anastomosis is sutured to the iliac arteries or to a previously placed aortic graft in patients who have had a previous aortic surgery (infrarenal aneurysm, aortofemoral graft) or endovascular repair

Reimplanting Intercostal Arteries

It is only after finishing the aortic reconstruction that we reattach 2 to 4 ICA, which we have previously selected and preserved. This is done by side biting the aortic graft and reattaching the ICA using a button technique we have previously reported

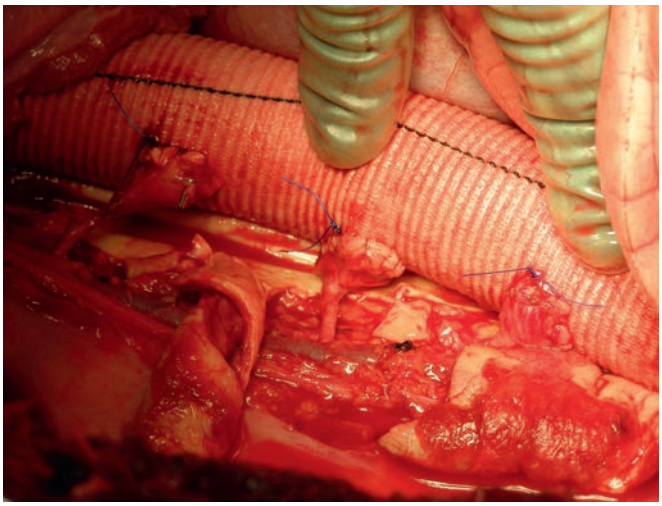

Figure 77.10 In the most extensive aneurysms with many open intercostal arteries we re-attach intercostal arteries identified with preoperative spinal artery MR angiography or by patency and location between T8 and L2 at surgery, as shown in this operative photo.

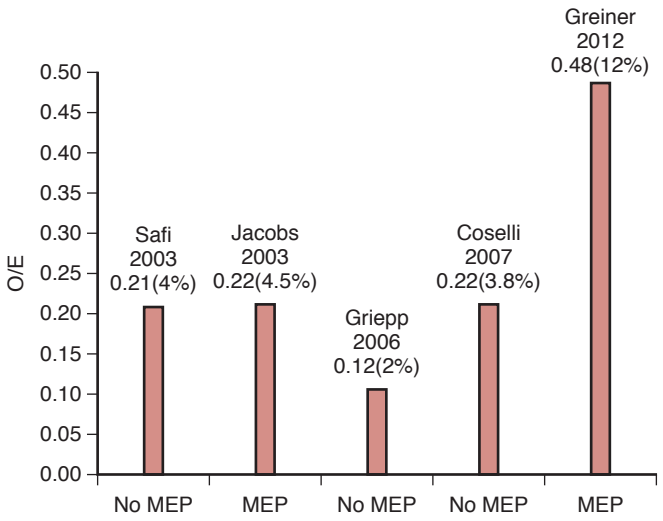

Figure 77.11 Motor evoked potentials have given us a good understanding of the relationship of mean arterial pressure to spinal cord perfusion, but the use of motor evoked potentials *(MEPs)* to select intercostals for reimplantation has not decreased the incidence of paraplegia, as indicated by comparing multiple reports with and without MEPs, which have similar observed/expected *(O/E)* ratios for paraplegia. Griepp used MEPs, but their use did not lead to intercostal re-implantation (therefore, we labeled him as no MEP); but in his and others' experience, MEP loss was reversed by raising arterial pressure.

(Fig. 77.10).[82] Although there are a variety of intercostal re-attachment techniques published, in our opinion, only those with in line flow have reasonable patency rates, while end on bypass grafts fail most often because of low flow. However, it should be acknowledged there is no good data on re-implanted intercostal patency rates.

Some surgeons use motor evoked potentials (MEPs) or somatosensory evoked potentials (SSEPs) or both to select intercostals for reimplantation, but there is little evidence that using MEPs is any more successful than other selection criteria, although MEPs may be helpful to monitor adequacy of arterial perfusion pressure.[83–87] In addition, evoked potential monitoring requires assisted circulation to prevent MEP loss due to peripheral nerve ischemia that occurs with a simple cross clamp surgical technique (and in EVAR and TEVAR with occlusive sheaths in the iliac arteries). Loss of MEPs from peripheral nerve ischemic fatigue interferes with the ability to monitor MEP changes caused by spinal cord ischemia. In addition, use of assisted circulation simply to monitor evoked potentials complicates the surgery without providing any demonstrated reduction in paralysis risk (Fig. 77.11). We re-attach ICA only in the most extensive aneurysms to reduce the risk of delayed paraplegia and sequence reattachment at the end of aortic reconstruction so organ, pelvic, and lower extremity ischemia are not prolonged. The goal is to complete the surgery in 3 to 5 hours with as little blood loss as possible using good surgical technique. Longer operations make it more difficult for the anesthesiologist to keep the patient stable.

IMPACT OF ENDOVASCULAR TREATMENT

The introduction of thoracic endovascular aortic repair (TEVAR) has added additional dimensions to open surgery by creating treatment options not previously available in treating aortic dissection, thoracic and thoracoabdominal aneurysm, and traumatic injury[88–91] In elderly patients, TEVAR has replaced open surgery and medical management for most problems confined to the DTA (see Chapter 79). However, in younger patients with longer life expectancy, TEVAR is practiced with greater restraint (the exception is traumatic aortic transection) because of perceived durability issues. There are several situations where open DTA/TAAA repair and TEVAR complement each other.

Aneurysm formation proximal to a previous open TAAA repair or staging thoracoabdominal repair with TEVAR followed by TAAA repair are examples of TEVAR's complementary potential, which may decrease treatment risk (Fig. 77.12A, B).[92] Suturing a Dacron graft to a thoracic endograft may require a modified felt technique because of size mismatch (see Fig. 77.12C). In aortic dissection, TEVAR may greatly simplify treatment in patients who eventually need surgical repair by converting a Crawford type 2 repair to a type 4 repair (Fig. 77.13A-C). Another patient we treated required open TAAA repair after a failed EVAR. Follow-up CTA revealed a retrograde thoracic dissection with a contained rupture that was treated with a TEVAR (Fig. 77.14A-C).

As indicated previously, in the modern era, aneurysms confined to the DTA are usually treated with endografts if suitable landing zones are present or can be created. For open DTA repair, the same principles apply as we have discussed for TAAA repair except that the incision is usually limited to a thoracotomy; although in aneurysm extending to the celiac artery, the costochondral margin may be cut or a thoracoabdominal incision is performed to get adequate exposure for the distal anastomosis. In DTA repair, ICAs are not reattached,

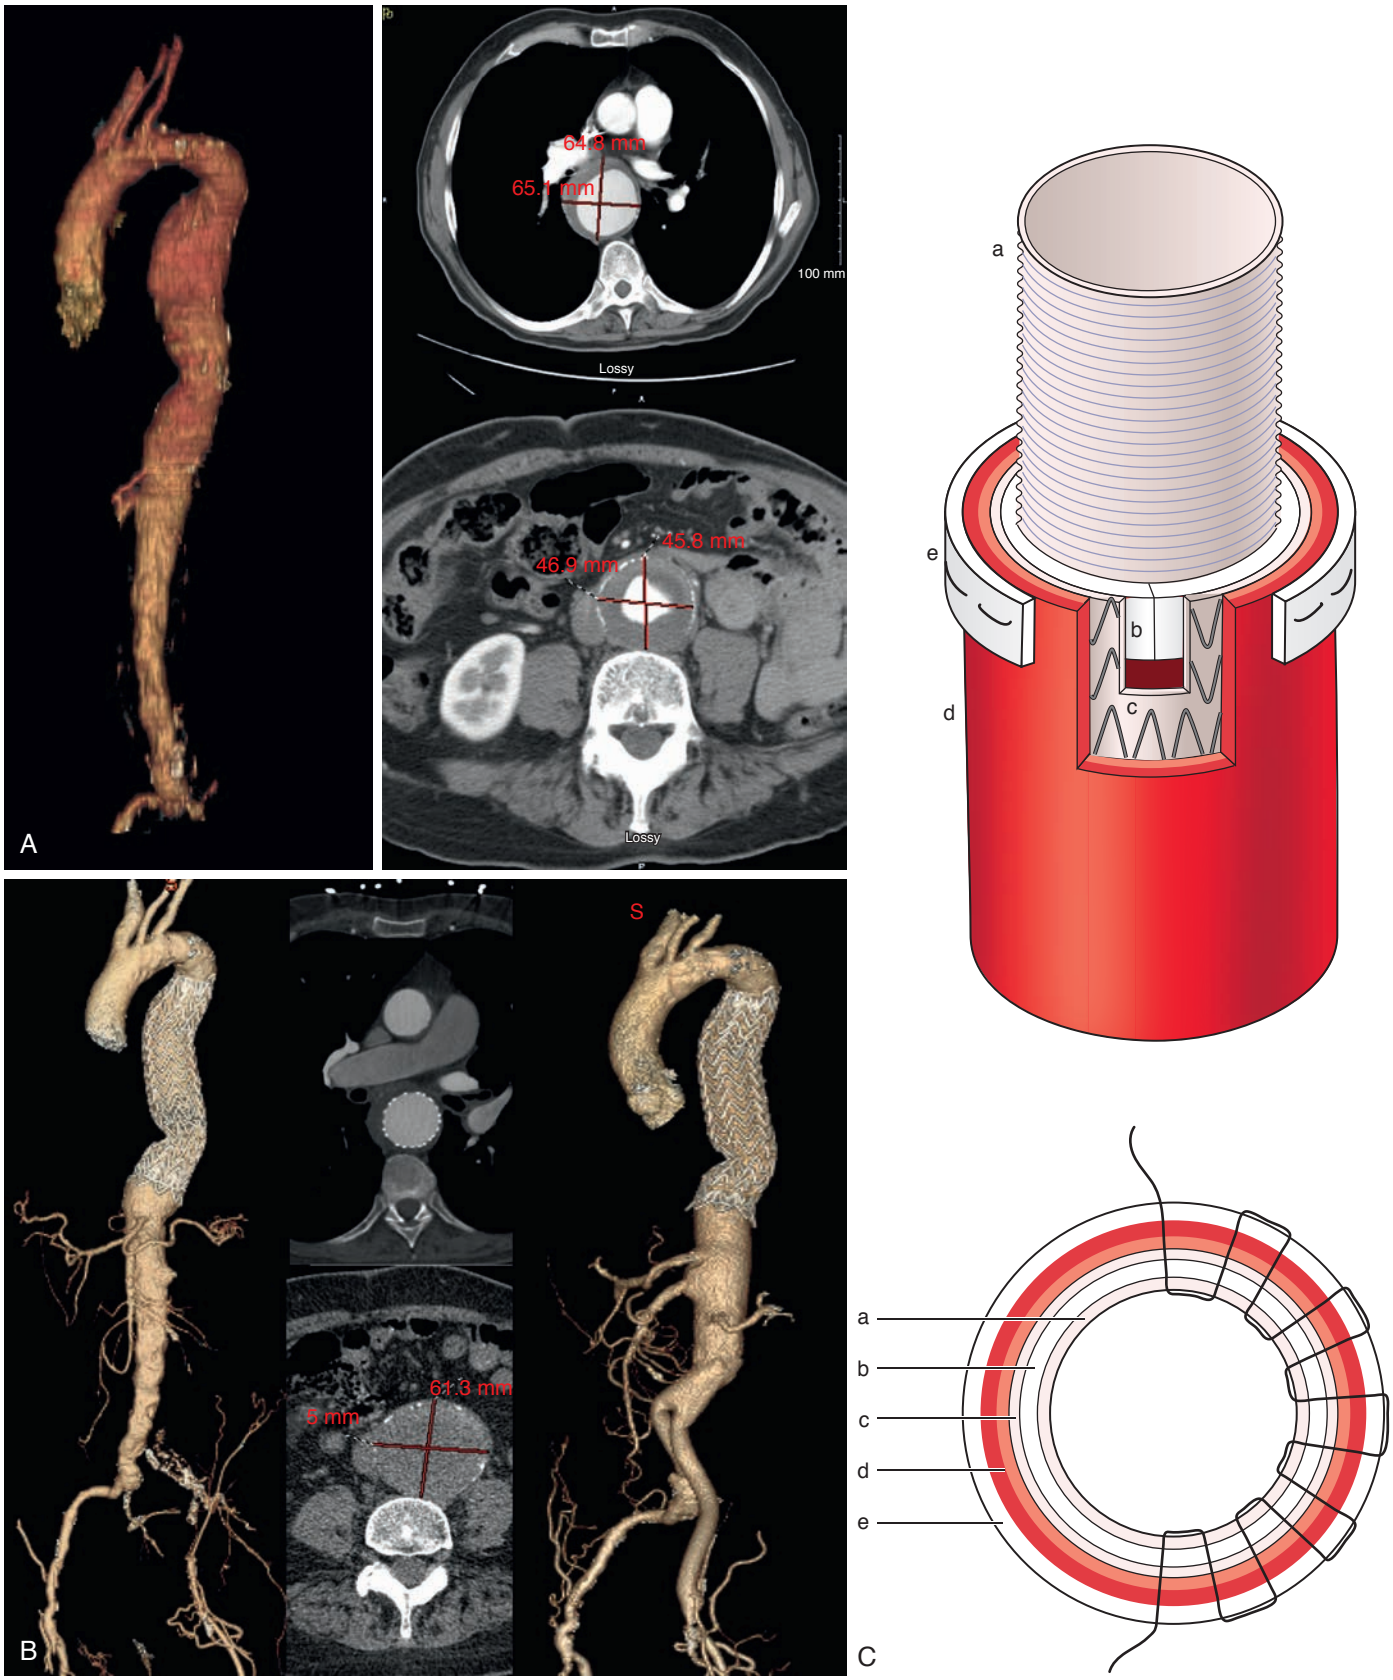

Figure 77.12 Staged repair when possible may reduce operative morbidity by allowing a lower better tolerated thoracoabdominal incision as in this patient who had the thoracic portion of a type 2 thoracoabdominal aneurysm repaired with TEVAR (A), followed 2 years later with a Type 4 TAAA repair of the remaining aneurysmal aorta with suture to the previous TEVAR (B) and avoided a higher risk Type 2 TAAA repair. (C). Sewing a Dacron graft to an endograft may require a double felt technique because of size mismatch when endografts are large diameter. In closer matched grafts, just an outer felt strip is necessary, but the aortic wall should be included with the endograft anastomosis. *a* is Dacron, *b* is inner felt strip, *c* thoracic endograft, *d* aortic wall, *e* outer felt strip and horizontal mattress suture.

