EPIDEMIOLOGY OF PERIPHERAL ARTERIAL DISEASE

Incidence and Prevalence

Peripheral arterial disease (PAD) is defined as chronic, atherosclerotic occlusive disease of the lower extremities. It has become a major global health problem, largely secondary to aging of the world's population, combined with the growing prevalence of risk factors such as diabetes, smoking, hypertension, and dyslipidemia. The increasing burden of PAD has resulted in mortality, morbidity, and escalating public health costs associated with care for the disease and its complications. Accurate information on PAD prevalence and incidence is limited because a large proportion of affected individuals have preclinical disease or atypical symptoms, and PAD screening (e.g., ankle-brachial index [ABI] testing) is not routinely used. As a result, epidemiologic data have been drawn from isolated community screening studies, data on symptomatic states such as intermittent claudication (IC), and by extrapolation from other measured diseases (e.g., diabetes) and events (amputation) with known relationship to underlying PAD.

Epidemiologic studies have estimated that more than 200 million individuals are currently affected by PAD worldwide.[1] This prevalence rate has increased by approximately 25% over the preceding decade. The growth of PAD is evident in both high-income countries (HICs) and low- and middle-income countries (LMICs), with LMICs and the Pacific Rim/Southeast Asia region specifically demonstrating higher rates of growth

Abstract

Peripheral arterial disease (PAD), defined as chronic occlusive disease of the lower extremities, is a major and growing health problem, estimated to affect more than 200 million individuals around the globe. Aging of the world's population, combined with diabetes, smoking, dyslipidemia, and hypertension are the critical risk factors and significant socio-economic disparities exist. Most individuals with PAD are asymptomatic, and the most common symptom is intermittent claudication (IC). A small minority (< 10%) develop chronic limb threatening ischemia (CLTI). Even in its asymptomatic stage PAD carries significant risk for reduced survival and major cardiovascular events, and is associated with progressive decline in function. Progression of disease from IC to CLTI may occur in up to 20% of patients, associated with similar risk factors but especially diabetes, smoking, and renal disease. Improved staging systems, such as the SVS Threatened Limb Classification System may allow for improved prognosis and evidence based treatment algorithms.

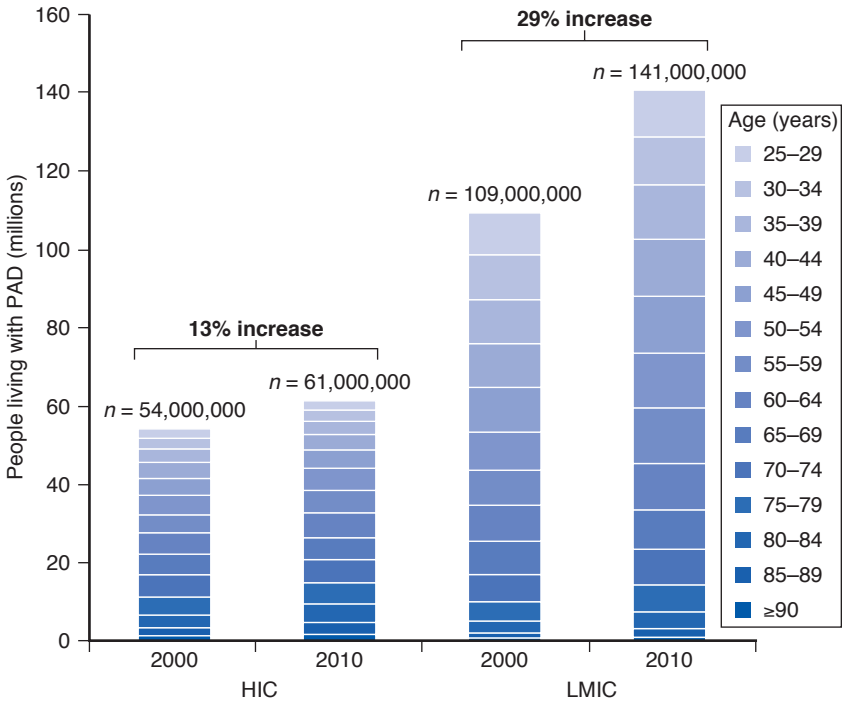

Figure 104.1 Estimated global prevalence of peripheral arterial disease *(PAD)* by age in high-income countries *(HICs)* and low- and middle-income countries *(LMICs)* in 2000 and 2010. (From Fowkes FG, Aboyans V, Fowkes FJ, et al. Peripheral artery disease: epidemiology and global perspectives. *Nat Rev Cardiol*. 2017;14(3):156–170.)

(Fig. 104.1). Sex- and age-related prevalence of PAD differs somewhat around the globe. In HIC, men and women appear approximately equally affected and the prevalence rises from less than 5% younger than age 50 to approximately 20% in individuals older than 80 years. In LMICs, age-specific rates appear higher in women compared with men. Many studies have demonstrated that women have lower ABI than do men, although the reasons for this observation are unclear and not readily explained by differences in established risk factors for atherosclerosis. Data on PAD are sparse from many areas of the world, and concerted public health efforts will be needed to develop more accurate models of incidence, prevalence, and outcomes. These efforts are justified by the economic impact of disability and health resource use that is engendered by PAD.

Data from the US population estimate that 8.5 million Americans are living with PAD.[2] There is a strong age-dependent increase in the United States, with a prevalence of greater than 20% in individuals older than 80 years (Fig. 104.2).[3] Nehler et al. estimated US incidence and prevalence of PAD over the years 2003 to 2008 using a broad capture of claims data from multiple insurers. including Medicare, Medical, and commercial plans.[4] They reported an annual incidence rate of 2.35% and an overall prevalence of 10.69% among the enrollees.

Estimates of the prevalence of IC and critical limb ischemia (CLI) are fraught with similar limitations and are likely to be systematically undervalued. Estimates of IC prevalence have been derived from community questionnaire studies and, for CLI, using administrative (billing) data on hospitalizations, procedures, and amputations. IC is estimated to affect up to 6% of individuals older than 65 years in Western countries.[5] It is recognized that many PAD patients describe atypical leg pain syndromes (non–calf pain or calf pain with nonclassic

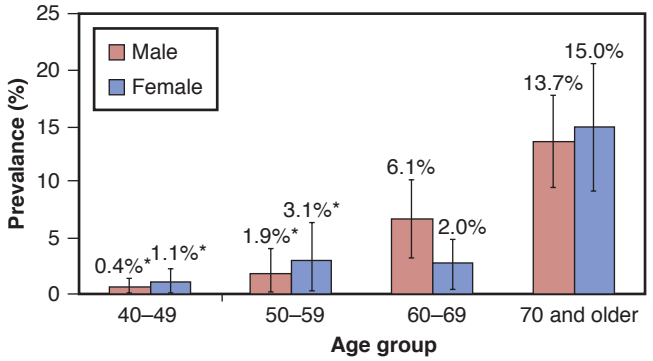

Figure 104.2 Estimated age-specific prevalence of PAD in the United States from the National Health and Nutrition Examination Survey 1999-2000. *Relative standard error > 30%. (From Selvin E, Erlinger TP. descriptors) that are not accurately captured. Estimates of CLI incidence and prevalence have ranged from 0.02% to 0.35% and 1.2% to 2.35% across studies of disparate adult populations.[4,6,7]

Risk Factors

PAD is a chronic manifestation of systemic atherosclerosis in the arteries of the lower extremities. As such, it shares many risk factors with other clinical atherosclerotic conditions such as coronary artery disease (CAD) and cerebrovascular disease (CVD). However, differences in the profile of PAD, CAD, and CVD patients have been characterized, and the strength of association of specific risk factors varies across the clinical syndromes, as well as across anatomic patterns (Fig. 104.3).

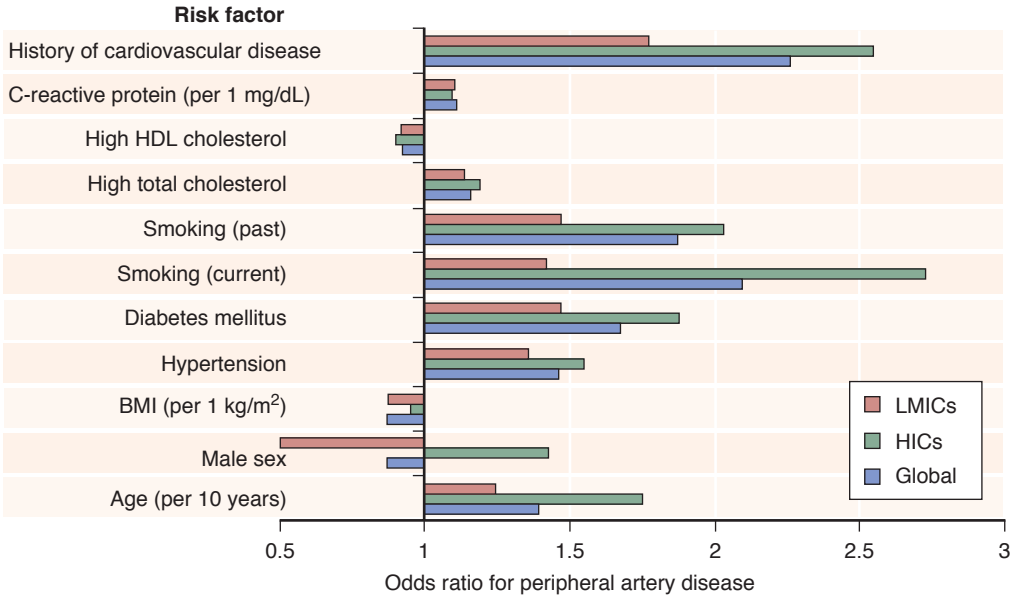

Figure 104.3 Risk factors for PAD across the globe, in both low- and middle-income and high-income countries (*LMICs* and *HICs*, respectively). *BMI,* Body mass index; *HDL,* high-density lipoprotein. (From Fowkes FG, Aboyans V, Fowkes FJ, McDermott MM, Sampson UK, Criqui MH. Peripheral artery disease: epidemiology and global perspectives. *Nat Rev Cardiol.* 2017;14(3):156-170.)

Demographics

Age is the strongest risk factor for PAD. The disease is rare in individuals younger than 40 years, rises in prevalence in the sixth to eighth decades, and may affect 25% or more of individuals 80 years and older.[3,8-11] As mentioned previously, sex-related differences in PAD appear to be different around the globe, although the prevalence of more advanced, symptomatic stages of disease is consistently higher in men.

Several studies have demonstrated higher rates of PAD and poorer outcomes for black populations in comparison with non-Hispanic or Hispanic white populations (Fig. 104.4).[2,3,12-15] Reasons remain unclear because this disparity is not accounted for based on an imbalance of traditional risk factors such as age, smoking, diabetes, or hyperlipidemia.

Smoking

Cigarette smoking is a strong and independent predictor of PAD across populations. Several studies have demonstrated odds ratios in the range of twofold to fourfold.[3,10,16] Secondhand smoke exposure appears to also carry increased risk for PAD, although data in this regard are limited.[17,18]

Diabetes

Diabetes has been strongly associated with PAD prevalence and severity. Odds ratios reported for diabetes are similar to those for smoking, in the range of twofold to fourfold.[3] This association is modified by age and the duration of diabetes, such that older individuals with more than a decade of diabetes are at highest risk. The combination of diabetes and smoking is most insidious, portending a high risk for PAD severity, amputation, and mortality. Multiple studies have demonstrated that long-term outcomes of PAD are adversely influenced by the presence of diabetes, including reduced survival and a fivefold increased rate of limb loss.[19]

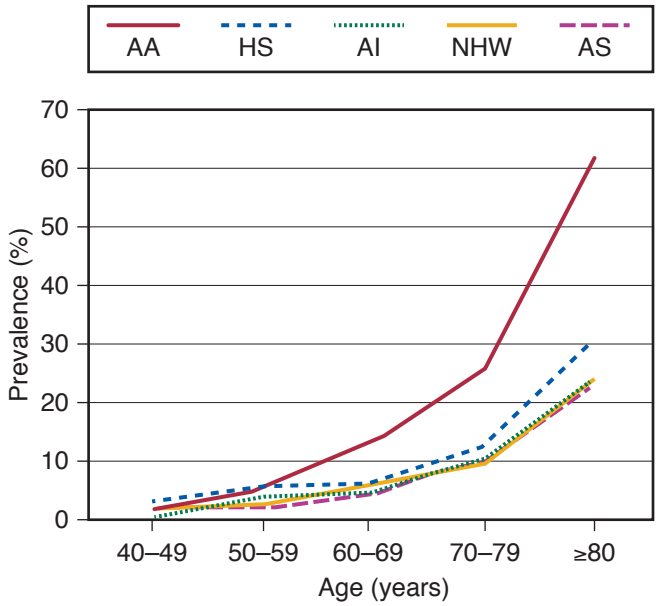

Figure 104.4 Estimated United States prevalence of PAD by age and ethnicity in (A) men and (B) women. *AI,* Aorto-iliac; (From Allison MA, Ho E, Denenberg JO, et al. Ethnic-specific prevalence of peripheral arterial disease in the United States. *Am J Prev Med.* 2007;32(4):328-333.)

Hypertension

Hypertension is common in the PAD population. The association is consistent across many epidemiologic studies, although less

strong than that seen with smoking and diabetes. Because age is a common risk factor for both, the independent association between hypertension and PAD appears weaker on multivariable analyses.

Dyslipidemia

Elevated total cholesterol (TC) and reduced high-density lipoprotein (HDL) levels have been associated with PAD in multiple studies. The ratio of TC/HDL was a strong predictor in both the San Diego population study[12] and the Physician's Health Study.[20] Some studies have demonstrated a link between elevated triglyceride levels and PAD.[21] The relationship between PAD and low-density lipoprotein (LDL) levels appears less consistent, and no target LDL values for therapy have been developed specific to PAD.

Obesity

Data specifically relating obesity to PAD are inconclusive. Some studies suggest a U-shaped relationship.[22,23] The distribution of body fat may be of greater relevance. Central obesity, more consistently linked to diabetes and to the "metabolic syndrome" (the cluster of central obesity, hypertension, elevated triglycerides, low HDL, elevated fasting blood glucose), appears of greater relevance to PAD than overall obesity.[24,25]

Inflammation

Elevated biomarkers of systemic inflammation have been consistently associated with atherosclerosis in general and PAD specifically. Plasma levels of C-reactive protein and fibrinogen have shown consistent associations with PAD.[3,26] Both of these biomarkers have also been associated with PAD severity and with adverse outcomes in symptomatic patients. Indeed, CLI patients appear to have the most pronounced proinflammatory phenotype across the spectrum of clinical atherosclerosis syndromes. Circulating cytokines such as interleukin-6 and adhesion molecules (soluble intercellular adhesion molecule-1, soluble vascular cell adhesion molecule-1) are also elevated in PAD patients.[27] The predictive value and clinical utility of these markers, as well as other candidate biomarkers such as D-dimer, β2-macroglobulin, asymmetric dimethylarginine, and cystatin C, remain undefined.[28-30]

Homocysteine

Several studies have demonstrated a statistical relationship between elevated plasma levels of homocysteine and PAD.[31] However, the strength of the association is moderate when controlled for other risk factors.[20] In addition, homocysteine levels have not been clearly associated with progression or severity of PAD, and studies of folate supplementation (which reduces homocysteine) have shown no consistent effects on PAD.[31]

Socioeconomic Status

PAD has been associated with lower socioeconomic status, including lower levels of income and education.[32,33] These associations span race/ethnicity and are only partly explained by traditional risk factors such as smoking. A recent analysis from the Atherosclerosis Risk in Communities (ARIC) study demonstrated that household income, educational attainment, and area-level deprivation index were strong predictors of hospitalization for advanced PAD.[33] These findings were attenuated but not eliminated after controlling for age, sex, race, risk factors, and access to healthcare. Mechanisms may include psychological stress, health literacy, and nutrition.

ANATOMIC DISTRIBUTION OF DISEASE AND CLINICAL CORRELATIONS

A broad spectrum of anatomic lesion distribution and disease severity is encountered in the PAD population. Lower extremity arterial disease has been anatomically described by the levels (segments) affected—aorto-iliac (AI), femoropopliteal (FP), and tibiopedal (TBP). These descriptors are both clinically useful and tend to be associated with patterns of risk factors across the spectrum of disease presentation. For example, smokers have a high frequency of AI and FP disease, whereas diabetes is more typically associated with TBP and FP involvement. There is also a clear relationship between disease pattern and clinical presentation. Patients with IC typically present with AI and/or FP disease, often with a single segment involved. In contrast, severe limb ischemia (SLI) or CLI generally results from involvement of at least two arterial segments or severe TBP disease. This correlation is largely a reflection of the development of collateral pathways of blood flow circumventing single-level (especially proximal) occlusions.

Cohort studies including vascular imaging provide greater insight into anatomic distribution of lesions across subgroups of patients. Smoking tends to be more highly associated with AI and FP involvement, whereas diabetes is strongly linked to FP and TBP patterns of disease.[19,34-36] Diehm et al. examined angiograms from a series of 2659 patients who had undergone endovascular interventions for PAD. Proximal (AI) disease was associated with younger age, smoking, and male sex, whereas TBP disease was associated with diabetes and advanced age. Rueda et al. described patterns of disease among a cohort of 450 patients who had undergone angiography and revascularization for CLI at a single institution.[37] They found that more than half of such patients had occlusions in the popliteal or TBP segments, and another 30% had combined FP and TBP occlusions; these patterns were particularly common in patients with diabetes and/or end-stage renal disease (ESRD).

CLINICAL SYNDROMES OF PERIPHERAL ARTERIAL DISEASE, STAGING AND NATURAL HISTORY

Individuals afflicted with PAD may be grouped by clinical presentation, with the largest proportion being asymptomatic. Atypical leg symptoms, classic IC, and CLI signs or symptoms are frequent indications for referrals to vascular specialists for evaluation and treatment. We will consider each of these distinct subgroups and describe modes of presentation, staging, prognosis,

TABLE 104.1 Stages of Chronic Limb Ischemia

Fontaine Grade	Rutherford Category	Clinical Description	Objective Criteria
I	0	Asymptomatic	Normal treadmill or reactive hyperemia test
IIa[a]	1	Mild claudication	Completes treadmill exercise[b]; AP after exercise >50 mm Hg but at least 20 mm Hg lower than resting value
IIb[a]	2	Moderate claudication	Between categories 1 and 3
	3	Severe claudication	Cannot complete standard treadmill exercise[b]; AP after exercise <50 mm Hg
III[a]	4	Ischemic rest pain	Resting AP <30-50 mm Hg; ankle or metatarsal PVR flat or barely pulsatile; TP <30 mm Hg
IV	5	Minor tissue loss	Resting AP <50-70 mm Hg; ankle or metatarsal PVR flat or barely pulsatile; TP <40 mm Hg in nondiabetics, <50 mm Hg in diabetics; $tcPO_2$ <30 mm Hg
	6	Major tissue loss[c,d]	Same as Rutherford 5 (Fontaine IV)

[a]Grades II and III correspond to critical limb ischemia.
[b]Five minutes at 2 miles per hour on a 12% incline.
[c]Nonhealing ulcer or focal gangrene with diffuse pedal ischemia.
[d]Extending above transmetatarsal level, or foot no longer salvageable.
AP, Ankle pressure; *PVR*, pulse volume recording; *$tcPO_2$*, transcutaneous oxygen; *TP*, toe pressure.
From Rutherford RB, Baker JD, Ernst C, et al. Recommended standards for reports dealing with lower extremity ischemia: revised version. *J Vasc Surg*. 1997;26(3):517–538; and Norgren L, Hiatt WR, Dormandy JA, et al. Inter-society consensus for the management of peripheral arterial disease (TASC II). *J Vasc Surg*. 2007;45:S34.

and key disease modifiers. The reader is referred to other chapters in the text for detailed discussion of diagnostic testing modalities, medical therapies, and use of vascular interventions.

Classification schemes for PAD have used clinical descriptors and associated objective measures (Table 104.1). The Fontaine and Rutherford systems have been widely adopted for this purpose. They have been useful for developing treatment algorithms and prognosis across the broad spectrum of PAD. However, recent efforts to improve staging of limb-threatening disease may provide greater predictive value for endpoints such as amputation and are discussed later.

Asymptomatic Disease

The majority of individuals with PAD detected by noninvasive testing are asymptomatic.[38] Reasons for the lack of symptoms may include lower severity/burden of disease, adequate collateral artery reserve, and limited levels of activity among older subjects or those with sedentary lifestyle or with other sources of disability.

Despite the lack of claudication or CLI symptoms, asymptomatic PAD carries significant cardiovascular risk and mortality and is associated with functional decline (Fig. 104.5). Criqui demonstrated that individuals with asymptomatic PAD had an overall 2.7-fold greater risk of mortality and a 5.6-fold greater risk of CAD related death.[39] Thus the importance of diagnosing PAD in asymptomatic individuals relates to counseling and treatment of associated atherosclerosis risk factors. Notably, mortality and CV risk are strongly associated with both reduced ABI and with elevated ABI (>1.4) consistent with vessel calcification.[40,41] These data demonstrate an important relationship between the severity of PAD as determined by objective testing and long-term mortality, independent of symptoms.

Work from McDermott has highlighted that individuals with asymptomatic PAD have significant physical impairments and tend to decline further over time, leading to increased sedentariness.[13,42,43] Manifestations included reductions in daily physical activity, walking velocity, and 6-minute walk distance. These findings have been correlated to reduced calf muscle mass, increased calf muscle fat content, and impaired peripheral nerve function in asymptomatic subjects. The reversibility of these muscle and nerve changes remains unknown.[44]

The risk of progression from asymptomatic PAD to symptomatic states is not well defined. A meta-analysis estimated that 7% (4%-11%) of asymptomatic patients deteriorate to IC over a 5-year period.[45]

Intermittent Claudication

IC is a clinical syndrome characterized by reproducible leg pain brought on by exercise and relieved by rest. Other causes of leg pain that must be considered in the differential diagnosis include neurogenic (e.g., spine disease), venous, joint, and other musculoskeletal disorders. Instruments such as the Rose and San Diego Claudication questionnaires have been used in clinical and epidemiologic studies to distinguish IC from other conditions.[46,47] In clinical practice a careful history, combined with a physical exam and simple noninvasive studies, readily establishes the diagnosis in the majority of patients. However, it is well recognized that atypical leg symptoms are common in PAD patients, including pain that may also occur while standing still or sitting and discomfort or fatigability with exercise that does not cause the individual to stop walking.

IC may affect proximal (buttock, hip, thigh) or distal (calf) muscles, although calf pain is by far the most common presentation. Symptom location reflects arterial disease proximal to that level. Thus AI disease frequently presents with proximal muscle symptoms (buttock, hip, or thigh), with or without associated

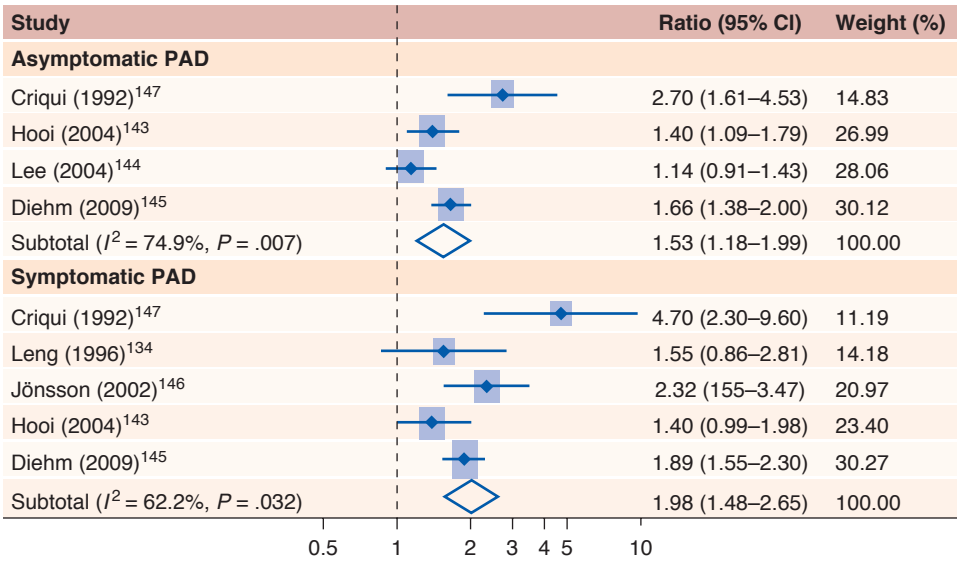

Figure 104.5 Estimated odds ratios for all-cause mortality for individuals with asymptomatic or symptomatic peripheral arterial disease *(PAD)*. (From Fowkes FG, Aboyans V, Fowkes FJ, McDermott MM, Sampson UK, Criqui MH. Peripheral artery disease: epidemiology and global perspectives. *Nat Rev Cardiol*. 2017;14(3):156-170.)

calf pain, whereas FP disease will manifest as calf pain with exercise. An important corollary is that individuals with isolated infrapopliteal (TBP) disease frequently do not have claudication symptoms, although foot claudication in plantar muscles has been described.

Severity of IC is generally described in terms of the initial claudication distance, based on walking in daily life or on a treadmill test. Patients with severe IC are generally unable to complete a standard 5-minute treadmill protocol (2 mph, 12% incline). These individuals often describe symptom onset within minutes of walking that forces them to stop, producing significant disability and impaired QoL. Functional testing of patients with IC demonstrates a broad range of impairment in lower limb strength, balance, and associated loss of mobility. Moreover, functional decline over time in IC is significant and is associated with the severity of PAD (e.g., ABI), as well as other factors such as age, race, and socioeconomic status.[42,43,48]

Numerous studies have associated IC with long-term risk for cardiovascular events and mortality, highlighting the importance of diagnosis, medical therapy, and surveillance in these patients.[39,49,50] Over 5 years, approximately 20% of patients with IC experience a major CV event and mortality ranges between 10% and 15%, (see Fig. 104.5). Data from large registries have demonstrated that symptomatic PAD is strongly associated with CV events and mortality, even more strongly than isolated CAD or CVD.[51-53] Despite this natural history, undertreatment of patients with symptomatic PAD has been a consistent finding across studies comparing the use of antithrombotic and lipid-lowering medications across PAD, CAD, and CVD populations.[9,54] These studies and others indicate that the delivery of guideline-based medical care remains suboptimal for patients with all stages of PAD.

The limb prognosis for patients with IC is generally considered as benign; however, a significant minority of patients will progress in the degree of disability and severity of limb threat.[55,56] In a recent systematic review, 21% of IC patients experienced deterioration of limb status over a 5-year period.[45] Symptomatic deterioration is greatest within the first year after diagnosis. Risk of major amputation has been estimated at less than 1% per year across a number of studies, although accurate data are limited. Risk for progression from IC to SLI/CLI is associated with similar underlying factors as for baseline PAD, although diabetes and continued smoking appear of heightened significance.

Limb-Threatening Ischemia

The terms CLI and SLI have been defined clinically as an advanced stage of PAD in which pain at rest in the foot or tissue necrosis (gangrene or nonhealing ulceration) has occurred. These terms connote a severe impairment of limb perfusion insufficient to maintain baseline tissue requirements. Although this clinical presentation is easily distinguished from asymptomatic PAD and IC, it represents a very broad range of hemodynamic compromise and associated limb threat. As such, there remains ongoing debate as to its definition, the corresponding objective criteria, and the overall relevance of this terminology in current practice. More recent consensus efforts have suggested the alternative terminology of "chronic limb-threatening ischemia" (CLTI) to be more broadly inclusive of the full spectrum of ischemia and neuropathy that are seen in these patients.[57] This subtle change implies that absolute threshold values for perfusion deficits that are "critical" are not readily defined across the population at risk and may vary in relation to the degree of

tissue loss or infection that coexists in the individual patient and limb. In this chapter, we use the term CLI only when referencing studies in the literature that used the historical definition.

Historically, hemodynamic criteria associated with the definitions of CLI or SLI have differed for rest pain versus tissue loss and vary by technique used (e.g., ankle pressure [AP], toe pressure [AP], ankle or toe index, tissue oximetry). Typical values associated with ischemic rest pain are an absolute AP less than 40 to 50 mm Hg and TP less than 30 mm Hg. With tissue loss, these defining values are typically increased to AP less than 50 to 70 mm Hg and TP less than 40 to 50 mm Hg, respectively. In the Fontaine and Rutherford schemes, rest pain and tissue loss are assigned different stages and Rutherford further discriminates "minor" (Rutherford 5) from "major" (Rutherford 6) tissue loss. Of note, the definition of Rutherford 6 used in the literature has ranged from a nonsalvageable foot to necrosis extending anywhere proximal to the forefoot, leading to difficulty in analysis of treatment outcomes and prognosis of disease. All of these issues argue for a more consistent and comprehensive staging system for the threatened limb, as outlined later.

CLI affects a minority of individuals with PAD, variably estimated at between 1% and 10%. The prevalence of CLI has been estimated at 1.3% of an insured US adult population and 0.5% to 1.2% of Swedish adults older than 60 years.[4,7] A recent meta-analysis estimated the prevalence of CLI at 0.8%.[58] Risk factors for CLTI include all of those relevant for PAD, with a notably higher preponderance of diabetes and renal disease. Many of these patients do not relate an antecedent history of classic IC, presenting with rest pain or tissue loss as the initial clinical manifestation of PAD. This may relate to the anatomic distribution of disease (e.g., predominantly infrapopliteal involvement), coexistent peripheral neuropathy, reduced mobility from comorbid factors, or an acute inciting event such as trauma or foot infection. Careful examination of the limb and foot should evaluate for signs of ischemia, infection, skin breaks, and bony involvement and document the presence and quality of pulses and Doppler signals.

Numerous studies have documented the adverse systemic and limb prognosis associated with a diagnosis of CLI. These patients have a greater burden of coexistent CAD and CVD and are at high risk for major CV events, mortality, and amputation. A recent systematic review examined the natural history of CLI, summarizing data from 13 studies and 1527 patients who did not receive limb revascularization.[59] At 1 year, estimated mortality was 22% (12%-33%) and major amputation had occurred in 22% (2%-42%). However, these data are limited in generalizability because many patients with CLI undergo revascularization.

Given the high cardiovascular risk and its importance for clinical decision-making in CLI, multiple studies have sought to define prediction models for mortality and major amputation (Table 104.2).[60-66] Predictors have included advanced age (>75 or 80 years), renal failure, coronary heart disease, congestive heart failure, diabetes, CVD, tissue loss, body mass index, dementia, and functional status. Frailty is a recently identified functional measure that is also of clear importance in this population.[67,68] All of these tools have been developed retrospectively using data from cohorts who have undergone revascularization, thereby excluding those who were managed conservatively or treated by primary amputation. None have been prospectively tested across the full spectrum of CLI/CLTI patients presenting for evaluation and treatment.

Limb prognosis in this patient population has a broad range consistent with the spectrum of presentation from rest pain through minor and major tissue loss, with or without infection. The need for improved staging to better define amputation risk and to appropriately compare treatment outcomes led to the recent development of the Society for Vascular Surgery Lower

TABLE 104.2 Summary of Risk Prediction Models for Patients With Chronic Limb-Threatening Ischemia Who Have Undergone Revascularization

	Endpoints	Critical Factors	Reference
Taylor et al.	Mortality, ambulatory failure (median follow-up 2 years)	Age, race, ESRD, CAD, COPD, DM, dementia, baseline ambulatory status	Taylor et al.[65]
FINNVASC	Perioperative (30 day) mortality, limb loss	DM, CAD, gangrene, urgent operation	Biancari et al.[66]
PREVENT III	AFS (1 year)	ESRD, tissue loss, age >75, CAD, anemia	Schanzer et al.[60]
BASIL	Survival (2 years)	Age, CAD, smoking, tissue loss, BMI, Bollinger score, serum creatinine, ankle pressure (number measured and highest value), prior stroke/TIA	Bradbury et al.[61]
CRAB	Perioperative (30 day) mortality, morbidity	Age >75, prior amputation/revascularization, tissue loss, ESRD, recent MI/angina, emergency operation, functional dependence	Meltzer et al.[62]
Soga et al.	Survival (2 years)	Age, BMI, nonambulatory status, ESRD, cerebrovascular disease, tissue loss, left ventricular ejection fraction	Soga et al.[64]
VQI	AFS (1 year)	Age, tissue loss, DM, CHF, serum creatinine, ambulatory status, urgent operation, weight, bypass conduit used	Simons et al.[63]

AFS, amputation-free survival; *BMI,* body mass index; *CHF,* congestive heart failure;; *TIA,* transient ischemic attack.

Extremity Threatened Limb Classification System.[57] This system stratifies limb risk by grading three critical factors—Wound, Ischemia, and foot Infection ("WIfI")—similar to a "TNM" system for malignancy (Table 104.3). The staging system applies to all patients with rest pain or tissue loss, combined with objective evidence of PAD. Each of the three key factors is graded on a four-level scale, and the 64 combinations were assigned to four stages of clinical severity expected to correlate with amputation risk at 1 year. Multiple studies have been published demonstrating that WIfI staging is strongly associated with amputation and wound-healing outcomes.[69-72] These studies confirm that WIfI stage 1 is associated with very low amputation risk, whereas stages 3 and 4 are more likely to require revascularization and are at increased risk for limb loss. WIfI stage may also predict wound healing time[69,73] and has been correlated with costs of care.[74] Further efforts will be needed to prospectively

TABLE 104.3 Society for Vascular Surgery Threatened Limb Classification System (WIfI) and Relationship to Amputation Risk

Component	Score	Description		
W (Wound)	0	No ulcer (ischemic rest pain)		
	1	Small, shallow ulcer on distal leg or foot without gangrene		
	2	Deeper ulcer with exposed bone, joint or tendon ± gangrenous changes limited to toes		
	3	Extensive deep ulcer, full thickness heel ulcer ± calcaneal involvement ± extensive gangrene		
I (Ischemia)		ABI	Ankle pressure (mm Hg)	Toe pressure or $TcPO_2$
	0	≥0.80	>100	≥60
	1	0.60-0.79	70-100	40-59
	2	0.40-0.59	50-70	30-39
	3	<0.40	<50	<30
fI (foot Infection)	0	No symptoms/signs of infection		
	1	Local infection involving only skin and subcutaneous tissue		
	2	Local infection involving deeper than skin/subcutaneous tissue		
	3	Systemic inflammatory response syndrome		

SVS WIfI Clinical Limb Stage

Based on Estimated Risk of Amputation at 1 Year

	Ischemia – 0				Ischemia – 1			
W-0	1	1	2	3	1	2	3	4
W-1	1	1	2	3	1	2	3	4
W-2	2	2	3	4	3	3	4	4
W-3	3	3	4	4	4	4	4	4
	fI-0	fI-1	fI-2	fI-3	fI-0	fI-1	fI-2	fI-3

	Ischemia – 2				Ischemia – 3			
W-0	2	2	3	4	2	3	3	4
W-1	2	3	4	4	3	3	4	4
W-2	3	4	4	4	4	4	4	4
W-3	4	4	4	4	4	4	4	4
	fI-0	fI-1	fI-2	fI-3	fI-0	fI-1	fI-2	fI-3

SVS WIfI Clinical Stage and 1-Year Rate of Major Amputations

Weighted Mean of Published Studies, N = 2779 Patients[a]

Clinical Stage 1	Very low risk	0.75%
Clinical Stage 2	Low risk	5.9%
Clinical Stage 3	Moderate risk	8.4%
Clinical Stage 4	High risk	25%
Clinical Stage 5 = Unsalvageable limb

validate and refine this system using large population-based registries.

Screening for Peripheral Arterial Disease

The role of screening for PAD has been controversial. Given the strong association of PAD with mortality and CV events, some have advocated for ABI screening, which is noninvasive, simple, and inexpensive. However, the US Preventive Services Task Force found the evidence to support PAD screening as insufficient in terms of the balance of benefits and harms.[75] A recent systematic review concurred that the evidence to support PAD screening was lacking.[76] Current Society for Vascular Surgery guidelines recommend against population screening for PAD; however, they suggest that targeted screening may be reasonable among individuals at higher risk (e.g., age >70 years, diabetes) if it would improve risk stratification or influence medical therapy.[77] The 2016 AHA/ACC guidelines also recommend targeted ABI testing in asymptomatic individuals at increased risk for PAD, which they define as age older than 65 years, age 50 to 64 with risk factors for atherosclerosis or family history of PAD, age older than 50 with diabetes plus one additional risk factor, or any individual with established atherosclerosis in another vascular bed (e.g., coronary, cerebral).[78]

Surveillance of Peripheral Arterial Disease Patients With Established Disease

The benefit of surveillance for patients with asymptomatic PAD is unclear. However, patients and their primary providers should be made aware of the presence of the disease and the signs and symptoms of its advancement. Those with diabetes or history of CLTI should have regular foot examinations and be counseled on preventive foot care. Symptomatic patients with objectively determined PAD are typically followed long-term to monitor for symptomatic worsening or disease progression. Many patients with mild-moderate IC are treated with smoking cessation, optimal medical management, and exercise. Others with disabling symptoms may require revascularization. The current SVS guideline recommends that all patients with IC be followed annually to assess for compliance with medical and lifestyle management, as well as for evidence of progression, with clinical exam and noninvasive testing (ABI).[77] The AHA guideline concurs with the need for long-term clinical follow-up.[78] Patients with IC or CLI who have undergone revascularization are monitored more closely, including surveillance of the vascular reconstruction. Although level 1 evidence is lacking, multiple cohort studies and the aforementioned guidelines support a benefit for duplex ultrasound surveillance of vein bypass grafts to promote long-term patency. It is less clear if surveillance of prosthetic bypass grafts or endovascular interventions is beneficial, although it is commonly used in clinical practice. Assessment of lower extremity functional performance, new or recurrent symptoms, and a complete foot examination should be a component of semiannual or annual visits in all patients following vascular interventions.

The management of lower extremity peripheral artery disease (PAD) represents one of the most challenging problems for the vascular specialist. Although its worldwide prevalence is unknown, it is estimated that 8 to 12 million Americans are affected by lower extremity PAD.[1,2] In an analysis of 2381 patients participating in the United States National Health and Nutrition Examination Survey, the prevalence of PAD was found to be 4.3% overall, progressively increasing with each decade of aging: 0.9% (40 to 49 years of age); 2.5% (ages of 50 to 59); 4.7% (ages of 60 to 69); and 14.5% (age >69).[3] The prevalence of PAD is expected to increase in the United States and worldwide as the population ages, cigarette smoking persists, and the epidemics of diabetes mellitus, hypertension, and obesity continue to grow.[2]

In accordance with the increasing prevalence of PAD, the number of lower extremity revascularization procedures has been increasing; among US Medicare beneficiaries, the number of revascularizations has increased from 357 to 581 per 100,000 between 1996 and 2006.[4] Decisions regarding the management of lower extremity PAD pose a unique challenge owing to the

Abstract

Decision making in lower extremity peripheral artery disease represents one of the most challenging and nuanced algorithms in vascular surgery. Optimal management is highly individualized, tailored to patient-specific goals, factoring in clinical presentation, anatomic pattern of disease, conduit availability, functional status, perioperative risk, and long-term survival. Medical management, principles of decision-making, and future directions for treatment of peripheral artery disease are discussed herein.

complex interplay of factors that must be considered, including the underlying pathology and its natural history, anatomic defect, degree of ischemia, availability of conduit, comorbid conditions, functional status, ambulation potential, and suitability of anatomy for successful revascularization. Appropriate management of lower extremity PAD requires a firm understanding of these factors for good decision making.

Patients with lower extremity ischemia are typically divided into two groups—those with intermittent claudication and those with chronic limb-threatening ischemia (CLTI)—depending on symptoms at presentation. The term "chronic limb-threatening ischemia" is now preferred to describe the condition previously referred to as critical limb ischemia. Claudication and CLTI are managed differently because of major differences in their natural histories and expected clinical outcomes after treatment. In general, there is more consensus among clinicians regarding decision making for CLTI because the natural history of untreated CLTI more frequently leads to limb loss than does claudication. Appropriate decision making requires an understanding of the systemic nature of the disease. Patients with CLTI often have severe associated cardiovascular comorbidities and are generally older and in poorer health than those with claudication. Treatment must therefore be structured accordingly. In contrast, patients with claudication typically seek treatment for the relief of lifestyle-limiting pain with ambulation. These patients exhibit a more benign natural history with respect to limb loss, with amputation rates of 1% to 7% at 5 years and clinical deterioration of the limb in only 25%.[5-7] As with CLTI, claudication is a marker of significant systemic atherosclerosis, with associated cardiovascular mortality rates at 1, 5, and 10 years as high as 12%, 42%, and 65%, respectively.[5-7] All patients with PAD require medical management of their cardiovascular disease, and many also benefit from either endovascular or open revascularization, as discussed later.

MEDICAL MANAGEMENT

Because atherosclerosis is a systemic disease, the initial treatment of lower extremity PAD must include risk factor modification. PAD patients are at significantly increased risk for premature cardiovascular events, including myocardial infarction (MI), stroke, and death.[8,9] PAD is an important indirect marker for systemic atherosclerosis.[10] Any patient older than 40 years who is found to have an ankle-brachial index (ABI) of less than 0.90 has significant PAD, even in the absence of symptoms.[11] Interestingly, more than 50% of patients with an abnormal ABI fail to show typical symptoms of claudication or CLTI, owing to the coexistence of other major comorbidities, a condition sometimes referred to as "chronic subclinical lower extremity ischemia."[12] There is wide agreement that risk factor modification is indicated for any patient with lower extremity PAD, regardless of symptom presence or severity. Several guidelines have been published[13-17] regarding the use of screening for PAD, including a clinical practice guideline from the Society for Vascular Surgery (SVS) Lower Extremity Guidelines Writing Group.[18] The authors recommend accepted preventive strategies for systemic atherosclerosis and comprehensive tobacco cessation interventions, as well as education on signs and symptoms of progression of PAD to the symptomatic state. As a corollary, a systematic review of screening for PAD concluded that there was no evidence for revascularization in patients with asymptomatic PAD, although screening may help to identify a population in whom aggressive medical therapy may be warranted to prevent cardiovascular and cerebrovascular events.[19] The natural history of asymptomatic PAD is also not well studied. Unfortunately, there are currently no data available to accurately predict which patients will go on to develop symptoms in the future.

Risk Factor Modification

The risk factors associated with PAD are similar to those classically linked with coronary artery disease (CAD). Investigators from the Framingham Heart Study analyzing "factors of risk" for CAD were first to identify demographic and comorbid factors independently associated with systemic atherosclerosis.[20] Numerous reports since have confirmed that advanced age, tobacco use, diabetes, dyslipidemia, and hypertension are the primary risk factors associated with PAD (Fig. 105.1). More recent studies have identified non-Hispanic black race,[3,21] chronic renal insufficiency,[3,22] and elevated homocysteine levels[23,24] as additional factors. All patients with the diagnosis of PAD require appropriate risk factor modification, regardless of whether more aggressive therapy is also being contemplated. Risk factor modification is discussed in detail in Section 2: Atherosclerotic Risk Factors.

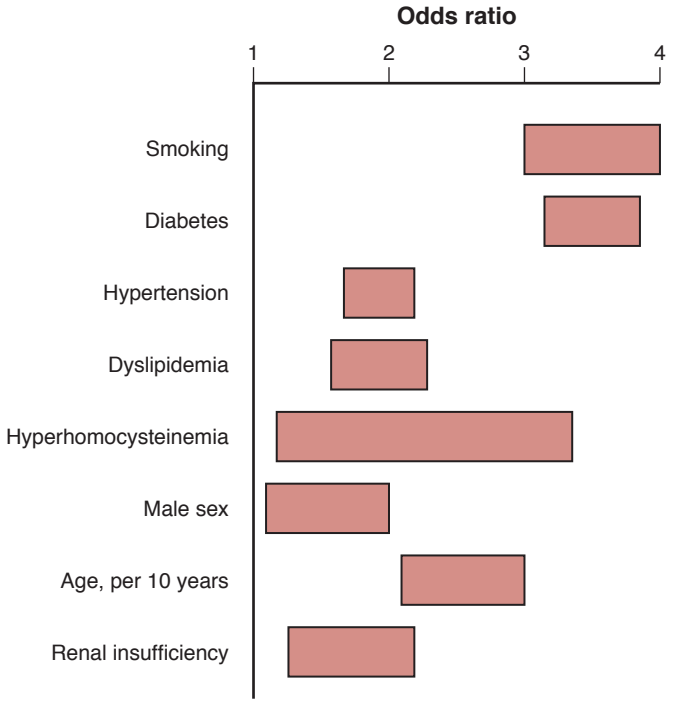

Figure 105.1 Odds ratios for risk factors for symptomatic peripheral artery disease. (Adapted from Norgren L, Hiatt WR, Dormandy JA, et al. TASC II Working Group. Inter-Society Consensus for the Management of Peripheral Arterial Disease (TASC II). *J Vasc Surg.* 2007;45(Suppl S):S5-S61.)

Exercise Therapy for Claudication

Multiple reports have clearly demonstrated improvements in pain-free ambulation and overall walking performance with structured exercise training.[7,25-27] Data from more than 20 randomized trials have confirmed that exercise therapy is the best initial treatment of intermittent claudication.[27] The benefits of exercise extend beyond improvement in the symptoms of claudication. Regular aerobic exercise reduces cardiovascular risk by lowering cholesterol and blood pressure and by improving glycemic control. In most patients, claudication initiates a downward spiral of cardiovascular deconditioning that can result in an annual mortality rate as high as 12%.[27] Ambulation distance can decline at a rate of 8.4 m/year beginning with symptom onset.[28] This cycle can be halted and even reversed with exercise training. In a recent report from Japan, Sakamoto and colleagues showed that the implementation of structured exercise resulted in a 5-year cardiovascular event–free survival rate of 80.5% in patients with PAD, compared with 56.7% in untreated matched controls.[29]

The current American College of Cardiology/American Heart Association (ACC/AHA) guidelines support supervised exercise for the treatment of intermittent claudication as a level IA recommendation.[15] The guidelines suggest that exercise training, in the form of walking, should be performed for a minimum of 30 to 45 minutes per session, 3 to 4 times per week, for a period not less than 12 weeks. During each session, the patient should be encouraged to walk until the limit of lower extremity pain tolerance is reached, followed by a short period of rest until pain relief is obtained, then a return to exercise. This cycle should be followed for the duration of the session. As the pain-free interval of ambulation increases, the level of exercise should be increased (Box 105.1).[25]

Although exercise therapy would appear easy to implement, effectiveness is often limited by poor patient compliance. Studies have shown the superiority of clinic-based exercise programs over home-based programs.[7] However, effective exercise training is not possible in up to 34% of patients because of comorbid medical conditions, and an additional 30% of patients simply refuse to participate in exercise training.[30] In addition, supervised exercise training programs are usually not covered by third-party insurance plans, although it may be in the near future by Medicare. Therefore, even though exercise therapy in motivated patients offers proven benefits, its effectiveness is applicable to only approximately one-third of patients presenting with intermittent claudication.

BOX 105.1 Key Components of a Structured Exercise Program for Claudication

Role of the Primary Clinician

- Establish the diagnosis of PAD using the ABI or other objective vascular laboratory evaluations.
- Determine that claudication is the major symptom limiting exercise.
- Discuss the risks and benefits of therapeutic alternatives, including pharmacologic, percutaneous, and surgical interventions.
- Initiate systemic atherosclerosis risk modification.
- Perform treadmill stress testing.
- Provide formal referral to a claudication exercise rehabilitation program.

Exercise Guidelines for Claudication[a]

- Include warm-up and cool-down periods of 5-10 min each.

Types of Exercise

- Treadmill or track walking is the most effective exercise for claudication.
- Resistance training may be beneficial for individuals with other forms of cardiovascular disease, and its use (as tolerated) for general fitness is complementary to but not a substitute for walking.

Intensity

- Initially, set the treadmill to a speed and grade that elicits claudication symptoms within 3-5 min.
- Patients walk at this workload until they experience claudication of moderate severity, at which point they take a brief rest period, either standing or sitting, to permit symptoms to resolve.

Duration

- The exercise-rest-exercise pattern should be repeated throughout the exercise session.
- The initial duration usually consists of 35 min of intermittent walking. This should be increased by 5 min each session until 50 min of intermittent walking can be accomplished.

Frequency

- Perform treadmill or track walking 3-5 times per week.

Role of Direct Supervision

- As walking ability improves, the exercise workload should be increased by modifying the treadmill grade or speed (or both) to ensure the stimulus of claudication pain during the workout.
- As walking ability improves, it is possible that cardiac signs and symptoms (e.g., dysrhythmia, angina, ST-segment depression) may appear. These events should prompt physician reevaluation.

ABI, Ankle-brachial index; *PAD,* peripheral artery disease.

[a]These general guidelines should be individualized and based on the results of treadmill stress testing and the patient's clinical status. A full discussion of the exercise precautions for persons with concomitant diseases can be found elsewhere for patients with diabetes (Ruderman N, Devlin JT, Schneider S, Kriska A. *Handbook of Exercise in Diabetes.* Alexandria, VA: American Diabetes Association; 2002), hypertension (*ACSM's Guidelines for Exercise Testing and Prescription.* In: Franklin BA, ed. Baltimore, MD: Lippincott, Williams & Wilkins; 2000), and coronary artery disease (*Guidelines for Cardiac Rehabilitation and Secondary Prevention/American Association of Cardiovascular and Pulmonary Rehabilitation.* Champaign, IL: Human Kinetics; 1999).

From Stewart KJ, Hiatt WR, Regensteiner JG, et al. Exercise training for claudication. *N Engl J Med.* 2002;347:1941-1951.

Pharmacologic Treatment of Claudication

Pharmacologic therapy for intermittent claudication has been the subject of intense research for more than 30 years. To date, only two drugs (pentoxifylline and cilostazol) have achieved FDA approval for the treatment of intermittent claudication in the United States. However, a number of other medications have been investigated, with varying degrees of evidence supporting their efficacy (Table 105.1). These include a number of drugs and supplements with various reported mechanisms of action such as changes in tissue metabolism (naftidrofuryl, levocarnitine), enhanced nitric oxide production (L-arginine), and vasodilatory effects (statins, buflomedil, prostaglandins, angiotensin-converting enzyme inhibitors, K-134).

Cilostazol

Cilostazol (Pletal) gained FDA approval in 1999 for the treatment of intermittent claudication. Oral administration of this phosphodiesterase III inhibitor increases cyclic adenosine monophosphate (cAMP) and results in a variety of physiologic effects, including the inhibition of smooth muscle cell contraction and platelet aggregation. Cilostazol is also thought to decrease smooth muscle cell proliferation, a process that has been implicated in coronary artery restenosis following percutaneous transluminal angioplasty.[31] Finally, cilostazol has a beneficial effect on plasma lipid concentrations, resulting in a decrease in serum triglycerides and an increase in HDL. Although the precise mechanism by which cilostazol improves the symptoms of intermittent claudication is unknown, it is likely a combination of these effects.

Several controlled clinical trials, including a meta-analysis, have confirmed the efficacy of cilostazol.[32,33,34] Results have shown increased maximal walking distances up to 50%, as well as significant improvements in health-related quality of life (QoL) measures.[33] There is also increasing evidence that cilostazol may modulate the synthesis of vascular endothelial growth factor (VEGF), potentially stimulating angiogenesis in patients with chronic lower extremity ischemia.[35]

The benefits of cilostazol in the treatment of intermittent claudication were compared with those of pentoxifylline in a randomized controlled trial performed by Dawson and associates.[32] They found that cilostazol therapy significantly increased maximal walking distance by 107 m (54% increase), compared with a 64-m improvement in the pentoxifylline group (30% increase). There was no difference in maximal walking distance improvement between the pentoxifylline and placebo groups. Regarding the durability of the effect, a recent pooled analysis of nine randomized controlled trials demonstrated a significant benefit in maximal walking distance compared with placebo at 6 months.[36]

Cilostazol has a moderate but notable adverse effect profile that includes headache, diarrhea, and gastrointestinal discomfort. Its use is contraindicated in patients with congestive heart failure, and high plasma drug levels may result when taken in combination with other medications metabolized by the liver via the cytochrome P-450 pathway.

The adverse effects of cilostazol can be minimized by initiating a progressive treatment regimen, starting at 50 mg/day for 1 week, increasing to 50 mg twice a day the following week, and finally achieving the standard dose of 100 mg twice a day in week 3. Of the pharmacologic agents used to treat claudication, cilostazol has the most data supporting its clinical use.

DECISION MAKING FOR REVASCULARIZATION

Patients with lower extremity PAD present with a wide spectrum of symptoms, ranging from asymptomatic, to only minor exertional leg pain, significant walking impairment, or even ulceration or gangrene. Therefore the first critical step in decision making for the treatment of PAD is to confirm that PAD is responsible for the patient's symptoms (see Chapter 18). In brief, noninvasive vascular laboratory testing is indicated for patients with a history consistent with vasculogenic claudication, rest pain/metatarsalgia, or tissue loss. Measurement of ABI is the most common PAD screening and diagnostic tool used. An ABI of ≤0.90 is highly sensitive and specific for the identification of PAD when compared with the "gold standard" of invasive arteriography (evidence of a hemodynamically significant peripheral arterial stenosis).[16] Complete physical examination will often disclose pulse deficits, but intact pulses at rest do not exclude hemodynamically significant PAD. After the symptom complex (either claudication or CLTI) is determined to be secondary to PAD, decision making depends on symptom severity and whether the symptoms are acute or chronic. The following discussion relates to chronic lower extremity ischemia; acute ischemia is discussed in Chapter 100.

Decision making regarding revascularization is based first on symptom status and a sophisticated understanding of the natural history of the patient's condition. Treatment strategies may thus be very different for patients with disabling claudication compared with those with CLTI because the risk of limb loss is dramatically different for the two conditions. Anatomic classification systems, such as the Trans-Atlantic Inter-Society Consensus (TASC) classification system, may assist in gauging the extent of angiographic disease. Although the TASC II classification system can be helpful in the revascularization decision-making process (i.e., endovascular or open), atherosclerotic burden as measured by arteriography is not the sole factor upon which treatment decisions should be made. Notably absent from the TASC classification system are any features relating to degree of ischemia, wounds, infection, functional status, and conduit availability, all of which are extremely important determinants of revascularization success. Clearly, angiographic anatomy alone cannot guide therapy.

Another critical element of decision making focuses on determining whether a patient will achieve meaningful benefit from a technically successful procedure. Technical success does not always equate directly with clinical success. As a result, it is important to assess baseline functional status, as well as the burden of comorbid conditions. Patients who are either bedbound at baseline or who have prohibitive medical risk may incur significantly more benefit from a treatment that differs from the TASC II recommendations (based on lesion type alone),

TABLE 105.1 Pharmacologic Treatment of Claudication

Drug	Mechanism of Action	Clinical Benefit	Adverse Effects	Current Clinical Role
Pentoxifylline	Methylxanthine derivative; improves oxygen delivery by enhancing red blood cell deformability; may inhibit platelet aggregation[34]	Improved PFWD and MWD over placebo[65,135,136]	May interfere with blood clotting, particularly when taken in combination with warfarin	FDA approved for use
Cilostazol	Phosphodiesterase III inhibitor; inhibits smooth muscle cell contraction and platelet aggregation	Improved MWD compared with pentoxifylline and placebo[135,137,138]	Headaches, diarrhea, GI discomfort; contraindicated in patients with history of congestive heart failure	FDA approved for use
Naftidrofuryl	Serotonin antagonist thought to improve aerobic metabolism	Improved PFWD; no improvement in MWD[139,140]	Minor GI, flatulence, abdominal discomfort	Widely available in Europe; not FDA approved
Levocarnitine	Carrier molecule involved in the transport of long-chain fatty acids; increases the availability of energy substrate for skeletal muscle metabolism	Improved PFWD and MWD compared with placebo[141]; no benefit was seen over exercise alone[142]	Flu-like symptoms	Available over the counter as a dietary supplement, not subject to FDA approval
HMG-CoA reductase inhibitors	Unknown; may alter vasomotor tone or stimulate angiogenesis[143]	Improved pain-free walking time; no improvement in maximal walking time compared with placebo[144]	Headache, abdominal pain, constipation; rarely, increased liver enzymes, cholestatic hepatitis, rhabdomyolysis	FDA approved for cardiovascular protection, not specifically for treatment of claudication
Buflomedil[145,146]	α_1 and α_2 antagonist, causing vasodilation; also inhibits platelet aggregation and enhances red blood cell deformability	Improved PFWD and MWD compared with placebo[147]	Lethal and nonlethal neurologic and cardiovascular adverse events have been reported[148]	Not FDA approved; studied in phase 2 trials
L-Arginine[149,150]	Amino acid precursor of endothelial-derived nitric oxide; indirectly modulates vasodilation of vascular smooth muscle	Improved MWD (with IV administration) compared with placebo[150]; no improvement over placebo when studied with oral formulation over 6 months[118]	GI distress[151]	Not FDA approved; studied in phase 2 trials
Prostaglandins: Prostaglandin E_1,[120] prostaglandin I_2,[152-154]	Vasodilatory effects; inhibit platelet aggregation	Prostaglandin E_1 improved MWD compared with placebo[120]; beraprost (prostaglandin I_2) has demonstrated conflicting results[152-154]	Headache, flushing, GI distress[119,120]	Not FDA approved; studied in phase 2 trials
Angiotensin-converting enzyme inhibitors	Vasodilation through reduction in angiotensin II, sympathetic inhibition, and improvement in endothelial function through preservation of bradykinin[52]	Ramipril improved pain-free walking time and maximal walking time over placebo[52]	Hypotension, headache, cough; rarely, hepatotoxicity, Stevens-Johnson syndrome, angioedema	FDA approved for cardiovascular protection, not specifically for treatment of claudication
K-134[155]	Novel phosphodiesterase III inhibitor; inhibits smooth muscle cell contraction and platelet aggregation	Primary analysis showed no benefit; mixed effects model showed both K-134 and cilostazol to improve peak walking time	Headache, nausea, diarrhea, tachycardia	Not FDA approved; studied in phase 2 trials

FDA, Food and Drug Administration; *GI,* gastrointestinal; *HMG-CoA,* hydroxy-3-methylglutaryl-coenzyme A; *MWD,* maximal walking distance; *PFWD,* pain-free walking distance.

to more appropriately balance the chances for functional limb salvage with the risks of periprocedural morbidity. Included in this evaluation is an assessment of the available conduit, should bypass be required. The challenge of decision making in PAD is accurately assessing each of these factors and synthesizing a plan that optimizes the likelihood of a favorable outcome for each individual patient.

Defining Treatment Success

Optimal treatment must ultimately be tailored to each patient. Although the general goal of any revascularization, whether for claudication or CLTI, is to increase the perfusion to the extremity as measured by physiologic testing, there are several other aspects that define treatment "success." These will not be the same for every patient with lower extremity PAD.

Limb- and Patient-Centered Outcomes

Traditional definitions of treatment success included technical outcomes such as graft/stent patency. However, graft patency may not correlate well with limb preservation; Simons et al. found that 10% of patients who underwent lower extremity bypass for CLTI failed to achieve clinical improvement despite having a patent graft at 1 year postoperatively.[37] Other outcome measures such as survival or amputation-free survival (AFS) have also been widely used. Some have questioned the appropriateness of these endpoints. In a critique of the Bypass Versus Angioplasty in Severe Ischemia of the Leg (BASIL) trial,[38] Conte noted that lower extremity bypass is generally not offered as a life-saving therapy, and therefore survival is not an appropriate measure for comparisons between revascularization strategies.[39] In addition, Conte stressed the importance of limb- and patient-centered outcomes, such as freedom from re-intervention. This shift toward more patient-centered outcomes is reflected in the SVS objective performance goals (OPGs) (https://www.vascularweb.org/research/clinicalresearch/Pages/cli-objective-performance-goals.aspx). These guidelines were developed specifically for comparative evaluations of different treatments for CLTI,[40,41] but the endpoints chosen are key components of treatment success for PAD, namely major adverse limb events, which included both freedom from major amputation as well as from re-intervention. This novel approach shifts the focus of outcome measures from technical success rates such as primary and secondary patency to one that acknowledges a burden incurred by the patient with each intervention that is required to maintain that limb and function (Table 105.2).

Claudication

For patients with claudication, surgeon-defined, procedural endpoints may not accurately capture all relevant outcomes. Some have challenged the traditional approach to patients with claudication.[42,43] Given the more benign natural history with respect to limb loss, nonoperative therapy is traditionally recommended as the first line of treatment; limb loss is therefore not a logical measure of treatment success. Kalbaugh and colleagues, using the Short Form (36) Health Survey (SF-36), found that

TABLE 105.2 Chronic Limb-Threatening Ischemia Endpoint Definitions and Event Rates Reported by the Society for Vascular Surgery Working Group for the Development of Objective Performance Goals for Evaluating Catheter-Based Treatment[a]

Endpoint	Definition	Event Rate (%) (95% CI)
Safety Outcomes (30 Day)		
Major adverse cardiovascular event (MACE)	Myocardial infarction, stroke, or death (any cause).	6.2 (4.7-8.1)
Major adverse limb event (MALE)	Above-ankle amputation of the index limb or major re-intervention (new bypass graft, jump/interposition graft revision, or thrombectomy/thrombolysis).	6.1 (4.6-7.9)
Amputation	Above-ankle amputation of the index limb.	1.9 (1.1-3.1)
Efficacy Outcomes (1 Year; All Rates Are Freedom From Event)		
Perioperative death or MALE	Perioperative death (30 days), or any MALE	76.9 (74.0-79.9)
Amputation-free survival (AFS)	Above-ankle amputation of the index limb or death (any cause).	76.5 (73.7-79.5)
Re-intervention or amputation or stenosis (RAS)	Any re-intervention, above ankle amputation of the index limb, or stenosis	46.5 (42.3-51.2)
Re-intervention or amputation (RAO)	Any re-intervention or above ankle amputation of the index limb.	61.3 (58.0-64.9)
Limb salvage	Freedom from above-ankle amputation	88.9 (86.7-91.1)
Survival	Freedom from death (any cause)	85.7 (83.3-88.1)

[a]As reported by the Society for Vascular Surgery Working Group for the development of objective performance goals for evaluating catheter-based treatment.
CI, Confidence interval.
Data are pooled from prospective trials of vein bypass surgery in CLTI.

reassurances about the benign natural history of their condition did little to alleviate patients' symptoms. Conversely, intervention for claudication improved QoL scores considerably. Improvements were similar to those found after coronary artery bypass surgery for angina and were half as beneficial as hip replacement surgery. In a more recent series, Taylor and coworkers reported significant symptomatic improvement after intervention for claudication in nearly 80% of treated patients.[44] Revascularization in this series was exceedingly safe, with no early amputations and a 99% limb salvage rate at 5 years.

Although it is accepted that revascularization is not appropriate in every case, there is clear evidence that QoL is improved by revascularization in many instances.[45-48] Indeed, the recent focus on patient-oriented endpoints has stimulated new research in the objective measurement of QoL for patients undergoing lower extremity revascularization. Various questionnaires have emerged as tools to measure QoL. Unfortunately, there is no consensus on the ideal questionnaire to use for the evaluation of patients with PAD. The two most commonly used surveys are the SF-36 and the Nottingham Health Profile.[49,50]

Chronic Limb-Threatening Ischemia

Taylor and colleagues recently studied 331 consecutive patients treated for Rutherford class 5 and 6 ischemia (tissue loss).[51] A bypass was deemed clinically successful if all four outcome criteria were met: (1) bypass patency until wound healing occurred, (2) limb salvage for at least 1 year, (3) maintenance of ambulatory status for at least 1 year, and (4) survival for at least 6 months. The authors found acceptable results when examining these components separately, including a graft patency rate of 72% and a limb salvage rate of 73% at 36 months. However, the clinical success rate, defined as the achievement of all four criteria, was only 44%. Furthermore, patients who presented with impaired ambulatory status, end-stage renal disease, gangrene, and infrainguinal disease (each independent statistical predictors) were especially prone to failure (Table 105.3).[51] Prospects for a successful outcome became progressively dismal as the number of independent negative predictors increased. Patients harboring two of these independent predictors of failure experienced approximately a 33% probability of success; those with three predictors, a 10% probability of success; and those with all four independent predictors of failure, less than a 5% probability of success. Similar studies using consensus definitions of success are needed to help guide decision-making regarding who should receive intervention and who should not.

TABLE 105.3 Probability of Failure After Bypass[a] When the Clinical Condition Is Present at Presentation

Predictor Variable	Probability of Failure (%)	Odds Ratio (95% CI)
Impaired ambulation	58	6.4 (2.9-14.4)
Infrainguinal disease	46	3.9 (1.6-9.8)
ESRD	35	2.5 (1.2-5.4)
Gangrene	34	2.4 (1.5-4.0)
Hyperlipidemia	11	0.6 (0.34-0.93)

[a]Defined as patent bypass until healed, limb salvage for 1 year, maintenance of ambulation for 1 year, and survival for 6 months.
CI, Confidence interval; *ESRD*, end-stage renal disease.
From Taylor SM, Cull, DL, Kalbaugh CA, et al. Critical analysis of clinical success after surgical bypass for lower extremity ischemic tissue loss using a standardized definition combining multiple parameters: a new paradigm of outcome assessment. *J Am Coll Surg*. 2007;204:831-839.

Treatment Guidelines According to Anatomic Disease Classification

Several classification systems have been developed that characterize PAD on the basis of anatomic descriptions of lesion type and location. The major goals have included standardization of reporting disease burden, development of methods to correlate disease burden with clinical severity, and development of recommendations for method of intervention. Although these classification schemes provide some value, they notably fail to capture major factors that determine the success of intervention.

Trans-Atlantic Inter-Society Consensus Classification

In January 2000 the TASC for the Management of Peripheral Arterial Disease published a document authored by a working group of representatives from 14 surgical vascular, cardiovascular, and radiologic societies.[52] An updated document (TASC II) was published in January 2007. These important works not only classified the lesions but also provided treatment recommendations according to lesion type. The TASC working group has classified anatomic patterns of disease involvement (types A through D) for both the aortoiliac (Fig. 105.2) and femoropopliteal (Fig. 105.3) segments, based on recommended treatment (endovascular versus open surgery). The TASC working group advocated endovascular treatment for TASC type A lesions and open surgical treatment for TASC type D lesions. For TASC type B and C lesions, the authors concluded that there was insufficient evidence to definitively recommend one modality over the other.[53]

Runoff Score

In 1986 the SVS and the International Society for Cardiovascular Surgery published reporting standards for lower extremity ischemia, which included the description of a runoff score to characterize the status of the outflow vessels distal to the distal anastomosis of a lower extremity revascularization procedure[54]; this was revised to the current version in 1997[55] to better incorporate the contribution of pedal vessels. The score values range from 0 to 10 (with 0 being completely patent, disease-free outflow) that is calculated based on the degree of occlusion and the relative contribution to outflow of each vessel. This formula translates into a description of the resistance in the outflow bed and therefore was designed to facilitate comparisons of expected bypass patencies. A simplified four-level version

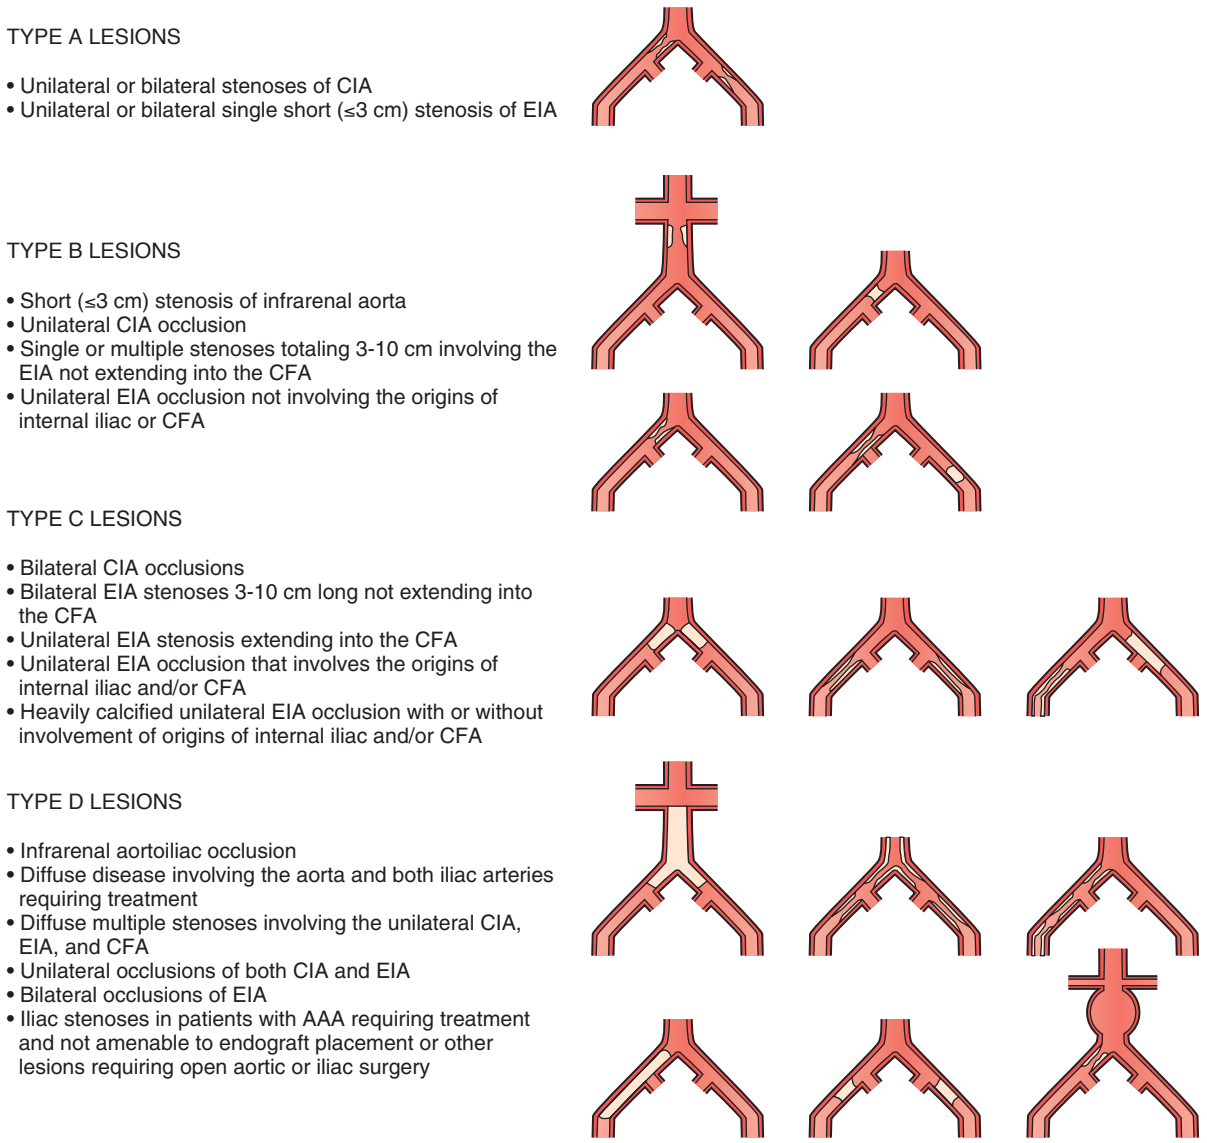

Figure 105.2 Trans-Atlantic Inter-Society Consensus classification of aortoiliac lesions. *AAA*, Abdominal aortic aneurysm; *CFA*, common femoral artery; *CIA*, common iliac artery; *EIA*, external iliac artery. (Redrawn from Norgren L, Hiatt WR, Dormandy JA, et al. TASC II Working Group. Inter-Society Consensus for the Management of Peripheral Arterial Disease (TASC II). *J Vasc Surg*. 2007;45(Suppl S):S5-S61.)

(scores 0 to 3) is also described that applies the weighting units to the outflow in an all-or-none fashion based on the presence of any hemodynamically significant stenosis. The authors note explicitly that neither of these systems should be used to the exclusion of other systems, and do not offer these as a scheme for making treatment decisions.

TREATMENT GUIDELINES ACCORDING TO PRESENTATION

Claudication

Traditional treatment recommendations for intermittent claudication have balanced the risk of intervention against the natural history of the disease. It has long been appreciated that claudication is a marker for more serious potential manifestations of systemic atherosclerosis. With the goal of preserving life and limb, many experts agree that the best strategy is to initiate systemic medical therapy aimed at reducing cardiac morbidity. This strategy is based on the low relative risk of limb loss in patients with claudication compared with the significant relative risk of stroke, MI, and death. The ACC/AHA guidelines suggest that the risk of major limb amputation for a patient with intermittent claudication is approximately 1% per year, whereas the risk of cardiac death is approximately 3% to 5% per year.[15,56-58] Treatment strategies have therefore stressed cardiovascular risk factor modification and medical therapy as the best initial treatment for patients with PAD symptoms limited to intermittent claudication. Medical treatment for intermittent

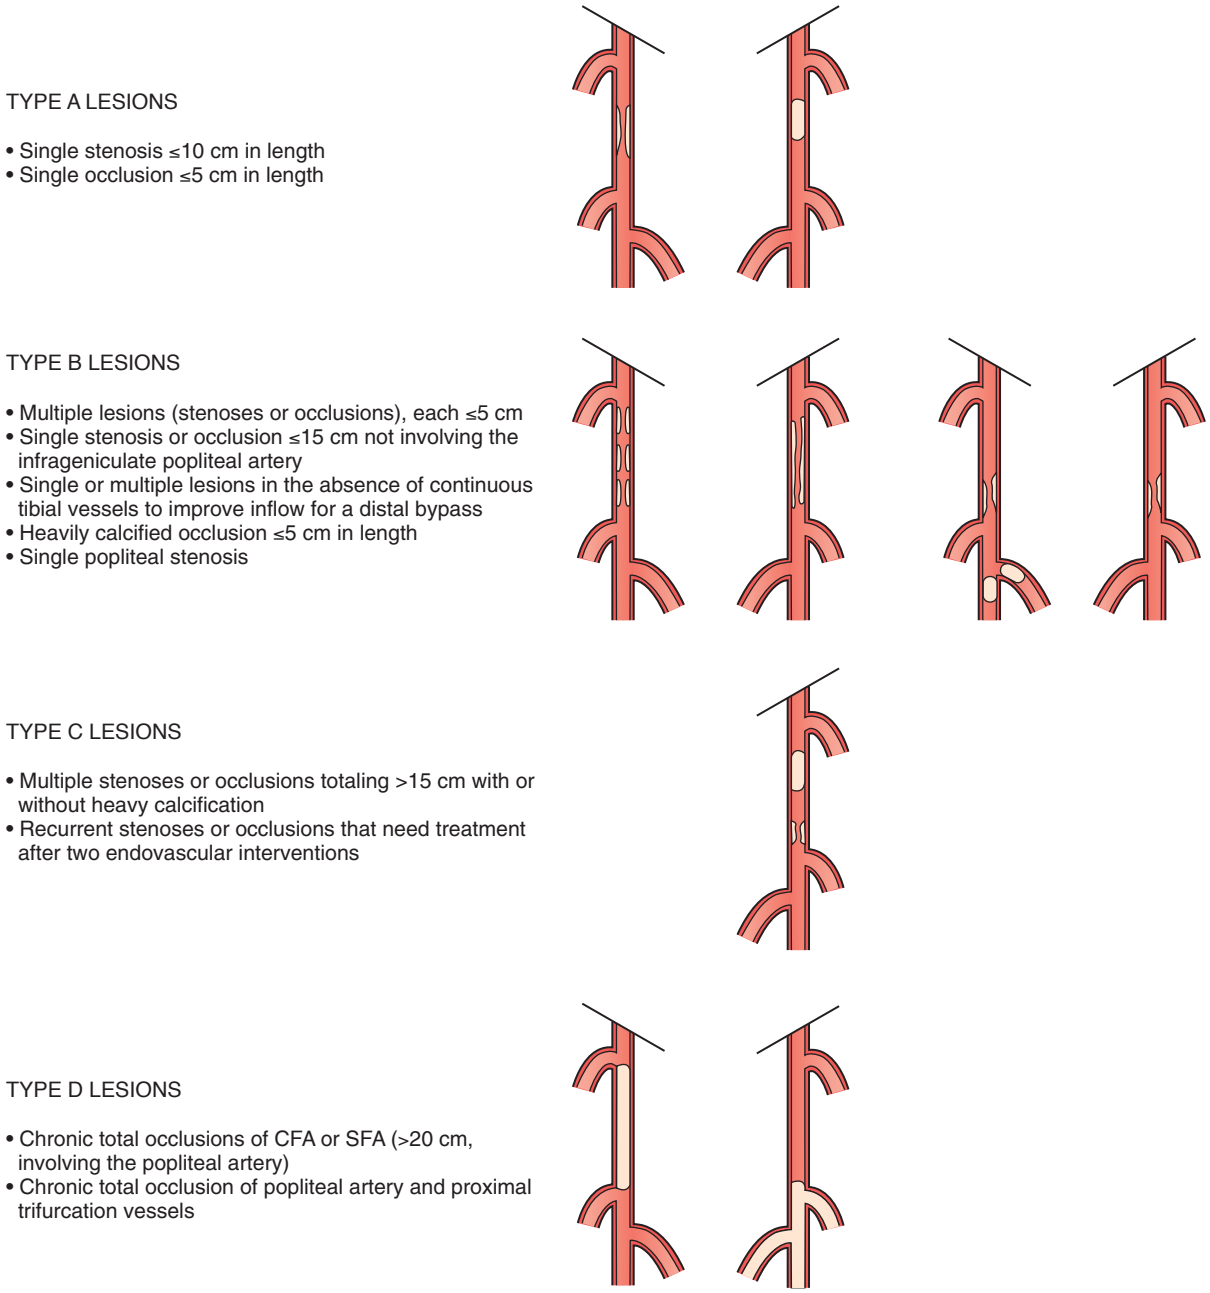

Figure 105.3 Trans-Atlantic Inter-Society Consensus classification of femoropopliteal lesions. *CFA*, Common femoral artery; *SFA*, superficial femoral artery. (Redrawn from Norgren L, Hiatt WR, Dormandy JA, et al. TASC II Working Group. Inter-Society Consensus for the Management of Peripheral Arterial Disease (TASC II). *J Vasc Surg*. 2007;45(Suppl S):S5–S61.)

claudication consists of smoking cessation, exercise training, and pharmacologic therapy, as already described. Revascularization is recommended only in cases of severe claudication and only after medical therapy has failed.

Medical Therapy Versus Revascularization

The role of smoking cessation in treating the symptoms of claudication is unclear. Although studies have shown that smoking cessation can improve walking distance in some cases, these findings are not universal.[59] However, the association between tobacco cessation and the reduction of subsequent cardiovascular events is undisputed. The rationale for smoking cessation is therefore based on reducing patient mortality and slowing the overall atherosclerotic disease process.

Currently available pharmacologic agents for claudication have already been discussed (see section "Pharmacologic Treatment of Claudication"). The ACC/AHA guidelines recommend, in addition to routine antiplatelet therapy, a therapeutic trial of cilostazol (100 mg 2 times a day) as an effective method for increasing overall ambulation (class I recommendation). This agent is limited to patients with PAD and intermittent claudication and no history of congestive heart failure, because cilostazol

is a phosphodiesterase-3 inhibitor capable of exacerbating ventricular dysfunction.[15] Unfortunately, adverse effects prevent the routine use of cilostazol in up to 15% of patients.[32,33]

When comparing medical to endovascular therapy, there are abundant data supporting the efficacy of medical therapy. For instance, the Edinburgh walking study consisted of a randomized trial to determine outcome differences in patients with intermittent claudication treated with angioplasty and stent versus medical management (daily low-dose aspirin, lifestyle modification) after 2 years. These investigators found no difference in maximal walking distance, treadmill distance until onset of claudication, and QoL measures between the two groups.[60] Supervised exercise therapy has also been compared with primary stenting for disabling claudication due to aortoiliac occlusive disease in the Claudication: Exercise Versus Endoluminal Revascularization (CLEVER) trial.[61] At 6-month follow-up, they reported that change in peak walking time was greatest for supervised exercise, intermediate for stenting, and least with pharmacologic therapy (mean change versus baseline, 5.8 ± 4.6, 3.7 ± 4.9, and 1.2 ± 2.6 minutes, respectively; $P < .04$ for the comparison of supervised exercise versus stenting). QoL evaluation revealed significant improvements in both the supervised exercise and the stenting groups compared with pharmacologic therapy, but the benefit was greater in the stenting group than in the exercise group.