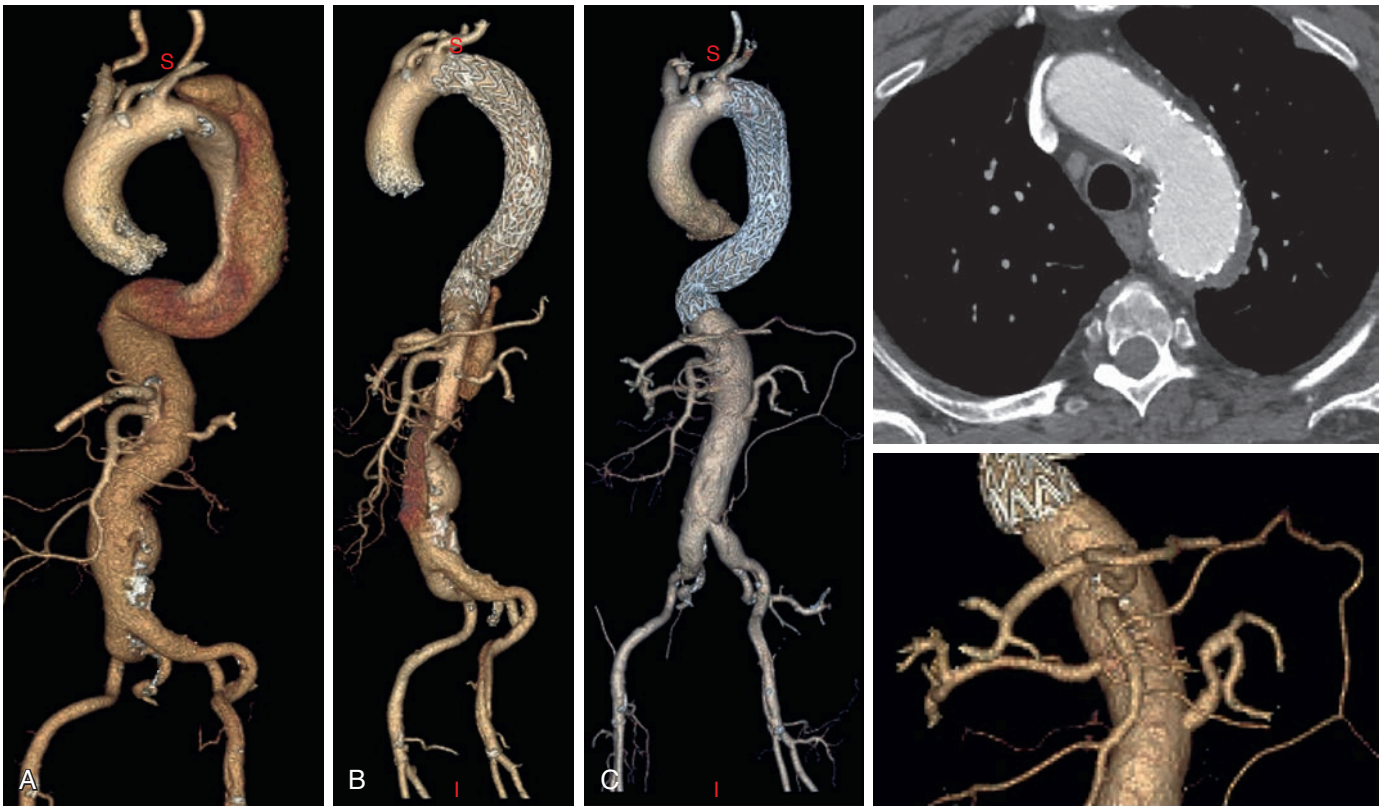

Figure 77.13 (A) An example of complete treatment of a rapidly expanding type B aortic dissection with (B) TEVAR and remodeling of the thoracic aorta. (C) Followed 9 months later with type 4 TAAA repair sutured to the thoracic endograft converting the need for type 2 subacute repair to an elective type 4 repair of a type B aortic dissection.

and direct renal perfusion cannot be done; however, we do use the other adjuncts of spinal fluid drainage (SFD) including hypothermia, steroids, mannitol, and naloxone without AC.

POSTOPERATIVE CARE

After open TAAA repair, patients are managed in the Intensive Care Unit (ICU) for 2 to 4 days depending on clinical progress. They are ventilated until adequately awake and able to breathe without assistance. This may be a few hours after repair of a Crawford type 4 aneurysm or 2 days after a Crawford type 2 aneurysm if there are no complications. Because patients are intentionally hypothermic to reduce metabolism and oxygen demand, we let them rewarm gradually with no attempt at rapid rewarming with Bair Huggers or other heating devises. Patients have continuous spinal fluid drainage to keep SFP below 6 mm Hg until they are awake enough to determine if spinal cord function is normal. After the patient can lift legs, SFP is monitored, but spinal fluid is not drained unless weakness develops. Cardiac function and hemodynamics are optimized with adequate volume replacement and inotropic support. Mean arterial pressure is kept above 90 mm Hg for the first 48 hours to maximize collateral perfusion of the spinal cord, while fresh frozen plasma and naloxone infusions are continued for 48 hours. Because of its negative effects following spinal cord ischemia, we do not use morphine for analgesia and prefer Fentanyl both intra- and postoperatively.[93] Propofol is used for sedation rather than benzodiazepines, because we want the patients to awaken easily for neurologic evaluation and weaning from the ventilator.

Delayed paralysis can occur after TAAA surgery. Delayed weakness is treated by increasing the mean arterial pressure and CI, draining spinal fluid, and restarting neuroprotective medications. In our experience, delayed deficits can sometimes be reversed if interventions are undertaken immediately. However, patients that cannot establish adequate collateral circulation to the spinal cord after surgery remain vulnerable to paralysis if spinal cord oxygen delivery is compromised by decreased cardiac function, hypotension, hypoxemia, or anemia.

OUTCOMES

Study of surgical outcomes has gone beyond operative and perioperative mortality and morbidity to include functional recovery and quality of life measures from the patient's perspective.

SPINAL CORD ISCHEMIA

Since the 1940s, spinal cord ischemia leading to paraplegia or paraparesis has been the most unpredictable and feared complication of thoracic aortic repair. Adams' landmark paper linked

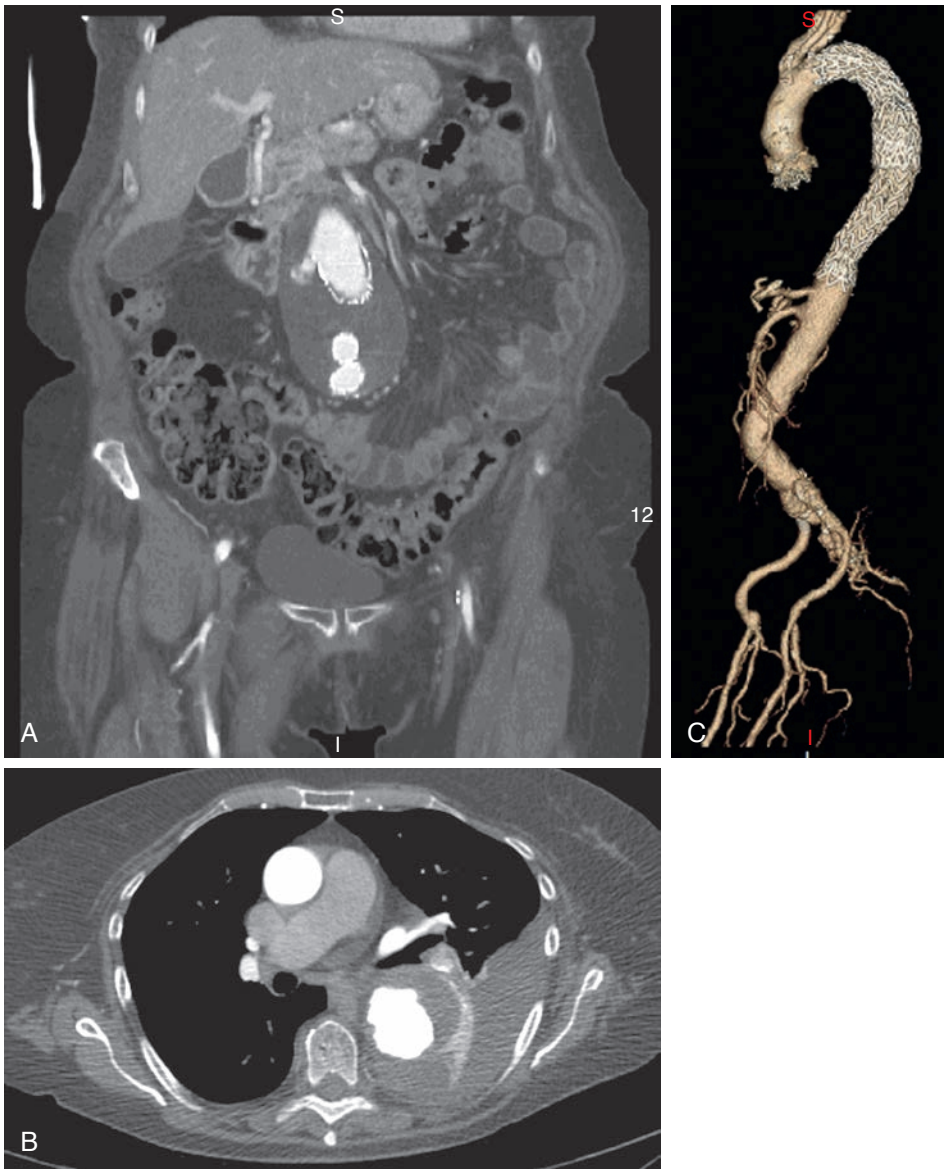

Figure 77.14 This patient required a C4 thoracoabdominal repair to rescue a failed EVAR that was sitting in the middle of a 7-cm aneurysm (A). To our surprise, at her follow-up CT, angiogram 4 months after repair her entire descending thoracic aorta was aneurysmal from a presumed retrograde dissection, which we believe was caused by the aortic clamp at her thoracoabdominal repair (B). We successfully treated this rather threatening appearing new aneurysm with pleural effusions with a TEVAR (C).

the anatomic variations of spinal cord arterial anatomy to neurologic complications of aortic surgery.[1] Adams's paper identified the Greater Radicular Artery (arising from the artery of Adamkiewicz between T8 and L2 spinal levels in 85% of humans) as most important, because it supplied an especially vulnerable region of the spinal cord in the lower thoracic aorta where there were fewer feeding radicular arteries and the anterior spinal artery is smaller. Even though the anterior spinal artery is continuous, the ascending portion from the greater radicular artery (GRA) is small with high resistance to blood flow and retrograde perfusion from aortic shunts and cardiopulmonary bypass. There are also muscular cushions associated with this ascending ASA that implies possible neurochemical factors that may potentiate spinal cord ischemia.[94–96] The decline in spinal cord blood flow and paraplegia risk with aortic occlusion is proportional to the number of open ICA in the length of aorta replaced, which varies depending on the pathology. On average, half the intercostals are occluded from the disease process with even more chronically occluded in degenerative aneurysms.[97] This patient data obviously shows that the pruning of ICA by the disease process leads to auto collateralization that reduces spinal cord ischemic risk associated with aortic replacement. Surgeons have focused primarily on an anatomic paradigm of paraplegia prevention for the last 60 years by attempting to identify and reattach critical ICA. This effort has failed to prevent paralysis because, as experimental and clinical studies have demonstrated, spinal cord circulation during and after aortic occlusion and aneurysm repair is via collateral arteries, such

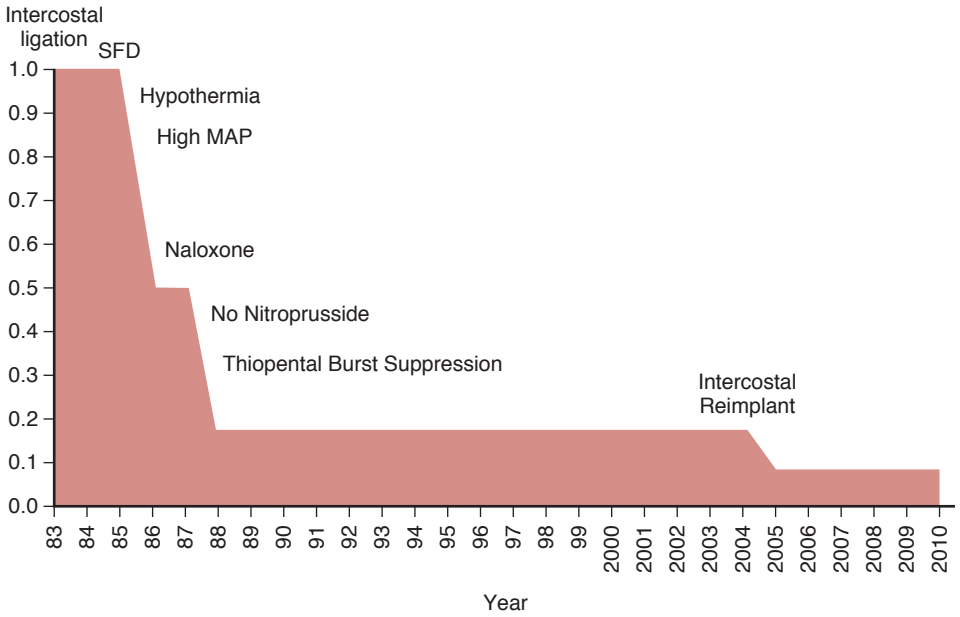

Figure 77.15 By applying the experimentally validated spinal cord protection strategies of hypothermia, spinal fluid drainage *(SFD)*, neurochemical protection (naloxone, barbiturates, steroids), and optimizing arterial pressure (MAP >90 to 100) and cardiac function, we reduced paraplegia incidence by 80% to 85% without assisted circulation or intercostal replantation. Replanting intercostals had a modest effect in the highest risk aneurysms (O/E declined from 0.34-0.18 in C2 aneurysms) by reducing delayed paraplegia, supporting the concept that the most important factors relate to prolonging cord ischemic tolerance, and maximizing the collateral perfusion as it recovers.

that manipulation of physiologic factors that impact the perfusion pressure in the collateral network, tissue oxygen delivery, and ischemic tolerance of the spinal cord are more effective at preserving spinal cord function.[98] Thus, even though the cause of spinal cord ischemia is anatomic, the most important neuroprotective strategies in our opinion are physiologic.

Physiologic Spinal Protection

The most elegant and insightful research into how the collateral circulation responds to interruption of direct intercostal and lumbar artery blood flow has been done by Etz and Greipp who described the coaxial collateral network concept.[99] In an experimental pig model, they found that the more acutely obstructed ICA increases the decline in collateral network pressure. More importantly, they found that spinal cord blood flow and recovery of collateral perfusion pressure occurs quite rapidly to 40% of pre-occlusion values within 24 hours and to 80% within 72 hours even with no open ICA. The most important experimental factors for optimizing this collateral perfusion network and protecting the spinal cord until collateral recovery occurs are as follows: hypothermia; spinal fluid drainage to keep SFP low, high arterial perfusion pressure (MAP), maintaining tissue oxygen delivery (avoid anemia and hypoxia, maintain cardiac index-CI); and neurochemical protection (naloxone, steroids, and barbiturates).[72,73,75,100–107] Elevated levels of excitatory amino acid neurotransmitters, which are reduced by naloxone, have also been implicated in exacerbating injury in spinal cord ischemia. In addition, it is important to avoid stealing effects of arterial vasodilators such as nitroprusside.[108] Applying these experimentally validated principles and interventions, we reduced our paralysis incidence by 82% to 85% with O/E ratios going from 1 to 0.15 to 0.18 without assisted circulation or intercostal re-implantation (Fig. 77.15).[8,109]

Expected Paralysis Model

To study paraplegia outcomes more comprehensively, we developed a mathematical model for calculating expected paraplegia based on the extent of aortic replacement and clinical presentation (acute, dissection) based on Crawford's results of TAAA surgery done without neuroprotective adjuncts (where C1, C2, C3, C4, and TAA indicates the number of those aneurysms):

$$E = [0.1C1 + 0.2C2 + 0.05C3 + 0.02C4 + 0.01TAA] + [0.3(\text{acute} + \text{dissection})]$$

The model was validated with over 5000 patients and accounted for over 98% of the variability in paraplegia between clinical reports (Fig. 77.16A).[5,8] The model calculates O/E ratios for paraplegia and can be used to analyze clinical outcomes traditionally expressed as percent paralysis, which is misleading because it does not account for clinical variations in patient populations regarding extent of aneurysm and acuity. We have now modeled over 15,000 patients from clinical reports in the last 25 years, and it is evident that paraplegia rates have declined significantly (about 75%, see Fig. 77.16B), which published reports show that the decline can be divided into two eras with most of this decline occurring since 1997 (Era 2 of the modern era). The transition from Era 1 to 2 marks a change away from Adams's anatomic paradigm to the more physiologic

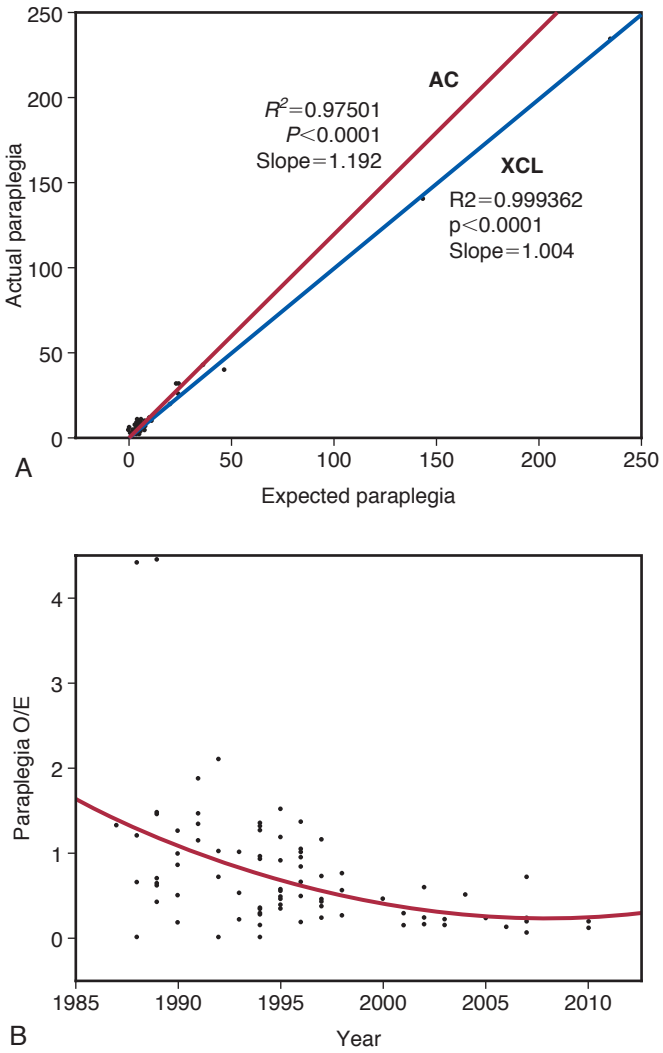

Figure 77.16 The paraplegia risk model accurately predicts ($R^2 > 0.97$) paraplegia risk when no effective spinal cord protection strategies are used and shows that assisted circulation *(AC)* and Crawford's simple crossclamp technique *(XCL)* have similar paralysis risk, which is consistent with experimental data. Using this model to calculate O/E ratios allows for a much more accurate understanding of the effects of protective strategies than using percent paralysis, which does not account for variation in a population of known clinical factors that affect paralysis risk. This modeling allows populations and techniques to be normalized for comparison.

TABLE 77.1 In Multivariate Modeling of Our Patients Cardiac Index Was More Important Than Age in Protection From Paraplegia While Extent of Replacement (Crawford Type C2), Dissection and Acute Presentation Were Associated With Increased Paralysis Risk

Variable	Odds Ratio	*P*-Value
Cardiac index	0.556/unit	.0038
Dissection	5.26	.0001
C2	6.35	<.0001
Acute	2.24	.0378
Age	1.035/year	.0763

TABLE 77.2 Younger Patients Have Less Risk for Paralysis and Mortality but in a Multivariate Model Age Is Less Significant Than Cardiac Index (Table 77.1), Which May Indicate That Better Cardiac Function Is Important in Collateral Perfusion Dynamics

Group	No. of Patients	O/E Ratio	% Paralysis	% Mortality
<60 years	153	0.06	1.4	0.7
>60 years	617	0.28	5.7	8.9

neuroprotective interventions of spinal fluid drainage, hypothermia, increased MAP, and neurochemical protection based on the experimental literature. The experimental literature also failed to validate assisted circulation when used alone to prevent paralysis in primates, pigs, and dogs, because perfusion of the abdominal aorta and iliac arteries did not improve blood flow to the lower thoracic spinal cord.[110–112] Other factors such as epidural analgesia and neuraxial narcotics may increase paralysis risk.[113–115] The extent of replacement (Crawford type) and dissection are proportional to open ICA at risk. In addition, physiologic instability (hypotension and anemia) of acute processes (rupture, dissection, infection, trauma, and underlying cardiac and pulmonary disease) are all important in the predictive model and explain why the model accounts for so much of the variation in clinical reports. However, also significant in multivariate analysis is cardiac function (Table 77.1). CI declines with age and statistically is more important than age.[116,117] Cardiac function fits with the collateral circulation concept by associating a stronger pump with more effective collateral perfusion and may explain one of the reasons older patients have increased paralysis risk [O/E 0.06, 1.4% <60 years; O/E 0.28, 5.7% >60 years] (Table 77.2).[5]

Impact of Physiologic Protection Measures

The experimental observations are consistent with our own experience and the analysis of clinical outcomes in over 5000 patients where assisted circulation and simple cross clamping without protective adjuncts both had the same O/E ratios of about 1 (Fig. 77.17A). However, if spinal fluid drainage is added to both techniques, the O/E ratios decline on average to between 0.4 to 0.5, and if we model the results from Era 2 when hypothermia and increased MAP were added by most surgeons to spinal fluid drainage, the O/E ratios declined further to a mean of about 0.25 (see Fig. 77.17A).[118]

From this analysis, if spinal fluid drainage, hypothermia, perfusion pressures (MAP), and, in our experience, neurochemical protection are optimized, outcomes are independent of technique of repair (simple cross clamp, assisted circulation, or hypothermic arrest) and O/E ratios are equivalent. It is also apparent that the variation (range) of O/E ratios within techniques reflects

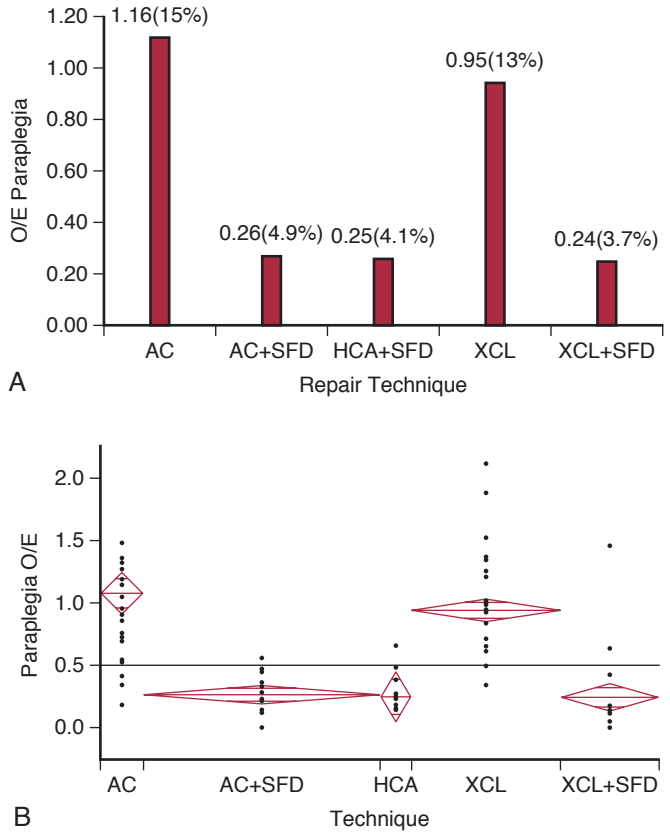

Figure 77.17 (A and B) It is evident that the reason paraplegia rates have declined is the clinical application of spinal cord protective strategies that have demonstrated experimentally to be effective, such as spinal fluid drainage, hypothermia, high perfusion pressure, neurochemical protection and measures that enhance cord oxygen supply-demand balance. These interventions are effective regardless of technique of repair *(AC, HCA, XCL)*. However, there is also variation within technique (B), which we think is a reflection of the stringency (effectiveness) of application of the protective strategies. This variation in application may also explain the very poor outcomes in smaller centers that do not have the resources or experience to apply these principles of spinal cord protection consistently. *AC,* assisted circulation; *HCA,* hypothermic circulatory arrest; *SFD,* spinal fluid drainage; *XCL,* Crawford's simple crossclamp technique.

the aggressiveness of applying effective spinal cord protective strategies (see Fig. 77.17B). This effectiveness issue is demonstrated by two randomized trials of spinal fluid drainage separated by a decade from the same institution. Crawford's early study, showing no benefit from spinal fluid drainage, did not control SFP, but just withdrew 50 mL of spinal fluid while maintaining normothermia and using nitroprusside. Coselli's later study controlled SFP, used hypothermia, and increased MAP, and demonstrated a significant protective effect from SFD with O/E ratios declining to 0.22.[119,120]

Evoked Potential Measurement and Intercostal Reimplantation

SSEPs and MEPs used by some surgeons to identify critical ICA have added greatly to our clinical understanding of the role of arterial perfusion pressure and intercostal artery reimplantation in spinal cord protection. Greipp and Jacobs have shown that intraoperative spinal cord ischemia reflected by loss of MEPS after aortic occlusion is reversed in most patients just by raising the MAP to 100 mm Hg and observing the return of MEP's.[85,121,122] However, they came to opposite conclusions about intercostal reimplantation with Greipp's studies (O/E 0.14) demonstrating no necessity or benefit to reimplanting intercostals, while Jacobs (O/E 0.25) found that using MEPs is necessary to select which intercostals to implant. To study this issue, in 2005 for the first time, we started reimplanting intercostals that we identified by MRA or by patency and location (85% GRAs arise between T8 and L2), primarily to reduce delayed paraplegia occurring from hypotensive events post repair (sepsis, MI, bleeding, dialysis, drugs). Our O/E ratios declined modestly from 0.18 to 0.11 for all patients, and this effect was most noticeable in the most extensive C2 aneurysms where O/E declined from 0.34 to 0.18.[123] From our experience and Greipp's, it is apparent that intercostal reimplantation is not the most important factor in paralysis prevention but may play a role in the most extensive aneurysms.

Descending Thoracic Aneurysms

These same spinal cord protection principles apply to open DTA repair. Even though modern series of open DTA are limited in number because of TEVAR, Safi and Coselli published their results of a large series of DTA with comparable results. Coselli compared Crawford's simple crossclamp technique (XCL) (2.3% paraplegia) and AC (4% paraplegia) in 387 (4% mortality) patients with no statistical difference in paralysis risk and Safi 2.3% (O/E 0.9) paralysis (8% mortality) in 300 patients most treated with AC + SFD.[124,125] This compares with our own experience in 166 (0.6% paraplegia, O/E 0.11, 7% mortality [1.6% elective, 9% acute]) XCL + SFD open DTA patients.

PULMONARY COMPLICATIONS

The most common complications following open TAAA repair is pulmonary, with prolonged ventilation, pneumonia, or respiratory failure occurring in up to 27% of patients. As many as 8% to 10% require tracheostomy, and half of those patients die from respiratory failure. This high pulmonary risk is because 80% of patients are active or former smokers, and 40% of patients have varying degrees of COPD limiting their pulmonary function and reserve.[126–128] These factors are exacerbated by age, osteoporosis, chronic renal disease, and congestive heart failure, which all are associated with loss of strength and loss of respiratory muscle strength, producing reduced maximum inspiratory and expiratory pressures (MIP, MEP) and reduced endurance (MVV). This loss of pulmonary muscle strength is associated with mortality in the elderly.[129–137] The incision itself reduces lung function postoperatively: after simple thoracotomy, it takes 10 to 15 days for FEV1, MIP, and MEP and 15 to 30 days for FVC to return to baseline.[138] The higher the interspace level of the thoracoabdominal incision the more difficult weaning from ventilator support will be. With incisions in the 8th interspace and below, patients are usually extubated within a few hours, but patients with 5th interspace thoracoabdominal incisions for extensive Crawford type 2 aneurysms may be

ventilator dependent for 2 to 4 days even without complications. Routine use of continuous positive airway pressure (CPAP) and adequate pain control may improve lung function and shorten intubation after surgery.[138] It is very evident to most surgeons who treat TAAA that postoperative pulmonary problems are a major harbinger of prolonged hospitalization and increase the effect of age on mortality risk. The effects of age and chronic disease on respiratory and skeletal muscle strength may be the most important underlying factors in survival and functional recovery. This suggests that preoperative strengthening regimens may improve strength and functional capacity and possibly reduce mortality risk.

MORTALITY

Mortality in our database (15,000 patients from 86 published reports in the last 25 years) averaged 9.3% (95% confidence 8.1-10.4, median 9.9%, range 4.1-37.2). Since many reports do not separate elective and acute operations, for better comparison of mortality between reports, we developed a mortality model that accounted for 86% of the variation between published reports:

$$\text{Expected Mortality} = [\text{acute} + \text{predicted paraplegia}] \times 0.38$$

This model was predictive with $R^2 = 0.86$, $P < .0001$. The mean O/E ratio was 1.00 ($P < .0001$, 95% confidence 0.842-1.168, median 1.07 range 0.22-7.61).[5] The model quantifies what we inherently know from experience, which is that patients with acute pathology (rupture, dissection, mycotic aortitis, acute plaque hemorrhage, trauma) or who develop paraplegia account for most of the mortality and that these patients die because they have a fatal event such as myocardial infarction or stroke or do not have the reserve functional capacity (pulmonary, cardiac, renal) or physical strength to survive as is the case in many patients with respiratory failure. Operative or postoperative bleeding can cause shock leading to multiorgan failure and death. Acute patients are at increased risk not only from unstable clinical conditions but also because they have not been screened for renal, pulmonary, coronary, or valve disease that could be corrected or optimized to reduce operative risk or exclude them from treatment, because operative risk was unacceptably high. These factors are reflected in the effect of age on mortality from our own data. For elective surgery, the operative mortality was 0.0 for patients less than 60 years of age and increased with each decade to 5.7% for patients 80 years or older who were highly selected. However, for acute patients, the mortality increased from 1.6% for <60 years to 42.9% for >80 years. In patients older than 80 presenting acutely with creatinine >2.0, the mortality was 67% (Table 77.3). As with paraplegia, the operative mortality in published reports has declined significantly ($P < .0001$) in the last 25 years from an Era 1 O/E mean of 1.46 (11.34%, 95% confidence 1.2285-1.6930) to 0.72 (7.99%, 95% confidence 0.534-0.903) in Era 2.[5] Because paraplegia has such a high mortality risk (27% overall, 45% for >70 years, 100% >80 years of age), its decline accounts for almost half (43%) of this improvement in mortality (Table 77.4). The causes of the remaining decline are much harder to determine but may be related to better centralization of care in larger referral centers in Era 2 with the average number of patients in reports increasing from 114 to 384. Patient selection may also play a role, although there is no data on this.

TABLE 77.3 Mortality by Decade in 771 or Our Patients Surgically Treated for Thoracoabdominal and Thoracic Aortic Aneurysms. Acute Patients Were Defined as Having Rupture, Contained Rupture, Acute Dissection, Mycotic Aortitis, Trauma, Plaque or Intramural Hemorrhage

RENAL FUNCTION

Poor renal function is associated with more complications, paraplegia, and mortality risk in most clinical reports, because it reflects a less robust patient with more advanced cardiac and pulmonary co-morbidities and less physical strength and reserve to survive such a physical assault. Postoperative dialysis–dependent renal failure is associated with a 50% to 60% mortality risk and preserving renal function and avoiding dialysis reduces mortality risk and improves long-term survival. Age and baseline renal function are the most important mortality risk factors in

most clinical reports. Normothermic renal perfusion in complete or partial cardiopulmonary bypass has not been effective in reducing renal failure, with permanent dialysis dependent renal failure rates up to 15%, because normothermia does not prolong ischemic tolerance, and hypotensive renal perfusion is inadequate especially for perfusing kidneys with any glomerular sclerosis.[139–141] Perfusing at higher pressures with moderate or deep hypothermia (hypothermic arrest or cold renal perfusion decreasing renal temperature to <20°C during occlusion), however, appears to provide effective renal protection with dialysis rates of 3% or less in most reports whether cold blood or crystalloid is used.[142–145] These results are consistent with our renal protection strategy of rapidly flushing each kidney with 300 to 400 mL of 4°C renal perfusion solution, which along with a 30% renal artery revascularization rate (endarterectomy or bypass), has resulted in 3.2% postoperative dialysis (80% of which are in acute patients) but only 0.8% permanent dialysis with most patients recovering baseline renal function within 14 days.[146]

EFFECT OF SURGICAL TECHNIQUE ON MORBIDITY

We have demonstrated with data from the experimental literature, published reports, and our own experience that a more complete understanding of the mechanisms of injury and protection in aortic surgery can lead to improved results. This effort requires a team approach using anesthetic, surgical, and ICU protocols that are evidence based and data driven. One of the controversies concerning TAAA repair is which technique to use: AC + SFD, XCL + SFD, or HCA. Some surgeons have strongly held opinions about the best method, but as the data tells us, equivalent results are attainable with each approach if experimentally supported principles are followed. However, patient physiology or anatomy may dictate the technique such as AC if the patient cannot tolerate one lung anesthesia, the cardiac strain of proximal cross clamping, or HCA if there is no place for a proximal aortic clamp. The different techniques each have strengths and weaknesses. XCL + SFD is surgically simpler with fewer steps associated with cannulating, it is easier to avoid hypotension, does not require heparinization, and results in faster surgery but is a more difficult anesthetic because of left heart strain and hypertension from very proximal aortic clamping. AC + SFD reduces cardiac strain but is associated with hypotensive perfusion, more bleeding because of heparinization, and is more complicated because of cannulating and decannulating for bypass. However, many cardiac surgeons use this technique. HCA is the most complicated technique and takes the most time, because HCA is such an extreme state, requiring long cooling and rewarming times, which means longer time on cardiopulmonary bypass and is associated with more bleeding because of coagulopathy, extreme systemic hypothermia, and total heparinization. However, profound hypothermia provides excellent organ protection from the ischemia of aortic occlusion.