In summary, when weighing medical therapy versus revascularization for the treatment of intermittent claudication, the risk-to-benefit ratio favors initial medical therapy in most cases. However, medical therapy may be effective in as few as 30% of patients because of noncompliance and drug intolerance. When revascularization is chosen, modern approaches have become predominantly endovascular owing to its reduced procedural risks compared with open surgery. However, an analysis of practice patterns in New England between 2003 and 2009 demonstrated that an increasing proportion of lower extremity bypass procedures were performed for claudication in recent years (from 19% to 31%, $P < .0001$). In addition, the percent of patients with a history of previous endovascular intervention has steadily increased (from 13% to 23%, $P = .02$).[62] The authors suggest that the high rates of prior endovascular intervention seen may reflect a "treatment trap"; after the decision has been made to intervene procedurally for claudication, surgeons may feel obliged to perform an open revascularization if a prior endovascular approach has failed to resolve symptoms. Of note, the 1-year incidence of major amputation after intervention on claudicants was 1.6% in this study; although this is low, it is a devastating outcome after a procedure for claudication. Clinical decision making ultimately must incorporate not only the risks and benefits of various treatment strategies but also a discussion of realistic expectations as to the extent to which treatment will improve symptoms and improve QoL.

Endovascular Treatment Versus Open Surgery (see Chapters 106 through 110)

Ultimately, the selection of the best method of revascularization for an individual with claudication is based on a balance between the risks of the specific intervention and the degree and durability of improvement that can be expected from the intervention.[53] Because the natural history of vasculogenic claudication is relatively benign, that balance usually does not favor open surgery. In contrast, its relatively low morbidity and mortality make endovascular therapy particularly attractive,[53] and when it is anatomically feasible, endovascular therapy is often preferred to open surgery for most cases of claudication.[60] However, it is important to note that a growing body of evidence suggests that the concept that an endovascular option "does not burn any bridges" is false.[63,64]

Anatomy is one of several important considerations when selecting the best interventional modality for patients with claudication as well as those with CLTI. Prospective studies dating to the 1980s have characterized the arterial lesions and anatomy most conducive to long-term patency after angioplasty. Johnston and colleagues demonstrated in a prospective analysis that the arterial anatomy and clinical presentation most amenable to long-term patency and success using angioplasty were focal arterial lesions in large-diameter vessels with adequate outflow.[65] Outcomes were more favorable in nondiabetic patients presenting with claudication than in those with CLTI. The arterial segment best managed with percutaneous transluminal angioplasty is thus the common iliac artery, a vessel with all the favorable anatomic characteristics identified by Johnston's study. Atherosclerotic lesions in this segment are usually focal and possess good outflow. Angioplasty patency rates at 5 years generally exceed 70%.[44] Conversely, long-segment arterial disease, such as a long superficial femoral artery occlusion, is probably best treated with open bypass from the standpoint of durability of the revascularization. Diffuse multisegmental disease, more common with CLTI, can present a therapeutic dilemma.

Chronic Limb-Threatening Ischemia

CLTI is defined as chronic lower extremity PAD with either ischemic rest pain or the tissue loss (nonhealing ulcers or gangrene) (see Chapter 104). Typically, symptoms have to be present for more than 2 weeks and associated with an ankle pressure less than 50 mm Hg or a toe pressure less than 30 mm Hg.[60] Although far fewer patients present with CLTI than with intermittent claudication, CLTI patients consume the vast majority of treatment resources. A surprisingly small fraction of patients (<5%) with intermittent claudication progresses to CLTI. Patients with "chronic subclinical ischemia"—those with low perfusion and ankle pressures but who are asymptomatic for a variety of reasons—are also at risk for the development of limb ischemia.[60]

Prognosis for CLTI is considerably worse than for intermittent claudication; as many as 25% of CLTI patients progress to major limb amputation within 1 year, and 25% die of cardiovascular complications within 1 year.[66] However, CLTI populations are quite heterogeneous and it is therefore difficult to precisely define its natural history. For example, CLTI patients in the placebo arm of the Circulase trial experienced an 87% limb salvage rate at 6 months,[67] a limb salvage rate not dissimilar from the treatment arms in the BASIL trial *(Bradbury AW)* or

the PREVENT III trial.[68] Decision making for CLTI commonly poses three dilemmas: whether to treat medically or with intervention; if treating with intervention, whether to amputate or revascularize; and if revascularizing, whether to use endovascular intervention or open surgery.

Medical Therapy Versus Revascularization

The natural history of untreated CLTI is poorly understood because most functional patients receive some type of revascularization. Limb loss and cardiac death are common; 1-year mortality ranges from 20% to 30%, with cardiac deaths outnumbering noncardiac deaths four to one.[69] The best information regarding the natural history of nonrevascularized limbs in patients with CLTI comes from the placebo arms of pharmacotherapy trials of patients with unreconstructable vascular disease. Results suggest that this subgroup has a dismal prognosis, with nearly 40% of limbs progressing to amputation at 6 months.[70] Therefore, in functional patients, some type of revascularization is almost always preferable to medical therapy.

However, medical therapy for CLTI is not without some noteworthy successes. Indeed, wound care centers have become common adjuncts to many vascular surgical practices (see Chapter 115). Ischemic ulcer healing rates of 55% have been reported from dedicated centers using modern wound care methods such as negative-pressure wound therapy, intense débridement, and antibiotic therapy.[71] However, wound healing in such situations is often slow, laborious, and unpredictable. To date, pharmacotherapy for CLTI has failed to yield any major breakthroughs. The routine use of prostanoids, vasodilators, antiplatelet agents, and even hyperbaric oxygen for the treatment of ischemic ulcers remains of unproven benefit.[71]

In summary, revascularization is an essential component in the relief of CLTI. Although medical adjuncts geared at risk factor modification may be important to slow the progression of systemic atherosclerotic disease, they play a secondary role in the treatment of the severely ischemic limb. In those rare cases in which vascular disease is truly unreconstructable, a trial of intensive wound care, preferably at a dedicated wound care center, may yield satisfactory healing rates for motivated patients with superficial ulcerations, or it may avoid major limb amputation in high-risk patients who are approaching the end of life.

Limb Amputation Versus Revascularization

For the overwhelming majority of patients with CLTI, revascularization is the interventional treatment of choice. However, primary limb amputation continues to be required in 10% to 40% of CLTI patients, owing to overwhelming infection or unreconstructable vascular disease.[72] Unreconstructable vascular disease accounts for nearly 60% of patients requiring secondary amputation.[71] In many of these cases, revascularization has failed due to disease progression, recurrent ischemia, or persistent infection or necrosis despite a patent revascularization.

Although counterintuitive, limb amputation and prosthetic rehabilitation can be an excellent option, offering an expedient return to a reasonable QoL in selected cases. Maintenance of ambulation can exceed 70%, and maintenance of independence can exceed 90% in young, good-risk patients after below-knee amputation.[73] Clearly, amputation should be considered a tool capable of extending functionality and not a failure of treatment in these cases. If there is the potential for some degree of rehabilitation, the limb amputation should be performed at the lowest possible level at which healing can be expected, because the work of walking increases dramatically as the level of amputation becomes more proximal. Typically, patients with well-controlled medical comorbidities, a palpable femoral pulse, a warm calf, and no signs of infection are likely to heal after a below-knee amputation (see Chapters 111 and 112).

The use of an immediate postoperative prosthesis (IPOP) may also aid in expediting a patient's recovery following below-knee amputation. This technique, first described in the 1960s, gained favor following a publication, the Prosthetic Research Study, by Burgess and colleagues.[74] They reported that the use of a rigid cast placed intraoperatively facilitated faster healing and return to ambulation. Folsom and colleagues studied this technique in a population where the indication for amputation was not trauma, but rather severe infection or unreconstructable PAD.[75] Of 65 patients, 86% returned to independent ambulation, with an average time to ambulation of 15.2 days following below-knee ambulation. A more recent comparative analysis of IPOP compared with traditional soft dressings demonstrated no difference in complication rates, and a lower incidence of revision (soft dressings 27.6% vs. IPOP 5.4%, $P = .021$).[76]

Patients with major tissue loss who are too sick or infirm to realize the benefit of limb revascularization should undergo palliative primary above-knee amputation. However, judging patients "too sick or infirm" can be difficult. Obviously, a nonambulatory, elderly, nursing-home patient with knee contractures and neuropathic heel ulcers would qualify for a palliative above-knee amputation. For patients who are minimally ambulatory, with multiple comorbidities, the decision is less clear-cut. An individualized judgment is required to determine whether these patients will be better served by primary amputation or limb revascularization. In a single-institution study of 1000 consecutive revascularizations for CLTI, preoperative functional performance status was the most important predictor of postoperative functional outcome—even more important than limb salvage itself.[77] This finding strongly suggests that there is a definite subset of patients who are too sick or debilitated to realize the functional benefits of revascularization. Although more work is needed to better define such patients, this cohort is likely best suited for primary amputation.

Endovascular Treatment Versus Open Surgery (see Chapters 106 to 110)

For many years, the classic treatment approach for CLTI has been open surgery. CLTI is usually associated with multilevel arterial disease that is not ideally suited to percutaneous intervention. Diffuse, extensive PAD causing CLTI in both aortoiliac and femoropopliteal locations (see Figs. 105.2 and 105.3) is best treated by surgical bypass according to TASC.[78] However, the primacy of surgical bypass for CLTI management has been challenged in recent years and has become the subject of intense

debate. Those who favor open surgery for the treatment of CLTI often cite superior reconstruction patency and increased durability.[79-81] However, open surgery is usually associated with higher perioperative morbidity and longer hospitalization.[82] In addition, long-term postoperative graft surveillance is necessary to maintain a patent infrainguinal bypass, as has been shown in well-performed studies from both Europe and North America suggesting that such surveillance is economically justified by preventing vein graft occlusion and late amputation.[83,84] A re-intervention rate of 20% to 30% to treat failing grafts due to intrinsic vein graft stenoses is usually necessary to maintain the increased durability attributed to open surgery.[83,85] Last, successful surgery depends on the presence of a suitable venous conduit for bypass.[86,87] Those who favor interventional treatment cite the low morbidity and mortality associated with a procedure that is usually performed on an outpatient basis.[88] Although proponents acknowledge the limited reconstruction patency rates associated with endovascular treatment, especially for the high-risk lesions often encountered in CLTI, they argue that restenosis rarely jeopardizes subsequent surgery.[88-90] In contrast, others have found that prior ipsilateral intervention has a negative influence on subsequent bypass. An analysis of the BASIL data by treatment received found 1-year AFS was 40% for bypass that followed a failed endovascular intervention, compared with 70% for the bypass-only group.[64] The authors therefore do not endorse the concept of a "free shot" with an endovascular first approach. Nolan et al. also found a correlation of graft failure and prior endovascular intervention; in a study of CLTI patients who underwent lower extremity bypass in New England, those with a prior failed endovascular intervention had a higher incidence of major amputation (31% vs. 20%; $P = .046$) and graft occlusion (28% vs. 18%; $P = .009$) at 1 year.[91] Although a causative relationship has not been established, the concept of "burning bridges" with an aggressive endovascular-first approach clearly deserves further study.

Situational Perfusion Enhancement

Proponents of endovascular intervention frequently cite the phenomenon of situational perfusion enhancement and its role in the treatment of CLTI. They argue that there is a population of asymptomatic patients with subclinical lower extremity ischemia and very low perfusion pressures. These patients become symptomatic only when they develop incidental foot ulceration and do not have the circulatory reserve to heal. A boost in arterial perfusion, even transiently, usually allows healing of the ulcer. After the ulcer is healed, maintenance of enhanced perfusion is not critical, and recurrent ischemia is usually well tolerated as the patient resumes the subclinical ischemic state. Endovascular intervention proponents therefore argue that inferior reconstruction patency rates after such interventions are inconsequential. Although the phenomenon of situational perfusion enhancement has been observed and reported anecdotally, it should be accepted with caution. If the ulceration is a sporadic event (e.g., the result of minor incidental trauma), a situational boost to perfusion could be sufficient to accomplish healing. However, if the ulcer is the result of neuropathic changes in the foot, in which case ulcer recurrence is the rule rather than the exception, a more durable reconstruction is probably indicated. The role of situational perfusion enhancement in patients who develop ischemic rest pain is likewise unclear.

BASIL Trial

There is a striking paucity of level I data to guide decision making for endovascular treatment versus open surgery. In the United Kingdom the BASIL study represents the only randomized controlled multicenter trial comparing angioplasty to open surgery for severe limb ischemia.[92] In this study of nearly 450 patients randomized to bypass or balloon angioplasty for the initial treatment of infrainguinal disease, the findings support much of what is known about the two modalities and underscore several important caveats. Using AFS as the primary endpoint, the authors found that patients treated with bypass first had comparable outcomes to patients treated with balloon angioplasty first at 6 months (amputation or death = 21% with bypass first vs. 26% with balloon angioplasty first; P = not significant). Although the early mortality was similar in both treatment groups, surgery was associated with higher morbidity. Crossover treatment after initial therapy (surgery to angioplasty or angioplasty to surgery) was common in both treatment groups, with more than half the angioplasty arm and approximately one-third of the surgical arm requiring further intervention. At the end of 5 years, 55% of patients were alive without amputation, 8% were alive with amputation, 8% were dead after amputation, and 29% were dead without amputation. After 2 years, both AFS (hazard ratio, 0.37; $P = .008$) and overall survival (hazard ratio, 0.34; $P = .004$) were better in the surgical arm.

The BASIL trial reinforces several principles. It clearly supports the phenomenon of situational perfusion enhancement. Patients who have lower extremity ulceration that would be expected to heal with conventional wound therapy and enhanced perfusion within 6 months are good angioplasty candidates. The TASC document currently recommends angioplasty over open surgery when the desired outcomes of the two modalities are comparable.[78] However, angioplasty is probably not appropriate when recurrent ulceration and persistent ischemic symptoms are expected to exceed 6 months. The advantage of having surgery first becomes apparent at 2 years. If it appears that the patient's life expectancy or the course of the disease will exceed 2 years, surgery is probably the more appropriate first intervention. Finally, the degree of treatment crossover in the BASIL trial was arguably its most remarkable finding. It stresses that angioplasty and open surgery are not "either-or" therapies but are complementary. It underscores the importance of training surgeons who manage lower extremity ischemia so that they possess both open and endovascular skill sets.[93]

Ongoing Trials

The lack of high-quality evidence to guide therapy in patients with CLTI has prompted the initiation of two more large-scale trials that deserve mention. The BASIL-2 trial (http://www.birmingham.ac.uk/research/activity/mds/trials/bctu/trials/portfolio-v/Basil-2/index.aspx, accessed 27 March 2016) is a

multicenter, randomized clinical trial of "vein-bypass first" or "best endovascular therapy first" approach in patients with severe limb ischemia; it began recruitment across England, Scotland, and Northern Wales in June 2014.[94] The investigators seek to recruit 600 patients over a 3-year period. The primary outcome is AFS. A number of secondary outcomes will also be analyzed, including major adverse limb events, health-related QoL, crossover and re-intervention rates, and cost-effectiveness measures.

In the United States a similar effort is underway to further define the best treatment strategy for patients with CLTI, the Best Endovascular versus Best Surgical Therapy in Patients with CLI Trial (BEST-CLI) (ClinicalTrials.gov: NCT02060630; www.BESTCLI.com, accessed March 27, 2016).[95] This multicenter clinical trial seeks to randomize 2100 patients with CLTI, across the United States and Canada, to either best open or best endovascular therapy; the first patient was enrolled in September 2014. The primary endpoint is major adverse limb events. Planned secondary endpoints include freedom from clinical failure and from hemodynamic failure, health-related QoL, and cost-utility analysis.

Hopefully, these two landmark studies, if completed successfully, will better inform the complex decision-making process necessary to choose between endovascular treatment and open surgery for patients with CLTI.

Threatened Limbs, With or Without Peripheral Arterial Disease

In recognition of the fact that PAD patients are a subset of patients at risk for limb loss due to a variety of potential etiologies (diabetes mellitus, most commonly), the SVS commissioned the Lower Extremity Guidelines Working Group to create a more comprehensive classification system to serve as a more robust decision-making aid for this broader category of patients. This new classification framework, entitled the SVS Threatened Limb Classification System [Mills JL, Conte MS, Armstrong DG, et al. The Society for Vascular Surgery Lower Extremity Threatened Limb Classification System: risk stratification based on wound, ischemia, and foot infection. *J Vasc Surg*. 2014;59:220–234.] incorporates three major factors that impact amputation risk and clinical management: Wound, Ischemia, and foot Infection (WIfI). The intent of this new SVS WIfI classification system is to stage patients across a broad spectrum of lower extremity arterial occlusive disease of varying severity and distribution. In the SVS WIfI system, wounds are classified from grade 0 through grade 3, based on size, depth, severity, and anticipated difficulty achieving wound healing. Ischemia is classified from grade 0 through grade 4 according to ABI, ankle systolic pressure, toe systolic pressure, or transcutaneous oximetry. Infection is classified from grade 0 through grade 3 based on simple objective clinical observations. The combination of grades is used to categorize the limb into one of four clinical stages that correlate with major amputation risk at 1 year. Multiple studies have validated the SVS WIfI system as an accurate way in which to predict amputation risk and stratify patients to permit more meaningful analyses of outcomes for various forms of therapy in this challenging heterogeneous population.[96-101]

Impact of Conduit Availability, Preoperative Functional Status, and Comorbid Disease

Decision making in the treatment of lower extremity PAD has focused on *how* to treat patients. In the future, as the financial condition of the healthcare system continues to deteriorate, decision making will focus on *who* to treat. It is naïve to believe, for instance, that all patients who present with CLTI will benefit from aggressive intervention. Indeed, in the BASIL study cited earlier, an independent data-monitoring committee overseeing patient enrollment in this trial found that half the patients with severe limb ischemia were regarded as unsuitable or unfit for any form of revascularization. The authors concluded that patients eligible for revascularization represent the tip of an iceberg, the true dimensions of which remain incompletely defined.[92] Interventional treatment cannot and should not be offered to everyone. The true task, then, is to refine definitions of success and construct tools using evidence-based data to help distinguish patients who will benefit from therapy from those who will not. This necessitates study of not just those who undergo revascularization, but also those patients for whom either palliation or primary amputation is offered in order to truly capture the denominator of this problem.

Conduit Availability

The availability of adequate conduit for open bypass plays a critical role in the decision of how best to treat a patient with lower extremity PAD, particularly CLTI. Great saphenous vein of adequate caliber, even if it must be harvested from the contralateral leg, remains the conduit of choice for open bypass.[102] It has been shown to have superior durability compared with all other conduit choices: prosthetic grafts, short saphenous vein, spliced arm vein, and vein cuffs.[103] In the absence of good-caliber great saphenous vein for bypass, an endovascular revascularization becomes a more attractive option. Having said that, multiple authors have demonstrated excellent outcomes in large surgical bypass series using alternative autogenous vein options (cephalic vein, basilic vein, short saphenous vein).[104-106] Performance of vein mapping prior to arteriography is essential because of the strong influence it can have on the decision of how aggressively to pursue an endovascular revascularization strategy.

Influence of Comorbid Conditions and Preoperative Functional Status

The patient's ability to tolerate an open revascularization must be assessed as part of the decision-making process. Several studies have sought to identify factors associated with perioperative morbidity and mortality. Using data on 9556 patients identified from the National Surgical Quality Improvement Program between 2007 and 2009, the 30-day mortality associated with lower extremity bypass was 1.8%.[107] The incidence of nonfatal cardiac complications is higher. In a cohort of 2907 patients who underwent lower extremity bypass in New England between 2003 and 2007, cardiac complications occurred in 7.2%.[62]

TABLE 105.4 Morbidity After Infrainguinal Bypass for Claudication and Chronic Limb-Threatening Ischemia

	First Year	3-5 Years
Time for healing	15-20 weeks	—
Wound complications (%)	15-25	—
Persistent lymphedema (%)	10-20	Unknown
Graft stenosis (%)	20	20-30
Graft occlusion (%)	10-20	20-40
Major amputation (%)	5-10	10-20
Graft infection (%)	1-3	—
Perioperative death (%)	1-2	—
All death (%)	10	30-50

Several other complications, both local and systemic, have been well described (Table 105.4). These are discussed, as well as recommendations for preoperative risk assessment, in Chapter 32 and Section 7.

Beyond the risk of perioperative complications, the likelihood a patient will derive mid- to long-term benefit from an open revascularization must be included in the decision-making process. Several studies have sought to characterize risk factors for poor outcomes after open bypass. Among those with CLTI, several predictors of reduced AFS are well established (Table 105.5). Although many of these are comorbid conditions such as advanced age and chronic kidney disease, others are elements of functional status, such as preoperative ambulation or independent living. In addition, prior contralateral major amputation has been shown to predict worse outcomes after open bypass.[108] Although none of these studies identifies a single risk factor that is prohibitive for open bypass, for patients who present with a constellation of risk factors, including impaired functional status, the likelihood of long-term benefit from revascularization is reduced.

RISK PREDICTION MODELS

Decision making in lower extremity PAD requires a highly individualized approach based on a number of preoperative factors. Several risk prediction models have been developed to aid in patient-specific risk stratification. These tools use statistical modeling based on patient data to identify predictors of a specific outcome, then apply a weighting system to them, such that a score may be given that corresponds to a likelihood of that outcome. For an individual patient, the score is based on the presence or absence of these factors. The sum then corresponds to a risk category, derived from the statistical modeling. The performance of the risk score can be assessed by tests of discrimination and calibration and should ideally be validated using data from another cohort of patient data. An ideal risk score uses easily obtainable and clearly defined factors that are available preoperatively. This allows the surgeon to calculate the score and offer a bedside risk prediction. However, it is important to note that these risk scores are derived using a specific endpoint, at a specific point in time, and therefore should similarly be narrowly applied. When used properly, risk scores provide evidence-based risk stratification, individualized to each patient. Several scores have been described; they differ slightly in the outcome they predict, and the time point at which the outcome is predicted.[109-112] In addition, some have been externally validated in additional patient cohorts and have been tested using new endpoints. There is some commonality among the most widely recognized grading systems (Table 105.6), and some important differences described in more detail in later sections. However, it is important to note that prediction models complement clinical judgment rather than replace it, and more research is needed to optimize these models. In particular, some have suggested that future study should incorporate clinical inputs beyond those used in the models described later, such as the degree of ischemia, extent of tissue loss, and presence of infection.[113]

ANGIOGENESIS FOR PERIPHERAL ARTERIAL DISEASE

For patients with CLTI who lack a revascularization option, novel alternative therapies may offer benefit. Angiogenesis is a naturally occurring phenomenon in response to tissue ischemia and is promoted by proangiogenic factors, including VEGF, fibroblast growth factor, hypoxia-inducible factor-1α, and hepatocyte growth factor[114,115] Following the first case report using VEGF in a human subject by Isner and colleagues in 1996,[116] the modulation of growth factors to stimulate angiogenesis has become an area of interest in the treatment of lower extremity PAD, particularly in patients who are not candidates for surgical or interventional techniques. The concept of therapeutic angiogenesis entails efforts to increase the concentration of proangiogenic factors, thereby stimulating growth of new blood vessels from preexisting blood vessels to treat ischemic disease; this may be accomplished by administration of recombinant proteins or gene therapy that induces overexpression of these factors.[114,117] Therapeutic angiogenesis may also be induced by implantation of stem cells and endothelial progenitor cells. Both bone marrow–derived and peripheral blood–derived stem cells have been studied for their utility in stimulating vasculogenesis; both intraarterial and intramuscular techniques have been studied. The putative concept by which angiogenesis improves limb perfusion is through the enlargement of collateral blood vessels and possible direct stimulation of wound healing by growth factors. Preclinical animal models, such as the rabbit hind limb ischemia model, have clearly shown that angiogenic gene therapy can improve limb perfusion compared with placebo-treated animals. Growth factors act as mitogens that stimulate endothelial cell proliferation in response to local tissue ischemia, but the mechanism has not been completely

TABLE 105.5 Recent Studies Identifying Independent Predictors for Select Outcomes in Patients With Chronic Limb-Threatening Ischemia

delineated.[118] Several studies of therapeutic angiogenesis have now been conducted, including phase III clinical trials.[119-124]

Overall, the data have failed to demonstrate a consistently significant clinical benefit for any of these therapies. Results of several phase II and III clinical trials are summarized in Table 105.7.[117b-117c]

Future Developments

Alternative strategies for the pharmacologic treatment of vascular disease are under investigation, including those aimed at the neovascularization of ischemic tissue and the prevention of intimal hyperplasia. Similar to other fields, such as oncology, the mapping of the human genome promises to advance therapeutic approaches to the treatment of lower extremity PAD. Several target genes and small molecules that are regulated by oxygen tension have been implicated in stimulating angiogenesis via the hypoxia-inducible factor pathway; research is ongoing to define the therapeutic potential of prolyl-4-hydroxylase inhibitors, mediators of the thioredoxin systems, the peroxisome proliferator-activated receptor gamma coactivator 1-α protein, microRNAs, and oligonucleotides.[125] Therapeutic ultrasound has also been investigated in mouse models of hind limb ischemia for the potential to stimulate neovascularization via multiple angiogenic pathways.[126] Investigations of immune modulation therapy, targeting the inflammatory component of vascular disease in an effort to decrease the development and progression of atherosclerosis and possibly angioplasty-associated intimal

TABLE 105.7 Summary of Phase II and III Trials of Molecular and Cellular Proangiogenic Agents in Patients With Peripheral Artery Disease

Trial	Therapy	Population	Result
Growth Factors			
Rajagopalan et al. (RAVE) 2003[126a]	VEGF	105 patients with disabling claudication	No difference in walking distance or quality of life
Kusumanto et al. 2006[126b]	VEGF	54 patients with diabetes and critical limb ischemia	No difference in amputation rate at 100 days
Nikol et al. (TALISMAN) 2008[126c]	FGF	125 patients with critical limb ischemia	No difference in ulcer healing at 25 weeks
Powell et al. (HGF-STAT) 2008[126d]	HGF	104 patients with critical limb ischemia	No difference in adverse event rates; no difference in major amputation or death at 6 months
Shigematsu et al. (TREAT-HGF) 2010[126e]	HGF	40 patients with critical limb ischemia	Significant improvement in rest pain or ulcer size at 12 weeks (70.4% HGF versus 30.8% placebo, $P = .014$)
Belch et al. (TAMARIS) 2011[126f]	FGF	525 patients with critical limb ischemia	No difference in major amputation or death at 1 year
Stem Cells			
Walter et al. (PROVASA) 2011	BMMNC	40 patients with critical limb ischemia	No difference in ABI or major amputation at 3 months
Powell et al. (RESTORE-CLI) 2012	BMMNC (Ixmyelocel-T)	77 patients with critical limb ischemia	No difference in amputation-free survival at 12 months
Teraa et al. (JUVENTAS) 2015	BMMNC	160 patients with severe limb ischemia	No difference in major amputation at 6 months

hyperplasia, are encouraging. Other areas of research aimed at advancing our understanding of vascular disease include viral-directed gene transfer, targeted antibiotic therapy, and alternative circulating cell–free oxygen delivery vectors.

Future Trends

Decision Analysis

Decision analysis is a field of study that applies statistical methods and probabilities from existing literature to model various hypothetical outcomes for a given set of competing options.[127] Decision analysis begins with identifying a problem for which there is more than one potential solution. A decision tree is then constructed that incorporates a valuation of any number of factors that would influence the decision, along with the likelihood of each branch along the decision tree occurring, such that the outcome associated with several different choices can be simulated. Rather than just imagining the outcome associated with different choices, decision analysis allows for predictions of outcomes, based on input data from the existing literature. Decision analysis is often applied to clinical scenarios where randomized controlled trials of competing therapies cannot be carried out. It often incorporates factors such as cost and QoL associated with various treatment options. One of the most important roles of model-based decision analysis is to identify which data parameters or assumptions can change policy decisions. This is done through sensitivity analysis, in which each parameter is varied through a wide range of possible values. If this variation does not lead to a change in policy conclusions, one can feel confident that the results of the analysis are likely to hold true in most clinical scenarios. Conversely, if an uncertain parameter is found to be influential, this may identify an important area for future research. Decision analysis can play an important role in clinical decision making in the treatment of PAD.

Brothers and colleagues used decision analysis to assess three different strategies for the management of CLTI: primary amputation, revascularization, or expectant management (Fig. 105.4).[128] They found that revascularization was associated with a gain of 1.1 quality-adjusted life years (QALYs) compared with primary amputation and 1.2 QALYs compared with expectant management. In terms of cost associated with the three treatment strategies, sensitivity analysis predicted revascularization to be the least costly treatment per QALY, as long as 1-month patency exceeds 11%. The authors conclude that revascularization offers the greatest benefit in terms of QALY and cost in the management of CLTI.

Nolan and colleagues applied decision analysis to treatment of claudicants with TASC B and C lesions of the superficial femoral artery.[129] Using a hypothetical cohort of claudicants with either TASC B or C lesions, they modeled treatment with either angioplasty and stenting or great saphenous vein bypass for the outcome measure of QALYs. They found that TASC B lesions were best treated with angioplasty and stenting. However,

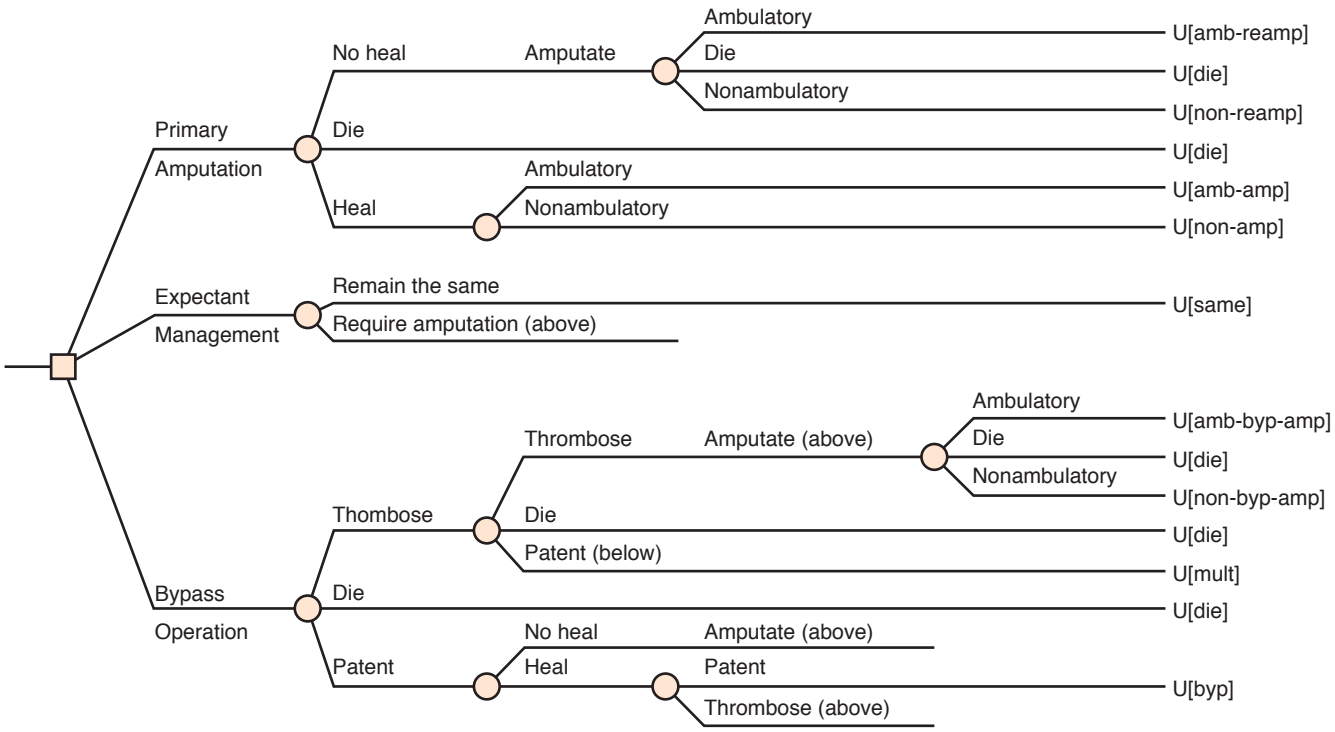

Figure 105.4 Decision tree of principal management options for patients with critical limb ischemia. Square nodes represent a decision point and round nodes represent a probability of an event occurring based on existing literature. The outcomes, which in this study are utility values (translated into quality-adjusted life years [QALYs]), are designated with the following abbreviations: *byp*, success after revascularization; *mult*, success after multiple revascularizations; *amb-amp*, ambulatory after amputation; *non-amp*, nonambulatory after amputation; *amb-reamp*, ambulatory after reamputation; *non-reamp*, nonambulatory after reamputation; *amb-by*, ambulatory after amputation following failed revascularization; *non-byp-amp*, nonambulatory after failed revascularization and amputation; *same*, condition remains the same; *die*, death occurs. (From Brothers TE, et al. Justification of intervention for limb-threatening ischemia: a surgical decision analysis. *Cardiovasc Surg*. 1999;7:62–69.)

for patients with TASC C lesions, angioplasty and stenting was preferred only in certain conditions. Using sensitivity analyses, they showed that stenting surpasses efficacy of open bypass for TASC C lesions if the primary patency of stenting is greater than 32% at 5 years, if patient age is greater than 80 years, or if operative mortality for open bypass exceeds 6%.

Cost-effectiveness analyses are another type of decision analysis with several applications in healthcare research, and clinical decision making in PAD. Barshes and colleagues recently published a review of the methods of cost-effectiveness analysis, anticipating their increased utility as a healthcare financial crisis looms in the United States (Fig. 105.5).[130] We believe that decision analysis and cost-effectiveness analyses will play a growing role in informing decision making in PAD in the coming years.

Cost Considerations

As healthcare costs continue to rise, decision making will increasingly be influenced by governmental and third-party payers. There is conflicting evidence regarding the most cost-effective methods of treating lower extremity PAD. Although there is evidence that revascularization is cost-effective compared with primary amputation,[86,131-134] the cost differential between strategies varies depending on the expense of rehabilitation after primary amputation in most series.[132] Indeed, primary amputation for patients forgoing rehabilitation (as might occur in a nursing-home patient) is cheaper than revascularization. Therefore economic decision-making depends on the patient's postoperative rehabilitation potential, which is often determined by preoperative functional status.[77] Despite the debate concerning the economic merits of one treatment over another, most would agree that the current financial system can ill afford to pay for multiple revascularizations of a single ischemic limb. The scenario becomes even more cost-prohibitive if, after multiple revascularizations, major limb amputation results anyway. Future economic decision making will therefore require the identification of the most cost-effective single treatment for patients who present with PAD and, more specifically, CLTI.

Unmet Needs

Definitive high-level evidence on which to base treatment decisions, with an emphasis on clinical and cost effectiveness, continues to be lacking. Treatment decisions in PAD are individualized, based on life expectancy, functional status, anatomy of the arterial occlusive disease, and surgical risk. For patients with aortoiliac disease, endovascular therapy has become first line therapy for all but the most severe patterns of occlusion, and aortofemoral bypass surgery is a highly effective and durable

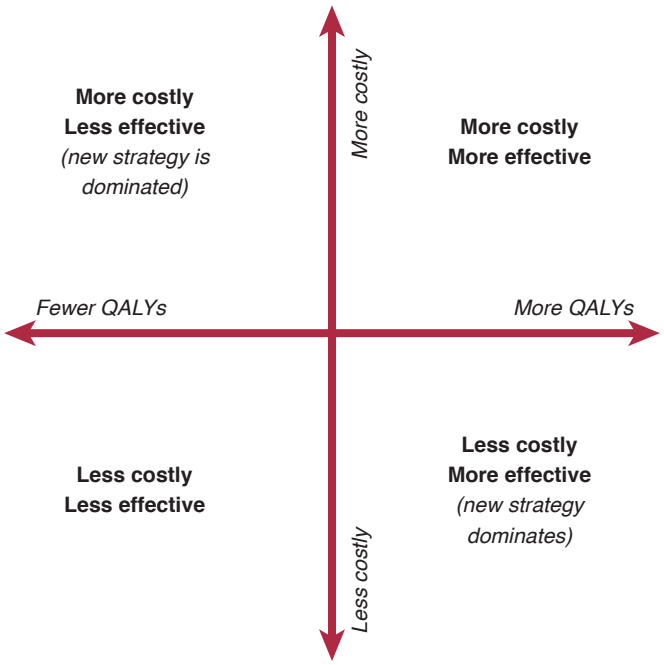

Figure 105.5 Two-dimensional plane demonstrating the relationship of incremental costs *(vertical axis)* and incremental effectiveness *(horizontal axis)* for two possible interventions. If a new intervention is both more costly and less effective than a current intervention *(upper left quadrant)*, it is not economically preferred. If a new intervention is less costly and more effective *(lower right quadrant)*, it is economically preferred. Formal cost-effectiveness analysis is useful for situations described by the upper right and lower left quadrants. Most frequently, a cost-effectiveness analysis focuses on the upper right quadrant to address the question of whether the more effective treatment is "worth" its greater cost. *QALYs*, Quality-adjusted life years. (From Barshes NR. A primer on cost-effectiveness analyses for vascular surgeons. *J Vasc Surg*. 2012;55(6);1794–800.)

treatment for the latter group. For infrainguinal disease, available data suggest that surgical bypass with vein is the preferred therapy for patients likely to survive 2 years or more, and for those with long segment occlusions or severe infrapopliteal disease who are acceptable surgical risk. Endovascular therapy may be preferred in patients with reduced life expectancy, those who lack usable vein for bypass or who are at elevated risk for operation, and those with less severe arterial occlusions. Patients with nonreconstructable disease, extensive necrosis involving weight bearing areas, nonambulatory status, or other severe comorbidities may be considered for primary amputation or palliative measures. Given the myriad of contributing factors, each with its own extensive list of possible values, the possible combinations of disease states and patient situations are perhaps too numerous to ever study individually. A "clean" study, comparing two treatments in a population that is balanced on all factors may not be achievable, even in the best of randomized controlled trials. Despite herculean efforts on the part of the BASIL-2 and BEST-CLI investigators, it stands to be determined whether either of these studies will ultimately provide conclusive enough evidence that providers feel these questions of optimal treatment have been answered once and for all.

Third-party payers in our current healthcare system will increasingly insist on the delivery of evidence-based care. Quality will be defined, increasingly monitored, and financially linked to compliance with Medicare All-Care measures. Care for lower extremity PAD will increasingly become protocol driven, placing a premium on value and durability. For all of the important reasons previously mentioned, future studies should continue to analyze the impact of comorbidities in patients with PAD. These studies need to be conducted in patients undergoing surgical bypass, endovascular repair, primary amputation, and conservative treatment because the effect of comorbidities can be very different based on the treatment type. A diverse set of standardized endpoints that attempt to capture the diverse experience relevant to patients with PAD needs to be defined. The time points at which these endpoints are studied also should be standardized. In this way, valid risk estimates can continue to inform the way we take care of patients and, in doing so, improve evidence-based patient care. Finally, the definitive treatment of lower extremity PAD has traditionally relied on procedural therapy, either open or endovascular revascularization. We are now at an exciting time point where mapping of the human genome, improved understanding of angiogenesis, and the growing ability to manipulate stem cell differentiation all hold great promise in providing meaningful medical solutions that may render many interventions unnecessary or render them more effective.

SELECTED KEY REFERENCES

Bradbury AW. BASIL Trial Participants. Bypass versus angioplasty in severe ischemia of the leg (BASIL): multicenter, randomized controlled trial. *Lancet*. 2005;366:1925–1934.

This rare randomized controlled multicenter trial concluded that surgery and angioplasty have similar amputation-free survival at 6 months (thus favoring angioplasty as the best first approach), but surgery has better amputation-free survival after 2 years. This study stressed the complementary nature of the two treatment approaches.

Conte MS, Bandyk DF, Clowes AW, et al. Results of PREVENT III: A multicenter, randomized trial of edifoligide for the prevention of vein graft failure in lower extremity bypass surgery. *J Vasc Surg*. 2006;43:742–751.

This large, multicenter trial evaluated the efficacy of edifoligide for the prevention of vein graft failure for patients who underwent lower extremity bypass for critical limb ischemia. Although it found no significant benefit associated with the drug, this cohort represents the largest and most extensively followed prospective dataset of patients with critical limb ischemia. As such, it has formed the basis for several other significant studies in this patient population.

Conte MS, Pomposelli FB, Clair DG, et al. on behalf of the Society for Vascular Surgery Lower Extremity Guidelines Writing Group. Society for Vascular Surgery practice guidelines for occlusive disease of the lower extremities: Management of asymptomatic disease and claudication. *J Vasc Surg*. 2015;61:2s–41s.

The Society for Vascular Surgery Lower Extremity Guidelines Writing Group reviewed the current evidence supporting clinical care in the management of asymptomatic peripheral artery disease and intermittent claudication. Although first acknowledging the paucity of level 1 evidence, the group recommended revascularization for claudication "in selected patients with disabling symptoms, after a careful risk-benefit analysis." They also determined that there was inadequate evidence to support screening for peripheral artery disease in asymptomatic patients.

Goodney PP, Schanzer A, Demartino RR, et al. Vascular Study Group of New England. Validation of the Society for Vascular Surgery's objective performance goals for critical limb ischemia in everyday vascular surgery practice. *J Vasc Surg*. 2011;54(1):100–108, e4.

The Society for Vascular Surgery developed objective performance goals (OPGs), as standardized metrics for expected outcomes in lower extremity revascularization for critical limb ischemia (CLI), based on aggregate data from randomized trials of lower extremity bypass. In response to this, the authors sought to confirm the validity of these targets in everyday vascular surgery practice using a large, regional database. They concluded that these OPGs are feasible, and endorsed the use of such benchmarks for quality improvement initiatives, clinical trials, and comparisons of risk-adjusted outcomes in the treatment of CLI.

Mills JL, Conte MS, Armstrong DG, et al. on behalf of the Society for Vascular Surgery Lower Extremity Guidelines Committee. The Society for Vascular Surgery Lower Extremity Threatened Limb Classification System: Risk stratification based on wound, ischemia, and foot infection. *J Vasc Surg*. 2014;59:220–234.

The Society for Vascular Surgery Lower Extremity Guidelines Committee created a classification scheme for limb threat that reflects the contribution that diabetes mellitus plays in limb threat, as well as the expanded range of current techniques for revascularization in comparison to the previously established systems. This WIfI score was intended "to permit more meaningful analysis of outcomes for various forms of therapy in this challenging, but heterogeneous population." WIfI assigns a score to grade the severity and extent of the wound, ischemia, and foot infection. The resultant score corresponds to four threatened limb clinical stages that estimate risk of amputation and potential benefit of revascularization.

Norgren L, Hiatt WR, Dormandy JA, et al. Inter-Society Consensus for the Management of Peripheral Arterial Disease (TASC II). *J Vasc Surg*. 2007;45(supplS):S5–S67.

The TASC II document updates TASC and represents the latest evidence-based data on the natural history and treatment of lower extremity PAD.

Taylor SM, Kalbaugh CA, Blackhurst DW, et al. Determinants of functional outcome after revascularization for critical limb ischemia: an analysis of 1000 consecutive vascular interventions. *J Vasc Surg*. 2006;44:747–756.

Although retrospective, this large series demonstrated that functional performance after intervention for CLI is often determined by factors other than limb salvage. Postoperative functional outcomes were most profoundly impacted by the patient's preoperative medical condition and functional status.

Atherosclerotic disease of the abdominal aorta and iliac arteries is one of the most common therapeutic challenges encountered by vascular surgeons. The British anatomist and surgeon John Hunter first appreciated the implications of aortic bifurcation occlusive disease in the late 1700s. His dissection specimens remain on view at the Hunterian Museum in London and laid the groundwork for Leriche's later appreciation of the disease process that bears his name.[1] The modern era of surgical reconstruction for complex atherosclerotic occlusive disease began in 1947 with the successful endarterectomy of a heavily

Abstract

Aortoiliac occlusive disease may present with a variety of symptoms, ranging from claudication to critical limb ischemia. Diagnosis may be made by history and physical with noninvasive hemodynamic studies and supplemented typically by axial imaging. The most common options for inline treatment are aortoiliac endarterectomy, which is rarely performed, and aortobifemoral bypass. The latter operation has an excellent long-term patency and is well-tolerated in appropriately selected patients.

diseased common femoral artery (CFA) by Portuguese surgeon dos Santos.[2] Wylie et al.[3] in San Francisco extended this new technique to the aortoiliac (AI) level 4 years later, but it would be another 10 years before synthetic grafts were regularly used for aortic bypass grafting. Early preference for aorta-to-iliac artery grafting would eventually be supplanted by the more durable aortobifemoral bypass (ABFB) procedure.

In recent years, advances in our understanding of the biology of atherosclerosis and in our ability to treat arterial occlusive disease percutaneously have had a dramatic impact on the treatment algorithms for peripheral artery disease (PAD) as a whole and for aorto-iliac occlusive disease (AIOD) in particular. The growing range of treatment options allows us to tailor therapy to the particular clinical situation, and ongoing improvements in graft material, surgical technique, and perioperative management have contributed to a steady decline in postoperative morbidity and mortality. Given the advent of less invasive therapeutic options, traditional aortobifemoral grafting is increasingly being performed for more complex patterns of disease or as a secondary or tertiary procedure in the setting of recurrent disease.[4] High levels of patient satisfaction and excellent long-term outcomes, however, remain the hallmark of aortobifemoral surgical revascularization. This chapter reviews the role of direct operative reconstruction in the current surgical management of AIOD.

PATHOLOGY AND CLINICAL PRESENTATION

Pathology

AIOD typically begins at the aortic terminus and common iliac artery origins and slowly progresses proximally and distally.[5] Progression is variable but may ultimately result in total aortic occlusion (Fig. 106.1). When collaterals are adequate, claudication symptoms are often tolerable and can be successfully managed nonoperatively for many years. Approximately one-third of patients operated on for symptomatic AIOD have significant orificial profunda femoris occlusive disease, and more than 40% have significant superficial femoral artery (SFA) disease. Disease can also extend to the level of the renal arteries (see Fig. 106.1). Although early reports indicated that up to one-third of patients with aortic occlusion went on to develop renal artery thrombosis during a period of 5 to 10 years,[6] later prospective studies failed to confirm this observation.[7] Renal or mesenteric arterial involvement sufficient to warrant concurrent repair is seen in only a minority of patients with AIOD.

Collateral Circulation

Although focal AI atherosclerotic disease commonly gives rise to claudication of varying degrees, it is rarely associated with chronic limb threatening ischemia (CLTI). This is largely the result of abundant collateralization around the point of obstruction, which reconstitutes the infrainguinal system with sufficient flow to ensure adequate resting tissue perfusion (Fig. 106.2).

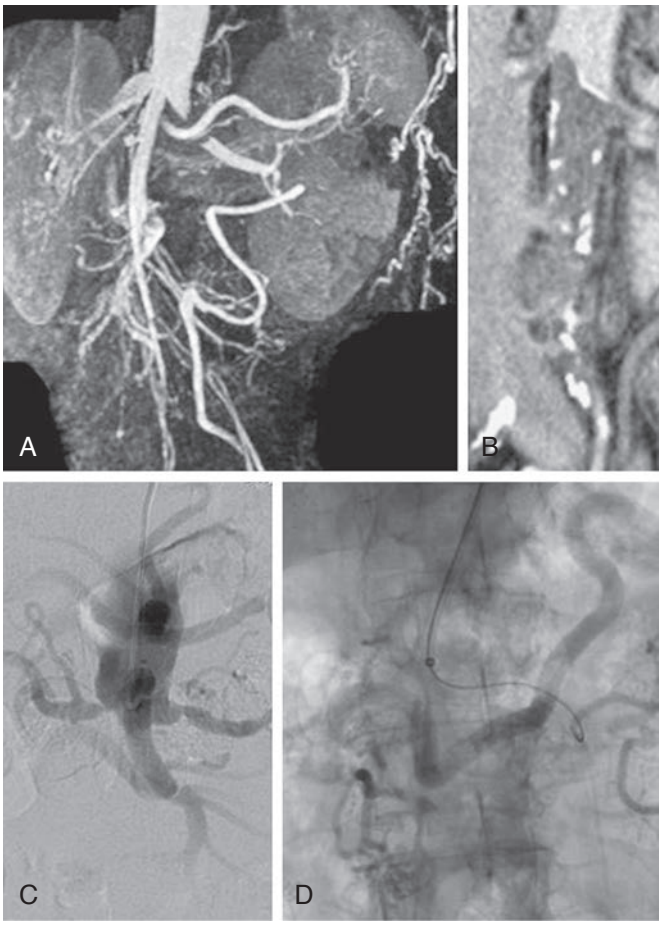

Figure 106.1 Two patients with total aortic occlusion extending to the level of the renal arteries. (A and B) Coronal computed tomography images in one patient demonstrate propagation of thrombus into the renal arteries *(arrow)*. (C and D) The second patient also has associated renal artery occlusive disease. Meandering mesenteric arteries are demonstrated in both patients.

The primary compensatory networks develop from the lumbar and hypogastric feeding vessels and connect to circumflex iliac, hypogastric, femoral, and profunda recipients. Additional collaterals that arise in more severe cases include the internal mammary artery–to–inferior epigastric connection and the superior mesenteric artery–to–inferior mesenteric artery and hemorrhoidal artery pathway. The latter connection comprises the arc of Riolan and the meandering mesenteric artery (Fig. 106.3); it is important to recognize the presence of such a large and significant collateral because it should be preserved during surgical reconstruction.

Epidemiology

The majority of patients presenting today with AIOD have diffuse disease at multiple levels of the vascular tree; in most cases, AIOD is found in combination with femoropopliteal or infrageniculate occlusive disease. Patients with isolated AIOD are generally younger, have a higher relative prevalence of smoking and hypercholesterolemia,[8] are nearly as likely to be female as male, and typically have a normal life expectancy.[9]

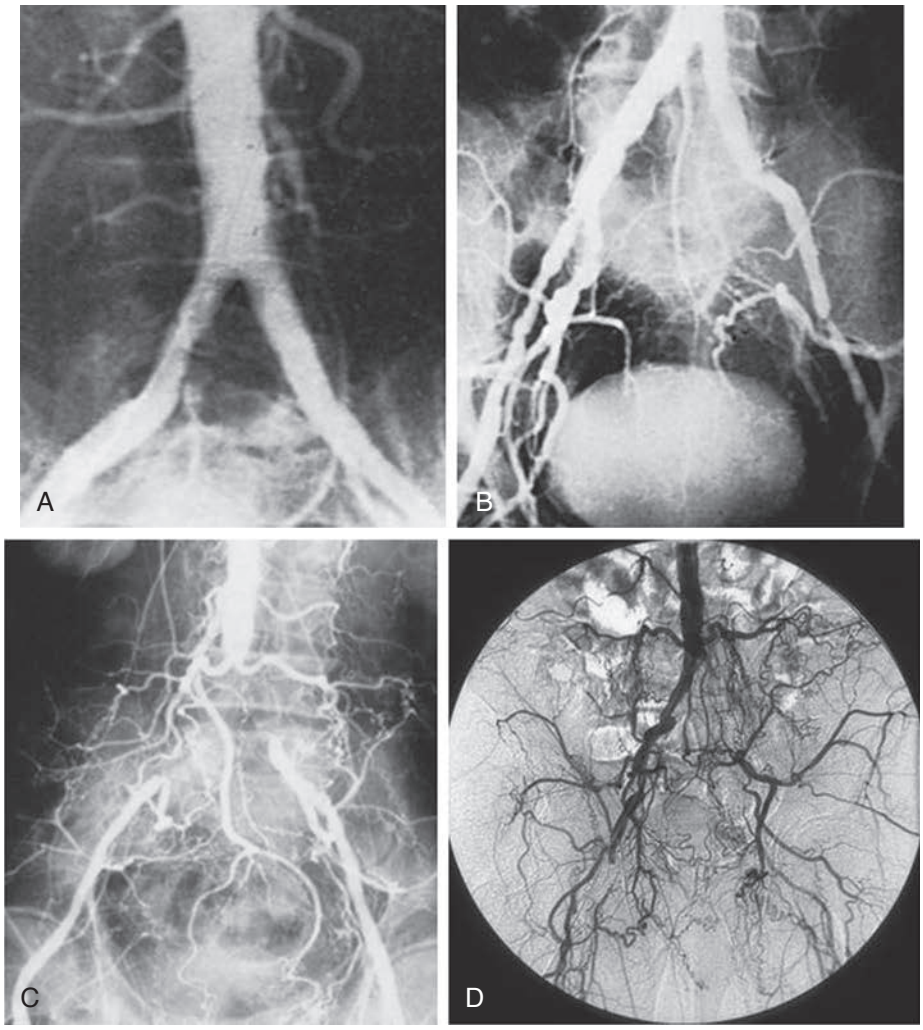

Figure 106.2 (A to D) Aortoiliac occlusive disease of increasing severity, with a progressively well-developed pattern of iliolumbar to hypogastric and femoral circumflex collateralization. Male patients with a disease distribution illustrated in B to D may be impotent secondary to compromised hypogastric perfusion.

In contrast, patients with more extensive multilevel disease are commonly older, more frequently have diabetes and hypertension, and are more likely to be male and to have concomitant cerebrovascular, coronary, and visceral atherosclerosis.[8] Not surprisingly, patients with diffuse, multisegmental disease often present with ischemic rest pain or more severe perfusion impairment, leading to tissue loss or gangrene as opposed to isolated claudication.[10] Such patients manifest a significant reduction in life expectancy compared with their age-matched counterparts.[9]

A particularly virulent form of atherosclerotic disease is often found in young women who smoke.[11,12] Radiographic imaging in this subset of patients typically reveals atretic, narrowed vasculature with diffusely calcific atherosclerotic changes. Frequently, a focal stenosis is found posteriorly at or proximal to the aortic bifurcation (Fig. 106.4). This disease distribution and characteristic patient profile have been termed *small aortic syndrome* or *hypoplastic aortic syndrome*.[13] Such patients invariably have an extensive smoking history but may lack other typical risk factors for atherosclerosis. The diminutive size of the aorta and iliac vessels has important treatment implications in such patients; the durability of endovascular intervention or local endarterectomy is generally poor, particularly in the presence of continued cigarette use.

Presenting Symptoms

Chronic obliterative atherosclerosis of the distal aorta and iliac arteries commonly is manifested as symptomatic arterial insufficiency of the lower extremities, producing a range of symptoms from mild claudication to the spectrum of CLTI. Patients with hemodynamic impairment limited to the AI system may have intermittent claudication of the calf muscles alone or involvement of the thigh, hip, or buttock; patients with CLTI usually have multilevel disease of the AI and infrainguinal arteries. Those presenting with claudication secondary to AIOD are, on average, nearly a decade younger than those with claudication stemming from infrainguinal occlusive disease.[11] Up to 30% of affected men may have difficulty achieving and maintaining an erection owing to inadequate perfusion of the internal pudendal arteries.[14] In men, the well-characterized constellation of symptoms and signs known as Leriche syndrome, associated

with terminal aortic occlusion, includes claudication (thigh, hip, or buttock), atrophy of the leg muscles, impotence, and reduced femoral pulses.[15] The equivalent impact of impaired pelvic perfusion in women remains poorly understood but has attracted investigative attention.[16]

DIAGNOSIS

History and Physical Examination

The diagnosis of AIOD can usually be made after a careful history and physical examination. In a patient with multiple vascular risk factors, claudication, and absent femoral pulses, the diagnosis of AIOD is straightforward. In other patients, symptoms of claudication can sometimes be difficult to distinguish from those of hip arthritis or nerve root irritation due to lumbar disk disease or spinal stenosis.[17]

The variability of presenting signs and symptoms in patients with AIOD may cause diagnostic confusion. Although proximal claudication is most common, patients with AIOD in isolation or those with combined infrainguinal disease may present exclusively with calf claudication. Although the involved muscle groups may be atrophic from disuse in claudicants, the lower extremities frequently appear well perfused at rest. Femoral and even pedal pulses may be palpable at rest, reflecting the presence of robust collateral networks; pulses may diminish or become absent only after exercise. Similarly, a palpable thrill or audible bruit at the lower abdominal or groin level may only become detectable after exertion. Conversely, femoral bruits or diminished femoral pulses arising from CFA or profunda femoris stenoses can mistakenly be attributed to AI inflow disease.

Noninvasive Hemodynamic Assessment

Noninvasive arterial segmental systolic blood pressure measurements and pulse volume recordings can help confirm a clinical diagnosis of PAD and define the level and degree of obstruction (see Chapter 18).[18] A resting difference of 20 mm Hg systolic or greater between the brachial and the proximal thigh pressures reflects a significant stenosis in the aorta or iliac arteries, but it may be confounded by proximal SFA occlusion. A further reduction in pressure between the thigh and ankle level suggests concomitant femoropopliteal or tibial outflow disease. In patients with disabling symptoms with normal or near-normal resting ankle-brachial indices, repeating measurements after provocative graded exercise treadmill testing can be particularly useful if there is still clinical suspicion of AIOD. A careful history and physical examination combined with noninvasive hemodynamic studies usually provide sufficient data to establish the diagnosis. Further imaging is warranted only after risk/benefit assessment and the clinical decision to intervene has been reached.

Diagnostic imaging modalities that also facilitate revascularization planning include duplex ultrasound and axial imaging in the form of computerized tomographic angiography (CTA), magnetic resonance angiography (MRA), and arteriography; this topic will be discussed in Chapter 105.

INDICATIONS FOR SURGICAL INTERVENTION

Impact of Endovascular Treatment

A significant paradigm shift has occurred in the treatment of PAD.[17,19] Angioplasty and stenting have become first-line therapy for most patients with AI, renal, subclavian, and coronary occlusive disease.[20] Whereas percutaneous treatment of the aorta and iliac arteries was previously limited to short-segment, TransAtlantic Inter-Society Consensus (TASC) type A or B iliac lesions, it is now routinely applied to even long-segment (TASC type D) occlusions extending the length of the iliac arteries. In no other vascular territory has the shift from open surgery to interventional treatment been more apparent than in the AI segment. Using the Nationwide Inpatient Sample, one report documented an 850% increase in the use of percutaneous transluminal angioplasty and stenting for AIOD from 1996 to 2000, along with a simultaneous decrease of 16% in the rate of aortobifemoral grafting.[20] Further reflecting this transformation in management strategy, in anatomically favorable circumstances, concomitant renal or mesenteric artery stenosis might be treated percutaneously as a staged initial procedure, even when subsequent open surgical AI reconstruction is planned.[21] Decision making for surgical versus endovascular treatment is discussed in detail in Chapter 105.

In the current era, in which direct reconstruction for AIOD has been relegated to a second- or even third-line therapy, open bypass is increasingly undertaken in patients in whom endovascular treatment has failed or in those with such extensive disease that an endovascular approach is deemed inadvisable. This paradigm shift has been reflected in reports documenting the increasing complexity of aortobifemoral grafting, with a higher incidence of suprarenal clamping, adjunctive visceral revascularization, simultaneous operative inflow and outflow disease, and repeated grafting.[4,22] Patients with a combination of more proximal aneurysmal disease and common or external iliac occlusive disease continue to be good candidates for open reconstruction, although this group will continue to diminish with ongoing technologic advancements. Even patients with extensive calcification at the aortic bifurcation thought to be at risk for rupture with balloon angioplasty or those with disease extending to the CFA are no longer considered unsuitable for an endovascular approach. The incidence of rupture has proved low in the former group, and the introduction of low-profile covered stents and techniques of primary stenting is likely to further increase the safety of endovascular treatment in this setting. The latter patient subgroup can be managed with a hybrid approach, whereby the CFA plaque is treated with a traditional endarterectomy and patch repair and the iliac component is concurrently addressed with endovascular techniques.[23]

Patients with early recurrence of AIOD after angioplasty or stenting represent a growing group for whom open surgical repair may be indicated. Patients with significant renal failure in whom endovascular therapy entails a prohibitive risk of triggering dialysis dependence may also be considered better suited for operative repair. Complications of endovascular treatment, including dissection and vessel rupture, are infrequent indications for surgical reconstruction.

Claudication

The traditional indications for surgical reconstruction for symptomatic AIOD are disabling claudication, ischemic rest pain, and tissue loss. Claudication is a relative indication for intervention, given the natural history of the disease. Multiple reports, among them the Framingham Heart Study, indicate that patients with claudication have increased rates of cardiovascular mortality but an overall low risk of associated limb loss.[5,24] The majority of claudicants demonstrate a stable pattern of disease throughout their lifetimes or have an improvement in symptoms as a result of risk factor modification, whereas 20% to 30% require operation within 5 years as a result of disease progression. The annual rates of mortality and limb loss in patients with claudication have historically been reported as 5% and 1%, respectively.[25] Some have suggested that claudicants with AIOD are more likely to progress to CLTI.[26] In any case, the degree of disability that a particular level of claudication represents remains a subjective assessment by both the patient and the surgeon. As the associated risks of AI balloon angioplasty and stenting have fallen and the relative success rates have risen in recent years, the threshold for offering endovascular treatment to claudicants at all points along the clinical spectrum has significantly decreased. Indeed, patients once considered appropriate only for risk factor modification, exercise therapy, and medical treatment are now increasingly being offered percutaneous revascularization as a primary treatment option. Balloon technology is also increasingly being applied to hypogastric arterial disease, primarily for buttock or hip claudication, to a degree not previously seen and not paralleled by an increase in surgical revascularization.[27]

The indications for surgical reconstruction for claudication have not shifted appreciably during this same period. Given its relatively benign natural history, conservative treatment continues to be appropriate for many patients with claudication. In contrast to patients with CLTI, it has been argued that an overly aggressive approach might place patients without limb-threatening conditions at unnecessary risk for adverse outcomes. The majority of claudicants remain stable for years, allowing time for collateral pathways to develop; this often results in sufficient improvement, making intervention unnecessary.[28] On the other hand, in patients of low surgical risk with disabling symptoms from disease limited to the aortobifemoral segment, surgical bypass is an appropriate option. With current levels of perioperative morbidity and mortality, bypass can be undertaken safely and with the expectation of excellent long-term patency.

Chronic Limb-Threatening Ischemia

Although broad in spectrum, CLTI is associated with a more significant risk of amputation without revascularization. As such, the presence of ischemic rest pain, frank ulceration, or digital

gangrene are well-accepted indications for surgical correction of AIOD. Patients with pregangrenous skin changes or frank gangrene typically have hemodynamically significant infrainguinal as well as AIOD.[10] Thus, whereas patients treated for claudication or rest pain usually require only a single-stage inflow operation, simultaneous or staged inflow and outflow revascularization should be considered in patients with tissue loss (see under the section Multilevel Occlusive Disease).

Patients with an aortic or iliac source of distal emboli, typically from an ulcerated atheromatous plaque or so-called shaggy aorta, represent another group in which operative reconstruction is usually indicated.[29] Such patients may lack symptoms of claudication, and the culprit lesion(s) may not be hemodynamically significant. In these cases, the goal of intervention is to prevent recurrent distal embolization.

Studies have documented the generally excellent outcomes of aortobifemoral grafting in elderly patients, suggesting that in older patients who are otherwise good surgical risks, surgical therapy should not be withheld.[30] Conversely, lower long-term patency rates with aortic bypass in younger patients or those with small aortic diameters suggest caution for considering early surgical intervention in such patients.[30]

SURGICAL TREATMENT

The modern therapeutic armamentarium for treatment of PAD is barely half a century old. Its development has been marked by several landmark advances, among them the discovery of the anticoagulant heparin by Best in the early 1930s, the advent of arteriography in 1927, the first application of arterial homografts by Gross in 1948 and prosthetic grafts by Voorhees in 1952, and the introduction of balloon angioplasty by Gruntzig in 1974 and of stenting by Puel and Sigwart in 1986. Continual improvements in surgical instrumentation and suture materials to facilitate vascular reconstruction and general advances in perioperative management, including cardiopulmonary care, infection control, and blood product use, have further contributed to the dramatic progress made. Historically the surgical options for AIOD included AI endarterectomy, aortobiiliac bypass, ABFB, and extra-anatomic bypass (iliofemoral, femorofemoral, or axillofemoral; see Chapter 107). Given superior long-term patency, aortobifemoral grafting is currently considered the open revascularization procedure of choice unless the patient is a poor surgical candidate.

Preoperative Preparation

Careful assessment of the factors that influence operative risk and postoperative complications is an important component of the surgical management. Patient selection should be based on an objective evaluation of the patient's comorbidities, functional limitations, and life expectancy. Particular attention should be paid to those patients with the identified risk factors of cardiac, renal, or pulmonary disease (see Chapters 42-44). Cerebrovascular, hepatic, and hematologic status should also be reviewed, with further attention given to those with a personal or family history of hypercoagulability (see Chapter 38).

In patients with known renal insufficiency, elective AI surgery should not immediately follow diagnostic angiography; if possible, it should be delayed to allow recovery from the nephrotoxic effects of contrast. Similarly, preoperative fluid status should be optimized, avoiding extremes of hypovolemia or fluid overload to minimize the risk of postoperative renal compromise or congestive heart failure. This is particularly important if concomitant renal revascularization is being considered, which necessitates a period of renal ischemia and confers additional risk in the form of potential emboli or perioperative renal hypoperfusion. Patients with significant pulmonary dysfunction can usually be identified by history and physical examination, making routine pulmonary function testing unnecessary. If compromised pulmonary reserve is present, an aggressive regimen of preoperative pulmonary rehabilitation in the form of steroid and bronchodilator therapy may be beneficial to optimize the perioperative status.[31] Smoking cessation is critical, and preoperative weight loss in obese patients is of further value in this regard. Perioperative pulmonary risk can also be reduced by the use of postoperative epidural analgesia and by strict adherence to protocols aimed at preventing postoperative deep venous thrombosis and pulmonary embolism.

Coronary Artery Disease

Nearly half of patients proceeding to surgery for AIOD have significant coronary artery disease.[32] The reduced perioperative mortality and morbidity seen with AI surgery in recent years is largely due to advances in the management of concomitant coronary disease (see Chapter 42). Specifically, better preoperative identification of the small number of patients in need of initial coronary revascularization, awareness of the benefit of a waiting period between coronary stenting and major noncoronary vascular surgery, improved perioperative pharmacologic management of patients with impaired myocardium, and more focused efforts to tailor operative and postoperative fluid administration to the individual patient's myocardial reserve are all well-recognized advances.[33,34] Nevertheless, myocardial infarction remains the leading perioperative and long-term complication of AI surgery. Although the trend has clearly swung toward less extensive preoperative cardiac evaluation, it is not unreasonable to assume that all patients undergoing AI reconstructive surgery have some degree of coronary disease and would likely benefit from basic preventive measures. The use of perioperative beta blockade in high risk patients is one example (see Chapter 42).[35] Although the administration of aspirin was routinely discontinued in the past, the cardioprotective value of continuing aspirin through the time of AI reconstruction has now been clearly documented.[36] In contrast, although lower extremity, carotid, and even coronary revascularization is increasingly being performed without discontinuation of clopidogrel, its use is still thought to be prohibitive in major aortic surgery, given the associated bleeding risk.[37,38] The use of mechanical bowel preparations and bowel-sterilizing oral antibiotics was previously common practice, but is no longer routine. Finally, all patients should receive appropriate preoperative intravenous antibiotics to ensure adequate tissue levels at the time of the skin incision.

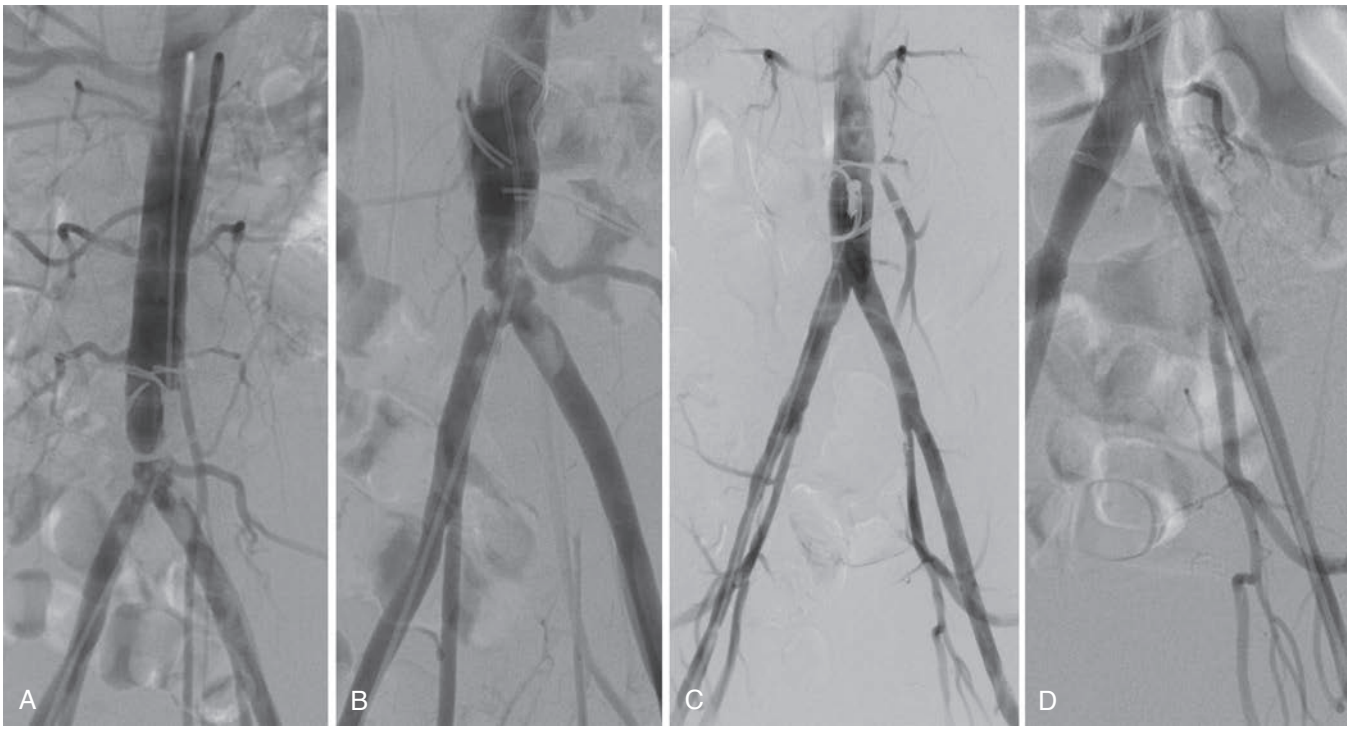

Figure 106.5 Anteroposterior (A) and left anterior oblique (B) angiographic images of bulky calcific atherosclerotic disease limited to distal aorta and proximal common iliac arteries, amenable to aortoiliac endarterectomy. Note the hypertrophic inferior mesenteric artery and iliolumbar collateral vessels. (C) Completion angiogram after distal aortic and bilateral common iliac artery endarterectomy and Dacron patch angioplasty. (D) Continued durability of result 3 years postoperatively.

Aortoiliac Endarterectomy

The first successful endarterectomy of an atherosclerotic CFA lesion by dos Santos was serendipitous, in that he had not originally intended to remove any intima or media. His success, after multiple failed attempts, was attributed to the novel use of heparin.[2] Wylie et al.[3] soon extended this technique to the AI level, and during the 1950s and 1960s, endarterectomy was the standard therapy for severe AIOD. Enthusiasm for the procedure dimmed, however, with the introduction of prosthetic graft material 10 years later, and AI endarterectomy was largely replaced by bypass grafting.

Patient Selection

Since endarterectomy eliminates the need for a prosthetic graft, it is an appealing alternative in the setting of infection and removes the possibility of myriad late graft-related complications. Advocates have likewise pointed to the advantages of endarterectomy in younger patients or those with small vessels who are less than ideal candidates for endovascular therapy or aortobifemoral grafting.[39] Patients with erectile dysfunction attributable to proximal hypogastric occlusive disease are also well suited to this approach. Such patients can be expected to have a greater degree of improved pelvic perfusion after thorough endarterectomy of their AI and hypogastric segments compared with those undergoing ABFB grafting, and high rates of restored sexual function have been reported.[39,40]

Endarterectomy is most feasible and durable when it is applied to focal stenotic lesions in large-caliber, high-flow vessels. Indeed, the technique has proved particularly efficacious in patients with localized disease limited to the distal aorta or proximal common iliac arteries (Figs. 106.4 and 106.5), and excellent long-term patency rates, on a par with aortic bypass grafting, have been reported.[39,41-43] In distinction, results in cases of long-segment disease involving the entire infrarenal aorta and extending into the external iliac arteries have been disappointing.[44] Endarterectomy is now rarely performed for AIOD, having fallen into disfavor owing to its relative technical difficulty, potential for significant blood loss, and poor durability as well as the clear advantages of bypass grafting in this location. The rise of endovascular therapy is further eroding the already small proportion of patients considered suitable for endarterectomy. As a result, the number of vascular surgeons who are comfortable and facile with this technique is limited.

Technique

Endarterectomy is a direct disobliterative, debulking technique that takes advantage of the pathologic localization of atherosclerosis to the intima and media. Typically, a cleavage plane is easily developed between the plaque and the outer layers of the vessel wall, with the exact plane dependent on the size, location, and muscle content of the involved artery. Haimovici[45] has characterized the three cleavage planes encountered in the operative setting as subintimal, transmedial, and subadventitial.

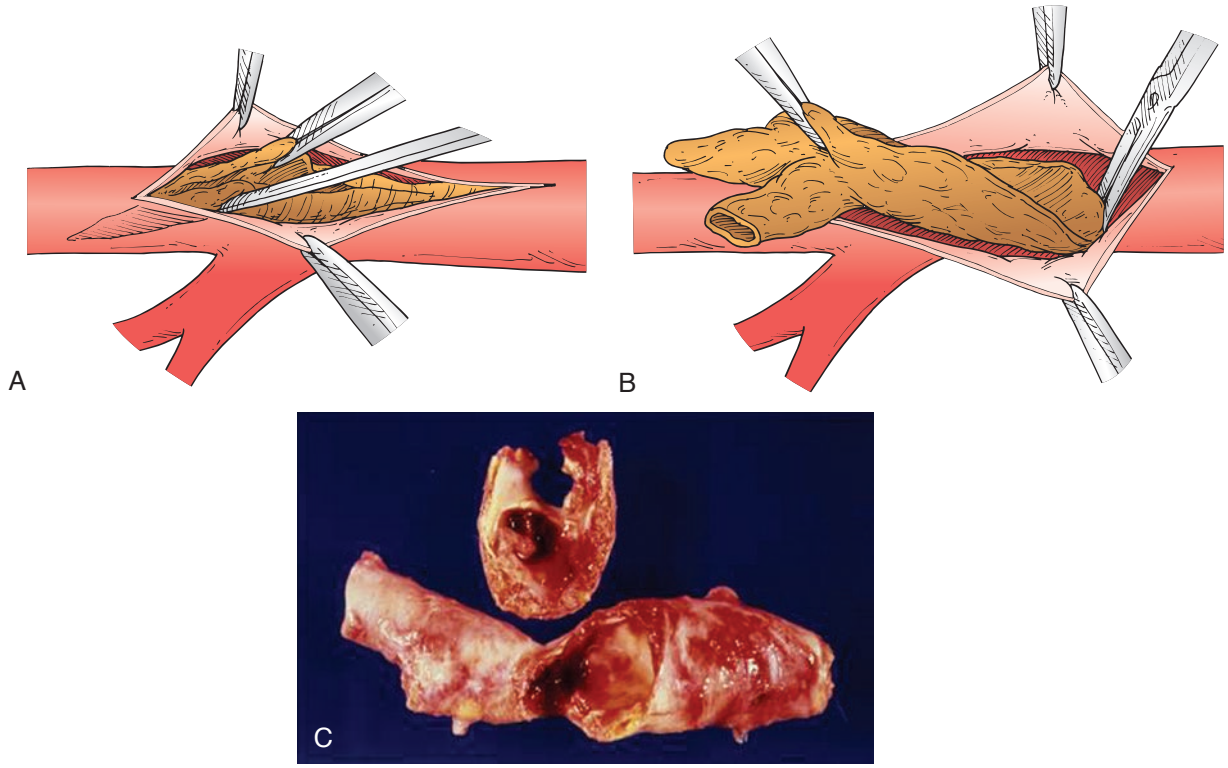

Figure 106.6 (A) The technique of endarterectomy involves the initial separation of plaque in the appropriate cleavage plane, with mobilization facilitated by a fine spatula. (B) Ideally, the endarterectomy is terminated by feathering to a tapered endpoint. (C) Photograph of an operative specimen removed by endarterectomy.

In his view, the last two planes are preferable because the subintimal plane predisposes to subsequent thrombosis. The residual outer layer is generally of sufficient mechanical strength to hold surgical sutures and to resist disruption or progressive enlargement when subjected to arterial pressure. Rarely the residual adventitia may be so attenuated that reconstruction of the wall with a patch or, in extreme cases, an interposition graft proves necessary. In practice, this most often occurs when the plaque is extensively calcified.

The various techniques all involve blunt separation of the plaque, termination by spontaneous tapering or sharp division, and careful attention to the endpoints (Figs. 106.5 and 106.6). Tacking sutures should be used when necessary, particularly to secure the distal endpoint, which must be firmly adherent to resist dissection or flap elevation leading to thrombosis. The simplest technical approach is the so-called open method, which employs a longitudinal arteriotomy that allows direct visualization of both endpoints as well as the entire endarterectomized surface; this technique is most commonly used for disease limited to the aorta and common iliac arteries. If primary closure is problematic due to small vessel caliber, patch angioplasty with vein, synthetic, or bovine pericardial material should be undertaken.

Extraction, eversion, and semiclosed methods are variations that can be helpful in specific anatomic situations. The last technique, useful to treat the external iliac arteries, involves arteriotomies at both the proximal and distal extents of the plaque and the initiation of plaque excision at the endpoints, similar to that undertaken in the open technique. A ringed stripper is then advanced between the endpoints to complete the plaque disengagement, obviating the need for full exposure of the treated segment. In the early 1970s, Inahara[46] modified the technique of eversion endarterectomy first described by Harrison et al.,[47] whereby the circumferentially dissected iliofemoral arterial segment is transected distally and passed proximally under the inguinal ligament into the pelvis before being endarterectomized and later reattached.

Aortobifemoral Bypass

Adequate intravenous access, intra-arterial pressure monitoring, Foley catheter placement, and preoperative antibiotics to minimize the risk of infection are routine aspects of aortic replacement surgery. Although the use of intraoperative blood salvage is advantageous in patients with relative anemia, its cost-effectiveness has not been firmly established in routine cases.[48] Attention should be paid to maintaining normothermia throughout the procedure to reduce the significant organ dysfunction and operative mortality associated with intraoperative hypothermia.[49] This is typically achieved with the use of forced-air body warming devices. ABFB grafting is performed under general endotracheal anesthesia. An epidural catheter is usually placed for postoperative pain control.