We have examined the different methods of repair by quantifying total morbidity, which we define as observed number paralyzed + number of deaths divided by the expected (calculated from our models) to give an overall morbidity O/E ratio. Our analysis shows that total morbidity was comparable between techniques but showed a significant decline from Era 1 to Era 2 in all categories (Table 77.5).

TABLE 77.5 Total Morbidity O/E Is Sum of Paralysis and Death/Expected Sum Calculated From the Mortality and Paraplegia Predictive Models. This Ratio Is a Way of Evaluating the Overall Effectiveness and Risk by Procedure Technique. There Was No Statistical Difference Between Techniques but There Was Between Eras. The Primary Driver of Reduced Morbidity Was Reduction in Paraplegia Incidence but Centralization of Care Into Larger Centers May Also Play a Role.

LONG-TERM SURVIVAL AND QUALITY OF LIFE

There have only been a few studies of long-term survival after TAAA repair and even fewer on quality of life measures.[147–149] These data show that there is mortality within the first year after surgery from COPD, paraplegia, and renal failure, but after one year, although survival is lower, it more closely matches age matched expected survival with 69% to 78% survival at one year and 45% to 68% survival at five years, depending on the mean age of the patients in the study; however, females over 70 had significantly worse long term survival than males. After the first year, the quality of life scores was similar to age matched populations, but there was a marked difference in stamina in the older TAAA patients. The conclusion from these studies is that approximately 80% of patients return to

preoperative quality of life, but if there is dialysis or paraplegia or both, quality and length of life is severely reduced.

Since the US Food and Drug Administration (FDA) approved the first thoracic endovascular aortic repair (TEVAR) in 2005, its use has rapidly increased.[1,2] In a relatively short period of time, TEVAR for descending thoracic aortic aneurysms (DTAAs) and various other aortic pathology has not only become the preferred treatment method but also the standard of care. For many reasons, mainstream TEVAR technology has advanced at a rapid pace since the release of the first commercially available endograft. Investigational work continues through a combination of clinical trials, industry-sponsored research, physician-driven device modifications, and investigational device exemptions. The penultimate goal of in-line branch vessel preservation during repair of complex thoracoabdominal aortic aneurysms (TAAAs) appears to be technically feasible, efficacious, and durable.[3,4,5-9] In contrast to EVAR, most clinical TEVAR data originate from industry-sponsored, nonrandomized comparisons with open

Abstract

Thoracic aortic aneurysms (TAAs) are a relatively uncommon disease process which occurs more frequently in older individuals. There is an equal gender distribution, and various pathologies are associated with TAA. There are few signs or symptoms of TAAs. The natural course of TAA is one of progressive aortic expansion, which may be associated with an increased risk of life-threatening aneurysm rupture if not treated in a timely manner. Conventional treatment options are medical management for smaller aneurysms and open surgical repair, which includes replacing the diseased aortic segment with a prosthetic graft; unfortunately the latter is associated with a higher than desired rate of intraoperative and postoperative adverse events. Thoracic aortic endovascular repair (TEVAR) is an alternative approach for treating thoracic aneurysms, which appears to have a lower morbidity and mortality compared with open repair. Long-term data from industry-sponsored TEVAR studies are available and comparative analyses have been completed which have validated the use of TEVAR in a variety of thoracic aortic pathology. Advancing TEVAR technology using branches and fenestration to treat thoracoabdominal aortic aneurysms has shown immense promise but has yet to be approved for use in the United States.

repair of DTAAs, as well as from single-center experiences or registry data that combine different pathologic processes and indications. Nonetheless, TEVAR has emerged as an attractive option for the treatment of a wide range of thoracic aortic pathology.

Indications

Thoracic aortic disease remains one of the leading causes of death in the United States[10] and accounts for more than 11,000 deaths annually, with estimated incidence of 5.6 to 10.4 cases per 100,000.[11-13] Based on epidemiologic data, the increase appears to be multifactorial in nature and includes an aging population, along with improved educational awareness of patients and healthcare providers.[14,15] Indications to treat thoracic aneurysms depend on various factors, including aneurysm diameter, rate of growth, anatomic location, presence of symptoms, and general medical condition of the patient (see Chapter 76). Similar criteria should be rigorously applied for both open and endovascular repair: diameter ≥5.5 to 6.0 cm with saccular morphology, rapidly expanding aneurysms, symptomatic aneurysms, and rupture. The main considerations supporting TEVAR over open repair are based on physician experience, patient anatomy, and underlying comorbidities. There are select situations in which repair at a smaller diameter may be considered including nonsaccular aneurysms, symptomatic or ruptured, and those associated with connective tissue disorders.

Anatomically, if considering TEVAR, there should be suitable landing zones (≥20 mm) proximal and distal to allow adequate seal and exclusion of the aneurysm, as well as appropriately sized arterial access to deliver the stent-graft. Anatomy is not the only parameter in treatment planning; age and risk assessment play a significant role in selecting the appropriate treatment. Societal guidelines have recognized the absence of high-quality data to support the increasing use of TEVAR. The Society for Thoracic Surgeons Endovascular Task Force has emphasized an individualized approach.[16,17] A Cochrane review confirmed that clinical equipoise exists between TEVAR and open repair of thoracic aortic aneurysms (TAAs) due the paucity of supporting data.[18,19]

In the presence of suitable anatomy, TEVAR appears to be an acceptable first choice for most, based on its lower morbidity and mortality. However, enthusiasm for TEVAR should be tempered by the paucity of follow-up data and requirement for lifelong follow-up. Consideration should be given to open repair in younger patients with longer life expectancies and apparent low risk for open repair. For higher-risk individuals the decision is straightforward because clinical results favor an endovascular approach. Long-term data may eventually support a more liberal use of TEVAR in lower-risk individuals, particularly in light of the demonstrated significant perioperative reduction in risk with TEVAR (see later).[11] In the absence of high-level evidence comparing the results of open repair and TEVAR, some investigators advocate TEVAR only when the predicted operative risk is less than the risk associated with conventional open repair.[12]

In the patients without "ideal" TEVAR anatomy, the risk/benefit assessment becomes more challenging to equate. Many aneurysms impinge on major arterial branches that may need to be covered for adequate seal. In these situations the safety of branch sacrifice must be balanced against continued observation and open repair. The alternatives would be use of snorkel technique, fenestrated/branched endograft, and surgical bypass, which maintain perfusion while extending the seal zone. The incremental risks of planned branch occlusion should be carefully evaluated when considering TEVAR; presumably this option would be appropriate in a select situation (high risk with large aneurysm). This category encompasses those with cardiac or pulmonary comorbidities that preclude safe open repair or "high-risk" anatomic conditions. The durability of TEVAR can be compromised by treating aortic pathology outside of the IFU, this includes large diameter necks, angulated aortic segments, and circumferential thrombus lining the seal zones. Significant angulation of the arch (>60 degrees) adjacent to the proximal portion of the aneurysm increases the difficulty of device tracking and may compromise seal. TEVAR should be performed with caution in patients with life-threatening allergies to intravenous contrast or to nickel or stainless steel and in those who cannot be monitored reliably.

APPROVED DEVICES FOR THORACIC ENDOVASCULAR AORTIC REPAIR

The pace of development of commercially available TEVAR devices has lagged behind that of EVAR devices, presumably because of lower incidence of DTAA, larger device profiles, challenging hemodynamic forces of the thoracic aorta, and proximity to the great vessels. Despite these hurdles, steady progress has been made, with several new or modified thoracic devices released (see Chapter 79). Five commercially available devices (Table 78.1) have completed regulatory trials and are approved for use in the United States.

Gore Conformable Thoracic Aortic Graft Device

The Gore thoracic aortic graft (TAG) endoprosthesis (W.L. Gore and Associates, Flagstaff, Arizona) was the first thoracic endograft approved in the United States. The Conformable TAG (C-TAG) endoprosthesis is a third-generation device that was approved January 2012. The device conforms to the aortic wall, which improves aortic wall apposition and minimizes the risk of proximal bird-beaking. The C-TAG device is constructed with an expanded polytetrafluoroethylene (ePTFE) tube reinforced with ePTFE/fluorinated ethylene propylene film and an external nickel-titanium (nitinol) self-expanding stent affixed to the graft (Fig. 78.1). This device uniquely deploys from the middle of the graft outward, a design characteristic intended to prevent windsock effect at the proximal fixation. A circumferential PTFE sealing cuff is located on each flared end. Device lengths, diameters, and delivery profile are documented in Table 78.1. Based on the IFU the C-TAG is designed to be oversized 7% to 22%.

Medtronic Valiant Captivia Device

In January 2014 the Valiant thoracic stent graft (Medtronic, Santa Rosa, California) was approved for use in the United States. It is a modified Talent endograft without the longitudinal connecting bar and has been widely implanted outside of the United States. The device is composed of a monofilament woven polyester graft attached to sinusoidal nitinol springs that are placed on the outside of the graft. The modular design consists of an eight-peaked bare metal proximal FreeFlo configuration that evenly distributes radial force across the proximal aortic neck (Fig. 78.2). Valiant has a wide assortment of diameters and lengths, with both closed web and open FreeFlo stents available (see Table 78.1). Oversizing 10% to 20% in relation to the native aorta is recommended.

Cook TX2 With Pro-Form

The Cook TX2 (Cook Medical, Bloomington, Indianapolis) was approved for commercial use in 2008 and is a two-piece modular graft consisting of woven Dacron fabric sewn to self-expanding stainless steel Z-stents. The Pro-Form modification uses a trigger-wire release mechanism that improves proximal conformity and wall apposition. During device deployment, the proximal stent remains in a trifold configuration, which improves deployment accuracy and avoids a windsock effect. Unique to this device, the metal stents are located on the inside of the graft in the sealing zone but outside on the remainder (Fig. 78.3). Active fixation is provided by barbs on both ends; these barbs are intended to prevent migration and component separation. Device sizes and lengths are located in Table 78.1.

Cook Zenith Alpha

In September 2015 the Cook Zenith Alpha (Cook Medical) received FDA premarket approval. This lower profile device (18 or 20 F) addresses most access limitations. The two-piece modular graft consists of external nitinol stents and woven polyester fabric sewn together. Similar to the TX2, the Alpha uses active fixation. Gold radiopaque markers near the ends of the device improve visualization (Fig. 78.4) and a wide range of sizes and lengths are available (Table 78.1).

Bolton Relay

The Bolton Relay Thoracic Stent-Graft with Plus Delivery System (Bolton Medical, Sunrise, Florida) is a one-piece endograft made of woven polyester fabric sewn to self-expanding polished nitinol stents. Longitudinal support is provided by a curved nitinol support strut that aids aortic conformability. The device was

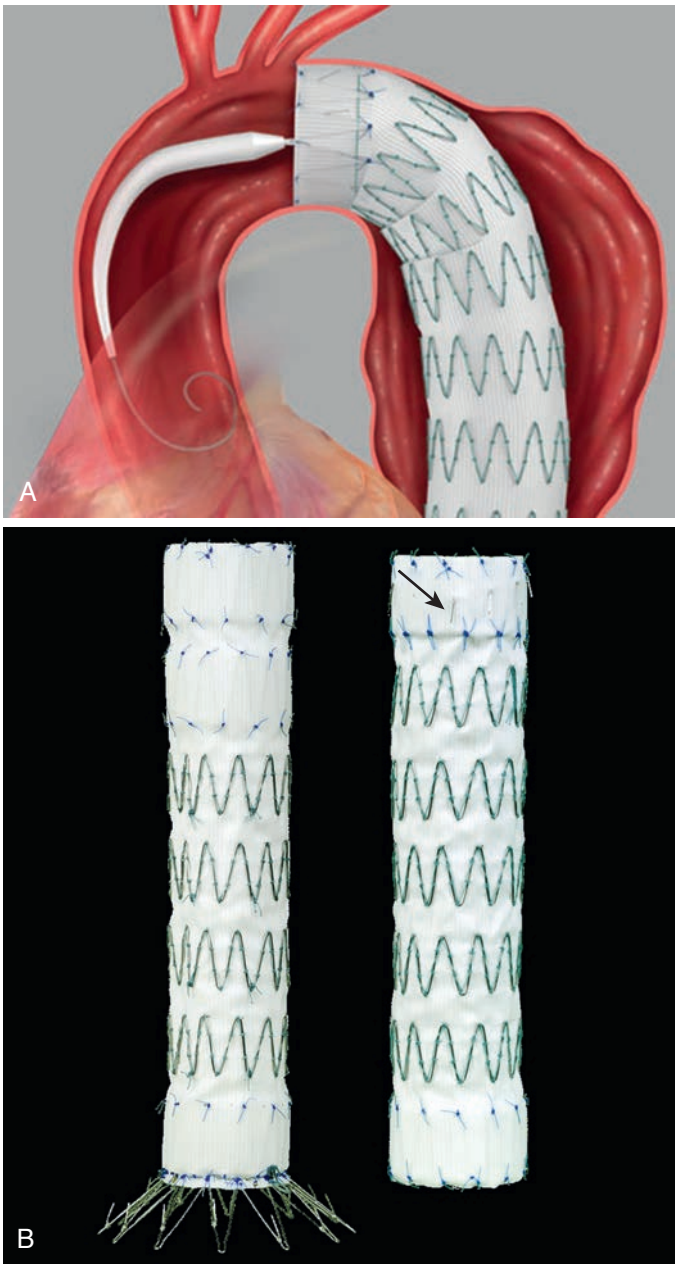

Figure 78.3 **A,** Schematic of Cook TX2 endograft with Pro-Form modification for improved proximal conformity and wall apposition. **B,** Cook TX2 device. approved in September 2012. The transport delivery system consists of a hydrophilic braided outer coaxial sheath, flexible secondary sheath with a through lumen that facilitates device advancement and precise endograft deployment. Active proximal fixation is provided by bare stents on the Relay plus device and nonbare stent (NBS) configurations are also available. The device is available in straight and tapered designs and oversizing of 10% to 15% is recommended. A wide range of diameters and lengths are available (Table 78.1; Fig. 78.5).

PLANNINGTHORACIC ENDOVASCULAR AORTIC REPAIR FOR THORACIC ANEURYSMS

Relevant Anatomy

Careful assessment of anatomy and meticulous preoperative planning are essential for successful TEVAR. Although anatomic requirements can be device specific, adequate arterial access and sealing zones are essential for all. Several anatomic features, when present, may facilitate TEVAR success or render it very difficult.

Aorto-Iliac Anatomy

Most procedures use common femoral artery access. Vessel calcification, small lumen diameter, and tortuosity can have a profound impact on the procedure. The right iliac artery is typically favored for device access, whereas the contralateral side is reserved for diagnostic catheters. An ideal access vessel should be ≥7 mm in diameter to accommodate larger delivery sheaths. The proximal external iliac typically has the smallest diameter and is prone to calcified plaque, which can restrict device insertion. This is a particular problem in women, whose

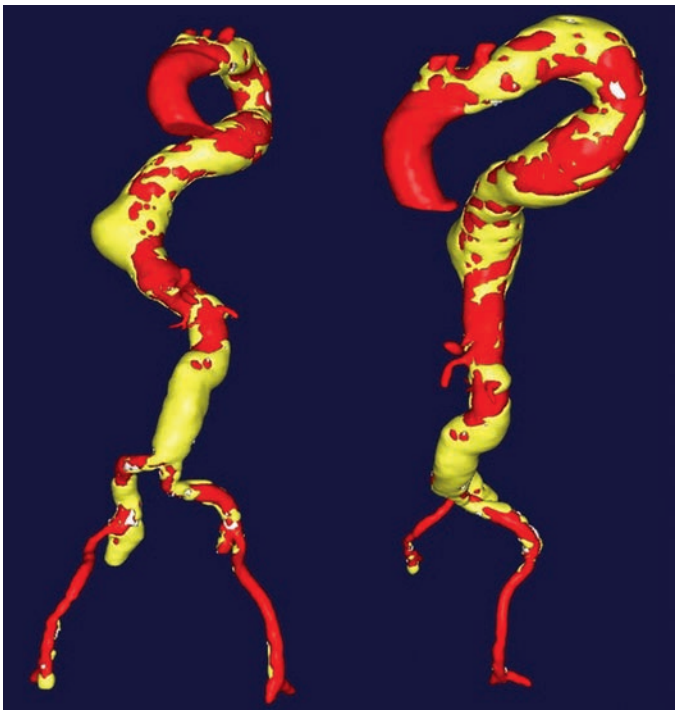

Figure 78.6 Three-dimensional reconstruction of the entire aorto-iliac tree demonstrating tortuosity at the level of the aortic arch, descending thoracic aorta, abdominal aorta, and iliac arteries.

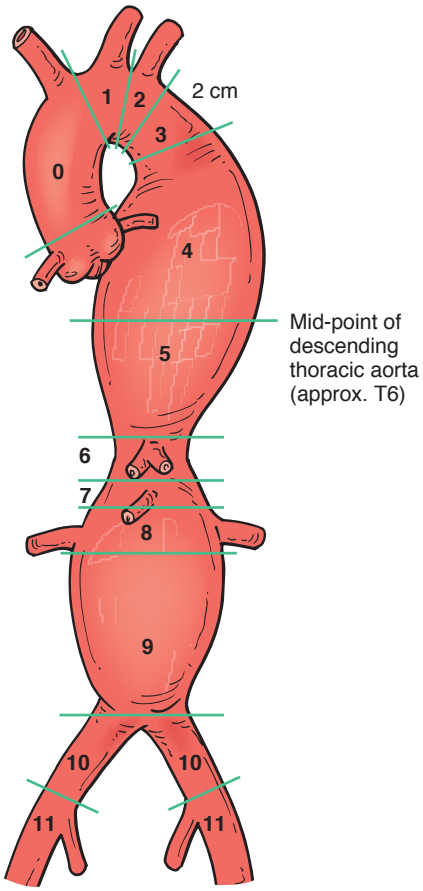

Figure 78.7 Eleven landing zones for thoracic aorta interventions.

iliofemoral arteries tend to be smaller.[14] Prior TEVAR studies required an iliac conduit in up to 15% of patients.[20] If the narrowest segment of the iliac is less than the expected diameter required for the planned device, access may be shifted proximal to the common iliac artery. Rarely, the entire iliac system is hostile and consideration should be given to alternative access techniques (crack and pave) or direct aortic access. An alternative approach for dealing with unfavorable iliac anatomy is the use of an internal endoconduit.[21] A 10- or 12-mm covered stent is deployed across the diseased iliac segment and aggressively inflated, which creates a controlled vessel rupture. The dilated 10-mm graft will allow sheath sizes up to 22 F, and 12-mm grafts up to 24 F. Planned embolization of the internal iliac artery may be needed if the occlusive disease is adjacent to the internal iliac artery. The use of hydrophilic sheaths and lower profile devices (Cook Alpha) should decrease the need for adjunctive techniques.

The abdominal aorta rarely presents an anatomic hindrance to device delivery, but tortuosity of the thoracic aorta can be challenging in the presence of aneurysmal disease because it frequently is associated with thoracic aortic elongation and exaggeration of normal curvatures. As illustrated in Fig. 78.6, this is particularly relevant in a large descending thoracic aorta when cephalocaudal elongation causes exaggeration of the posterior-anterior course of the aorta as it enters the aortic hiatus. This tortuosity, if combined with increased angulation at the transition from the arch to the proximal descending aorta may result in difficulty with device tracking due to bending of the delivery sheath at multiple flexion points as it negotiates the severely angulated regions.

Aortic Sealing Zones

Adequate TEVAR fixation in the proximal and distal landing zones is essential for durable performance. TEVAR reporting standards were published by the Society for Vascular Surgery (SVS) and 11 landing zones described for thoracic aortic disease (Fig. 78.7).[16] This anatomic standardization aids in determining procedural risk and complexity in relation to the site of fixation and length of aortic coverage. Several publications have shown that the frequency of neurologic events correlates with location of the proximal landing zone.[18,22] The proximal attachment zones define the proximal edge of the TEVAR device in relation to branch vessels: zone 0: proximal to the innominate artery; zone 1: proximal to left common carotid artery (CCA); zone 2: proximal to origin of the left subclavian artery (SCA); zone 3: proximal descending thoracic aorta (<2 cm from left SCA); zone 4: 2 cm distal to SCA extending to proximal half descending thoracic aorta (T6 vertebral body); zone 5: distal half descending thoracic aorta to celiac artery; zone 6: celiac artery to top of superior mesenteric artery (SMA); zone 7: SMA to suprarenal aorta; zone 8: perirenal aorta; zone 9: infrarenal aorta; zone 10: common iliac arteries; zone 11: external iliac arteries.

Atherosclerotic aneurysms typically are not limited to one focal area, and the degenerative process usually involves apparently normal adjacent aorta. This is important in selection of landing zones and device length. Although 2 to 3 cm is

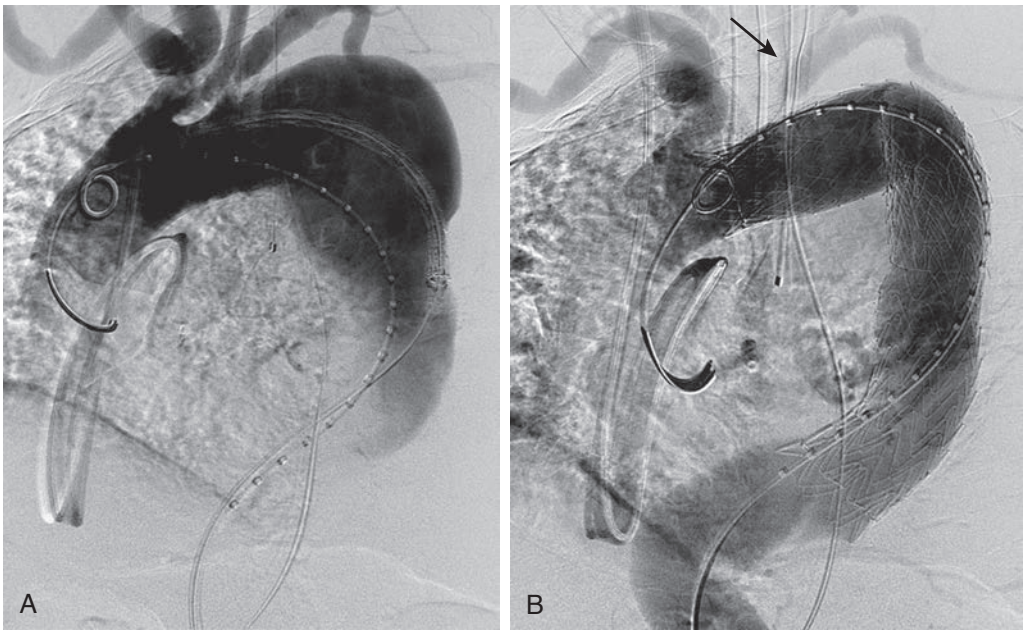

Figure 78.8 **(A)** Operative thoracic aortography demonstrating a large thoracic aortic aneurysm. Note the parallel proximal and distal landing zones. **(B)** Completion aortography showing the thoracic endograft deployed proximal to the left subclavian artery with exclusion of the aneurysm. Note the retrograde filling of the left subclavian artery without endoleak *(arrow)*.

considered adequate for most devices, a longer seal zone may be preferable in angulations to decrease the occurrence of endoleaks and migration and protect from late aneurysmal degeneration. The urge to cover longer aortic segments should be tempered by the increased risk for spinal cord ischemia. If anatomically feasible, the landing zone should ideally be parallel in configuration, distal to the left SCA, and proximal to the celiac artery (Fig. 78.8). Sealing in curved portions of the aorta, generally near the left SCA, presents added complexity. The longitudinal stiffness of the device can limit device apposition to the inner curve. The minimum sealing length in these regions should focus on the inner curvature rather than to the outer curve. The proximity of the sealing zones to major branches should be carefully evaluated to avoid branch vessel occlusion. If indicated, a surgical bypass should be considered to maintain patency of the branch vessel or a chimney/snorkel technique used to preserve in-line flow.

Operative Planning and Options

Imaging

Preoperative imaging studies delineate morphologic features of the aneurysm, branch vessel anatomy, and quality of access vessels. Computed tomographic angiography (CTA) is capable of providing all necessary anatomic information (see Chapter 27). A 128-slice computed tomography (CT) scanner provides high definition and very fast scan acquisition times. It provides three-dimensional volume rendering capability and maximum intensity projections, along with sagittal and coronal reconstructions. Imaging software such as M2S (M2S, West Lebanon, New Hampshire), Vitrea (Vital Images, Minnetonka, Minnesota), and Aquarius (TeraRecon, San Mateo, California) offer additional tools, such as reconstructions orthogonal to line of flow and virtual grafts to aid in procedure planning. When patients are unable to undergo CTA, gated magnetic resonance angiography (MRA) should be considered.

The preoperative CTA needs to include the aortic arch, chest, abdomen, and pelvis with and without contrast enhancement to adequately evaluate the quality of the native vessels. Tortuosity is best delineated by three-dimensional reconstructions. Qualitative evaluation of arch disease (i.e., atheromatous burden), as well as location of vertebral arteries, is critically important when landing in zones 0, 1, or 2. Assessment of pelvic perfusion is essential for evaluating risk of spinal cord ischemia, especially in patients who have undergone prior aortic repair, or in anticipation of long aortic segment coverage.

Sizing

Accurate measurements of access vessels and sealing zones are critically important for determining appropriate graft sizes. Excessive oversizing may cause graft infolding, poor seal due to gutter formation, and possible aortic neck degeneration from excessive radial force. Aortic diameters are best measured on orthogonal reconstructions, especially in areas of tortuosity and angulation. If reconstructions are not available, the short axis is a reasonable estimate of the true diameter.[23] Neck diameters between the proximal and distal sealing zones can vary, which may lead to inaccurate sizing. Appropriate aortic length measurements are necessary to calculate device lengths. This can be difficult because the thoracic aorta moves posterior lateral in the proximal portion and anterior medial near the diaphragm. The presence of an aneurysm exacerbates this tortuosity. A centerline flow measurement from a three-dimensional reconstruction provides the best length estimate, although this can still underestimate endograft length because the devices follow the greater curvature, especially in large aneurysms.

Identification of Landing Zones

The lack of adequate landing zones both proximally and distally is not infrequently encountered. Extension into zone 2 to achieve adequate seal proximally was required by more than 20% of patients in some regulatory trials.[20] Although coverage of the left SCA is generally well tolerated because of a rich collateral network,[24-29] routine exclusion should be discouraged because both experimental and clinical evidence suggests that not all patients can tolerate the occlusion safely.[29-31] The left SCA is an important vessel for perfusion of both the spinal cord and the brain via the left vertebral artery.[32] It provides blood flow to the spinal cord through the internal mammary and anterior intercostal branches.[33] The decision to preserve or cover the left SCA has undergone a substantial paradigm shift. Although early-generation cases underwent a left carotid–subclavian bypass or transposition, later reports of safe coverage resulted in indiscriminate coverage of the left SCA.[24-28] Current data support and guidelines recommend preserving left SCA flow due to the risk of brainstem stroke and spinal cord and arm ischemia.[34,35] A dominant left vertebral artery is present in greater than 60% of patients, which coincides with an absent or atretic right vertebral artery. Intuitively, these findings place patients at increased risks for posterior circulation infarct. Intentional left SCA coverage without revascularization significantly increases the overall risk of stroke, especially for the posterior circulation (5.5% vs. 1.2%).[36,37] Coverage without revascularization has been linked to an increased risk for spinal cord ischemia in a review of EUROSTAR (European Collaborators on Stent/Graft Techniques for Aortic Aneurysm Repair) registry data.[35] On multivariate analysis, left SCA coverage without revascularization was an independent predictor of spinal cord ischemia, with an odds ratio of 3.49.

When reconstruction is undesirable, careful preoperative imaging should be performed to assess the patency of the right vertebral artery connecting to the basilar artery and circle of Willis, to identify patients unable to tolerate left SCA occlusion. Mandatory left SCA revascularization is imperative in the presence of a dominant left vertebral artery, left internal mammary to coronary artery bypass, presence of left arm hemodialysis access, aberrant right SCA, hypoplastic or absent right vertebral artery, termination of left vertebral artery in the posterior inferior cerebellar artery, occluded internal iliac arteries, or anomalous origin of the left vertebral artery from the arch.[29,34,38,39] Revascularization should also be considered when an elevated risk for paraplegia exists with extensive coverage of the thoracic aorta combined with previous infrarenal aortic replacement. Delayed revascularization can be performed in cases of arm ischemia without untoward effects.[34,39] Revascularization by either left CCA to left SCA bypass or SCA transposition can be performed. Transposition eliminates one source of type II endoleaks; technically it can be more challenging and less desirable in situations where the left SCA is aneurysmal or displaced by the **descending thoracic aorta.** Preservation of a posteriorly located vertebral artery can be difficult, and for this reason most surgeons prefer carotid-to-subclavian bypasses (see Chapter 118) combined with ligation or embolization of the proximal left SCA. The updated SVS practice guidelines recommend routine left SCA revascularization be performed prior to TEVAR in elective situations.[38]

Debranching of the Arch Vessels

Several alternative treatment options have emerged to maintain branch vessel perfusion during TEVAR in zones 0 to 2; these include hybrid procedures with in situ fenestration, extra-anatomic bypasses, endovascular debranching with chimney techniques, and open aortic debranching. The goals of each technique are to extend the proximal landing zone, maintain branch vessel perfusion, lower the risk of a type Ia endoleak, and decrease procedure related adverse events. Thoracic aneurysms juxtaposed to the left CCA can be technically challenging. If coverage of the left carotid artery is necessary, several options are available to maintain carotid perfusion. More frequently an extra-anatomic carotid-carotid bypass is performed. This requires bilateral common carotid exposure through oblique neck incisions and tunneling a ringed 6- or 8-mm PTFE graft retroesophageal. Caution should be taken because larger grafts may compress the esophagus and cause dysphagia. Carotid bypasses have been found to be durable (3-year primary patency rate of 88%).[40] In select situations when inflow from the right CCA is inadequate and the patient is high risk for open arch reconstruction, sequential extra-anatomic bypasses should be considered. This would involve performing a series of bypasses originating from the left common femoral to the left axillary artery then from the left SCA to left CCA. The length and number of bypasses creates concern when defining patency rates.[41] Endovascular debranching techniques for the left CCA have been described.[42] Exposure of the left CCA allows retrograde access into the aortic arch and the creation of a left carotid to SCA bypass if needed. TEVAR deployment from the femoral and retrograde CCA covered stent placement extending into the arch is performed (chimney technique).[43] The covered stent is deployed to the same level as the TEVAR. Limited results have shown this technique to be an acceptable option for high-risk patients.