Exposure

The initial vascular exposure and proximal and distal vessel control are attained before the institution of systemic anticoagulation in

an effort to minimize blood loss. The femoral vessels are typically exposed first through bilateral longitudinal or oblique incisions to reduce the time during which the abdomen is open and the viscera are exposed. The extent of exposure is dictated by disease severity and the level of reconstruction planned at the CFA and its bifurcation. In general, the distal extent of the dissection involves circumferential control of the proximal SFA and profunda femoris arteries; the inferior epigastric and circumflex iliac branches at the anatomic transition from the external iliac to the CFA mark the proximal extent of the dissection. A circumflex femoral arterial branch frequently arises from the posterior aspect of the distal CFA and must be controlled to avoid troublesome backbleeding. The inferior aspects of the retroperitoneal tunnels through which the graft limbs will course to reach the femoral region are begun with blunt digital dissection posterior to the inguinal ligament, which can be partially divided posteriorly to prevent graft limb compression. The tunnels should track directly along the anterior aspect of the external iliac artery, with care taken to elevate all soft tissues to ensure that the ureters remain anterior. A crossing vein normally present beneath the inguinal ligament must be ligated or carefully avoided to prevent bleeding during the tunneling process.

Infrarenal aortic exposure is often performed through a transperitoneal approach by a longitudinal midline laparotomy, although some prefer a transverse incision. This incision typically extends from below the xiphoid process to just inferior to the umbilicus; as such, it is shorter than the incision normally employed for abdominal aortic aneurysm repair. The abdomen is explored for any intra-abdominal abnormalities, and the stomach is palpated to ensure proper positioning of the nasogastric tube. The transverse colon is retracted cephalad, and the small bowel is shifted to the patient's right side. The ligament of Treitz is then taken down, and the duodenum is mobilized to the right, allowing access to the infrarenal aorta. A fixed, self-retaining retractor is placed to aid exposure, with care taken to protect the displaced bowel from retractor blade injury. The retroperitoneal tissue overlying the aorta is dissected superiorly to the level of the left renal vein, and the larger lymphatic vessels encountered within the retroperitoneal lymphatic network are ligated. If renal artery reconstruction is not planned, the dissection can often be limited to the region between the renal arteries and the inferior mesenteric artery. Extensive dissection anterior to the aortic bifurcation and proximal left iliac artery should be avoided because the autonomic nerve plexus regulating erection and ejaculation in men sweeps over the aorta in this region. If exposure in the area of the plexus proves necessary, dissecting along the right lateral aspect of the infrarenal aorta and reflecting rather than transecting the tissue overlying the terminal aorta and proximal iliac arteries can minimize the risk of iatrogenic neurogenic sexual dysfunction.

Should thrombus or significant aortic calcification extend to the level of the renal arteries, it may be necessary to continue the proximal aortic dissection to the suprarenal level to allow safe proximal clamp placement. Alternatively, proximal control may be obtained by intraluminal balloon deployment or supraceliac clamping via the gastrohepatic ligament. In all cases, it is important to extend the reconstruction close to the level of the renal arteries to minimize the risk of failure secondary to disease progression in the remnant infrarenal aortic neck. If end-to-side repair is planned, exposure and control of all relevant lumbar or accessory renal arteries before the aortotomy is performed helps avoid backbleeding, which can be challenging to control with cross-clamps in place and the aorta compressed. The superior aspects of the graft limb tunnels are completed with further digital manipulation from above and below, again with care taken to maintain a course anterior to the iliac vessels but posterior to the ureters. The left limb tunnel passes beneath the sigmoid mesentery and slightly more laterally to avoid disruption of the autonomic nerve plexus. Moist umbilical tapes or Penrose drains are passed with a smooth aortic clamp to mark the tunnels. After vessel exposure and tunnel creation, but before vascular occlusion, a standard intravenous bolus of heparin sodium anticoagulation is given. Additional doses may be necessary, depending on the length of the operation and the requirement for additional periods of flow occlusion, and may be guided by the measurement of the activated clotting time. For peripheral vascular operations, the initial dose typically ranges between 70 and 100 units/kg, and an activated clotting time in the 250- to 350-second range is adequate.

Clamp Placement

With non–contrast-enhanced CTA guidance, when available, to delineate sites of heavy calcification, the aorta is carefully palpated to identify the optimal sites for application of the cross-clamps. In the event of asymmetrical plaque, the technique of clamping soft plaque against hard plaque minimizes the risk of emboli. It also lessens the risk of a traumatic clamp injury, which can be a formidable technical problem in a heavily calcified aorta. Anterior to posterior clamping may be necessary in the presence of a soft anterior but calcified posterior aortic wall. Appropriate atraumatic vascular clamps are selected, and after sufficient time is allowed for the heparin to circulate, the aorta is clamped first proximally or distally at the site of least disease to avoid dislodgement and potential distal embolization of plaque. The distal clamp is usually placed above or below the inferior mesenteric artery. The proximal clamp is placed just below the renal arteries if the disease pattern does not obligate suprarenal clamping, with as little dissection of the renal artery origins as possible.

If an end-to-end anastomosis is planned, the aorta is transected several inches below the proximal clamp, and the distal aorta is oversewn in two layers with running monofilament suture or stapled with a surgical stapler (Fig. 106.7A). A short segment of the distal aortic cuff is often excised to improve exposure of the aortic neck and aid precise proximal reconstruction. This maneuver also allows the graft to lie more flatly against the vertebral column rather than in an anterior orientation, and facilitates retroperitoneal coverage (Fig. 106.8). If necessary, it is important to carry out a complete thromboendarterectomy of the infrarenal neck (see Fig. 106.7B). Removal of all thrombotic debris and calcified plaque facilitates both suture placement and creation of a widely patent proximal anastomosis. Brief repositioning of the proximal clamp to the suprarenal position

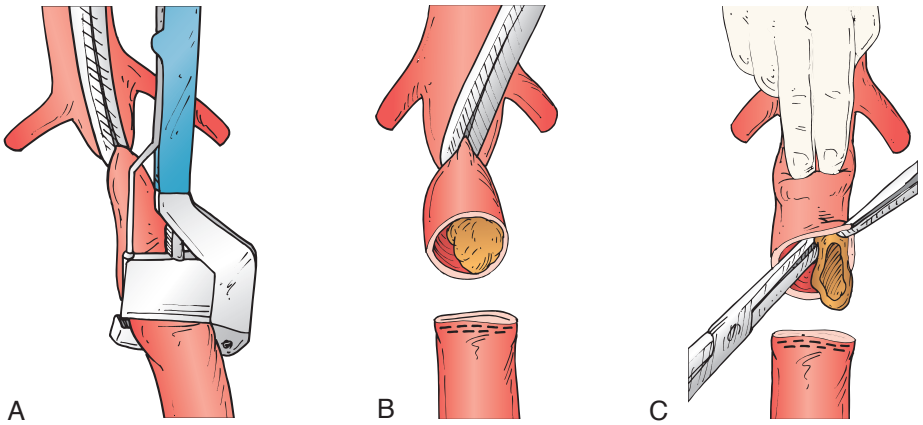

Figure 106.7 (A) The end-to-end proximal anastomosis for aortofemoral reconstruction can be initiated with the infrarenal aorta cross-clamp placed in an anteroposterior direction, as close to the origin of the renal arteries as possible. The aorta is then stapled or occluded with a second clamp just proximal to the origin of the inferior mesenteric artery. (B) After excision of a short segment of aortic cuff, a complete thromboendarterectomy of the remaining proximal cuff is carried out. (C) Brief digital or clamp control of the juxtarenal aorta may prove necessary to complete the thromboendarterectomy.

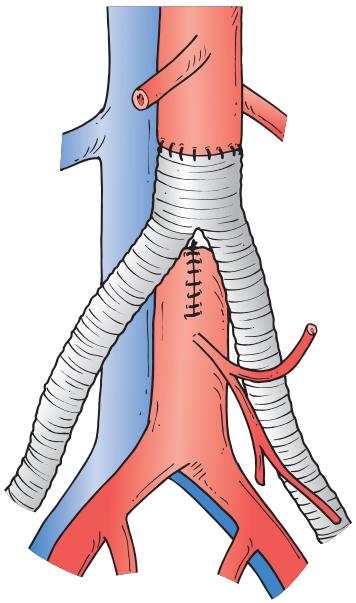

Figure 106.8 The end-to-end proximal anastomotic configuration for aortofemoral reconstruction allows the graft to lie flat against the vertebral column and results in less turbulent flow.

or the application of digital pressure sufficient to temporarily occlude the suprarenal aorta may be helpful to ensure the thorough removal of all intraluminal debris (see Fig. 106.7C). Mobilization and cephalad or caudad retraction of the left renal vein can facilitate adequate exposure of the juxtarenal aorta. Division of the left renal vein is usually unnecessary but acceptable if additional exposure is required, provided the adrenal, lumbar, and gonadal collateral branches are preserved. If suprarenal clamping is undertaken, concurrent clamping of the renal arteries is advisable to prevent the potentially adverse effects of inadvertent emboli.

A minority of patients present with an aortic occlusion extending to the level of the renal arteries. These patients are best managed by controlling the renal arteries and then thrombectomizing the infrarenal cuff, without placement of an infrarenal proximal aortic clamp, which could displace thrombotic material proximally. The aortic plug encountered at this location is often soft, propagated, secondary thrombus that can be easily removed with a Kelly clamp. After aortic pressure is used to flush out the remaining plug, suprarenal control is briefly used. Remnant debris is cleared from the infrarenal cuff, the aorta is flushed again, the renal arteries are backbled, and then an infrarenal clamp is placed.

Graft Selection

A bifurcated graft appropriately sized to match the aorta and femoral vessels is selected. Although some surgeons prefer polytetrafluoroethylene grafts, knitted polyester (Dacron) grafts are more commonly used. Current low-porosity knitted versions have excellent handling and hemostatic properties and a proven track record of durability (see Chapter 64). They also develop a more stable pseudointima than earlier woven grafts, although their tendency to dilate over time has been documented.[50] Woven polyester grafts can also be used and may tend to dilate less during long-term follow-up. Greater appreciation of the importance of sizing the graft to the runoff vessels followed an early experience with limb thrombosis believed to be secondary to sluggish flow from oversizing.[51,52] Bifurcated grafts measuring 18 by 9 mm or 16 by 8 mm are typically chosen for male patients; grafts measuring 14 by 7 mm or even 12 by 6 mm are usually suitable for female patients.

Anastomoses

One technical consideration related to ABFB grafting that has prompted considerable debate involves the type of proximal anastomosis. The published literature has established that both end-to-end and end-to-side techniques are acceptable and effective. Despite strong preferences expressed by various surgeons, neither approach has demonstrated overall superiority, but each may be preferred in certain circumstances.

End to End

Those favoring an end-to-end configuration claim that it facilitates a more comprehensive thromboendarterectomy of the proximal stump and allows a better in-line flow pattern, with less turbulence and more favorable hemodynamic characteristics (see Fig. 106.8).[53] Lower rates of proximal suture line pseudoaneurysm and better long-term patency rates reported

in some series lend support to this view.[54] Stapling or oversewing of the distal aorta with the end-to-end technique also has the benefit of reducing the risk of clamp-induced emboli to the lower extremities after release of the distal clamp compared with the end-to-side option. Further, those in favor of this approach assert that because the graft lies flatter in the retroperitoneum, this enhances the ability to close the retroperitoneum over the graft, resulting in a lower rate of late graft infection and aortoenteric fistulae; there is, however, little direct evidence to support this claim. Finally, the creation of an end-to-side anastomosis can be technically challenging in a heavily diseased aorta, particularly if it is partially occluded by a side-biting clamp (favored by some surgeons). In the setting of concomitant aneurysmal disease or complete aortic occlusion extending up to the level of the renal arteries, an end-to-end approach should be used.

End to Side

There are certain circumstances in which an end-to-side proximal anastomosis is advantageous. The most common indication is in patients with occluded or severely diseased external iliac arteries but patent common and internal iliac arteries, in whom the interruption of forward aortic flow may result in the loss of critical pelvic perfusion. Without the retrograde flow through the external iliac arteries normally present in an end-to-end configuration, pelvic ischemia, ranging from mild hip claudication to severe buttock rest pain or ulceration, may result.[55,56] Additional ischemic complications, such as erectile dysfunction in men and rarely seen paraplegia secondary to cauda equina syndrome,[57] can potentially be avoided with an end-to-side approach. Preservation of either a large inferior mesenteric artery, sometimes necessary to avert colonic or mesenteric ischemia, or an important accessory renal artery arising from the distal aorta or an iliac artery can more easily be accomplished with an end-to-side technique. Alternatively, these vessels can be reimplanted onto the side of an end-to-end graft.

Technique

For end-to-end proximal anastomoses, the main body of the graft is shortened to minimize graft redundancy and to allow the graft limbs to straddle rather than to override the transected aortic stump (see Fig. 106.8). The anastomosis is performed with running 3-0 polypropylene suture. If an end-to-side anastomosis is to be performed, a beveled anastomosis is fashioned after an approximately 3-cm longitudinal aortotomy is created as close to the renal arteries as practical (Fig. 106.9). Care is taken to remove all loose debris and mural thrombus from the excluded portion of the aorta, and a particular effort is made to ensure adequate backflushing of clot and debris before re-establishment of forward flow in the native aorta and graft. Side-biting clamps are best avoided in performing an end-to-side anastomosis because they compress the aortic sidewalls, rendering both adequate thromboendarterectomy and accurate suture placement more difficult (see Fig. 106.9).

After completion of the abdominal portion of the procedure, the graft limbs are clamped with soft-jaw insert clamps and flushed with heparinized saline. They are then passed through

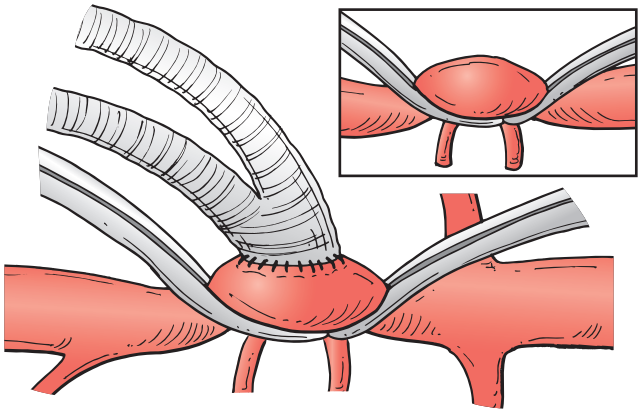

Figure 106.9 An end-to-side proximal anastomosis for aortofemoral grafting is required to preserve antegrade pelvic perfusion in situations in which retrograde flow would be compromised by heavily diseased or occluded external iliac arteries.

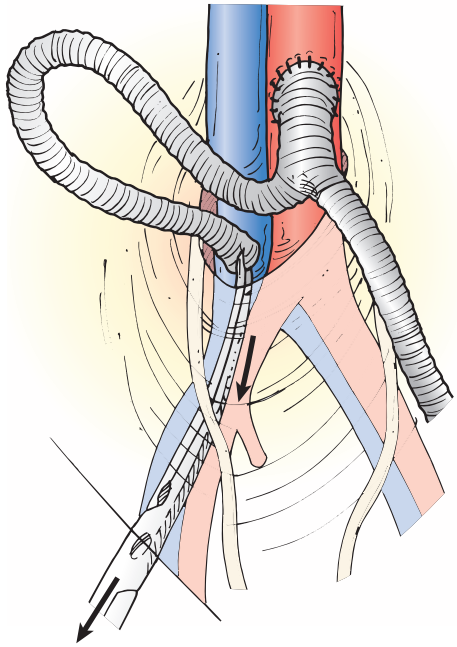

Figure 106.10 Aortobifemoral graft limbs are carefully tunneled beneath the ureters to avoid kinking.

the retroperitoneal tunnels, with care taken to prevent twisting and to eliminate excess redundancy (Fig. 106.10), and attention is turned to the distal anastomoses. Proximal femoral control is typically obtained with either a soft-jaw clamp or a Satinsky clamp placed from a lateral direction, and distal control is usually achieved with vessel loops or atraumatic bulldog or profunda clamps. For those patients with normal femoral and distal runoff, a longitudinal arteriotomy limited to the distal CFA is sufficient. More commonly, extension of the arteriotomy across the profunda femoris artery origin and profundaplasty will prove necessary (see the section Adjunctive Profundaplasty). The distal anastomoses are completed in a beveled end-to-side fashion with 5-0 polypropylene, again carrying out retrograde and antegrade flushing maneuvers before the anastomoses are completed and flow is restored. It is important to alert the

anesthetic team before clamp release, given the expected blood pressure drop with reperfusion.

Closure

Before wound closure, the surgeon must confirm adequate distal perfusion and absence of distal embolization. The quality of the pulses and Doppler signals just beyond the distal anastomosis and at the pedal level is assessed, as are the color, temperature, and general appearance of the feet. If the revascularization is deemed satisfactory and no further distal reconstruction is to be undertaken, the effects of heparin can be reversed by administering protamine sulfate (1 mg/100 units of circulating heparin) at the surgeon's discretion to help attain hemostasis. Once hemostasis is sufficient, the abdomen is irrigated and the retroperitoneum is closed over the proximal anastomosis and graft behind the duodenum to the extent possible. If adequate retroperitoneal coverage is not possible, particularly with an end-to-side proximal anastomosis, a sleeve of omentum should be fashioned to cover any exposed segment of the anastomosis and to separate the graft from the adjacent bowel. It is important to tack down this omental apron to prevent small bowel herniation. The groin wounds are copiously irrigated and the deeper tissue is closed in several layers with absorbable Vicryl sutures.

Adjunctive Profundaplasty

The important role of profundaplasty in preserving the long-term patency of anatomic or extra-anatomic grafts in patients with AIOD has been widely established.[9,44,58-61] In patients with normal proximal SFAs and profunda femoris arteries, the distal anastomosis of an aortobifemoral graft can be performed to the CFA. However, most patients with AI disease severe enough to warrant aortofemoral bypass in the endovascular era have both profunda and SFA disease that limits outflow and increases the likelihood of graft thrombosis. In patients with severe AI, SFA, and profunda disease causing CLTI, a concomitant profundaplasty may be sufficient to sustain the patency of the inflow graft and to salvage the limb, particularly if there is good profunda collateral circulation to a patent popliteal artery. Some authors have even recommended that the aortofemoral bypass graft limb should be extended to the profunda in every case of SFA occlusion, even in the absence of orificial profunda disease, arguing that a "functional" obstruction on the order of 50% stenosis is present in these patients.[62] Although this position has not been universally adopted, it is now common practice to extend the hood of the distal anastomosis over the origin of the profunda femoris artery to enhance the graft outflow, particularly if the SFA is occluded or severely diseased. In the presence of significant CFA or profunda femoris origin plaque, an endarterectomy or profundaplasty is almost always indicated (Fig. 106.11). The need for adjunctive profundaplasty should be determined at the time of preoperative angiography. Although anatomic variations are not uncommon, the profunda typically arises as a posterolateral branch off the terminal CFA. As such, proper visualization requires dedicated oblique views because subtle disease can easily be obscured by the overlying SFA in the anteroposterior projection.

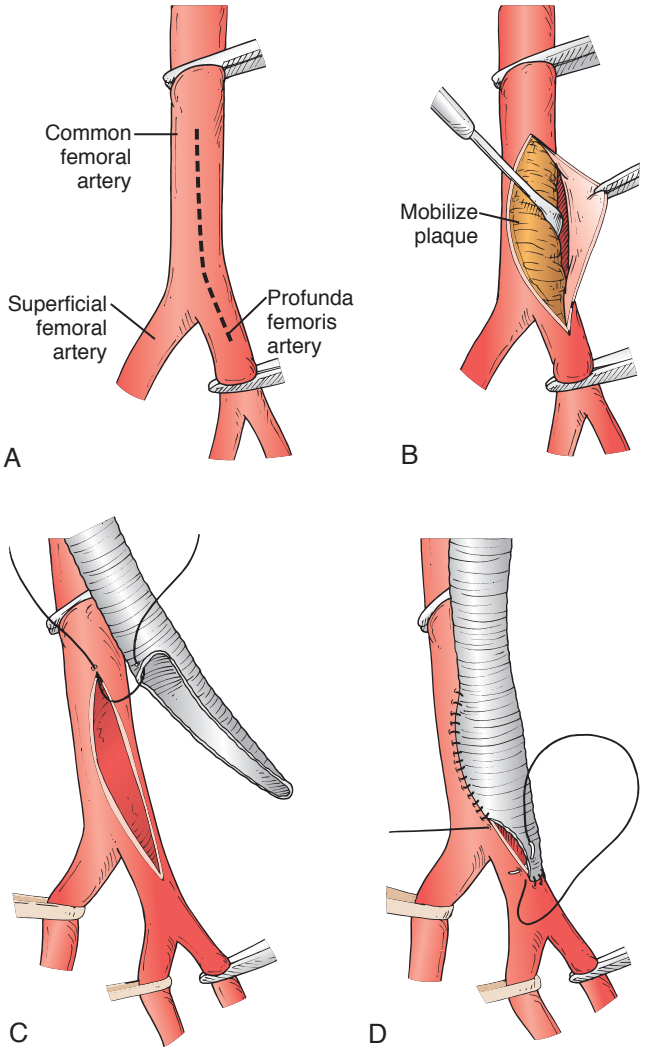

Figure 106.11 (A to D) In the setting of superficial femoral artery and orificial profunda femoris artery disease, extending the common femoral arteriotomy to the origin of the profunda and performing a profundaplasty before completion of the distal anastomosis of the aortobifemoral bypass can improve outflow and maximize graft patency.

Technique

The profunda is usually exposed by distal extension of the dissection used to access the CFA, although a lateral approach through a fresh tissue plane with medial retraction of the sartorius can be used to avoid a scarred or infected groin. Every effort should be made to spare all collateral branches arising from the CFA and profunda femoris artery because they may prove vital to preservation of lower extremity perfusion in the event of later graft thrombosis.

Once exposed, the CFA and profunda femoris should be palpated to gauge the degree of atherosclerotic plaque present, particularly given the well-known tendency of angiography to underestimate the extent of disease. Profunda arterial plaque not uncommonly ends at the first or second major branch point. The profunda orifice can be visually inspected after the CFA is incised, and its lumen can be further assessed by noting the quality of backbleeding and by gentle interrogation with a

series of sizing metal probes. The dissection is continued along the anterior aspect of the artery as necessary; the extent is guided by the location of a suitable endpoint as identified by palpation, inspection, and reference to the preoperative angiogram. The lateral femoral circumflex vein coursing deep to the SFA and crossing anteriorly over the proximal profunda must be ligated in most cases. Isolated orificial plaque can sometimes be entirely removed by an eversion technique through the CFA. If it becomes necessary to extend the arteriotomy to the profunda, care should be taken to avoid incising the crotch of the superficial and deep femoral arteries. The endarterectomy is performed as described earlier. In the event that an extensive endarterectomy proves necessary, it may be preferable to close the endarterectomy site with a vein or bovine pericardial patch, onto which the distal anastomosis can then be attached, rather than to create a long profunda patch with the graft limb.[58] If an outflow bypass is to be performed, this can be taken off either the distal patch or the graft limb.

Other Operative Considerations

External Iliac Anastomosis

Early in the operative experience for AI occlusive disease, the tendency was to place the distal anastomosis of aortic bypass grafts at the iliac level. With time came a growing appreciation of the benefits of extending the distal anastomosis to the femoral level; creation of the distal anastomosis is technically easier at the groin level, and long-term patency rates for aortobifemoral grafts are notably improved compared with AI grafts.[63] In addition, with meticulous surgical technique and improvements in graft materials, the feared increase in graft infection caused by moving the distal dissection to the femoral level has not proved to be a significant problem in the majority of patients.[64] There are certain circumstances, however, in which performing an aortobiiliac bypass remains advantageous. Patients with hostile groin creases from prior surgery or radiation therapy, for example, are likely to be better served by this option, as are obese, diabetic patients with an intertriginous rash at the inguinal crease and patent external iliac arteries. Excellent preoperative imaging and intraoperative confirmation of suitable anatomy are necessary if one chooses this reconstructive alternative.

Multilevel Occlusive Disease

The optimal management of patients with multilevel occlusive disease is often difficult to determine. The question frequently arises whether or under what circumstances concomitant versus staged outflow procedures should be performed in association with an inflow operation. The impact of synchronous SFA disease on the results of AI revascularization remains undefined in the current literature; some reports have indicated similar patency rates between patients with and without SFA occlusion,[22] whereas others have reported lower long-term patency rates in this setting.[65,66] If an atretic or prohibitively diseased profunda is present in addition to a severely diseased SFA, infrainguinal bypass grafting is likely to be necessary to ensure sufficient outflow for graft patency and perfusion of the foot. An investigation that specifically addressed the impact of diabetes concluded that diabetic patients with multilevel occlusive disease were no more likely to require subsequent infrainguinal revascularization after an inflow reconstruction than were nondiabetics.[67] Further, although up to 80% of patients with claudication and both inflow and outflow disease manifest symptomatic improvement after aortofemoral bypass grafting alone,[10,68] some studies indicate that as many as two-thirds have some degree of persistent claudication.[69]

No single criterion mandates a combined procedure; however, the severity of distal ischemia is probably the most important factor to be considered. If significant tissue loss is present, concurrent inflow and outflow procedures are probably warranted if limb salvage is to be achieved. In deciding whether a staged approach is appropriate, the patient's ability to tolerate a prolonged operative procedure must be weighed against the potential risk of wound and graft infection resulting from redissection in the groin and the risk of progressive tissue loss during the initial recuperative period. When it is performed with several teams operating simultaneously, concurrent inflow and outflow revascularization can be completed in a timely and safe manner. Indeed, several reports found no significant differences in perioperative mortality or morbidity in patients undergoing multilevel reconstruction and those having a major inflow procedure alone.[70,71]

Associated Renal or Mesenteric Artery Occlusive Disease

In recent decades, the introduction of potent new antihypertensive drugs and the growing application of percutaneous interventions have had a significant impact on treatment of renal artery occlusive disease. Balloon angioplasty and stenting are likewise playing an increasing role in mesenteric occlusive disease. Whether to address coexisting renal or mesenteric disease at the time of aortic reconstruction is a challenging decision that warrants careful consideration of multiple individual factors, the obligatory increase in operative time and complexity and the greater operative mortality and morbidity. In the setting of multidrug-refractory hypertension or ischemic nephropathy believed to have a potentially reversible functional component on the basis of a thorough diagnostic assessment, simultaneous repair of significant renal occlusive disease may be indicated. Combined repair is also appropriate when accessory renal arteries arise from the diseased aortic segment. Simultaneous revascularization is more controversial when the functional significance of the renal artery stenosis is uncertain or is thought to be clinically silent.

Advocates of an aggressive treatment approach cite the clinical deterioration seen with the progression of untreated renal artery occlusive disease and the increasing safety of combined aortic and renal reconstruction. Those who favor a more conservative position believe that the increased surgical risk does not offset the potential clinical gain. Perioperative mortality rates for patients undergoing simultaneous aortic and renal repair have consistently been in the 5% to 6% range,[72-74] in comparison to rates of 1.7% and 0.7% for those undergoing renal or aortic reconstruction alone, respectively.[72] A favorable response to hypertension has been reported in 60% to 70% of patients

undergoing combined revascularization, and improvement in renal excretory function has been reported in up to 33% of patients.[72,73] The most common reconstruction approach is aortorenal bypass from the aortic graft, with the use of either saphenous vein or prosthetic graft. In select cases, in situ thromboendarterectomy, endarterectomy with reimplantation onto the aortic graft, or extra-anatomic splenorenal or hepatorenal grafting may prove preferable (see Chapter 126). With regard to visceral artery occlusive disease, strict attention to preservation of the inferior mesenteric artery usually suffices to prevent postoperative mesenteric ischemia, and simultaneous revascularization of the celiac or superior mesenteric arteries is rarely required. Staged open or percutaneous revascularization of the renal or mesenteric arteries is another option in specific circumstances, although the role of simultaneous renal reconstruction versus angioplasty before or after surgery remains unclear.[75,76]

Coexistent Abdominal Aortic Aneurysms

While open repair of infrarenal abdominal aortic aneurysms is most typically completed with an aortic tube or aortobi-iliac graft, coexistent AIOD may necessitate aortofemoral bypass grafting. Although aortofemoral bypass grafting is more complex than aortic tube or aortobi-iliac reconstruction in patients with both aneurysmal disease and iliac outflow occlusive disease, our own institutional experience has led us to believe that concern for associated increased short- or longer-term mortality in such patients is not justified and should not be the basis for denying surgery. A review of more than 1000 consecutive open abdominal aortic aneurysm repairs performed over a recent 20-year period at the Brigham and Women's Hospital revealed a significantly higher postoperative morbidity rate in the 10% of patients undergoing aortofemoral reconstruction but similar 30-day mortality and 5-year survival (unpublished data, Division of Vascular and Endovascular Surgery, Brigham and Women's Hospital).

Retroperitoneal Approach

Although the retroperitoneal approach to the infrarenal aorta is a well-accepted alternative to the more standard transperitoneal technique in the setting of aneurysmal disease, it is also favored by some surgeons in select patients with occlusive disease.[77,78] This option may be advantageous in patients with a history of multiple prior abdominal operations, abdominal wall stoma, concurrent renal or mesenteric arterial disease requiring suprarenal exposure, or severe cardiopulmonary disease. Stated benefits of reduced pulmonary morbidity and lower rates of postoperative ileus have not been consistently supported by the literature.[79] Clear disadvantages of the retroperitoneal approach include the attendant difficulty in accessing the right renal and iliac arteries and the right groin, particularly in obese patients.

The technique involves placing the patient on an inflatable beanbag in the partial right lateral decubitus position, with flank extension. The hips are rotated as far posteriorly as possible to maximize exposure to the right femoral arteries. An oblique incision is created from the left lateral border of the rectus abdominis to the posterior axillary line, and the lateral third of the 11th rib is excised. The retroperitoneal plane is identified, and the peritoneal contents are mobilized anteriorly to reveal the left iliac artery and infrarenal aorta (see Chapter 71).

Minimally Invasive Approaches

Reflecting widespread trends toward more minimally invasive approaches in other areas of surgery, the technique of performing aortofemoral bypass grafting through a shorter midline incision has been reported.[80] The described minilaparotomy is less than 10 cm long, and the procedure is undertaken without displacement of the small bowel. Enthusiasm for the technique is currently limited.

There has also been recent, ongoing interest in applying laparoscopic techniques to the treatment of AIOD. This approach has been supported by a small body of literature mainly composed of individual case series (Table 106.1).[81-84] Some enthusiasts have championed a more limited application with hand-assisted techniques and smaller incisions,[85] whereas others have advocated for the use of complete laparoscopic or robot-assisted revascularization.[86-88]

The presumptive benefits of reduced hospital length of stay, less perioperative pain, and fewer postoperative complications are balanced against longer operative times and the absence of long-term data to support the durability of this alternative strategy. The lack of exposure to the technique during routine general and vascular surgical training, the associated inherent technical challenges and prohibitive learning curve, and the declining indications for this approach with the advent of even less invasive endovascular alternatives have contributed to its limited popularity. Whereas morbidity and mortality rates for laparoscopic aortic bypass approach those for open aortic reconstruction (see Table 106.1), lower rates of gastrointestinal and pulmonary complications have been noted. Proponents of laparoscopic surgery also highlight the minimal incidence of incisional hernias and adhesion-related bowel obstruction. Open conversion rates in the reported series to date have generally been low but reached the 20% range in two reported series.[94,96] Although long-term patency rates for laparoscopic bypass have yet to be defined, intermediate-term results compare favorably with those reported for open ABFB.[84,97,99]

RESULTS

The short- and long-term results of both endarterectomy and ABFB have generally been excellent, particularly in more recently published series. When endarterectomy is performed for disease limited to the distal aorta and proximal iliac segments, 5-year patency rates of 95% and 10-year rates between 85% and 90% are consistently achieved.[42-44,46] In contrast to the nearly 7% perioperative mortality rates reported in the early experience of endarterectomy, more recent reports reflect improvements in patient selection and perioperative management, with rates as low as 1%.[41-44]

Several large meta-analyses evaluating the comprehensive experience with ABFB grafting from its inception in the mid-1950s through the 2000s have indicated similar overall 30-day mortality rates of between 4.0% and 4.4%.[100-102] Several more recent single-institution series that better reflect the current era

report an operative mortality of near 1%,[22,30,67,103-105] on par with that of elective abdominal aortic aneurysm repair. Increasing age, chronic pulmonary disease, and a low-volume hospital setting predict higher perioperative mortality (Table 106.2).

The accumulated experience to date has shown that 5-year primary patency rates between 85% and 90% and 10-year rates between 75% and 85% can be expected with aortobifemoral grafting (see Table 106.2).[22,30,65,67,100-107] Age has proved to be a significant predictor of outcome[108]; in one report, primary patency rates at 5 years were greater than 95% for patients older than 60 years but only 66% for those younger than 50 years (Fig. 106.12).[30] Although it is not clear why younger patients have inferior long-term patency rates, one could speculate that they have a more aggressive form of atherosclerosis or are at a different point in disease evolution than their older counterparts.

The reported influence of gender on graft patency has been more inconsistent, with some studies indicating less favorable outcomes in women and others demonstrating equivalent long-term patency rates in men and women.[22,30,65,100] Similarly, conflicting results have been documented with regard to the impact of preexisting SFA occlusion, with some but not all reports suggesting improved late patency when a simultaneous outflow procedure is performed at the time of aortobifemoral grafting.[22,65,66] In contrast, the benefits of combining profundaplasty with the inflow procedure have been unambiguously demonstrated.[9,44,58-61] Of note, no major differences in aortobifemoral graft durability have been noted between the transperitoneal and retroperitoneal approaches, between end-to-end and end-to-side anastomotic techniques, or between the indications of claudication and CLTI.[22,30,78,79,100] The single series directly comparing percutaneous treatment of AIOD with aortobifemoral grafting demonstrated similar 3-year secondary patency and limb salvage rates.[109]

In general, patients with occlusive disease limited to the AI region can expect to have excellent relief of symptoms after aortobifemoral grafting; those with multilevel disease generally have a lesser degree of symptom reduction. In one study, more than 80% of patients reported satisfaction with their result 5 years after undergoing ABFB.[110] Similarly, although 10-year survival rates are as low as 50% in patients with diffuse disease, those with more localized AI disease have a life expectancy not appreciably different from that of their normal age- and sex-matched counterparts.[9,111,112]

It has been questioned whether the excellent outcomes of aortic bypass surgery, the result of decades of technical refinement, and accumulated experience with the procedure remain valid in the modern endovascular era.[113] In the most comprehensive report to date, a meta-analysis spanning the last 40 years, a decrease in patency rates for both ABFB and iliofemoral bypass grafts was noted over time when results were compared by decade of publication.[102] Postulated reasons for this finding have included greater operative complexity (i.e., more reoperative indications and an increased need for suprarenal clamping, adjunctive visceral

TABLE 106.2 Outcomes of Aortobifemoral Bypass: Operative Mortality and Long-Term Patency Rates

segment revascularization, or concomitant outflow procedures) and a substantial decline in the experience of more recently trained surgeons in open aortic reconstruction.[113] Supportive evidence for this view can be found in one report indicating increased mortality and lower long-term patency rates when ABFB is performed in the setting of chronic infrarenal aortic occlusion.[114] As yet, no data are available on the outcome of aortic bypass surgery after failed endovascular revascularization.

Early Complications

Reported overall morbidity rates range from 17% to 32% after aortic surgery for occlusive disease (Table 106.3).[a] Cardiac complications are the most common cause of mortality[22,68] and result from the hemodynamic stress associated with major vascular surgery and the obligatory fluid shifts during the early postoperative period. Pulmonary complications are also common and are most likely to occur in the elderly or those with chronic obstructive pulmonary disease, a significant smoking history, or poor preoperative nutritional status.[115] Adequate pain control, appropriate diuresis, and strict attention to pulmonary toilet are important measures to prevent the development of pneumonia and the progression of relatively benign alveolar collapse to more extreme degrees of pulmonary collapse.

Acute renal failure after aortic reconstruction for occlusive disease is relatively uncommon in patients with normal preoperative renal function, even when suprarenal clamping proves necessary. Adequate hydration and the avoidance of repetitive aortic cross-clamping and perioperative hypotension are valuable prophylactic maneuvers; less clear is the benefit of the adjunctive use of mannitol and furosemide (Lasix) to trigger diuresis before aortic cross-clamping. Our limited ability to alter the natural history of acute tubular necrosis or the effects of atheroemboli

TABLE 106.3 Complications of Aortobifemoral Bypass

Complication	Percentage
Early (Perioperative)	
Hemorrhage	1-2
Renal failure	<5
Acute limb ischemia	1-3
Bowel ischemia	2
Groin complications (lymphocele, lymphocutaneous fistula, wound infection, hematoma)	3-15
Sexual dysfunction	≤25
Ureteral injury	<1
Spinal cord ischemia	0.25
Pneumonia	<7
Myocardial infarction	1-5
Death	0-4
Late	
Graft thrombosis	5-30
Graft infection	0.5-3
Aortoenteric fistula	<3
Anastomotic pseudoaneurysm	1-5

results in some inevitable progression to dialysis dependence; those patients with a preoperative creatinine concentration greater than 1.8 mg/dL [159 µmol/L] are at much higher risk for this complication.[116]

Ureteral injury during dissection, graft tunneling, or retroperitoneal closure can usually be avoided with careful, diligent surgical technique. Spinal cord ischemia is a particularly devastating complication of infrarenal aortic surgery, and one that is thought to be potentially preventable. The central component of prophylaxis is careful preservation of hypogastric perfusion; however, the use of gentle technique to minimize the risk of atheroemboli and the avoidance of perioperative and postoperative hypotension have also proved to be important preventive measures.[117] Fortunately, this complication is rare, occurring in only 0.3% (4 of 1209) of reconstructions for AIOD in one series.[118]

Hemorrhage

Bleeding complications associated with AI endarterectomy, particularly for extensive disease, were partly responsible for the waning popularity of this technique. With modern suture and patch materials and the less extensive disease typically repaired in the current era, bleeding associated with endarterectomy has become less of a problem. For patients undergoing aortobifemoral grafting, postoperative hemorrhage is a relatively rare event, occurring in 1% to 2% of cases.[119] This rarity is due in part to a greater awareness of bleeding disorders, better intraoperative anticoagulation and blood product management, and improved hemostatic properties of the grafts used (see Chapter 37).

Bleeding points in the anastomotic suture line after a test release of the aortic or femoral clamps are usually effectively managed with repair sutures reinforced with felt pledgets. It is important to replace the clamp before placing any necessary repair stitches because attempted placement under tension risks extending the defect and worsening the bleeding. In cases in which the walls of the infrarenal aortic cuff are particularly thin after thromboendarterectomy, a previously positioned sleeve of graft advanced over the aortic suture line can act as a prophylactic bolster. Intraoperative venous injuries can occur during dissection between the aorta and vena cava or from a tear in a lumbar vein; such injuries can often be controlled with judicious tamponade. A number of sealants, glues, and thrombin-based hemostatic adjuncts are now available to help control troublesome diffuse oozing and persistent needle hole bleeding.

Delayed bleeding may occur if the postoperative blood pressure is appreciably higher than the pressure at the time of closure. Blood products, including platelets and fresh frozen plasma, are the preferred replacement fluid in most cases during the early postoperative period, particularly if intraoperative blood loss was significant and the patient is considered at risk for dilutional coagulopathy. Careful postoperative monitoring of the abdominal girth, hematocrit, bladder pressure, coagulation parameters, and hemodynamic status is paramount to identify ongoing bleeding significant enough to require urgent reoperation (see Chapter 34).

Intestinal Ischemia

Intestinal ischemia after aortic reconstruction has been reported in 2% of cases.[120] The involved segment is usually the rectosigmoid, and the cause is multifactorial. Although sacrifice of either the primary or the main collateral source of perfusion to the colon during reconstruction is the most common causative event, perioperative hypotension leading to insufficient perfusion and atheroemboli are other possible contributors. If compromised bowel perfusion is recognized intraoperatively after the creation of an end-to-end anastomosis, inferior mesenteric artery reimplantation is indicated. Although some surgeons advocate routine reimplantation of all patent inferior mesenteric arteries as the safest means to avoid colonic malperfusion,[121] this practice has not been universally adopted. Intraoperative detection of ischemia can be difficult, and all of the various techniques of doing so have their limitations. In addition to direct visual assessment, interrogation of Doppler flow along the antimesenteric border, measurement of the inferior mesenteric artery stump pressure, and administration of intravenous fluorescein have been used. Given the frequency of delayed presentation, maintaining a high index of suspicion and having a low threshold for performing sigmoidoscopy during the early postoperative period are critical in the effort to avoid potentially catastrophic colonic perforation.

Late Complications

Late complications after aortobifemoral grafting include graft limb thrombosis, aortoenteric fistula, graft infection, and anastomotic pseudoaneurysm (see Table 106.3).

Graft Thrombosis

Graft thrombosis is the most frequently encountered late complication (see Chapter 46). It occurs in as many as 30% of cases in some series in which the grafts were observed for 10 years or longer.[122] Occlusion of the entire graft is relatively rare and usually stems from placing the proximal anastomosis inappropriately low in relation to the renal arteries, with subsequent progression of proximal atherosclerosis. A more commonly encountered scenario is unilateral limb thrombosis, which most often reflects progressive intimal hyperplasia at the distal anastomosis or progression of outflow disease. Flow can frequently be restored with aggressive efforts using special thrombectomy catheters designed to remove the chronically adherent fibrinoid thrombus typically encountered. If inflow is successfully restored, revision of the distal anastomotic site with a profundaplasty or extension of the graft may prove necessary. If more extensive progression of outflow disease is identified, or if extraction of a distally propagating thrombus is unsuccessful, the addition of an outflow graft may be needed to ensure patency of the revascularized limb. A femorofemoral or axillofemoral graft usually suffices as a secondary source of inflow when an aortobifemoral limb is not successfully reopened.

False Aneurysm

Anastomotic false aneurysms are far less common in modern practice compared with the early experience of aortic grafting, but they continue to be seen as a late complication in 1% to 5% of cases (see Chapter 48).[119,123] They arise secondary to a weakening in the suture line as a result of structural fatigue or fabric degeneration. Undue tension, poor suturing technique, and focal weakening of the recipient arterial wall after endarterectomy have been implicated as causative factors. Infection undoubtedly plays a role in many cases, despite the frequent absence of any obvious clinical signs; *Staphylococcus* species are the predominant organisms identified in culture. Femoral anastomotic false aneurysms are most common and typically are manifested as a slowly enlarging, asymptomatic groin bulge. Proximal anastomotic false aneurysms are often discovered incidentally during radiographic evaluation for other reasons or come to attention when they rupture. Given the potential complications of thrombosis, embolization, or rupture, repair is generally recommended for femoral false aneurysms larger than 2 cm or aortic false aneurysms greater than 50% of the graft diameter. Treatment usually consists of débridement of the degenerated tissue and placement of a short interposition graft.

Graft Infection

Prosthetic graft infection is a particularly feared complication of aortic reconstruction, given its high associated morbidity and mortality (see Chapter 47).[124] The diagnosis is typically reached by a combination of clinical suspicion and computed tomography (CT) or isotope-labeled leukocyte scanning, with the groin being the most common site of presentation. On occasion, exploration is needed to confirm or to refute the diagnosis. Preventive efforts include strict adherence to sterile technique, particularly in the setting of infected, distal ulcerations, and the timely administration of preoperative antibiotics. Graft contamination at the time of implantation is difficult to prove but is believed to be common. Once infection is diagnosed, graft excision is usually indicated.

Aortoenteric Fistula

Aortoenteric fistula is another relatively rare but potentially devastating late complication associated with aortobifemoral grafting (see Chapter 49).[125] The most common pathophysiologic process is erosion of the proximal aortic suture line through the third or fourth portion of the duodenum, although fistulae between the iliac anastomoses into the small bowel or colon are also well described. The diagnosis can be challenging and typically involves some combination of CT scanning, endoscopy, and angiography. The classically described triad of gastrointestinal bleeding, sepsis, and abdominal pain is present in only a minority of patients. Far more commonly, a small, self-limited "herald bleed" presages a large gastrointestinal bleed, which can be massive in nearly a third of cases. In many respects, treatment is similar to that for graft infection; extra-anatomic bypass and graft removal are usually required, in addition to repair of the involved gastrointestinal tract. Dedicated efforts to ensure adequate tissue coverage between the graft and the overlying bowel before abdominal wall closure are important in preventing this highly lethal complication.

ISOLATED PROFUNDAPLASTY

The last 3 decades have been marked by an increased awareness of the critical role of the deep femoral artery in achieving successful lower extremity revascularization. Profunda circulation is frequently spared, even in the setting of severe obliterative disease of both the AI and femoropopliteal arterial segments. When present, profunda occlusive disease is often limited to the orifice or proximal segment (Fig. 106.13). This has important implications for the unique role of the profunda in maintaining collateral perfusion because even in the presence of proximal profunda disease, the more distal segments beyond the obstruction can continue to support key anastomotic networks. In extreme cases, these pathways can serve as the sole limb-sustaining bridge between pelvic or abdominal wall inflow vessels proximally and geniculate connections distally. In some diabetic patients, however, profunda disease is more diffuse, and distal collaterals are minimal.

The value of the profunda in supplying sufficient distal perfusion in the setting of SFA occlusion has been known since the early 1960s. Although isolated profundaplasty is less common in the current era of more aggressive percutaneous and open surgical reconstruction for lower extremity occlusive disease, it can be an effective alternative to either balloon angioplasty or surgical bypass of the SFA. It is particularly useful when infected infrainguinal grafts require removal or in the setting of failed bypass grafts when suitable autogenous conduit is absent and "redo" surgery is less appealing. It may also allow healing of a below-knee amputation in situations in which distal bypass is no longer an option.

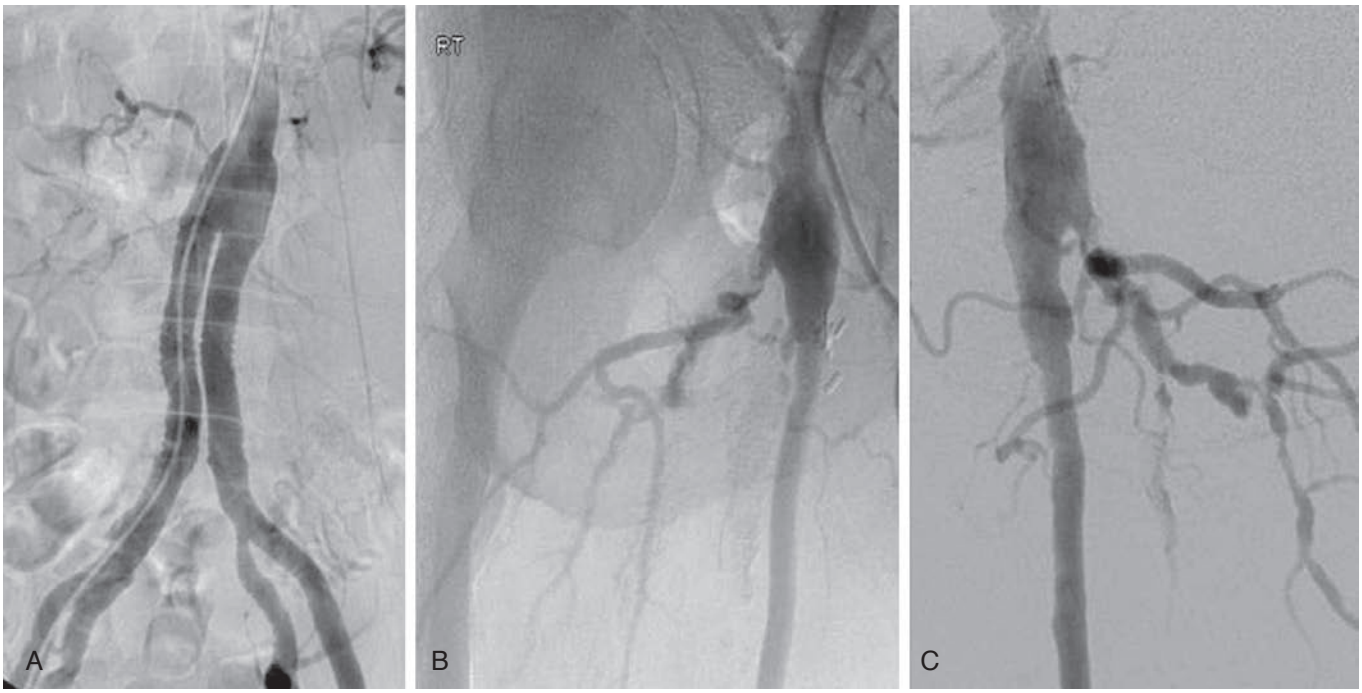

Figure 106.13 A patient with widely patent aortobifemoral and bilateral femoroperoneal bypass grafts (A) developed limiting bilateral thigh claudication secondary to profunda femoris occlusive disease (B and C). Symptoms resolved after bilateral staged isolated profundaplasties.

Although profunda femoris occlusive disease can be detected with DUS, CT, and MRA, formal angiography remains the diagnostic gold standard. The optimal conditions for an isolated profundaplasty are widely patent inflow and good distal profunda runoff beyond a diseased proximal profunda; longer diseased segments are more amenable to profunda bypass. Hemodynamic criteria assessing the resistance across the knee joint have also proved useful in predicting the clinical success of profundaplasty in particular patients. The operative technique is as described earlier for adjunctive profundaplasty. Associated mortality and morbidity are low, with morbidity most commonly related to a lymphatic leak or other groin-related issues. Three-year limb salvage rates in the range of 75% have been reported in patients with critical ischemia, and 5-year patency rates of 88% have been achieved when isolated profundaplasty was performed for claudication.

CHAPTER 107

Aortoiliac Disease: Open Extraanatomic Bypass

JOSEPH SCHNEIDER

FEMOROFEMORAL BYPASS 1417
AXILLOFEMORAL BYPASS 1418
OBTURATOR BYPASS 1421
SUMMARY 1422

Direct replacement or in-line bypass procedures for aortoiliac or infrainguinal arterial disease were developed in the 1950s. The procedures discussed in this chapter were generally developed shortly after that as alternatives to more direct procedures. These alternative "extra-anatomic" bypass procedures offered the potential benefit of a less formidable operation than aortofemoral bypass in patients with advanced comorbidities, a less hazardous approach in patients with "hostile abdomen" (previous surgery, visceral stomas, or active infection including infection of previously placed vascular grafts among these), and as a remote site for bypass grafts in the face of arterial infection to reduce the risk of reinfection of the newly placed grafts. Two of the procedures, axillofemoral and femorofemoral bypass, are clearly less injurious to the patient than would be direct aortofemoral bypass. However, the so-called obturator bypass is probably more injurious than a direct femoropopliteal bypass, but obturator bypass remains the standard approach to re-vascularize the lower leg in the face of groin sepsis or other problems that make a more conventional procedure in the groin undesirable. The technical demands of these extraanatomic procedures are distinct from and the hemodynamic and patency results may not be the same as those of the direct procedures that they replace. This chapter will address the indications, preoperative evaluation, conduct of the procedure, follow-up, and performance expectations for these procedures.

Although the procedures described are mature and have not changed appreciably in decades, their roles continue to evolve. Younger patients tend to have more discrete proximal arterial disease and are more likely to be treatable with the rapidly expanding set of endovascular tools. In contrast, older patients with more comorbidities tend to have more diffuse arterial disease; for them, endovascular techniques may not be optimal.[1] However, endovascular techniques continue to improve and the fraction of patients for whom endovascular solutions are applicable is likewise increasing.[2-4] On the other hand, more conventional surgical techniques such as aortofemoral bypass, once thought too invasive for older patients with multiple comorbidities, may now be extended to these patients, since anesthesia and perioperative critical care have also continued to improve, thus reducing the risks of these procedures. Nonetheless, the inexorable aging of Western populations will likely result in progressively older and frailer patients for whom these extraanatomic procedures may be appropriate. The outcome of critical limb-threatening ischemia is quite poor if the patient is not first treated with some technique to enhance limb blood flow[1,5,6]; if the patient has any level of independence and function, some procedure will ultimately be required to maintain the limb. Finally, femorofemoral bypass has become a key component of aorto-uni-iliac endovascular aortic aneurysm repair. Thus, although the procedures may be mature, the profiles of the patients for whom they are appropriate have evolved and will likely continue to do so.

As with any procedure, all efforts should be made to optimize the patient's status and to treat any coexisting problems before proceeding to surgery. In particular, any infection should be treated and controlled with drainage and antibiotics to the extent possible. Preoperative "optimization" of any medical problems including diabetes mellitus, coronary artery disease, congestive heart failure, and nutritional deficits is also desirable. Treatment of any of these problems will improve the patient's general condition and reduce the risk of infection of the graft. However, because extra-anatomic bypasses are often required

in urgent or emergent situations, such patient "optimization" may not be possible.

Preoperative planning requires enough anatomic information to assess the appropriateness of the procedure, both inflow in the "donor" artery and outflow (the common, deep, and superficial femoral arteries). This has traditionally required conventional transarterial catheter–based angiography. Computed tomography (CT) angiography has suffered from the interference of calcium in atheromas, which are nearly always present in patients with diffuse atherosclerotic disease, and artifacts from implanted metal devices as well as calcium, but the emergence of dual-energy CT has markedly improved the quality of CT angiography in these patients.[7,8] Magnetic resonance imaging (MRI) has also advanced significantly, now with the ability to produce high-quality angiograms without contrast as well,[9] although the proprietary nature (with associated lack of uniform naming) of these techniques and dependence on high-flux systems seems to have limited the deployment and publication of scientific articles describing the clinical use of these newer MR techniques. Planning with the exclusive use of ultrasound-based techniques would be unusual and would be appropriate in only a very small number of cases.

Any of these procedures may be contraindicated in patients at extreme medical risk with only brief expectations of survival. Obturator bypass in particular is a significantly invasive procedure, clearly physiologically taxing; it may constitute a larger injury than some patients can be expected to tolerate. One should seriously question performing any of these procedures in the face of active, inadequately treated infection; if there is no alternative, then one should at least consider an autologous graft, such as great saphenous vein or femoral vein or perhaps an antibiotic-soaked protein-impregnated graft.[10]

FEMOROFEMORAL BYPASS

Femorofemoral bypass was first described as a stand-alone procedure in 1952,[11] but the first substantial series of patients with follow-up information was published in 1960.[12] The procedure involves diversion of some blood from one iliac system to the contralateral leg and depends on the concept that one healthy iliac artery has the capacity to supply adequate flow to both the ipsilateral donor leg and the contralateral recipient leg.[13] Femorofemoral bypass has been a frequently applied procedure in patients with dominant unilateral iliac artery disease and more recently in patients whose suboptimal "donor" iliac artery can be improved with endovascular techniques.[14-16] Even more recently endovascular techniques have continued to improve and many patients who would have been treated with femorofemoral bypass may now be completely treated by hybrid or purely endovascular techniques. Femorofemoral bypass has also found a new application as an accompaniment to aorto-uni-iliac endovascular aortic aneurysm repair.[17] One should also consider the more direct common iliac-to-femoral bypass, which appears to have the same performance as the benchmark aortofemoral bypass procedure.[18,19]

If there is any question about the adequacy of the inflow because of disease in the iliac arterial system, one should consider a pharmacologic physiologic stress test of the inflow,[20,21] treat the diseased inflow with endovascular techniques as discussed previously, or abandon the plan for femorofemoral bypass in favor of an alternative procedure. With respect to outflow, either a minimally diseased normal-caliber deep femoral or minimally diseased superficial femoral artery provides sufficient outflow in most cases to support graft patency (as discussed further on) and adequately improve perfusion of the leg. It is rarely necessary to add a simultaneous infrainguinal bypass procedure on the recipient side to enhance distal perfusion, at least to treat resting ischemia of the recipient limb.

Femorofemoral bypass is performed with the patient in the supine position under general, regional, or—in selected patients—even local anesthesia. Prophylactic antibiotics are appropriate in elective cases and targeted antibiotics are appropriate for patients with active infection who require urgent treatment. The operation may be performed with a limited area of sterile preparation to include only the lower abdomen, groins, and upper anterior thighs, but in most cases we would perform the operation with preparation and draping to include the entire anterior abdomen to allow access to the iliac arteries or even the aorta should this become necessary and both legs circumferentially to allow intraoperative assessment of perfusion at the level of the ankles at the end of the operation. In most cases longitudinal groin incisions provide the most flexibility for the placement of anastomoses after the donor and recipient femoral arterial systems have been inspected. A graft is tunneled from one groin to the other in an inverted U configuration, usually in the subcutaneous area (anterior to the abdominal wall fascia) but on rare occasion in the retrofascial space from one groin incision to the other. This tunnel can be created with a specialized tunneler or simply with finger dissection and a large clamp. Care must be taken to avoid entering the peritoneal cavity and, in the case of previous abdominal surgery, great care must be taken in tunneling through scarred areas to prevent visceral injury. The first ever femorofemoral bypass was performed with an endarterectomized occluded superficial femoral artery autograft; a small fraction of such procedures are performed with venous or arterial autografts or allografts, primarily in the face of infection or intestinal or urinary stomas, but the vast majority are performed with prosthetic material. Although multiple prosthetic graft types have been touted as superior to their alternatives, there is no compelling evidence that polyester fabric, supported polyester, expanded polytetrafluoroethylene (ePTFE), supported ePTFE, heparin bonding, other graft lining, or any other graft type is superior in terms of hemodynamics or patency in the femorofemoral application. Thus our practice is to use a 6- or 7-mm supported ePTFE graft depending on patient size and native arterial diameter.

One key technical point is to prevent kinking of the graft in the anteroposterior direction, especially in patients with protuberant abdomens, either by shortening of the anastomosis or placing the anastomosis more distally (possibly to include the deep femoral or superficial femoral arteries or both) to allow a less acute angle at the heel of the anastomosis.[22] Another key point is to create the subcutaneous tunnel in a more uniform larger radius arc, generally by making the most superior part

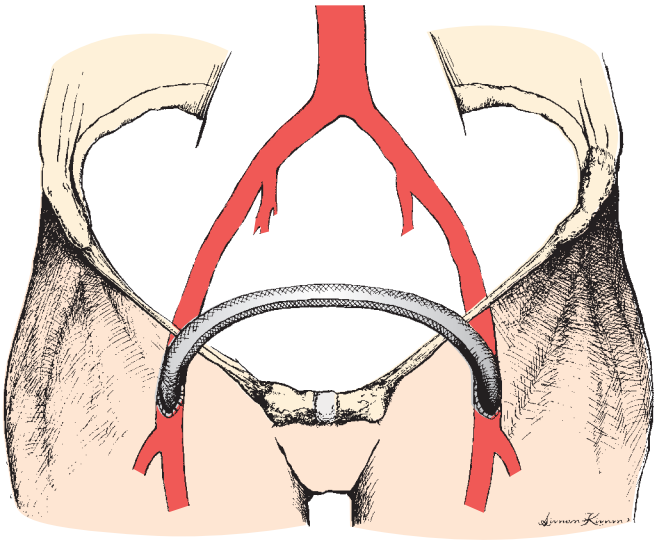

Figure 107.1 Standard "inverted C," perhaps better termed "inverted U," configuration of a femorofemoral bypass graft.

of the graft well superior to the pubis (Fig. 107.1) to reduce the risk of kinking in the coronal plane.

Intravenous heparin or, in the case of patient heparin sensitivity, another suitable short-acting anticoagulant is administered prior to clamp placement to allow arteriotomies and anastomoses. Arteriotomy and anastomotic sites are selected based on review of the preoperative arteriogram and local examination of the artery at the time of exploration of the femoral arteries; these may include the common, deep, or superficial femoral artery or some combination thereof. A conventional end graft–to-side artery anastomosis, as described in earlier chapters, is nearly always appropriate on both sides; it may be facilitated by extending the arteriotomy and the toe of the graft onto the deep or superficial femoral artery or even placing the entire anastomosis to the deep or superficial femoral artery. The right and left anastomoses may be performed simultaneously, thus saving significant time if two surgeons are available. If the anatomy dictates extension of the anastomosis onto the deep femoral artery, as may be necessary in the face of disease in the origin of that artery, this may actually reduce the tendency of the graft to kink adjacent to the anastomosis. Once the anastomoses have been completed and the clamps removed, a sterile continuous-wave Doppler should be used to confirm that flow is enhanced in the recipient side outflow artery or arteries and that there is no apparent deterioration in flow in the donor-side outflow arteries. Once again, as long as there is a normal diameter, minimally diseased or adequately improved donor iliac artery, the graft should not "steal" from the donor leg at rest.

Some authors have observed that femorofemoral graft patency is better if the superficial femoral artery is patent on the recipient side, but we and others have observed no difference.[14,23] We make sure that there is adequate outflow to at least the deep or superficial femoral artery. This is done by using adjunctive techniques such as the graft anastomotic hood to perform a "patch angioplasty" as necessary to ensure that a 3.5-mm diameter dilator will pass easily beyond the toe of the anastomosis and into at least one of the recipient superficial or deep femoral arteries. We have found that this is generally associated with adequate patency.

Patients are treated with antiplatelet agents (aspirin alone appears adequate). Hospital length of stay is determined primarily by comorbidities; some patients may be ready for discharge on postoperative day 1 or 2. Although the literature is sparse with respect to the value of surveillance noninvasive testing,[24] we have adhered to a program of surveillance with ankle-brachial indices, continuous-wave Doppler waveforms at the ankle, and graft duplex scans every 3 months for the first year, twice in the second year, and yearly thereafter if graft performance is stable, just as we do for infrainguinal bypass grafts.[25]

Operative mortality for femorofemoral bypass should be much less than 5%. A femorofemoral graft does not perform as well as a direct aortofemoral bypass based on patency or hemodynamic improvement.[14] In particular, femorofemoral bypass may not be a hemodynamically complete treatment for claudication. However, femorofemoral bypass performs acceptably and may be a better choice than direct aortofemoral bypass based on patient factors. Predicted patency at 5 years for patients whose indication is atherosclerotic occlusive disease should be about 70%, based on assessment of recent pertinent publications as detailed in this chapter in the previous edition of this text, and is probably better in patients having femorofemoral bypass as part of aorto-uni-iliac endovascular repair of aortic aneurysm.[26,27] Causes of failure include technical errors, progression of inflow or outflow disease, and perianastomotic stenosis due to intimal hyperplasia. There are few complications specific to femorofemoral bypass, but they would include visceral injury, particularly if the graft is tunneled in a retrofascial position or if there is a hernia. In difficult circumstances with a high-risk patient, a femorofemoral bypass is a relatively low-risk way to reperfuse a leg with dominant unilateral iliac artery disease and is likely to be an essential skill for the vascular surgeon for the foreseeable future.

AXILLOFEMORAL BYPASS

The first reported axillofemoral bypass procedures were performed to treat patients at unacceptable risk for conventional aortofemoral bypass and for extraanatomic bypass at the time of removal of infected grafts.[28] Examples of two of the three primary indications for axillofemoral bypass are as follows: (1) patients with symptomatic aortic and/or bi-iliac arterial occlusive disease thought to be at excessively high physiologic risk for direct aortic repair, (2) patients with infected native aortas or aortic grafts or the closely related problem of aortoenteric fistulas, and (3) patients with a hostile abdomen, generally with multiple previous surgeries, active intra-abdominal infection, or the presence of intestinal or urinary stomas. Although there was a period of popularity of axillofemoral bypass as a primary procedure for aortoiliac occlusive disease—for example, as promoted by Johnson[29] and later by the group at the Oregon Health Sciences University[30]—it is fair to say that this approach was not widely adopted. There was also a period of interest

generated by the Albany group for axillofemoral bypass combined with ligation of the infrarenal aorta as primary treatment for abdominal aortic aneurysm,[31] but this approach was generally abandoned when it was observed that a number of such patients later died of ruptured abdominal aortic aneurysm.[32] Conventional thinking in the peak period of the operation was that axillofemoral bypass should nearly always be performed in a bifemoral configuration[33]; however, some of these same advocates later reported that axillounifemoral bypass performed as well as axillobifemoral bypass.[34] Thus the choice of an axillounifemoral versus axillobifemoral configuration should be based on whether one or both legs would benefit from improved flow.

Many patients with aortic and/or bi-iliac arterial occlusive disease are now treated completely or partially with the ever-expanding endovascular armamentarium. Furthermore, it is likely that some of these patients who might have been selected for axillofemoral bypass in the past are now seen as at manageably low risk for direct aortofemoral bypass. Thus axillofemoral bypass has likely declined in volume from a peak in the 1970s and 1980s. Nevertheless, this procedure remains an essential tool for the vascular surgeon. Similar to the assumption with femorofemoral bypass, axillofemoral bypass assumes that one axillosubclavian artery has adequate blood volume flow capacity to supply the donor side arm and one or both legs, at least at rest.

One unique preoperative question is which axillary artery is to be used for the donor. The graft is generally tunneled in the midaxillary line and lateral abdomen from the donor axillary artery to the ipsilateral femoral recipient artery. Coexistent thoracic or abdominal problems may dictate the side of the procedure; the impending need for thoracotomy or abdominal surgery for other problems may dictate use of the contralateral axillary artery. The presence of intestinal or urinary stomas may dictate contralateral placement of the axillofemoral graft. Some surgeons ask the patient on which side they sleep and will place the graft contralaterally, although it is not clear that this is really necessary. If none of these alternatives seems to point to one or the other side, most surgeons would place the graft on the side of the more symptomatic leg, certainly if an axillounifemoral configuration is to be used, but there is otherwise no clear evidence to support any advantage to placement of the axillofemoral graft on the more symptomatic side. We would recommend against placement of an axillofemoral bypass based on the side of an existing arteriovenous hemoaccess fistula, since this might provoke or worsen existing steal symptoms in that arm, but we are aware of no description of such an occurrence, published or otherwise. In any case, we insist on a triphasic brachial artery Doppler waveform and a blood pressure no more than 10 mm Hg lower in the proposed donor arm than in the contralateral arm. If these criteria are not met, we will proceed to upper extremity angiography and, if necessary, inflow artery treatment prior to surgery.[35]

The procedure is performed with the patient in the supine position. Although it may be possible to perform segments of the operation with local or regional anesthesia, creating the axillofemoral tunnel would be difficult; for practical purposes, the operation is always performed with general anesthesia. We place a gel pad or a towel-wrapped 1-L bag of fluid between the operating table and the posterolateral back on the side of the axillofemoral graft to elevate the flank and lower chest to allow slightly more posterior prepping and draping for better visualization during tunneling. Some surgeons position the ipsilateral arm at the patient's side, but we have always positioned the ipsilateral arm at 90 degrees abduction both to allow visualization of the ipsilateral lateral chest and abdomen during tunneling and to elevate the clavicle slightly to enhance exposure of the donor axillary artery. The sterile preparation should be wide and should include at a minimum the anterior and ipsilateral neck base and supraclavicular fossa over to the anterior shoulder area, the axilla, anterior and ipsilateral chest and abdomen, and the groin and superior anterior thigh. In particular, we have always thought it prudent to prep widely to allow for a thoracotomy in case of an injury or other problems with the axillosubclavian donor artery, although we have never had to proceed to thoracotomy. In the case of axillobifemoral bypass, the preparation and draping must include the contralateral lower abdomen, groin, and anterior upper thigh. Prophylactic antibiotics or—in the case of active infection—targeted antibiotics are administered.

Groin exposure is identical to that outlined earlier for femorofemoral bypass. The donor axillary artery is exposed with a transverse incision a few centimeters inferior to the clavicle and by splitting of the pectoralis major muscle fibers. The axillary artery should be exposed and controlled from the clavicle medially to the pectoralis minor muscle laterally, typically over a length of 3 to 4 cm. This artery is more fragile than the more familiar common femoral artery and great care must be taken not to injure it during dissection and clamp placement and for the same reason during creation of the anastomosis, since sutures are more likely to tear through the artery.

A subcutaneous tunnel is created from the ipsilateral groin incision to the axillary artery exposure incision. In the early experience with axillofemoral bypass, a separate flank incision was required about half the distance from the axillary artery exposure incision to the ipsilateral groin incision since there were no adequate tunnelers to traverse the entire distance. However, there are now several tunnelers that will traverse the entire distance and do not require the intermediate incision in the flank. We use a 65-cm Gore tunneler, although it is no longer manufactured and the reader is advised to consult graft and instrument suppliers regarding available tunnelers. Care must be taken to remain in a subcutaneous plane, superficial to the abdominal wall deep fascia, to avoid entering the thoracic cavity during tunneling. Although some have advocated tunneling anterior to the pectoralis minor muscle or even division of the pectoralis minor, we have always tunneled posterior to the pectoralis minor.

Axillofemoral bypass is virtually always performed with a prosthetic graft and, as with femorofemoral bypass, there is no clear advantage of one graft type over another. Although both polyester and ePTFE grafts can be purchased with preconstructed connections between the axillofemoral and femorofemoral components, given the current relative infrequency of axillofemoral bypass, most surgeons probably perform the procedure with two segments of straight graft, anastomosing one graft to

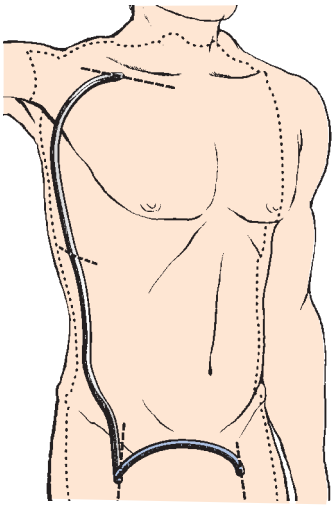

Figure 107.2 Typical area of exposure for an axillobifemoral bypass graft. The right axillary artery is the donor artery in this case. The intermediate incision in the right lower chest or upper flank is generally unnecessary if an appropriate tunneler is used.

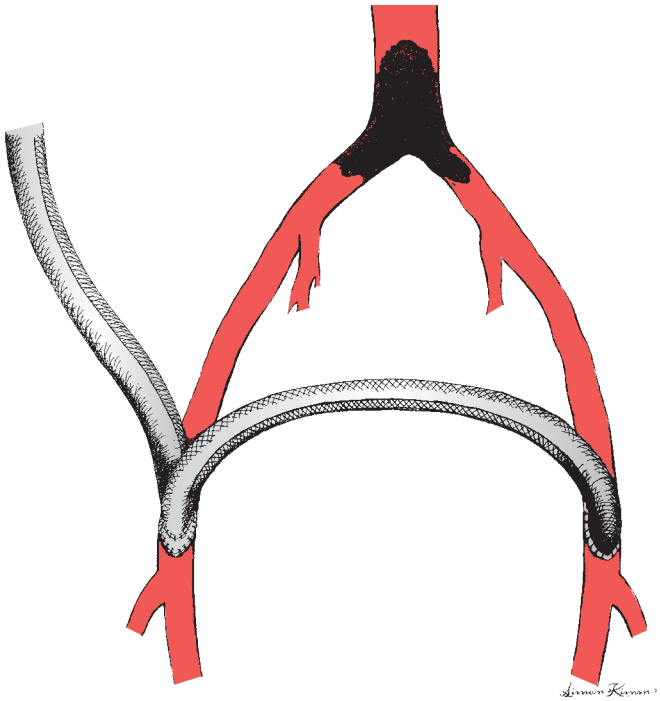

Figure 107.3 Typical configuration of an axillobifemoral bypass graft. In this case the right axillary artery is the "donor" and the axillofemoral component has been anastomosed to the native right common femoral artery, after which the right end of the femorofemoral component has been anastomosed to an ovoid graftotomy in the anterior wall of the anastomotic hood of the axillofemoral component.

the other (Fig. 107.2). We tend to use an 8-mm supported ePTFE graft for the axillofemoral component and, if the bypass is to be axillobifemoral, a 6-mm supported ePTFE graft for the femorofemoral component. On rare occasions in performing an axillounifemoral bypass in a small patient, a 6-mm-diameter graft may be used, in part to try to enhance velocity, which may improve patency.[36,37]

Heparin or another suitable short-acting anticoagulant is administered before clamps are placed on the arteries. As with femorofemoral bypass, conventional end graft-to-side artery anastomoses are usually appropriate. An axillobifemoral bypass with two separate graft segments requires four anastomoses, including one that connects the axillofemoral and femorofemoral components; pairs of these may be performed simultaneously. Thus axillofemoral bypass, particularly axillobifemoral bypass, is greatly facilitated if two surgeons are present.

It is critical to create the axillary artery to graft anastomosis such that there is no tension on this anastomosis when the arm is abducted. We employ two technical concepts to try to avoid this problem. First, the anastomosis should be placed as far medially as possible on the axillary artery, since this part of the artery will move less than the more lateral part of the artery when the arm is abducted; this tends to bring the graft into a more nearly parallel relationship to the artery, also reducing the tendency to produce traction on the anastomosis when the arm is abducted. The principle of leaving the pectoralis minor muscle intact and tunneling the graft posterior to this muscle tends to force the surgeon to keep the anastomosis medial. A second principle is to allow some redundancy of the graft and even some bowing into the axilla posterior to the pectoralis minor muscle.[38]

In the "heyday" of axillobifemoral bypass, a commonly recommended technical point was to place the connection between the femorofemoral and axillofemoral components as close to the femoral artery anastomosis as possible so as to try to maximize flow throughout the entire length of the axillofemoral graft. This concept is plausible and we adhere to it, but there is no observational evidence that it provides a real advantage. It is usually simple to either complete a conventional femorofemoral bypass and then sew the axillofemoral graft to a graftotomy in the ipsilateral anastomotic hood of the femorofemoral graft or, alternatively, to complete the anastomosis between the inferior end of the axillofemoral graft and then sew the ipsilateral side of the femorofemoral graft to a graftotomy in the femoral anastomotic hood of the axillofemoral component (as depicted in Fig. 107.3). In either case, unlike a pliable native artery, where a simple arteriotomy creates an adequate opening, a prosthetic graft tends to be rigid and not to gap adequately after a simple longitudinal graftotomy. Therefore anastomosing a graft to the side of a prosthetic graft requires excision of an oval of the graft material at the point where anastomosis is to be created. No matter whether the graft is performed in axillounifemoral or axillobifemoral configuration, the same principles described earlier for femorofemoral bypass to assure adequate outflow (e.g., using the graft hood as a patch or assuring that a 3.5-mm diameter metal dilator will pass easily into at least one outflow artery) are equally applicable to axillofemoral bypass.

A sterile handheld Doppler probe is used to confirm that flow is augmented in the outflow artery or arteries with the graft open versus with the graft clamped. The surgeon must also assure that there is normal flow in the distal arm on the donor side—for example, by confirming the presence of a palpable pulse in the radial artery or by confirming satisfactory

pulse oximetry in a digit with the graft open (with blood flowing to the lower extremity or extremities.

Just as with femorofemoral bypass, an axillofemoral graft does not perform as well as a direct aortofemoral bypass based on patency or hemodynamic improvement.[39] In fact, our previous work suggests that the predicted ankle-brachial index after axillofemoral bypass with normal (undiseased) infrainguinal outflow is less than 0.7, compared with slightly more than 1.0 after direct aortofemoral bypass.[39] However, axillofemoral bypass performs acceptably and may be a better choice than direct aortofemoral bypass based on patient factors.

The literature of axillofemoral bypass has what is likely the broadest range of reported long-term patencies for any open vascular surgical procedure, probably related to the broad range of patient characteristics in that literature.[26] However, a fair estimate for predicted patency at 5 years among patients whose indication is atherosclerotic occlusive disease should be about 60% to 70%. In a patient with bilateral iliac artery disease that cannot be improved adequately on at least one side with endovascular techniques to allow a femorofemoral bypass, a patient with an infected native aorta or aortic graft, or a "hostile" abdomen, an axillofemoral bypass provides a less invasive approach to reperfusing one or both legs.

With respect to surveillance of axillofemoral bypass, the literature is even less revealing than for femorofemoral bypass. Just as with femorofemoral bypass, since the predicted patency for axillofemoral bypass is clearly less than for aortofemoral bypass, we are much more aggressive with noninvasive surveillance and obtain ankle pressures, ankle-level Doppler waveforms, and graft duplex scans every 3 months for the first year, twice in the second year, and yearly after that.[25] Complications specific to axillofemoral bypass include disruption of the anastomosis from the axillary artery to the graft[40] and thromboembolic complications in the native arteries after thrombosis of the axillofemoral graft.[41]

OBTURATOR BYPASS

Shaw and Baue first described three cases of obturator bypass as a method to maintain perfusion of the leg after dealing with arterial infection in the groin.[42] The technique requires tunneling a graft from the iliac arterial system through the obturator fossa in the pelvis to the infrainguinal arterial system, a path proposed at least 2 years before Shaw and Baue's first description.[43]

The primary indication for this procedure is arterial infection in the femoral triangle. Our most recent experience with this operation has been predominantly in patients with infected aneurysms as complications of arterial puncture for angiography or endovascular procedures; other causes, however, are related to recreational drug use; infection early or late after direct surgical exposure of the femoral artery for embolectomy, endarterectomy, or other direct arterial surgery; or "hostile groin"—for example, after previous procedures or therapeutic radiation.

The operation is performed with the patient in the supine position with the entire ipsilateral leg circumferentially prepped and draped so that the entire leg is available and can be moved in the sterile field just as one would do for infrainguinal bypass. The groin and abdomen are also prepped and draped to allow access to the iliac arteries or the aorta if necessary. Inflow is typically from the ipsilateral common or less often the external iliac artery, although inflow could be taken from the aorta or the contralateral iliac arterial system. The approach is most often through an oblique ipsilateral low abdominal incision and retroperitoneal exposure of the iliac arteries, although a transperitoneal approach and control of the inflow artery is also possible. Outflow is usually the above knee popliteal or superficial femoral artery, exposed as would be the case for femoropopliteal bypass (see Chapter 109), although on occasion this will involve the deep femoral system or an infragenicular popliteal or other more distal artery. The graft is tunneled through the obturator foramen posterior to the adductor longus (Fig. 107.4). The obturator foramen is approached medial to the external iliac vein and posterior to the superior aspect of the pubic ramus, and the obturator internus muscle is bluntly dissected away from the obturator membrane. The obturator membrane is very strong; it cannot be perforated bluntly and requires incision with scissors, scalpel, electrocautery, or another suitable technique. It is difficult to see this well enough to perforate under direct vision, certainly if a small incision is used, and care must be taken not to damage adjacent structures

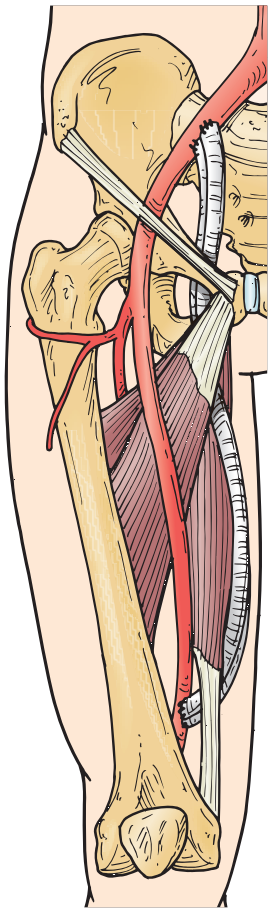

Figure 107.4 Typical course of the obturator bypass graft, in this case originating from the most proximal portion of the right external iliac artery, passing through the obturator foramen, and terminating at the popliteal artery.

such as the urinary bladder in creating the tunnel and the defect in the obturator membrane. The incision should be in the anteromedial part of the obturator membrane to avoid the obturator nerve and artery. The graft is usually placed in the potential space between the adductor magnus posteriorly and the adductor longus and brevis anteriorly, although it may be brought into the area of the superficial femoral artery by bringing the tunnel between the adductor longus and brevis muscles. Anastomoses to the inflow and target arteries are performed in conventional fashion, with heparin or other suitable anticoagulation during the time that the arteries are clamped. Conventional end graft-to-side native artery anastomoses as described elsewhere in this text are nearly always appropriate for both donor and recipient arteries.

Shaw and Baue's first three cases were all performed with polyester textile grafts. However, it is clear from the original publication that there was persistent infection in at least two of these operations, one patient ultimately dying from complications of infection, and we would recommend autologous grafts whenever possible. In our experience, we have never used other than an autologous vein graft.

As is the case of the other two procedures described in this chapter, obturator bypass probably does not perform as well as the index procedure of femoropopliteal bypass as measured by patency. Five-year estimated primary patency is probably in the range of 50% to 60%.[44-46] However, once again this procedure is far superior to the alternatives in the situations for which obturator bypass is appropriate. We use the same postoperative protocol for obturator bypass graft surveillance (ankle-brachial indices, ankle-level continuous wave Doppler waveforms, and graft duplex scan every 3 months in year 1, every 6 months in year 2, and yearly thereafter) as we do for conventional infrainguinal bypass grafts.[25] Complications specific to obturator bypass include urinary bladder injury or other visceral injury at the time of surgery.

SUMMARY

Each procedure described in this chapter will provide acceptable perfusion to the target limb and acceptable long-term patency. Limb loss is rare for all of these procedures with a patent bypass graft. Obturator bypass can be expected to perform nearly as well hemodynamically and with respect to patency as a conventional infrainguinal bypass, such as a femoropopliteal bypass. However, it is clear that femorofemoral and axillofemoral bypasses do not achieve quite the same hemodynamic and patency results as seen after direct aortofemoral bypass. Nevertheless, each of these procedures provides a way of solving difficult problems in patients who are not suitable for the more conventional approaches owing to comorbidities, infection, or other factors. The indications and patient selection criteria for femorofemoral and axillofemoral bypass have evolved and, on balance, these procedures are probably less often used than they were 20 years ago. In sum, familiarity and experience with these procedures is essential to the practicing vascular surgeon, since these may be the best way to solve some very difficult problems. Obturator bypass may actually be increasingly applicable because of the continuing rise in the frequency of transfemoral endovascular procedures and parenteral use of recreational drugs, both accompanied by a risk of femoral arterial infection. Although not often the first choice for most patients requiring infrainguinal bypass, in the face of groin infection, previous surgery or radiation in the groin, or other unusual situations that dictate avoidance of arterial reconstruction in the groin, the obturator bypass is an essential procedure to maintain perfusion of the leg.

Abstract

Endovascular techniques play a crucial role in the treatment of aortoiliac occlusive disease. Treatment should be tailored to the individual patient's symptoms and comorbidities, as well as the location and extent of disease. This chapter highlights the most recent developments in the endovascular management of aortoiliac occlusive disease.

Keywords

iliac

hybrid procedure
claudication

Endovascular techniques play a crucial role in the treatment of aortoiliac occlusive disease. Treatment should be tailored to the individual patient's symptoms and comorbidities, as well as the location and extent of disease. This chapter highlights the most recent developments in the endovascular management of aortoiliac occlusive disease.

BACKGROUND

Progress in endovascular surgery has resulted in a continued shift in the treatment of patients with aortoiliac occlusive disease to less invasive forms of therapy. Early pioneers such as Dotter and Gruntzig developed balloon angioplasty.[1] Subsequent work in stent development by Palmaz gradually improved the treatment of patients with aortoiliac disease.[2-4] Improvements in technology such as higher resolution imaging, lower profile systems, premounted balloon-expandable stents, self-expanding stents, and stent grafts have resulted in better outcomes with fewer complications. Vascular surgeons now widely incorporate these treatment modalities into their practices. Today the majority of patients with aortoiliac occlusive disease can be safely treated with either percutaneous endovascular procedures or, in patients with more advanced aortoiliac occlusive disease, by means of stent grafts and hybrid open-endovascular approaches.

INDICATIONS

There are both patient- and lesion-specific indications for aortoiliac intervention. Patient-specific indications for treatment include lifestyle-limiting claudication, rest pain, and tissue loss. Less frequent indications include vasculogenic impotence and atheroembolization to the lower extremities. As for all vascular reconstructions, the expected benefits of the proposed procedure must be weighed against the potential risks in view of patient comorbidities.

Limb Ischemia

Patients with hip, buttock, thigh, or calf claudication constitute the largest group of patients who undergo aortoiliac endovascular revascularization. Patients with chronic limb-threatening ischemia (CLTI) manifesting as either rest pain or tissue loss frequently have multilevel occlusive disease. In such patients, the aortoiliac disease is commonly diffuse and complex, often extending into the common femoral arteries (CFAs) and associated with infrainguinal occlusive disease. Patients without significant CFA occlusive disease can typically be treated with percutaneous approaches that improve lower extremity perfusion sufficiently to resolve rest pain or heal minor ischemic ulceration. In patients with a significant CFA disease burden, combined femoral artery endarterectomy and patch angioplasty with simultaneous aortoiliac stenting or stent grafting often provides adequate perfusion to treat CLTI and claudication.

Younger Patients

Patients younger than 50 years have worse outcomes following aortoiliac endovascular therapy. However, the same also applies to open surgical approaches such as aortobifemoral bypass.[5-8] Many younger patients cannot be absent from work for the 6 to 8 weeks of recovery required after open aortic surgery, and thus may opt for the less invasive endovascular approach acknowledging a potentially less durable outcome compared with open surgical reconstruction. In addition, many men are concerned about the relatively high incidence of erectile dysfunction following open aortobifemoral bypass and thus choose an endovascular approach.

Embolization

Less frequently encountered are patients who present with spontaneous embolization to the lower extremity, or so-called blue toe syndrome, who may benefit from endovascular therapy. This is a controversial indication for endovascular therapy and usually involves placement of a bare or covered stent to trap the underlying pathogenic atherosclerotic lesion and prevent further embolization.[9-11] Endovascular intervention is typically not indicated for patients whose atheroembolization was provoked by arterial catheterization procedures. In the absence of subsequent catheterization, the risk of recurrent embolization is low.

Improving Inflow for Concomitant Procedures

Endovascular therapy for aortoiliac disease is frequently required as an adjunct to various open infrainguinal procedures to provide adequate inflow. It may be performed simultaneously with lower extremity bypass or femoral-femoral bypass. Indications for treatment in this setting include a resting systolic pressure gradient proximal to the intended infrainguinal bypass of greater than 10 mm Hg or a vasodilator-enhanced systolic gradient of greater than 20 mm Hg.

CONTRAINDICATIONS

There are no absolute contraindications to the endovascular treatment of aortoiliac occlusive disease. Relative contraindications are largely anatomic and include juxtarenal aortic occlusion, circumferential heavy (>1 mm) calcification, hypoplastic aortic syndrome, and juxtaposition to aneurysmal disease. Renal insufficiency is also a relative contraindication owing to potential contrast-induced nephropathy (CIN), although preventive regimens and minimal contrast techniques have reduced the impact of this complication.[12-14]

RELEVANT ANATOMY: TRANS-ATLANTIC INTER-SOCIETY CONSENSUS CLASSIFICATION

Lesion-specific indications for the endovascular therapy of aortoiliac occlusive disease can be guided by the Trans-Atlantic Inter-Society Consensus (TASC) guidelines. The TASC classification (Fig. 108.1), revised in 2007, offers more current guidelines on the use of endovascular therapy based on lesion anatomy.[15] In general, endovascular therapy is the recommended first-line therapy for TASC A, B, and increasingly TASC C lesions as

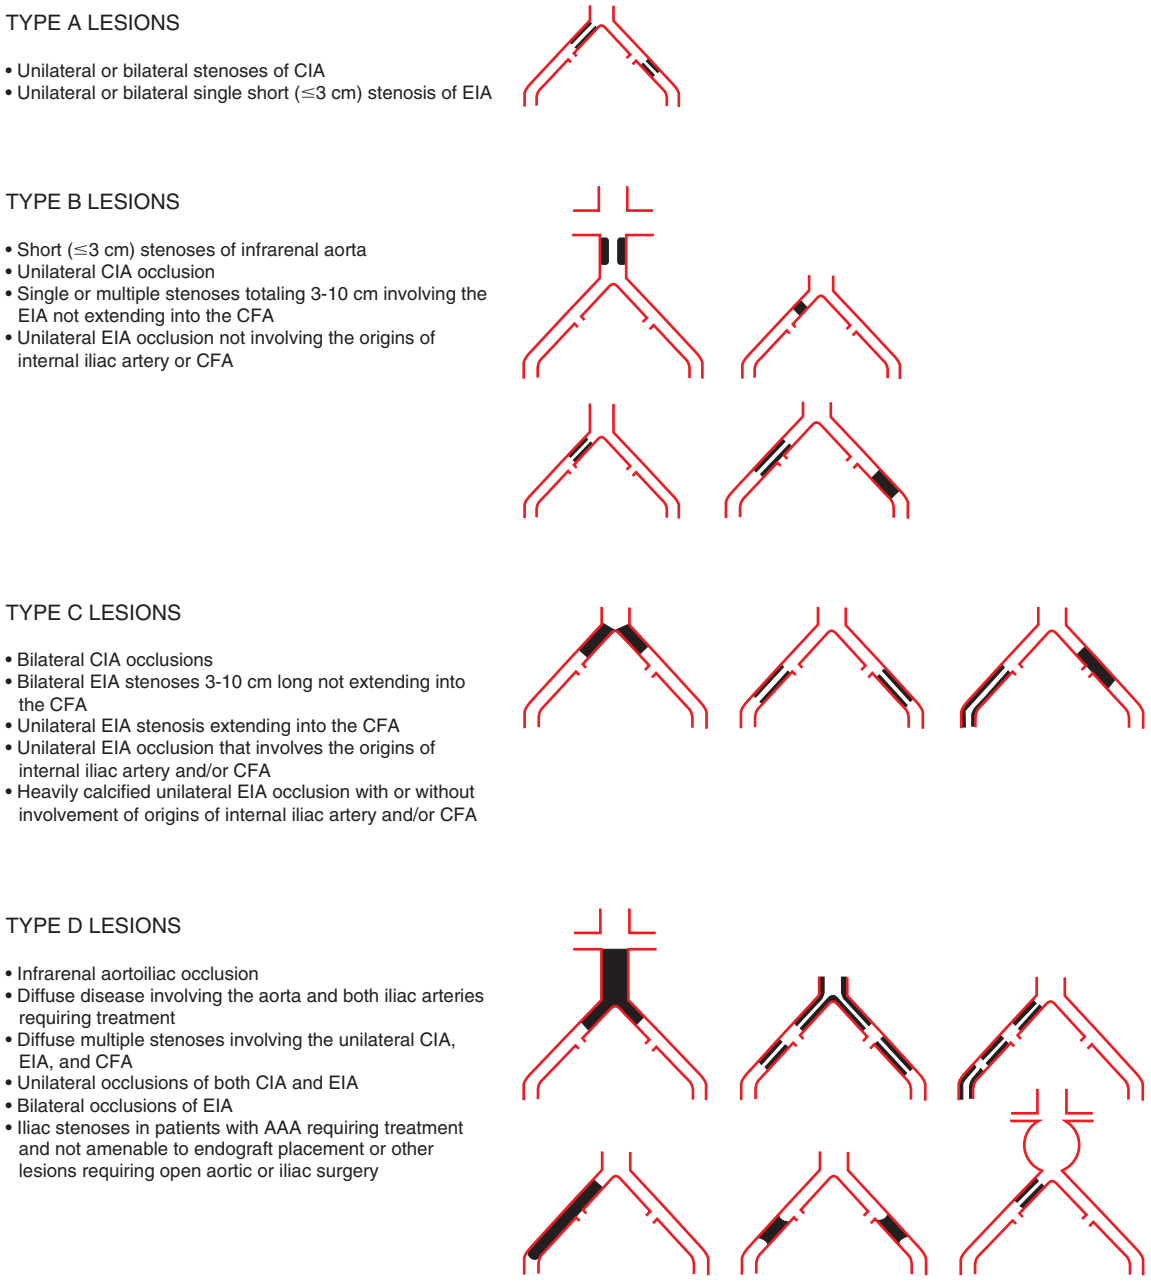

Figure 108.1 Trans-Atlantic Inter-Society Consensus (TASC) classification of aortoiliac lesions. *AAA,* Abdominal aortic aneurysm; *CFA,* common femoral artery; *CIA,* common iliac artery; *EIA,* external iliac artery. (Redrawn from Norgren L, Hiatt WR, Dormandy JA, et al. TASC II Working Group: Inter-society consensus for the management of peripheral arterial disease (TASC II). *J Vasc Surg.* 2007;45(Suppl S):S5–S7.)

endovascular techniques improve. Good-risk patients with TASC type C disease can also be treated with open surgery, depending on patient preference. Surgery is usually recommended for TASC D lesions, but advanced endovascular approaches are also now being applied with good results in these lesions.[16] High-risk patients with TASC C and D disease, CLTI, and advanced comorbidities such as severe chronic obstructive pulmonary disease, unreconstructable coronary artery disease, or a low cardiac ejection fraction may be treated with endovascular therapy, acknowledging that this approach will be less durable than open surgical options.

PATIENT EVALUATION AND OPERATIVE PLANNING

Primary Evaluation

Once a decision has been made that intervention is indicated (see Chapter 105), the location and extent of the occlusive disease must be determined, beginning with a history and physical examination. The presence of hip, thigh, or buttock claudication; impotence; a lower quadrant abdominal or CFA

bruit; and diminished femoral pulses all suggest aortoiliac occlusive disease. Noninvasive physiologic arterial studies, such as ankle-brachial index (ABI) and toe pressure measurements, are usually indicated. In patients with a history consistent with vasculogenic claudication but a normal pulse exam or resting ABI, treadmill testing may help differentiate vascular from neurogenic symptoms.

Noninvasive Imaging

Just as for open aortobifemoral bypass, additional diagnostic studies are indicated before endovascular intervention to assess the disease location, extent, and degree of calcification. The use of arteriography as a purely diagnostic tool is infrequent because of the widespread availability of less invasive imaging modalities that provide anatomic detail with less risk. The choice of endovascular versus open revascularization can be made by employing imaging modalities to evaluate the aortoiliac segment such as duplex arterial mapping, magnetic resonance angiography (MRA), and computed tomographic angiography (CTA). All these modalities have benefits and drawbacks.

Duplex Arterial Mapping

Duplex arterial mapping of the aortoiliac segment and CFAs can adequately assess the location of hemodynamically significant lesions (Fig. 108.2). It is particularly helpful to assess CFA disease burden, which may potentially alter a planned percutaneous approach through the CFA to an open CFA endarterectomy and concomitant iliac stent/stent-graft placement. This modality is especially useful in patients with renal insufficiency who are at risk for contrast-induced renal dysfunction.[17] Drawbacks of duplex arterial mapping are that it provides only a semiquantitative assessment of the degree of iliac calcification, it may not adequately image the iliac system due to overlying bowel gas or body habitus, and it requires significant time and a highly trained vascular technologist.[18,19] These constraints have prevented duplex arterial mapping from becoming more widely adopted in this setting.

Magnetic Resonance Angiography

MRA can reliably assess the aortoiliac arterial segment, although its accuracy varies widely between institutions. A major drawback is that MRA fails to accurately assess the degree of calcification of aortoiliac lesions. It remains contraindicated in patients with renal insufficiency over concerns regarding increased risk of nephrogenic systemic fibrosis due to gadolinium.

Computed Tomographic Angiography

The presence of severe calcification has significant implications for planning. Circumferential calcification thicker than 1 mm is a relative contraindication to aortoiliac angioplasty and stenting because of the potential risk of fracture and arterial rupture. In patients with significant comorbidities in whom intervention is mandated by CLTI, use of a stent graft may be considered in an attempt to limit the incidence of clinically significant arterial perforation. In this setting, CTA has been used with success to assess calcification of the aortoiliac segment before intervention. The major disadvantages of CTA include exposure to ionizing radiation and the need for iodinated contrast agent, with the risk of contrast-induced renal dysfunction. In appropriate patients, CTA can accurately assess lesion location, extent, and degree of calcification, and the severity of aortoiliac and femoral disease can be classified according to TASC. This additional information allows the formulation of an appropriate procedural plan and the selection of either open or endovascular therapy.

Evaluation for Common Femoral Artery Disease

The choice of a percutaneous or an open femoral approach is based on the burden of CFA disease. Patients with greater than 50% CFA stenosis on preoperative imaging are usually treated with a hybrid approach that entails open iliofemoral endarterectomy, patch angioplasty, and simultaneous stent or stent-graft placement. Stent grafts are frequently used in

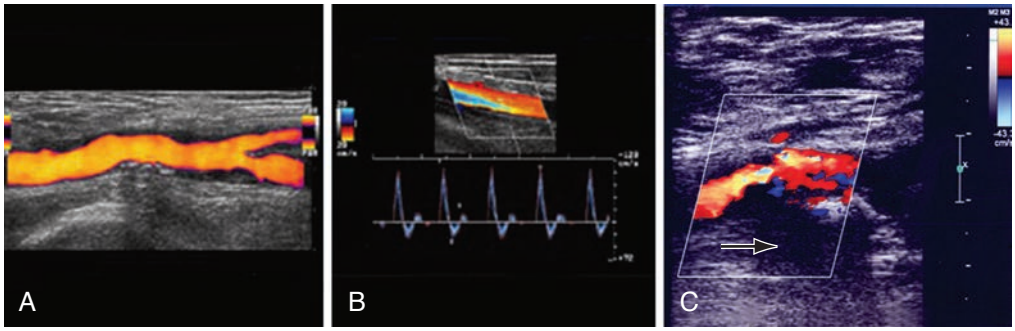

Figure 108.2 Duplex mapping of the common femoral artery. (A) Longitudinal view of the common femoral artery (power imaging) and the bifurcation of the superficial and deep femoral arteries. (B) Doppler spectral waveform from a normal right femoral artery. The Doppler signal was obtained from a longitudinal view with the Doppler sample volume placed in the middle of the lumen. The characteristic triphasic Doppler signal shows a brisk upstroke to peak systole, reversal of blood flow during early diastole, and a forward flow component during late diastole. (C) Longitudinal view of the common femoral artery with greater than 50% stenosis due to posterior plaque as depicted by the arrow.

conjunction with open endarterectomy especially in the presence of calcific external iliac artery (EIA) disease due to the risk of arterial rupture and bleeding with bare metal stents (Fig. 108.3). In patients with less severe CFA disease, a percutaneous approach can be undertaken.

Concomitant Aortic Disease

Aortic angioplasty and stenting for lesions proximal to the aortic bifurcation warrant special consideration because these lesions are frequently exophytic and calcific. Emphasis should be placed on obtaining an adequate hemodynamic response; acceptance of an imperfect completion image is critical to avoid aortic rupture. Because of the exophytic nature of these lesions, primary stent or stent-graft placement to trap potential atheroembolic debris should be considered, especially for lesions suspected of being an atheroembolic source, to minimize the potential for embolic complications.

TECHNIQUE

Pretreatment Considerations

Before intervention, the patient's history and all pertinent imaging studies are reviewed, and informed consent is obtained. Testing for coagulation and renal function are essential.

Avoiding Contrast Nephropathy

CIN is defined as an increase in serum creatinine greater than 25%, or greater than 0.5 mg/dL (44.2 µmol/L), within 3 days of intravascular contrast administration in the absence of an alternative cause. Serum creatinine usually returns to baseline within 14 days; however, some patients may progress to acute kidney failure requiring dialysis. CIN is the third most common cause of new-onset acute renal failure in hospitalized patients.[20] The incidence may be as high as 25% in patients with preexisting renal impairment or certain risk factors such as diabetes, congestive heart failure, advanced age, and concurrent administration of nephrotoxic drugs.[21] The single most important risk factor of CIN is chronic kidney disease, which increases the risk by more than 20 times. It is generally accepted that the risk of CIN in patients with estimated glomerular filtration rate (eGFR) ≥60 mL/min is extremely low. Studies have suggested that a threshold for CIN exists for patients with eGFR 40 to 45 mL/min and significant concern should be raised in patients with severe renal dysfunction with eGFR less than 30 mL/min. Patients with both renal impairment and diabetes have up to a 50% risk of developing CIN. The majority of studies regarding CIN have been in patients having intra-arterial (IA) contrast administration—in particular, cardiac interventions. It has been assumed that intravenous (IV) contrast administration has the same risk as IA injection; however, this assumption is being challenged in recent studies. Several trials in patients receiving IV contrast have shown low risk of CIN in patients with eGFR greater than 40 mL/min. Among patients that did develop CIN, none progressed to dialysis and none had fatal outcomes. Recommendations have therefore been proposed that for patients receiving IA contrast and eGFR less than 60 mL/min, full preventive measures should be done. On the other hand, for patients receiving IV contrast, preventive measures should be undertaken for eGFR less than 45 mL/min. Preprocedural volume loading and the use of low-osmolar or iso-osmolar contrast agents can decrease the risk of CIN.[22-24] However, the risk is not eliminated, even when an iso-osmolar contrast agent is used.[25,26] The risk of CIN correlates with contrast volume. Contrast volume in excess of 5 mL/kg strongly predicts CIN requiring dialysis. A second contrast dose within 48 hours also significantly increases the risk of CIN. Because free radicals are postulated to mediate CIN,[27] alkalinizing renal tubular fluid with sodium bicarbonate[28] has been shown to reduce injury. Merten and coworkers reported a single-center randomized controlled trial comparing the infusion of sodium chloride versus sodium bicarbonate as the hydration fluid to prevent renal failure in patients with stable renal insufficiency undergoing diagnostic or

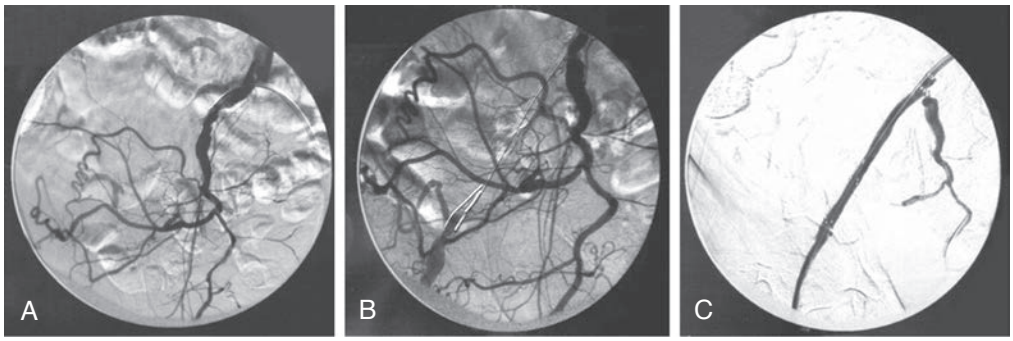

Figure 108.4 (A) External iliac artery occlusion approached through the contralateral common femoral artery. (B) Subintimal crossing of the complete occlusion with a reentry catheter. (C) Contralateral placement of a bare metal stent into the external iliac artery, allowing for placement in the proximal portion of the common femoral artery.

interventional procedures requiring radiographic contrast agent.[14] The absolute risk reduction of CIN (defined as 25% change in serum creatinine) using sodium bicarbonate compared with sodium chloride was 11.9%, resulting in a number-needed-to-treat of 8.4 patients to prevent one case of renal failure. A recent meta-analysis and systemic review of the literature confirmed that sodium bicarbonate hydration decreased the risk of CIN, without a significant risk of renal replacement therapy or in hospital mortality or congestive heart failure compared with controls. Similar results were seen for risk of CIN when sodium bicarbonate was compared with normal saline alone (OR, 0.39; 95% confidence interval [CI], 0.20-0.77). There have been conflicting results for the use of N-acetylcysteine with more than 40 trials and 13 meta-analyses, with the most meticulous meta-analysis not supporting the use of N-acetylcysteine to reduce the risk of CIN.

Patients with eGFR less than 60 mL/min receiving IA contrast should therefore receive IV hydration. If sodium bicarbonate is used, the initial IV bolus is 3 $mL \times kg^{-1} \times h^{-1}$ (154 mEq/L sodium bicarbonate in dextrose and water) for 1 hour immediately before contrast injection, followed by continuous administration of the same fluid at a rate of 1 $mL \times kg^{-1} \times h^{-1}$ during the period of contrast exposure and for 6 hours thereafter.[14] Use of the lowest volume of contrast (<5 mL/kg) to achieve satisfactory image quality is encouraged. This may require the use of dilute contrast, which can affect image quality. If possible, repeat contrast injections within 72 hours should be avoided. Diuretics should be routinely withheld on the day of contrast injection. Metformin is not a risk for CIN, and the injection of contrast is not contraindicated in patients taking this medication. However, serious complications (lactic acidosis) may rarely occur in patients taking metformin who subsequently develop acute kidney insufficiency. For this reason, it is recommended that metformin be stopped 48 hours prior to any contrast injection.

Determination of Approach

Common iliac artery (CIA) disease is generally treated through an ipsilateral, retrograde approach. If the CIA is occluded, contralateral flush catheter placement should be considered so that a complete diagnostic study can be performed before any intervention. This technique also provides access to protect the contralateral CIA from injury during ipsilateral CIA intervention. A complete diagnostic arteriographic examination includes a study of the pararenal aorta to exclude abdominal aortic aneurysm, oblique pelvic imaging of the iliac bifurcations to determine internal iliac artery patency and origin, and adequate views to evaluate CFA bifurcation disease. In general, the contralateral oblique projection shows the iliac artery bifurcations, whereas the ipsilateral oblique projection best displays the profunda origins at the femoral artery bifurcations. Finally, complete imaging of the infrainguinal runoff is requisite before inflow intervention. If such imaging is done only after completion of the intervention, differentiating preexisting distal occlusive lesions from emboli may be problematic. External iliac disease is generally better approached from the contralateral side because it permits more extensive treatment of the EIA into the proximal portion of the CFA if needed (Fig. 108.4).

The procedure begins with placement of an arterial sheath to facilitate catheter exchanges. The lesion is crossed with the use of a catheter–guide wire combination. An angle-tip catheter with a floppy-tipped guide wire is used to cross the lesion first, followed by the catheter. In difficult cases, hydrophilic wires may be used (see Fig. 108.4B). After advancing the catheter across the lesion, the wire is removed; free aspiration of blood ensures that the catheter tip is intraluminal.

Determination of Hemodynamically Significant Lesion

Pressure measurements across the lesion should be obtained by connecting the hub of the catheter and/or the side arm of the vascular sheath to the IA pressure monitor. Alternative options include the "pullback method," in which an end-hole catheter is withdrawn from proximal to distal across the lesion over a 0.014-inch wire. Most consider a peak-to-peak systolic pressure gradient of 10 mm Hg or greater at rest to be hemodynamically significant. In the absence of a resting gradient, IA nitroglycerin (100-200 μg) or papaverine (25 mg) can be administered distally to reveal the significance of a lesion. The maximal increase in pressure gradient occurs 20 to 40 seconds after vasodilator

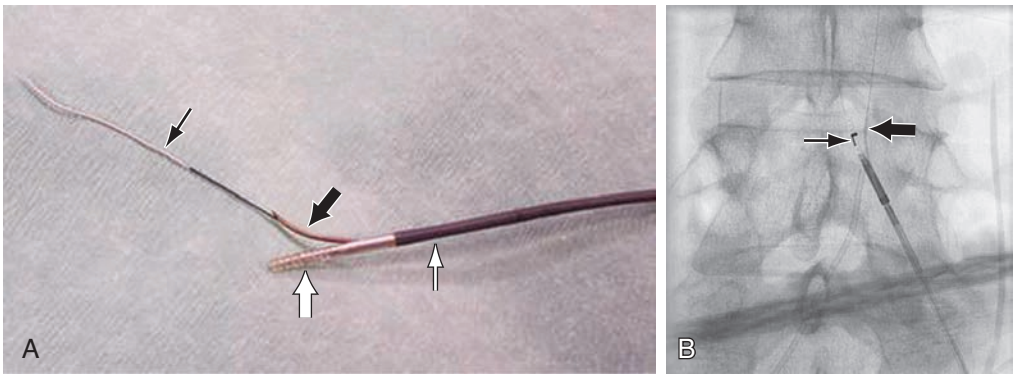

Figure 108.5 Reentry catheters. (A) Outback LTD catheter. The cannula *(large black arrow)* is deployed, and the 0.014-inch guide wire *(small black arrow)* is advanced through it. The nosecone *(large white arrow)* has the radiopaque "LT" orientation marker. The catheter shaft is indicated by the *small white arrow*. (B) Outback catheter. The cannula is deployed *(large arrow)*, with free passage of the guide wire into the true lumen of the aorta. Note the "L" configuration *(small arrow)*.

injection. If the mean pressure gradient increases to above 10 mm Hg, the lesion may be considered for treatment.

Techniques to Recanalize Chronic Totally Occluded Iliac Arteries

Contralateral Approach

When attempting to recanalize an occluded CIA in a retrograde fashion, the guide wire frequently follows a subintimal path. Once this has occurred, it may be difficult to redirect the guide wire into the lumen. An antegrade approach from the contralateral CFA is frequently successful, especially if there is a CIA stump and the CIA is not flush-occluded. A hooked catheter is used to probe the occlusion. The lesion can then be crossed with the use of hydrophilic guide wire and a supporting catheter. As soon as the guide wire has crossed the obstructive lesion and lies within the ipsilateral EIA lumen, a catheter can be advanced over the wire to confirm intraarterial placement. Depending on the proximity of the occlusion to the aortic bifurcation, a crossover sheath can be placed over a stiff guide wire or the wire can be snared from the ipsilateral CFA and a sheath can be placed in a retrograde fashion.

Brachial Approach

In the presence of a flush CIA occlusion, a contralateral femoral approach to cross the lesion is frequently unsuccessful; transbrachial or ipsilateral retrograde femoral approaches are more likely to achieve success. A brachial approach reduces the risk of creating or extending an aortic dissection and provides better "pushability." The presence of significant subclavian artery occlusive disease obviously limits this approach.

Reentry Wires and Catheters

The development of reentry wires and catheters has greatly increased the technical success of crossing arterial occlusions. Crossing wires and catheters designed to cross chronic total occlusions (CTO) typically involve a wire that based on a mechanical drive system potentiates passage of the wire through the true lumen of the CTO either through a vibration or rotating action. The majority of these devices have been tested in the femoral-popliteal vascular bed and their utility in the iliac vessels is uncertain.

Reentry catheters facilitate crossing CTO by a subintimal approach. There are no data to suggest any advantage to crossing an iliac CTO, either through the native lumen or subintimally. The Outback reentry catheter (LuMend Inc., Redwood City, California) is a single-lumen catheter designed to facilitate access and positioning of a guide wire within the peripheral vasculature from a remote vascular entry site using a retractable needle to pierce the intima and gain access to the true lumen (Fig. 108.5). The Pioneer catheter (Medtronic, Minneapolis, Minnesota) works by a similar mechanism but contains an intravascular ultrasound probe in the distal portion that assists in orienting the reentry needle toward the flow lumen. To use this catheter, a 300-cm-long, 0.014-inch guide wire is passed subintimally beyond the CTO. Usually an 0.035 wire is used to make the initial subintimal plane and then exchanged for the 0.014 wire. The reentry catheter is then advanced beyond the CTO under continuous fluoroscopy. An angiogram is performed via the contralateral access to confirm traversal of the occlusion and positioning of the lateral exit port of the catheter at the aortic bifurcation proximal to the occlusion. In the case of the Pioneer catheter, this is done with IVUS. The precise location and orientation of the lateral exit port are confirmed by aligning the fluoroscopic guide. The nitinol cannula is then advanced forward through the lateral exit port under continuous fluoroscopy. Applying firm but guarded forward pressure while deploying the cannula may contribute to a successful puncture. Free passage of the 0.014-inch wire indicates true lumen access, and is confirmed by contrast injection through a catheter placed over the wire. The catheter can be exchanged for a 3-mm-diameter angioplasty balloon that is used to dilate the subintimal tract and puncture site. This step enables a catheter to pass and allows exchange for a standard 0.035-inch guide wire to facilitate and perform stenting in a conventional manner (Fig. 108.6).

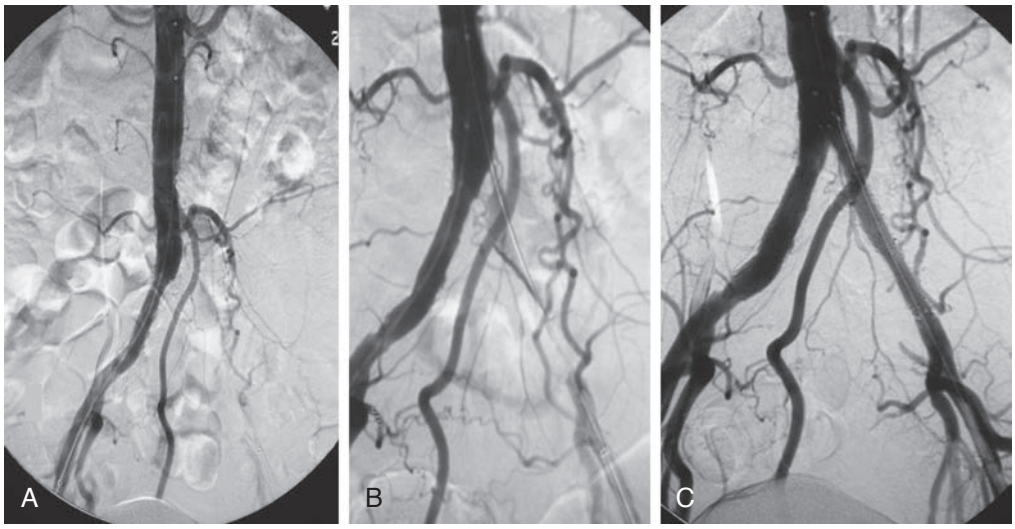

Figure 108.6 Results using a reentry catheter. (A) Pelvic arteriogram showing complete occlusion of the left common and external iliac arteries. (B) Glide catheter advancement into the aorta after reentry at the aortic bifurcation. (C) Retrograde stent-graft placement into the common iliac artery. Aortic Bifurcation Lesions

Technical Approach

Lesions at the aortic bifurcation have been traditionally treated using the "kissing balloons" technique. Simultaneous balloon dilation at the origins of both CIAs is advocated, even in the presence of a unilateral lesion, to protect the contralateral CIA from dissection, plaque dislodgement, or subsequent embolization. A retrospective review of patients undergoing percutaneous treatment for unilateral CIA occlusive lesions by Smith and associates challenged this long-established practice.[29] In this report, 175 patients with unilateral ostial iliac artery lesions were treated with percutaneous transluminal angioplasty (PTA) or stenting without contralateral protection; in only two patients did the contralateral unprotected CIA develop mild stenosis (17% and 24%, respectively). The authors concluded that protection of the contralateral CIA during PTA or stenting of the ipsilateral proximal CIA is not mandatory.

Aortic Bifurcation Advancement

Because calcified lesions at the aortic bifurcation are not amenable to balloon dilation alone, the "kissing stents" or "aortic reconstruction" technique is applied (see Fig. 108.6C).[30] The aortic bifurcation reconstruction technique is technically successful; however, some have expressed fear that extension of the proximal ends of the stents into the distal aorta ("aortic advancement") may serve as a nidus for thrombus formation.[31] Recent work in a small series of 52 patients demonstrated that radial mismatch of stent to aortic lumen in which the iliac stents did not oppose the aortic wall was significantly associated with restenosis.[32]

Concomitant Femoral Endarterectomy

Preoperative duplex ultrasound, CTA, or MRA can help determine which CFA should be used for percutaneous access. If such studies identify significant CFA disease, an open femoral approach with combined endovascular iliac therapy and femoral endarterectomy should be strongly considered (Fig. 108.7A).[33] The CFA is exposed from the circumflex femoral branches down to the femoral bifurcation. The CFA is punctured under direct vision, and the iliac lesion is crossed prior to endarterectomy. This technique allows complete assurance of intraluminal wire placement distally at the endarterectomy site. For cases in which retrograde guide wire passage is not possible, a percutaneous approach from the contralateral femoral or brachial artery can be used to cross the iliac lesion or a reentry catheter can be used at the completion of the endarterectomy. The guide wire can then be brought out through the femoral artery. With wire access in place, proximal and distal control is obtained, and a longitudinal arteriotomy is created, allowing for standard endarterectomy and patch angioplasty. Before patch completion, the center of the patch is punctured with an 18-gauge needle, and the guide wire is brought out through the needle. Patch closure is then completed, and flow is restored. An appropriate sheath can then be passed over the wire to allow iliac stenting. Stents may be extended down to the proximal endpoint of the endarterectomy and patch if necessary (Fig. 108.7B).

Stent Sizing

Selection of the appropriate balloon or stent diameter is of utmost importance for a successful intervention. Slight oversizing of 5% to 10% is recommended, except in the case of heavily calcified lesions that may rupture. The optimal vessel diameter can be estimated from the adjacent normal arterial segment or by comparison to the same vessel on the contralateral side. A calibrated catheter inserted into the vessel allows measurement of the artery. The length of the balloon or stent should cover the diseased area without damaging the normal vessel. If in doubt when balloon-dilating a lesion, it is wise to undersize. A larger balloon can be used if the initial result is not satisfactory. With

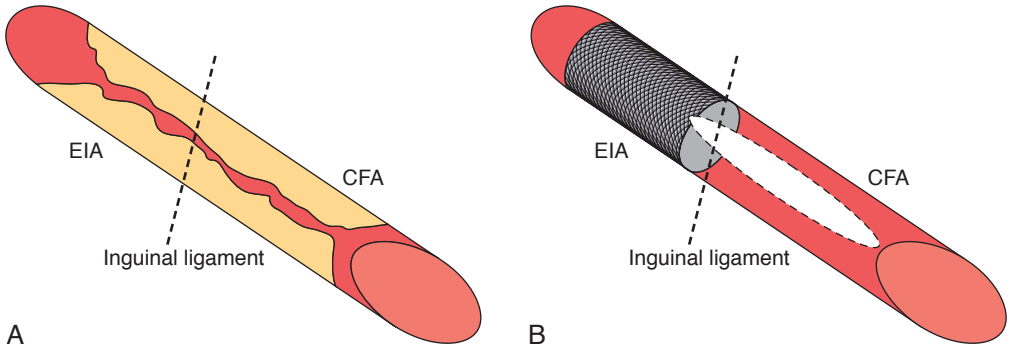

Figure 108.7 Operative technique for an open femoral approach to the diseased common femoral artery (CFA) and external iliac artery (EIA). (A) The common femoral artery is exposed from the circumflex femoral branches, distal to the femoral bifurcation. The common femoral artery is punctured under direct vision, and the iliac lesion is crossed before endarterectomy. Wire access is left in place, and a standard subintimal endarterectomy with patch angioplasty is performed. Before completion of the patch angioplasty, the patch is punctured in the center with an 18-gauge needle, and the guide wire is brought out through the center of the patch. After patch angioplasty is complete and flow is restored, a short sheath can be placed over the wire and through the center of the patch. (B) Iliac stenting can be performed such that the distal endpoint of the stent is just proximal to the endarterectomy and patch angioplasty.

balloon expandable stents, this rule does not apply, because an undersized stent usually cannot be exchanged for an optimal one. Balloon inflation should be gradual to avoid trauma to the adjacent normal vessel. A waist on the balloon indicates the lesion location; the waist disappears after successful dilation. Mild pain during dilation is acceptable and indicates stretching of the adventitia; excessive pain may indicate impending arterial rupture (see Fig. 108.3A and B). The technical success of the intervention is judged not only by the angiographic appearance, but more importantly, by measurement of any residual pressure gradient. Less than 20% residual stenosis and a less than 10 mm Hg systolic pressure gradient is considered a technical success. The determination of success should be based on the translesional pressure gradient measurement; angiographic criteria are less reliable.[31,34] Intravascular ultrasound may also be used to assess the technical result following iliac or aortic stent placement; it better demonstrates stent arterial wall apposition and gives a three-dimensional assessment of the stented iliac artery.

Stent Selection

Commercially available stents are numerous and fall into four main categories: balloon-expandable bare metal stents, self-expanding bare metal stents, balloon expandable stent grafts, and self-expanding stent grafts. Features of balloon-expandable stents and stent grafts include precision of placement, high radiopacity, and high hoop strength. However, they are less flexible than self-expanding stents and become permanently deformed if external force is directly applied to them.

Placement of a balloon-expandable stent generally requires the sheath to be advanced beyond the lesion, especially in severe stenoses, to avoid dislocation of the stent on the balloon. The stent mounted on the balloon is inserted into the sheath and positioned across the lesion using bony landmarks or road mapping. The sheath is then retracted, and the balloon is inflated to expand the stent. Since self-expanding stents and stent grafts are mounted on a carrier device and constrained by an outer sheath, the introducer sheath does not need to cross the lesion. Stent deployment is achieved by holding the carrier device with one hand and retracting the outer sheath with the other. Selection of an iliac artery stent depends on availability and the operator's familiarity with specific devices. In addition, iliac artery tortuosity, introducer sheath diameter, and intrinsic lesion characteristics influence the selection of an appropriate stent type. Short, eccentric, calcified lesions, typically occurring at the aortic bifurcation, are best treated with balloon-expandable stents owing to the ability to place them with great precision. In contrast, whenever the stent must follow a tortuous path or is to be placed from the contralateral side over the aortic bifurcation, self-expanding stents are advantageous because of their flexibility.

RESULTS

Percutaneous Angioplasty Versus Selective Stenting

PTA of focal iliac artery stenoses has demonstrated acceptable success rates (Table 108.1).[35] The reported 4-year success rates for iliac angioplasty are approximately 44% to 65%. Complications associated with angioplasty include vessel dissection, abrupt closure, spasm, and thrombus formation. Moreover, several studies evaluating the use of PTA for iliac artery occlusions showed a significant embolization incidence, which led some to question the usefulness of PTA in this patient subset.[36,37] In a study of 106 patients, kissing iliac stents showed good results in aortic bifurcation disease (a location that can be problematic for balloon angioplasty), with primary and secondary patency rates of 78% and 98%, respectively, at 3 years.[38]

Several randomized studies have compared stenting with standalone PTA. The Dutch Iliac Stent Trial Study Group

performed a randomized comparison of primary balloon-expandable stent placement with primary angioplasty, followed by selective stent placement in patients with iliac artery occlusive disease. Iliac patency ranged from 97% (122 of 126 patients) at 3 months to 83% (90 of 109 patients) at the final mean follow-up of 5 years in the patients with primary stent placement; it ranged from 94% (113 of 120 patients) to 74% (67 of 90 patients) in the patients treated with PTA and selective stent placement. This difference was not significant. The study also showed that selective stent placement was more cost-effective than primary stenting of iliac artery stenosis.[34,39] However, 43% of patients randomized to balloon angioplasty underwent stent placement for a suboptimal result during the primary procedure. Twenty-five of 143 patients (17%) treated with primary stent placement needed reintervention in the iliac artery segment because of the development of symptomatic or hemodynamic (by noninvasive testing) restenosis. In the PTA and selective stent placement group, 28 of 136 patients (21%) needed reintervention. Complication rates were nearly double (4% vs. 7%) in the angioplasty group.[34]

Primary Stenting Versus Selective Stenting

Other randomized trials have shown primary stenting to be superior to selective stent placement in terms of both hemodynamic parameters and Rutherford classification (see Table 108.1). These include a meta-analysis comparing the results of PTA versus stent placement for iliac occlusive disease.[40] This meta-analysis of more than 1300 patients compared selective with primary iliac artery stenting and found significantly higher initial technical success (>90%) and improved primary patency rates (>70% at 2 and 5 years) in both claudicants and those with limb-threatening ischemia treated with primary stenting.[40] Because critical ischemia was considered an independent risk factor for failure, the authors stratified patency rates for claudication versus critical ischemia. The 4-year primary patency rate for claudication, with technical failures excluded, was 68% (range, 65%-74%) after PTA, compared with 77% (range, 72%-81%) after stenting. The 4-year primary patency rate for critical ischemia, with technical failures excluded, was 55% (range, 48%-63%) after PTA, versus 67% (range, 55%-79%) after stenting. The authors concluded that stent placement reduced the risk of long-term failure by 39% compared with PTA alone. Disease severity (claudication versus critical ischemia) was an independent predictor of long-term failure. However, whenever initial success was achievable, no statistically significant difference in long-term patency was found between stenoses and occlusions.

Long-Term Results

Murphy summarized the results of 18 published studies of primary iliac artery stent placement in a total of 2058 limbs (see Table 108.1).[41] Using weighted averages, the technical success rate was 97%, the complication rate was 6%, and the 5-year primary and secondary patency rates were 73% and 85%, respectively. Although iliac stent treatment has been in clinical use for more than 15 years, few reports of long-term patency are available. Schurmann and colleagues published a 10-year follow-up of 110 patients with iliac arterial occlusive disease who underwent implantation of self-expanding stents.[42] The mean patient age was 57 years, and 93% were claudicants. Based on angiographic or color duplex imaging follow-up in 105 patients and clinical follow-up in five patients, primary

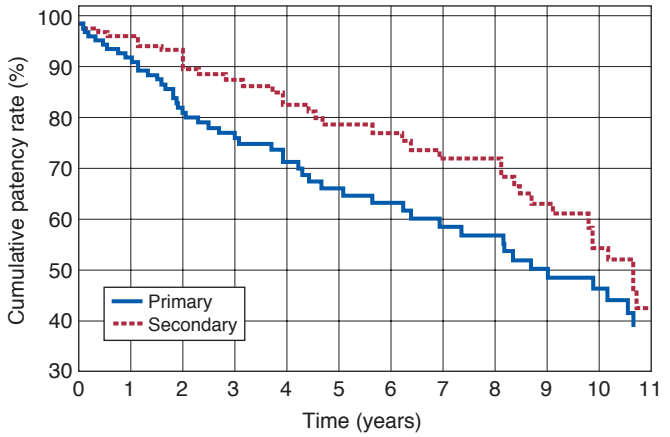

Figure 108.8 Long-term primary and secondary patency rates in 126 iliac lesions treated with stent placement. (From Schurmann K, Mahnken A, Meyer J, et al. Long-term results 10 years after iliac arterial stent placement. *Radiology*. 2002; 224:731–738.)

cumulative stent patency rates were 66% ± 5 after 5 years and 46% ± 6 after 10 years; secondary patency rates were 79% ± 4 and 55% ± 6.3, respectively. Mean follow-up time was 5.7 years. Restenosis occurred in 51 of 126 (41%) lesions after a mean of 3.9 years. Seventeen patients (16%) underwent surgical bypass of the aortoiliac segment that had been stented—14 because of stent restenosis, and three because of stenosis in other iliac arterial segments (Fig. 108.8).

Patency Based on Trans-Atlantic Inter-Society Consensus Classification

Trans-Atlantic Inter-Society Consensus Types A and B Lesions

Outcomes of iliac intervention depend on TASC lesion classification. Galaria and associates reported 10-year patencies for patients with TASC A and B lesions.[43] Indications for intervention were claudication (77%) or critical ischemia (23%). Altogether, 276 patients (all men; average age, 64 ± 11 years; range, 32-87 years) underwent 394 interventions. Sixty-two percent of the lesions were TASC type A, and the remainder were type B. Of the 394 primary interventions, 51% included the placement of stents. Technical success (defined as <30% residual stenosis) was achieved in 98% of treated vessels. The procedure-related mortality rate was 1.8% at 30 days and 4.7% at 90 days; the procedure-related complication rate was 7%. Hemodynamic success (defined as a rise in the ABI >0.15) was achieved in 82%. The average baseline Society for Vascular Surgery symptom score was 3.4 + 0.9, which improved to 1.9 ± 0.8 following intervention. Within 3 months, 84% of patients demonstrated clinical improvement. The cumulative assisted patency rate was 71% ± 7 at 10 years. The presence of two-vessel femoral runoff, two or more patent tibial vessels, or both was associated with improved patency. Limb salvage rates were 95% ± 2 and 87% ± 9 at 5 and 10 years, respectively. By Cox proportional hazards analysis, hypertension, hypercholesterolemia, and chronic renal insufficiency were associated with increased risk of primary

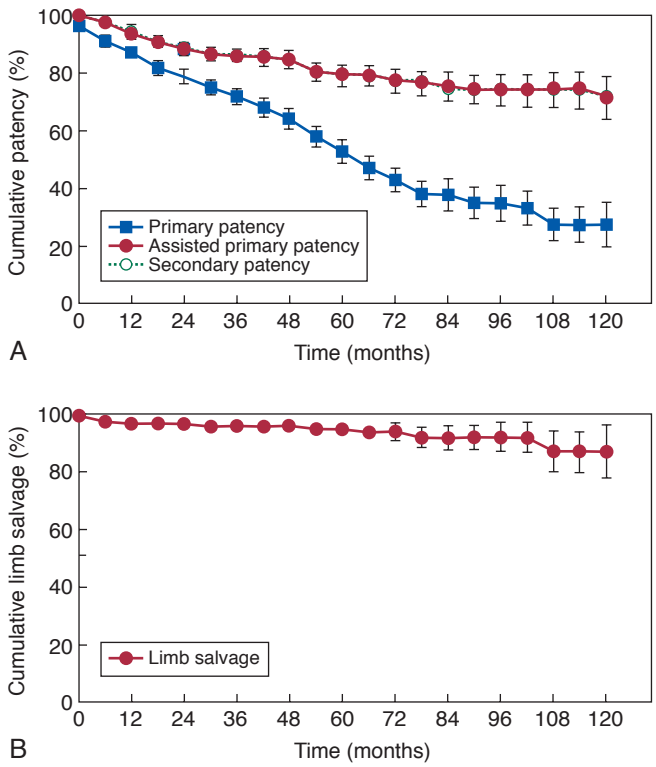

Figure 108.9 (A) Cumulative primary patency, assisted primary patency, and secondary patency (superimposed in assisted primary patency) intervals for all vessels. (B) Cumulative limb salvage for all patients. In both (A) and (B), the values are the mean ±. A standard error less than 10% for all data points by life-table analysis. (From Galaria II, Davies MG. Percutaneous transluminal revascularization for iliac occlusive disease: long-term outcomes in Trans-Atlantic Inter-Society Consensus A and B lesions. *Ann Vasc Surg*. 2005;19:352–360.)

failure, whereas the presence of immediate hemodynamic improvement was associated with increased long-term patency. Stent use did not influence outcome. These results approach those reported for surgical aortoiliac bypass grafting. For comparison, in a meta-analysis of 23 studies of aortoiliac or aortofemoral bypass grafts published between 1970 and 1996, de Vries and Hunink calculated limb-based patency rates of 91% and 86.8% at 5 and 10 years, respectively, for patients with claudication, and patency rates of 88% and 82%, respectively, for patients with critical ischemia (Fig. 108.9).[48]

Trans-Atlantic Inter-Society Consensus Types C and D Lesions

Although iliac angioplasty and stenting of TASC types A and B common iliac lesions achieve a patency similar to that of open surgical reconstruction, patients with diffuse aortoiliac occlusive disease (TASC types C and D lesions) have markedly inferior patency with bare metal stenting when compared with aortobifemoral bypass. Recently several authors have documented promising results in the treatment of more complex TASC types C and D iliac lesions. Jongkind and coworkers recently reported a meta-analysis of the late results of the endovascular treatment of complex iliac occlusive disease.[49] Five-year primary patency ranged from 60% to 86%, with secondary patency rates of 80% to 98%. In a series of 212 patients with chronic

iliac occlusions, successful recanalization was accomplished in nearly 90% of patients, with marked clinical improvement in the vast majority.[50] In another series of 109 iliac artery CTOs, primary patency at 5 years in the CTO group was 82% versus 91% in patients treated for stenosis.[51] Stent graft placement has been shown to improve outcomes in patients with TASC C and D lesions. This will be subsequently discussed later.

Patency With Concomitant Common Femoral Artery Disease

Chang and colleagues recently reported their long-term results of combined endovascular and open treatment of iliofemoral occlusive disease.[45] A total of 171 patients underwent 193 CFA endarterectomies and iliac stent or stent-graft placement. Indications were rest pain (32%), tissue loss (22%), and claudication (46%). EIA lesions were present in 39%, combined CIA and EIA lesions in 61%, and complete CIA-EIA occlusions in 41% of patients. Stent grafts were used in 41% of patients. Technical success was reported in 98%, with clinical improvement in 92% of patients. Five-year primary, primary-assisted, and secondary patency rates were 60%, 97%, and 98%, respectively. Endovascular reintervention was required in 14% of patients; inflow surgical procedures were required in 10%. By logistic regression analysis, the use of stent grafts compared with bare stents was associated with significantly higher primary patency (87% ± 5 vs. 53% ± 7; $P < .01$).

Predictors of Failure

Disease extension into the EIA increases procedural complexity and decreases the durability of the intervention. The presence of external iliac disease was a predictor of decreased primary and primary assisted patency rates.[50,52-54] In a study by Powell and coworkers, patients with severe EIA disease treated with bare metal stents had a 1-year primary patency rate of only 47%.[50,53] These patients also had poor rates of hemodynamic and clinical improvement after intervention. Many required surgical inflow procedures or subsequent endovascular reintervention to maintain aortoiliac patency. Other reported predictors of worse outcome after iliac artery angioplasty are female gender,[55] renal insufficiency, and CLTI.[54] Timaran and associates concluded that women with EIA stents had the poorest outcomes. More recent work by Danczyk and coworkers failed to find a difference in outcome between patients treated with bare metal stents for EIA versus CIA lesions.[56] Other groups have noted that small vessel diameter and female gender are factors predictive of failure.[57]

Stent Grafting

Stent grafting has in the past been used primarily to treat patients with isolated iliac aneurysms, iatrogenic perforations or ruptures, arteriovenous fistulae, and on occasion severe aortoiliac occlusive disease, especially those with small calcified EIAs, who are not candidates for open surgical intervention. These devices are stainless steel, nickel-cobalt-titanium-steel alloy (Elgiloy), or nitinol stents covered with Dacron or polytetrafluoroethylene (PTFE).[44,58,59] More recently stent grafts have become more routinely used to treat patients with aortoiliac occlusive disease, especially TASC C and D lesions.

Stent-Graft Patency

Stent-graft treatment of patients with severe aortoiliac occlusive disease (85% TASC types C and D lesions) was reported by Rzucidlo and colleagues.[44] The use of stent grafts increased the primary and primary assisted patency at 1 year to 70% and 88%, respectively, compared with patients treated with stents alone, and led to 100% early hemodynamic and clinical success. There was a trend toward improved primary iliac artery patency in patients who underwent concomitant common femoral endarterectomy. At 6 and 12 months, the primary patency rates in patients who underwent concomitant common femoral endarterectomy were 94% and 94%, respectively, compared with 79% and 53% in patients who did not undergo endarterectomy.

Long-term results of stent grafts for the treatment of complex aortoiliac occlusive disease have been reported. At 3 and 5 years after intervention, the primary patency rates of the iliac segment were 80% and 80%, respectively; corresponding primary assisted patency rates were 95% and 95% (Fig. 108.10). Primary patency using stent grafts differed significantly depending on TASC classification. Patients with TASC type B iliac lesions had a 100% 5-year patency rate. Those with TASC type C iliac lesions had the lowest 5-year primary patency—significantly lower than TASC type D iliac lesions when type B lesions were removed from the log-rank analysis (61% vs. 85%; $P = .04$; unpublished data).

Others have reported the use of stent grafts to treat diffuse iliac occlusive disease. Nevelsteen and coworkers placed 29 stent grafts in 24 patients to treat claudication ($n = 7$) or limb-threatening ischemia ($n = 17$).[60] Mean primary and secondary cumulative patency rates after 1 year were 85% and 95%, respectively. All patients in this series underwent outflow procedures—that is, profundaplasty or femoral distal grafting. Psacharopulo has demonstrated 91% 2-year primary patency in patients treated with self-expanding stent grafts for TASC D lesions.[47] These patients also underwent concomitant femoral endarterectomy.

Predictors of Failure for Stent Grafting

CFA disease was a significant predictor of failure at long-term follow-up.[44] The 5-year primary patency rate was 88% for patients who had concomitant CFA endarterectomy and iliac stent grafting, versus 66% for stent grafting alone ($P = .04$; relative risk, 8). This finding has prompted more intense evaluation of the CFA plaque burden before proceeding with iliac intervention (Fig. 108.11).

Most recently, Mwipatayi and coworkers reported the 5-year results of the COBEST trial,[47] a randomized study comparing primary patency of bare metal stents to stent grafts in patients with aortoiliac occlusive disease. The 5-year primary patency was significantly improved from 50% to 95% at 18 months in patients with TASC C and D lesions treated with a covered stent compared with bare metal stent treatment. There was no

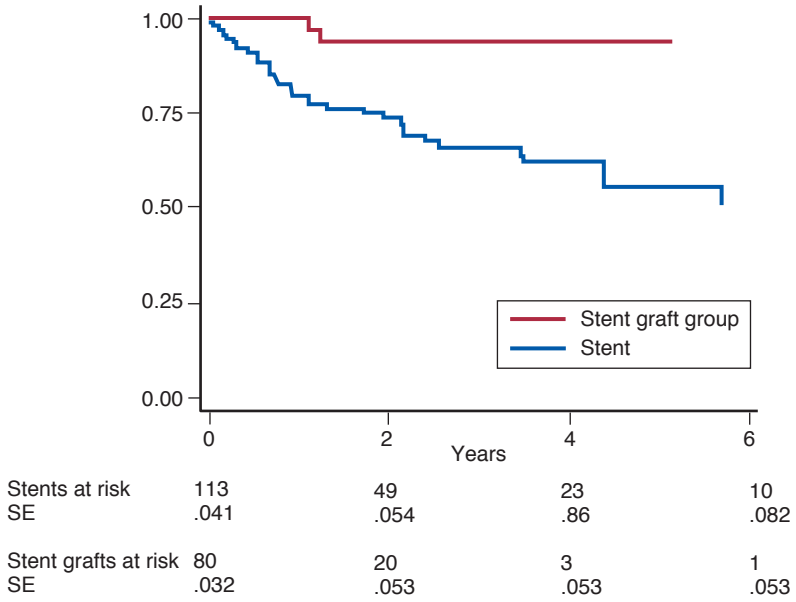

Figure 108.10 Kaplan-Meier curve estimate for primary stent-graft patency of severe occlusive iliac artery disease compared to patients treated with bare metal stents. A standard error less than 10% at 5 years.[45]

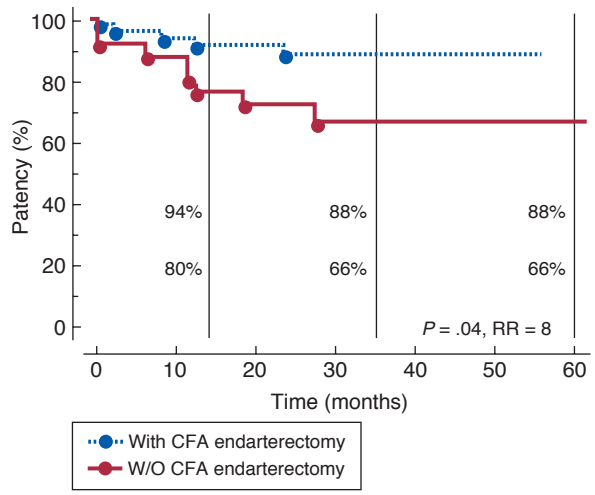

Figure 108.11 Kaplan-Meier primary patency curves for patients with common femoral artery (CFA) disease as a variable. Patients with concomitant CFA endarterectomy had significantly better patency than those without (W/O) endarterectomy (88% vs. 66% at 60 months; $P = .04$). *RR,* Relative risk.

difference in patency in patients with TASC B lesions. Use of a stent graft and Rutherford class were the only predictors of patency.

Mortality

It has been estimated that the life expectancy of patients with peripheral artery disease (PAD), especially those with intermittent claudication, is reduced by about 10 years compared with the general population.[61-63] The main cause of death in patients with PAD is cardiac disease, accounting for 40% to 60%. Overall mortality rates from all causes in patients with intermittent claudication are approximately 30% after 5 years, 50% after 10 years, and 70% after 15 years.[64] About 10% to 20% of patients die of cerebrovascular disease, and about 10% die of other vascular causes, mainly ruptured aortic aneurysms. Nonvascular causes account for about 20% to 30% of deaths, with the most frequent being cancer.[64] In a prospective follow-up study of more than 550 patients with CLTI, 21.9% of patients were deceased after 1 year, and 31.6% after 2 years.[63] The overall incidence of cardiovascular death was 34.5%, compared with 8.5% of deaths resulting from nonvascular causes. These numbers, based on large series, are well reflected in the small population studies of patients undergoing endovascular treatment for iliac occlusive disease. Long-term mortality rates reported by Schurmann and associates for patients treated with iliac stents were 17% after 5 years and 36% after 10 years.[42] Galaria and colleagues reported that patient survival by life-table analysis was 38% at 10 years for patients with TASC types A and B lesions treated with angioplasty and stenting of the iliac arteries.[43] It can be hypothesized that successful treatment of claudication might prolong survival time; however, there are no study findings proving this hypothesis.

COMPLICATIONS

Bypass surgery has superior long-term durability, with 5-year patency in excess of 80%, but it has been associated with a perioperative complication rate of up to 30%.[65-67] Recovery from aortobifemoral bypass typically requires weeks of absence from work, a financial burden that many patients cannot absorb. Thus, less invasive endovascular treatment for aortoiliac occlusive disease has largely supplanted aortobifemoral bypass, because focal iliac disease is well treated with angioplasty or stent placement. These less-invasive options are not without complications, however. These complications can be categorized as contrast related, access related, and remote.

Contrast Related

Patients with preprocedure renal insufficiency are at greatest risk for postprocedure nephropathy. As previously discussed, patients with serum creatinine greater than 1.5 mg/dL (133 µmol/L) should be treated with sodium bicarbonate infusion.[14,27,28,68] In addition, contrast volume should be limited. Patients with creatinine greater than 2.5 mg/dL (221 µmol/L) are treated with a combination of intravascular ultrasound and pre-and postprocedure pressure measurements.

Sheath Site Related

The incidence of local complications related to access and sheath insertion is 1% to 3%, but this can be reduced by accurate placement of the puncture site in the CFA, avoiding high and low punctures. Most sheath sites can be closed with suture-type closure devices to decrease the incidence of hematoma and CFA pseudoaneurysm.[69]

Iliofemoral arteriography is performed to determine the suitability for closure device use. If the femoral artery is small (less than 5–6 mm) or if significant calcification is present, the sheath is removed after the activated clotting time has decreased to less than 200 seconds and manual pressure is applied. If CFA disease is not well defined before intervention, posterior plaque disruption by means of the initial needle puncture can cause acute CFA occlusion. Femoral artery occlusion is obvious on physical examination by the loss of color and pulses; immediate operative intervention with groin exploration is necessary.

Remote

Arterial Rupture

Arterial rupture is an uncommon (<1%) but potentially serious complication. Arterial rupture most often occurs in the setting of angioplasty or stenting of small, heavily calcified EIAs. When the procedure is performed under local anesthesia, significant flank or back pain typically precedes arterial rupture. If such pain occurs, no further dilation should be performed. Patients under regional or general anesthesia do not exhibit these symptoms. Arterial rupture can usually be treated with stent graft placement to seal the injury (see Fig. 108.3A–C). A balloon occlusion catheter may be needed to stabilize hypotensive patients. This must often be placed from the contralateral femoral artery to allow upsizing of the ipsilateral femoral sheath to one sufficient to allow stent-graft placement.

Arterial Dissection

Arterial dissection has been described as a complication of PTA. Proximal or distal progression of iliac dissection can occur beyond the site of intervention. The typical cause is overdilation of a small calcified artery. Treatment consists of the extension of stenting to stop flow-limiting occlusion due to the dissection.

Embolization

Distal embolization is uncommon in the absence of aggressive predilation prior to iliac stent placement. Appropriate assessment by pre- and postprocedural arteriography, physical examination, and Doppler evaluation is important to detect this complication.

POSTOPERATIVE MANAGEMENT

There are well-accepted criteria for reporting procedural success, clinical improvement, and patency, and the proper use of these standards for outcomes is critical. Initiation of a program of ongoing care to monitor and treat modifiable risk factors is also an important aspect of postoperative management. Risk factor management is critical and is discussed in Chapter 105 and generally includes antiplatelet and statin therapy. Regular follow-up should be performed at 1 and 6 months, and then yearly to assess patient outcome. This should include a history, pulse examination, and hemodynamic evaluation such as ankle brachial index measurements.

Criteria for Reporting Significant Change in Clinical Status

Clinical assessment expressed grossly in terms of "symptomatic relief" is notoriously unreliable because it lacks objectivity. Combining standard clinical categories with objective noninvasive testing can overcome this weakness. For reporting purposes, the designation "clinically improved" requires an upward shift by at least one clinical category (see Chapter 103, Table 103.3), except for those with actual tissue loss, who must move up at least two categories and reach a level of claudication to be considered improved. In addition, to attribute the improvement to treatment, objective evidence of hemodynamic improvement must be documented; an increase of more than 0.10 in ABI is recommended. If the ABI cannot be accurately measured (e.g., those with diabetes and medial calcinosis), the systolic toe pressure (which is less commonly affected by vessel incompressibility) or any measurable pressure distal to the revascularization can be substituted.

Criteria for Patency

The determination of iliac stent patency should be based on objective findings. Although physical examination can detect the presence of a palpable femoral pulse, iliac stent patency should be demonstrated by an accepted vascular imaging technique such as arteriography, color-flow duplex ultrasound, or magnetic resonance imaging. A diameter reduction within the stented segment of greater than 50% indicates significant restenosis. A biphasic or triphasic Doppler waveform should be noted at the CFA level. Although no clear duplex criteria for the iliac segment exist, most would consider a doubling of the peak systolic velocity indicative of restenosis, especially with an ABI drop greater than 0.1.

Quality of Life Outcomes

Few trials have looked at quality of life (Qol) outcomes after the treatment of iliac occlusive disease with stents. The Dutch

Iliac Stent Trial Study Group reported that at early follow-up, all RAND 36-Item Health Survey scores increased substantially in both patients treated with angioplasty alone and patients treated with selective stenting.[70] Qol assessments (consisting of the RAND 36, time tradeoff, standard gamble, rating scale, health utilities index, and EuroQol-5D) were completed by 254 patients in telephone interviews performed before treatment and after 1, 3, 12, and 24 months. When the two treatments were compared, no significant difference was observed ($P > .05$). All measurements showed a significant Qol improvement after treatment ($P < .05$). The RAND 36-Item Health Survey, which measures physical functioning, role limitations caused by physical problems, and bodily pain, and the EuroQol-5D were most sensitive to the impact of revascularization. Compared with the external patient group (i.e., patients with intermittent claudication who participated in an exercise program), patients in the trial had lower Qol values before and higher values after revascularization. The proportion of trial patients with pre-revascularization values below the 95% CI of the reference values among the exercise group ranged from 21% (standard gamble) to 67% (RAND 36 physical functioning). After revascularization, these proportions decreased significantly. At 2-year follow-up, the proportion of trial patients with health values equal to or higher than the upper 95% confidence limit of the reference values among the exercise group ranged from 62% (EuroQol-5D) to 78% (RAND 36, bodily pain). At 5 years after treatment, all scores, except that for general health perception, were still markedly higher than the pretreatment scores in both groups.[39] Survival analyses showed no differences in RAND 36 scores between the two treatment groups over the follow-up period.

When we compared the Qol scores of the two treatment groups 5 years after treatment with data from age-matched controls in the literature, the scores of patients treated with PTA and selective stent placement were as high as those of age-matched controls in all dimensions. However, the scores of patients treated with primary stent placement were substantially lower for physical functioning, physical role functioning, vitality, bodily pain, and general health perception. Scores for emotional role functioning, social functioning, mental health, and health change were equivalent to those in age-matched controls.[39] The authors therefore concluded that cost rather than effectiveness may be the decisive factor in the choice of percutaneous treatment.

Abstract

Open surgical lower extremity arterial bypass remains the most durable option for infrainguinal revascularization for chronic atherosclerotic occlusive disease. Although increasingly many patients are well served by endovascular therapy, it is still important to be familiar with the available techniques of lower extremity bypass so that patients aren't denied viable options for limb salvage. Infrainguinal bypass is defined as any major arterial reconstruction using a bypass conduit, whether it be autogenous or prosthetic, originating at or below the inguinal ligament. Inflow sites may include the common, deep, and superficial femoral arteries as well as the popliteal or even the tibial arteries. The bypass insertion site may be the superficial femoral, above- or below- knee popliteal, tibial, peroneal, pedal or plantar artery. Improvements in patient evaluation and selection and in the conduct of infrainguinal bypass operations have resulted in a more aggressive and generally more successful approach to distal arterial reconstruction, especially for patients with chronic limb-threatening ischemia (CLTI), many of whom might otherwise face major limb amputation. CLTI is a broad disease spectrum and increasing evidence suggests that low to moderate risk patients with good quality autogenous conduit have better outcomes with bypass than complex endovascular therapy.

The most important keys to success when performing lower extremity bypass are the caliber and quality of the venous conduit and the application of meticulous postoperative duplex and hemodynamic-based surveillance. This chapter reviews multiple methods and techniques for obtaining a nearly "all-autogenous policy" for infrainguinal bypass and also addresses use of prosthetic conduits with adjunctive techniques to optimize bypass outcomes when vein is truly lacking. Use of alternative veins and alternate anatomic exposures of a variety of lower extremity arteries are also reviewed to broaden the readers' options when confronted with redo cases or particularly challenging anatomy, especially when faced with limited available vein conduit. Expected patency and limb salvage rates are also presented in tabular form contrasting a variety of conduit options.

Keywords

leg bypass
infrainguinal bypass
vein bypass
peripheral artery disease
duplex graft surveillance
graft stenosis
restenosis

Lower extremity arterial reconstruction is most commonly performed in patients with moderate to severe limb ischemia due to atherosclerotic peripheral artery disease (PAD). Although the techniques described that follow may also be applied to patients with traumatic, aneurysmal, and nonatherosclerotic conditions, this chapter focuses exclusively on patients with PAD. *Infrainguinal bypass* is defined as any major arterial reconstruction using a bypass conduit, either autogenous or prosthetic, that originates at or below the inguinal ligament. Inflow sites therefore include the common, deep, and superficial femoral arteries as well as the popliteal or even the tibial arteries. The bypass insertion site may be the femoral, above- or below-knee popliteal, tibial, peroneal, or pedal artery. During the past 2 decades, progress in patient evaluation and selection and in the conduct of infrainguinal bypass operations has resulted in a more aggressive and generally more successful approach to distal arterial reconstructions, especially for patients with chronic limb-threatening ischemia (CLTI), many of whom would otherwise face major limb amputation. CLTI is a spectrum. Determining whether revascularization is required for wound healing and if performed, whether open bypass or endovascular therapy is the best initial option is still contentious due to observer bias, widely variable levels of technical expertise and lack of prospective, randomized data to support any given approach. Although graft patency and limb salvage rates have demonstrated continuous improvement, there remains a critical need for detailed clinical studies examining the cost-effectiveness of infrainguinal bypass as well as patient quality of life (QoL) outcomes to ensure the appropriate use of these procedures and to permit meaningful comparison with less invasive endovascular therapies.

INDICATIONS

The two primary indications for infrainguinal bypass are claudication and CLTI.

Claudication

Patients who are significantly disabled by claudication, such that they are unable to perform their primary occupations or comfortably carry out the activities of daily living, and those whose lifestyles are significantly limited are potential candidates for infrainguinal bypass. A trial of smoking cessation, lifestyle modification, and exercise, with or without medical therapy, is usually indicated before operative intervention (see Chapter 105). There is consensus that bypass is preferable to angioplasty in patients with TransAtlantic Inter-Society Consensus (TASC) type D lesions, that is, complete common femoral artery (CFA) or superficial femoral artery (SFA) occlusions or complete popliteal and proximal trifurcation occlusions; however, bypass may also be applied to patients with types B and C lesions (see Chapter 109).[1] Operation should be offered only if the benefit-to-risk ratio is high *and* if anatomic characteristics suggest a favorable and durable result. The primary reason for intervention in claudicants is to improve lifestyle or QoL, given that the risk of severe clinical deterioration (20%) or major limb amputation (5%) during a 3- to 5-year period is low.[1,2] In most centers with extensive infrainguinal bypass experience, claudicants constitute only 15% to 30% of patients, with the majority of patients undergoing bypass for CLTI. These data reflect practice patterns in tertiary referral centers and may not reflect the realities of community-based practices.[3]

Critical Limb Ischemia and Chronic Limb-Threatening Ischemia

Patients with advanced CLTI generally require intervention. Such patients previously fell into Fontaine III and IV[4] and Rutherford 4 to 6 categories (see Chapters 104 and 105).[5-7] The most recent European consensus document defines CLI as follows: persistent, recurring ischemic rest pain requiring opiate analgesia for at least 2 weeks and ankle systolic pressure lower than 50 mm Hg or toe systolic pressure lower than 30 mm Hg; or ulceration or gangrene of the foot or toes and ankle systolic pressure lower than 50 mm Hg; or toe systolic pressure lower than 30 mm Hg (or absent pedal pulses in diabetics).[8] Wolfe and Wyatt[9] further subdivided patients meeting the longstanding definition of CLI into critical or subcritical ischemia on the basis of subsequent, observed amputation risk. Subcritical ischemia is present in patients with rest pain and ankle pressure higher than 40 mm Hg. Critical ischemia is defined as rest pain and tissue loss or ankle pressure lower than 40 mm Hg. This distinction is based on a retrospective analysis of 20 publications analyzing 6118 patients. At 1 year, 27% of patients with subcritical ischemia achieved limb survival without revascularization, in contrast to only 5% in the group of patients with critical ischemia. In practice, these data indicate that certain extremely high-risk patients with subcritical ischemia might be managed medically (nonoperatively) but that virtually all patients who are expected to live more than 1 to 2 years with true "critical ischemia" require either bypass or major limb amputation. Because of inconsistencies with terminology and the inappropriate application of the term critical limb ischemia to patients with diabetes, the Society for Vascular Surgery Lower Extremity Guidelines Committee created a more comprehensive threatened limb classification system intended to stratify amputation risk in patients across the spectrum of CLTI.[10] This system is based on objective grades Wound (W), Ischemia (I) and Foot Infection (FI) to calculate a threatened limb clinical stage from 1 to 4 has been validated in multiple studies to be highly predictive of 1-year major limb amputation risk.[11]

PREOPERATIVE ASSESSMENT

There is widespread recognition that patients requiring infrainguinal bypass frequently have medical comorbidities, including diabetes mellitus, chronic obstructive pulmonary disease, and renal insufficiency; there is a particularly high prevalence of associated coronary artery disease (CAD). The incidence of perioperative myocardial infarction ranges from 2% to 6.5% after lower extremity arterial reconstruction; approximately 70% of both perioperative and late mortality in these patients is due to concomitant CAD.[12-15] Significant CAD is a nearly universal

accompaniment of PAD. What remains controversial is determining which individuals are most likely to benefit from a detailed preoperative cardiac assessment and possible coronary intervention before undergoing infrainguinal bypass. Proposed algorithms have ranged from routine cardiac evaluation of all PAD patients to an almost nihilistic approach.[16]

Patients with CLTI pose a more complex problem because, especially for WIfI Stage 3 and 4 patients, there is a high anticipated amputation rate without lower extremity arterial reconstruction.[9] CLTI patients have an even greater prevalence of CAD than claudicants do as well as a significantly reduced 5-year mortality, primarily due to associated CAD. However, because CLTI patients also tend to be older and have more comorbidities, cardiac intervention in such individuals has higher reported morbidity and mortality rates than in the general population of patients with isolated CAD targeted for intervention.[16] My approach in CLTI patients is to assume they all have significant CAD. Perioperative blood pressure control, antianginal regimens, and treatment for congestive heart failure are optimized.[17-20] I would recommend postponement of infrainguinal bypass in CLTI patients to allow further cardiac evaluation only in the presence of frequent or unstable angina, recent myocardial infarction, poorly controlled congestive heart failure, critical aortic stenosis, or symptomatic/untreated arrhythmia. Even in these instances, the cardiac evaluation should be focused and expeditious. Invasive coronary intervention should be pursued only if patient and anatomic characteristics are favorable, the benefit-to-risk ratio is high, and the delay to perform the intervention is not prolonged. In the absence of such cardiac instability, CLTI patients are best treated with meticulous perioperative medical care and expeditious lower extremity revascularization.[21,22] Prolonged delays before limb revascularization in CLTI patients increase morbidity and amputation risk.[23] In patients requiring vascular reconstruction, the focus has turned sharply toward maximizing medical therapy rather than performing multiple, expensive, and sometimes ambiguous preoperative cardiac tests so that the patient can be "cleared for surgery." A large, well-designed prospective randomized trial failed to show a benefit of cardiac revascularization before vascular surgery in patients with stable cardiac symptoms. (see Chapter 32 for a detailed discussion of perioperative cardiac evaluation and treatment.)[24]

PREOPERATIVE IMAGING

Infrainguinal bypass requires a careful assessment of the extent of arterial disease as well as a detailed anatomic characterization of the inflow and outflow arteries (see Chapters 25 and 105). Standard arteriography is still the "gold standard" for most patients. Computed tomographic angiography has improved and is now the dominant preoperative imaging modality for aortic aneurysm disease; however, in the periphery, the small caliber of the infrainguinal arteries and the presence of calcification in multiple vessels (associated with increasing age and diabetes) limit the applicability of computed tomographic angiography, especially in CLTI patients.[25] Magnetic resonance angiography[26] is continually improving,[27-31] and particularly for patients with claudication, preoperative duplex imaging, also referred to as duplex arterial mapping (see Chapter 21),[32,33] may provide sufficient anatomic information to proceed directly to the operating room without formal arteriography. In this circumstance, immediate pre-bypass arteriography in the operating room is a reasonable approach. For most patients, however, especially for those with CLTI, I prefer to perform the initial diagnostic angiography in a separate setting, for several reasons. One reason is that for an increasing number of CLTI patients, endoluminal techniques are a reasonable option.

On the basis of a careful assessment before angiography, including the indications for intervention, anatomic considerations (based on duplex imaging), and the patient's functional status, comorbidities, and availability of vein conduit (see Chapter 105), I try to determine whether a given patient with TASC type C or D disease would be best served by endoluminal therapy or open bypass. If endoluminal therapy is the preferred option, I vigorously pursue endoluminal treatment at the time of diagnostic arteriography. If open bypass is preferable, I focus on optimal visualization of potential target arteries and obtain multiple views, as required, to ascertain that no unexpected inflow disease is present that would require treatment before proceeding with infrainguinal bypass. Detailed high-quality diagnostic arteriograms can be obtained and reviewed carefully before proceeding with bypass. In some patients, selection of outflow arteries may be difficult, and this area of decision making can be improved if films are reviewed and discussed with colleagues. Confining the initial procedure to diagnostic or therapeutic angiography obviates time constraints and scheduling difficulties that arise in the operating room when trying to perform angiography and open reconstruction in one sitting. I reserve that approach for carefully selected patients whose arterial anatomy has already been fairly well delineated by preoperative magnetic resonance angiography or duplex scanning. This confines the "one-stop approach" primarily to claudicants undergoing bypass for isolated, single-level femoropopliteal disease.