Thoracic aneurysms encroaching on the innominate artery are the most challenging to manage. Hybrid endovascular repair options are described. Involvement of zones 0 and 1 are often managed with an open arch debranching originating from the proximal ascending aorta (Fig. 78.9). Through a median sternotomy, a bifurcated prosthetic graft is sewn to the ascending aorta, the innominate artery, and the left CCA. A TEVAR can then be inserted and deployed.[44] Andersen proposed an algorithmic approach to the management of aortic arch disease. This technique was found to be successful but did carry a higher than expected rate of type A dissection and 30-day mortality (14.9%).[45]

Management of the Celiac Artery

If the distal landing zone is inadequate, the surgeon faces a similar situation as the left SCA. Adequate collateral circulation between the celiac axis and SMA is expected via the gastroduodenal and pancreaticoduodenal arcades, their presence helps to determine if the celiac can be covered.[46] Vaddineni et al.[47] reported seven

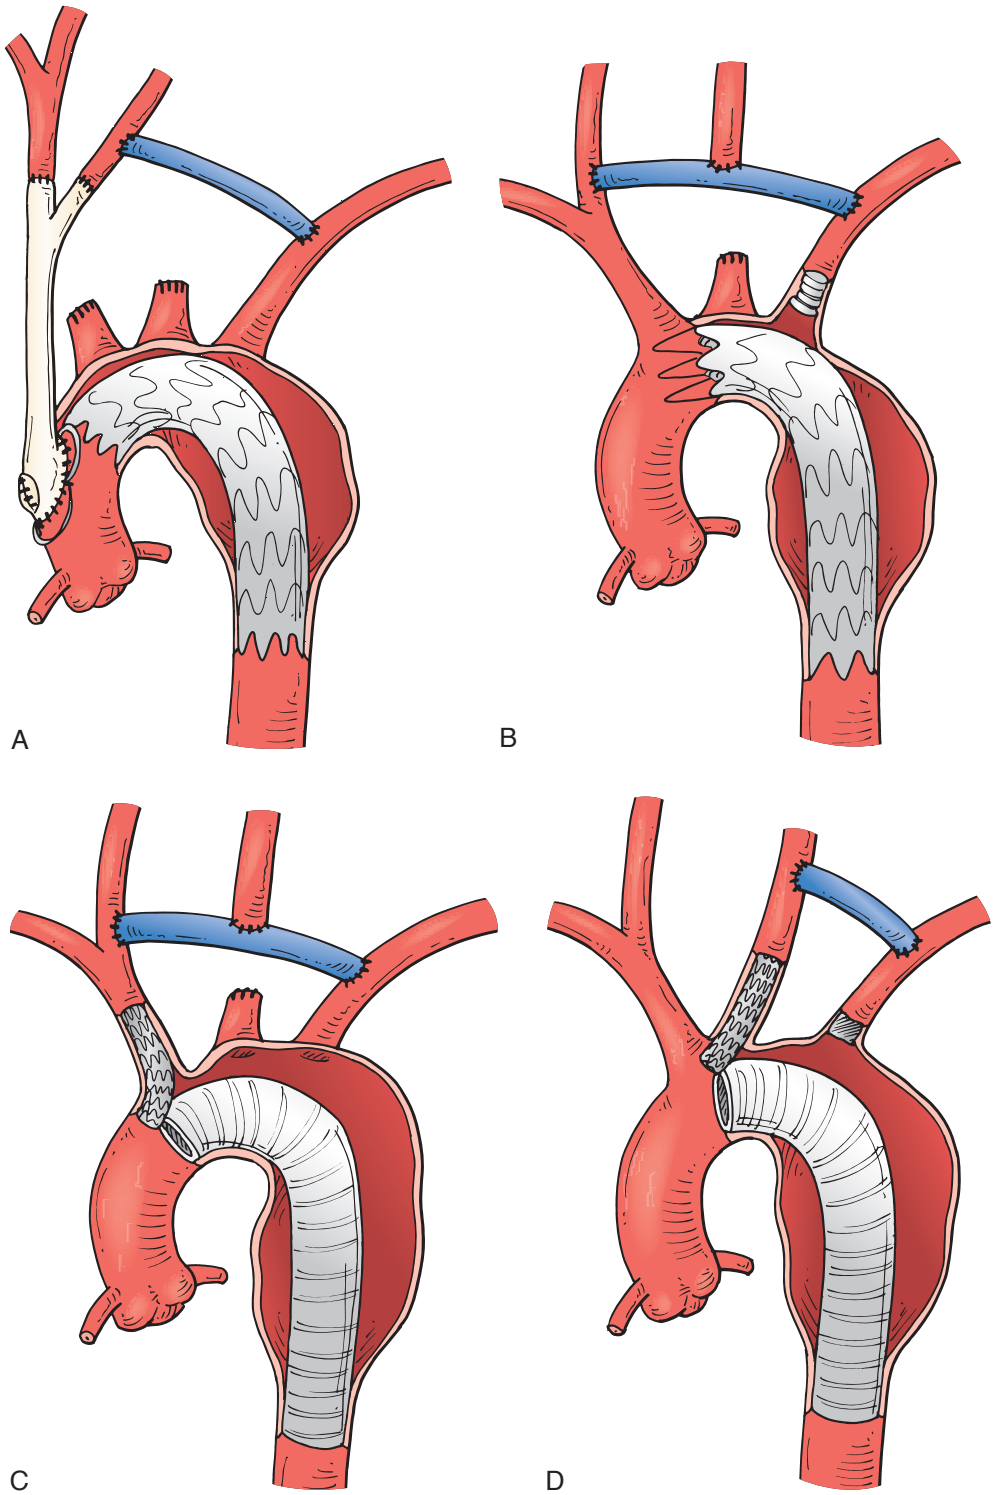

Figure 78.9 **(A)** Zone 0 hybrid arch debranching with thoracic aortic endovascular repair. **(B)** Zone 1 hybrid arch repair. **(C)** Right to left carotid-carotid bypass and left subclavian bypass to extend the proximal landing zone. **(D)** Zone 1 endodebranching.

such cases without mesenteric or spinal ischemic complications. If the collateral network is inadequate, consideration to preserving the celiac should be undertaken. Mehta et al. published a series of 31 patients undergoing TEVAR with celiac interruption. Postoperative mesenteric ischemic complications occurred in 6%, and another 6% sustained paraplegia. He concluded that celiac coverage was relatively safe in the presence of prominent SMA-celiac collaterals.[48] Outcomes of 18 patients with celiac coverage during TEVAR were published by Rose in 2015 and had similar results. Consistent with these studies, a review of the worldwide data reported a low rate (6% to 8%) of foregut ischemia associated with celiac coverage.[49,50] Use of periscope

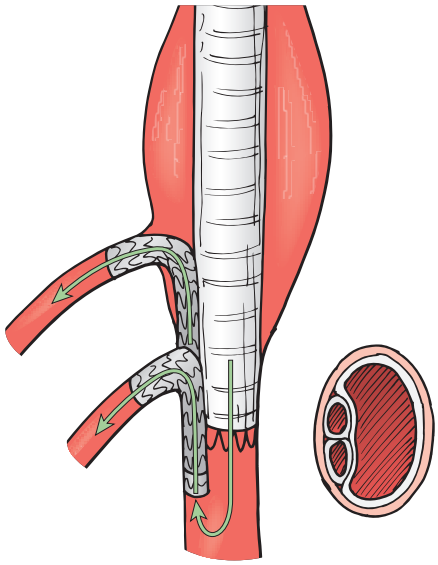

Figure 78.10 Thoracic aortic endovascular repair with downward periscope graft in the celiac artery and superior mesenteric artery.

grafts is an acceptable option in situations when celiac preservation is necessary and open revascularization unfavorable (Fig. 78.10). This technique has proved useful as a means of preserving or rescuing branch vessels in TEVAR seal zones. A self-expanding covered stent is inserted into the celiac artery via femoral access, and the TEVAR is deployed in the standard manner. Reinforcement of the self-expanding celiac stent may be necessary because of the steep downward angle created by the TEVAR.[43]

Adjunctive Measures for Neuroprotection

TEVAR is not without risk for spinal ischemia; there is consensus that patients with long-segment descending thoracic aortic coverage and antecedent or concomitant abdominal aortic grafting are at particular risk. In such circumstances, adjuncts are used, albeit without firm evidence. Such techniques have been evaluated mostly during open repair of TAAA. (For a more detailed discussion, the reader is referred to Chapter 77). Most centers selectively use cerebral spinal fluid (CSF) drainage in patients who are at an increased risk for spinal cord ischemia. The spinal drain is inserted preoperatively and maintained for 48 to 72 hours while CSF pressure is kept ≤10 cm H_2O. The advantages of selective drain use relate to an obligatory intensive care unit admission and hemorrhagic complications associated with catheter placement (0% to 3%).[49] CSF drainage has also been shown to effectively reverse delayed-onset paraplegia after TEVAR and should liberally be used if spinal cord ischemia is suspected.[51] Besides the anatomic features noted earlier, hemodynamic stability plays a crucial role in spinal cord ischemia because the underlying pathology appears to be poor collateral flow and decreased perfusion. Low intraoperative mean arterial blood pressure (less than 70 mm Hg) has been linked to spinal cord ischemia.[51] Except for the short time required for endograft deployment, when a relatively low blood pressure may be desired, an elevated pressure is preferred intraoperatively. Similar to open aneurysm repair, postoperative hypotension can precipitate spinal cord ischemia. The importance of the artery of Adamkiewicz, which is usually located between T8 and L2, has been debated extensively but has not clearly been linked to spinal cord ischemia. The EUROSTAR review found an association between T10 coverage and spinal cord ischemia; 40% of patients with spinal cord ischemia exhibited T10 occlusion, and only 18% did not suffer periprocedural paraplegia or paraparesis.[35] However, the association was not present on multivariate regression analysis. Accordingly, no recommendation can be made to avoid covering the T10 region.

Operative Technique

After the optimal site for device entry has been determined, the ipsilateral common femoral artery is exposed or can be accessed percutaneously.[52] The contralateral femoral artery or brachial may be accessed for placement of a marker catheter. Once access is established, a stiff wire is advanced into the ascending aorta. It is helpful to mark the back end of the wire on the table to detect any unintentional movements. When a conduit is needed, it is constructed through a small retroperitoneal incision in the ipsilateral lower quadrant. A 10-mm Dacron graft is anastomosed to the common iliac artery in an end-to-side fashion; this large-diameter conduit accommodates larger sheaths. The conduit can be accessed through the same incision or can be brought out through an incision in the lower abdomen or groin. Inserting the sheath through the graft wall rather than the open end provides better sheath stability during manipulations and decreases blood loss. At the end of the procedure, the conduit can be ligated or converted to an iliofemoral bypass if indicated. Iliac tortuosity can generally be addressed with stiff wires and hydrophilic delivery sheaths. On occasion, excessive tortuosity of the external iliac may require more proximal common iliac access. Aortography is performed through the marker catheter in a left anterior oblique projection (30 to 60 degree). The preoperative CT imaging should define the optimal angle. For visualization of the distal landing zone, especially near the celiac axis, a lateral projection is ideal. The angiogram locates branch vessels and can confirm the estimated length of endograft. Prophylactic placement of a guide wire or catheter in the celiac axis or SMA can be useful. In the event that imprecise deployment results in encroachment on the celiac axis or SMA, the wire provides ready access to the vessel for possible stent placement. Similarly, the left SCA can be accessed via the left brachial artery and provide access should restoration of flow be required. Once the landing zones are determined, the endograft is introduced under fluoroscopic guidance. The device is advanced past the target region and drawn back to eliminate any stored energy. Application of steady antegrade pressure on the wire keeps it positioned against the outer aortic curvature for accurate device deployment.

Acute angles in the descending thoracic aorta may render device tracking difficult. Various strategies, such as buddy wires, long sheaths, and distal graft deployment first, may be used to negotiate these areas. If these techniques fail, a body floss brachiofemoral wire may improve device tracking and delivery. When more than one device is needed, the smaller device should be deployed first. If both devices are the same diameter, strategies to create a longer overlap zone (7.5 to 10 cm) should be planned.

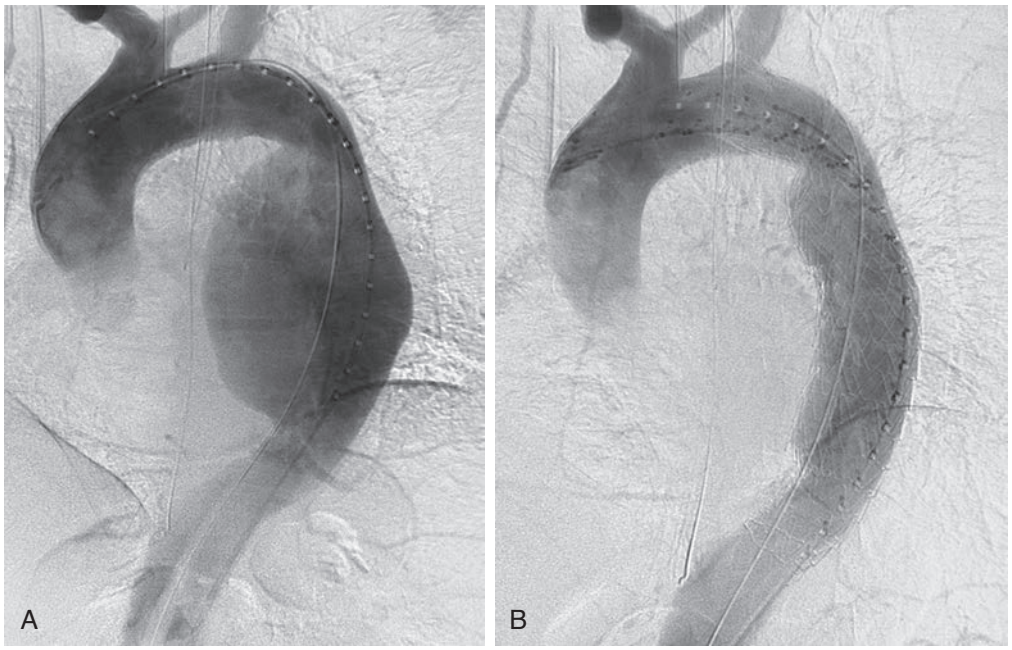

Figure 78.11 **(A)** Intraoperative angiogram showing a large fusiform descending thoracic arotic aneurysm. **(B)** Two TAG stent grafts are deployed to exclude the aneurysm.

When more than two devices are required, ideally the proximal and distal landing zones should be treated and the third (largest) device bridges the gap between the first two components. For large proximal aortic aneurysms, deploying the distal endograft first may be preferable because it stabilizes the proximal endograft which improves deployment accuracy. All techniques benefit from temporary reduction of mean arterial pressure, which decreases the windsock effect that may result in distal endograft migration. Infrequently, adenosine-induced cardiac asystole or rapid cardiac pacing may be necessary. Completion angiography confirms accurate stent graft placement, as well as the absence of endoleaks (Fig. 78.11). Types I and III endoleaks should be addressed by additional balloon inflation or insertion of extension pieces. Care should be exercised during sheath removal because iatrogenic iliac artery injuries are often recognized at this stage. Iliofemoral angiography after the sheath has been pulled into the distal external iliac artery aids in evaluating vessel integrity. Maintaining wire access is of paramount importance; balloon control and endovascular repair with covered stents can be lifesaving.[53]

Postoperative Management

If a spinal drain is present, CSF pressures should be maintained at ≤10 cm H_2O. If the patient is awake and neurologically intact, the drain can be clamped and removed the following day. Maintaining a modestly elevated mean arterial pressure (≥80 mm Hg) is an important adjunct; acceptance of an even higher pressure limit should be used if a neurologic deficit is detected. After TEVAR, neurologic assessments should occur at 1-hour intervals for the first 6 hours and thereafter every 2 hours. If a neurologic change occurs, patients are transferred to the intensive care unit and mean arterial pressure pharmacologically increased to greater than 100 mm Hg and a spinal drain inserted. If neurologic symptoms resolve, pharmacologic support to maintain a mean arterial pressure greater than 80 to 100 mm Hg is continued at the physician's discretion. If no improvement is seen within 4 to 6 hours, magnetic resonance imaging is performed to evaluate for spinal cord infarction.

Follow-Up

Recommended follow-up at 1 month and 1 year includes a CT scan of the chest with and without contrast enhancement, preferably with delayed imaging to detect subtle endoleaks. Thereafter annual CT scans are recommended for life. MRA can be used with most grafts, and the frequency of surveillance imaging is undergoing critical appraisal to reduce radiation exposure, cost, and patient inconvenience.

Results

The feasibility of TEVAR for descending thoracic aortic pathology is firmly established; however, indications for intervention are poorly defined due to a paucity of data. Despite a large body of literature published in the past 10 years, randomized trials have not adequately compared TEVAR with open surgery. The availability of long-term results is mostly limited to industry sponsored studies, and what exists fails to reflect device evolution and maturation of general learning curves. Most single-center and registry reports include a combination of anatomic locations, diverse pathology, and various stent-graft types along with varying degrees of urgency, all of which makes comparison of results difficult. These concerns were recognized by the SVS, which published reporting standards for TEVAR in 2010, and an updated set of guidelines reflective of current TEVAR practice

TABLE 78.2 US Food and Drug Administration Pivotal Trial Results

	# Enrolled	Spinal Cord Ischemia	30-Day Mortality	1-Year Endoleak Rate	Technical Success	Freedom From Aneurysm-Related Mortality
Gore TAG	140	2.8%	2.1%	3.9%	98%	97% at 3 years
Cook TX2 Starz Trial	160	5.6%	1.9%	3.9%	98.8%	94.1% at 5 years
Medtronic Talent Valor Trial	195	8.7%	2.1%	12.2%	99.5%	96.9% at 1 year

is in preparation. In addition to the SVS guidelines, there exists an expert consensus document published and supported by the Society of Thoracic Surgery. This publication describes criteria for intervention and defines optimal therapy based on data collected from earlier generation endografts. Similar shortcomings are common in the open surgical literature on the topic and prevent accurate comparisons of mortality and morbidity between the two modalities. This is exaggerated by the typically low-risk patients in surgical series; most patients undergoing TEVAR are usually in a higher risk category.