Defining Bypass Target Arteries

In nearly all patients in whom infrainguinal bypass is indicated, suitable target arteries can be identified (Fig. 109.1) if diagnostic angiography is properly performed.[34,35] Only a tiny fraction of individuals, usually those following multiple failed reconstructions, have no identifiable target artery.[36] Detailed runoff views are necessary, including magnified lateral views of the foot. Such films can be obtained in nearly all patients with adjunctive techniques such as foot warming, local administration of intraarterial vasodilators, and proper positioning of the diagnostic catheter. It is frequently helpful to advance the catheter selectively into the SFA or popliteal artery to obtain adequate views of the infrapopliteal and pedal circulations, especially in patients with diabetes mellitus. Intraarterial runoff films with bolus injections performed while the diagnostic catheter is positioned in the aorta may fail to adequately define the runoff. If percutaneous access has been achieved from a contralateral, retrograde femoral approach, selective films can be obtained by advancing a wire and an appropriate diagnostic catheter over the aortic

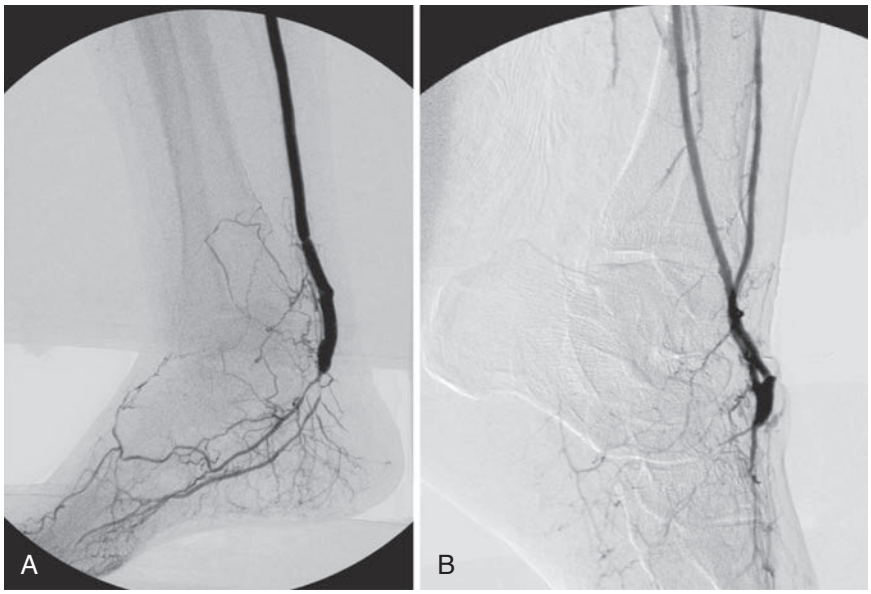

Figure 109.1 Detailed diagnostic arteriography with fixed imaging, proper timing, and appropriate catheter placement almost always identifies suitable target arteries. Each of the patients depicted had popliteal artery occlusion and extensive trifurcation and long-segment tibial disease, but diagnostic studies identified suitable target arteries in the foot. (A) Completion arteriogram after inframalleolar posterior tibial bypass in a patient with diabetes and forefoot gangrene. Despite a small-caliber outflow vessel, the bypass remains patent, and the ischemic foot ulcers healed and have not recurred at 2 years. (B) Completion arteriogram after bypass to a diseased dorsal pedal artery. Despite poor outflow and diseased arch and pedal vessels, the graft remains patent at 1 year. This patient with diabetes healed and ambulates with a transmetatarsal amputation.

bifurcation and selectively down the affected extremity. In selected patients with normal inflow based on physical examination and noninvasive studies, an ipsilateral antegrade approach may be more expeditious to identify suitable runoff vessels, with the additional advantage of requiring a reduced contrast load (Fig. 109.2). Such an approach is especially useful in diabetic patients with renal insufficiency and noninvasive studies that suggest isolated infrapopliteal disease.

Despite optimal angiographic techniques, there may be a small number of patients in whom no suitable target can be identified. Selective exploration of dorsal pedal or distal posterior tibial arteries with flow detectable by Doppler or duplex imaging may identify a graftable recipient artery. Pomposelli et al.[36] reported a surprisingly high success rate under these circumstances, although I believe that this situation is relatively uncommon if diagnostic angiography has been optimally performed. In short, there are few patients who are truly unreconstructible from an anatomic standpoint owing to the lack of a suitable outflow target vessel.

Figure 109.2 Lateral foot view obtained by distal selective superficial femoral arterial catheter injection identifies excellent collaterals from the distal peroneal artery to both the dorsal pedal and posterior tibial circulations.

Autogenous Vein Assessment

Since Kunlin's first description of the successful use of autogenous femoropopliteal vein bypass for arteriosclerosis obliterans,[37,38] there is universal agreement that autogenous vein is the best conduit for infrainguinal bypass at all levels.[39,40] Great saphenous vein (GSV) is the most readily available and durable conduit. Assessment of vein availability and quality is critical and should be carried out before embarking on the operation.[41-43] I routinely perform preoperative duplex mapping of the GSV. If the ipsilateral GSV is absent, unsuitable, or of insufficient length for the anticipated bypass, I also scan the ipsilateral small saphenous vein, the contralateral great and small saphenous veins, and the upper extremity veins, to locate a suitable vein and to identify any extenuating circumstances that might arise during the conduct of the operation. Patients are scanned with a light tourniquet in place and with the limb dependent, as described by Blebea et al.[44] I prefer to use veins that are soft, compressible, and at least 3 mm in diameter. Calcified or sclerotic veins are rejected. Soft, compressible veins between 2 and 3 mm in diameter are worthy of exploration, but if they do not distend appropriately, the operation should be modified either by harvesting a better-quality vein (based on preoperative duplex studies) or by shortening the length of the proposed bypass, if possible,

by selecting alternative inflow or outflow sites. The type and quality of the bypass conduit are the most important determinants of infrainguinal bypass success; efforts to maximize conduit quality will be rewarded.

Vein harvesting can be performed through long continuous incisions, skip incisions, or endoscopically. Endoscopic vein harvest has become common in cardiac surgery. Although there are a few enthusiasts, it has not been widely adopted by vascular surgeons for leg bypass, likely owing to equipment costs, learning curve issues, and concerns about damaging vein segments when a long conduit is needed. There are no convincing data to support any specific harvesting technique.[45-49] Regardless of the harvesting technique, poor-quality or marginal vein should be rejected. The search for high-quality vein is worth the time and effort, even if vein splicing or bypass shortening is required. Every effort should be made to perform all infrainguinal bypasses with vein conduit (all-autogenous policy). Long-term results should not be sacrificed for the sake of expediency at the initial operation. Saphenous vein performs well in the reversed,[50-54] nonreversed,[55] and in situ[56-64] configurations; the technique chosen is dictated primarily by conduit availability, anatomic considerations, and surgeon preference and experience.

OPERATIVE PLANNING

Operative planning for infrainguinal bypass involves the most complex decision making a vascular surgeon is called on to provide. More than any other operation, infrainguinal bypass taxes one's ingenuity, and requires the surgeon to anticipate and carefully consider numerous alternatives and potential complications both during preoperative evaluation and in the conduct of the reconstruction itself. Foremost, the major anatomic lesions and their hemodynamic significance must be identified.[65-67]

Concomitant Inflow Disease

Adequate inflow should be ensured before commencing with infrainguinal bypass. Selected inflow lesions can be treated either percutaneously in advance, at the time of preoperative diagnostic arteriography, or at the same operative sitting (hybrid procedure). Iliac artery lesions of hemodynamic significance should be addressed in nearly all claudicants before proceeding with infrainguinal bypass. For patients with CLTI, an iliac lesion with a resting gradient of less than 5 to 10 mm Hg may be acceptable if the pulse and Doppler waveform at the selected inflow site (e.g., femoral artery) are normal. In patients with claudication or CLTI presenting with rest pain alone in the absence of tissue loss (WIfI: W0, I3, fI 0), an isolated iliac angioplasty without concomitant infrainguinal bypass may suffice if the iliac lesion is of sufficient hemodynamic importance. In such patients with tandem lesions, the profunda-popliteal collateral index may be helpful in predicting whether an inflow procedure alone will be sufficient to alleviate the patient's symptoms.[65] An index greater than 0.25 indicates a large pressure gradient across the knee joint and suggests that inflow disease correction and profundaplasty alone are unlikely to be adequate.[68-70]

Proximal Anastomotic Site

Before operation, the surgeon must define the inflow source, which need not be the CFA. There is abundant evidence that originating shorter bypasses from the deep femoral, superficial femoral, popliteal, or, in rare cases, one of the tibial arteries results in patency rates equivalent to those achieved when the CFA serves as the bypass origin. Short bypasses are frequently useful in patients with diabetes mellitus and primary infrapopliteal arterial occlusive disease as well as in individuals with limited available vein conduit who present with failure of a previous reconstruction. On the basis of hemodynamic data and anatomic imaging, the surgeon should commence the operation with the optimal inflow site in mind. However, if unanticipated arterial disease is identified or vein quality and length are worse than anticipated once the operation is under way, the surgeon should have alternative bypass origins in mind that can be used to shorten the bypass length without compromising hemodynamics. If there is uncertainty about the appropriateness of the inflow site at exploration, its hemodynamic suitability can be assessed by direct intraarterial pressure measurements that can be compared with the transduced radial artery pressure. A resting gradient exceeding 10 mm Hg is significant, as is a drop in pressure exceeding 15% after the administration of intraarterial papaverine.[66,67,71] If a significant gradient is identified at the selected inflow site, a more proximal inflow site above the culprit lesion should be selected, or the responsible lesion should be addressed by local endarterectomy or angioplasty. This problem occasionally arises with iliac or common femoral lesions whose hemodynamic significance was not appreciated at the time of preoperative arteriography, particularly lesions consisting primarily of posterior plaque that may have been masked if appropriate oblique projections were not obtained.

Associated Femoral Endarterectomy

Whenever the CFA is used as the site of origin for bypass, significant occlusive disease involving the origin and proximal deep femoral artery should usually be addressed concomitantly. The endarterectomy often begins in the CFA. After the division of veins that cross the anterior surface of the deep femoral artery, the femoral arteriotomy is carried out beyond the posterior tongue of disease that extends a variable distance down the deep femoral artery, usually at least to its first or second portion. Tacking sutures may or may not be needed at the distal endpoint. The arteriotomy can be closed with a vein patch or a segment of endarterectomized SFA. This patch can then be opened longitudinally to serve as the origin for the infrainguinal bypass (modified Linton's patch technique; Fig. 109.3). Alternatively, if the vein caliber is excellent (>4 mm), a longer venotomy can be made in the vein conduit, which then serves simultaneously as a profundaplasty patch and the bypass origin; this technique should not be used if the arterial wall is markedly thickened or if the caliber of either the native donor artery or the vein conduit is small to avoid compromising the origin of the vein graft at the proximal anastomotic heel. Incorporation of a venous

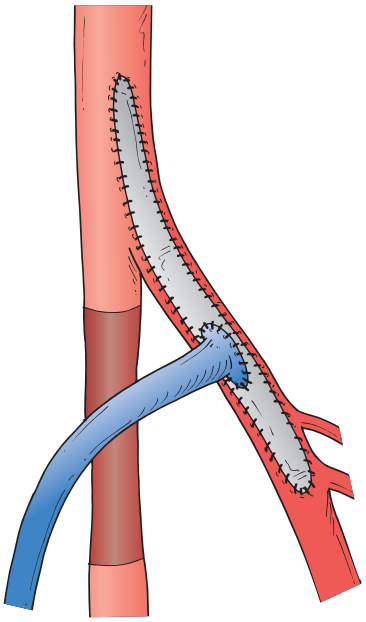

Figure 109.3 Linton's vein patch technique after endarterectomy of the distal common and proximal deep femoral arteries, with anastomosis of the reversed vein graft to the patch.

side branch as part of the anastomotic heel is another useful technique when the donor arterial wall is thick or there is a caliber mismatch between the donor artery and the vein bypass conduit (Fig. 109.4). Correction of significant deep femoral disease at the time of infrainguinal bypass is clinically important; should the bypass ever fail, adequate deep femoral artery perfusion may prevent the development of severe, recurrent limb ischemia.

Distal Anastomotic Site

Although inflow artery selection is generally straightforward, outflow site selection frequently requires greater judgment. The general principle of infrainguinal reconstruction is to bypass all hemodynamically significant disease and to insert the bypass into the most proximal limb artery that has at least one continuous runoff artery to the foot. Thus, if the popliteal artery reconstitutes distal to an SFA occlusion and at least one tibial or peroneal artery is in continuity with the foot, the popliteal artery would be selected as the outflow site. It is possible, however, and sometimes desirable to bypass to an isolated or so-called blind popliteal segment.

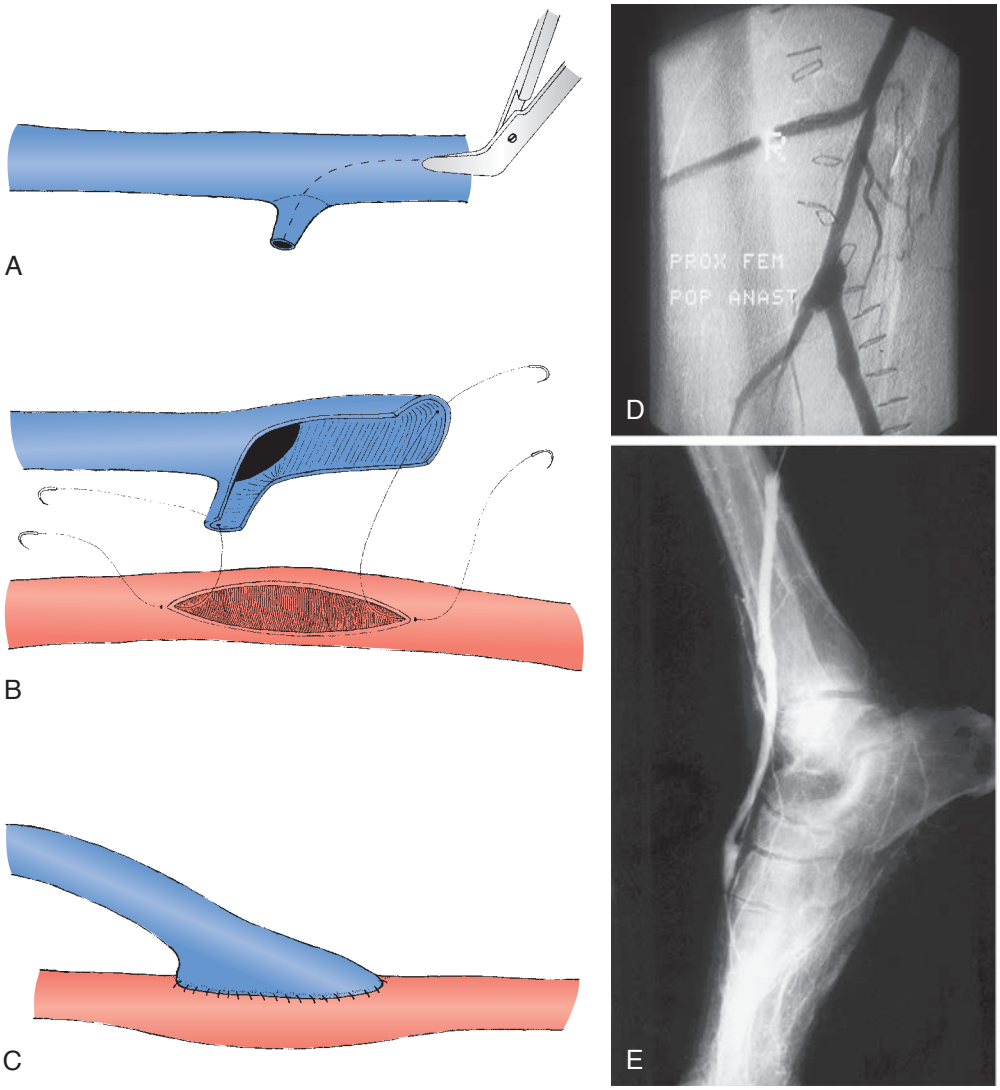

Figure 109.4 The venotomy through the reversed vein is extended through a suitable side branch (A) and anastomosed to the inflow artery (B and C) to avoid anastomotic stenosis at the graft heel.[37,72] This technique can be used at either the proximal anastomosis (D) or the distal anastomosis (E) and is useful when the vein caliber is small or the arterial wall is thickened.

Isolated Popliteal Target

An isolated popliteal artery is defined as a patent popliteal artery segment at least 5 cm long but with only geniculate collaterals and no major distal tibial or peroneal runoff artery in direct continuity with the foot. Such bypasses function surprisingly well and are especially useful in patients with limited vein availability.[73-78] They may also be more useful in patients with claudication or rest pain than in those with frank tissue necrosis, for whom anything less than providing pulsatile flow directly to the foot may be insufficient for healing. In the presence of tissue loss, I prefer bypass to an artery in direct continuity with the foot. Five-year assisted primary or secondary patency rates of 50% to 74% have been reported for such blind-segment popliteal bypasses.[76] Successful bypasses to isolated tibial artery segments have also been reported.[74]

Tibial, Peroneal, and Pedal Targets

Although most claudicants require only femoropopliteal bypass, a high proportion of patients with CLTI require tibial or pedal bypass. In general, the most proximal segment of tibial or peroneal artery that is continuous with the foot should be chosen as the outflow site. Thus, a patent anterior tibial or posterior tibial artery in direct continuity with the foot and pedal arch would be chosen over the peroneal artery as an outflow site if suitable vein length is available. There is still some controversy about whether one should choose the proximal or mid peroneal artery or a patent pedal artery for patients with tissue loss.[79] Most authors have found no adverse effects on graft patency or limb salvage for peroneal bypasses compared with tibial or pedal bypasses,[80-82] but Pomposelli and others have made a strong case for pedal bypass,[36] particularly in diabetic patients with tissue loss.[83] They emphasize the importance of restoring a pedal pulse to maximize forefoot reperfusion. The pedal arteries are also more superficial and more easily exposed than the anatomically disadvantaged, deeply located peroneal artery. If the bypass must originate in the groin and the proximal or mid peroneal artery is of good quality on arteriography and has abundant collaterals with the foot (see Fig. 109.2), I generally perform a shorter bypass to the peroneal artery, especially if vein conduit length is a limiting factor. If the peroneal artery is diseased or does not appear to collateralize well with the foot, I preferentially bypass to the foot or ankle and splice vein if required to obtain sufficient length. I prefer dorsal pedal or paramalleolar posterior tibial–plantar artery insertion sites for short bypasses originating from the popliteal artery in diabetic patients with tissue loss.[84] Shortening the bypass in such patients allows one to optimize vein conduit quality, and the choice of an inframalleolar target artery maximizes forefoot perfusion.

OPERATIVE EXPOSURES

Standard Anterior Approach to the Common Femoral and Profunda Femoris Arteries

Thorough knowledge of anatomy and facility with multiple surgical exposures are critical to the success of infrainguinal bypass.[85] The standard approach to the CFA and the profunda femoris artery (PFA) is provided by a vertical incision overlying the CFA. This anterior approach allows complete exposure and mobilization of the CFA and its bifurcation; more proximal exposure can be obtained by dividing the recurrent portion of the inguinal ligament or the entire ligament (Peter Martin incision). Distal extension allows exposure of the PFA. Division of the lateral femoral circumflex vein offers access to the proximal PFA; careful progressive division of numerous crossing veins allows extensive exposure of the PFA. In selected patients, alternative exposures have been described.

Alternative Approaches to the Profunda Femoris Artery

If previous infection or scarring from multiple previous reconstructions makes standard exposure difficult and if there are no significant occlusive lesions in the CFA or proximal PFA, the mid or distal PFA can be approached laterally, anteromedially, or posteromedially (Fig. 109.5).[74,86-89] The lateral approach is the most useful for infrainguinal bypass. The incision is placed in the upper thigh lateral to the sartorius muscle. The sartorius and SFA are retracted medially. The raphe between the adductor longus and vastus medialis is incised to expose the PFA. This approach is useful when vein conduit length is limited or femoral triangle scarring is prohibitive. The surgeon must be certain that there are no hemodynamically significant lesions proximal to the PFA if this approach is used. With these caveats in mind, use of the PFA origin for distal bypass does not compromise long-term patency.[88,89] Similarly, the SFA[90] and popliteal artery[88-91] can be used as inflow source in carefully selected patients without compromising graft patency.

Exposures of the Popliteal and Tibioperoneal Arteries

The standard exposures of the above-popliteal and below-knee arteries are through medial leg incisions, usually made by deepening the saphenectomy incision. Lateral approaches to these vessels are occasionally useful and are well described elsewhere.[91] The posterior tibial and proximal to mid peroneal arteries are usually approached medially. The distal third of the peroneal artery is most expeditiously exposed by means of a lateral leg incision directly over the distal fibula. A short segment of fibula is carefully removed to expose the distal peroneal artery immediately beneath.

Posterior exposures of the popliteal, posterior tibial, and peroneal arteries are sometimes useful (Fig. 109.6).[92,93] Diabetic patients frequently have relatively normal inflow to the popliteal trifurcation. If the inflow site is the below-knee popliteal artery and the most appropriate target artery is the distal posterior tibial or distal peroneal artery, and if the small saphenous vein is of good quality on duplex imaging, one can perform the entire operation with the patient in a prone position through a posterior approach. These approaches have been well described by Ouriel[93] and should be considered not only in selected reoperative situations (e.g., failed bypass through a medial approach), but also if conduit length is limited and ipsilateral

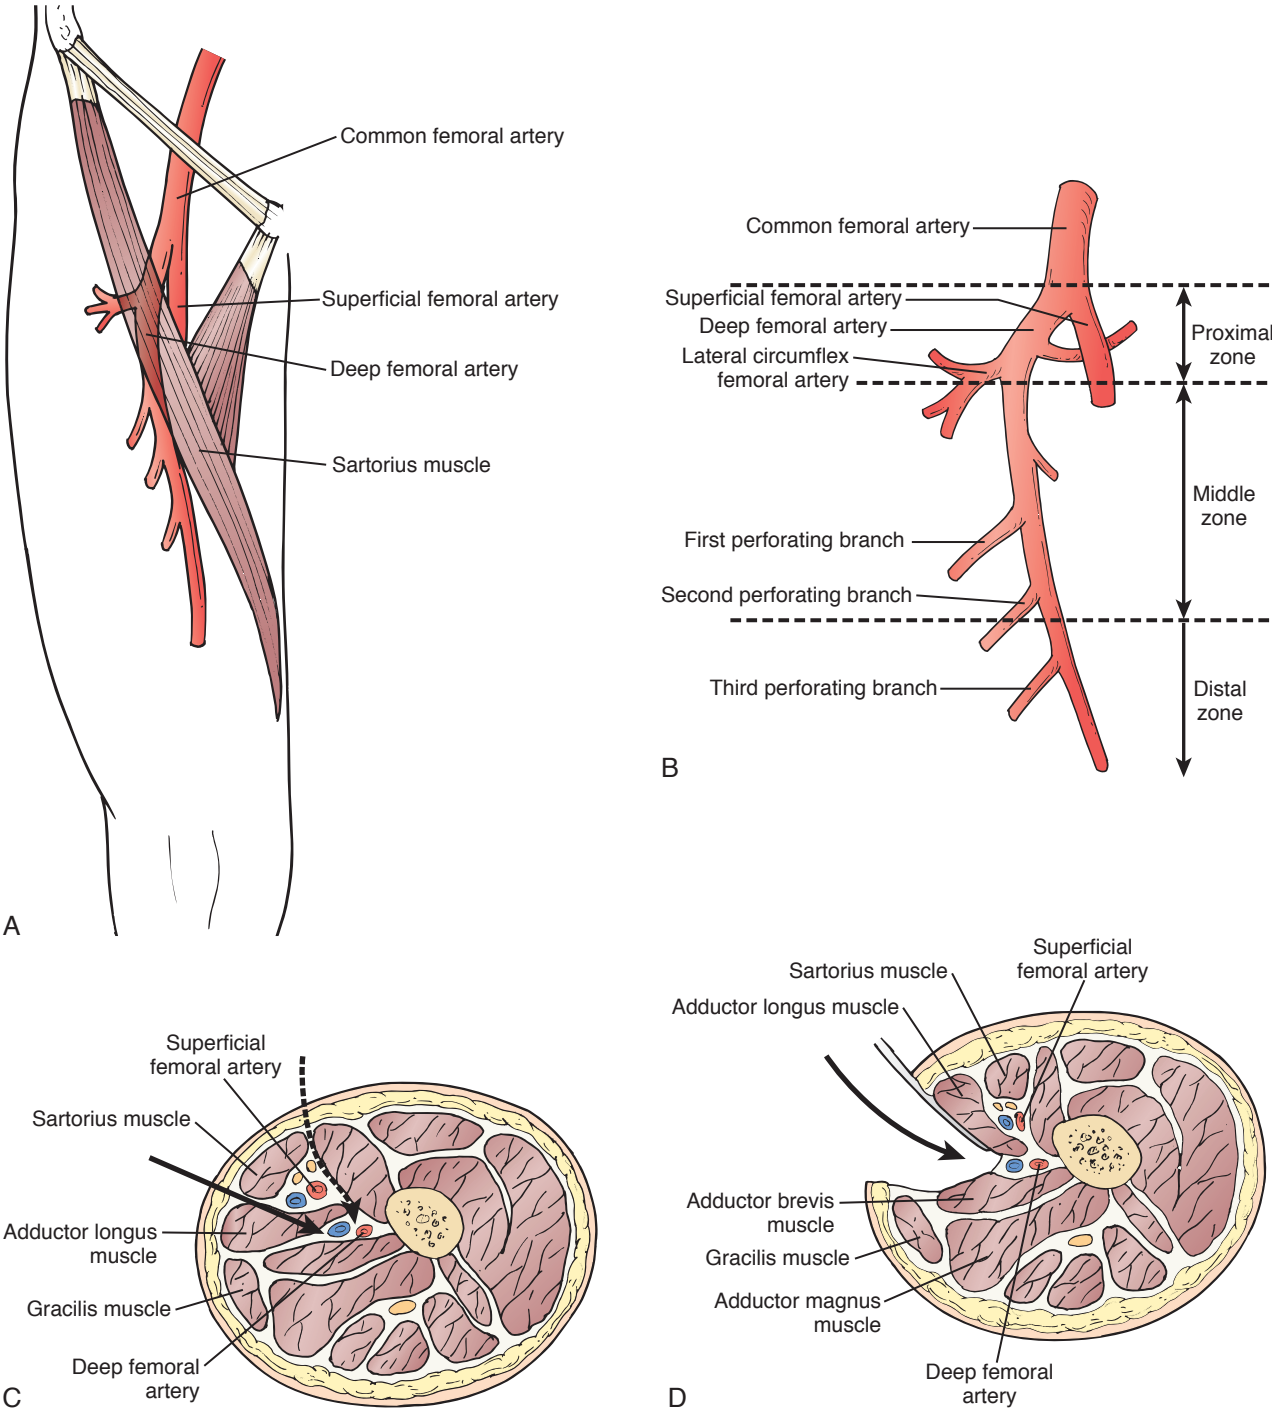

Figure 109.5 Alternative approaches to the distal deep femoral artery[88] are useful for reoperative femorodistal bypass and when it is desirable to shorten the bypass because of limited length of vein conduit.[89] (A) Location of the deep femoral artery. Note the surface landmarks used to identify its course. (B) The deep femoral artery can be divided into three zones: proximal, middle, and distal. (C) Transverse section of the thigh (viewed from above) shows the plane of dissection when the anteromedial approach *(solid arrow)* is used. Alternatively, the deep femoral artery can be approached through an even more anterior route *(dashed arrow)* by making an incision along the lateral border of the sartorius and retracting this muscle and the superficial femoral neurovascular bundle medially to reach the distal deep femoral artery. (D) Posterior approach to the distal deep femoral artery. Note the fascial plane and structures separating the deep femoral artery from superficial femoral vascular structures and isolating it from the subsartorial canal.

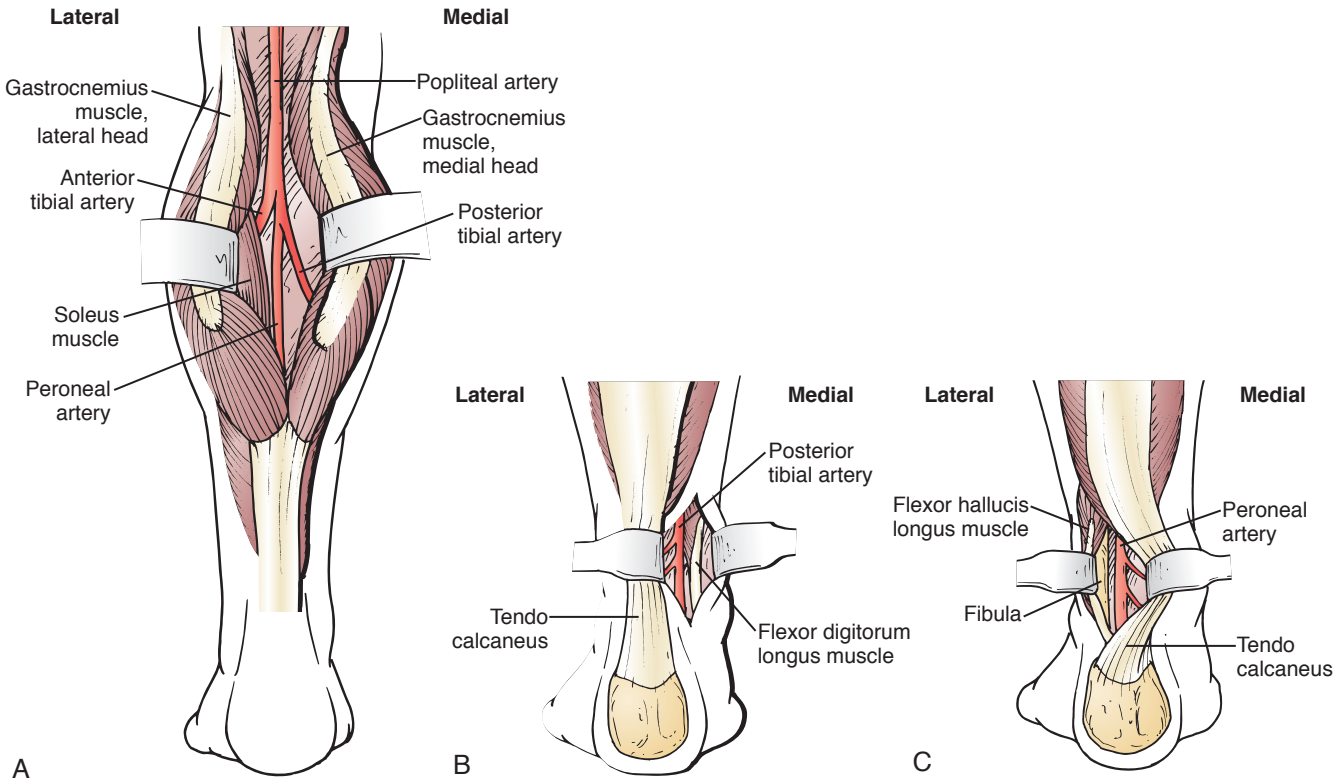

Figure 109.6 Posterior exposures.[95] (A) Exposure of the popliteal and proximal crural arteries through a posterior approach. The two heads of the gastrocnemius muscle are separated, and the soleus muscle is lysed from its tibial origin. (B) Exposure of the posterior tibial artery through a posterior approach. The tendo calcaneus is retracted laterally. The flexor digitorum longus muscle is reflected medially in the lower portion of the calf because the artery lies posterior to the lateral border of this muscle near the level of the malleoli. (C) Exposure of the peroneal artery through a posterior approach. The tendo calcaneus is retracted medially and the flexor hallucis longus muscle is reflected laterally to expose the artery in the groove next to the fibula.

SSV is unavailable. Commitment to an all-autogenous bypass approach requires ingenuity and familiarity with numerous anatomic exposures and techniques to allow shortening of the bypass or to permit operation in a virgin field that is unscarred by previous operations. When such distal origin bypass grafts are used, a pneumatic tourniquet instead of vascular Silastic loops or clamps is occasionally useful to circumvent severe distal arterial calcification.[94] A thorough working knowledge of alternative exposures and the occasional use of the pneumatic tourniquet are of great benefit in performing reoperative bypass.

CHOICE OF CONDUIT

Autogenous conduit options for infrainguinal bypass include ipsilateral and contralateral GSV,[96] small saphenous vein,[97,98] femoral vein,[99] arm (basilic and cephalic) vein,[100-105] endarterectomized segments of the SFA,[106] cryopreserved vein,[107-109] and radial artery.[110,111] Prosthetic options include Dacron, heparin-bonded Dacron, human umbilical vein, polytetrafluoroethylene (PTFE) with and without a distal cuff, and, most recently, expanded PTFE (ePTFE) covalently bonded with heparin. In my group's reported 10-year experience, we performed 93% of infrainguinal bypasses with all-autogenous conduits.[112]

Autogenous Grafts

The preferred conduit is the GSV as it outperforms all other conduit choices. If the ipsilateral GSV is absent, I do not hesitate to harvest the contralateral GSV and see no merit in saving this vein for possible use later.[96] Numerous reports suggest that the contralateral GSV is subsequently needed in no more than 20% to 25% of patients. I therefore advocate using it when necessary and performing a more difficult alternative vein reconstruction at a later time in those relatively few patients who require it. Exceptions occur whenever the contralateral limb is already ischemic, as manifested by severe claudication, rest pain, or ischemic ulceration. If the contralateral limb is asymptomatic and the ankle-brachial index exceeds 0.6, I have experienced no significant wound healing complications from harvesting the GSV from the groin to the midcalf level. This approach usually allows the bypass to be performed with one segment of GSV and obviates the need to harvest arm vein and splice veins. Other groups prefer to harvest arm vein if the ipsilateral GSV is unavailable, preserving the contralateral GSV for later use.[100,113]

Alternative veins are used when the GSV is unavailable or of insufficient length.[114] Duplex mapping is useful to identify

suitable vein sources. The small saphenous vein is suitable if the proposed bypass is relatively short. It is possible to perform a common femoral–to–above-knee popliteal bypass or a PFA–to–below-knee popliteal bypass with one complete segment of saphenous vein harvested from the ankle to the knee. If a longer bypass with spliced vein is necessary, I prefer to use arm vein because it is less awkward to harvest. LoGerfo et al.[115] and Holzenbein et al.[104] described novel techniques of harvesting the upper arm basilic, median cubital, and cephalic veins in continuity with valve lysis of the basilic segment and use of the cephalic segment in a reversed configuration to provide a relatively long, unspliced autogenous conduit. The femoropopliteal deep vein is occasionally useful for shorter bypasses but is large in caliber and more difficult to harvest; arm vein is therefore generally preferred. Treiman et al.[111] reported the use of the radial artery as a bypass conduit in selected patients requiring short infrageniculate bypasses, with good early results. Cryopreserved vein grafts are expensive and have not performed well in clinical practice[107,108]; they may serve a niche role when revascularization is required after the removal of an infected bypass graft and autogenous vein is unavailable to create a new bypass through clean tissue planes.[108]

Prosthetic Grafts

PTFE is the most commonly used prosthetic conduit for infrainguinal bypass, although reports suggest that in the above-knee position, it is not superior to Dacron.[116-118] A prospective randomized trial from the United Kingdom reported by Devine et al.[119] suggested that heparin-bonded Dacron was superior to PTFE for above-knee popliteal bypasses. The 3-year primary patency for heparin-bonded Dacron was 55% compared with 42% for PTFE ($P < .044$). Both of these patency rates are inferior to those of GSV, however, and the early apparent advantage of heparin-bonded Dacron over PTFE disappeared with longer follow-up.[120]

Vein Cuffs

For bypasses that insert below the knee, the addition of a vein cuff confers a significant patency advantage (52% patency at 2 years for PTFE with vein cuff vs. 29% for PTFE with no cuff) and also improves limb salvage (84% vs. 62%; $P < .03$).[121] My experience and that of others suggests that a distal vein cuff, patch or collar improves 2- to 3-year patency for infrageniculate bypass when PTFE is required.[122-126] Nevertheless, the results are still inferior to those of vein bypasses, even when alternative veins are used; these data emphasize the validity of the all-autogenous policy. If vein is truly limited, however, PTFE is an acceptable choice, and available data suggest that distal anastomotic modification with autogenous tissue is a worthwhile adjunct. The only prospective randomized clinical trial used a Miller cuff (Fig. 109.7).[121] A distal Taylor patch (Fig. 109.8)[122,124] and the St. Mary's boot (Fig. 109.9)[126] may yield equivalent results. Neville et al.[128,129] reported an alternative PTFE adjunct consisting of anastomosis of a PTFE graft to an infrageniculate artery using a vein patch, analogous to the technique originally described by Linton. At least in their hands, this adjunct seems to work as well as a Miller cuff or Taylor patch. However, the only randomized prospective trial of such adjuncts used the Miller cuff, and this trial has not been repeated to my knowledge.

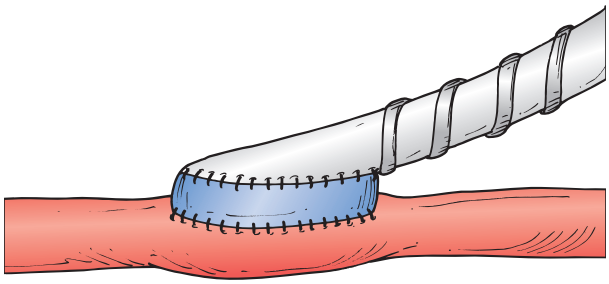

Figure 109.7 The Miller cuff technique[123,127] improved the patency of below-knee popliteal and tibial polytetrafluoroethylene bypass grafts when used as a distal anastomotic adjunct in a controlled randomized clinical trial.[121]

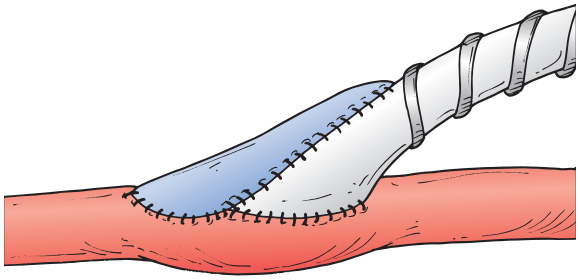

Figure 109.8 The Taylor patch technique can improve the patency of infrageniculate polytetrafluoroethylene bypass grafts.[122,124]

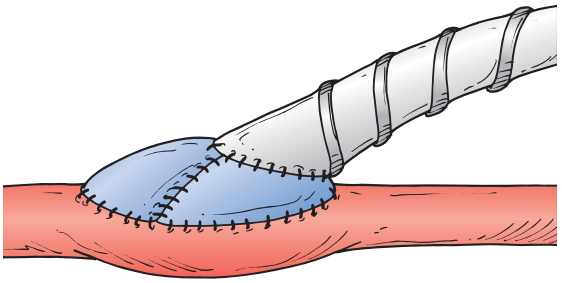

Figure 109.9 The St. Mary's boot or prosthetic venous collar technique[126] combines the attributes of the Taylor patch and the Miller cuff.

Human Umbilical Vein and Adjunctive Arteriovenous Fistula

Human umbilical vein is less commonly used than PTFE, primarily because it is thicker and more cumbersome to handle and due to concerns about subsequent aneurysmal degeneration.[130] Dardik et al.[131] reported excellent results using human umbilical vein with an adjunctive distal arteriovenous fistula to promote increased graft flow velocity; there are no prospective trials comparing this technique with alternative prosthetic conduits, such as PTFE. A single prospective trial did not demonstrate any benefit of the addition of an arteriovenous fistula to femoral-infrapopliteal bypass with vein cuff.[132]

Heparin-Bonded Polytetrafluoroethylene

The most recent addition to the inventory of prosthetic infrainguinal bypass conduits is ePTFE to which heparin has been covalently bonded. The commercially available product was originally called Carmeda BioActive Surface (CBAS).[133] Preclinical studies suggest that biologically active heparin has been successfully covalently bonded to ePTFE without causing systemic anticoagulative effects.[134] The drug is biologically active, at least in baboons and dogs, for up to 12 weeks.[135] In animal models of thromboresistance (short 3- and 4-mm grafts), CBAS appears to prevent early ePTFE graft thrombosis; this effect may persist up to 180 days, although not as strikingly. It also appears to reduce early platelet and fibrin deposition in animal models.

There is no proof, however, that these experimental findings will translate into improved prosthetic graft patency in humans. The five published reports of CBAS for peripheral infrainguinal bypass suffer from major flaws, including lack of randomization, lack of control groups, small numbers of patients, selection bias, large numbers of patients with relatively prosthetic-friendly above-knee popliteal insertion sites, lack of intermediate follow-up (beyond 2 years), and flawed or unreliable life tables.[133,136-139] In two of these five series, anastomotic adjuncts such as patches were used in addition to CBAS grafts, further confounding interpretation. In addition, aggressive combination antiplatelet therapy (oral and low-molecular-weight heparin) was used by nearly all the authors; this combination is not routinely used in North America.

If one assumes that there is no patient overlap between the two studies from the same center (an assumption that may well be false),[136,139] the published human experience with CBAS infrainguinal grafts consists of 356 grafts with the following insertion site distribution: 142 (41%) above-knee popliteal, 115 (33.5%) below-knee popliteal, 75 (21.8%) femorocrural or tibial, and 24 indeterminate (one study does not specify target arteries).[140] The estimated number of patients available with documented follow-up in all five human clinical CBAS studies combined is as follows: 95 above-knee popliteal, 45 below-knee popliteal, and 25 femorocrural at 1 year; and 48 above-knee popliteal, 16 below-knee popliteal, and 9 femorocrural at 2 years. The data and follow-up length are thus insufficient to support assertions of improved patency conferred by covalently bonded heparin grafts. Long-term studies of this intriguing bioactive graft are needed to determine whether covalent heparin bonding confers any significant patency benefit. Heparin-induced thrombocytopenia has also been rarely reported with these grafts.

Graft Comparison

Table 109.1 summarizes the available level I data comparing conduit types with outcome.[118-124,132,141-145] Vein is superior to all prosthetic materials, even in the above-knee position.[145-147] The randomized clinical trials comparing human umbilical vein with PTFE have been inconclusive.[143,144,148] The addition of rings to PTFE conferred no benefit in the single prospective randomized clinical trial conducted.[149] Thus, the most prudent recommendation is to use autogenous vein whenever possible for infrainguinal bypass. This dictum holds true not only for primary infrainguinal bypasses but also for reoperations, in which vein conduits outperform all other options.[150,151] For long bypasses, ipsilateral GSV, contralateral GSV, and spliced vein are employed in decreasing order of preference. If only 5 to 15 cm of extra length is required and a more distal origin site is not feasible, eversion endarterectomy of a proximal segment

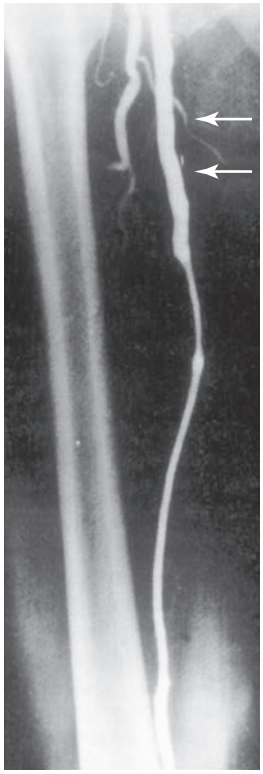

Figure 109.10 When vein length is limited, an eversion endarterectomy of a proximal superficial femoral artery segment *(arrows)* can be performed.[106] The everted arterial segment is anastomosed to the available vein graft to create an all-autogenous conduit of sufficient length for the required bypass to be performed.

of the SFA with anastomosis to the available vein conduit is a useful technique that avoids the harvesting and splicing of additional vein (Fig. 109.10).[106] For shorter bypasses, arm vein or small saphenous vein is effective, with the latter being especially useful when a posterior approach is applicable.

If vein is truly unavailable after a thorough search, PTFE, human umbilical vein, or Dacron are reasonable options for above-knee bypass. The initially favorable results with heparin-bonded Dacron were not confirmed during longer follow-up,[119,120] so there appears to be no advantage to heparin-bonded Dacron conduit for above-knee bypass. A prospective randomized trial of human umbilical vein versus heparin-bonded Dacron showed no difference in patency in the above-knee popliteal position,[154] and published trials of PTFE versus Dacron have shown no clear difference.[116-118,120] For infrageniculate insertion sites, PTFE with distal anastomotic modification (cuff, boot, or patch) is recommended if vein is unavailable. There is inadequate evidence to state a preference in terms of standard ePTFE versus heparin-bonded or carbon-coated PTFE. The single prospective randomized trial of standard PTFE versus carbon-impregnated PTFE for infrageniculate bypass showed approximately 30% primary patency, with no difference between groups at 3 years.[155]

BYPASS TECHNIQUE

Reversed, nonreversed, and in situ conduits appear to work equally well. The choice is primarily one of surgeon preference. Arm veins pose special challenges. Regardless of which type of conduit is used, meticulous technique and gentle vein handling are critical.

Reversed Vein Bypass

Harvest of the GSV begins with a groin incision two finger-breadths lateral to the pubic tubercle. Preoperative duplex vein mapping and drawing of a line with indelible ink directly over the vein conduit assist in following the course of the vein and avoiding the creation of skin flaps. The saphenofemoral junction at the fossa ovalis should be identified to ensure that the true GSV rather than an anterior or large posteromedial branch is being exposed. Once the main trunk is identified, the incision is extended distally, directly over the vein, with a No. 10 blade or Cooley scissors. I frequently leave short skin bridges, especially in the thigh and about the knee level, to avoid the creation of long skin flaps. If exposure or branch ligation is difficult or if the course of the main vein is unclear, the skin directly over the vein is divided. The periadventitial tissue, not the vein wall itself, is grasped gently to avoid damage to the conduit. Side branches are meticulously ligated with 3-0 or 4-0 silk and divided. Leaving a short stump is preferable to placing a ligature too close to the main trunk and compromising the lumen. When first exposed, the vein should be soft and blue. Sclerotic segments are whitish and rubbery. Vein spasm can turn a blue vein white and should be treated with local papaverine or lidocaine irrigation.

Sufficient length of vein should be harvested for the proposed bypass to be performed. If adequate vein of good quality is not available, alternative inflow or outflow arteries should be considered to shorten the bypass; otherwise, alternative vein must be harvested from another site and spliced on a back table. Vein quality is extremely important, and segments less than 3 mm should not be used. Once an adequate length of vein is identified, it is ligated proximally and distally and prepared on the back table by a senior surgeon while the rest of the team exposes the inflow and outflow arteries.

The vein is cannulated with a 3-mm olive or Marks tip needle and gently distended with chilled autologous blood (50-60 mL) to which 1000 units of heparin and 60 mg of papaverine have been added. With gentle irrigation, the vein should flow readily, distend smoothly, and be free of fibrotic and nondistensible segments. Missed or small avulsed branches are repaired with longitudinally oriented 6-0 or 7-0 Prolene sutures on a BV-1 or BV-175 needle. Overly forceful distention of the conduit should be avoided because it damages the endothelium. The entire length of the conduit is inspected to ensure that there are no sclerotic areas, no areas of persistent spasm, no strictures at branch ligature sites, and no bleeding branches. Once preparation is complete, the distal end of the vein is ligated with 3-0 silk, leaving the suture ends long; the prepared conduit is stored in chilled blood until the graft is ready to be tunneled. Proper intraoperative planning should result in minimal vein storage time. Many believe that autologous blood, rather than saline, better preserves graft endothelium.[156]

Proper graft tunneling of reversed grafts is important. For primary leg bypasses with GSV, I prefer to tunnel the graft in a deep anatomic plane to avoid kinking and graft exposure should wound complications ensue. For above-knee popliteal bypasses, a subsartorial plane is frequently easier than a true anatomic tunnel. A large-caliber hollow-bore metal tunneler with a removable obturator is used. For below-knee popliteal and proximal to mid posterior tibial or peroneal bypasses, I generally prefer an anatomic tunnel between the two heads of the gastrocnemius for initial bypasses. It is often wise to tunnel reoperative bypasses subcutaneously to avoid scarring and render graft surveillance and revision easier. This approach is advantageous because the alternative vein conduits often used in these circumstances are at higher risk for the development of graft stenosis. Bypasses to the anterior tibial artery can be tunneled through the interosseous membrane (anatomic) or a lateral subcutaneous plane.

Arm Vein Harvest and Vein Splicing

If leg vein length is inadequate or unavailable or if additional conduit is required, arm vein should be used. Arm veins, especially the basilic vein, are more fragile and demanding to harvest. Branches should be carefully identified and ligated a short distance away from their junctions with the main trunk to avoid troublesome bleeding from an injury at the crotch between the branch and the parent vein. Large branches are suture or doubly ligated. The initial distention of the vein is performed with heparinized saline and papaverine because defects in thinner walled arm veins are more difficult to visualize and repair if blood is used as the initial irrigant. Once major leaks have been controlled, the vein graft is prepared and stored in chilled blood as mentioned earlier. It is worth considering that arm veins frequently harbor abnormal segments containing intrinsic lesions such as webs, synechiae, and sclerotic valves. Angioscopy of such high-risk conduits may be a useful adjunct (see later under Angioscopy).

In situ Vein Bypass

In situ bypass can be used successfully in many patients with intact ipsilateral GSVs. Proponents suggest that the vein-artery size match is frequently optimized by this technique.[157] This technique requires the use of a radial cutting blade (Mills valvulotome)[58] or fixed-diameter circumferential blades such as the Hall[59] and LeMaitre valvulotomes to accomplish valve lysis.[62,158] The proximal segment of GSV is initially mobilized in the groin as it would be for reversed vein bypass. The distal GSV is then mobilized in the region of the projected distal arterial anastomosis. The vein may be exposed by an open technique along its entire length, through skip incisions, or endoscopically. After systemic heparinization, the vein is transected below a Satinsky clamp placed at the saphenofemoral junction, and the stump is closed with running 5-0 Prolene suture. The most proximal valve is excised under direct vision with Potts scissors, and the vein is spatulated and sewn end to side to the selected arterial anastomotic site, usually the CFA. Arterial flow is allowed into the vein conduit; if the conduit is of large caliber, a circumferential valvulotome can be inserted from distal to proximal to lyse the valves. Many surgeons prefer to more carefully control valve lysis by progressive serial valvulotomy through large side branches, progressing from proximal to distal. The Mills valvulotome is introduced through side branches; the leaflets are usually just distal to branches and are oriented parallel to the skin. Under arterial pressure, the valve sinuses distend, and the valve leaflets are displaced toward the center of the lumen, where they can be safely engaged by the valvulotome and cut by sharp retraction on the valvulotome under direct visualization. The final valves are lysed from the distal end of the vein. The quality of the vein and the success of lysis are then assessed; flow should be highly pulsatile from the end of the conduit before the distal anastomosis is performed.

After completion of the anastomoses, the quality of pulsation and flow is assessed by palpation and handheld Doppler interrogation. The entire graft should be evaluated from proximal to distal; it can be manually compressed or occluded distal to the Doppler probe. The presence of continuous outflow despite distal graft compression indicates an arteriovenous fistula; these branches should be ligated. With either the reversed or the in situ technique, careful handling of the vein is important. The assurance of adequate valve lysis and the detection of major arteriovenous fistulae can be challenging; the type of completion study used depends on the type, source, and quality of the conduit and surgeon preference.

INTRAOPERATIVE COMPLETION STUDIES

Infrainguinal bypass can be complicated by insufficient or inadequate arterial exposure; inappropriate inflow or target artery selection (Fig. 109.11); intrinsic conduit defects; technical defects associated with clamp injury, local endarterectomy, anastomosis creation (Fig. 109.12), and valve lysis; graft tunneling errors (Fig. 109.13); and coagulation or platelet aggregation abnormalities. The surgeon should strive to avoid these complications but must be prepared to recognize and correct them should they arise. Ignorance is not bliss, and the best opportunity to correct a problem is at the initial operation. Failing to address a significant defect and hoping for the best compromises patient outcome and increases stress on the operating surgeon. "Take-backs" to the operating room for hemorrhage or graft thrombosis are inevitable, but their frequency can be markedly reduced by meticulous technique, prudent decision making, and routine completion studies to ensure a technically optimal result.

There are four options for completion assessment that can be used alone or in combination: distal pulse palpation and Doppler flow assessment, with and without manual compression of the graft[159,160]; completion arteriography[161-163]; intraoperative duplex scanning, with and without papaverine administration[164,165]; and angioscopy.[166-178]

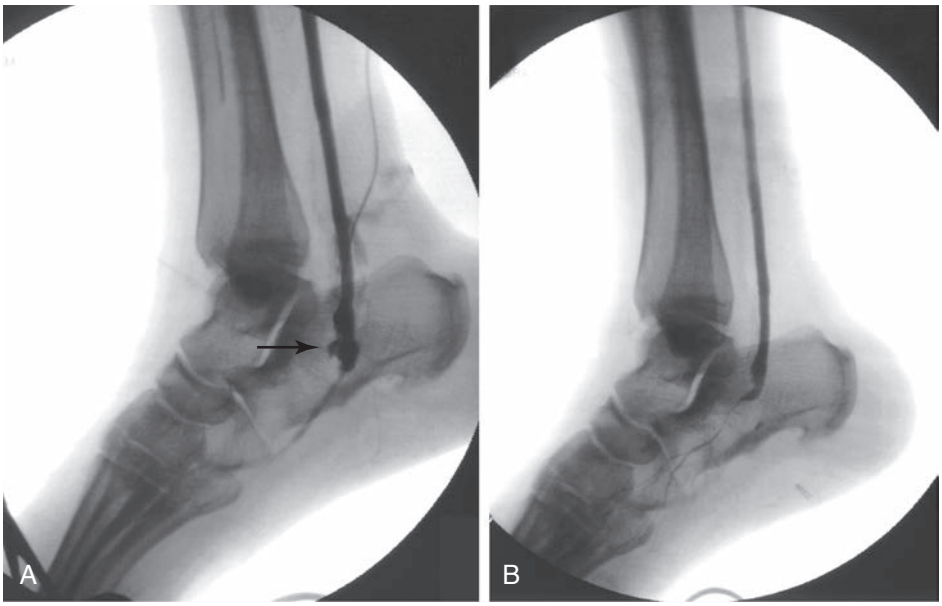

Figure 109.11 (A) Completion arteriography demonstrates poor runoff, with minimal branching of the target plantar artery *(arrow)*. The initial exposure was inadequate, leading to incorrect selection of the target artery (lateral plantar). (B) The anastomosis was relocated to the medial plantar artery, and the graft remains patent 2 years postoperatively.

Doppler Flow Assessment

Doppler flow assessment should always be performed. Restoration of a palpable distal pulse or Doppler flow that clearly diminishes with manual occlusion of the bypass graft documents graft patency. These techniques are sufficiently sensitive to detect only major conduit, technical, or outflow problems, however. Therefore other, more complex techniques should also be employed.

Arteriography

For reversed vein conduits, arteriography is the simplest and most effective completion study. With improved intraoperative imaging capabilities, it has become relatively easy to rapidly evaluate the conduit, tunnel, anastomoses, and outflow for significant graft-threatening lesions with minimal contrast material and little additional time (see Fig. 109.13). Renwick et al.[162] identified defects requiring correction in 27% of infrainguinal bypasses using intraoperative angiography, despite a normal appearance by visual inspection and external pulse palpation. The 2-week primary patency was 100%, compared with 72% in a control group without completion arteriograms. Mills et al.[161] prospectively evaluated 214 consecutive infrainguinal bypass grafts with routine completion angiography and identified significant lesions requiring revision in 8% of grafts, with a higher incidence in tibial than in popliteal reconstructions. The 30-day primary patencies were 99% for femoropopliteal bypasses and 93% for femorodistal grafts. Angiography may not be sufficiently sensitive to detect incomplete valve lysis during the performance of in situ or nonreversed grafts.[173,175]

Duplex Ultrasound

Bandyk et al.[164] Johnson et al.[165] and their colleagues have championed intraoperative duplex scanning after in situ bypasses and reported significant abnormalities requiring correction in 12% of cases. Lesions associated with focal peak systolic velocities exceeding 250 cm/s are repaired. In low-flow grafts without identifiable technical defects, if target artery relocation or graft extension is not possible, consideration is given to either the performance of an adjunctive arteriovenous fistula to augment graft flow velocity or the administration of postoperative anticoagulation. The short-term patency of infrainguinal bypasses with normal findings on intraoperative duplex scanning is superb. Intraoperative graft duplex scanning requires the availability of a machine and a technician, however, and most surgeons are less familiar with this technique and find it cumbersome to use. These issues have prevented its widespread application, although I have found it useful in difficult reoperative cases, particularly when alternative, spliced, or valve-lysed vein segments are used.[179]

Angioscopy

Angioscopy has been employed to evaluate the conduit by many clinical investigators,[166-178] who have used it to evaluate harvested arm vein[168] or as an adjunct to valve lysis to permit in situ bypass with minimal skin incisions.[180-182] Marcaccio et al.[174] analyzed the use of intraoperative angioscopy in a series of 113 arm vein bypasses and identified significant intraluminal disease in 62.8% of cases; previous thrombosis with recanalization (54%) was the most commonly encountered lesion, followed by complex weblike lesions at valve sites or possibly associated with previous venipuncture. Angioscopy was used to correct 95.8% of vein abnormalities judged to be significant and allowed an "upgrade" of the conduit quality. The 1-month patency rate was 95.5% in grafts judged to be normal initially or after repair, compared with only 70% in conduits judged to be of inferior quality even after attempted repair. Wilson et al.[167] reported a similar yield of prognostically important information with intraoperative angioscopic evaluation of conduits. Angioscopy

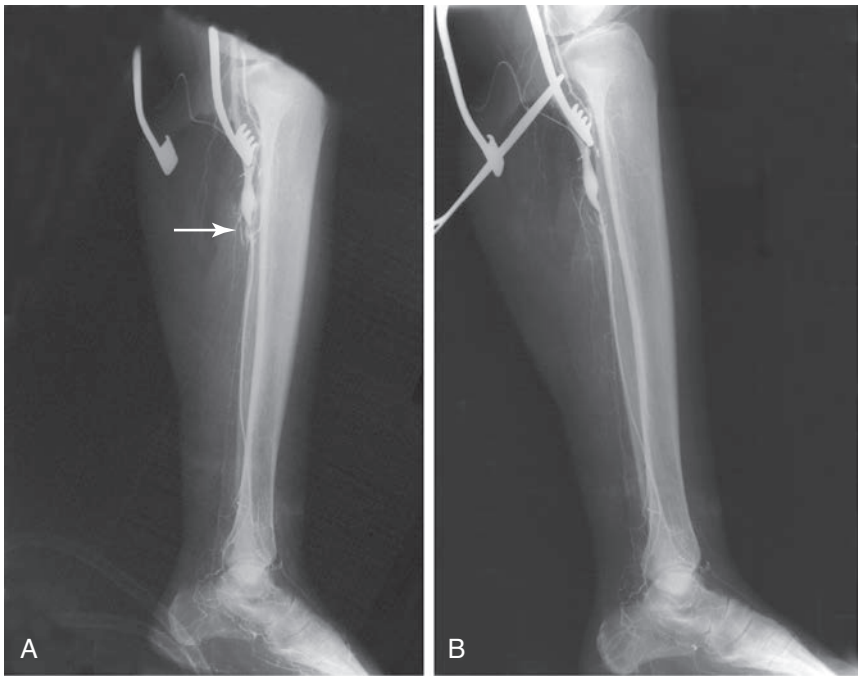

Figure 109.12 (A) Completion arteriography identifies a significant distal anastomotic defect *(arrow)*, despite a good graft pulse and distal continuous wave Doppler signal. (B) The anastomosis was re-explored, the defect was corrected, and the graft is patent at 3 years.

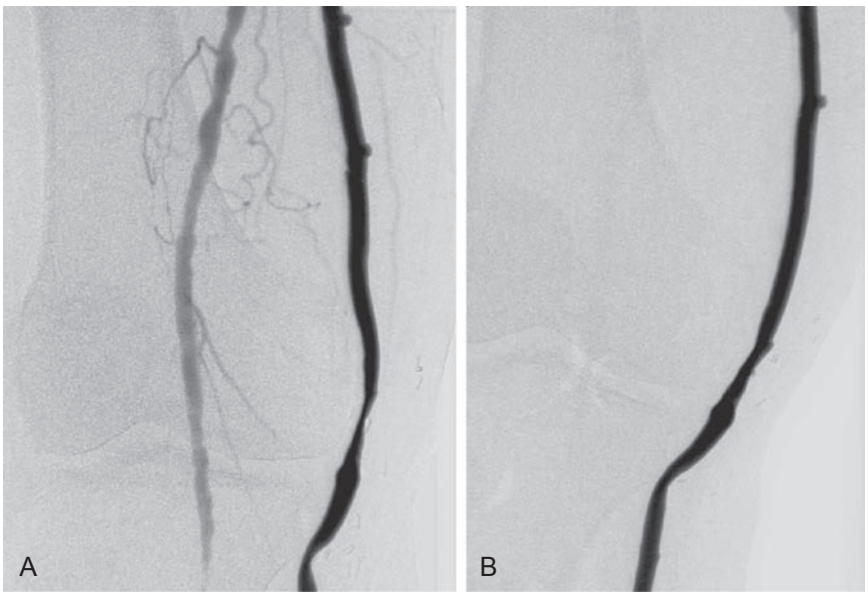

Figure 109.13 (A) Routine completion arteriography identifies an unsuspected site of graft compression in the tunnel, despite a good distal graft pulse and continuous wave Doppler signal. (B) The site was explored, the compression was released, and the graft is patent at 2 years.

thus appears to be most useful for assessing arm vein conduits or ensuring the adequacy of valve lysis for in situ conduits. Wound and vein harvest incisional complications can compromise outcome and prolong hospital stay.[183-187] Several groups have reported the adjunctive use of angioscopy both to assist in the performance of valve lysis and to allow in situ bypass to be performed with minimal skin incisions[171,180-182,187-195]; whether these techniques improve outcome is uncertain.

Some objective assessment of the bypass, its anastomoses, and the outflow is an important component of infrainguinal bypass. I still recommend completion arteriography but recognize that duplex scanning and angioscopy are important adjuncts, especially in higher risk situations and with use of nonreversed or in situ conduits in which complete valve lysis is critical. It seems even more important to perform routine completion studies in an era when the volume of open bypass procedures

has fallen at most centers owing to a paradigm shift toward endovascular therapy.

RESULTS

Outcomes must be reported according to the Society for Vascular Surgery reporting standards.[5-7,196] Graft patency, limb salvage, and mortality are objective endpoints. Somewhat subjective endpoints are durability, functional outcome, and quality of life.

Objective Endpoints

The outcomes of infrainguinal bypass procedures have traditionally been reported solely in terms of graft patency, limb salvage, and patient survival rates. Several factors affect outcome when it is considered in these terms. Conduit type is the major determinant of long-term graft patency, with vein outperforming prostheses for all varieties of infrainguinal bypass. For vein conduits, vein quality[197-199] and caliber[199-201] are the most critical determinants of success. Vein grafts less than 3 to 3.5 mm in diameter are inferior whether they are used in situ or reversed.[200,202,203] GSV is superior to alternative vein sources.[114,202] Reduced graft patency has been attributed to high outflow resistance or poor runoff,[199,204,205] although poor runoff is somewhat difficult to define, and autogenous vein grafts frequently remain patent in the presence of striking outflow disease (Fig. 109.14). Other factors, such as patient age and diabetes, do not appear to adversely affect graft patency, although diabetic patients exhibit prolonged wound healing times.[205] Most investigators agree that the presence of end-stage renal failure is associated with reduced graft patency and increased limb loss and mortality.[206-215] Anesthetic type has not been conclusively shown to influence graft patency or perioperative mortality.[216,217]

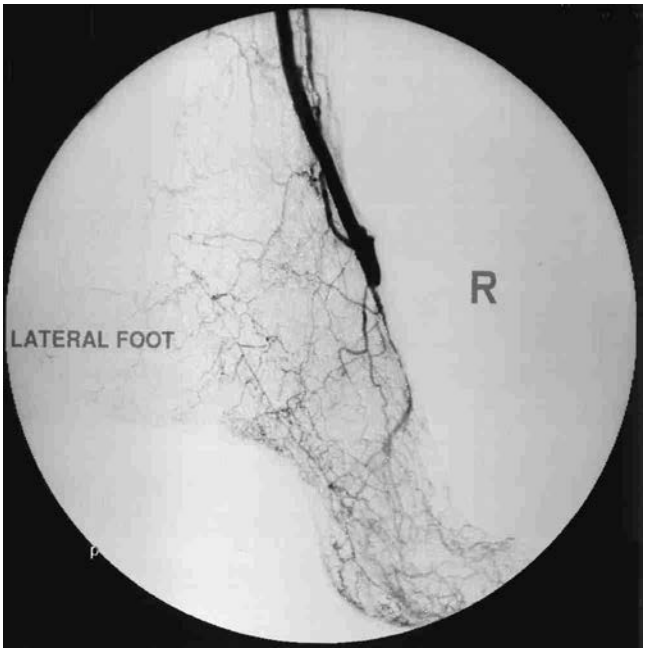

Figure 109.14 Distal view of completion arteriogram after popliteal artery–to–dorsal pedal artery reversed vein bypass in an 82-year-old diabetic man with chronic renal disease and a functioning renal transplant. Despite significant disease of the distal dorsal pedal artery, the patient's toe amputation healed and the graft has remained patent, with normal graft flow velocities, for more than 6 years.

Graft Patency

Patency Definitions

Patency may be primary, assisted primary (most applicable to vein grafts), or secondary. A graft with *primary patency* has been continuously patent without any actions being performed to maintain graft patency, except for treatment of more proximal or distal disease not involving the graft or its anastomoses. Dilations or minor revisions performed for stenoses or other structural defects before occlusion occurs do not constitute exceptions because they are intended to prevent eventual graft failure.[5-7,196] A graft with *assisted primary patency* required an intervention (either percutaneous or open surgical) to maintain patency but never occluded. A graft with *secondary patency* thrombosed but was successfully thrombectomized. Primary patency thus reflects the durability of the initial reconstruction, assisted primary patency reflects the impact of graft surveillance and timely reintervention, and secondary patency reflects the persistence of the surgeon in restoring graft patency after failure. The most meaningful endpoints are thus primary and assisted primary patency.

Comparison of Graft Types

Randomized prospective trials demonstrate equivalence between in situ and reversed vein conduits (Table 109.2).[218-225] The use of these techniques is thus dictated by operative considerations and surgeon preference and experience. Vein is superior to all prostheses, even in the above-knee popliteal position. Expected patency data, based on a review by Dalman[226] and several meta-analyses,[143,206,227-232] are summarized in Tables 109.3 to 109.6 and Figs. 109.15 and 109.16.

Subjective Endpoints

Durability

Choice of initial revascularization approach (endovascular vs. open) and conduit selection (autogenous vs. prosthetic) are likely to affect outcomes, especially in patients in whom durability of the intervention is an important consideration. Recently published data suggest that the durability of the intervention may be important for subsets of patients. In particular, the Bypass versus Angioplasty in Severe Ischaemia of the Leg (BASIL) trial concluded that for patients who lived more than 2 years after randomization, a bypass-first revascularization strategy was associated with a significant increase in subsequent overall survival as well as a trend toward improved amputation-free survival. Recent studies of endovascular and open approaches to patients with CLTI suggest that for WIfI Clinical Stage 4 patients, endovascular therapy has a very high reintervention rate and high wound non-healing rate[233] and at least one publication suggests that the limb salvage rate is higher in these patients with bypass.[234] These data suggest that with proper stratification based on the underlying burden of disease, extent of ischemia,

and depth of the wound as well as with an improved comorbidity index, one could select patients who would benefit more from bypass than from endovascular therapy as the initial revascularization approach.

The BASIL trial clearly demonstrated that patients who received prosthetic grafts for severe limb ischemia (constituting 25% of the surgical group) experienced reduced amputation-free survival compared with those who received vein grafts ($P = .003$).[235] In addition, the BASIL authors observed that patients who underwent bypass surgery after an initial failed angioplasty experienced significantly worse amputation-free survival than did those who underwent bypass first as the initial therapy ($P = .006$), suggesting that there is a real potential adverse impact of the endovascular-first approach for all patients with severe limb ischemia. Others, including the Vascular Surgical Group of New England, have made similar observations. Nolan et al.[236] reviewed 1153 patients who underwent lower extremity bypass from 2003 to 2008. Patients who had undergone a prior ipsilateral-failed percutaneous intervention had significantly higher rates of graft occlusion and major limb amputation at 1 year by multivariate analysis. A detailed investigation of therapy for lower extremity occlusive disease in South Carolina documented a marked increase in the number of procedures required

to obtain similar limb salvage rates coincident with the increase in endovascular therapy during a defined period.[237] Taken together, such data strongly suggest that patients with severe limb ischemia and long-segment atherosclerotic disease who have useable vein, lack severe comorbidities, and have a life expectancy of at least 2 years are likely to be best served with an open surgical approach first with autologous vein.

Functional Outcomes

Whereas graft patency and limb salvage are objective and important endpoints, numerous investigators have recognized that functional outcomes are equally important. Nicoloff et al.[238] emphasized that an ideal outcome—defined by the expectations of a patent graft, healed wound, no need for reoperation, independent living status, and continued ambulation—was extremely difficult to achieve in patients with CLI. Only a small fraction of patients in their report (14.3%) met these basic criteria for success. Golledge et al.[239] from South Australia, using similar criteria, showed that only 22% of patients had an ideal outcome. Abou-Zamzam et al.[240] identified preoperative independence and ambulation as the best predictors of postoperative independence and continued ambulation. These data emphasize the severity of underlying comorbidities in CLI patients and the difficulties encountered in obtaining functional limb salvage.

Goshima et al.[241] from the University of Arizona analyzed a consecutive series of 318 patients undergoing infrainguinal bypass, 72% for CLI. Three nontraditional outcome measures were used to explore outcomes and to define the clinical realities of treating patients with CLI: index limb reoperation rate within 3 months of bypass, hospital readmission rate within 6 months, and wound healing time. Perioperative mortality was less than 1%, mean length of initial hospital stay was 9 days, 30-day graft patency was 97%, and 3-month limb salvage was 97%. Five-year limb salvage in a similar group of patients from the same center was 91%, and the costs of bypass combined with

The *vertical line* indicates when above-knee saphenous vein grafts surpassed PTFE grafts.[141] *AK,* Above knee; *BK,* below knee.

graft surveillance and revision for 5 years were equal to or less than those for patients undergoing major limb amputation.[242] However, 49% of patients required at least one reoperation within 3 months, and 50% required readmission to the hospital within 6 months. The cumulative length of stay for all readmissions was 11 days. More than half of CLI patients required more than 3 months of postoperative care to achieve wound healing. The presence of preoperative tissue loss increased the odds of reoperation by 3.1-fold (95% confidence interval, 1.9 to 6.8), whereas ischemic tissue loss, renal failure, and diabetes were independently associated by multivariate analysis with the need for readmission. Diabetes mellitus was the sole independent risk factor for prolonged wound healing (odds ratio, 3.4; 95% confidence interval, 2.3 to 6.2).

Outcome measurements have undergone a re-examination led by the initial effort of Conte et al.[243] to develop objective performance goals. The Society for Vascular Surgery's objective performance goal criteria were externally validated in 1039 lower extremity bypass operations for CLI in patients who were not on dialysis and in whom autologous vein grafts were placed.[244] The objective performance goal criteria included patients at clinical high risk (>80 years of age and tissue loss) and anatomic high risk (infrapopliteal target and lack of single-segment saphenous vein) and showed that major adverse limb events and major adverse cardiovascular events were more common in the high-risk groups.

In sum, these data suggest that to better select patients for open bypass or endovascular therapy, reconsideration of the input (i.e., burden of disease or baseline of disease classification and a risk comorbidity index) as well as the output (i.e., objective performance goals and functional outcomes) will be necessary. Further studies using such functional or patient-related outcomes are needed to place the role of infrainguinal bypass in perspective,[232,245-252] particularly to allow comparisons with less invasive techniques such as subintimal angioplasty or even primary amputation in selected high-risk patients with CLTI. Although it is generally agreed that nearly all patients with CLTI are best treated with revascularization, it is clear that both economic and functional outcome issues mandate the consideration of alternative therapies, at least for certain subsets of patients with CLTI, such as individuals confined to chronic care facilities, those who are minimally ambulatory, and patients with extensive tissue loss and infection who are receiving chronic renal replacement therapy.[206,240,249,252-255] This issue is addressed in depth in Chapter 105.

Cost-Effectiveness and Risk Stratification

With respect to cost-effectiveness, the initial cost savings of endovascular therapy compared with open bypass for patients with severe or critical limb ischemia is lost after 1 year.[256-258] Several authors have developed predictive indices to help select patients who have better (or worse) outcomes after open bypass surgery. These include studies performed by the group in Greenville, South Carolina (LEGS score), the Prevention of Infrainguinal Vein Graft Failure (PREVENT) III trial, the Finland National Vascular (FINNVASC) registry, and metrics developed from data derived from the BASIL trial.[259-262] The Greenville group, in a series of 677 patients fairly evenly split between endovascular and open surgery, showed that impaired ambulatory status at the time of presentation, diabetes, end-stage renal disease, gangrene, and prior vascular intervention all increased the risk of failure. The presence of multiple comorbidities increased the risk of failure dramatically.

It is worth reviewing the FINNVASC, PREVENT III, and BASIL outcome prediction models. The FINNVASC score assigns one point each for diabetes mellitus, foot gangrene, CAD, and urgent operation, and the predictive model stratifies risk on a scale of 1 to 4 based on the sum of the points. The FINNVASC score has been externally validated. The PREVENT III prediction model assigns end-stage renal failure on dialysis 4 points, tissue loss 3 points, age older than 75 years 2 points, and CAD 1 point and stratifies risk into low (≤3 points), medium (4-7 points), and high (≥8 points). This prediction model has also been validated. The stratification system derived from BASIL used tissue loss, body mass index, serum creatinine concentration, Bollinger score, age, smoking, coronary disease, and ankle pressure and produced a complex model of mortality calculation that is likely too complex for standard clinical use and may not apply to all patients with CLTI because the study inclusion criteria differed from CLI as previously defined. Nonetheless, it seems that multiple comorbidities, especially those that are

common to the major reports, need to be considered in offering a patient a bypass and trying to gauge the outcomes (Table 109.7).

Quality of Life

A substantial amount of new data, derived primarily from two large prospective trials (PREVENT III and BASIL),[a] is beginning to put the role of successful bypass in the proper perspective. It also lends support to long-standing impressions about the effectiveness of leg bypass in relieving ischemic symptoms and improving quality of life in properly selected patients.[236-238,269-274] Patients with CLTI have a markedly reduced quality of life compared with a normal control population,[238,260] and their quality of life is markedly improved by successful bypass.[260,263,264] It is also becoming evident, especially in CLTI patients with severe ischemia and higher grade wounds, that ongoing graft patency, at least for the first 1 to 2 years, is critical to the maintenance of this quality of life improvement.[268,269,275,276] Tissue loss at presentation and graft-related events or failure of percutaneous transluminal angioplasty (PTA) during the first 1 to 2 years after the index revascularization are associated with reduced quality of life and increased resource utilization. Thus, although the early BASIL results showed no difference in outcomes between bypass and PTA for CLI,[275] the published intermediate follow-up analysis suggests that bypass is more effective than PTA in all but the most unfit patients. The bypass-first group had a better amputation-free survival (relative risk, 0.85) and a lower all-cause mortality than the angioplasty-first group (relative risk, 0.65; $P < .009$), probably because of the high failure rate of PTA and the more frequent need for reintervention to maintain patency.[257,258] For patients with severe ischemia, particularly diabetics and those with tissue loss, ongoing vascular patency is important for maintaining quality of life and preventing amputation.[241,268] These important findings may eventually lead to a gentle swing of the therapeutic pendulum away from endovascular therapy and back toward open bypass, at least for relatively fit CLI patients with TASC type C or D disease, available vein conduit, and estimated life expectancy of more than 2 years.[276,277]

POSTOPERATIVE MANAGEMENT

After bypass, patients should generally be maintained on their preoperative medical regimens for the control of angina, arrhythmia, congestive heart failure, and hypertension. Patients with a recent history of congestive heart failure are at high risk for prolonged hospital stay and readmission.[214,239,241] Care should be taken to avoid volume overloading in these patients, and

they may require supplemental diuresis. Perioperative beta blockade should be continued in the absence of contraindications; in moderate- and high-risk patients undergoing vascular surgery, beta blockade with targeted heart rate control reduces cardiac complications and improves mortality.[18-20]

Antiplatelet Therapy

Most patients with PAD are already receiving antiplatelet therapy, usually aspirin (81 or 325 mg daily). Aspirin has well-recognized cardiac and cerebral protective effects and may also improve early graft patency.[278-288] Clopidogrel may also be used,[289] but it is more expensive and may have an increased risk of complications compared with aspirin alone. Most vascular surgeons consider antiplatelet therapy essential for patients undergoing infrainguinal bypass.

Anticoagulation

There are insufficient data on which to base a recommendation concerning anticoagulation after lower extremity bypass. A single long-term, randomized, prospective trial of 130 patients by Kretschmer et al.[290] from Vienna demonstrated improved vein graft patency and limb salvage rates and improved patient survival in those randomized to receive phenprocoumon. An important clinical report, the Dutch Bypass Oral Anticoagulants or Aspirin (BOA) trial, summarized a study of 2690 lower extremity bypass patients randomized to anticoagulation versus antiplatelet therapy (aspirin).[291-293] Although overall differences were not significant, subgroup analysis suggested that oral anticoagulation improved vein graft patency compared with aspirin, whereas aspirin improved prosthetic graft patency compared with anticoagulation. If these data can be confirmed, it is likely to alter the typical practice in North America, where surgeons tend to treat vein graft patients with aspirin and to anticoagulate those with prosthetic grafts. The BOA trial, however, noted that anticoagulated patients had nearly double the major bleeding risk of patients receiving antiplatelet therapy, suggesting that anticoagulation should be used selectively in subgroups at greatest risk. A recent structured review suggests that anticoagulation may be beneficial in high-risk grafts, such as redo procedures or in the presence of poor arterial outflow.[294]

Such a selective approach has been recommended by the University of Florida group on the basis of a small randomized study of patients with high-risk vein grafts.[295] High-risk grafts were defined on the basis of poor arterial runoff, suboptimal vein conduit, and reoperative cases. Patency (74%) and limb salvage (81%) rates at 3 years in the high-risk group randomized to warfarin and aspirin were significantly higher than in the aspirin-only group (51% and 31%, respectively), although again, bleeding was much more common in the group receiving warfarin.

Although this seems to be a logical approach, a Veterans Affairs cooperative trial reached a different conclusion based on 665 patients with infrainguinal bypasses who were randomized to aspirin and warfarin versus aspirin alone.[296] Vein graft patency was not increased by the addition of warfarin to aspirin; in contrast, prosthetic graft patency was significantly improved by anticoagulation, but at the expense of double the risk of hemorrhagic events. These data all suggest a potential role for postoperative anticoagulation that requires larger trials with higher statistical power to permit an evidence-based recommendation. Until then, most surgeons will continue to routinely employ antiplatelet therapy (aspirin 81 to 325 mg daily) and add anticoagulation in selected groups at highest risk (e.g., prosthetic infrageniculate grafts, poor outflow, reoperative cases, poor or alternative vein conduit).

Wound Care

All patients with CLTI are at risk for pressure ulcers not only in the affected limb but also in the contralateral limb and the

sacrum. Unremitting nursing care is essential to prevent these complications. Considerable wound care is also required to achieve healing of ischemic foot lesions and forefoot amputations. FI should have been controlled before revascularization. Basic science wound studies suggest that débridement and formal toe and forefoot amputations for areas of tissue ulceration or gangrene should be delayed 4 to 10 days after bypass to maximize tissue reperfusion and to allow the clear demarcation of marginal areas (see Chapters 115 and 116).

COMPLICATIONS

The major early postoperative complications of infrainguinal bypass are wound problems, bleeding, graft occlusion, graft infection, and death (see Table 109.2). The results of the PREVENT III trial from 83 enrolling centers probably reflect realistic complication rates in clinical practice.[265] The authors of this study reported the following early complication rates in a prospective trial of more than 1400 infrainguinal vein grafts in patients with CLI: death (2.7%), myocardial infarction (4.7%), major amputation (1.8%), graft occlusion (5.2%), major wound complications (4.8%), and graft hemorrhage (0.4%). Late complications include persistent lymphedema, graft infection, graft aneurysm, and graft stenosis.

Early Graft Occlusion

With experienced judgment and intraoperative attention to detail, early graft occlusion should be uncommon. Should a graft fail in the early postoperative period, the most important principle is to identify and to correct the underlying cause.[297] If no cause can be identified, the prognosis for long-term patency is poor. The outcome is much more favorable if the cause can be ascertained and addressed. The most common correctable culprits are anastomotic, local endarterectomy, or clamp defects; valve defects; poor conduit quality; and inadequate outflow.

When the patient is returned to the operating room, one can usually begin by exploring the distal anastomosis first. If the graft hood is pulsatile, an arteriogram is obtained. If not, the hood is opened and gentle distal thrombectomy and graft thrombectomy are performed with balloon catheters of appropriate caliber. If the graft is a reversed vein, both proximal and distal anastomoses usually require exploration. An uninflated balloon catheter is passed from proximal to distal; a second catheter can be tied to the first one and drawn uninflated proximally. The tie is cut, the second catheter is inflated, and the graft is then thrombectomized from proximal to distal. Once the thrombus has been evacuated, heparinized saline is forcibly irrigated through the graft to flush any residual thrombotic debris out the distal graftotomy. Both anastomoses can then be carefully inspected; if a distal anastomotic defect is identified, the graftotomy can be extended down the outflow artery and closed with a patch. If no defects are identified, the graft incisions are closed, and thorough arteriography of the entire graft and the outflow is performed. Significant conduit or anastomotic lesions should be corrected. If unsuspected or previously unappreciated outflow disease is identified, the graft should be extended beyond the lesion or to an alternative outflow artery if one is available. If a marginal vein conduit was used at the initial procedure and no focal defect is identified at re-exploration, one should consider replacing the conduit; this decision is difficult and may require the harvesting of additional vein or, if none is available, converting to a prosthetic conduit if outflow is sufficient.

Late Graft Occlusion

Late graft occlusion should be treated only if the patient's symptoms are severe enough to warrant intervention. When vein conduit is limited, I attempt thrombolysis, mechanical thrombectomy, or both and treat the underlying lesion responsible for graft failure. The results of this approach are generally poor, however. My preference for late graft occlusions is to perform a new bypass with autogenous vein, which provides superior results and durability.[151] If vein is unavailable and thrombolysis is contraindicated or fails, a repeated bypass with PTFE and a vein patch or cuff is the best option. The optimal therapy for graft occlusion is to prevent its occurrence by identifying graft-threatening stenosis before the onset of graft occlusion through routine postoperative duplex graft surveillance.

GRAFT SURVEILLANCE

Vein graft surveillance is critical to the long-term success of infrainguinal bypass. It has been well documented for more than 3 decades that nearly one third of autogenous vein grafts develop lesions that threaten graft patency.[298] Most such lesions, especially in the first 1 to 2 years after graft implantation, are intrinsic to the graft itself and result from intimal hyperplasia.[299-301] Later, inflow and outflow lesions may develop and reduce graft flow, thus threatening ongoing graft patency. All these lesions can be readily identified, graded for severity, and monitored for progression by means of a program of ankle-brachial index determination and duplex graft surveillance.[112,222,242,302-313] I obtain the first study within 4 weeks of surgery, either before hospital discharge or at the first postoperative visit.[303] Serial studies are performed every 3 months for 1 year, every 6 months for 2 additional years, and annually thereafter. Grafts with focal lesions associated with a peak systolic velocity greater than 300 cm/s or a velocity ratio greater than 3.5 to 4.0 undergo prophylactic repair to prevent graft stenosis.[311,312] Grafts that develop low-flow velocities over time (peak systolic velocity <45 cm/s throughout the graft) or a drop in ankle-brachial index exceeding 0.15 in the absence of detectable graft lesions undergo arteriography to search for inflow, outflow, or missed graft lesions.

Abundant clinical data from multiple investigators and a single prospective randomized trial by Lundell et al.[314] suggest that vein graft surveillance improves long-term vein graft patency by approximately 15%. Although one trial questioned the benefit of vein graft surveillance,[267] that surveillance protocol was flawed, the endpoints were inappropriate, and the follow-up was too short to detect a difference.[308] Cost-benefit analyses both in Europe[313] and in the United States[242] confirm that vein

graft surveillance is cost-effective. Graft occlusion is a morbid and costly event,[242,268] and its prevention is worthwhile. Graft surveillance of prosthetic grafts has not been shown to be beneficial.[315,316]

TREATMENT OF GRAFT AND ANASTOMOTIC STENOSES

Vein graft stenoses are solitary and focal in approximately 80% of cases. Multiple focal synchronous or metachronous lesions are identified in 15% to 20% of grafts; diffuse long-segment graft narrowing, presumably due to myointimal hyperplasia, is uncommon (3% to 5% of cases).[300] If recurrent limb ischemia requires treatment in the latter circumstance, graft replacement is the treatment of choice.

There are multiple options for the treatment of focal graft lesions; selection of the optimal therapy depends primarily on the length of the lesion, the timing of its occurrence (early [<3 to 6 months] vs. late [>3 to 6 months]), and the patient's comorbidities. Focal lesions that develop after the sixth postoperative month respond fairly well to PTA,[317,318] and data suggest that use of a cutting or scoring balloon is superior to standard balloon angioplasty.[319,320] If a graft stenosis is treated by PTA, it should be closely observed by duplex ultrasound because the recurrence rate is generally higher than after open repair. Stent placement in infrainguinal vein grafts should be avoided.

If open repair is chosen, there are several options, depending primarily on the characteristics and location of the lesion. Circumferentially fibrotic midgraft lesions are best treated with excision and segmental interposition vein grafts. Less extensive lesions are amenable to vein patch angioplasty. There are no data demonstrating the superiority of patch versus interposition grafting,[307] but circumferentially fibrotic, napkin ring–like lesions are better treated with replacement. Focal, less fibrotic lesions, particularly related to valves, can be treated with valve excision and vein patch through a longitudinal graftotomy that extends proximal and distal to the site of the lesion. Intraoperative completion angiography or duplex scan should be performed to document resolution of the lesion.

Focal juxta-anastomotic lesions often develop in the vein graft itself, immediately adjacent to the arterial anastomosis.[300] These lesions can be treated by either patch angioplasty or short interposition grafts (Fig. 109.17). Another option that eliminates the need to harvest additional vein conduit is proximal anastomotic translocation.[321] This procedure involves resecting the lesion and oversewing the graft stump near its origin. If the vein graft below the stenosis is of good caliber, the graft can be transposed to an alternative inflow artery. For example, if the original anastomosis was to the CFA, and if the PFA is large and its origin is free of disease, the PFA can be exposed, and the graft can be mobilized below the proximal stenosis and swung over or transposed to reoriginate from the PFA. Distal juxta-anastomotic stenoses can usually be vein patched, but if the outflow artery has also developed progressive occlusive disease, a better option is a jump graft to a more distal target artery if one is available. These procedures have been described in detail elsewhere.[321]

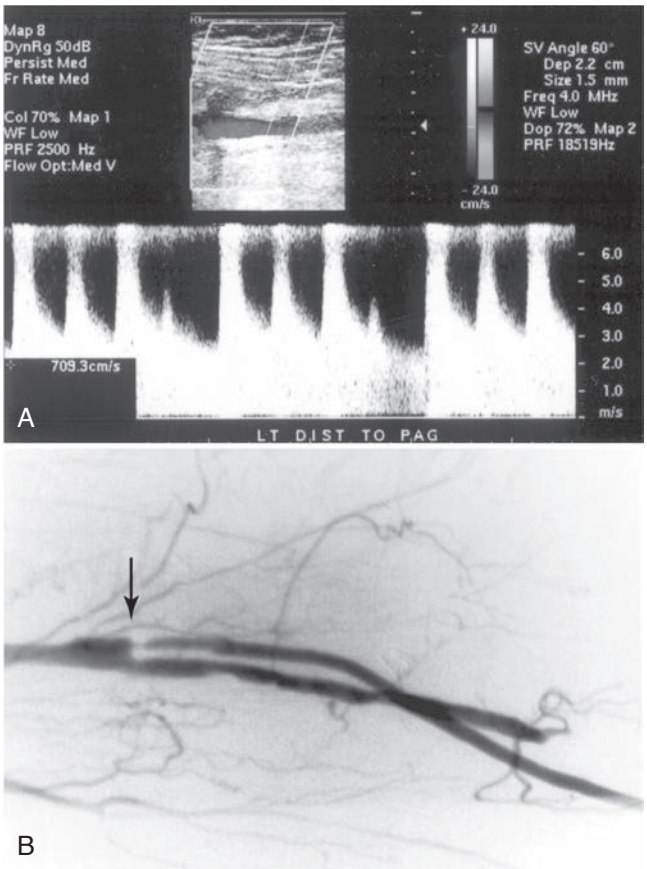

Figure 109.17 Duplex surveillance identified a critical vein graft stenosis in the proximal aspect of a femoropopliteal vein graft. (A) Marked spectral broadening and pronounced elevation of both the peak systolic and end-diastolic velocities are diagnostic of a high-grade vein graft stenosis. (B) A focal, severe proximal graft stenosis *(arrow)* was confirmed by arteriography and treated with a short interposition vein graft harvested from the upper extremity.

Although imperfect, the BASIL trial is the only published, prospective randomized trial of open bypass versus endovascular therapy for severe limb ischemia. Key points include significantly poorer outcomes for prosthetic compared with autogenous bypass conduits and trends toward improved overall survival and improved amputation-free survival in patients treated with bypass first who lived more than 2 years.

Conte MS, Bandyk DF, Clowes AW, et al. PREVENT III Investigators. Results of PREVENT III: a multicenter, randomized trial of

edifoligide for the prevention of vein graft failure in lower extremity bypass surgery. *J Vasc Surg*. 2006;43:742–751.

Landmark study of a novel molecular therapy for the prevention of vein graft failure in patients undergoing infrainguinal revascularization for critical limb ischemia. Despite a well-conceived trial design, an impeccably executed study, and high-quality surgical results at multiple centers, the proposed molecular therapy was found to result in no significant improvement in any of the primary endpoints.

Conte MS, Geraghty PJ, Bradbury AW, et al. Suggested objective performance goals and clinical trial design for evaluating catheter-based treatment of critical limb ischemia. *J Vasc Surg*. 2009;50:1462–1473.

Important paper defining objective performance goals to evaluate safety of lower extremity arterial disease treatment modalities. Major endpoints include major adverse limb events and major adverse cardiovascular events.

Faries PL, Arora S, Pomposelli FB Jr, et al. The use of arm vein in lower-extremity revascularizations: results of 520 procedures performed in eight years. *J Vasc Surg*. 2000;31:50–59.

This Boston group has long championed an all-autogenous approach. Their study shows that autogenous arm vein can be used successfully in a wide variety of lower extremity revascularization procedures and achieves excellent patency and limb salvage rates, generally much higher than those reported for prosthetic or cryopreserved grafts.

Mills JL, Fujitani RM, Taylor SM. The characteristics and anatomic distribution of lesions that cause reversed vein graft failure: a five-year prospective study. *J Vasc Surg*. 1993;17:195–206.

Postoperative duplex surveillance was prospectively performed during a 66-month period in 227 patients after infrainguinal vein graft placement to determine the causes of graft failure. The authors found that a significant portion of these failures occurred during the intermediate postoperative period (3 to 18 months), usually as a result of focal intrinsic vein graft lesions that are readily detectable by duplex surveillance. They concluded that duplex vein graft surveillance is warranted by the 21% incidence of potentially remediable graft failure.

Mills JL, Conte MS, Armstrong DG, et al; on behalf of the Society for Vascular Surgery Lower Extremity Guidelines Committee. The Society for Vascular Surgery Lower Extremity Threatened Limb Classification System: Risk Stratification based on Wound, Ischemia, and Foot Infection. *J Vasc Surg*. 2014;59:220–234.

Mills JL. The application of the Society for Vascular Surgery Wound, Ischemia, and foot Infection (WIfI) classification to stratify amputation risk. *J Vasc Surg*. 2017;65(3):591–593.

The SVS WIfI Classification defines baseline limb risk based on grades of Wound, Ischemia and foot Infection to create Clinical Stages of amputation risk (from 1-4). Even with revascularization, limb status based on WIfI Clinical Stage stratifies amputation risk. Future application and evolution of this rubric may be helpful in selecting the best revascularization approach in a given clinical scenario.

Stonebridge PA, Prescott RJ, Ruckley CV. Randomized trial comparing infrainguinal polytetrafluoroethylene bypass grafting with and without vein interposition cuff at the distal anastomosis. The Joint Vascular Research Group. *J Vasc Surg*. 1997;26:543–550.

This study was undertaken to determine whether an interposition vein cuff improved the short- and medium-term patency and limb salvage rates of femoral above-knee and below-knee popliteal artery polytetrafluoroethylene (PTFE) bypass procedures. The authors found that there was no improvement in patency rate with the use of a distal anastomosis interposition vein cuff in above-knee PTFE grafts, but there was a statistically significant advantage when PTFE grafts were anastomosed to the popliteal artery below the knee. Vein cuffs or patches seem to be beneficial in those relatively uncommon patients requiring infrageniculate bypass in whom autogenous vein is not available.

Szilagyi DE, Elliot J, Hageman JH, Smith RF, Dall'olmo CA. Biologic fate of autogenous vein implants as arterial substitutes: clinical, angiographic, and histopathologic observations in femoro-popliteal operations for atherosclerosis. *Ann Surg*. 1973;178:232–246.

Infrainguinal vein grafts implanted in 377 patients during a 10-year period were studied by serial arteriography to determine their natural history. This study set an early standard for long-term follow-up and demonstrated its importance in patients undergoing such procedures.

Watelet J, Soury P, Menard JF, et al. Femoropopliteal bypass: in situ or reversed vein grafts? Ten-year results of a randomized prospective study. *Ann Vasc Surg*. 1997;11:510–519.

Long-term studies with good follow-up provide the best information about treating patients with chronic diseases. For example, this study reported the results of 100 femoropopliteal bypass procedures performed in 91 patients during 5 years who were randomly divided into two statistically comparable groups: 50 in situ vein grafts and 50 reversed vein grafts. One conclusion: small veins do not work as well, even when they are used in situ.

INTRODUCTION

Despite a lack of "level 1" evidence to date indicating durable clinical superiority over alternative treatment options, endovascular treatment (ET) is increasingly used to treat infra-inguinal peripheral arterial disease (PAD) in patients presenting with both intermittent claudication (IC) and chronic limb threatening ischemia (CLTI).[1-7] The reasons for this probably include the attractiveness to patients of reduced periprocedural morbidity and mortality; the fact that, in many countries, PAD is increasingly treated by physicians who cannot offer surgical intervention; and the marketing of endovascular devices by industry. Although practice varies considerably, in the United Kingdom (UK) and many other countries, transluminal or subintimal plain balloon angioplasty (PBA), with the use of "bail out" bare metal stents (BMS) where post-PBA angiographic appearances and/or flow are considered to be unacceptable, is still widely considered to be the current endovascular "standard of care" for the management of infra-inguinal PAD.[8] This is because newer endovascular technologies, in particular drug coated balloons (DCB) and drug eluting stents (DES), have not as yet been shown to produce superior clinical outcomes and are associated with significantly increased procedural costs. Indeed, in the UK, the National Institute for Health and Care Excellence (NICE) has currently recommended against the use of DCB and DES within the National Health Service (NHS) until such time as randomized controlled trials (RCTs) provide evidence of clinical and cost-effectiveness within the currently accepted UK "willingness to pay" (WTP) thresholds.[9,10] At the time of writing this is £20,000 per quality adjusted life year (QALY) (https://www.nice.org.uk/guidance/cg147). Although, due to their rigorous scientific methodology and unbiased provenance, UK NICE guidelines are used to inform clinical practice and healthcare spending in many other countries, even within

Abstract

Endovascular treatment of infra-inguinal disease in patients presenting with intermittent claudication and chronic limb threatening ischaemia (CLTI) still lacks a sound 'level 1' evidence base. While new endovascular technologies and techniques such as drug coated balloons, drug eluting stents, re-entry devices, debulking devices, low profile systems, and the use of novel access points may have improved anatomical outcomes, to date, there is limited evidence that this has translated into improved clinical outcomes when compared to plain balloons and stents or, indeed, lower extremely bypass. There also remains doubt as to whether such complex interventions can be cost-effective at commonly accepted willingness to pay thresholds. At the same time, the evidence base underpinning the clinical and cost-effectiveness of physical (exercise) and medical therapies for the treatment of peripheral arterial disease grows ever stronger. There is, therefore, an urgent need for a more thoughtful and evidence-based approach to endovascular therapy for infra-inguinal disease. To that end, the inter-societal (SVS, ESVS, WFVS) Global Vascular Guidelines on CLTI aim to improve outcomes and the quality of reporting; and advocate a more holistic, multi-disciplinary and evidence-based approach to the management of these challenging patients. At the same time, publicly-funded randomised controlled trials on-going in the US (BEST-CLI) and UK (BASIL-2 and BASIL-3) will help better define the role of infra-inguinal endovascular therapy in patients with CLTI characterised by different severities of clinical presentation (WIfI) and anatomic burden of disease (GLASS).

the UK, not everyone agrees with NICE's position on these matters.

Looking to the future, new ET technologies such as bioresorbable stents[11-14] and scaffolds,[15] bifurcated stents,[16] "tacking,"[17] robotic ET,[18] paclitaxel infusion,[19] angioscopic assisted ET,[20] and endovascular venous "arterialization"[21] may offer some promise but, at the present time, remain unproven and should be considered highly experimental.

The decision to proceed with infra-inguinal revascularization, and to offer ET rather than an alternative therapy, is based upon clinical presentation, physical examination, pattern of disease, co-morbidity, previous interventions, availability of autologous conduit, and the outcome of shared decision making with the patient and, where appropriate, the family.

Various recommendations regarding the indications for ET have been published over the years. Hitherto, probably the most widely referenced have been Trans-Atlantic Inter-Society Consensus (TASC) guidelines, which contain recommendations regarding the appropriateness of ET based largely upon lesion severity in the aorto-iliac (AI), femoropopliteal (FP), and most recently, infrapopliteal (IP) segments.[22] While possibly helpful in patients presenting with IC, who usually have relatively simple and discrete single level disease, treatment recommendations based upon individual lesion severity are likely to be much less useful in CLTI patients who almost always present with complex, extensive, multilevel, and increasingly, IP disease. In such patients, a more "holistic" approach to the assessment of overall burden of disease is required.[23] This is the approach taken in Global Vascular Guidelines (GVG) on CLTI, a collaborative effort between the US Society for Vascular Surgery (SVS), European Society of Vascular Surgery (ESVS), and the World Federation of Vascular Societies (WFVS), which will be discussed further below (https://vascular.org/research-quality/clinical-practice-documents/global-vascular-guidelines).

At the present time, the role of infra-inguinal ET, and which type of ET is most appropriate, in the management of IC and CLTI remains uncertain and controversial, with a very wide range of views being expressed at scientific meetings and in the literature. This controversy and lack of consensus stem primarily from the fact that the currently published literature and datasets are seriously lacking in both quantity and quality. Numerous analyses of this datasets are already readily available, as are numerous descriptions of innovative but largely unproven endovascular techniques, and the aim of this chapter is not to provide more of the same. Rather, the authors seek to respectfully challenge some of the current thinking regarding infra-inguinal ET and offer an alternative vision for the future based upon high quality, unbiased, preferably randomized, pragmatic trials that will define the clinical and cost-effectiveness of different endovascular technologies and techniques in appropriate subsets of patients presenting with IC and CLTI due to infra-inguinal atherosclerotic disease as part of overall multimodality care.

INTERMITTENT CLAUDICATION

Based upon a thorough analysis of the available published evidence, the quality of which was rigorously assessed using GRADE (http://www.gradeworkinggroup.org/), in 2012, NICE made a number of recommendations regarding the management of people with IC (Table 110.1). Although these recommendations have no direct legal force in the UK, clinicians and payers (public and private) are expected to follow them and to have good reason for not doing so. As a result of its robust and transparent processes, and strict conflict of interest policies, NICE recommendations have very considerable international reach and affect clinical practice and public and private payer

TABLE 110.1 UK National Institute for Health and Care Excellence Recommendations Regarding the Management of People With Intermittent Claudication

Supervised Exercise Program

- Offer a supervised exercise program to all people with intermittent claudication.
- Consider providing a supervised exercise program for people with intermittent claudication which involves:
  - 2 hours of supervised exercise a week for a 3-month period
  - encouraging people to exercise to the point of maximal pain

Angioplasty and Stenting

- Offer angioplasty for treating people with intermittent claudication only when:
  - advice on the benefits of modifying risk factors has been reinforced **and**
  - a supervised exercise program has not led to a satisfactory improvement in symptoms **and**
  - imaging has confirmed that angioplasty is suitable for the person.
- Do not offer primary stent placement for treating people with intermittent claudication caused by aorto-iliac disease (except complete occlusion) or femoropopliteal disease.
- Consider primary stent placement for treating people with intermittent claudication caused by complete aorto-iliac occlusion (rather than stenosis)
- Use bare metal stents when stenting is used for treating people with intermittent claudication.

Bypass Surgery and Graft Types

- Offer bypass surgery for treating people with severe lifestyle-limiting intermittent claudication only when:
  - angioplasty has been unsuccessful or is unsuitable **and**
  - imaging has confirmed that bypass surgery is appropriate for the person.
- Use an autologous vein whenever possible for people with intermittent claudication having infra-inguinal bypass surgery.

Naftidrofuryl Oxalate

- Consider naftidrofuryl oxalate for treating people with intermittent claudication, starting with the least costly preparation, only when:
  - supervised exercise has not led to satisfactory improvement **and**
  - the person prefers not to be referred for consideration of angioplasty or bypass surgery.
- Review progress after 3-6 months and discontinue naftidrofuryl oxalate if there has been no symptomatic benefit.

reimbursement in many countries. Within the UK, from a medicolegal viewpoint, a decision not to follow NICE guidance without explaining to the patient why an alternative course of action is being recommended, and without documenting that in the case records, leaves the physician vulnerable to criticism. Despite this, it is still probably the case that many patients in the UK are being offered ET, and even bypass surgery, for IC without having been offered a (supervised) exercise program, without having been given appropriate support to stop smoking, and without having been medically optimized. The reasons for this are complex but unfortunately probably reflect practice in many other countries.[24] The important question at time of writing is whether there has been any change in the evidence base since 2012 that would lead NICE, or indeed any other independent guideline body elsewhere in the world,[25] to now make materially different recommendations regarding infrainguinal ET for IC.[26]

While imperfect, the evidence that, preferably supervised, exercise therapy continues to be the most clinically and cost-effective first-line treatment for most patients with IC remains extremely convincing. A recent meta-analysis of seven RCTs concluded that an ET-only strategy for IC was not associated with any improvement in functional capacity or clinical outcomes, whereas exercise and exercise combined with ET was associated with a significant increase in total walking distance, ankle brachial index (ABI), and a reduced risk of future revascularization or amputation.[27]

Furthermore, the evidence that lifestyle modification and so-called "best medical therapy" (BMT) aimed at reducing overall cardiovascular risk significantly improves outcomes in patients with PAD, whether they undergo ET or not, grows ever stronger.[28] By contrast, unfortunately, hard evidence that advanced endovascular technologies and techniques, such as DCB and DES, durably improve important clinical outcomes in patients with IC remains lacking.[29] As discussed later in further detail, most of the literature on ET for infra-inguinal PAD comprises industry-funded trials aimed primarily at obtaining marketing approvals from various regulatory authorities. While one understands why such studies are done, one cannot help reflecting that they often represent a significant "missed opportunity" to gather clinically important data that would help physicians and their patients make truly informed, evidence-based decisions regarding ET. Arguably, the largest industry-sponsored trial with the longest follow-up is that evaluating the Zilver PTX DES.[30] Although 5-year anatomic outcomes were favorable, due to the limited and unusual method of reporting the clinical outcomes, the trial design, and the large numbers of patients in whom complete follow-up data were unavailable, it is difficult to draw any firm conclusions regarding the clinical and cost-effectiveness of this device and thus its role in current practice.[31,32] One respectfully wonders why sponsors would embark upon large and expensive RCTs of ET for (predominantly) IC without reporting treadmill walking distances (or another validated objective quantifiable measure of individual patient improvement), which, while imperfect, has been for many years and still remains the most widely accepted primary outcome in IC trials. Such reporting of symptomatic improvement would probably be mandatory in a phase III trial of a new medical or physical therapy for IC. It is also worth noting that although more than 90% of the patients in the Zilver PTX trial had IC, they also enrolled CLTI patients, and these two very different conditions and patient groups were largely conflated in the analysis. Methodologically, this is very difficult, many would argue impossible, to justify; and yet such conflation occurs repeatedly in the literature. So the thorny question is why should patients and payers be expected to accept a far inferior level of reporting in trials of ET (and open surgery for that matter) for PAD compared to that which would be expected of new medical and physical therapies? Although there have been setbacks, such as the negative results from EUCLID,[33,34] overall, the gap in terms of both quantity and quality between the evidence base for medical and interventional (ET and surgical) treatment of PAD appears to be widening in favor of the former.[35]

While the precise role, if any, of dual antiplatelet therapy for PAD patients undergoing ET remains to be defined,[34,36] data from the SVS Vascular Quality Initiative (VQI) obtained in more than 40,000 patients show that DAPT does appear to improve survival after lower extremity revascularization, especially in the higher risk patients.[37] As such, further trials of combination and novel antiplatelet agents in subgroups of PAD patients, both as part of BMT and as an adjunct to ET, would seem to be warranted. In particular, the possible adverse impact of aspirin and clopidogrel resistance on outcomes after ET requires further evaluation, and individualized antiplatelet therapy may be the future.[38]

Similarly, while the role, if any, of long-term anticoagulation with vitamin-K antagonists in PAD patients remains uncertain, the availability of a range of direct oral anticoagulants (DOACs) offers new therapeutic possibilities both as part of BMT and as an adjunct to intervention.[39] While VOYAGER (https://clinicaltrials.gov/ct2/show/NCT02504216) results still are awaited at time of writing, those of COMPASS, which randomized 27,395 participants with stable atherosclerotic vascular disease to receive rivaroxaban (2.5 mg twice daily) plus aspirin (100 mg once daily), rivaroxaban (5 mg twice daily), or aspirin (100 mg once daily), have recently been published.[40] The primary outcome was a composite of cardiovascular death, stroke, or myocardial infarction. The study was stopped for superiority (4.1% vs. 5.4%, 24% reduction) of the rivaroxaban-plus-aspirin group after a mean follow-up of only 23 months. The net clinical benefit of rivaroxaban plus aspirin over aspirin alone was estimated at 20% (4.7% vs. 5.9%) and appears to represent a very considerable additional level of risk reduction over standard antiplatelet therapy, which, in the UK, is clopidogrel (in preference to aspirin). Importantly, just more than 27% of the patients in all three arms (7470 patients combined) had a history of PAD as an entry criterion.[41] These powerful data accord with the observation that many PAD patients exhibit a prothrombotic, hypofibrinolytic diathesis. The fact that, in the COMPASS trial, rivaroxaban alone was not better than aspirin alone suggests that both coagulation and platelet function may need to be modified in order to optimize clinical outcomes.[42] This may be especially so in PAD patients who have undergone ET leading

to the exposure of prothrombotic and inflammatory surfaces, and perhaps particularly when non-bioresorbable devices have been implanted. While further careful evaluation of the COMPASS trial results is required and bleeding risks need to be carefully considered, as will the cost implications in many healthcare economies, this and other trials appear to have the potential to usher in a new "standard of care" for at least some, perhaps even the majority, of PAD patients being treated medically with and without with ET.

The evidence for lipid lowering therapy in people at increased cardiovascular risk is extensive, and although much of it concerns patients presenting with coronary artery disease, there are also a number of authoritative, strongly evidence-based management guidelines concerning the use of statins in patients with PAD. In a recent US study, the authors concluded "use of the recommended intensity of statin therapy in compliance with 2013 American College of Cardiology/American Heart Association lipid management guidelines is associated with significantly improved survival and lower major adverse limb events (MALE) rate in patients undergoing revascularization for CLTI. Adherence to current guidelines is an appealing target for quality improvement."[43]

The role of drugs for symptom relief, as opposed to cardiovascular risk reduction, in patients with IC, either as a standalone therapy or in combination with ET, remains uncertain. In the UK, NICE have recommended that it is reasonable to try naftidrofuryl for 3 to 6 months in patients who have not benefited sufficiently from supervised exercise and who do not want to consider ET or surgical revascularization. With regard to cilostazol, a recent Cochrane review concluded that the drug improves walking distance in people with IC secondary to PAD and that although there is an increase in adverse side effects, they are generally mild and treatable. However, the authors further concluded that there is currently insufficient data on whether taking cilostazol results in a reduction of all-cause mortality and cardiovascular events or an improvement in quality of life, and that further research is required.[43a] In addition to providing symptom relief as a standalone therapy, there is also some evidence that cilostazol can improve outcomes following ET. For example, in a subanalysis of the ZEPHYR study that used propensity score-matching analysis, the investigators reported that cilostazol was associated with a significantly lower incidence of restenosis 1 year after DES implantation for FP lesions.[44] This is another area arguably worthy of further study in an attempt to improve ET durability and reduce reintervention rates.

A number of groups have explored the hypothesis that lifestyle modification, BMT, (supervised) exercise therapy, and revascularization can work synergistically for the clinical benefit of patients with IC and also improve the cost-effectiveness of intervention.[27] For example, statin use is associated with a reduction in postoperative cardiovascular events[45] and may increase the long-term success of intervention. Unsurprisingly, continued smoking very significantly reduces the benefits of intervention while greatly increasing the risks.[46] Although in many countries it would be considered inappropriate to deny ET to patients with IC solely on the basis that they choose to continue to smoke,[47] hopefully, there would be wide agreement that the impact of that decision on the risks and benefits of the proposed ET would form an important part of shared decision making and be documented in the case record. The corollary is that all patients presenting with IC should be offered evidence-based smoking-cessation therapy,[48,49] and that such therapy should be given adequate time to be effective, before proceeding with ET (or surgical bypass).

In the UK, the long-term results of a RCT of supervised exercise, PBA, or combined treatment for patients with IC due to FP disease have recently been published.[50] Although follow-up was incomplete, with only 111 of 178 patients initially recruited being available for assessment a median of just over 5 years after randomization, the PBA and PBA plus supervised exercise groups had a higher ABI than the supervised exercise only group. This did not translate into a significant difference in important clinical outcomes; however, as noted previously, the patient numbers in each group were small. The authors concluded that PBA, supervised exercise, and combined treatment were equally effective long-term treatment options for patients with IC due to FP disease, and suggested that combined treatment has the potential to reduce the rate of symptomatic restenosis and reintervention. However, there was no cost-effectiveness analysis and, more generally, whether adjuvant strategies to improve the long-term clinical effectiveness of ET for IC, in terms of symptom relief, are cost-effective remains uncertain.

In the United States, the CLEVER study has also published its results. With regard to the AI segment, the authors concluded that, while supervised exercise and stent revascularization resulted in better outcomes than medical therapy alone at 18 months, they did not differ in terms in functional status or health related quality of life (HRQL).[51] With regard to cost-effectiveness, the investigators concluded that both supervised exercise and stent revascularization were economically attractive by US standards relative to medical therapy only. However, revascularization is significantly more expensive than supervised exercise and associated with uncertain incremental clinical benefits resulting in an estimated cost per QALY of around $122,000.[52]

In summary, since NICE published its recommendations in 2012, there has been no new evidence to seriously challenge the primacy of lifestyle modification,[49] BMT,[53] and (supervised) exercise therapy as first line for the majority of people who present with IC.[54-56] Not only is such therapy highly clinically effective, from a health economic (cost-utility) perspective it is likely to dominate intervention in most patients and healthcare settings. Furthermore, while "level 1" evidence for the effectiveness of, increasingly combination, medical therapy is increasing, progress in acquiring a "level 1" evidence base for ET in patients with IC appears to have stalled for the time being.

All that said, in the real world, there are many patients with IC who do not want or cannot manage to modify their lifestyle, are not concordant with BMT, have no interest in engaging with a (supervised) exercise program,[57] and who demand intervention, perhaps viewing it as a "quick fix" for their problem. At the same time, there remain many clinicians who are extremely enthusiastic about ET for IC and have a very low threshold for intervention. As noted previously, this is a highly controversial area with a

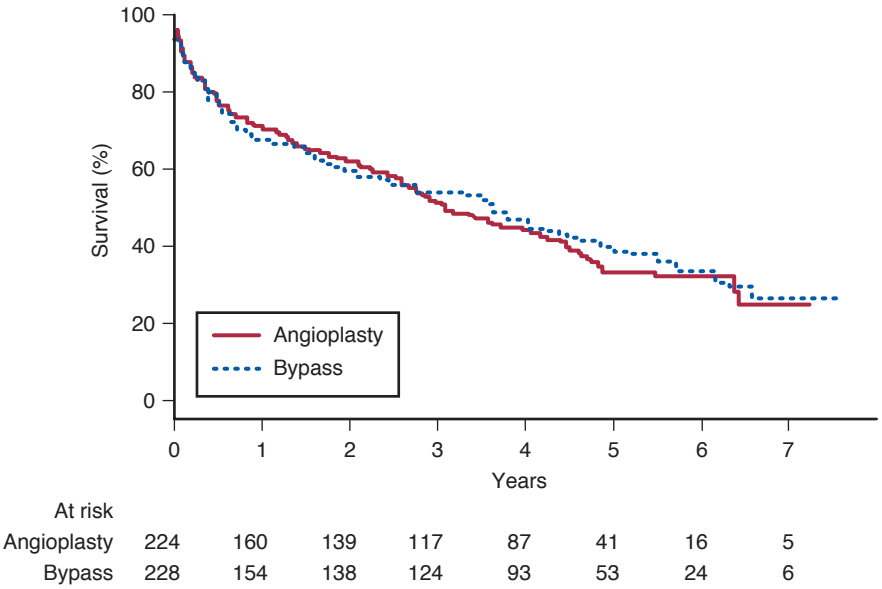

Figure 110.1 Bypass versus angioplasty in severe ischemia of the leg-1 trial (2008 analysis): survival to primary endpoint of major amputation of trial leg or death (amputation free survival). (From Bradbury AW, Adam DJ, Bell J, et al. Multicentre randomised controlled trial of the clinical and cost-effectiveness of a bypass-surgery-first versus a balloon-angioplasty-first revascularisation strategy for severe limb ischaemia due to infrainguinal disease. The Bypass versus Angioplasty in Severe Ischaemia of the Leg (BASIL) trial. *Health Technol Assess*. 2010;14(14).)

wide range of views and practice depending on specialty and the healthcare system (re-imbursement) that pertains in each different country. However, one would hope that, given the obvious limitations of the existing evidence base, most clinicians would agree that further RCTs are required to define the appropriate role of ET in the management of IC. Indeed, calls for such trials are repeatedly made in many published papers and during conference presentations on the subject. When designing such trials, existing and emerging data strongly suggest that ET for IC should not be viewed isolation, but as part of a more "holistic" multimodality treatment package that aims not just to durably improve walking distance but also to retard disease progress, minimize further intervention, and reduce future cardiovascular and overall morbidity and mortality.[58]

CHRONIC LIMB THREATENING ISCHEMIA

Bypass Versus Angioplasty in Severe Ischemia of the Leg Trials

The UK National Institute of Health Research (NIHR) Health Technology Assessment (HTA) funded bypass versus angioplasty in severe ischemia of the leg (BASIL) trial (now referred to as BASIL-1) remains the only completed and published RCT to have compared a "bypass-surgery-first" with a "balloon-angioplasty-first" revascularization strategy in patients with CLTI due to infra-inguinal disease.[59] The trial was conducted in 27 UK hospitals and enrolled 452 patients with CLTI who, in the opinion of the responsible vascular surgeon and interventional radiologist, required and were suitable for both bypass surgery and PBA. The primary endpoint was amputation-free survival (AFS); secondary endpoints included overall survival (OS), HRQL, and cost-effective use of hospital resources. AFS at 1 and 3 years was not significantly different for surgery and PBA. An interim analysis showed that surgery was associated with significantly lower immediate failure, higher 30-day morbidity, and lower 12-month reintervention rates than angioplasty; 30-day mortality was similar. Beyond 2 years from randomization, hazard ratios (HRs) were significantly reduced for both AFS (adjusted HR 0.37; 95% confidence interval [CI] 0.17-0.77; $P = .008$) and OS (HR 0.34; 95% CI 0.17-0.71; $P = .004$) for surgery relative to PBA. Considering the follow-up period as a whole, AFS and OS did not differ between treatments. However, for patients surviving beyond 2 years from randomization, bypass was associated with reduced HRs for AFS (HR 0.85; 95% CI 0.50-1.07; $P = .108$) and OS (HR 0.61; 95% CI 0.50-0.75; $P = .009$), equating to an increase in restricted mean OS of 7.3 months ($P = .02$) and AFS of 5.9 months ($P = .06$) during the subsequent follow-up (Figs. 110.1 and 110.2). Vein bypass and PBA performed better than prosthetic bypass. HRQL was nonsignificantly better in the surgery group. Over the first year, hospital costs for bypass were significantly higher than for PBA. However, by 3 and at 7 years the differences in cost between the two strategies were no longer significant. Patients randomized to surgery lived, on average, 29 days longer at an additional average cost of £2310. A 36-month perspective showed no significant difference mean quality-adjusted life times for PBA and surgery. However, the failure rate of PBA was high (25%), and patients who underwent bypass after failed PBA fared significantly worse than those who underwent bypass surgery as their first procedure. Only a minority of patients had been medically optimized by the time they were referred to the vascular service with CLTI, and for many patients there appear to have been missed opportunities to diagnose and manage their CLTI earlier when prospects for a successful outcome would probably have been materially greater.

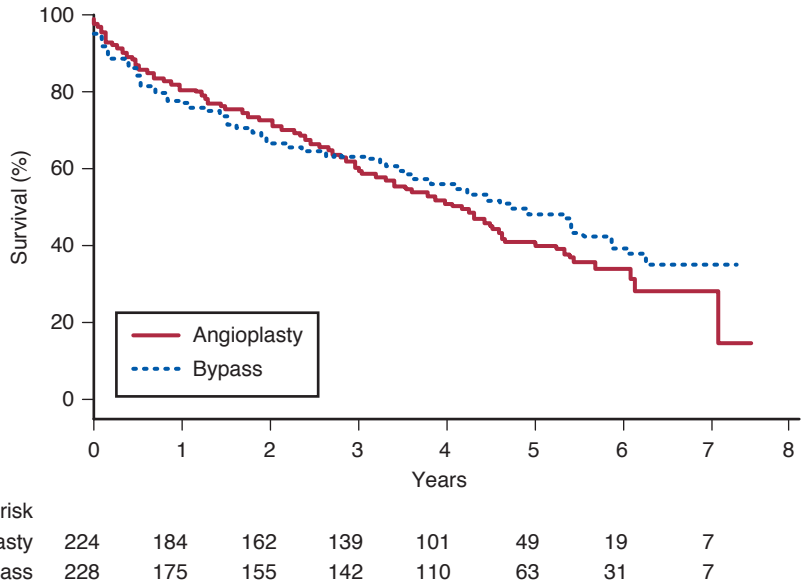

Figure 110.2 Bypass versus angioplasty in severe ischemia of the leg-1 trial (2008 analysis): survival to death from any cause. (From Bradbury AW, Adam DJ, Bell J, et al. Multicentre randomised controlled trial of the clinical and cost-effectiveness of a bypass-surgery-first versus a balloon-angioplasty-first revascularisation strategy for severe limb ischaemia due to infrainguinal disease. The Bypass versus Angioplasty in Severe Ischaemia of the Leg (BASIL) trial. *Health Technol Assess*. 2010;14(14).)

On the basis of these data, the BASIL investigators suggested the following for patients with CLTI due to infra-inguinal disease:

- When deciding whether to perform bypass surgery or PBA first, clinicians should consider estimating anticipated life expectancy by using the BASIL survival prediction model or similar tool.
- Patients expected to live less than 2 years should be considered for ET in the first instance, as it is associated with less morbidity and cost, and such patients may be unlikely to enjoy the longer-term benefits of surgery.
- Patients expected to live beyond 2 years should be considered for vein bypass surgery first.
- Patients who cannot have a vein bypass are probably better served by an attempt at ET in the first instance than prosthetic bypass.
- A ET first approach is not necessarily a "free shot," as the success of subsequent bypass may be compromised by failed ET.
- Further research is required to:
  - confirm or refute the BASIL findings and recommendations
  - validate the BASIL survival prediction model and other such tools
  - examine the clinical and cost-effectiveness of new forms of ET

Like all RCTs, BASIL-1 has several shortcomings, and the results have to be interpreted carefully.

BASIL-1 is now quite an old study with patients having been randomized between August 1999 and June 2004. It is often argued that, given advances in endovascular expertise, techniques and technologies, were the trial to be repeated, an ET-first strategy would prove the more clinically and cost-effective option for the great majority of, perhaps all, patients. While that is possible, when comparing like for like patients and disease patterns, in reality there is limited evidence to support that contention and one cannot assume that such an outcome would be likely. So, while immediate ET technical success rates are probably higher now than they were 10 to 15 years ago, there is no evidence as yet that this translates into superior long-term clinical outcomes. Indeed, the current trend of offering complex ET to CLTI patients who, due to frailty and/or extreme disease severity, may previously have been offered primary amputation or conservative treatment seems likely to reduce the overall success of infra-inguinal ET when compared with those observed in BASIL-1. However, it is very important not to fall into the trap of comparing "apples and oranges," and using historical controls is fraught with problems. At the same time, the last 10 to 15 years have seen significant advances in anesthetic and surgical expertise and techniques, such that the results of VB in current practice may well be superior to those observed in BASIL. But again, we cannot just assume that is the case. There is no doubt that the overall performance of bypass surgery in BASIL-1 was significantly adversely impacted by the fact that 25% were completed using prosthetic grafts, which performed extremely poorly and indeed significantly worse than PBA.[60] Although that reflected practice at the time, were the prosthetic grafts to be removed from the BASIL-1 analysis, the advantages for bypass surgery over PBA, especially in the longer term, would probably become more marked. Furthermore, it is worth pointing out that the relatively good performance of PBA in BASIL-1 "intention to treat" analysis is at least partly explained by the fact that although there was a high immediate and early failure rate for PBA, many such patients went on to have successful bypass. However, enthusiasts for an ET-first revascularization strategy will justifiably point to the improved anatomic outcomes consistently reported with DCB and DES, albeit mainly in patients with IC and not CLTI. In truth, no one can confidently predict what a rerun of BASIL-1, comparing VB with current "best ET," would show, and further RCTs are required to further define the role of modern ET and bypass surgery in the management of CLTI in current practice.

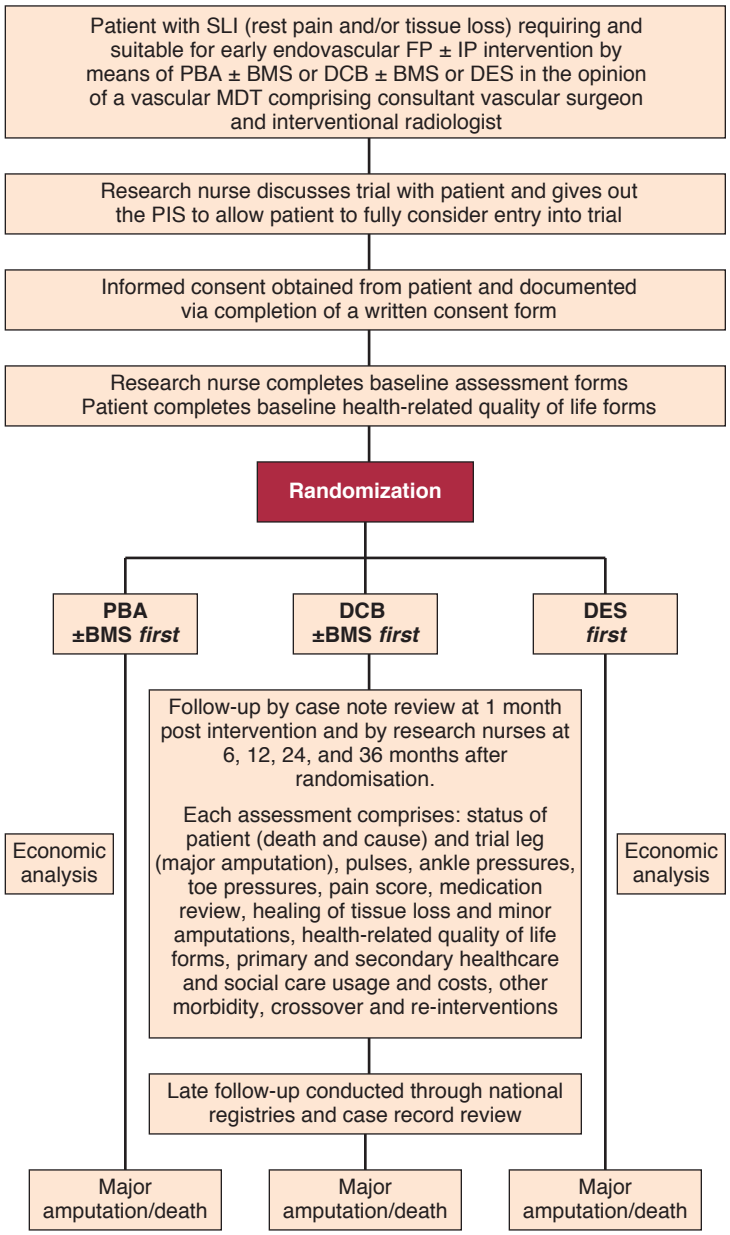

Figure 110.3 Balloon versus stenting in severe ischemia of the leg (BASIL-3) trial flow diagram of study design (CONSORT diagram). *BMS*, Bare metal stents; *DCB*, drug coated balloons; *DES*, drug eluting stents; *FP*, femoropopliteal; *IP*, infrapopliteal; *MDT*, multidisciplinary team; *PBA*, plain balloon angioplasty; *SLI*, severe limb ischemia. (From Hunt BD, Popplewell MA, Davies H, et al. BAlloon versus Stenting in severe Ischaemia of the Leg-3 (BASIL-3): study protocol for a randomised controlled trial. *Trials*. 2017;18:224.)

To that end, one of the research recommendations made in the 2012 UK NICE PAD guidelines was for a RCT to address the clinical and cost-effectiveness of DCB and DES in the management of CLTI due to FP disease. The UK NIHR HTA subsequently funded the BASIL-3 trial,[61] which is currently randomizing 861 patients to FP PBA +/– "bail out" BMS, or DCB +/– "bail out" BMS, or primary DES, and expects to publish its results in 2023 (Fig. 110.3).

A further consideration is that approximately 75% of the ET in BASIL-1 were FP. The original trial analysis of the cohort as whole does not, therefore, tell us very much about outcomes specifically in IP disease, which is increasingly prevalent in modern practice. However, a recent subgroup analysis of the 104 patients in BASIL-1 who underwent IP VB ($n = 56$) or PBA ($n = 48$) has now been published.[62] As expected, due to randomization, the two groups were very similar at baseline. Primary technical success was nonsignificantly higher for VB (86%) than for PBA (73%), as was 30-day mortality (7% vs. 2%). By contrast, in-hospital morbidity following the randomized procedure was significantly higher after VB (RR 2.86, 95% CI 1.25-6.53, $P = .01$), as was median hospital stay (18 vs. 10 days, $P < .0001$), although there was no difference in overall median hospital stay between randomization and the primary endpoint (43.5 VB vs. 42 PBA days). AFS was 32% lower in the PBA group (HR 0.68, 95% CI 0.42-1.10, $P = .1$) and OS was 40% lower (HR 0.60, 95% CI 0.36-1.02, $P = .06$). In terms of the quality of revascularization, time to healing of tissue loss was 70% quicker in favor of VB than PBA (HR 1.69, 95% CI 0.88-3.26, $P = .1$). Relief of ischemic rest pain was also more than twice as common in the VB group (HR 2.19, 95% CI 1.27-2.78, $P = .005$), with more patients pain-free at 5 years (Fig. 110.4).

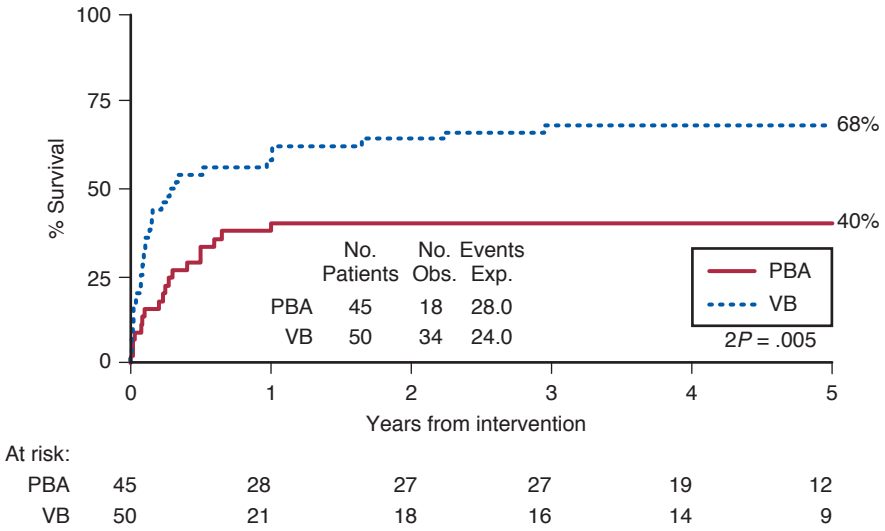

Figure 110.4 Bypass versus angioplasty in severe ischemia of the leg-1 infrapopliteal subgroup analysis, relief of ischemic rest pain (HR 2.19, 95% CI 1.27-2.78, $P = .005$). *PBA*, Plain balloon angioplasty; *VB*, vein bypass. (From Popplewell MA, Davies HOB, Narayanswami S, et al. A comparison of outcomes in patients with infrapopliteal disease randomised to vein bypass or plain balloon angioplasty in the bypass vs. angioplasty in severe ischaemia of the leg (BASIL) trial. *Eur J Vasc Endovasc Surg*. 2017;54(2):195–201.)

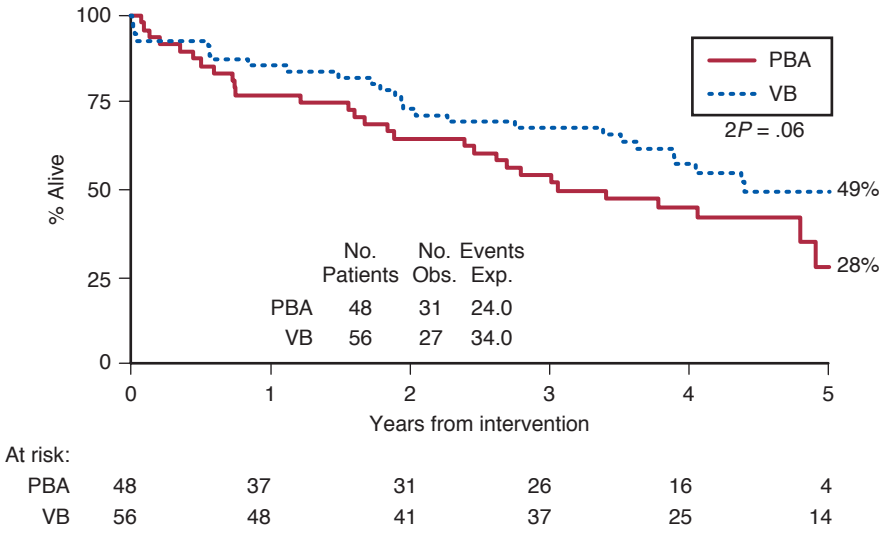

Figure 110.5 Bypass versus angioplasty in severe ischemia of the leg-1 (BASIL-1) infrapopliteal subgroup analysis, overall survival (HR 0.60, 95% CI 0.36-1.02, $P = .06$). *PBA*, Plain balloon angioplasty; *VB*, vein bypass. (From Popplewell MA, Davies HOB, Narayanswami S, et al. A comparison of outcomes in patients with infrapopliteal disease randomised to vein bypass or plain balloon angioplasty in the bypass vs. angioplasty in severe ischaemia of the leg (BASIL) trial. *Eur J Vasc Endovasc Surg*. 2017; 54(2):195–201.)

While, with the exception of relief of rest pain, the BASIL-1 IP subgroup results do not meet standard criteria for statistical significance, the direction of the effect consistently favors vein bypass and the CIs rule out the possibility of clinically important effects in favor of PBA in this cohort. The improvement in OS with bypass surgery is particularly striking and very nearly reaches statistical significance ($P = .06$), despite small numbers (Fig. 110.5).

However, ET enthusiasts will argue that PBA alone via a common femoral access point using 035 wire technology no longer represents "standard of care" and that a rerun of BASIL-1 using ultrasound guided micropunctures, low profile wires, re-entry devices, drug technologies, debulking devices, and innovative entry points[63,64] and retrograde approaches[65] would lead to dramatically different outcomes and conclusions.[66] Although this is entirely possible, as yet there is no "level 1" evidence that this is, in fact, the case, and further trials are required.

The BASIL-1 data also demonstrate that while objective binary endpoints such as AFS, OS and limb salvage (LS) are important, there is often a discrepancy between these and patient-reported outcome measures (PROMs). While the primary aim of infra-inguinal ET, and indeed bypass surgery, is to prevent major limb amputation, for a significant minority of people, retention of their leg does not necessarily result in better HRQL. Thus a significant proportion of BASIL patients undergoing ET, while they survived and retained their leg, were not relieved of their ischemic rest pain and continued to have wounds on their feet, sometimes for the rest of their lives. Of course, this was also true of some patients undergoing VB, although the proportion was smaller.

So, when designing RCTs to evaluate and compare (different types of) ET and VB for CLTI, many would argue that endpoints such as PROMs and HRQL that assess the quality of revascularization should have primacy over objective binary clinical endpoints (such as AFS); and even more so over hemodynamic

and anatomic endpoints, which have been repeatedly shown to have an unreliable relationship with clinical success. Thus, two patients with identical AFS can have very different journeys to their endpoint and so personal views as to whether their revascularization was successful for them or not. These considerations are also important when it comes to determining cost-effectiveness, which is usually assessed through cost-utility analyses resulting in estimation of cost per QALY. As discussed previously, the same arguments and considerations apply equally well to studies of patients undergoing infra-inguinal ET and bypass surgery for IC.

As such, it remains far from clear whether CLTI patients who require IP revascularization and who are suitable for VB should have bypass or ET as their primary revascularization procedure. In other words, should such patients only have ET when they cannot have VB, or vice-versa? Related to this is the question of how far the surgeon should be prepared to go in splicing together lengths of perhaps suboptimal vein and/or using prosthetic material before they conclude that ET is in their patient's best interests. Again, these are highly controversial questions, and there is a wide range of opinion and practice. A recent systematic review of IP ET revealed a pooled technical success of 91.1% but a 1-year primary patency of only 62%.[67] Mortality and amputation rates in the 6769 patients studied were 15.1% and 14.9%, respectively, at 12 months. The authors commented that considerable heterogeneity and publication bias were present in most studies and concluded that procedural and clinical outcomes in the IP segment were "suboptimal." But the results of VB can also be suboptimal, and even in centers of excellence, the associated mortality and morbidity rates remain significant.[68,69]

One of the research recommendations made in the 2012 UK NICE PAD guidelines was for a RCT to address this very important question, and the UK NIHR HTA subsequently funded the BASIL-2 trial.[70] BASIL-2 is currently randomizing up to 600 patients who require IP revascularization to a VB first versus a "best" ET first revascularization strategy and expects to publish its results in 2022 (Fig. 110.6).

Best Endovascular Versus the Best Surgical Therapy in Patients With Critical Limb Ischemia

The need for large independently funded, unbiased, multicenter pragmatic trials is also widely recognized in the United States. The US NIH–funded Best Endovascular Versus the Best Surgical Therapy in Patients With Critical Limb Ischemia (BEST-CLI) trial is a prospective, randomized, multidisciplinary, controlled, superiority trial designed to compare treatment efficacy, functional outcomes, HRQL, and cost in patients undergoing best ET or best open surgical revascularization (http://www.bestcli.com/; Fig. 110.7).[71] BEST-CLI is currently randomizing at well over 100 sites in North America and in a number of European countries. The pragmatic trial design requires consensus on patient eligibility by at least two investigators, but leaves the choice of specific procedural strategy within the assigned revascularization approach to the individual treating clinician. Patients with suitable single segment of saphenous vein available for potential bypass will be randomized within Cohort 1 (n = 1620), while patients without will be randomized within Cohort 2 (n = 480). The primary efficacy endpoint of the trial is Major Adverse Limb Event (MALE) free survival. Key secondary endpoints include reintervention and AFS, and AFS alone. As a result of close collaboration over a number of years, there are many similarities between BEST-CLI and the BASIL 2 and 3 trials. The investigators have agreed to share data so that appropriate individual patient data (IPD) meta-analyses can be conducted when all three trials have completed their collective randomization of up to 3500 CLTI patients.

At the time of writing, the authors are not aware of any other publicly funded, large pragmatic RCTs ongoing elsewhere in the world. If this is, indeed, the case, then that does seem quite extraordinary, given the global prevalence and importance of CLTI.

Global Vascular Guidelines on Chronic Limb Threatening Ischemia

GVG is collaborative effort between the US SVS, ESVS, and the WFVS, and is due to publish its full recommendations in early 2018. The main aims of GVG are to improve CLTI outcomes by:

- Promoting paradigms and tools as a framework for evidence based revascularization (EBR)
- Making specific practice recommendations based on GRADE levels of evidence
- Identifying gaps in the evidence and suggesting areas and methods for future research

GVG recommends that decisions regarding revascularization are based upon PLAn principles:

- **P**atient risk estimation
  - Candidacy for LS
  - Peri-procedural risk
  - Life expectancy
- **L**imb threat severity using the SVS Wound Ischemia Foot infection (WIfI) staging system[72]
- **AN**atomic pattern of disease using the GLobal Anatomic Staging System (GLASS; Tables 110.2 and 110.3) based upon high quality imaging that should include the foot and ankle, together with an assessment of the availability and quality of autogenous vein for bypass

The development of the GVG GLASS was considered necessary because previous anatomic schemes based on individual lesions (such as TASC) or overall burden of disease (Bollinger)[73] may not be useful in defining the infra-inguinal (FP and IP) Target Artery Path (TAP), which needs to be cleared of significant disease in order to restore and maintain in-line flow (limb based patency, LBP) to the foot, which is the primary technical goal of endovascular EBR. While the TAP usually includes the least diseased IP vessel, the choice of outflow vessel may be angiosome based, and in some patients, two outflow arteries may be treated (discussed later).

Bypass surgery requires adequate inflow and outflow and, perhaps most importantly, a suitable autogenous conduit. By

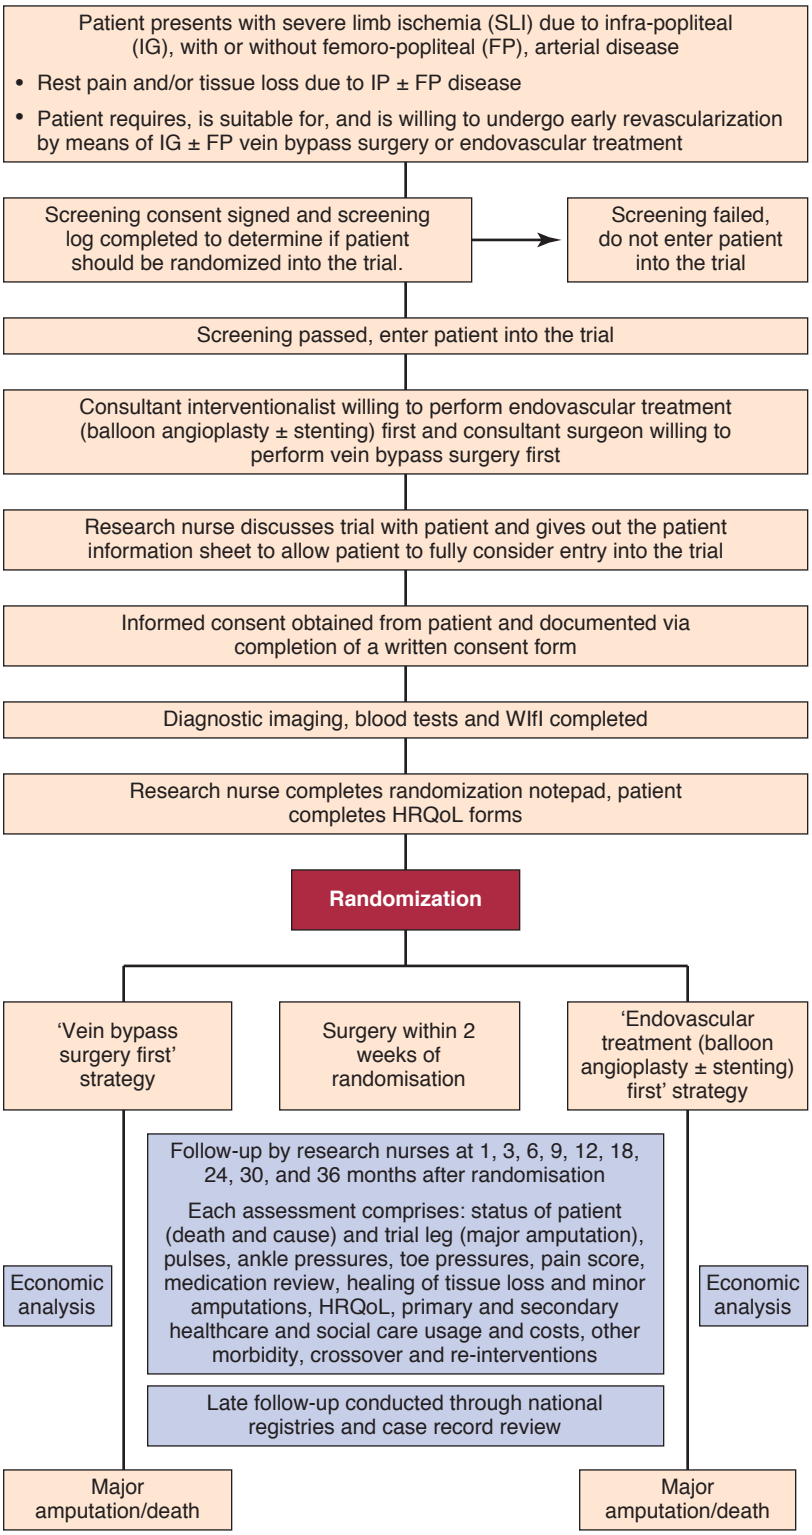

Figure 110.6 Bypass versus angioplasty in severe ischemia of the leg-2 flow diagram of study design (CONSORT diagram). *HRQoL*, Health related quality of life. (From Popplewell MA, Davies H, Jarrett H, et al. Bypass versus angioplasty in severe ischaemia of the leg-2 (BASIL-2) trial: study protocol for a randomised controlled trial. *Trials*. 2016;17:11.)

contrast, the success of ET is largely defined by the burden and complexity of atherosclerosis within the anticipated TAP.

Defining the planned ET TAP in each individual case is the basis for the GLASS framework. In defining the overall GLASS stage (I-III) for the limb, GLASS combines grade scores (0-4) from both the FP segment (origin of the SFA to the origin of the anterior tibial artery) and the IP segment (origin of the tibioperoneal trunk and the anterior tibial artery to the malleoli; see Tables 110.2 and 110.3). There are modifiers for heavy calcification and inframalleolar disease.

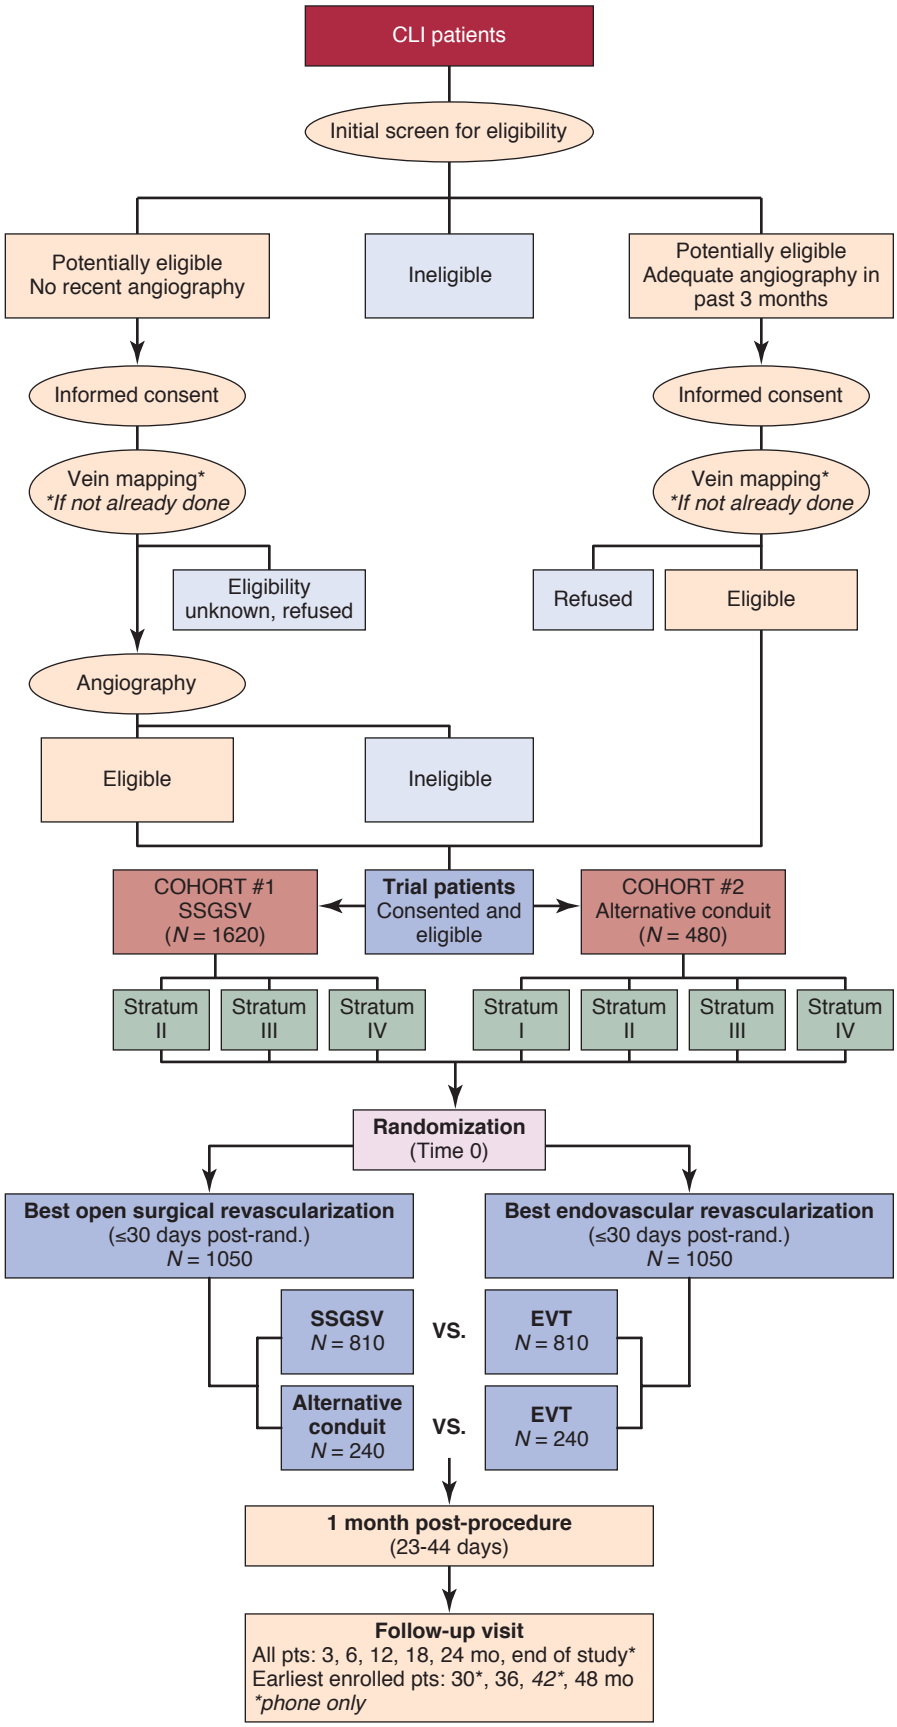

Figure 110.7 Best endovascular versus the best surgical therapy in patients with critical limb ischemia (BEST-CLI) trial patient flow chart. Stratum I: Ischemic Rest Pain (Rutherford Category 4) AND infrainguinal PAD without significant infrapopliteal occlusive disease, Stratum IL: Tissue loss with or without ischemic rest pain (Rutherford Category 5, 6) AND Infrainguinal PAD without significant infrapopliteal occlusive disease; Stratum Ill: Ischemic Rest Pain (Rutherford Category 4) AND Infrainguinal PAD with significant infrapopliteal occlusive disease; Stratum IV: Tissue loss with or without ischemic rest pain (Rutherford category 5, 6) AND Infrainguinal PAD with significant infrapopliteal occlusive disease. *CLI*, Critical limb ischemia; *EVT*, endovascular therapy; *PAD*, peripheral artery disease; *SSSGSV*, single-segment great saphenous vein. (From Menard MT, Farber A, Assmann SF, et al. Design and rationale of the best endovascular versus best surgical therapy for patients with critical limb ischemia (BEST-CLI) trial. *J Am Heart Assoc*. 2016;5(7):e003219.)

TABLE 110.2 Grading of Anatomical Severity of Disease in Global Anatomic Staging System (GLASS)

Femoropopliteal Segment	
0	Mild or no significant (<50%) disease
1	Total length SFA disease <⅓ (<10 cm); may include single focal CTO (<5 cm) as long as not flush occlusion; popliteal artery with mild or no significant disease
2	Total length SFA disease ⅓ to ⅔ (10-20 cm) may include CTO totaling <⅓ (10 cm) but not flush occlusion; focal popliteal artery stenosis <2 cm, not involving trifurcation
3	Total length SFA disease >⅔ (>20 cm) length; may include any flush occlusion <20 cm or non-flush CTO 10-20 cm long; short popliteal stenosis 2-5 cm, not involving trifurcation
4	Total length SFA occlusion >20 cm; popliteal disease >5 cm or extending into trifurcation; any popliteal CTO
Infrapopliteal Segment	
0	Mild or no significant (<50%) disease
1	Focal stenosis <3 cm not including TP trunk
2	Total length of target artery disease <⅓ (<10 cm); single focal CTO < 3 cm (not including target artery origin or TP trunk)
3	Total length of target artery disease ⅓ to ⅔ (10-20 cm); CTO 3-10 cm (may include target artery origin, but not TP trunk)
4	Total length of target artery disease >⅔ length; CTO >⅓ (>10 cm) of length (may include target artery origin); any CTO of TP trunk

IP grading is applied only to the primary selected vessel in the TAP.
Severe calcification (e.g., >50% of circumference, diffuse, bulky or "coral reef" plaques) within the TAP increases the within-segment grade by +1.
TP trunk disease is only included if the target vessel is the posterior tibial or peroneal artery.
CTO, Chronic total occlusion; *SFA*, superficial femoral artery; *TP*, tibioperoneal.

	IP Grade					

FP, Femoropopliteal; *GLASS*, GLobal Anatomic Staging System; *IP*, infrapopliteal.

The intention is that GLASS stage will be used to help predict the likelihood of ET technical failure and 12-month LBP as follows:

- Stage I: Average Complexity: expected technical failure <10% AND >70% 12-month LBP
- Stage II: Intermediate Complexity: expected technical failure <20% AND 50% to 70% 12-month LBP
- Stage III: High Complexity: expected technical failure >20% AND <50% 12-month LBP

These GVG concepts and tools will require verification and validation in different cohorts of patients undergoing ET, and bypass, for CLTI. However, it is hoped that they will provide a more thoughtful and logical means of identifying those patients who should be offered an ET first revascularization strategy based upon the condition of the patient, the status of the leg and foot, and the overall burden of atherosclerotic disease. It is also anticipated that they will help improve the quality of future research, partly by better defining subgroups of patients for study with the heterogeneity of the CLTI population as a whole.

FACTORS AFFECTING OUTCOMES

A wide range of factors has been reported to impact upon the short-, medium-, and long-term success of infra-inguinal ET in patients presenting with IC and CLTI.[74]

Smoking

As discussed previously, continued smoking is arguably the most powerful of the factors determining the overall prognosis of patients presenting with IC and CLTI, and also their outcomes following ET. For example, in one recent study of 647 patients, compared with never smokers, current (HR 2.45, 95% CI 1.62-3.71) and former (HR 1.62, 95% CI 1.14-2.29) smokers with PAD had higher rates of death.[75]

Best Medical Therapy

Patients presenting with PAD, in particular CLTI, are at greatly increased risk of cardiovascular morbidity and mortality. Despite this, PAD patients often receive suboptimal medical therapy, especially when compared with patients who present with coronary artery disease.[76] In addition to nontreatment, undertreatment and patient non-concordance with BMT both remain significant issues in everyday practice that will probably adversely impact the safety and clinical benefits of infra-inguinal ET.

Diabetes Mellitus

A growing proportion of PAD patients, and now probably the majority of patients undergoing ET for CLTI, suffer from diabetes mellitus (DM).[77] Diabetes affects the presentation, diagnosis, and management of PAD in many ways. However, perhaps surprisingly, several studies, including the BASIL-1 trial, have failed to convincingly identify DM as an independent predictor of outcomes following revascularization, although as a group they may be less likely to be offered revascularization.[78] A recent US study compared outcomes following bypass and ET at and below the knee in 2566 CLTI patients with and without DM using data from the 2008 to 2014 VQI.[79] Patients with DM were more likely to be black (18% vs. 14%), had more comorbidities, and more frequently underwent revascularization for tissue loss (85% vs. 58%) (all, $P < .001$). However,

DM did not significantly affect 1-year primary patency, major amputation, or mortality following bypass or ET. The authors concluded that aggressive LS should be pursued in patients with CLTI regardless of the presence of DM. While few would argue with this sentiment, the reality is that the extensive, heavily calcified IP and pedal disease so often seen in patients with diabetes, and those with ESRD which often co-exists, is a significant challenge to conventional ET, as well as surgical bypass. Advanced ET techniques aimed at dealing with this pattern of disease, such as SAFARI, have been around for more than 10 years.[80] However, how many patients will be suitable for these innovative ET approaches, how many physicians will be able to master the skills required, and the extent to which these techniques will impact long-term LS remains to be seen.

Gender

While some studies have found women with PAD to have worse outcomes,[81] including after surgical revascularization and ET,[82,83] others appear to have found the opposite.[84] As such, the nature of the relationship and the causes of any observed differences remain unclear.[85] One possibility is that, on average, women tend to have smaller vessels, which have been shown to predict poorer ET outcomes.[86] However, it seems likely to be far more complex than that. Further research is required to determine if there is a subgroup of women at predictably high risk of poor outcomes after infra-inguinal ET, or indeed bypass.[85]

Residual and Recurrent Disease

There is a considerable body of literature looking at the outcomes of infra-inguinal ET and surgical revascularization following previous intervention. As discussed previously, in the BASIL-1 trial, secondary surgical bypass following failed ET was associated with significantly lower AFS and OS when compared with those observed after primary bypass. Whether this is because failed ET directly jeopardizes subsequent bypass, or because failed ET selects out a subgroup of patients who were likely to have poor outcomes regardless of whether they had ET or bypass as their first intervention, remains unclear. Several other groups have addressed this question, and the results are somewhat conflicting. For example, in a recent study of 142 infra-inguinal bypasses, outcomes following primary bypass were not superior to those performed after unsuccessful ipsilateral IP ET. The authors concluded that unsuccessful IP ET does not have a negative impact on the outcome of subsequent ipsilateral distal bypass in patients with CLTI.[87] By contrast, in another study that evaluated bypass outcomes after failed ET, the authors found change in the bypass target to a more distal site was identified in nearly half of patients and concluded that "poor outcomes of open interventions after EVT can be expected if ET fails."[88] A further recent study, which used data for more than 7000 patients from the National Surgical Quality Improvement Program Targeted Vascular module, found that prior revascularization in patients treated for both IC and CLTI was associated with worse perioperative outcomes when compared with primary bypass. Furthermore, prior ET was associated with increased wound infections, whereas those with prior bypass had higher re-intervention rates. The authors concluded that "the increasing prevalence of patients undergoing multiple interventions stresses the importance of the selection of patients for initial treatment and should be factored into subsequent revascularization options in an effort to decrease adverse events."[89] So, whether a CLTI patient is primarily treated with ET or bypass, there is a significant chance that they will require further intervention(s); that reality should be shared with the patient and, where appropriate, their family, and also taken into account when offering different revascularization strategies.

Restenosis and, in particular in-stent restenosis,[90,91] leading to further interventions, remains a significant obstacle to clinically durable and cost-effective ET. In the FAIR trial, where 119 patients with in-stent restenosis were randomized to DCB or PBA, the authors concluded that "DCB for superficial femoral artery in-stent restenosis is associated with less recurrent restenosis and a better clinical outcome than PBA without an apparent difference in safety." No cost-effectiveness data were presented, most of the endpoints reported were anatomic, and follow-up was only 12 months.[92] In the PACUBA trial, where 74 patients with in-stent stenosis were randomized to DCB or PBA, the authors reported that DCB provided significantly higher patency rates, although this did not appear to translate into additional meaningful clinical benefit.[93] Further research is clearly required to define how best to prevent, detect, and treat such recurrent disease.[94,95] A related question is defining the optimal ET for vein bypass grafts that are considered to be "failing" due to within-graft and anastomotic stenoses. To date, there is little evidence that DCB offer a more clinically and cost-effective option than PBA.[96] However, further studies are required.