Technical Results

Three pivotal trials (Table 78.2) of the approved endografts (Gore, Medtronic, and Cook) have provided the best insight on TEVAR safety and efficacy primarily due to rigid follow-up of a uniform, well-defined population of good-risk surgical candidates undergoing elective operation. However, definitions, procedures, and inclusion criteria were not uniform among the studies, thus limiting direct study comparisons. In general, technical success is defined as delivery of the device to the intended location with satisfactory exclusion of the aneurysm and no type I or II endoleaks, and clinical success is defined as the outcomes of aneurysm-related deaths, rupture, endoleaks, and re-intervention. The demographics and early results are remarkably similar in all three trials. Male gender predominated, accounting for greater than 60% of patients. The average age at intervention was 71 years and average aneurysm diameter greater than 6 cm in all but one trial. With minor differences, demographic parameters, as well as risk factors, were in general well matched and successful TEVAR completion rates were expectedly high (≥98%). All technical failures were access related despite a high incidence of conduit use (9.4% to 21%), averaging nearly one in seven patients. Most of the conduits were to the common iliac artery and a few to the aorta. The number of devices implanted depended on the length of the **pathology**, the length of the available devices, and the tapering requirements of each device. Even with long nontapered devices, 56% of patients required more than one component. Although the VALOR trial did not report this statistic, the shortest aneurysm treated was 8 cm, and because of the minimum landing zones of 4 cm and the longest device length available, essentially all cases required more than one piece (average 2.7 per case). Extending into zone 2 for obtaining a proximal seal was not uncommon; it was performed in up to 20% of cases, and the VALOR trial reported deployment into zones 1 or 2 in 33% of cases.

Perioperative Outcomes

The early experience with first- and second-generation endograft devices in higher-risk individuals was associated with a high early mortality rate (9% to 12%) but did document TEVAR feasibility.[54,55] Recent trials report a 30-day mortality of 1% to 2%, which is significantly less than the 7% mortality of open surgical repair. Two TEVAR studies (Gore CTAG and Cook Zenith Alpha) using next-generation endografts confirmed these results with low 30-day mortality rates (0% to 1.5%) in a combined cohort of 176 patients.[56,57] Operative mortality, which includes all in-hospital deaths beyond 30 days, impacted the open surgical group far more than TEVAR (2% vs. 12% TAG study, 1.9% vs. 5.7% STARZ trial, and 2.1% vs. 7.9% VALOR trial).[20,58-60] Summarizing and applying statistical analysis to the data, it can be stated that TEVAR compares favorably with open repair with respect to operative mortality. In conglomerate, the three comparative clinical trials included 495 patients treated by TEVAR for anatomically suitable DTAA and 353 patients managed by open surgery; notably, these procedures mostly were performed in academic medical centers of excellence. Operative mortality for TEVAR was 2% compared with 8.5% for open repair ($P < .001$). However, with more liberal application of this technology, the European registry reported higher elective 30-day mortality (5.3%), but this included arch aneurysms. In a meta-analysis of 17 studies, Walsh et al.[61] found a significant reduction in mortality and major neurologic complication rates with TEVAR. Similar findings were consistent in a meta-analysis of 42 nonrandomized studies published in 2010 by Cheng et al. However, beyond 1-year the existing evidence suggests clinical equipoise when comparing TEVAR with open surgical repair.[62]

Late Results

Although many reports provide early and midterm results, the only long-term (5-year) data available originate from the Zenith TX2, Gore TAG, and Medtronic Valiant Studies.[11,54,55,63-71] One-year outcomes did reinforce the advantage of TEVAR in aneurysm-related survival, which averaged 95% across the trials, significantly better than the 89% for the combined open surgical repair. All three trials reported late TEVAR benefits continued for at least 5 years, noting that the early difference reflected the perioperative period with few if any late aneurysm-related mortalities in either group.[11,58,69-71] However, all-cause late survival showed minimal differences between open and endovascular modalities beyond 1 year, which not surprisingly mirrored the

findings of randomized **EVAR** trials.[11,63,67] At 5 years, overall survival rates in the Gore TEVAR and open groups (68% and 67%), and in the Cook TEVAR study (62.9% and 62.8%), indicated similar late effectiveness and sustained protection from aneurysm-related mortality for both procedures.[11] However, late outcomes are not as encouraging in high-risk populations. For example, in a series from Stanford (103 patients, 60 of whom were deemed inoperable) 5-year survival was only 31% compared with 78% for those who were open surgical candidates. This brings to question the appropriateness of any treatment in asymptomatic high-risk patients.[54]

Complications

Complications of TEVAR, like those of all endovascular procedures, can be divided into a general category common to all operative interventions and a procedure-specific category. General complications are not well detailed, and the FDA trials focused on combined trial-specific safety endpoints, which made individual complication rates difficult to determine. At any rate the incidence of major or serious adverse events strongly favors TEVAR over open repair in the three regulatory trials that compared similar metrics. As expected in a population with advanced age and atherosclerotic disease, cardiopulmonary complications dominated the early morbidity, although frequency and severity were less than open repair.[58,68] For example, the STARZ trial reported a cardiovascular complication rate of 15.6% (TEVAR) and 44.3% (open repair) with an identical incidence of pulmonary complications (15.6% vs. 44.3%).[58] The incidence of major or serious adverse events and other secondary measures, such as blood loss and hospital stay, were strongly in favor of TEVAR.

Vascular Complications

Vascular complications due to large sheaths in atherosclerotic arteries were relatively high in the early TAG trial (14%). They were reduced significantly (6%) in the follow-up confirmatory trial of the modified TAG device, which reflects a collective learning experience for TEVAR.[20] The spreading awareness of vascular access issues resulted in a reduction of vascular complications (5% to 7%) in recent reports.[20,59,72] The high incidence in the STARZ trial was not an indication of a higher complication rate because it was a difference in the definition of vascular events, which was more inclusive than other studies. Serious iliac artery injuries, a subset of vascular complications ranging from a tear to complete avulsion during sheath withdrawal (Fig. 78.12), are less common nowadays but remain potentially life-threatening. The prophylactic use of iliac conduits and endoconduits should be encouraged to avoid these injuries. The Cook Zenith Alpha endograft has addressed the universal need for a lower-profile TEVAR device. One-year data published by Illig et al. included 110 patients with technical success achieved in 98%, and no iliac conduits were used. However, severe iliac occlusive disease prevented two patients from receiving the endograft; these findings suggest that, despite a presumed expanded applicability of lower-profile devices, proper patient selection remains of utmost importance.

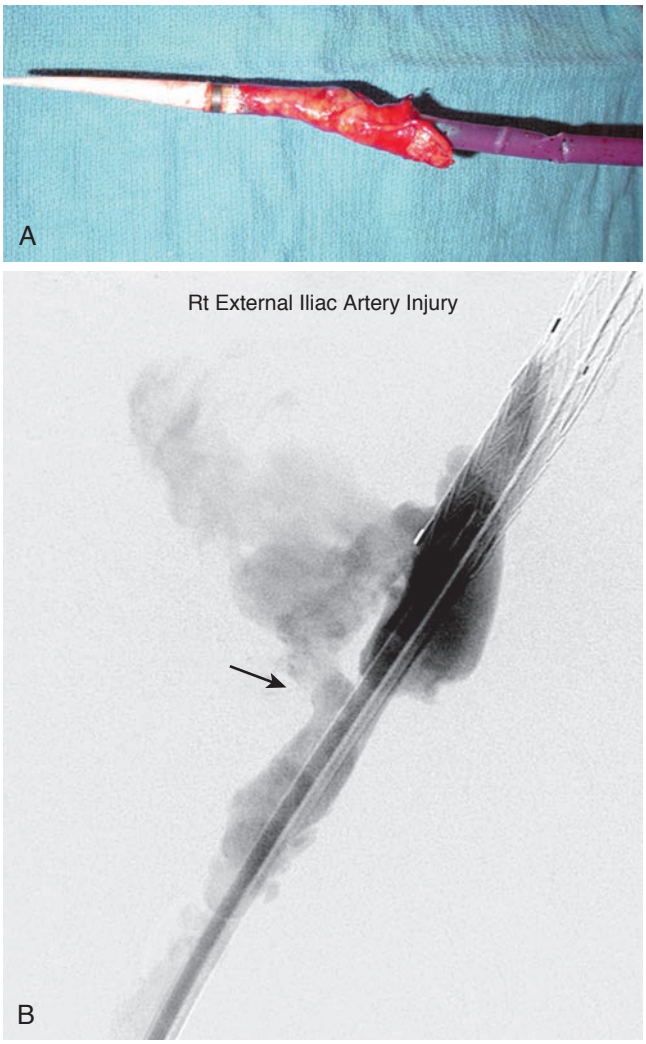

Figure 78.12 **(A)** Torn segment of an external iliac artery on the delivery system. **(B)** Angiography illustrating the injury *(arrow)*. The stent-graft in the iliac artery is from previously performed endovascular abdominal aortic aneurysm repair.

Neurologic Complications

Neurologic complications can be devastating after DTAA repair. Although stroke receives less attention than spinal cord ischemia, it is not uncommon and occurs at similar rates during open and endovascular repair (3% to 7%).[20,34,35,58,59] Deployment of the endograft proximal to the left CCA shows a strong association with perioperative stroke, probably secondary to manipulation of the arch with catheters, wires, balloons, and stent-grafts.[14,20,27] In the TAG study, stroke occurred in 14% of patients during zone 2 deployments versus 1% when TEVAR was placed distal to the left SCA.[73] Only the Zenith TX2 study reported dissonant results, with all four strokes occurring in patients that had a TEVAR placed distal to the left SCA.[58] This finding is difficult to explain but may relate to deployment of the TX2 device, which often started more proximal to eliminate tension and was adjusted to its final position. The importance of technique; limit aortic manipulations, meticulous cleansing of guide wires and catheters, and limited use of molding balloons cannot be

overemphasized enough to minimize the stroke risk. Independent predictors of stroke in the EUROSTAR registry included female sex and prolonged procedure time (>160 minutes).[35]

The TAG study showed a marked reduction in paraplegia and paraparesis in comparison with open repair (3% vs. 14%). The advantage of spinal cord protection with TEVAR was evident in all three FDA trials compared with open controls (6.2% vs. 13%; $P < .007$). The high incidence of spinal cord ischemia in the control group has been criticized by aortic centers of excellence, which report lower paraplegia rates (2.5% to 3%) associated with open DTAA repair.[74,75] The difference may represent the retrospective analysis of these reports, exclusion of high-risk patients with anastomoses in the distal arch requiring hypothermic arrest, variable use of neuroprotective adjuncts, and most notably lack of reporting of paraparesis as part of these series. Stone et al.[76] reported a spinal cord ischemia rate of 8.6% in a recent open repair cohort when paraparesis was included. If only devastating permanent paraplegia is considered, TEVAR (1.6% vs. 5.1%; $P < .0037$) is still favored. The reduced incidence of spinal cord ischemia with TEVAR may be related to avoidance of aortic clamping and reduced hemodynamic disturbances at the spinal cord level because of lack of blood loss from intercostal back bleeding.[77,78]

Several factors have been linked to spinal cord ischemia after TEVAR: concomitant or previous infrarenal aortic repair,* extensive thoracic aortic coverage,† renal insufficiency,[35,84] intraoperative hypotension (systolic blood pressure <80 mmHg),[80,51] and coverage of the hypogastric artery and left SCA.[34,35,78,86] Some of these risk factors are beyond the clinician's control, but many (coverage of the left SCA and hypogastric artery) can often be avoided by modifying the operative plan. The EUROSTAR data showed that left SCA coverage without revascularization was independently associated with spinal cord ischemia.[35] Recent reports suggest that left SCA revascularization should be performed more frequently than was previously recognized for either left upper extremity ischemia[39] or spinal cord protection.[34,35] Lumbar and pelvic collaterals account for 25% of spinal cord perfusion,[87] and thus compromised hypogastric flow contributes to spinal cord ischemia.[67] For that reason, preservation of the internal iliac and staged repair of synchronous aneurysms to allow time for collateral maturation are advocated.[51,81] In addition to preservation of left SCA and pelvic collateral flow, a strategy should be implemented to prevent SCI. Acher et al. used an aggressive intraoperative and postoperative neuroprotective intervention to reduce SCI associated with TEVAR.[88] Strategies to increase cord perfusion and reduce metabolism and oxygen demand were combined on 155 patients. The protocol included patient management by cardiac anesthesiologists, intraoperative hypothermia (34° C), intraoperative naloxone, mannitol and steroids, avoidance of arterial vasodilators, goal-directed blood pressure therapy (MAP 90 to 100 mm Hg), maintaining hemoglobin ≥10 g/dL and spinal drain. The mean thoracic aortic coverage was 25 cm, 81.1% had greater than 12 cm of coverage, and 49% had complete coverage from the left SCA to the celiac artery. In hospital mortality (1.9%), stroke (1.3%), and SCI (0.65%) rates were acceptable. Thus, based on the published data, intraoperative protective measures rather than rescue measures are strongly recommended.

Endoleaks

Early endoleak rates at 30-day follow-up were inexplicably high in the VALOR trial (26%) but far lower in the TAG trial (3.6%), STARZ study (4.8%), and EUROSTAR registry. This appears to be a definition issue because all endoleaks observed at any time before 30 days were included in the VALOR report, whereas only endoleaks at the 30-day follow-up were included in the other studies. At 1 year, endoleaks were present in 4% of patients (TAG and TX2) and 12.2% (Talent). In long-term follow-up of the TAG study, between 4% and 8% of patients had endoleaks at each time interval out to 5 years.[11,58,59] Long-term STARZ follow-up revealed a low annual endoleak rate (2% to 7%), which decreased in years 3 through 5. The endoleak incidence was consistently higher in the VALOR study (12% to 17%), and similar to the TX2 study the majority of endoleaks were defined as type II.[69-71] The incidence of endoleaks has decreased with device improvement.[9] The distribution of endoleak type was variable; the TAG study reported more type I and III endoleaks, whereas the other studies found a larger number of type II endoleaks. This again is likely a reporting issue because the TAG study relied on investigator reports, whereas the other trials used a core lab. Endoleaks were in general less common than in comparable EVAR series, with more type I and III endoleaks and fewer type II which accounted for most but not all re-interventions.[89,90]

Sac Enlargement

Aneurysm sac shrinkage is a surrogate marker for successful repair of all aneurysms, including DTAA (Fig. 78.13). Sac enlargement rates greater than 5 mm are encountered frequently with TEVAR and have been reported in 7% to 14% of patients at 1 year. The TAG pivotal trial reported late results in a longitudinal cohort: 5-year sac enlargement was 20%, and shrinkage was observed in 50%.[11] These rates may or may not apply to other grafts because the ePTFE material in the TAG study graft was somewhat porous, with a sac behavior resembling that of the original Gore Excluder.[91] Through 5-year follow-up, 84.6% of Talent patients had sac shrinkage or no change. Similar to Talent, the aneurysm sac decreased in size or remained the same in greater than 90% of Cook TX2 cases through 5 years. The TAG endograft was modified to a less porous ePTFE material and has shown a lower incidence (14%) of sac enlargement at 3 years.