End-Stage Renal Disease (Dialysis)

Overall and amputation-free survival remain poor in CLTI patients with end-stage renal disease (ESRD) regardless of revascularization strategy and, wisely, a prudent approach to patient selection has been advised.[97] Although comparative data are lacking, it would appear that most clinicians favor an ET over a bypass first revascularization strategy for most such patients on the grounds that it is probably the least worst option given that the morbidity and mortality associated with surgery can be very high.[98] This is an important area for research, as the number of people with ESRD presenting to vascular specialists with CLTI seems likely to continue to increase, especially in certain populations.[99,100]

Vessel Calcification

This an increasingly common finding, as the proportion of CLTI patients with DM and/or ESRD increases. Calcification can be quantified on CT angiography and related to technical failure rates.[101,102] However, how these data might alter decisions regarding ET (vs. surgical) revascularization remains unclear and such calcification remains a significant challenge.[103] Further research is required to assess the potential role of alternative technologies such as cutting balloons and debulking.[104]

Body Mass Index

There is a complex relationship between body mass index (BMI) and outcomes, including mortality, after ET (and bypass surgery) in CLTI patients. Underweight patients have the poorest prognosis both in relation to other co-morbidities but also as an independent predictor of LS. Similarly, normal weight patients appear to have a small but significant increase in mortality compared with overweight/obese patients.[105] This has been termed the "obesity paradox" and is not easily explained. In a recent study of 62,445 patients, although obesity (BMI > 30) did not impact in-hospital mortality in patients who underwent ET, obese patients did suffer more adverse events and stay in hospital longer, leading to significant cost implications.[106]

Race and Ethnicity

The relationship between race, ethnicity, and health outcomes has been widely studied and, as might be expected, varies considerably between different countries. Even within countries, the data can be conflicting.[107] Separating out the impact of genetics, environment, and socio-economic status is difficult.[108]

Re-admissions

Several studies have looked at factors that might predict early (typically 30-day) readmission to hospital after ET. In a recent study that used data on more than 60,000 hospitalizations from the 2013 to 2014 Nationwide Readmissions Databases, approximately 1 in 5 patients admitted for CLTI and undergoing revascularization were readmitted within 30 days. Presentation with ulcer or gangrene, age ≥65 years, female sex, large hospital size, teaching hospital status, known coronary artery disease, heart failure, DM, chronic kidney disease, anemia, coagulopathy, obesity, major bleeding, acute myocardial infarction, vascular complications, and sepsis were identified as independent predictors. However, the mode of revascularization was not independently associated with readmission. Infections (23.5%), persistent or recurrent manifestations of PAD (22.2%), cardiac conditions (11.4%), procedural complications (11.0%), and endocrine problems (5.7%) were the most common reasons for readmission.[109] Another study also found that unplanned readmission after ET is relatively common, especially in patients with CLTI, and was associated with substantially increased mortality. The authors concluded that awareness of risk factors for readmission may help providers identify patients at high risk who may benefit from early surveillance, and prophylactic measures focused on decreasing postoperative complications, thus reducing the rate of readmission and improving overall outcomes.[110]

INFLOW CONSIDERATIONS

Common Femoral Artery

Clinically important common femoral artery (CFA) plaque is generally bulky and eccentric and, while it may be quite focal, often co-exists with significant proximal and distal disease. Although it generally remains the case that most clinicians would favor a surgical approach for most patients, the primacy of CFA endarterectomy (CFE) over ET is being increasingly challenged.[111] In a study of 40 CFA stent procedures in 36 patients, 25 of whom had IC, mortality at 5 years was 38%; at 3 and 5 years, primary sustained clinical improvements were 77% and 73%; freedom from target lesion revascularization and target extremity revascularization were 79% and 73%; and in-stent restenosis rate was 28%. The significant predictors of in-stent restenosis were deep femoral artery (DFA) stenting and type III lesions. One stent fracture was found at 1 year and was without clinical consequence; no other stent fracture was noted. The authors concluded that "endovascular repair of the CFA and its bifurcation seems to provide sustained clinical and morphologic long-term results. Fear of stent fracture and local complications due to hip mobility are no longer relevant."[112] Other investigators have also reported encouraging results after CFA ET and the time for a large, pragmatic RCT in patients at average and high risk of CFE has probably come.[113-116]

Deep Femoral Artery

ET of the DFA, either as part of more extensive CFA stenting or more localized balloon angioplasty of often focal and heavily calcified orificial disease, remains highly controversial. Understandably, many vascular surgeons are very nervous at the thought of the origin of the DFA being covered by an endovascular device. At the present time, the number of patients in whom DFA ET would be appropriate and likely to be of clinical benefit would seem to be very small. However, with advances in endovascular devices and techniques that may change in the future.

Hybrid Procedures

The concept of the hybrid procedure has become increasingly fashionable, although few data are available.[117] As the term refers to an extremely heterogeneous collection of procedures, and identifying a suitable control population is problematic, making comparisons is difficult. Some would argue that a hybrid procedure exposes the patient to the worst to both worlds: the morbidity of open surgery and the lack of durability of ET. Others will say that it is entirely sensible to try to reduce the magnitude of open surgical revascularization whenever possible. Both positions are likely to be applicable to certain patients, and as ever, "case selection" is vital. What the concept of hybrid procedures does help to reinforce is the need for CLTI patients to be treated by physicians in centers that can offer both ET and open surgery with equal skill and facility. CFE with or without profundaplasty, combined with inflow and/or infra-inguinal ET, appears reasonable and logical and to be increasingly popular in centers where vascular specialists have both surgical and ET expertise and access to hybrid operating facilities.

OUTFLOW CONSIDERATIONS

Angiosome Targeted Endovascular Treatment

Much has been written about whether angiosome-targeted ET results in better outcomes when compared with so-called indirect revascularization. Overall, the data are somewhat conflicting, perhaps partly because different definitions of direct and indirect revascularization are used in the literature.[118] In a study of 486 patients undergoing direct revascularization (DR), indirect revascularization through collaterals (IR-tc), or indirect revascularization without collaterals (IR-wc), at 1 year the unhealed ulcer rate of the IR-wc group was significantly higher than that of the DR group and the IR-tc group; the LS rate of the IR-wc group was significantly lower than that of the DR group and the IR-tc group; and there were no differences in ulcer healing or LS between the DR and IR-tc groups. The authors concluded that directly revascularizing the feeding artery and indirectly achieving revascularization through collaterals can both be effective in patients undergoing IP ET for CLTI.[119] In another series of 139 CLTI patients undergoing IP ET, the authors concluded that "the angiosome concept had no impact on clinical success."[120] In a retrospective Brazilian study of 92 patients (109 legs) undergoing IP angioplasty, the authors "found no evidence to support revascularization based on the concept of the angiosome in preference to revascularization of the artery that is most amenable to endovascular treatment."[121] In a small series of 30 patients, the impact of isolated tibial angioplasty on the foot macro- and microcirculation was assessed. The authors reported a significant improvement in tissue perfusion immediately after the procedure but that the effect was global and not restricted to angiosome borders.[122] In another study looking at this issue, the authors concluded "in patients with CLTI and tissue loss receiving a peroneal bypass, patency of both peroneal branches and pedal arch was associated with a better healing rate and a better AFS rate irrespective of wound angiosome location."[123]

Treatment of Multiple Outflow Vessels

Related to the controversy over direct (angiosomic) versus indirect revascularization is the question of whether clinical outcomes can be improved by treating two outflow vessels. In a study from Japan, the authors treated 123 patients (137 limbs) with CLTI who had lesions of both the anterior and posterior tibial arteries. In 84 limbs, only one artery was treated, while in 53 limbs, both arteries were treated. The wound-healing rate was significantly higher (87% vs. 79%; $P = .003$), the time to wound healing was shorter (median, 83 vs. 142 days; $P = .01$), and the repeat peripheral vascular intervention rate was lower (15% vs. 35%; $P = .03$) in the two-vessel treatment group. The additional benefit of double revascularization was observed particularly in patients with a high WIfI clinical stage.[124] By contrast, a US study based on 673 limbs (528 patients) undergoing IP ET, mostly (77%) for tissue loss, multiple-vessel intervention did not improve outcomes when compared with a single-vessel intervention.[125] In a Brazilian study of 109 IP angioplasties, the authors concluded "it is unnecessary to treat the largest number of arteries possible in CLI patients. Instead, the most amenable artery for endovascular procedures should be treated to improve LS and secondary patency rates."[126] Although ET practice, especially below the knee, varies widely, that does appear to represent the majority view at the present time.

Pedal Intervention

As a result of the advances in ET technologies, techniques, and expertise, there has been increasing enthusiasm for treating pedal disease, especially via the retrograde approach, sometimes using the pedal loop technique.[127] However, as discussed previously, to date, there are few data to guide practice in this area.[128] In the RENDEZVOUS registry from Japan, 257 CLTI patients were divided into two groups according to whether pedal artery angioplasty (PAA) was performed ($n = 140$) or not ($n = 117$). The rate of wound healing was significantly higher (57.5% vs. 37.3%, $P = .003$) and time to wound healing significantly shorter (211 days vs. 365 days; $P = .008$) in the PAA group. In a multivariate analysis, non-ambulatory status, target wound depth and daily hemodialysis were as predictors of delayed healing. In the moderate-risk but not in the high-risk population, PAA significantly improved wound healing.[129]

Atherectomy

Atherectomy remains popular in some centers in some countries, but that is very much not the case in others. A recent thorough and well-referenced review of the current evidence for different forms of atherectomy concluded "atherectomy devices have continued to emerge as a major therapy in the management of peripheral vascular disease."[130] Some might take the view that, given how long these devices have been available in one form or another, it is surprising that they should still be regarded as emerging technologies. In a recent study that evaluated the combined use of directional atherectomy and DCB for CFA disease, the authors concluded that it was a "safe and effective alternative to surgery."[131] With respect to orbital atherectomy and CFA disease, in a subanalysis of the CONFIRM registry, the investigators took the view that "a randomized trial is needed to determine the ideal treatment strategy for calcified CFA disease."[132] In a review of different techniques for ET of SFA disease, the authors opined that "paclitaxel-eluting balloon (PEB) angioplasty, stenting, and directional atherectomy (DA) have provided new options for the treatment of superficial femoral artery disease; however, the comparative efficacy of these interventional strategies remains uncertain."[133] Another recent review concluded "increased use of atherectomy in all segments of the lower extremity arterial system has been observed, particularly in OBLs [office-based laboratories], without substantial evidence in the literature of increased efficacy compared with standard angioplasty with or without stenting. Generous Medicare reimbursement for in-office atherectomy procedures is likely contributing to the volume shifts observed."[134] As is

TABLE 110.4 Methodologic Issues With Existing Endovascular Literature

not infrequently the case when reviewing the ET literature, it is difficult to know what to make of the conflicting, often limited quality, data in this area. The cynic might say that one can only be reasonably confident of one thing: reimbursement drives practice.

Stent Graft

In the Japanese multicenter Viabahn trial that aimed to assess 1-year safety, efficacy, and invasiveness outcomes of endovascular stent grafting of symptomatic long lesions (≥10 cm) in the SFA as a substitute for above-knee open bypass surgery, the take-home message was "stent grafting appears to be a safe and less invasive alternative to above-knee bypass surgery, providing 88% to 92% primary patency at 12 months in long, complex lesions."[135] Of note, over 97% of the patients had IC, the follow-up was only 12 months, there was no cost-effectiveness analysis, and the only reported clinical outcome was disease-specific HRQL, which increased significantly from baseline.

CONCLUSIONS

Although ET for infra-inguinal PAD has been available for more than 20 years, and while no one doubts that it has an important role to play in the management of both IC and CLTI, at the present time, exactly what that role is, and what technologies are most clinically and cost-effective for which patients, remains unclear.[a]

While there is certainly no shortage of publications,[150] unfortunately, almost all of the reported studies have one or more serious methodologic limitations (Table 110.4) that hamper appropriate translation of the data to everyday clinical practice.[31,53,140,146,151-176] The habit of conflating data gathered in patients with IC and CLTI and focusing on often very short-term, anatomic rather longer-term clinical outcomes are particularly problematic. Given that most patients with IC, and even CLTI, will live more than 5 years, basing the choice of intervention on 6- and 12-month outcome data seems difficult to justify. Even where clinical data are presented, it is important to distinguish between clinical:

1. Efficacy: the ET results in important clinical benefit in a selected group of homogenous patients when performed by a selected group of clinicians (within an explanatory trial)
2. Effectiveness: the ET results in important clinical benefit for many different patients when delivered in most healthcare settings (within a pragmatic trial)

Although both types of trial are required to make progress, to date, virtually of the published ET data falls into the former (efficacy, explanatory) category. However, unfortunately, the results are often presented, and the ET in question marketed, as if they represent the latter, leading to ET devices and techniques being prematurely adopted by some as the new standard of care.

Although there are repeated calls in the literature and at conferences for pragmatic RCTs to demonstrate clinical and sometimes cost-effectiveness, the "inconvenient truth" is that such trials are in very short supply. The result is that to a very considerable extent we practice in absence of a credible "level 1" evidence base, especially when managing CLTI.[94,104,177-179] This leads to significant practice variations and the highly variable outcomes observed between and within countries.[180,181]

At vascular conferences around the world, discussions regarding revascularization, especially in CLTI, often take the form of adversarial debates where opposing factions set out the perceived pros and cons of surgery versus ET. While entertaining, in reality, this approach represents an oversimplification of the clinical challenge. The argument that "all" patients should receive surgery or "all" patients should have ET, or even that "all" patients should be offered revascularization, lacks credibility. The term CLTI refers to a heterogeneous group of patients with differing degrees of tissue damage, ischemia, and infection in association with a wide variety of patterns of arterial disease. As such, the remedy is likely to vary considerably between individuals. This paradigm is emphasized in the GVG on CLTI, which promotes tools such as WIfI and GLASS as a means of appropriately stratifying patients for ET and surgery as well as for future research.

The corollary of the above discussion and approach is that patients with CLTI, and indeed IC, should be managed in a center and by a multidisciplinary team that can offer all of the medical, physical (supervised exercise therapy, orthotics, rehabilitation), ET, and surgical (bypass, podiatry) treatment alternatives.[7] With regard to revascularization, although some physicians can perform ET and surgery, many do not have the skills and/or facilities to be able to offer both with equal facility. This will bias the treatment offered, probably to the detriment of patients. Given the growing complexity of ET and surgical revascularization for CLTI it is not surprising that a relationship has been observed between individual physician case volume

and outcomes.[182] While in some healthcare environments there may be barriers to referring patients on to colleagues with specific skill sets, even within the same institution, the well-established principles of comparative advantage are very likely to produce net long-term benefits to patients and clinicians alike.[183] While important, successfully overcoming the technical challenges posed by complex, multilevel, increasingly distal disease does not always guarantee optimal patient outcomes following initially successful ET, especially in the longer term. Other important ingredients of success include good relationships with community physicians and nurses, medical optimization,[184] and "prehabilitation" prior to intervention, together with well-organized, high-quality follow-up comprising, as necessary and appropriate, rehabilitation, orthotics, prosthetics, and ET/surgical surveillance protocols.

While in the wealthiest of countries, demonstrating the cost-effectiveness of adjuvant and new ET technologies may not (yet) be a requirement for reimbursement by public and private payers, in most healthcare settings around the world this is a very important issue.[185] From an economic viewpoint, each clinically and cost-ineffective intervention is associated with an opportunity cost that has both financial and nonfinancial elements in that, potentially, it prevents another patient from having an intervention that is cost-effective. From a UK perspective, the current striking difference in cost between PBA and DCB, and between BMS and DES, means that drug technologies would have to deliver highly superior clinical outcomes in order to justify their use within current commonly accepted WTP thresholds. So far, there is no evidence that this is the case for either IC or CLTI, and the outcome of BASIL-3 is keenly awaited.

In order to prevent a situation where vascular specialists are still as uncertain about the role of ET for the treatment PAD in a further 20 years as they are now, a new paradigm would seem to be required with regard to the development and evaluation of new endovascular techniques and technologies.[136] To that end, the IDEAL framework describes the advantages and disadvantages of a range of different research methodologies that can be used to provide varying levels of evidence and serve different purposes (Table 110.5; http://www.ideal-collaboration.net/). However, once the assessment stage has been reached, RCTs remain by far the most reliable means of comparing the clinical and cost-effectiveness of alternative treatment strategies and so should be the method of choice whenever practically and financially feasible.[186,187] There is no shortage of patients with IC and CLTI, and so such trials should not, in theory, be logistically difficult or take a long time to report. Funding of such trials by governmental or professional organizations greatly enhances the value of the resulting data by avoiding actual or perceived commercial sponsor bias.[188,189] Objective performance goals (OPGs) are a useful "stepping stone,"[190] but without pragmatic RCTs, OPGs cannot be refreshed, and so over time increasingly come to rely on historical controls. As such, RCTs are required to determine clinical and cost effectiveness once safety and efficacy OPGs have been met.

In summary, there is a growing realization that the quality of reporting needs to improve if advances in endovascular technology are to lead to better outcomes for patients who

TABLE 110.6 BASIL 2/3 and BEST-CLI Trial Endpoints

Endpoints	BASIL 2/3	BEST-CLI

ABPI, Ankle-brachial pressure index; *AFS*, amputation-free survival; *BASIL*, bypass versus angioplasty in severe ischemia of the leg; *BEST-CLI*, best endovascular versus the best surgical therapy in patients with critical limb ischemia; *EQ-5D*, EuroQol five dimensions questionnaire; *HRQL*, health-related quality of life; *MALE*, major adverse limb event; *POD*, perioperative death; *RAFS*, re-intervention and amputation-free survival; *TBPI*, toe-brachial pressure index; *VascuQoL*, vascular quality of life.

present with lower limb PAD. The authors of the SVS Reporting Standards eloquently express this as follows[191,192]:

"PAD represents a spectrum from asymptomatic stenosis to limb-threatening ischemia. The last decade has seen a tremendous increase in the variety of endovascular devices and techniques to treat occlusive disease. Like many evolving technologies, the literature surrounding therapy for endovascular arterial disease consists of mixed-quality manuscripts without clear standardization. Accordingly, critical evaluation of the reported results may be problematic. As such, providers and their patients make treatment decisions without the full benefit of a comparative effectiveness framework."

In an attempt to raise the quality of the science underpinning ET, and to promote evidence-based revascularization (EBR), GVG suggests the following quality standards when designing RCTs:

1. Inclusion and exclusion criteria should be limited to those essential to trial integrity.
2. IC and CLTI patients should not be enrolled within the same trial.
3. CLTI trials should include patients with tissue loss, not just rest pain.
4. An integrated limb-based limb threat system (such as WIfI)[72,125,149,193,194] and a whole limb anatomical classification system (such as GLASS) should be used to describe the clinical and anatomic characteristics of enrolled patients.
5. Clinical efficacy and clinical effectiveness should be clearly distinguished.
6. Use a range of endpoints (Table 110.6) including:
   a. Objective clinical: for example, AFS, MALE free survival, and time to wound healing[195] and relief of rest pain
   b. Subjective clinical: for example, patient-reported outcomes measures (PROMs) and HRQL instruments[196-198]; these permit a "time-integrated measure" measure of clinical disease severity from the patient's perspective
   c. Hemodynamic: for example, ankle and toe pressures and indices[199]
   d. Anatomic; for example, patency, restenosis, TLR, TVR
7. A full heath economic (cost-utility) analysis should be included so that each healthcare system can determine whether and how the clinical data should be used in relation to individual countries' WTP thresholds based on economic, societal, and political considerations.[200]
8. Follow-up patients for at least 2 to 3 years; 6- or 12-month follow-up periods are unlikely to be adequate and may well be misleading.
9. Publish all trial protocols, together with the full statistical analysis plan, in peer-reviewed journals to allow for independent, public, and transparent scrutiny.
10. Share data between RCTs to allow subsequent IPD meta-analyses and subgroup analyses.
11. The design, conduct, and reporting of trials should be free of commercial influence.[189]

CHAPTER 111

Lower Extremity Amputations: Epidemiology, Procedure Selection, and Rehabilitation Outcomes

CHRISTIAN BIANCHI and AHMED M. ABOU-ZAMZAM Jr.

EPIDEMIOLOGY 1483
Variation in Amputation Rates 1483
Effects of Ethnicity, Economic, and Social Factors 1483
Effect of Revascularization Rates 1483
INDICATIONS FOR AMPUTATION 1484
Impact of Diabetes 1484
Impact of Tissue Loss and Anatomy 1484
Impact of Delay in Presentation 1485
PRIMARY AMPUTATION VERSUS REVASCULARIZATION 1485
Groups Benefiting From Primary Amputation 1485
PERIOPERATIVE EVALUATION 1486
Perioperative Stages 1486
Reducing Perioperative Risk 1486
Managing Infection 1487
Planning Rehabilitation 1487
AMPUTATION LEVEL SELECTION 1487
Objective Testing and Clinical Judgment 1488
Physical Findings 1488
Skin Temperature Measurements 1488
Ankle and Toe Pressure Measurements 1488
Arteriography 1488
Radioisotope Scans, Scintigraphy, and Skin Perfusion Pressure 1488
Transcutaneous Oxygen Measurements 1489
Technique Selection 1489
REHABILITATION CONSIDERATIONS 1489
Amputation Wound Dressings 1490
Prosthesis Selection and Training 1491
FUNCTIONAL OUTCOME 1492
Impact of Amputation Level and Comorbidities 1492
Impact of Age 1493
Fate of the Contralateral Limb After Amputation 1493
Depression After Amputation 1493
SELECTED KEY REFERENCES 1493

Major lower extremity amputations continue to be part of all vascular practices despite the general approach of aggressive limb salvage. Although often viewed as a failure of treatment, major amputation should be considered a reconstructive and definitive treatment option. The convergence of several important factors, including the increased life expectancy of the population and the epidemics of diabetes and peripheral artery disease (PAD), suggests that amputations will remain an important issue facing patients and surgeons for the foreseeable future.

The goal of amputation is to remove all infected, gangrenous, and ischemic tissue and provide the patient with the longest functional limb. Avoidance of repeated amputations and uncomplicated healing of operative sites is crucial for the patient's optimal recovery and best functional rehabilitation or palliation.

Abstract

Despite advances in limb salvage, major lower extremity amputations continue to be part of all vascular practices. Major amputation should be considered a reconstructive, definitive treatment option. The goal of amputation is to remove all infected, gangrenous, and ischemic tissue and provide the patient with the longest functional limb. Appropriate level selection, careful attention to comorbidities and appropriate rehabilitation goals can lead to optimal patient recovery and meaningful functional outcomes.

EPIDEMIOLOGY

In the United States, approximately 60,000 major amputations (above the ankle) are performed annually.[1-3] Diabetes and PAD remain the major risk factors for lower extremity amputation worldwide.[4] Studies show that 25% to 90% of all amputations are associated with diabetes.[2,4] Patients with diabetes have an eightfold greater risk of amputation than those without diabetes.[3] This association is due to the presence of neuropathy and infection, as well as the increased prevalence of PAD in this patient population.

Despite the increase in diabetes, current published data support an overall decrease in major amputation rates.[5-7] A review of all Medicare claims from the Centers for Medicare and Medicaid Services between 1996 and 2006 showed a 29% decline.[5] Results were not different if above-knee amputations (AKAs) were studied distinctly from below-knee amputations (BKAs), because both decreased in similar magnitude. A report from the National Hospital Discharge Survey data on nontraumatic lower extremity major amputations (NLEAs) and National Health Interview Survey data on diabetes prevalence showed the age-adjusted NLEA discharge rate per 1000 persons decreased from 11.2 in 1996 to 3.9 in 2008, while rates among persons without diabetes were unchanged.[3] These trends were validated in a Scottish national cohort study from 2004 to 2008 where major amputations rates decreased by 40.7% from 1.87 per 1000 in 2004 to 1.11 per 1000 in 2008.[7] However, some recent data suggest that these decreases may have leveled off since 2009.[8]

Variation in Amputation Rates

There is significant regional variation in the performance of amputation around the world, which suggests that factors other than strict medical issues may affect amputation rates.[4-10] A study from the United Kingdom cited significant regional variation in amputation rates and stressed the need for consensus guidelines.[9] The Global Lower Extremity Amputation Study Group reported that the highest amputation rate (for a first major amputation) was 44 per 100,000 population per year among Navajo men, and the lowest rate was 2.8 per 100,000 per year in Madrid, Spain.[4] Physician experience plays a key role in the selection of amputation as a treatment. In the treatment of critical limb ischemia, surgeon caseload and hospital volume have been shown to affect amputation rates, with low volumes being associated with higher amputation rates.[11]

A study of a Medicare claims database demonstrated that the supply of vascular specialists influences the rate of amputation. A 0.30 increase in the number of vascular surgeons per 10,000 Medicare beneficiaries was associated with a 1.6% reduction in amputations.[12] The distribution of vascular surgeons and interventional radiologists in the United States is strongly correlated not only with regional medical needs but also with local climate, education, crime, and transportation. This observation suggests that policies to increase the supply of vascular specialists in underserved areas may reduce regional disparities in amputation rates.[12] Patient and healthcare provider education has also been demonstrated to reduce amputation rates.[13] Earlier identification of patients at risk leads to timelier referral, treatment, and intervention.

Effects of Ethnicity, Economic, and Social Factors

A complex interaction exists between race or ethnicity and amputation rates. In certain groups, such as the Native American Navajo population, amputation rates appear to be related to the high incidence of diabetes.[4] However, blacks are more likely than whites to undergo amputation as opposed to revascularization, even when controlling for the presence of diabetes.[14,15] These differences have been attributed to variations in access to healthcare, treatment of comorbidities, and possible physician and patient factors. Insurance status also has an effect on amputation rates. Patients without insurance coverage have higher rates of amputation than those with access to health insurance.[16] Data from the National Inpatient Sample documented that 34% of the 691,833 patients presenting with lower extremity ischemia from 1998 to 2002 underwent amputation. The primary amputation rates were significantly higher among patients who were nonwhite, low income, and without commercial insurance.[16] Similar results showed that black patients were 1.7 times more likely to have both primary and repeat amputation than other patients.[17] These findings may be affected by the recent changes in access to healthcare put forward by the Affordable Care Act. In Massachusetts, the expanded insurance coverage initiated in 2006 appears to have decreased some disparities that previously existed between whites and nonwhites presenting with PDA.[18] Whether this can be repeated on a national scale remains to be seen.

Effect of Revascularization Rates

Trends in the interplay between revascularization and amputation rates are complicated. Over a 10-year period the Mayo Clinic reported a 50% reduction in amputation rates that corresponded to increased rates of lower extremity revascularization by both surgical and endovascular (EV) techniques.[19] A Finnish study also demonstrated that an increase in revascularization rates correlated with a decrease in major amputation rates in elderly patients.[20] A US study of two national (Nationwide Inpatient Sample and National Hospital Discharge Survey) and four state databases demonstrated that both the number of lower extremity revascularizations and the number of major amputations have declined; this has been accompanied by a substantial increase in lower extremity EV interventions. From 1998 to 2003 the volume of major amputations decreased 16% regionally[1] (New York, California, New Jersey, and Florida) and 25% nationally.[5] However, minor amputations increased 4% regionally and 3% nationally. It has been speculated that the improved limb salvage rates are partially explained by the increase in total revascularization procedures (driven by EV interventions due to the perceived less morbidity). Earlier EV interventions, in less critical lesions, and expanding EV procedures in the patient at high-risk for open bypass may contribute to the decrease rates of major

amputations. In addition, failed EV procedures may not directly translate into amputations. Other possible factors contributing to lower rates of amputation include greater awareness of PAD, clear guidelines for medical management of atherosclerosis, risk factor modification, and improved wound care methods.

High-risk patients treated with EV intervention have superior rates of limb salvage and maintenance of ambulation compared with patients undergoing primary amputation. However, these patients have no better functional benefit than those treated with primary amputation after 1 year.[21] Indeed, when autologous vein is available, the long-term results of the Bypass versus Angioplasty in Severe Ischemia of the Leg (BASIL) trial indicate that the outcomes of a bypass surgery–first approach is superior to a balloon angioplasty–first strategy in terms of amputation-free survival.[22]

The ideal balance of EV and open surgical reconstructions has yet to be determined for lower extremity ischemia. Nationwide Inpatient Sample data suggest that lower extremity revascularizations have reached a plateau of approximately 140,000; similarly, major amputation may have settled near 60,000 annually.[1,2] The total number of revascularizations has increased due to rising numbers of EV procedures, and this may be underestimated because same-day EV procedures might not be included in the Nationwide Inpatient Sample database.[2] The Trans-Atlantic Inter-Society Consensus (TASC) II Working Group documented that the incidence of major amputations varies from 12 to 50 per 100,000 population per year.[23] With the aging of the population, future trends in these areas will have a great effect on healthcare expenditures.

INDICATIONS FOR AMPUTATION

Indications for amputation have traditionally been divided into acute ischemia, chronic ischemia, foot infection, severe traumatic injury, and lower extremity skeletal or soft tissue malignancies. Trauma and malignancy are beyond the scope of this chapter and are not discussed. In the presence of acute ischemia, major amputation is undertaken for irreversible ischemia, for severe ischemia with no revascularization options, or following unsuccessful attempts at revascularization. Amputation for chronic ischemia may be performed owing to failure of revascularization, lack of suitable conduit or target arteries, severe patient comorbidities, poor functional status, or extensive gangrene or infection such that foot salvage is not possible. Pedal sepsis without ischemia constitutes another major subgroup of patients undergoing amputation; this presentation is extremely common in patients with diabetes and associated neuropathy. Because the underlying indications for amputation frequently overlap, it can be difficult to compare indications for and outcomes of amputations reported in the literature.

Impact of Diabetes

The presence of PAD and diabetes, either alone or in combination, contributes to the majority of major nontraumatic lower extremity amputations. Li et al. describe the overall incidence of diabetes in patients undergoing amputation as approximately 60%.[3] This information is based on hospital discharge diagnoses and may not be entirely accurate. However, many general classifications overemphasize the role of diabetes and understate the role of concomitant ischemia. Malone reported the indications for amputation as follows: complications of diabetes (60%-80%), infection without diabetes (15%-25%), ischemia without infection (5%-10%), chronic osteomyelitis (3%-5%), trauma (2%-5%), and miscellaneous (5%-10%).[24] These general classifications have a certain degree of overlap and mask the true interaction between ischemia and diabetes. This simplistic breakdown does not provide clear insight into the true influence of ischemia or the full potential of revascularization to reduce amputation rates. In addition, because no revascularization is universally successful, amputation may ultimately follow revascularization.

Impact of Tissue Loss and Anatomy

Attempts have been made to more clearly categorize the indications for major amputation to explain why amputations continue to be performed despite aggressive revascularization programs.[25] When identifying the indications for amputation, it must be recognized that with chronic ischemia, limb loss may ultimately occur despite revascularization. In addition, patients may present initially with acutely or chronically ischemic limbs that are beyond any hope of salvage. The influence of gangrene and pedal sepsis must also be considered because they have a significant impact on the options for limb salvage. Lastly, patient comorbidities and ambulatory status influence the decision for amputation.

The TASC II Working Group reported that the rate of primary amputation in chronic critical leg ischemia is approximately 25%. Unreconstructable vascular disease is the most common indication for secondary amputations, which account for nearly 60% of patients.[23]

To more clearly delineate the reasons for major amputation in an academic vascular practice, a series of 131 consecutive major lower extremity amputations were reviewed and the indications for amputation clearly classified (Table 111.1). In this setting, more than 50% of patients who underwent amputation had prior attempts at limb salvage via revascularization or had no anatomically feasible revascularization options. This group of patients had exhausted the armamentarium of vascular surgery. Seventeen percent of patients were not considered candidates for aggressive attempts at limb salvage owing to a preexisting nonambulatory status (8%) or the presence of excessive surgical risk (9%). In addition, 32% of patients had nonsalvageable limbs at presentation due to extensive pedal gangrene, pedal sepsis, or a nonviable foot that mandated primary amputation.

Similar findings were reported by Nehler and colleagues in a series of 172 major amputations.[26] The indication for amputation was critical ischemia in 87% and complications of diabetic neuropathy without significant ischemia in 13%. Forty-six patients (30%) had prior bypass failures or amputations despite patent reconstructions, and 10 (6%) had no revascularization options; therefore, 36% had exhausted the resources of

TABLE 111.1 Indications for Major Amputation by Vascular Surgeons

Indication for Major Amputation	Percentage of Cases ($n = 131$)
Critical limb ischemia with failed revascularization	39
Extensive pedal gangrene	15
Unreconstructable arterial anatomy	11
Overwhelming pedal sepsis	9
Excessive surgical risk	9
Nonviable, acutely ischemic foot	8
Nonambulatory status	8

revascularization. Eighty-five patients (55%) underwent primary amputation because of severe comorbidities, poor functional status, extensive necrosis, or a combination of these factors. Together the previous studies highlight the central role of both ischemia and tissue loss in the determination of the need for major amputation.

The recently developed SVS-WIfI classification system may help to define the factors influencing limb salvage and need for amputation.[27] This system includes the key elements of Wound, Infection, and foot Ischemia (WIfI). By stipulating and quantifying these individual contributors to the threatened limb, the WIfI score can give greater detail than other available tools. Early validation studies have demonstrated that worsening WIfI stages are associated with major amputation in patients undergoing revascularization for chronic limb-threatening ischemia (CLTI).[28]

Impact of Delay in Presentation

The significant role of delay in patient presentation cannot be overstated. The mean time to vascular surgery consultation was 73 days for pedal tissue loss and 27 days for ischemic rest pain in the report by Nehler and colleagues.[26] This delay likely accounts for the large percentage of primary amputations in their series and underscores the need for patient and physician education. Indeed, in a report by Bailey and coworkers, only 24% of patients with critical limb ischemia were perceived as needing "urgent" vascular consultation, with a mean 8-week duration of symptoms before vascular evaluation.[29] This suggests that delayed patient presentation involves not just patient factors but also access issues and physician factors.

PRIMARY AMPUTATION VERSUS REVASCULARIZATION

The most important decision in treating CLTI is the initial determination of whether to attempt limb salvage or proceed with primary major amputation. Despite widespread discussion of great triumphs in revascularization, there is a growing awareness that primary amputation may be the best approach in specific patient subsets. As stated earlier, more than 140,000 lower extremity revascularizations are performed annually in the United States. In recent years, open revascularizations have been partially replaced by EV procedures, yet nearly 60,000 major amputations are still being performed each year.[1,2] This implies that the ratio of amputation to revascularization may be close to 1:2 nationally. Many specialty centers may have a much lower ratio, owing to the filtering effect of referring physicians. Many patients perceived as not being candidates for revascularization are treated locally with amputation and are never referred to these high-volume centers specializing in revascularization.

The ratio of major primary amputation to revascularization differs among facilities and may vary because of surgeon experience and practice protocols. One prospective study demonstrated that 43% of the 224 patients presenting with limb-threatening ischemia were treated by primary amputation, and 57% were treated with revascularization.[30] Diabetes mellitus, end-stage renal disease, tissue loss, and poor functional status were all predictors of treatment with amputation as opposed to revascularization.

Groups Benefiting From Primary Amputation

A very reasoned approach to patients presenting with CLTI is necessary. A thoughtful strategy considering the patient's comorbidities, the status of the foot, and the complexity of the required revascularization has been outlined by Nehler and colleagues.[31] In a good-risk patient with minimal pedal tissue loss, an aggressive attempt at revascularization should be undertaken with appropriate EV or open bypass techniques including the consideration of alternative vein conduits. However, when the patient's overall health status is poor or the foot lesions are extensive, primary amputation must be considered. An aggressive use of revascularization, particularly EV interventions, likely has resulted in limb salvage attempts in higher-risk patients that may have helped to decrease overall major amputations.[1,2] Despite this, secondary amputations are not an uncommon occurrence. In a study that included 358 consecutive patients (412 limbs), patients with limb loss despite patent EV interventions were compared with the rest of the EV-treated group and with those who underwent amputations with patent bypasses (APBs). Amputations occurring despite a patent revascularized segment constituted 38% of limb loss in open and 80% in EV-treated patients ($P = .001$). Most amputations in the EV group were performed within 3 months and the indications were extensive tissue loss or limb dysfunction after radical débridement of infection or gangrene (37%), recurrent infection (42%), and failure to reverse ischemia (21%).[32]

The perceived improved outcomes following revascularization compared with amputation have driven the belief that revascularization is always the better option. However, an examination of the data demonstrates that functional outcomes following

amputation may not be markedly different from those following revascularization for specific patient subgroups. Taylor and associates analyzed 553 patients who underwent 627 primary major limb amputations.[33] In patients younger than 60 years, functional outcomes following BKA were similar to those of patients undergoing successful revascularization. Such information lends credence to the observation that primary amputation should be considered not a failure of therapy but a valuable, important treatment option.[26,31,33]

The advances in percutaneous revascularization have raised the question of how best to treat the patient considered "unfit" for open revascularization. Taylor and coworkers reported an analysis of 314 patients treated for critical limb ischemia who were unsuitable for open revascularization owing to medical, functional, or mental comorbidities.[21] Patients were treated with either percutaneous transluminal angioplasty (PTA) or major amputation. The 131 patients treated with PTA had higher rates of maintenance of ambulation and independent living compared with the 183 patients treated with amputation. However, the PTA group had a higher mortality rate, and the advantages in ambulation and independent living lasted only 12 months and 3 months, respectively. In the "unfit" patient, EV treatment may indeed be no better than primary amputation.

Indeed, in patients with extensive foot lesions, severe comorbidities, or very unfavorable anatomy, primary amputation is often the best treatment option.[26,31,33] Because of delayed referral, many patients ultimately undergoing amputation present to the vascular surgeon with extensive pedal necrosis, which makes limb salvage unlikely, regardless of arterial targets for revascularization. End-stage renal disease presents a particularly difficult challenge, and the presence of advanced heel gangrene in this group of patients may best be treated with primary amputation.[34,35]

PERIOPERATIVE EVALUATION

Although surgeons have traditionally focused on the preoperative evaluation and near-term (usually 30-day) results of amputations, a lengthier view of the perioperative period can be helpful. For the patient, the overall experience is important and clearly lasts longer than the 30-day postoperative period. A more global view of the patient during the first year may help to identify key issues at different points in the patient's treatment and recovery. A team approach to the patient is useful during all stages of the perioperative period because the results in any series of amputations are directly related to the skill and enthusiasm of the people involved in the program.[36] Members of the team include the patient, family, surgeon, physiatrist, therapist, rehabilitation medicine specialist, prosthetist, nurse, social worker, psychologist, peer support group, and case manager. The common goal should be maximum recovery and rehabilitation after limb loss. The team should be flexible because different team members share the leadership and service responsibilities throughout the 12- to 18-month time frame that typically defines the perioperative period following a major amputation.

Perioperative Stages

The postoperative year-long continuum does not separate easily into "stages." However, for practical purposes, five stages in the treatment of the amputation patient have been described.[37]

Stage 1: This is the preoperative stage which starts with the very difficult decision of whether to amputate. This stage includes an assessment of the vascular status and decisions on attempts to improve circulation. The preoperative evaluation of a patient undergoing major amputation should strive to reduce perioperative complications and mortality. The preoperative evaluation should be rational and expeditious. Evaluation should include the duration and severity of limb ischemia, extent of tissue loss, presence of wound infection, and anatomic considerations of revascularization. An analysis of the patient's systemic comorbidities is essential and should be performed systematically. The surgeon typically is the team leader during this stage.

Stage 2: Once the surgery is completed, the acute hospital postoperative stage begins and is the time the patient spends in the hospital after the amputation until discharge. This stage typically ranges from 3 to 10 days. During this time, transition of care to the appropriate rehabilitation experts is appropriate. The surgeon is still involved because treatment for local and systemic complications is important.

Stage 3: The *immediate post acute hospital stage* begins with hospital discharge and extends 4 to 8 weeks after surgery. This is the time of recovery from surgery, a time of wound healing, and a time of early rehabilitation. During this phase the surgeon is less involved, but uncomplicated wound healing is essential to early rehabilitation.

Stage 4: The intermediate recovery period (stage 4) is the time of transition from a postoperative strategy to the first formal prosthetic device. It is during this stage that the most rapid changes in limb volume occur, due to the beginning of ambulation and prosthetic use. This stage begins with the completed healing of the wound and usually extends 4 to 6 months from the healing date.

Stage 5: The fifth stage (transition to stable stage) is defined as a period of relative limb stabilization, although the limb will continue to change to some degree for a period of 12 to 18 months after initial healing. The newer prosthesis will still require occasional adjustments, and visits to the prosthetist will remain relatively frequent until after the first year of prosthetic use. In this phase the patient should move toward social reintegration and higher functional training. The patient should become more empowered and independent from his or her healthcare practitioner during this period.

Reducing Perioperative Risk

The quoted overall mortality for major amputations is approximately 8%. Most reports double the mortality when comparing AKAs to BKAs.[38] A study of 2911 patients enrolled in the ACS National Surgical Quality Improvement Program (NSQIP) demonstrated a 30-day mortality of 7% for BKAs. Multivariate analysis identified renal insufficiency, cardiac issues, preoperative

sepsis, COPD, steroid use, and increased patient age as predictors of mortality.[39] The same study identified preoperative sepsis, regular alcohol use, steroid use, cardiac issues, renal disease, and contaminated/infected wounds to be independent predictors of developing postoperative complications. The overall perioperative complication rate was 34.4%. Local stump complications occurred in nearly 10% of patients. Of note, the incidence of cardiopulmonary, venous thromboembolic, and cerebrovascular events ranged from 0.5% to 2.1%. The low observed incidence is probably due to the current widespread use of beta blockers, statin therapy, and antithrombotic medications in the vascular patient.[40,41] A similar study involving 8696 veterans showed that AKA patients were older (69.0 vs. 66.5) and suffered a higher mortality (16.5% vs. 9.7%) when compared with BKA patients, whereas both groups had a similar rate of postoperative complications.[10] This study found that increased age, increased patient complexity, and admission with acute thromboembolism were predictive of death.[10]

Perioperative treatment with antiplatelet agents, statin medications, and beta blockade has been extensively studied in the general vascular surgery population, but many of these important studies included few patients undergoing major amputation.[40,41] Although the data now suggest a limited role of beta blockade in naïve patients, there does continue to be support for use of antiplatelet and statin medications in the patient population presenting for amputation.[41,42] With regard to the need for preoperative "cardiac clearance," the guidelines by the American College of Cardiology and the American Heart Association state that the purpose of preoperative cardiac evaluation is not to give medical clearance but rather to evaluate the patient's current medical status and cardiac risks over the entire perioperative period.[41] These guidelines recommend that no test be performed unless it is likely to influence the patient's treatment.[4,12]

The management of associated hypertension, diabetes, and renal failure should be optimized. Antiplatelet and statin medications can be safely continued throughout the hospitalization. The timing of hemodialysis in relation to operation is important in managing fluids and electrolytes in the perioperative period. An aggressive approach to normalize glucose levels is essential to ensure proper wound healing. VTE prophylaxis with either subcutaneous unfractionated heparin or low-molecular-weight heparin appears to be safe and effective.[43] The importance of thromboprophylaxis is reflected in the fact that up to 17% of all amputation-related deaths are caused by pulmonary emboli.[39] Noteworthy is the propensity of these patients to fall, and fall precautions should be instituted during the early postoperative care.

Managing Infection

Special consideration should be given to patients presenting with extensive pedal infection necessitating amputation. Aggressive control of infection, with surgical extirpation of the source and adjunctive intravenous antibiotics, is the mainstay of treatment. The two-stage approach of guillotine amputation followed by formal amputation several days later has a lower complication rate than single-stage amputation.[44] Guillotine amputation is a rapid procedure, but an additional operation to treat the amputation stump is necessary.

Another option in patients who are moribund is a physiologic cryoamputation, which can be performed safely at the bedside.[45,46] The materials needed to perform cryoamputation are dry ice, a large plastic bag, an umbilical tape to use as a tourniquet, towels, blankets, adhesive tape, and a heating pad. After parenteral analgesics are administered, an umbilical tape is tied around the affected extremity just proximal to the diseased area. A large plastic bag is placed over the distal leg and filled with dry ice, circumferentially covering the leg. The dry ice bag is wrapped with blankets and secured with adhesive tape. A heating pad covered with a protective towel is placed around the proximal extremity adjacent to the frost line. The opposite leg should be covered with numerous blankets to avoid collateral injury. The frost line and the frozen limb should be checked periodically by the nursing staff, and dry ice added as needed. This bedside procedure alleviates any time pressures for amputation, controls infection, and allows optimal treatment of associated conditions. If necessary, a cryoamputation can be maintained for several weeks. When the patient's status improves, he or she may be taken to the operating room for a one-stage amputation.

Planning Rehabilitation

Whenever possible, preamputation evaluation of rehabilitation and prosthetic candidacy should be performed. Centers with dedicated multispecialty teams have much more successful rehabilitation outcomes.[47] Understanding the various stages of the perioperative period and adjusting the areas of focus throughout the recovery period may optimize the outcomes. Tempering the patient's expectations, the timing of prosthetic use, and reinforcing the ultimate functional goals is best undertaken by the team members throughout the perioperative period.

AMPUTATION LEVEL SELECTION

The goals of amputation are (1) to eliminate all infected, necrotic, and painful tissue; (2) to achieve uncomplicated wound healing; and (3) to have an appropriate remnant stump that can accommodate a prosthesis. The length of the preserved limb has important implications for rehabilitation. Prosthetic use following major amputation puts an increased energy demand on the patient. Unilateral below-knee amputees require a 10% to 40% increase in energy expenditure for ambulation, and above-knee amputees require 50% to 70% more energy to ambulate.[24] This differential may explain why the successful rehabilitation rate is much lower following AKA than BKA. Prosthetic use is reportedly 50% to 100% following BKA but only 10% to 30% following AKA.[26,47-49] Interestingly, the true rate of ambulation is significantly lower than that of prosthetic use and shows a steady attrition in the 5 years following amputation.[26,48,49] Partial foot or toe amputations are minor procedures that preserve the majority of the extremity and allow ambulation without the need for bulky prostheses. Most minor amputations, including

toe and ray amputations, lead to minimal increases in energy expenditure and require simple orthotic inserts.

Failure of an amputation to heal is multifactorial. Much emphasis has been placed on assessing blood flow at the level of the amputation to predict wound healing. However, failure may be caused not just by ischemia but also by infection, hematoma, or trauma related to falls. This explains why no single test can predict with 100% accuracy the ability of an amputation to heal or, conversely, its inability to heal. Most tests are better at predicting wound healing than failure to heal. Thus using any single criterion may lead to unnecessarily proximal amputation.

The importance of optimizing level selection is underlined by the need to revise BKAs to AKAs in 15% to 25% of patients.[2,25,26,50] This revision rate is frequently accompanied by a perioperative mortality rate of greater than 5%.[24] Such events also lead to increased patient anxiety and fear of repeated, more proximal amputations.

Objective Testing and Clinical Judgment

The drive to maximize limb length in amputees and to minimize the need for revisions has led to a search for the optimal modality for selecting an amputation level. Physical findings (pulses, skin quality, extent of foot ischemia or infection, skin temperature), noninvasive hemodynamic tests (segmental arterial pressures, Doppler waveforms, toe pressures), invasive anatomic tests (angiographic scoring systems), and physiologic tests (skin blood flow, skin perfusion pressure, muscle perfusion, transcutaneous oxygen measurements) have all been extensively investigated.

Physical Findings

Physical examination is the essential first step in determining the level of amputation. The extent of gangrene and infection dictates the maximal length attainable. In this evaluation the presence of dependent rubor should be considered analogous to gangrene because this tissue is ischemic. The presence of pulses should be accurately assessed. The presence of a palpable pulse immediately proximal to a proposed amputation level predicts successful healing in nearly 100% of patients undergoing either major or minor amputation.[51,52] However, the absence of a pulse does not necessarily lead to failure of wound healing; therefore, sole reliance on the presence of a pulse leads to unnecessarily proximal amputations.

Using "clinical judgment," which incorporates physical findings and consideration of the patient's overall status, yields wound healing rates of 80% in BKAs and 90% in AKAs. Wagner and colleagues found that objective data may supplement clinical judgment but not replace it; more distal amputations were achieved with clinical judgment than with sole reliance on objective examinations.[53] Experience is important in the determination of amputation level; therefore, this should not be relegated to junior surgeons or trainees.

Skin Temperature Measurements

The subjective interpretation of skin temperature as a guide for amputation is not reliable. However, several investigators have demonstrated that objective, direct skin temperature measurement may predict amputation healing with an accuracy of 80% to 90%.[53,54] In a study comparing several noninvasive techniques, direct skin temperature measurement at the level of amputation with a threshold of 90°F demonstrated the best accuracy.[53] Special attention must be paid to room temperature, and comparison with a normal contralateral extremity can be helpful.

Ankle and Toe Pressure Measurements

The use of noninvasive hemodynamic tests has been extensively evaluated. Frequently used tests are segmental arterial pressures, Doppler waveforms, and toe pressures. Absolute ankle pressures greater than 60 mm Hg can predict the healing of BKAs with an accuracy of 50% to 90%. Calf pressures and thigh pressures have shown similar reliability.[2] However, Wagner and colleagues found that Doppler-derived pressures at the thigh, popliteal, calf, and ankle levels are less reliable than clinical judgment in predicting the healing of BKAs.[53] This inaccuracy may be due in part to the high prevalence of diabetes in this population, making measured pressures less reliable because of medial calcinosis.

The ankle-brachial index (ABI) should always be obtained, regardless of the presence of a palpable pulse. Marston and colleagues reported on the role of ABI in predicting the need for amputation in a cohort of high-risk patients with critical limb ischemia treated with meticulous wound care but without revascularization. In patients with an ABI less than 0.5%, 28% and 34% of limbs required amputation at 6 and 12 months, respectively, versus 10% and 15%, respectively, of limbs in patients with an ABI greater than 0.5 ($P = .01$).[55]

The use of toe pressures has been advocated as being predictive of forefoot amputation healing. Vitti and associates demonstrated universal failure of minor amputations in patients with diabetes and toe pressures less than 38 mm Hg.[56] However, there was no similar threshold value in patients without diabetes, limiting the usefulness of this parameter.

Arteriography

Invasive testing with arteriography has been investigated as a means of determining amputation level, but the correlation between arteriographic findings and healing potential has been poor. Dwars and coworkers found that angiographic scores did not correlate with amputation healing.[52] In fact, in their report, angiographic patency tended to be greater in limbs with failed or delayed healing than in limbs with successful healing.

Radioisotope Scans, Scintigraphy, and Skin Perfusion Pressure

All physiologic tests attempt to predict wound healing based on tissue perfusion or oxygen delivery at the proposed level of amputation. One technique of measuring skin blood flow involves injecting an intradermal isotope (xenon 133 or iodine 125) and then calculating blood flow by measuring the isotope washout rate using nuclear medicine scanning devices.[24,57] Malone and associates initially reported excellent results with xenon 133 clearance, with an accuracy of 92% to 97%.[58] However, in a follow-up report, this same group found that the overlap

in values between patients with healed and failed amputations made this test too unreliable.[57]

Sarikaya and coworkers used technetium (Tc) 99m sestamibi scintigraphy to predict the healing of extremity amputation based on deep tissue perfusion.[59] Perfusion to the ischemic limb was evaluated preoperatively based on the Tc 99m sestamibi uptake pattern. Nonviable tissue in the extremity was suggested by a clear-cut edge of perfused muscle. The most distal level of amputation was determined above the nonviable tissue. In their 25 patients the proposed level of amputation based on physical examination and Doppler study was changed to a lower level after Tc 99m sestamibi scintigraphy in 65% of cases, and all amputation wounds healed.

Skin perfusion pressure is another physiologic test to determine amputation level. This test involves a scintigraphic technique in which intracutaneous iodine 123 is injected at different amputation levels. External pressure is applied, and by measuring the washout of isotope, the skin perfusion pressure is determined. A level less than 20 mm Hg was predictive of wound failure in 89% of amputations, and a reading greater than 20 mm Hg predicted healing in 99%.[52] Skin perfusion pressure can also be measured by laser Doppler velocimetry, thus avoiding the need for isotopes and markedly simplifying the test.

Skin fluorescence uses a Wood or ultraviolet light following the intravenous injection of fluorescein dye. A qualitative determination of regional blood flow is used to determine the level of amputation. Success rates in predicting healing have ranged from 86% to 100%.[24] Owing to the wide availability of these tools and no requirement for radioisotope, this technique is more accessible than scintigraphic techniques. However, the fluorescein technique may be more affected by the presence of inflammation and cellulitis than are scintigraphic techniques.

Transcutaneous Oxygen Measurements

Transcutaneous oxygen measurement is a completely noninvasive method that may be used to select an amputation level. A small sensor is placed on the skin in the area of interest. By heating the sensor and skin to 44°C, local skin hyperemia results in decreased flow resistance and arteriolarization of capillary blood. The partial pressure of oxygen measured transcutaneously ($tcPO_2$) approximates the true arterial oxygen pressure in the area of interest.[60] The sensors can be placed anywhere on the body, and readings are given in millimeters of mercury (mm Hg). Absolute readings can be recorded, or readings in areas of interest can be indexed to a reference site (often the chest). The probes are small and atraumatic, and multiple sites can be tested simultaneously, depending on the machine. Readings in the supine position are more predictive than measurements in the dependent position or during supplemental oxygen breathing.[61] The values recorded are reliable and show an acceptable day-to-day variability in repeat measurements.[62]

Transcutaneous oxygen levels have an accuracy of 87% to 100% in predicting wound healing.[51,57,63] Malone and coworkers reported no amputation failures in patients with $tcPO_2$ greater than 20 mm Hg and universal failure when $tcPO_2$ was less than 20 mm Hg.[57] Unfortunately, other investigators have not confirmed any consistent absolute $tcPO_2$ threshold.[51,53] Some authors have reported a useful $tcPO_2$ threshold of 30 mm Hg, whereas others have reported 16 mm Hg as a cutoff value. In general, $tcPO_2$ readings greater than 40 mm Hg are associated with healing and readings less than 20 mm Hg are associated with failure.[60,63] The lack of a consistent minimal level is likely due to the fact that nutrient blood flow may be present even in the setting of $tcPO_2$ readings of 0 mm Hg. The $tcPO_2$ may be artificially low in the setting of infection, inflammation, or edema, and repeat measurements are advised once such processes have resolved. Incidentally, in addition to modest utility in predicting wound healing, $tcPO_2$ has accuracy in predicting outcome following revascularization. Increases in $tcPO_2$ of greater than 30 mm Hg following revascularization are predictive of a successful clinical outcome.[63]

In direct comparisons with segmental pressures and skin blood flow, $tcPO_2$ has been the most accurate predictor of wound healing.[57] This applies not only to major amputation but also to forefoot amputation.[64] Transcutaneous oxygen measurements are also more accurate than fluorescein dye injections.[57] In addition, $tcPO_2$ has several advantages over other tests in terms of ease of measurement, reproducibility, and simple instrumentation that can be readily introduced into any vascular laboratory.

Yamada and colleagues studied 211 patients with 403 ischemic limbs using skin perfusion pressure, toe pressure, ankle pressure, and $tcPO_2$.[65] The correlations between these methods demonstrate that the combination of skin perfusion pressure and toe pressure can accurately predict wound healing. However, the combination of skin perfusion pressure and $tcPO_2$ did not result in a more accurate prediction. A meaningful approach to the accurate determination of amputation level should therefore include a combination of physical findings, clinical judgment, and objective testing.[51-53,57,60]

Technique Selection

Whether skin temperature, skin blood flow or perfusion, or transcutaneous oxygen measurements are used depends on local experience and availability. Measurement of $tcPO_2$ is easily incorporated into a noninvasive vascular laboratory, requires minimal equipment and training, and is reliable and reproducible. For these reasons, our preferred objective test is $tcPO_2$, with a threshold value of 30 mm Hg. However, strict utilization of a single objective method, rather than taking all available clinical data into account, leads to unnecessarily proximal amputations and denies patients the best opportunity for successful rehabilitation. The various methods of predicting wound healing and their accuracies are shown in Table 111.2.[65]

REHABILITATION CONSIDERATIONS

In the United States there are approximately 1.6 million people living with limb loss. Vascular disease accounts for the majority (82%) of limb loss hospital discharges. It is projected that the number of people living with the loss of a limb will more than double by the year 2050 to 3.6 million.[38,66] Rehabilitation is

crucial to maximize the functional outcome of these patients. The significant physical and psychological changes following major amputation make rehabilitation a complex process. Integrated rehabilitation requires an interdisciplinary team that incorporates members from surgery, internal and family medicine, psychiatry, physical therapy, occupational therapy, prosthetics, social services, nursing, nutrition, and recreational therapy.

As mentioned earlier in this chapter, greater energy expenditure is required for ambulation in patients with higher levels of amputation. Energy expenditure and ambulatory rates at various amputation levels are shown in Table 111.3.[67] Many studies have shown that BKA patients have a significantly greater chance to achieve ambulation than AKA patients. In general, the goal is the preservation of maximal limb length at which a healed stump wound can be achieved.

Preoperative evaluation and amputation level selection should always include postoperative rehabilitation considerations. Preoperative ambulatory ability, comorbidities, age, and mental status affect rehabilitation potential. Patients with limited preoperative ambulatory function, age older than 70 years, dementia, end-stage renal disease, and advanced coronary artery disease perform poorly following amputation.[33]

A comprehensive treatment plan should be developed at the beginning of rehabilitation and updated frequently based on the patient's condition. A dedicated team approach clearly improves the ultimate outcome for amputees.[47,64] One report documented that successful rehabilitation following major amputation increased from 69% before the institution of a coordinated team approach to 100% after the development of such a team.[47]

Medical assessment and treatment should be targeted to optimize the patient's overall condition. Addressing comorbidities increases the patient's ability to participate in the rehabilitation process. Pain management is essential to ensure that amputees can actively participate in intensive rehabilitation and prosthetic training. Assessment and modification of health risk factors can improve long-term functional outcome. All patients should be encouraged to exercise daily to improve their performance of activities of daily living.

Amputation Wound Dressings

An important aspect of rehabilitation is the uncomplicated healing of the remnant limb. The role that early wound dressings play in ultimate wound healing and rehabilitation deserves special mention. Currently, no consensus exists on the most effective postoperative management strategy for individuals who undergo major amputation. Due to the longer residual limb and functional knee, there are more dressing options for BKA than AKA. Most practitioners elect a soft dressing following a standard AKA. Typical postoperative dressings and management strategies following BKA include soft gauze dressings with an elastic wrap; thigh-level rigid plaster dressings without an immediate prosthesis; thigh-level rigid plaster dressings with an immediate postoperative prosthesis (IPOP); short, removable rigid plaster dressings; and a prefabricated pneumatic postoperative prosthesis (prefabricated pneumatic IPOP).[68-73] A soft gauze dressing with a mild compression wrap is the most widely used dressing following BKA. Patients remain non–weight-bearing on the stump until the fitting of a prosthesis 4 to 6 weeks after surgery. There are concerns that this type of dressing may delay effective physical therapy and rehabilitation.

Data from controlled trials have found that for soft dressing strategies the uncomplicated healing rates, postoperative pain, prosthetic use, and mortality were not significantly different when compared with other types of dressings.[68,74,75] However, the data from controlled studies have shown that thigh-level rigid dressings lead to significantly shorter rehabilitation times than soft dressings when measured as time to initial gait

training.[76-79] An alternative technique known as IPOP placement, proposed by Berlemont in the 1950s, has been documented to improve both primary healing and rehabilitation rates.[79] An IPOP, which is applied at the initial operation, combines a rigid postoperative dressing with a temporary prosthesis and has been advocated for the early rehabilitation of nonischemic amputees. Concerns from surgeons include lack of familiarity with the prosthesis, fear of placing a hard cast on a potentially compromised remnant limb, and the inability to inspect the wound frequently. To allay these fears, a report from Schon et al. found that significantly fewer patients with a prefabricated pneumatic IPOP had postoperative complications (16%) when compared with patients receiving soft gauze dressings (65%).[74] Other investigators have suggested that placement of an IPOP may actually reduce the need for surgical revision of the amputation stump.[71]

Prosthesis Selection and Training

Prosthetic training plays an important role in rehabilitation. An appropriate durable prosthesis should be prescribed based on the individual's situation. Advanced prosthetic technology provides amputees with more choices. New functional designs and ultralight materials help amputees to live independently. Various lower extremity prostheses are commercially available for patients following AKA and BKA (Figs. 111.1 and 111.2).[67]

The advantages and disadvantages of different types of prostheses and the indications for their use depend on the individual patient and should be fully explored by the experienced prosthetist.[67,80] For example, microprocessor-controlled above-knee prostheses are now typical of the high-technology products (see Fig. 111.1B). These "intelligent" prostheses can change the orifice size, based on different walking speeds, to allow the appropriate shin swing time. The shin includes numerous sensors to accumulate biomechanical data, such as vertical loading amplitude and sagittal knee movement, to determine the direction and angular acceleration of the artificial knee joint. A software analysis system can optimize prosthetic characteristics through a process of data sampling and calculations up to 60 times in a 1.2-second gait cycle.[67,80] A patient wearing one of these prostheses can easily step up and sit on an examination table (see Fig. 111.1C).

Different types of prostheses are available to meet the needs of amputees with different amputation levels, physical conditioning, and exercise demands.[67] In general, persons of smaller stature with a slow to moderate cadence are better suited to smaller, simpler, and lighter hydraulic swing-control prostheses. Taller, more active ambulators benefit from larger, more powerful hydraulic swing-control prostheses.[81] Below-knee prostheses are generally much more lightweight than above-knee prostheses. The below-knee prostheses vary and include standard passive ankle designs, energy-conserving ankles, and open-type sockets that can accommodate slowly healing stumps (see Fig. 111.2).

Reasonable goals must be set for each patient. Many patients may not walk independently, but many wear prostheses, and the large majority return to their home environments. Although

all patients may be offered the eventual fitting of a prosthesis, only a fraction will actively walk with their prostheses. In a large series of major amputations, 42% used a prosthetic limb, and 92% of patients were able to return to community living, but only 29% of patients were able to walk outside the home with a prosthesis.[26]

FUNCTIONAL OUTCOME

The assessment of functional performance following major amputation is a complex issue that influences decision-making at the outset. The most important factors that influence functional outcome are age, preoperative functional status, comorbidities, mental status, amputation level, stump healing status, unilateral versus bilateral amputation, and postoperative rehabilitation. Integrative and vocational rehabilitation combined with newly designed prostheses allow high-level amputation patients to achieve independent lifestyles. Interdisciplinary management should be used in the care of all amputees. Preoperative and postoperative optimization of a patient's medical condition, intensive rehabilitation, wound care, pain management, and proper prosthesis fitting all significantly improve the patient's ultimate functional outcome. A key concept in defining functional outcomes is that success should be defined in relation to an individual's mobility prior to the development of their limb impairment. This patient-centered measure should be the ultimate measure of a successful outcome.[82]

Impact of Amputation Level and Comorbidities

Among amputees with healed stumps, 80% of those with BKAs can achieve ambulation, compared with only 38% to 50% of patients with AKAs.[83] Taylor and coworkers documented that patients older than 70 years had a threefold greater chance of not wearing a prosthesis, a 3.1-fold greater chance of death, a 2.3-fold greater chance of being nonambulatory, and a fourfold greater chance of losing functional independence at 1 year compared with patients younger than 50 years.[33] Patients aged 70 years or older and those with limited preoperative ambulatory ability, dementia, end-stage renal disease, and advanced coronary artery disease all had a significantly higher chance of experiencing death, nonambulatory status, loss of functional independence, and never using a prosthesis. Patients receiving an AKA who were not ambulatory preoperatively had a 10-fold greater chance of not wearing a prosthesis and twice the chance of death at 1 year. Amputees with dementia were 2.4 times less likely to wear a prosthesis. Patients with advanced comorbidities, including coronary artery disease, end-stage renal disease, and severe chronic obstructive pulmonary disease also had a greater chance of not ambulating following amputation.[33]

Through-knee amputation is not commonly performed because of poor soft tissue coverage and a higher risk of wound complications. However, in the patients with adequate residual skin and subcutaneous tissue, through-knee amputation is an

option. Through-knee amputees are able to achieve higher normal and maximal walking speeds with lower relative energy expenditure than above-knee amputees. In elderly patients or those with significant comorbidities preventing them from postoperative ambulation, through-knee amputation allows earlier weight-bearing with a lower risk of wound complications compared with BKA.[67]

Minor amputations, such as digital, ray, transmetatarsal, and midfoot amputations, are considered limb salvage procedures. Patients with digital or ray amputations may walk with little additional energy expenditure. Partial foot amputations require less ambulation energy than more proximal amputations. Pinzur and associates demonstrated that energy demands after midfoot, Syme, below-knee, through-knee, and AKAs are directly related to the level of amputation.[84]

Impact of Age

Patients younger than 60 years with well-controlled comorbidities who were ambulating preoperatively can anticipate an ambulatory rate of 70%, a survival rate of 80%, and an independent living rate of 90% at 1 year following major amputation.[33] A Canadian study showed that although older patients had more comorbidities at admission, they benefited as much as younger people from an intensive rehabilitation program with a comparable length of stay.[85] However, younger amputees continued to improve after 3 months, whereas older patients tended to plateau. In selected patients who developed stump wound complications but had good perceived healing potential, a "redo" BKA yielded better functional outcomes than conversion to an AKA.[86]

Fate of the Contralateral Limb After Amputation

Following a major amputation, many patients worry about the fate of their remaining limb. Patients surviving several years after the first amputation have a significant chance of needing a contralateral amputation. Fifteen percent to 35% of amputees with diabetes lose their remaining leg within 5 years.[87] The presence of renal failure is a particularly poor prognostic indicator of second limb amputation.[25] These facts underscore the need for diligence in protecting and surveying the remaining limb. Continued efforts focused on patient education and preventive foot care are essential. Periodic evaluation and management of PAD in the contralateral limb after unilateral amputation is important for the long-term functional outcome of these patients.

Depression After Amputation

As in other areas of vascular surgery, the successful completion of the operation is only the beginning of the patient's recovery. Although the surgeon may initially focus on the surgical wounds, other considerations are unique to the recovery of an amputee. Although depression is common following major amputation, especially in younger amputees, depression may itself be associated with a higher risk of major amputation.[88,89] The loss of a limb has been compared with the loss of a spouse in terms of magnitude. Although the feeling of bereavement abates over the first year, many amputees experience a continued sense of loss extending beyond 1 year.[90] In the recovery period, positive outcomes should continually be stressed, and clinical screening with appropriate medical therapy for depression should be considered. Amputees with significant depression may become malnourished owing to loss of appetite; malnutrition may delay healing, contribute to the development of pressure ulcers, and seriously affect the patient's overall recovery.

Successful rehabilitation can decrease the severity and incidence of depression following amputation.[91] Social discomfort, the appearance of the prosthesis, and individual coping skills should be addressed to aid in the recovery process.[92-94] The psychological impact of the loss of independence may be minimized by aggressive, focused rehabilitation that openly addresses the concerns of the amputee. Dealing with these issues requires the participation of psychologists, nurses, and geriatric and rehabilitation specialists and is an integral part to the successful management of these patients.

Abstract

Lower extremity amputation ranging from toe amputation to hip disarticulation offers an assortment of treatment options for a multitude of diseases including limb ischemia, infection and major trauma. Above-knee amputation and below-knee amputation are frequently performed and dramatically impact a patient's life. Understanding key principles allows for better prediction of the correct level of amputation for the patient while maintaining the maximal functionality that can be offered. Many opportunities exist to more accurately predict and allow for improved wound healing and functionality.

Limb amputation, practiced since the dawn of man, is one of the most effective surgical procedures.[1] With benefits ranging from pain relief in those with limb ischemia to control of sepsis and preservation of life in those with severe infection, amputation offers a clear path to cure the patient. Despite the importance of a well-executed amputation, the task is often relegated to the least experienced surgeon on the team. Meticulous surgical technique is critical to achieving an amputation that is both pain free and functional.

Historically, amputation was challenging due to the critical triad of hemorrhage, infection, and pain. In France, A. Pare introduced vessel ligatures, thus making the application of hot oil obsolete. Tourniquets were used by Morell, the French barber surgeon, in the battle of Besancon in 1674. Prior to the introduction of antisepsis by Joseph Lister in 1867, it is estimated that more than half of all amputees died from infection.[1]

GENERAL PRINCIPLES

The surgeon must ensure adequate blood supply, sufficient viable soft tissue for coverage, and intact bony architecture (Box 112.1). Other priorities include minimizing surgical trauma by avoiding crushing-type surgical instruments. Although surgical hemostasis is essential to successful amputation, there is a lack of consensus regarding the optimal methods. Beveled skin incisions should be avoided, skin should not be separated from underlying tissue, and skin flaps should not be under tension.

In general, a longer stump is preferred due to improved prosthetic fitting and biomechanics, but not at the cost of not amputating marginally perfused or infected tissue. Excessive soft tissue may interfere with prosthetic fitting and should be avoided. Overattention to minor dog ears and irregularity may satisfy immediate cosmetics at the cost of wound healing and flap viability.[2] Antagonistic muscle groups should be stabilized to prevent skeletal misalignment, a complication which is both detrimental functionally and cosmetically.[3] *Myoplasty*, the suture fixation of antagonistic muscle groups, may help in this regard, in addition to *myodesis*, the direct suturing of the musculotendinous unit to the bone. Excessive periosteal stripping may devascularize the bone, leading to the formation of ring sequestra.

Infected areas should be isolated with the use of mechanical barriers. Open "drainage" or guillotine amputation is usually warranted in the setting of gross infection.[4-8] A two-stage approach, delaying primary closure until a patient is clinically stable, may preserve limb length. Antibiotic coverage should be narrowed based on Gram stain and culture results, with discontinuation as soon as clinically warranted to prevent opportunistic infection such as *Clostridium difficile*.[9]

Protection of the amputation site with use of a rigid or soft dressing may prevent injury in the case of falls. Incisions must be well healed prior to weight bearing. Given their limited mobility, patients are at high risk for developing deep venous thrombosis (DVT) and should receive chemothromboprophylaxis.[10] Perioperative prophylactic antibiotic use is recommended to limit wound infection following amputation.[11]

BOX 112.1 General Principles of Amputation Surgery

- Assess arterial perfusion and bone architecture.
- Handle all tissue with atraumatic technique.
- Excise all nonviable and infected tissue.
- Apply tourniquet to minimize blood loss.
- Eliminate all sharp bone edges and fragments.
- Minimize number of cuts across muscle.
- Transect nerves sharply and allow retraction.
- Minimize use of electrocautery.
- Close wounds under no tension.
- Perform myodesis or myoplasty to stabilize antagonistic muscle groups.
- Use drains to reduce dead space.
- Provide prophylaxis for deep venous thrombosis.
- Administer prophylactic antibiotics.
- Avoid weight bearing until adequate wound healing has occurred.
- Use protective soft and rigid dressings.
- Avoid excessive cosmetic tailoring of wounds.
- Isolate infected or gangrenous tissue with barrier adhesive drapes.

AMPUTATION TYPES

Toe and Ray Amputation

Anatomy

The bony anatomy of the ankle consists of seven tarsal bones and five metatarsals (Fig. 112.1). The great toe has two phalanges, whereas the other toes have three. Medial and lateral sesamoid bones in the flexor tendons of the first toe provide stability. Joint capsules surround the interphalangeal and metatarsophalangeal hinge joints, and ligamentous and tendinous attachments work in concert with the plantar fascia to maintain structural integrity of the foot.

Technique: Toe Amputation

Toe amputation is appropriate for lesions of the middle and distal toe. A racket incision achieves tension-free closure. So-called for its shape like a tennis racket, the "handle" should lie longitudinally along the dorsal surface of the digit, in the midline for the second through fourth toes and away from the midline for the first and fifth toes (Fig. 112.2).

After incising the skin and soft tissues, the tendinous attachments are divided at the same level as the skin incision and the bone is trimmed back accordingly. If a disarticulation is warranted, a #15 blade is inserted into the joint capsule. Cartilage is excised with a rongeur and the bone edges are filed smooth. Excessive use of electrocautery should be avoided. Interrupted nonabsorbable monofilament sutures are used to close the wound in one layer.

Technique: Ray Amputation

A ray amputation includes resection of the digit and the metatarsal head. Ray amputations may be completed with a racket incision, with the "handle" or vertical portion extending proximal to the metatarsal head (Fig. 112.3). The skin and

soft tissues are incised, the tendinous attachments are divided and allowed to retract, and the metatarsal is transected before dividing the remaining soft tissues. Typically, the sesamoid bones are excised, associated flexor tendons are placed on tension and transected, and residual tendon is allowed to retract. Care should be taken to avoid injury to adjacent digital arteries and nerves.

Amputation of the first ray may significantly alter gait. As such, first ray amputation is prone to recurrent ulceration in up to 60% of patients.[12] Some advocate a complete transmetatarsal amputation (TMA) over first ray amputation.[13] A patient-specific approach is best.

Transmetatarsal Amputation

Anatomy

Proximal to the phalanges are five metatarsals (see Fig. 112.1). They are stabilized by the deep transverse metatarsal ligaments and plantar ligaments distally and the plantar metatarsal ligaments proximally. The proximal metatarsals articulate with three cuneiform bones and the cuboid laterally. Collectively the tarsometatarsal (Lisfranc) joint connects the midfoot and forefoot.

Technique

TMA is appropriate for wounds involving the entire forefoot or when multiple ray amputations are considered. TMA offers the ability to wear standard footwear with near-normal ambulation. TMA is contraindicated in cases of severe bony deformity of the midfoot and hindfoot which would lead to structural instability.

An incision extends transversely over the dorsum of the foot at the level of the distal metatarsals, coming to corners medially at the first metatarsal head and laterally at the fifth metatarsal head. Next, an incision extends from these corners onto the plantar surface across the base of the toes (Fig. 112.4). The extensor tendons are divided at the skin level, the periosteum is incised, and the metatarsals are divided with a bone saw, each approximately 3 mm shorter than the last, moving laterally. A gentle 30- to 45-degree plantar bevel may facilitate liftoff with

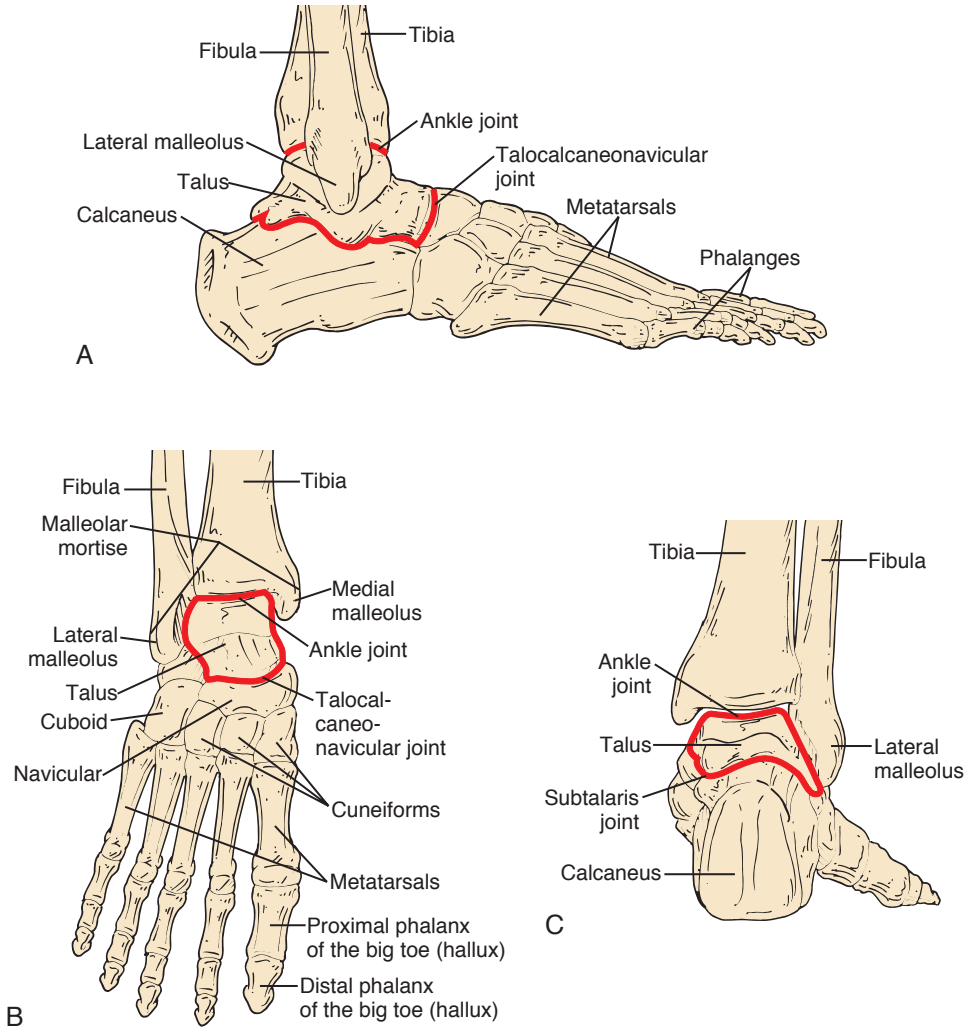

Figure 112.1 Bone Anatomy of the Foot. *Continued*

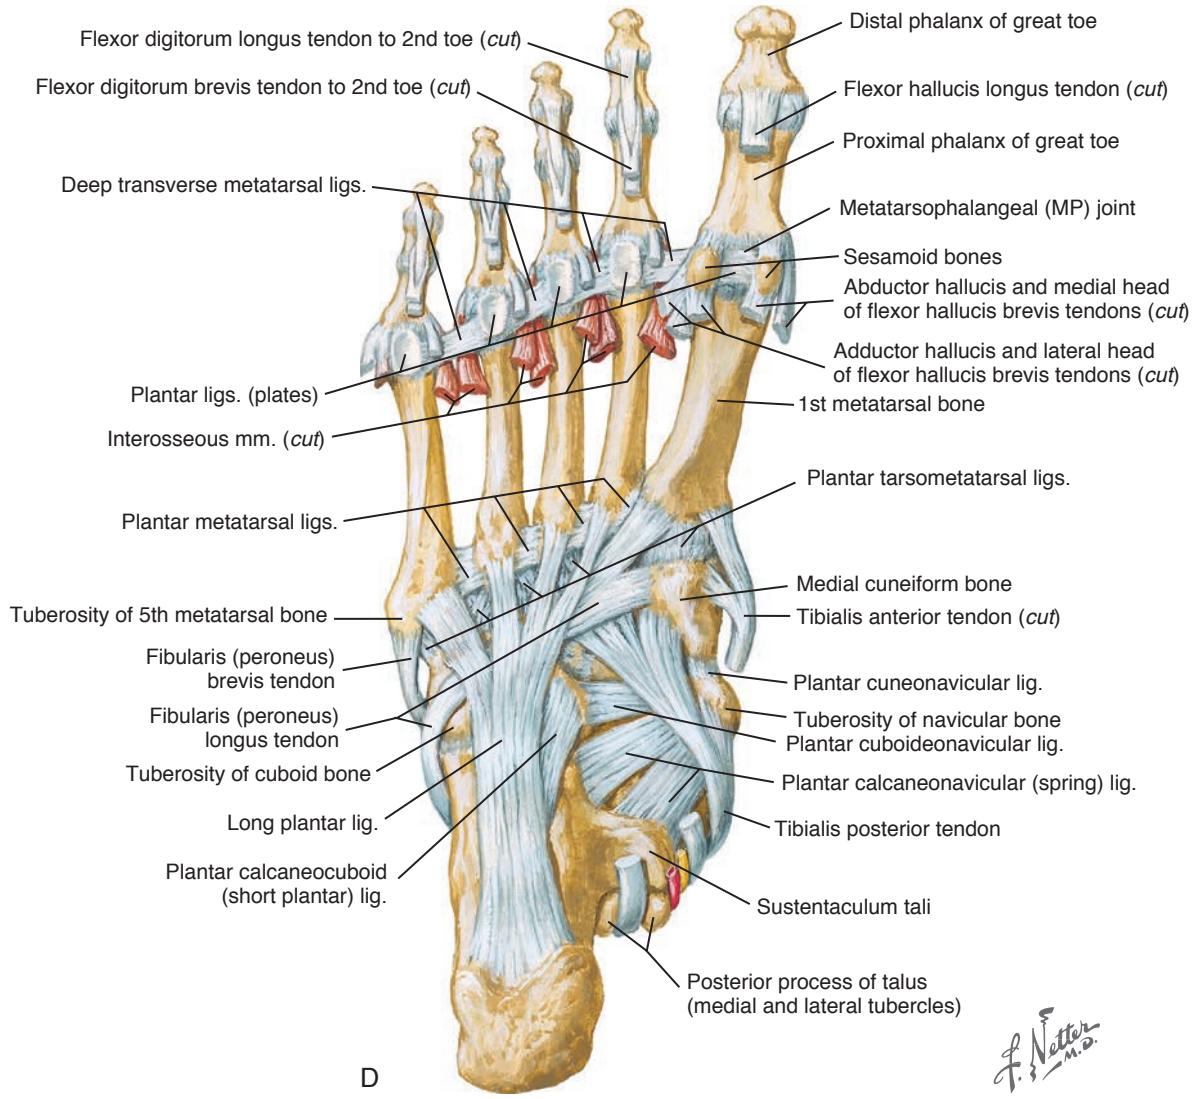

Figure 112.1, cont'd

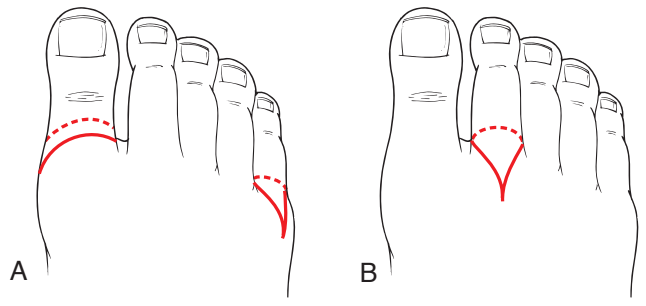

Figure 112.2 (A) Racket incision for first and fifth toe amputation. (B) Racket incision for second, third, and fourth toe amputation.

ambulation. After dividing the bone, the plantar myofascial attachments to the metatarsal heads are divided. The poorly vascularized tendons and sheaths in the plantar flap should be excised.