Migration, Device Integrity, and Rupture

Late endograft migration has been reported in 0% to 30% of patients, can occur at either end, and was more frequently seen with early generation devices.[83,81,92,93] The current devices clearly possess lower migration rates (0.7% to 3.9%). At 5 years, the TAG trial showed no late migrations (>10 mm) by investigator reporting.[11] Illustrating the variability in data sources, a core

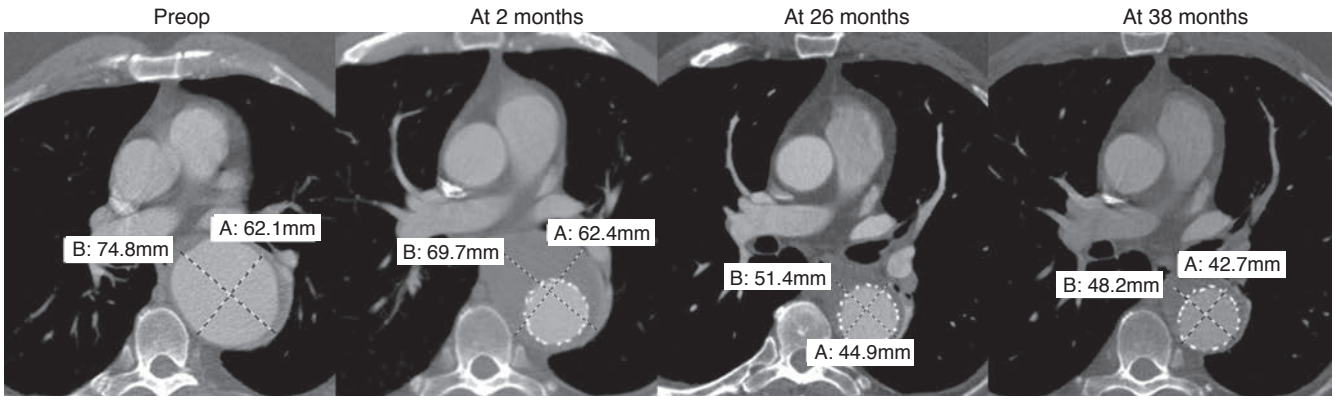

Figure 78.13 Serial follow-up computed tomography scans after thoracic endovascular aortic repair showing progressive sac shrinkage over a time course of 38 months.

laboratory evaluation of a limited number of patients from the same study reported 97% freedom from migration at 12 months, 87% at 24 months, and 83% at 3 years.[94] None of the migrations were clinically significant except for one associated with an arch aneurysm. Migration (>10 mm) was noted on both ends of the devices in the TX2 trial which reported 12 migrations (2 cranial, 9 caudal, 1 cranial and caudal) through 5 years. Retrospective analysis revealed that inadequate aortic neck anatomy was at fault.[69] Site-reported stent-graft migration was infrequently seen with the Talent device at 5 years (1% to 1.8%). None were associated with endoleaks, sac expansion, or required intervention.[70] A very low incidence of device migration was found in the RELAY registry, which had one migration at 24 months.[95]

Re-Interventions

Re-interventions are defined as procedures performed as a consequence of the initial endograft procedure. Early re-interventions were reported in 2.1% (pivotal TAG cohort) during the first year but in 10.7% in the Talent study. Most re-interventions for endoleaks used an endovascular approach. Interesting, STARZ-TX2 re-intervention rates through 1 year were similar between the two groups (4.4% TEVAR vs. 5.7% open surgery). Contrasting to this, long-term TAG study data showed TEVAR re-intervention rates were slightly higher (3.6% vs. 2.1%). Two TAG patients underwent surgical conversion, one for aorto-esophageal fistula and the second for device migration. Both interventions occurred during the first year of follow-up. Three patients had five additional endovascular interventions for endoleaks. Secondary procedures of any kind during the 5-year follow-up were reported in 15% of TAG patients and 32% of open repair. Although most TAG re-interventions were endoleak related, those following open aortic repair were wound complications, tracheostomy, and gastrointestinal tract–related problems. This high rate of secondary re-intervention performed in the open surgical group is contrary to conventional wisdom.[11,76] No TEVAR conversions occurred in the STARZ study, four open conversions were required in VALOR, and only two in RESTORE; indications for open conversion were similar to the Gore study.[95,69,70]

HYBRID ENDOVASCULAR REPAIR FOR THORACOABDOMINAL ANEURYSMS

For patients with inadequate landing zones above the visceral vessels or with extension of aneurysmal disease into the visceral aortic segment, TEVAR can still be performed. This is accomplished by relocating the visceral aortic branches with a bypass procedure originating from distal inflow sites (common iliac arteries or the infrarenal aorta). Exclusion of the TAAA with TEVAR or EVAR devices then follows. This hybrid endovascular technique has the theoretical advantage of replacing a thoracoabdominal exposure for a midline celiotomy, avoiding division of the diaphragm and aortic clamping, along with reducing visceral ischemia time. Intuitively, complication rates are presumed to be lower than those of open thoracoabdominal repair on the basis of the decreased physiologic stress of operating in one visceral cavity rather than in two.

Experience and long-term results are limited with this procedure, and indications and contraindications are poorly defined. The hybrid approach is considered for patients with TAAA who meet standard criteria for repair, but whose limited physiologic reserve prohibit an open repair, and complex anatomy precludes standard TEVAR. Hybrid repair of TAAA remains an extensive operation with high potential for postoperative complications. The most appropriate indication is a patient with significant pulmonary compromise but adequate cardiac and renal function. Indeed, advanced chronic obstructive pulmonary disease (COPD) commonly presents a management dilemma because of the threat of major pulmonary morbidity with open surgery, yet the presence of such COPD is a well-established risk factor for TAAA expansion and rupture (see Chapter 76).[96] Some surgeons find it preferable in all patients because it provides a better safety profile for extensive TAAA.[97] Poor cardiac function, end-stage renal disease requiring hemodialysis, lack of healthy distal aorta or iliac artery, and insufficient landing zones are relative contraindications. Limited data suggest there is little benefit in patients with type IV TAAA, unless associated with a visceral patch aneurysm or severe COPD.

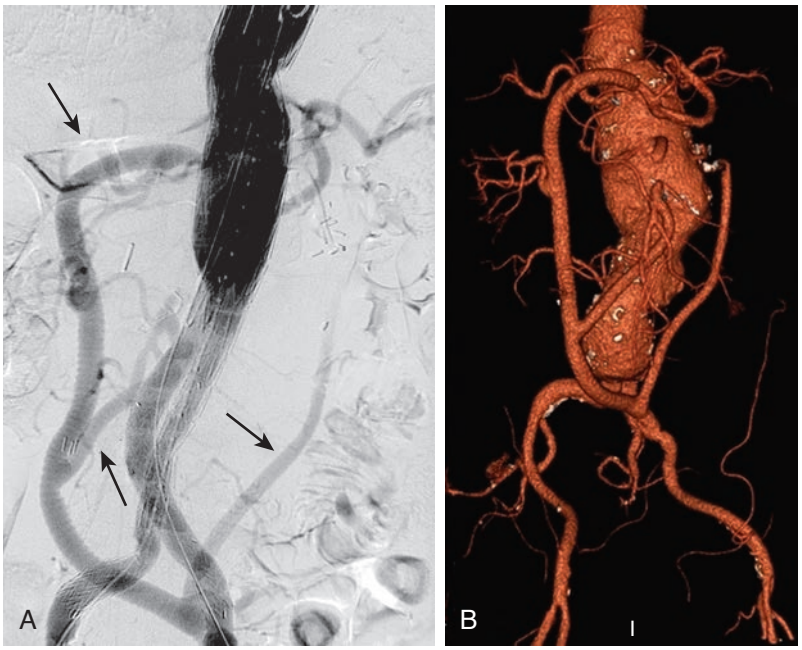

Figure 78.14 **(A)** A thoracic endograft is deployed into a bifurcated abdominal endograft. Retrograde bypass grafts originating from the distal common iliac artery to the celiac axis *(top arrow)*, the right renal artery *(bottom left arrow)*, and the left renal artery *(bottom right arrow)* are illustrated. **(B)** Three-dimensional reconstruction of a postoperative computed tomography scan.

The presence of landing zones and other anatomic requirements remain similar to those for TEVAR. As previously mentioned, a suitable inflow source for the bypass and adequate target vessels are necessary. Multiple renal arteries, severe occlusive disease of the aortoiliac segments, and severe calcification and/or tortuosity make this approach challenging. Access for endograft delivery can be facilitated by direct access through the iliac or aorta if part of the same procedure. In circumstances in which the surgeon chooses a staged procedure, a conduit can be tunneled to the femoral region and temporarily buried; it can be retrieved and used to introduce the endograft.

Additional planning for a hybrid procedure centers around the arteries to bypass and choice of inflow, which is based on patient anatomy and extent of the aneurysm. Previous infrarenal aortic repair or type IV TAAA repair presents a technical benefit in that the existing graft provides not only a secure landing zone but also a safe clamp and anastomotic site for inflow. If the aneurysmal disease extends to the distal aorta and no landing zone exists, a distal iliac is chosen for the inflow source and a standard EVAR device used (Fig. 78.14). If anatomy allows, an isolated infrarenal AAA repair with either a tube or bifurcated surgical graft may be performed first, from which retrograde bypasses to the visceral and renal arteries are constructed, followed by TEVAR. When inflow is derived from an iliac artery, the contralateral femoral artery is preferred for device access to avoid compromising blood flow through the bypasses. Alternatively, a side limb may be sewn onto the bypass graft itself and used as a conduit.

Standard inframesocolic aortic exposure provides adequate access and visualization of the visceral vessel origins. The iliac arteries are exposed if they are intended to be the inflow source. A variety of reconstruction configurations may be used; standard bifurcated Dacron grafts are frequently used with 6- or 7-mm limbs sewn to the recipient vessels. The hepatic bypass is usually routed retrogastric and anastomosed end to side to the common hepatic artery. To avoid kinking, the lengths of all grafts are predetermined under arterial pressure and visceral grafts routed in a "lazy C" fashion. The proximal end of the recipient vessels should be ligated to prevent type II endoleaks and the grafts are covered with an omental flap to minimize the risk of graft-enteric erosion. After revascularization of the visceral and renal arteries, endovascular exclusion of the TAAA is carried out.

The literature is limited, mostly because of small numbers, patient selection criteria, different levels of acuity, and various lengths of coverage. Reported technical success, defined as aneurysm exclusion without type I or III endoleak, ranges from 77% to 100%. Black reported a series of 29 patients with Crawford type I, II, and III aortic aneurysms, and mortality rates improved from 31% to 13%, there were no documented cases of spinal cord ischemia, and branch vessel patency was 98% at 8 months.[98] In another series, procedural time ranged from 239 to 368 minutes, and blood loss averaged 2 L.[99] Mean hospital length of stay was 26 to 27 days in the two largest series, with a median 9 day intensive care unit length of stay.[97,100] In a study that used a staged approach, the mean length of stay after TEVAR was 12 days.[93] However, it is important to recognize that mean organ ischemic time was considerably less (15 to 20 minutes) compared with open TAAA repair.[97,100] Data on intermediate-term outcomes suggest acceptable results. Chiesa et al.[99] reported no aneurysm-related or procedure-related complications with a median follow-up of 15 months. Zhou et al.[101] noted no late aneurysm-related mortality, whereas Resch et al.[102] reported two late aneurysm-related deaths in 13 patients. Two systematic literature reviews have been published. Moulakakis et al.[103] reviewed 19 publications that included 507 patients. A single-stage procedure was used in 55% of patients, and the 30-day mortality was 13%. Graft patency was 96% at 35 months; however, follow-up included only 22% of the total group. Irreversible spinal cord ischemia occurred in 4.5% of patients. Bakoyiannis et al.[104] reviewed 108 patients from 15

reports between 1999 and 2008. The technical success rate was 92%, and 30-day mortality 10%. Spinal cord ischemia occurred in 3% of patients, and 97% of branch grafts were patent at 10 months. The North American Complex Abdominal Aortic Debranching registry included 208 patients from 14 academic centers in North America. The 30-day mortality rate was 14% for all patients, 16% for TAAAs, and 9% for pararenal aneurysms. Mortality was directly associated with severity of comorbidities as determined by SVS clinical scores. Independent predictors of mortality were three-vessel revascularization, coronary artery disease, congestive heart failure, high SVS score, and chronic kidney disease. The mean length of stay was 21 days, and patient survival at 1 year was 77%.[105] Despite a perceived theoretical advantage, hybrid visceral debranching is associated with relatively high morbidity and mortality rates. The incidence of complications ranges widely from 19% to 59%.[100,106] Graft thrombosis is not uncommon (11% and 6.4%) and may result in end-organ ischemia.[100,106]

INVESTIGATIONAL DEVICES FOR THORACOABDOMINAL AORTIC ANEURYSMS

As endovascular technology continues to advance, a wide range of patients with thoracic and thoracoabdominal aortic pathology will benefit from device modifications that accommodate landing zones in the arch or perivisceral aorta while maintaining branch vessel perfusion. Building on basic platforms of TEVAR and EVAR, devices have been created to treat more extensive aortic pathology involving the branch vessels. Endovascular therapy of TAAA is rapidly evolving, and current midterm data strongly support its application. Specifics about each device and the complex techniques for device implantation are beyond the scope of this chapter (see Chapter 79). However, it is important to recognize the advancements and future benefits of these investigational devices. In 2001, Chuter et al. successfully implanted the first branched aortic endograft for treatment of a TAAAs (Fig. 78.15).[107] Fourteen years later, numerous reports have shown a high technical success (95% to 96%) combined with low 30-day mortality (7.8%).[108,109] Cook Medical was the first to develop a thoracic branch endograft and currently has two device options: off-the-shelf t-Branch device with four downward facing external cuffs and a custom-made device (CMD). Both devices have been implanted with very favorable results. These devices are available only in the United States under physician-sponsored IDE studies. Three other device manufacturers are in the process of developing commercially available off-the-shelf or custom-made multibranch endografts at the time of this writing. The Gore Excluder thoracoabdominal branch device is an off-the-shelf four-vessel branch device. Two design options are available: one has four downward facing cuffs and the other possesses two upward renal cuffs and two downward mesenteric branches. A US feasibility study was recently completed, and preliminary data are favorable. Medtronic is developing a modular branched endograft based on the Valiant and Endurant platforms for treatment of TAAA. Currently, this device is being investigated in a physician-sponsored IDE.

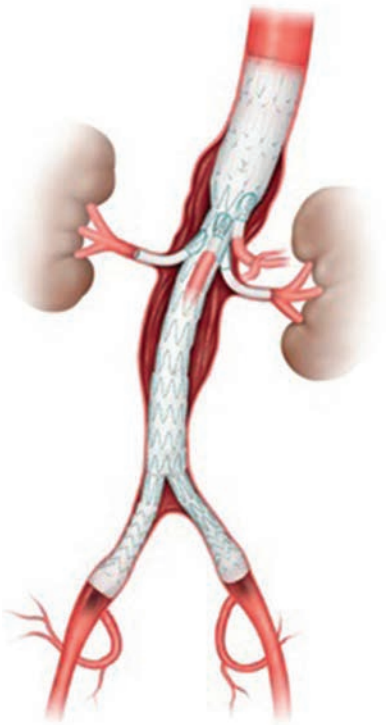

Figure 78.15 Cook Medical t-Branch device

Ferrer et al. investigated outcomes of TAAA patients treated with endovascular repair or open surgical repair from 2007 to 2014.[110] In this prospective database, 341 patients were compared using a propensity score matching. It was determined that patients undergoing endovascular repair had an early benefit in regard to the composite end point of mortality and paraplegia. However, no significant differences were found in spinal cord ischemia or renal insufficiency rates at 30 days and in survival. Midterm outcomes comparing Cook custom branch stent-graft (CSG) and standard off-the-shelf branch stent-graft (SSG) were reported by Fernandez. Fifty-five patients underwent repair using SSG and 83 with CSG. All stent grafts were deployed as intended, no open conversions were needed, and no differences were noted at all primary end points. However, it was recognized that use of SSGs for TAAA and pararenal AAA resulted in shorter wait times for surgery. Both devices were shown to be safe, effective, and durable. Additional supporting data from the Cleveland Clinic have shown that treatment of type II and III TAAA with fenestrated or branched endografts is a promising treatment option. Data from 354 patients from 2004 to 2013 were collected from a physician-sponsored investigational device exemption trial. A 96% technical success rate of 1305 fenestrations and branches were reported, type I or II endoleaks were rare (2.8%), permanent spinal cord ischemia occurred in 4%, and 7.6% of branches required re-intervention. At 36 months, secondary branch patency was 96% and freedom from aneurysm-related mortality was 91%. It was concluded that technical success and branch vessel patency are very good but re-interventions are not unexpected.

INVESTIGATIONAL DEVICES FOR AORTIC ARCH

Endovascular branched stent graft repair of aortic arch pathology is an alternative to complex debranching and/or open surgical repair. The development of conformable and adaptable arch devices specifically designed for deployment in zones 0, 1, and 2 are currently under investigation. Five endograft devices are being investigated: Medtronic Valiant Mona LSA, Gore TAG thoracic branch endoprosthesis, Cook Medical Zenith arch branched device, Endospan Nexus aortic arch system, and the Bolton Medical Ascending Thoracic device. Each of these devices eliminates the need for open surgical revascularization while extending the proximal landing zone. Similarities between the devices include the use of a through and through wire, precannulated side branches to facilitate device alignment and flexible bridging stents. The Cook Zenith is an off-the-shelf device with two branches and seals in the ascending aorta. Early data (38 patients) show an acceptable technical success of 84.2%. A follow-up study (27 patients) had improved technical success (100%), no 30-day deaths, and 11.1% stroke rate.[111,112] The Gore TAG branch endoprosthesis was created to land in zones 0 to 2 and is intended to eliminate the need for LSA debranching (Fig. 78.16). A preliminary feasibility (22 patients) study was published in 2016. Primary end points were met, including successful device delivery and patency of the side branches in 100%; there were no strokes or deaths at 30 days.[113] Results of the Valiant Mona LSA early feasibility study were just as favorable: technical success in nine patients was 100%, no endoleaks required secondary interventions, four minor nondisabling strokes occurred, and all branches remained patent.[114]