To reduce the risk of recurrent ulceration, some surgeons recommend Achilles tendon lengthening (ATL) or transection.[14]

MIDFOOT AND HINDFOOT AMPUTATIONS

Three proximal foot amputations are occasionally appropriate: Lisfranc tarsometatarsal disarticulation, Chopart midfoot amputation, and Syme amputation (Fig. 112.5).[15,16] Two rarely performed hindfoot amputations are the Boyd and Pirogoff amputations.[15,17-19] Hindfoot amputations are performed primarily in children to preserve length and growth centers.

Many surgeons recommend transtibial (below-knee) amputation if TMA cannot be performed or has failed. Others suggest that increased limb salvage rates can be achieved with the use of unconventional foot amputations.[18,20]

Anatomy

The tibia and the fibula articulate with the talus via the talocrural joint. The ligaments that join these bones are the deltoid, anterior and posterior talofibular, and calcaneofibular

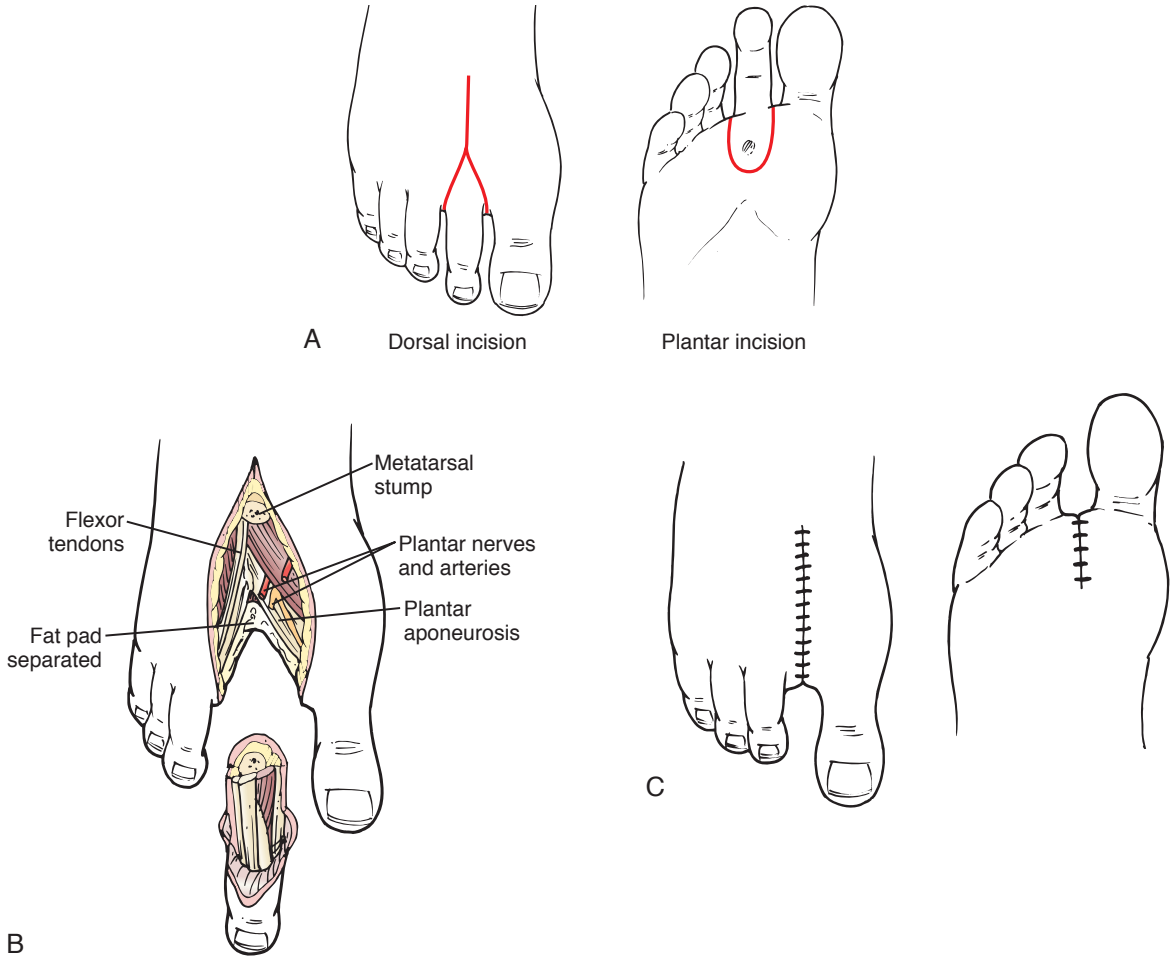

Figure 112.3 Ray Amputation Incision. (A) Note the plantar extension to include a mal perforans ulcer. (B) Transection of the metatarsal shaft. (C) Closure with nonabsorbable suture under no tension.

ligaments. The talus articulates with the calcaneus at the subtalar joint. The medial and lateral talocalcaneal ligaments and the cervical ligament support this joint. The talocalcaneonavicular joint is a multiaxial joint supported by the talonavicular and plantar calcaneonavicular ligaments. Supination (inversion) at this joint is produced by the tibialis anterior and posterior. Pronation (eversion) is produced by the peroneus longus and brevis. A heavy fibrofatty heel pad firmly adheres to the calcaneus and skin and provides protection during heel strike (see Fig. 112.1).

Because the strong ankle extensor attachments are divided in the performance of midfoot and hindfoot amputation, the Achilles tendon exerts unopposed plantar flexor forces on the residual foot. The Achilles tendon may require division or lengthening to prevent the development of an equinus deformity.

Lisfranc and Chopart Amputations

Lisfranc

Lisfranc first described this amputation in 1815. The incision results in a long plantar flap (see Fig. 112.5). Tendons and synovial sheaths are divided at the level of the skin incision. The first, third, fourth, and fifth tarsometatarsal joints are disarticulated. The second metatarsal is divided 1 to 2 cm distal to the medial cuneiform.[21] To reduce the risk of development of equinovarus deformity, Sanders recommended a modification of the Lisfranc amputation that preserves the base of the fifth metatarsal and the insertion of the peroneus brevis.[18] The Achilles tendon is released by either transection or Z-plasty.[22,23] The plantar fascia on the flap is approximated to the dorsal periosteum with absorbable sutures. The skin is approximated with interrupted monofilament sutures or staples.

Chopart

Described by Chopart in 1814, this amputation involves a long plantar flap similar to that used in the Lisfranc amputation (see Fig. 112.5) and is performed through the talocalcaneonavicular joint and the calcaneocuboid joint. An Achilles tenectomy is recommended. The extensor hallucis longus and the tibialis anterior tendons may be reattached to the talar neck. The extensor digitorum longus may be reattached to the calcaneus.[21]

Postoperative Considerations

Because the Lisfranc and Chopart amputations result in a dramatic alteration in normal foot biomechanics, their durability may be limited. A short-leg plaster cast is used over the sterile

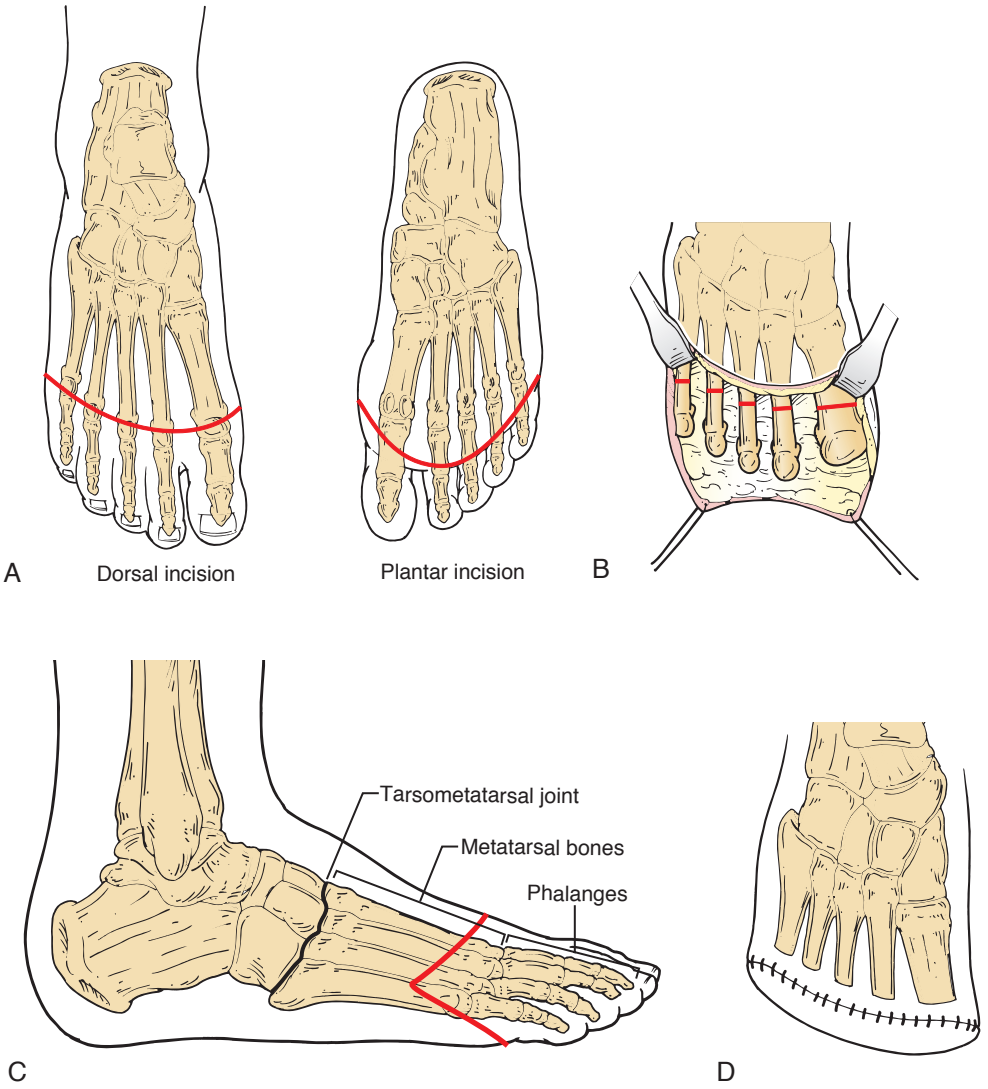

Figure 112.4 Technique of Transmetatarsal Amputation. (A) Dorsal and plantar incisions with disarticulation of the metarsophalangeal joints. (B) Level of bone transection. (C) Lateral view. (D) Closure with monofilament suture.

dressings. The cast must be molded to ensure that the talus is slightly dorsiflexed in relation to the tibia and that the calcaneal tuberosity is parallel to the long axis of the tibia. The cast is changed weekly to check wound healing. Weight bearing is allowed after 6 weeks. Patients with a Lisfranc amputation need little more than a toe filler with an ankle lace-up shoe. Patients with a Chopart amputation need a custom-fitted ankle-foot orthosis with a filler to hold the shoe adequately.

Syme Amputation

Syme first described this amputation in 1843. The anterior incision extends across the ankle just distal to the tip of each malleolus, while the posterior incision extends from the malleoli vertically down and across the sole of the foot (see Figs. 112.5 and 112.6). The extensor tendons are divided at the level of the skin incision. Next, the dorsalis pedis artery is ligated and divided. The ankle joint capsule is incised while plantar flexing the foot before dividing the medial and lateral ankle ligaments. The tendons of the posterior tibialis and flexor hallucis longus are transected, taking care to avoid injury to the posterior tibial artery. Next, the heel fat pad is carefully dissected by staying close to the calcaneus to avoid buttonholing. Finally, the ankle joint is disarticulated, and the specimen is passed off the table. In a one-stage amputation the malleoli are divided with a saw at the level of the articular surface of the tibia, and the width is reduced by vertical bone excision. Holes are drilled in the medial, anterior, and lateral parts of the distal tibia and fibula to secure the heel pad directly under the tibia. In a two-stage Syme amputation the wound is closed by suturing the heel flap to the dorsal fascia. Six weeks later the malleoli are removed through separate vertical incisions (see references by Hulnick et al.[24] and Richardson[25] for a detailed description of midfoot amputations).

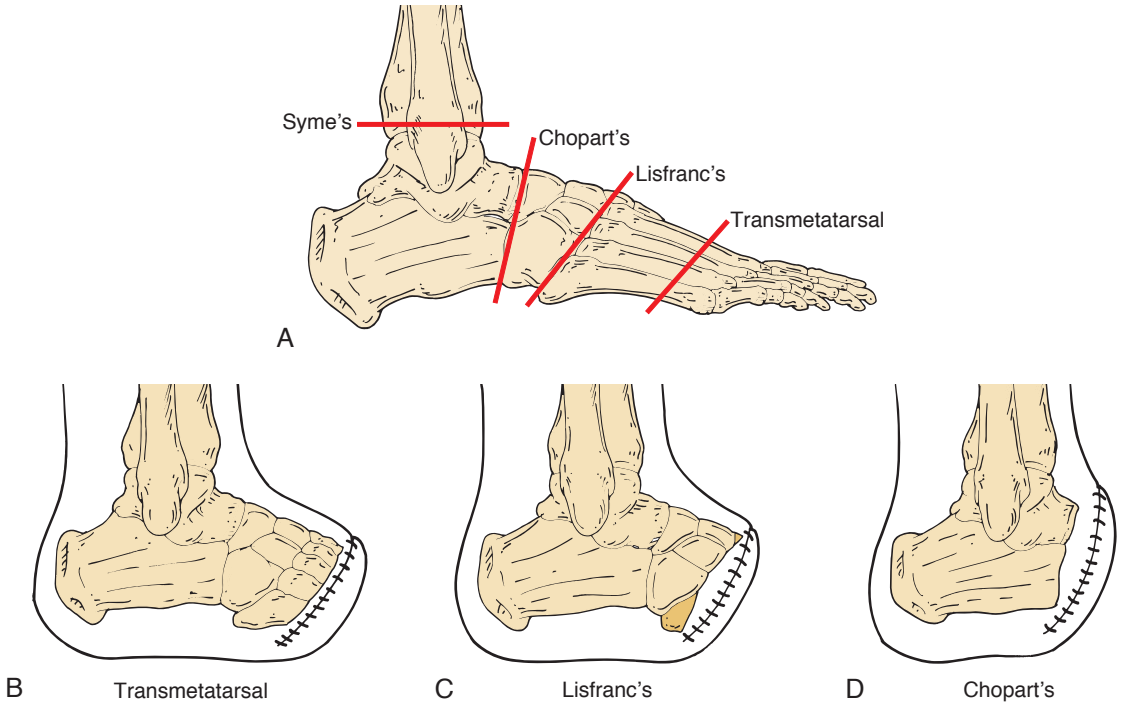

Figure 112.5 Levels of Foot Amputation.

Postoperative Considerations

The chief advantage of the Syme amputation is the preservation of limb length, which may obviate the need for a prosthesis during brief periods of weight bearing, such as during transfer from a bed to a wheelchair. The disadvantages include the slight leg-length discrepancy, which may lead to biomechanical side effects in more proximal or contralateral joints. Furthermore, the prosthesis is typically bulky at the ankle and less cosmetically appealing than a conventional below-knee prosthesis.

TRANSTIBIAL (BELOW-KNEE) AMPUTATION

Anatomy

The leg contains four muscle compartments. The anterior compartment contains the tibialis anterior, extensor hallucis longus, and extensor digitorum longus muscles, as well as the anterior tibial artery and vein and deep peroneal nerve. The lateral compartment contains two muscles: the peroneus longus and brevis, as well as the superficial peroneal nerve. The superficial posterior compartment contains the soleus, gastrocnemius, and plantaris muscles. Last, the deep posterior compartment contains the flexor digitorum longus, tibialis posterior, flexor hallucis longus, and popliteus muscles, the posterior tibial artery and veins, peroneal artery and veins, and tibial nerve. The tibial nerve courses adjacent to the posterior tibial artery and veins (Fig. 112.7). Posterior flaps, skew flaps, sagittal flaps, and medial flaps are based on corresponding musculocutaneous perforators; thus it is important to avoid separating the skin and soft tissue from its underlying muscle.[26]

Technique

Posterior Flap

The posterior-based flap described by Burgess et al.[27-29] is the most commonly used. Division of the tibia should be at minimum 12 to 15 cm (approximately four fingerbreadths) distal to the tibial tuberosity to create the most favorable biomechanics for ambulation with a prosthesis. To fashion flaps, some advocate using a two-thirds/one-third technique based on leg circumference (Fig. 112.8). The anterior incision of the amputation should be approximately two-thirds the leg's circumference. The length of the posterior flap is one-third the leg circumference and should be shaped in a gentle curve to reduce dog ears.

The skin, subcutaneous tissue, and fascia are incised starting with the transverse portion before extending along the posterior flap. The anterior and lateral compartment muscles are divided next. The periosteum of the tibia is incised and mobilized proximally and the tibia is divided using a bone saw. The fibula is divided approximately 1 to 2 cm proximal to the tibia. Removing too much fibula will result in a conical stump, both unsightly and a poor recipient of a prosthesis. A large amputation knife is used to create the posterior flap. The knife is maintained at a plane deep to the tibia and fibula, dividing the remaining posterior compartment musculature. Major vascular bundles are suture ligated. The tibial and peroneal nerves are sharply divided and allowed to retract proximally. The posterior flap musculature is trimmed of gross excess but allowed to remain sufficiently bulky to cushion impact once fit with a prosthesis.

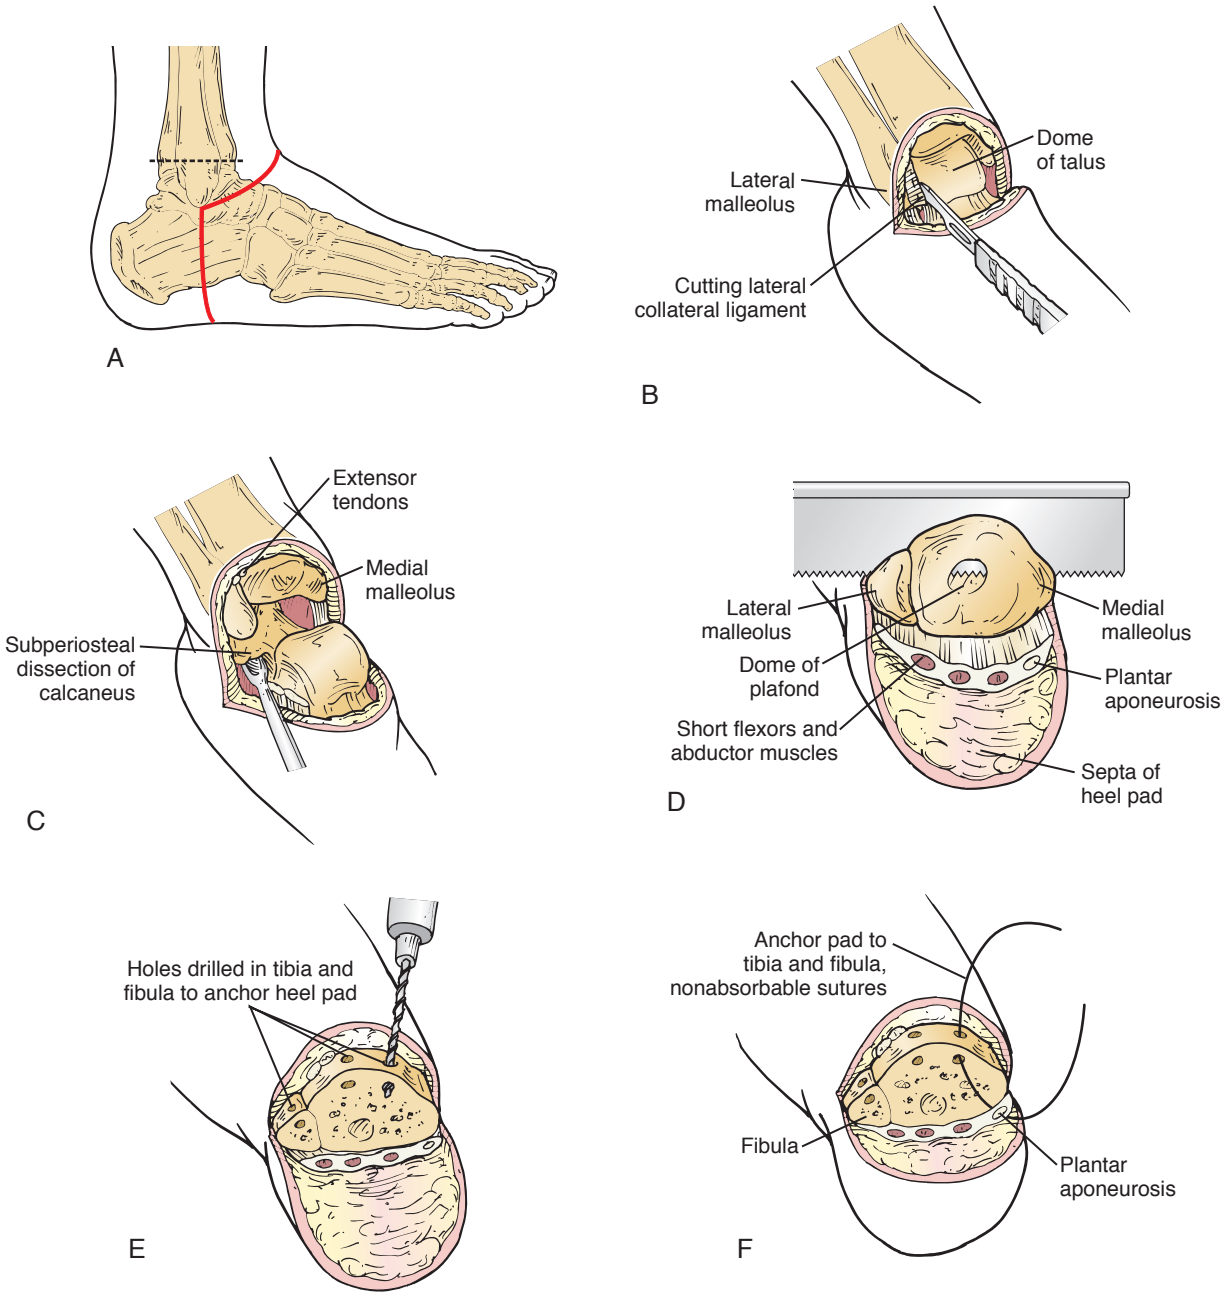

Figure 112.6 Syme Amputation. (A) Skin incision and bone transection level. (B) Exposure of the ankle and division of the ligaments. (C) Soft tissue dissection from the calcaneus. (D) Division of the tibia and fibula. (E) Holes drilled in the anterior aspect of the tibia and fibula. (F) Fascia lining the heel pad sutured to the bone.

Some surgeons prefer to advance the posterior flap 3 to 4 cm proximal to the tibial osteotomy.[30] If warranted, the soleus muscle can be excised up to the level of the tibial osteotomy, but the gastrocnemius and fascia must be preserved. The anterior tibia is beveled to avoid a sharp edge protruding through the skin. The sural nerve should be transected at least 5 cm proximal to the skin edge to prevent neuroma formation.

Some advocate a myodesis of the gastrocnemius. Two holes are drilled into the anterior surface of the tibia, and the gastrocnemius is affixed to the tibia with a nonabsorbable suture in an effort to maintain adequate coverage of the tibia. Bites are taken slightly behind the edge of the flap through the fascia as to create a lip of muscle over the anterior portion of bone. Prior to closure, the wound is irrigated with saline to remove bone dust and debris. The deep fascia is approximated with interrupted absorbable sutures. The skin is closed with staples or interrupted monofilament suture avoiding tightly compressing the flaps.

Sagittal Flap

If creation of a long posterior flap is not possible, sagittal or skew flaps may be used. In the sagittal flap technique described

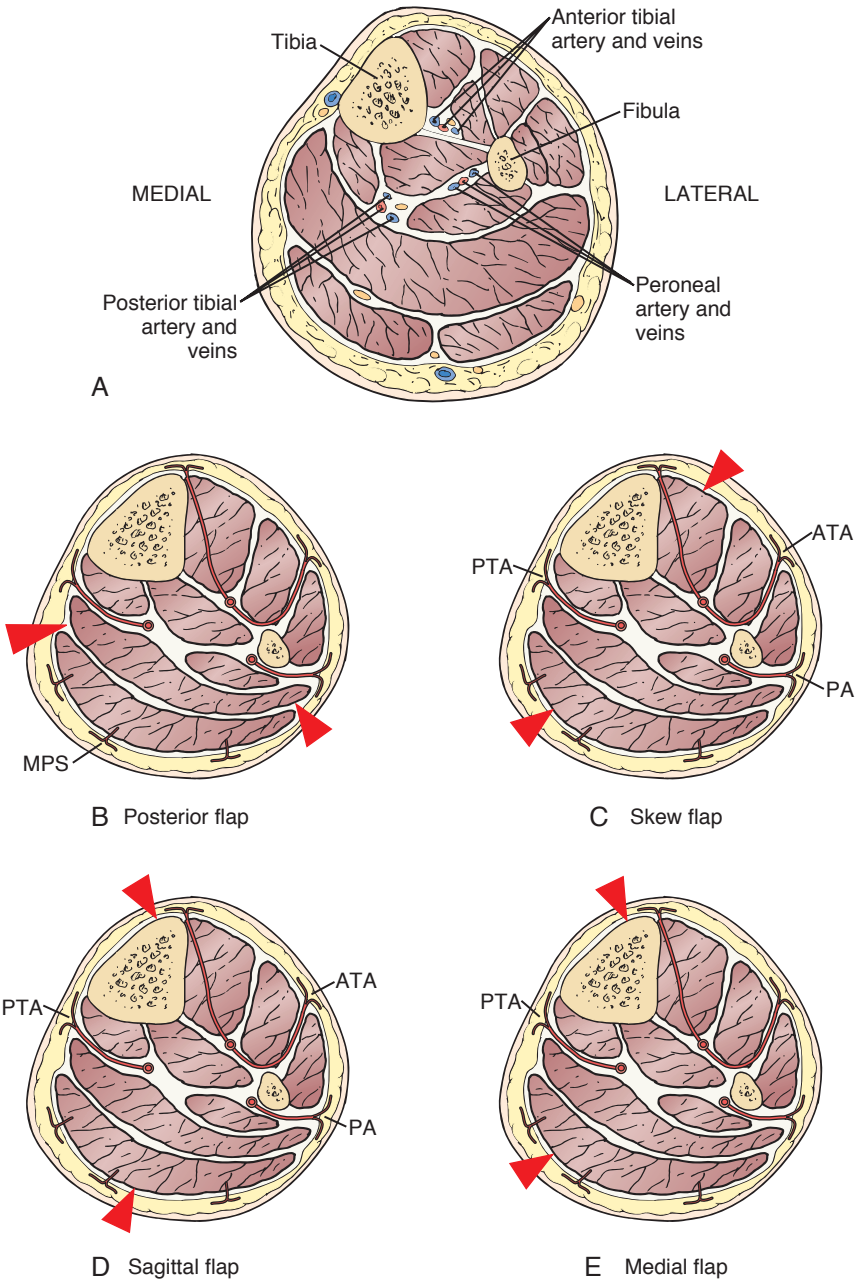

Figure 112.7 Cross-sectional Anatomy and Blood Supply to the Skin at the Level of Transtibial Amputation. Note the location of skin incisions *(red arrowheads)*. (A) Leg cross-section. (B) Posterior flap. (C) Skew flap. (D) Sagittal flap. (E) Medial flap. *ATA*, Anterior tibial artery; *MPS*, musculocutaneous perforators from the sural artery; *PA*, peroneal artery; *PTA*, posterior tibial artery.

by Persson, equal-length medial and lateral myocutaneous flaps are developed (see Fig. 112.7).[31] A myoplasty is performed to cover the tibia by suturing the anterior and lateral compartment muscles to the medial component of the gastrocnemius and soleus. A randomized comparison of sagittal versus posterior flaps showed no significant difference in outcome.[32]

Skew Flap

In the skew technique, equal anteromedial and posterolateral fasciocutaneous flaps are created (see Figs. 112.7 and 112.9). The posterior muscle flap is identical to the conventional long posterior flap based on the gastrocnemius muscle.[33] The skew technique may be of particular benefit when there is inadequate skin to create a conventional long posterior flap.

Fish-Mouth Flap

Before the development of the long posterior flap, the creation of equal anterior and posterior flaps was the most common transtibial amputation technique. The chief disadvantage was vulnerability of the anterior flap to ischemia.

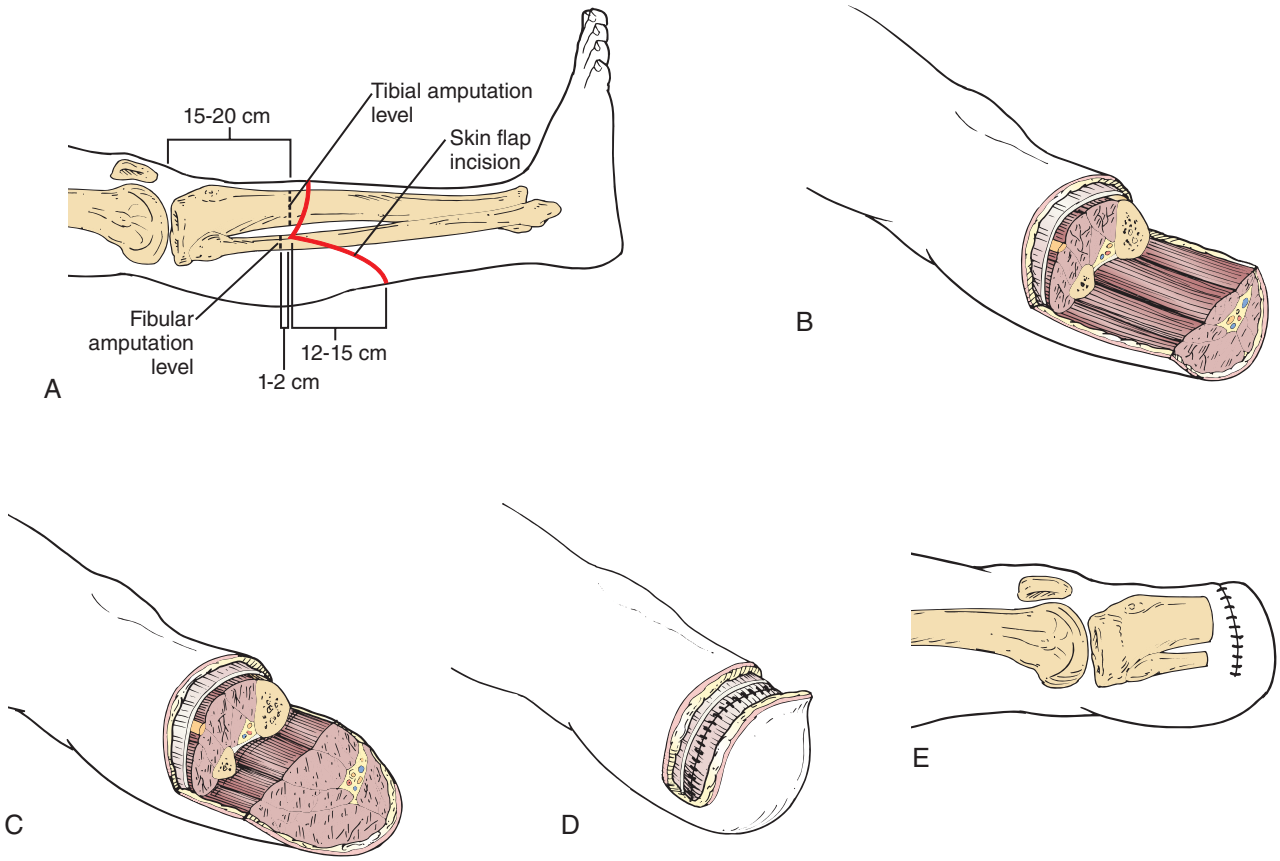

Figure 112.8 **Transtibial Amputation.** (A) Marking the skin incisions. (B) Fashioning the flaps after bone transection. (C) The soleus muscle is tailored to create a proper flap. (D) The posterior deep fascia is sutured to the anterior deep fascia and periosteum. (E) Closure of the skin flaps.

Medial Flap

A medially based flap technique, described by Jain and colleagues, may be appropriate in selected patients (see Figs. 112.7 and 112.10).[34] Based on thermographic imaging, a long medial flap and a shorter lateral flap are designed. A Cochrane review published in 2014 concluded that there was insufficient evidence to establish the superiority of one transtibial amputation technique over the others.[35]

Ertl Procedure

Tibiofibular bone bridging, known as the Ertl procedure, is thought by some to provide better transmission of energy from the distal femur to the prosthesis. The Ertl procedure uses a bone bridge between the tibia and fibula to provide a more stable weight-bearing surface. The fibula is harvested from the amputation specimen and serves as a bone graft.

Equal length skin flaps are created. The skin and soft tissues are excised, and the anterior muscle is divided. The tibia is divided with a bone saw, and the fibula is first divided approximately 2 to 4 cm distal to this point, depending on the distance from the tibia to the fibula. Next, the fibula is divided at a level of the tibial osteotomy, with care to preserve the peroneal artery and blood supply to the fibula. The posterior flap is then completed. Next, the facing portions of the tibia and fibula are trimmed parallel to accept the fibula bone bridge. The bone graft is affixed either with screws or permanent sutures. A myodesis of the soleus and gastrocnemius to the anterior tibia is completed before reapproximating the soft tissue and skin in two layers.[36-38] The superiority of this technique over traditional transtibial amputation has not been proven,[39] although one series of 32 patients receiving bone bridging of the distal tibia and fibula showed an improved quality of life with improved ambulation and decreased patient frustration.[40]

Guillotine Amputation

Patients presenting with severe infection may warrant an initial débridement amputation to obtain source control. Rapid removal of the offending limb via guillotine amputation offers the chance for patient stabilization. Revision and flap closure are completed once the patient's condition is more favorable. In two small trials, two-stage amputation was associated with lower overall infection rate.[4,5]

Cryoamputation

Cryoamputation is reserved for patients too ill for anesthesia and may be a treatment for severe gangrenous infection, severe ischemia, or myonecrosis. A tourniquet is applied proximally, and dry ice is packed around the limb. By physiologically isolating the limb, toxic byproducts and organic acids cannot circulate

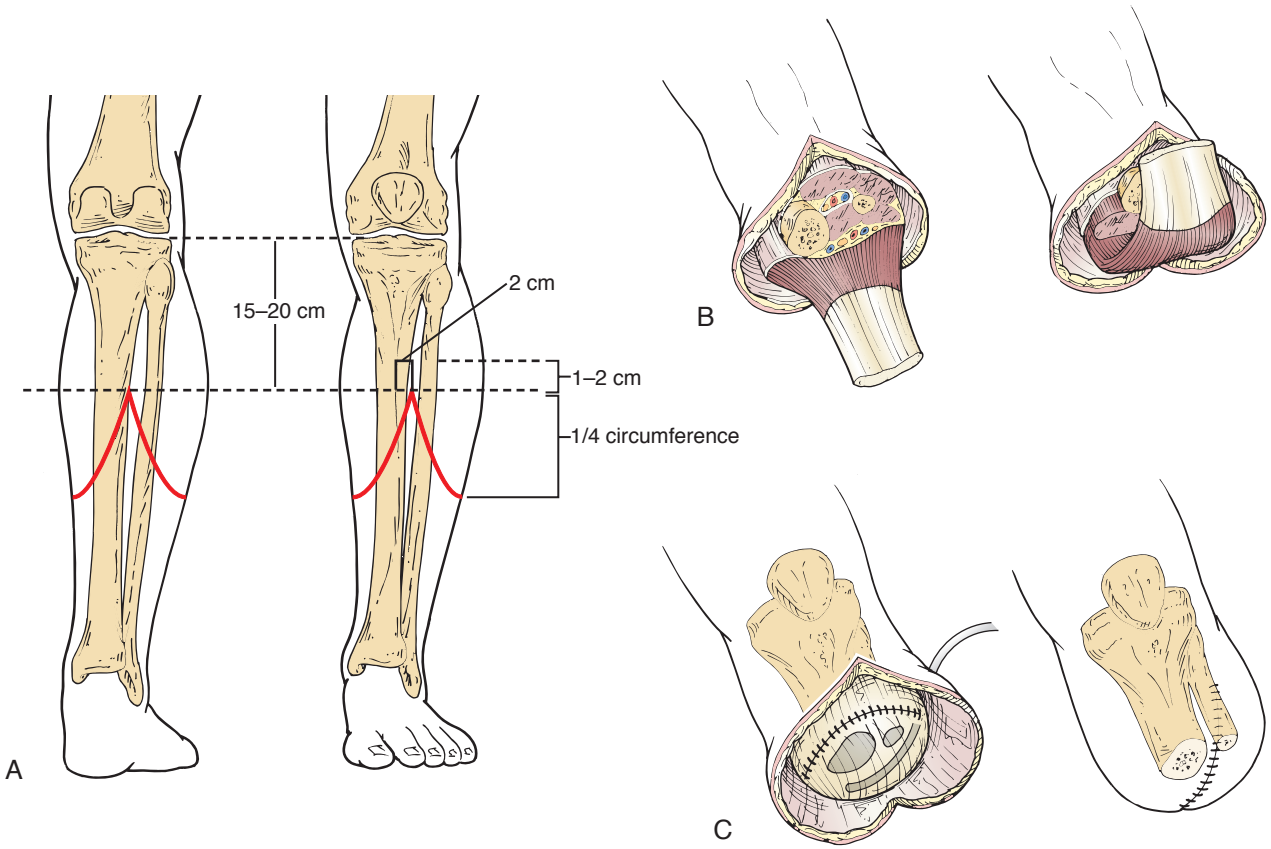

Figure 112.9 **Skew Flap.** (A) The incisions result in equal anteromedial and posterolateral skin flaps. The tibia is transected to 10 to 12 cm distal to the joint line. (B) The gastrocnemius muscle flap covers the tibia. (C) The skin is closed with nonabsorbable sutures.

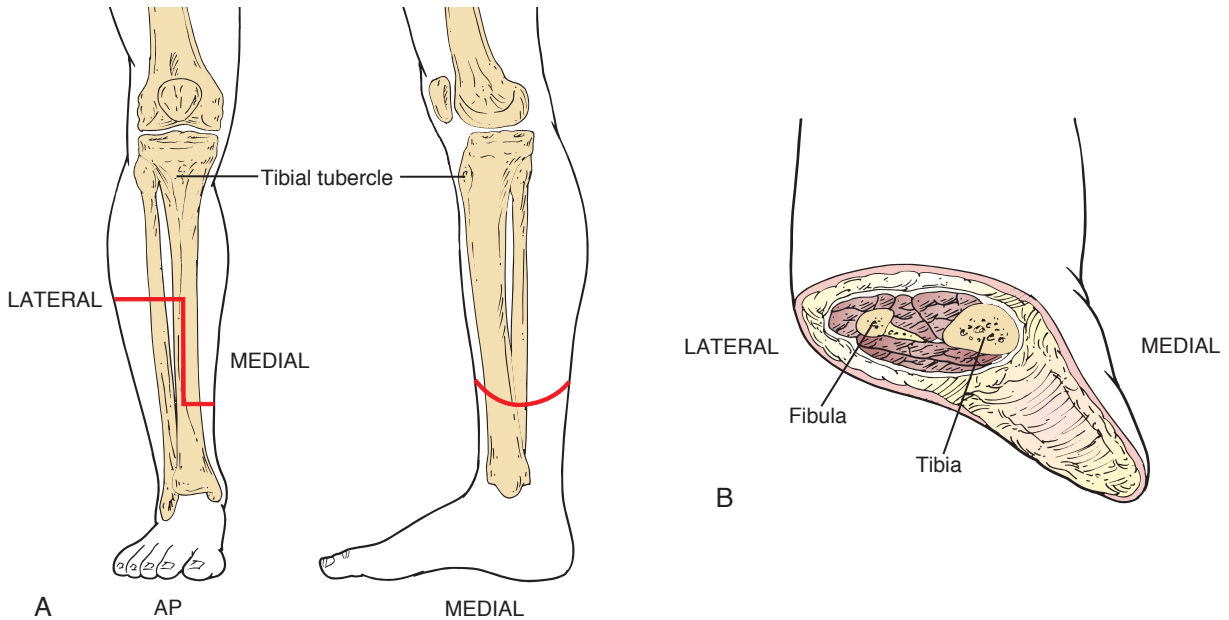

Figure 112.10 (A) Skin incision for a medially based flap. (B) View of the flap after transection. *AP*, Anterioposterior.

systemically. After the patient's status improves, a surgical amputation can be completed. Cryoamputation has been associated with improved mortality in comparison with emergency amputation in the frail and elderly.[41-43] Complications include migration of the frost line above the intended level of amputation and a substantial need for revision.[44]

Postoperative Considerations

There is a tendency for the patient to flex the knee joint, and over time a flexion contracture could occur without proper care. A knee immobilizer is kept in place with Velcro straps and be easily removed to examine the amputation wound.

Primary healing fails in 20% to 30% patients. Nehler et al. found only 55% of transtibial amputations were completely healed at 100 days, increasing to 83% at 200 days.[45] Furthermore, approximately 20% of patients undergoing transtibial amputation needed a higher-level amputation.[45,46] The decision to perform an amputation at a given level is complicated by patients who typically have significant comorbidities that limit wound healing.

THROUGH-KNEE AMPUTATION

Anatomy

Through-knee amputation requires the removal of the tibia, fibula, and articular surface of the distal femur. Of particular note is the treatment of the patellar ligament (also known as the patellar tendon), cruciate ligaments, and tendons of the hamstring muscles, because these structures are sutured to each other in a through-knee amputation. The patellar ligament is an extension of the quadriceps tendon, which stabilizes the patella and attaches distally to the tibial tuberosity. The hamstring tendons collectively are derived from the semitendinosus, semimembranosus, and biceps femoris muscles.

Technique

In patients with good rehabilitation potential who are not suitable candidates for transtibial amputation, a through-knee amputation may be an acceptable alternative. Through-knee amputation offers higher rates of successful ambulation when compared with transfemoral amputation. Some have actually advocated for primary through-knee amputation rather than transtibial amputation in selected patients.[47] However, 10% to 15% of patients undergoing through-knee amputation will require a higher level of amputation.[48]

We recommend a technique originally described by Mazet in which the distal femur is preserved and condyles are trimmed squarely (Fig. 112.11).[49,50] An alternative is the modified Gritti-Stokes amputation, which involves transection of the articular head of the femur with preservation and fixation of the patella as an end-cap to the leg. A fish-mouth incision is fashioned with its corners at the level of the mid condyles of the femur. The anterior flap is extended to the level of the tibial tuberosity and the posterior flap is extended to be the same length. Next,

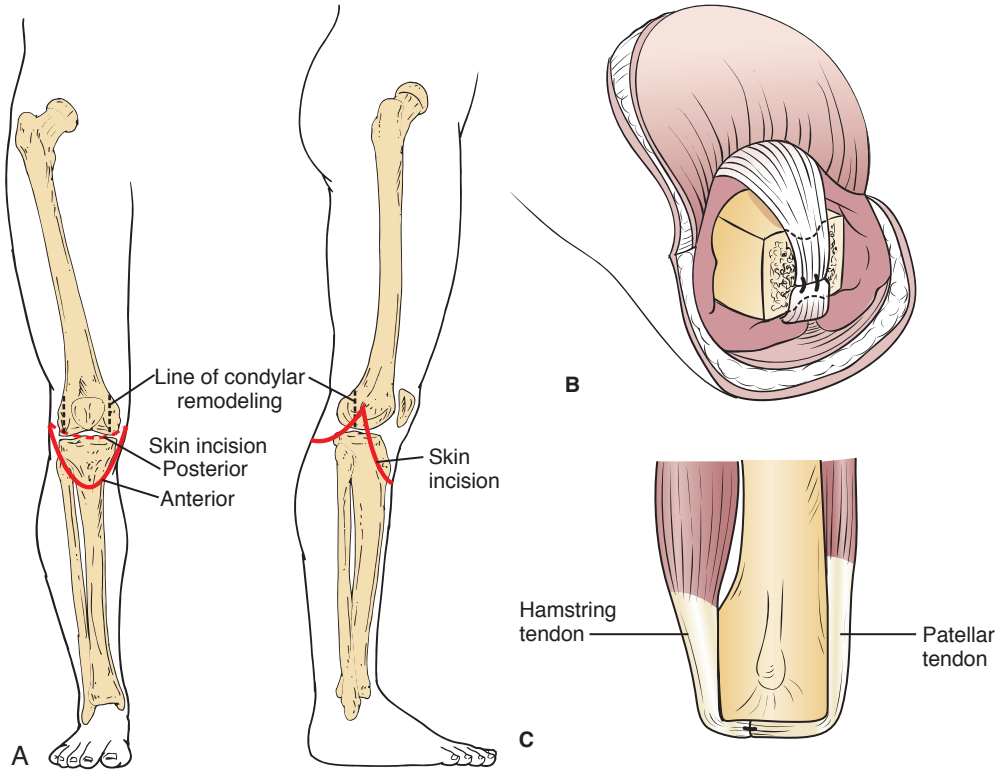

Figure 112.11 (A) Fish-mouth incision for through-knee amputation. (B and C) the patellar tendon is sutured directly to the residual cruciate ligament.

the skin is incised and the medial and lateral collateral ligaments are divided. The patellar ligament is divided from its attachment to the tibial tuberosity, preserving its length and then it is retracted proximally. The skin and deep fascial elements are dissected off the knee capsule before excising the knee capsule and dividing the cruciate ligaments. The popliteal artery and veins are suture ligated, and the common peroneal and tibial nerves are transected sharply under tension and allowed to retract. The popliteus and gastrocnemius muscles are divided along with the remaining tendons from their insertion sites; then the leg is removed. By dissecting very closely to the patella during its removal, the anterior skin flaps are preserved and buttonholing is avoided.

The menisci are removed, and the lateral one-third of the lateral condyle and medial half of the medial condyle of the femur are trimmed using a bone saw. The posterior surface is squared. The edges are smoothed with a rasp or bone saw. Next, the hamstrings are approximated to the patellar ligament while incorporating the cruciate ligaments in the bite. Finally, the fascia and skin are closed in two layers.

TRANSFEMORAL (ABOVE-KNEE) AMPUTATION

Anatomy

The thigh has three muscle groups: anterior, middle, and posterior. The anterior muscle group consists of the quadriceps femoris, sartorius, and tensor fascia latae. The medial group consists of the adductor longus, brevis and magnus, gracilis, and pectineus muscles. Posteriorly are the hamstrings: biceps femoris (long and short heads), semitendinosus, and semimembranosus. Of note, the adductors insert into the posterolateral femur along the linea aspera. The adductor magnus also inserts onto the adductor tubercle, a bony prominence on the medial epicondyle of the femur.

Technique

The femur is typically divided at the junction of the middle and distal one-third, or approximately 12 cm proximal to the femoral condyles, but if necessary division can be more proximal as long as tissue coverage exists. A fish-mouth incision is used, creating equal anterior and posterior flaps, although orientation can be varied (Fig. 112.12). After incising the skin and soft tissue, the superficial femoral artery and femoral vein are divided and controlled with suture ligature. The muscles are divided in the same plane, unless intending to perform a myodesis (see later). The femur is transected proximal to the corners of the fish-mouth incision using a mechanical saw and rough edges are filed as needed. The sciatic nerve is stretched, divided, and allowed to retract.

There is a tendency for the hip flexors to abduct and flex the thigh because the adductor muscles are no longer attached and able to oppose this motion. After creating flaps and incising the skin and soft tissue, muscles are then identified. The quadriceps is detached proximal to the patella, leaving some of its tendinous portion intact. The vastus medialis is reflected laterally off the intermuscular septum to expose the adductor magnus. The adductor magnus is sharply divided at its attachment to the adductor tubercle on the medial epicondyle and it is reflected medially to expose the femoral shaft. The vessels traversing the Hunter canal are ligated. The remaining gracilis, sartorius, semimembranosus, and semitendinosus are divided approximately 1 to 2 cm distal to the point of transection of the femur. The femur is exposed and cut with a mechanical saw, two to three holes are drilled into the lateral cortex, and one to two holes drilled into the posterior cortex of the remaining femur, approximately 1 to 2 cm from its end. The adductor magnus is wrapped over the end of the bone, with the femur held in maximal adduction then anchored using the lateral holes. Anterior and posterior sutures are used to prevent the muscle from sliding off the bone. The quadriceps muscles are wrapped over the end of the femur and sutured posteriorly, and the remaining posterior muscles are anchored posteriorly to the newly affixed adductor magnus.[51,52] Although reliable studies of myodesis have not been performed, it may benefit patients more likely to ambulate with an above-knee prosthesis.

Postoperative Considerations

The threat of wound contamination is of higher concern with transfemoral amputation. Dressings are left in place at a minimum of 4 to 5 days unless clinically compelled to remove earlier.

Patients with above-knee amputation (AKA) use 50% more energy to ambulate than those with below-knee amputation (BKA), and less than 10% of elderly vascular amputees ambulate effectively after transfemoral amputation.[53]

HIP DISARTICULATION

Anatomy

The hip joint is a ball-and-socket joint stabilized by a fibrous capsule, acetabular labrum, ligament of the head of the femur, iliofemoral, ischiofemoral, pubofemoral, and transverse acetabular ligaments. Anterior to the hip joint are the rectus femoris, iliopsoas, and pectineus muscles. Anterior to these muscles are the tensor fascia lata and sartorius. Posterior to the joint are the piriformis muscle, obturator internus and externus, superior and inferior gemelli, and quadratus femoris. These are among the other muscles of the hip and thigh not immediately adjacent to the hip joint also associated with ambulation.

Technique

The patient is positioned in a semilateral position. An anterior racket incision or a long posterior flap incision may be used (Fig. 112.13).[54] The anterior racket incision starts 2.5 cm medial to the anterior superior iliac spine, extends toward the pubic tubercle, and continues posteriorly distal to the ischial tuberosity and gluteal crease. The incision is continued anteriorly, medial

to the greater trochanter and the anterior inferior iliac spine before joining the incision at its origin. The skin and soft tissues are incised down to the external oblique aponeurosis and deep fascia of the thigh. The femoral vessels are suture ligated and the femoral nerve transected and allowed to retract. Next, the muscles of the hip joint are divided, starting with the sartorius at its origin and iliopsoas at its insertion site. The pectineus is divided at its origin on the superior pubic ramus. The gracilis muscle and three adductors are divided at their origins on the pubic rami. The obturator neurovascular bundle is divided, and the obturator externus muscle is divided from its insertion to the trochanteric fossa. The hamstrings are transected at the ischial tuberosity before dividing the tensor fasciae latae, gluteus maximus, and rectus femoris before dividing the remaining muscles attached to the greater trochanter. To complete the amputation, the ligamentous attachments and capsule of the hip joint are divided. The sciatic nerve is transected and allowed to retract and the specimen is passed off. The posterior quadratus femoris is sutured to the anterior iliopsoas and the lateral gluteus medius is sutured to the medial obturator externus. One may

elect to place closed suction drains in the subcutaneous space. Closure is in two layers: the gluteal fascia is approximated to the inguinal ligament and the skin is closed loosely with staples.[54]

Postoperative Considerations

Drains and a Foley catheter are left in place for a few days. Avoiding soilage from stool and urine may be a challenging yet important part of postoperative care. Chemothrombophrophylaxis is very important given the high risk for thromboembolic events.

PRINCIPLES OF POSTOPERATIVE CARE

In our practice, operative dressings are left in place for 5 days unless a clinical indication (e.g., fever, bleeding) warrants removal.[55,56] Some advocate for application of an immediate postoperative prosthesis (IPOP), reporting effective prosthetic ambulation at an earlier time when compared with conventional practice.[57,58] Drawbacks of IPOP include the need for a skillful multidisciplinary team, its lack of being universally available, and the inability to examine the wound when in place.[56,59,60]

Attention should be paid to control of blood sugar in the physiologic range and to maintaining adequate nutrition.

Operative Mortality

In the modern era, 30-day operative mortality ranges from 6% to 13% for major lower extremity amputations.[61-64] For minor amputations at the ankle or below, operative mortality drops to 2% to 4%.[45,46,65,66] Most lower extremity amputations are performed for ischemia and diabetes, with trauma and malignancy accounting for the remainder.[67,68] The most common causes of death following lower extremity amputation are cardiac complications (46%), sepsis (14%), and pneumonia (11%).[69] Overall 30-day mortality in a large retrospective analysis was 12.8% after AKA and 6.5% after BKA.[64] A retrospective study of 788 patients reported similar results,[69] whereas a study of more than 13,000 patients in Washington State confirmed stable 30-day survival rates dating back to 1987 (Fig. 112.14).[70]

There are many observational studies seeking to identify the predictors of operative mortality after lower extremity amputation. A study of more than 9000 patients used the ACS NSQIP database to perform a retrospective review of BKA and AKA patients. In patients undergoing AKA, 30-day mortality was more often associated with the following risk factors, in decreasing order: hemodialysis dependence, thrombocytopenia, total dependent functional status, age greater than 80 years, steroid use, congestive heart failure, preoperative sepsis, body mass index less than 18.5 kg/m^2, and dyspnea. In patients undergoing BKA, 30-day mortality was more often associated with the following risk factors, in decreasing order: age greater than 80 years, DNR status, hemodialysis dependence, totally dependent functional status, sepsis, and thrombocytopenia.[64] In another study of 30-day mortality after BKA, renal failure increased the risk of death by more than threefold to 62%.[71] Guillotine amputation for sepsis was associated with a 14.3% mortality compared with 7.8% in patients undergoing elective amputation.[60]

LONG-TERM SURVIVAL

The prevalence of major lower extremity amputation attributable to vascular disease in the United States was approximately 500,000 in 2005, with an expected increase by 50% by the year 2020.[72] One-year survival rates are lower in patients receiving a higher-level amputation (Table 112.1). The approximate 1-year survival following BKA is 65% to 80% versus 50% following AKA (Fig. 112.15).[46,63,69,70,73] In another perspective, the median survival was reported as 1 year for transfemoral amputation and 2.4 years for transtibial amputation.[74] Predictably, patients with diabetes and renal failure fare worse.[69,74] Of 390 British patients undergoing lower extremity amputation, diabetic patients' median time to death was 27.2 months versus 46.7 in nondiabetics.[69] Amputation patients on dialysis had a 1-year survival of 51.9%, amputation patients not on dialysis but with

(*$P < .001$ when post-1995 is compared with pre-1995.) (From Sandnes DK, Sobel M, Flum DR. Survival after lower-extremity amputation. *J Am Coll Surg.* 2004;199:394–402.)

a serum creatinine greater than 2 mg/dL had a 1-year survival rate of 55.9%, and non–dialysis-dependent patients had a 1-year survival rate of 75.4%.[69] Overall, long-term survival has improved following major lower extremity amputation, but there are no studies completed within the past 10 years to confirm this observation.[61,70]

FUNCTIONAL OUTCOME

After toe, ray, and transmetatarsal amputations, near-normal ambulation with conventional footwear is likely. Shoe fillers and simple orthoses allow for ambulation in a majority of patients.[a]

Following transtibial amputation for vascular disease, bipedal ambulation with a prosthesis is uncommon. Two recent reports indicate only approximately 25% of major lower extremity amputees ambulate with a prosthesis outside the home.[45,75] These patients were unable to use a prosthesis for a variety of reasons, including mental illness, cardiopulmonary insufficiency, inadequate balance, and stump problems.[45,79] A prospective study of 297 patients reported that those who received care in an acute inpatient rehabilitation facility had better functional outcome at 6 months than patients who were treated at home or in a skilled nursing facility.[80] Taylor and coworkers identified significant preoperative factors independently associated with not wearing a prosthesis. In order from greatest to least risk, these patients were nonambulatory before amputation (odds ratio [OR] 9.5), AKA (OR 4.4), homebound but ambulatory, (OR 3.0), older than 60 years (OR 2.8), or diagnosed with dementia (OR 2.4), end-stage renal disease (OR 2.3), or coronary artery disease (OR 2.0).[81] Older transfemoral amputees rarely (<10%) ambulate successfully with a prosthesis.[45,75,82] Dialysis-dependent renal failure is a strong predictor of nonambulatory status.

Despite the fact that few vascular amputees ambulate with a prosthesis outside the home, most maintain their preoperative living status. Highly motivated patients—as evidenced by a commitment to a strict rehabilitation program, including smoking cessation and weight loss—are more likely to achieve

long-term success.[83] In addition, patients with financial resources that allow participation in a well-organized rehabilitation program are more likely to be successful. Taylor and coworkers identified the following statistically significant preoperative factors that were independently associated with a failure to maintain an independent living status (in decreasing order of influence): age 70 years or older (hazard ratio [HR] 4.0), age 60 to 69 years (HR 2.7), level of amputation (HR 1.8), homebound ambulatory status (HR 1.6), and dementia (HR 1.6).[81] In the United States, Medicare reimbursement for a prosthesis is based on adequate patient motivation as well as the ability to achieve a defined functional state classified as a "K level" (Table 112.2).[84]

REAMPUTATION

Following an initial toe amputation, approximately 50% of patients eventually undergo additional ipsilateral or contralateral amputations. Following foot or ankle amputation, nearly 35% of patients progress to a higher-level amputation within 1 year.[46] Wound problems develop in 20% to 30% of patients following transtibial amputation.[45,69,82] Only half of these amputations are salvaged at the transtibial level. In addition, reamputation at the transfemoral level has been reported in 9.4% to 19.6% of transtibial amputees.[b] It has also been reported that 9.4% to 17% of transtibial amputees undergo contralateral major amputation within as little as 12 months.[46,62,69,82,85] Not surprisingly, the risk of ipsilateral reamputation at a higher level is inversely related to the level of the index amputation. Diabetic patients are almost twice as likely to have reamputation as are nondiabetic patients.[73,76] The 1-, 3-, and 5-year ipsilateral reamputation rate for diabetic patients are as follows: for

[b]References 45, 46, 62, 63, 69, and 82.

TABLE 112.2 K-Levels, A Classification System Created by the US Centers for Medicare and Medicaid Services Are Used to Stratify Potential Functional Ability in Amputees

Level 0:	Does not have the ability or potential to ambulate or transfer safely with or without assistance and a prosthesis does not enhance their quality of life or mobility.
Level 1:	Has the ability or potential to use a prosthesis for transfer or ambulation on level surfaces at fixed cadence. Typical of the limited and unlimited household ambulator.
Level 2:	Has the ability or potential for ambulation with the ability to traverse low level environmental barriers such as curbs, stairs or uneven surfaces. Typical of the limited community ambulator.
Level 3:	Has the ability or potential for ambulation with variable cadence. Typical of the community ambulator who has the ability to traverse most environmental barriers and may have vocational, therapeutic, or exercise activity that demands prosthetic use beyond simple locomotion.
Level 4:	Has the ability or potential for prosthetic ambulation that exceeds basic ambulation skills, exhibiting high impact, stress, or energy levels. Typical of the prosthetic demands of the child, active adult, or athlete.

toe amputees, 22.8%, 39.6%, and 52.3%, respectively; for ray amputees, 28.7%, 41.2%, and 50%, respectively; for midfoot amputees, 18.8%, 33.3%, and 42.9%, respectively; and for major amputees, 4.7%, 11.8%, and 13.3%, respectively. In a study analyzing factors that predict long-term resource use and survival after major amputation, the authors noted that complicated diabetes, renal failure, and undergoing index BKA were all associated with increased additional amputation-related procedures.[86]

COMPLICATIONS

Local

Bleeding

Reoperation for postoperative bleeding is reported in 3% to 8% of major lower extremity amputations.[45,61] Frequently, patients undergoing dysvascular amputations are on antiplatelet therapy, which may increase the likelihood of developing a hematoma. Despite this elevated risk, patients should still receive DVT prophylaxis, unless contraindicated.

Infection

The likelihood of wound infection following major lower extremity amputation ranges from 13% to 40%.[5,9,87] An increased risk of wound infection is associated with diabetes, preoperative wound infection, malnutrition, malignancy, advanced age, lack of insurance, wound hematoma, and prior prosthetic bypass grafts. Complete removal of synthetic graft material at the time of amputation can decrease the rate of stump infection.[88] A recent study reported wound infection or disruption in healing to be 10.4% after BKA and 7.2% after AKA. In this study, patients with elevated international normalized ratio (INR) and patients age 50 to 59 were more likely to develop wound complications after a BKA, whereas current smokers and obese patients were more likely to develop wound complications after AKA.[89]

Superficial infections can initially be treated by administration of broad-spectrum antibiotics and removal of skin sutures. Deeper infections necessitate more aggressive drainage and débridement. Vacuum dressings may be particularly effective in this setting.[22]

Contracture

Flexion contractures at the hip and knee joint develop in 3% to 5% of major lower extremity amputations. A fixed flexion contracture at the knee that exceeds 15 degrees prohibits effective prosthetic ambulation. After a significant contracture develops, it may be impossible to correct with physical therapy or surgery.[90] A rigid, removable dressing should be applied to prevent knee contractures. An aggressive postoperative knee exercise program should be initiated as soon as possible. Hip flexion contracture may be limited by positioning the patient in the prone position for brief periods.

Systemic

Cardiac

Myocardial infarction remains the most common cause of death following lower extremity amputation. In a study of 788 patients, 10.2% of patients experienced a cardiac complication: congestive heart failure (4.2%), myocardial infarction (3.4%), and arrhythmia (2.6%).[69] Antiplatelet agents and statins should be continued perioperatively, and one should aim to maintain adequate perfusion while avoiding overresuscitation in the perioperative and postoperative phases. Clinical suspicion of an adverse cardiac event should remain high.

Pulmonary

Following amputation, patients are at risk for respiratory complications, including pneumonia. Although there is insufficient evidence for the use of incentive spirometry, its use may limit atelectasis and at the very least engage the patient.

Venous Thromboembolism

Following lower extremity amputation, the risk of DVT is up to 50%.[10,91-93] Low-molecular-weight heparin administered prophylactically lowers this risk to 10%. It is our practice to prefer low-molecular-weight heparin for chemoprophylaxis, although unfractionated heparin is preferred in patients with severe renal impairment or weight less than 45 kg.

Renal Failure

Acute blood loss, general anesthesia, and any other cause for hypotension and end-organ malperfusion may put the patient at risk for acute kidney injury. New-onset renal failure following amputation ranges from 0.6% to 2.6%.[45,69]

Stroke

The incidence of stroke after major amputation ranges from 0.28% to 1.4%.[45,61] Stroke is a rare cause of perioperative death behind infection, cardiac event, and pulmonary embolus.[94]

Psychiatric

Posttraumatic stress disorder is common (20%-22%) after amputations for combat or accidental injuries. For vascular amputations the incidence is less than 5%. Risk factors for major depressive disorder include young age at the time of amputation, pain, neurotic personality, unhealthy lifestyle, and poor coping skills.[95,96] In addition, 16% of a sample of 239 patients undergoing vascular disease–related amputation experienced suicidal ideation.[97]

Pain

Chronic pain is reported by up to 95% of amputees.[98] Chronic ischemic stump pain may be difficult to detect by physical examination alone but is confirmed by a transcutaneous oxygen tension less than 20 mm Hg. Chronic infection, particularly related to residual prosthetic graft material, may also cause pain. Neuroma can develop at the site of transection of virtually any peripheral nerve. The pain is usually well localized and can be transiently or permanently blocked with anesthetic injection. Pressure points that develop over bone spurs or pathologic bone formation should be eliminated. Depression appears to complicate the treatment of pain in many amputees.[98]

True phantom pain is a complex, poorly understood pain syndrome. The incidence of phantom pain widely varies in the literature from 5% to 85%, depending on the diagnostic criteria.[99,100] Inadequate control of both preoperative and postoperative pain may increase the risk of chronic amputation pain.[101] Gabapentin has not been consistently effective in the treatment of phantom pain. Multimodality pain management is the cornerstone of a successful amputation rehabilitation program.[102]

INTRODUCTION

Diabetic foot disease poses a growing global public health challenge and a major financial burden on healthcare systems worldwide. The prevalence of diabetes is exploding worldwide and is expected to involve more than 500 million people in the next 10 to 15 years. Diabetes is the leading cause of foot pathology, causing foot ulcerations from neuropathy, infection, and ischemia. Indeed, most nontraumatic amputations in the United States and Canada are secondary to diabetic foot ulcers.[1,2] Among people within the United States, up to 15% have active ulcers and 1 in 4 have a lifetime risk of developing a diabetic foot ulcer.[3] Infection occurs in approximately half of diabetic foot ulcers, and many of these require amputation. As such, diabetic foot ulcers are one of the most costly aspects of diabetes care, and ulcer-related complications are the leading cause of hospitalization for diabetic patients.[4] This has led to a growing risk of amputation among diabetic patients, because 85% of patients presenting with a foot ulcer are at risk for a subsequent amputation.[5]

EPIDEMIOLOGY

Beyond their devastating complications, such as amputation, diabetic foot ulcers have also been associated with poor quality of life outcomes and a significant financial burden, both to the patient and to the economy through direct costs and lost productivity. The reduced mobility, multiple and prolonged hospitalizations and clinic visits, and the deteriorating quality of life lead to cardiovascular stress and an increased risk of

Abstract

Diabetic foot disease poses a growing global public health challenge and a major financial burden on healthcare systems worldwide. The prevalence of diabetes is exploding worldwide and is expected to involve more than 500 million people in the next 10 to 15 years. Diabetes is the leading cause of foot pathology, causing foot ulcerations from neuropathy, infection, and ischemia. Indeed, most nontraumatic amputations in the United States and Canada are secondary to diabetic foot ulcers. Among people within the United States, up to 15% have active ulcers and 1 in 4 have a lifetime risk of developing a diabetic foot ulcer. Infection occurs in approximately half of diabetic foot ulcers, and many of these require amputation. As such, diabetic foot ulcers are one of the most costly aspects of diabetes care, and ulcer-related complications are the leading cause of hospitalization for diabetic patients. This has led to a growing risk of amputation among diabetic patients, because 85% of patients presenting with a foot ulcer are at risk for a subsequent amputation.

mortality compared with the general population. In fact, patients with a diabetic foot ulcer have an annual mortality rate approaching 10%, with an increase to 20% annually if an amputation is performed. Diabetic patients who undergo amputation have a median incidence of mortality at 27 months postoperatively, compared with 47 months among nondiabetic patients with amputation.[6] In all, the 5-year relative mortality rate for those with diabetes who undergo a major limb loss is 70%.[7]

On average, treating diabetic foot ulcers has been estimated at $8000 to $17,000 in medical expenditures and those patients who subsequently undergo an amputation require $40,000 to $60,000, depending on the extent of the amputation and the associated hospital stay.[8] Limb amputations are also predictors of further deterioration in the patient's health. Among patients who have undergone a major lower extremity amputation, up to 40% will undergo amputation of the contralateral limb within 3 years.[9]

PATHOPHYSIOLOGY

The etiology of diabetic foot ulceration is a well-understood, but multifactorial and complex process (Fig. 113.1). Major risk factors associated with diabetic foot ulcer formation are diabetic peripheral neuropathy and peripheral arterial disease (PAD), which act either in isolation or concurrently. Other important risk factors include soft tissue infection, biomechanical abnormalities, peripheral edema, plantar callus formation, nephropathy, poor glucose control, age, and a prolonged diabetic course.[10] Abnormal foot biomechanics often results from structural foot deformities combined with the limited joint mobility and bony abnormalities found in diabetic patients. Trauma due to poorly fitting footwear also frequently plays a major role and ulcer formation. Ulceration of the heel often combines decubitus or pressure forces with ischemia, resulting in a difficult management issue.

Diabetic Neuropathy

Diabetes results in both somatic and autonomic neuropathy. The onset of somatic neuropathy is insidious and progressive, eventually resulting in the complete loss of foot sensation and placing the patient at a higher risk of unperceived foot trauma and ulceration.[11] Examples include puncture wounds while walking barefoot, burn wounds, and iatrogenic or self-induced trauma while cutting nails or grooming the skin. Furthermore, loss of sensation places the patient at a higher risk of injury when donning improperly fitted shoes.[12] Somatic neuropathy also leads to muscle wasting and eventual flexor-extensor muscle imbalance, weakening of the anterior calf muscles, and the development of an equinus deformity. The forefoot is the most common site of neurotropic ulceration as a result of those diabetes-induced muscle imbalances.[13] Patients with isolated diabetic somatic neuropathy have been found to be at a sevenfold increased risk of foot ulceration compared with other patients.[14]

Sympathetic autonomic nerve dysfunction results in reduced sweating accompanied by dry, fragile skin that is at a higher risk of cracking and fissure formation. This neuropathy can also result in arterial-venous shunting and impaired microvascular regulation of the skin.[15] As such, the insensitive diabetic foot may appear warm and well perfused, resulting in a false sense of security by both the patient and the provider as to the risk of diabetic ulcer formation.[11]

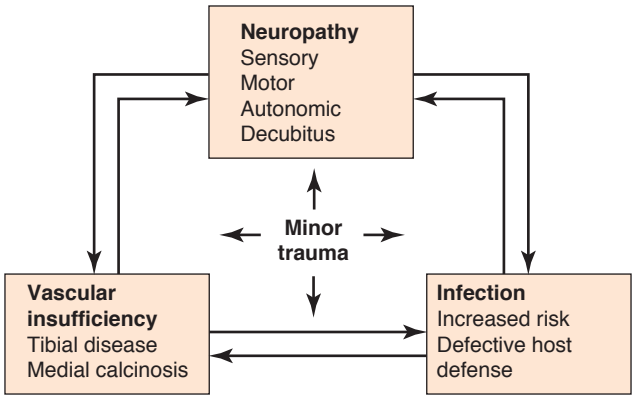

Figure 113.1 Multifactorial etiology of diabetic foot pathology.

Peripheral Arterial Disease

Arterial disease contributes to the development of 50% of diabetic foot ulcers and plays a role in 70% of the mortality among diabetic patients.[10,16] Arterial occlusive disease may be present in isolation or in combination with neuropathic disease in up to 45% of lower extremity ulcerations.[17] Although femoral artery disease occurs in an equal incidence with the nondiabetic population, infrapopliteal occlusive disease with heavy calcification is the classic picture of diabetic arterial disease. In addition, despite the basement membrane affected at the capillary level in those with diabetes, microvascular disease precluding revascularization in diabetic patients has been disproved. Diabetic patients are at a higher risk of digital artery disease with palpable pedal pulses that nonetheless can result in digital ulceration and subsequent impaired healing and gangrene. Despite the relatively common occurrence of an incomplete pedal arch in diabetic patients, tibial revascularization, especially to the angiosome in which the ulceration is located, is possible in the vast majority of diabetic patients to overcome foot ischemia.[18]

Soft Tissue Infection

Diabetic foot ulcers may present with or without infection with a classification proposed by the Infectious Diseases Society of America, including a PEDIS (perfusion, extent, depth, infection and sensation) score to guide assessment of severity and subsequent therapy (Table 113.1). A wound culture should be obtained when signs of an infection, such as purulence, cellulitis in the adjacent skin, malodor, and tissue necrosis, are present. However, ulcers that are otherwise clean and free from any local or systemic signs of infection should not be swabbed or cultured.[19] In the absence of a clinical suspicion of an active infection, a culture swab will likely report mixed skin flora that are not associated with an active infection, and unnecessary treatments might be prescribed. When a soft tissue culture is

TABLE 113.1 Summary of the Classification System of Diabetic Foot Infection by the International Working Group on Diabetic Foot Infection

Grade	Clinical Signs of Infection
1	None
2	Local process involving skin and subcutaneous tissue Erythema (if present) <2 cm No sign of systemic infection
3	Local process deeper than skin and subcutaneous tissue Erythema >2 cm Local abscess, osteomyelitis, septic arthritis, fasciitis No sign of systemic infection
4	Signs of systemic infection (>2 of the following); Temperature >38°C, or, <36°C Heart rate >90 bpm Respiratory rate >20 breaths/min $tcPO_2$ <32 mm Hg WBC >12, or, >10% bands

Signs of local infection; swelling, induration, erythema, tenderness, warmth, purulent discharge.

desired, samples obtained surgically or by curettage of the wound bed are more sensitive and specific in identifying the causative organisms and guiding therapy than swabbing the wound or drainage. In addition, diabetics have elevated serologic concentrations of adhesion molecules that bind monocytes, leukocytes, and platelets to the endothelium and impair its function, leading to diminished skin perfusion and healing, leading to a reduced ability to deliver antibiotics to sites of infection.[20,21]

Muscle and Bone Abnormalities

The changes in biomechanical forces that result from diabetic bony foot deformities create points of pressure that may eventually lead to ulceration (Fig. 113.2). These forces, combined with limited joint mobility, lead to structural deformities such as hallux valgus, claw toes, and abnormalities of the metatarsophalangeal joints. This process is exacerbated by neuropathy-induced lack of sensation in the diabetic foot. Muscular weakness can result in functional imbalances between the tendons of the foot with subsequent hammertoe development that is vulnerable to shoe trauma at bony prominences. The contracted toes also induce increased pressure at the plantar aspect of the metatarsal heads. In addition, Charcot changes and midfoot collapse due to neuro-osteoarthropathy, as well as restricted foot motion due to flatfoot deformities, equinus, and knee or back issues, may all add to the biomechanical stress experienced by the foot, worsen the degree of ulceration, and prevent adequate healing.[22]

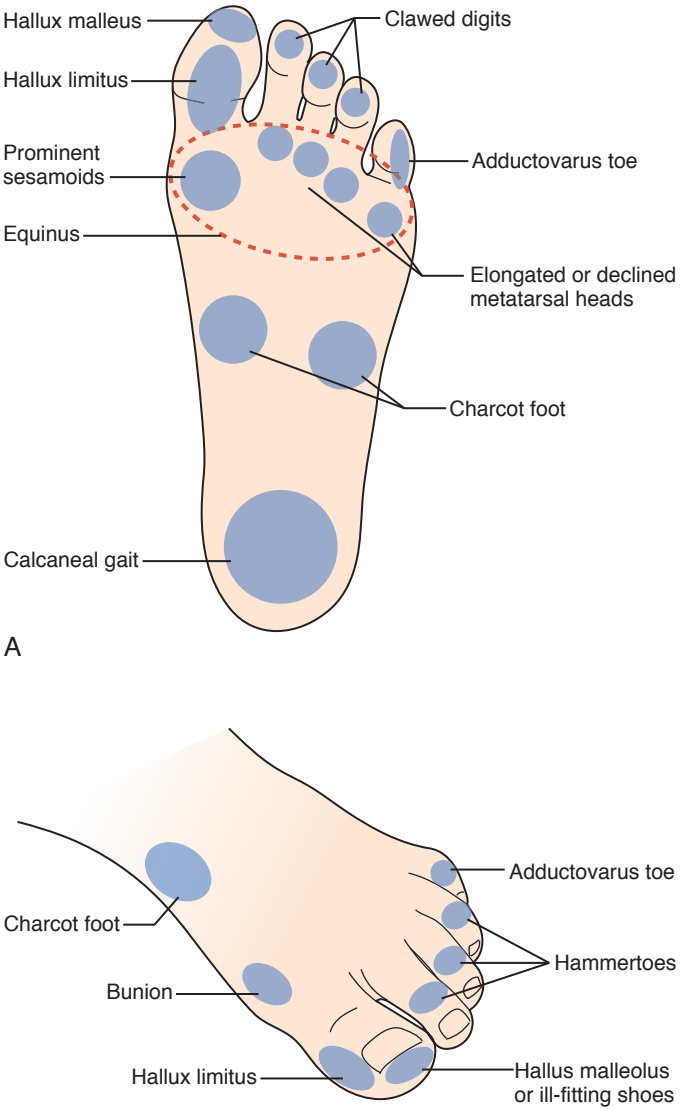

Figure 113.2 Locations of skin lesions on the diabetic foot with corresponding biomechanical etiologies related to the plantar (A) and dorsum (B) surfaces with an example of a diabetic dorsal foot wound (C).

PRESENTATION AND DIAGNOSIS

Patient History

A detailed medical and surgical history should be obtained from every diabetic patient with a foot ulcer to determine how

TABLE 113.2 The Essential Components of a Diabetic Foot Exam

Vascular	Neurologic	Dermatologic	Musculoskeletal
Palpate pedal and lower extremity pulses Look for distal hair growth on feet toes Assess capillary filling time in the toes	Test for loss of protective sensation by Semmes-Weinstein monofilament, biothesiometry, or electronic tuning fork Look for muscle atrophy of the feet	Note the ulcer depth, tissue in the wound bed, if bone is palpable Look for signs of infection around a wound (erythema, purulence) Inspect for other preulcerative lesions (blisters, calluses, corns)	Inspect for deformities Look for signs of Charcot foot (collapsed arch or hot, red swollen foot Check the dorsiflexion of the ankle and the great toe joint

the patient's diabetes is managed, whether the ulcer appeared suddenly or secondary to a traumatic incident, whether the patient traveled recently or acquired new footwear, and to determine the wound's duration and any noticeable changes in its appearance and character. Any previous wounds should also be documented, as well as any wound care treatments that the patient has received. Wounds that are accompanied by systemic symptoms suggestive of infection, such as malaise or cold sweats, should be treated without delay. Risk factors for diabetic foot ulceration, such as a history of peripheral neuropathy, symptoms of arterial disease, and bony deformities, as well as any previous vascular, orthopedic, or plastic surgical interventions, should also be documented.

Physical Examination

The diabetic foot physical examination must include dermatologic, neurologic, vascular, and musculoskeletal assessments (Table 113.2).[23] The skin of patients with advanced diabetic disease is usually dry and brittle because of peripheral neuropathy. Areas of hyperkeratosis indicate pressure points that are often accompanied by preulcerative or ulcerative changes (Fig. 113.3). Preulcerative changes may be subtle and can appear as pinpoint hemorrhages or shallow hematomas within the dermis. A waxy appearance of the callus may indicate fluid beneath the lesion and should be palpated for fluctuance. A hyperkeratotic lesion suspicious for underlying ulceration should be sharply débrided to inspect the underlying skin.

Figure 113.3 Diabetic foot ulceration with dry, brittle skin in an area of pressure.

Inspection of the foot may reveal the sequelae of motor neuropathy, such as atrophy of the intermetatarsal musculature and hollowing of tissue between the metatarsals and arch of the foot. The patient should also be examined for Charcot neuropathic osteoarthropathy, also known as "Charcot foot." The classic, but late, presentation of a "rocker bottom foot" in these patients creates severe midfoot plantar pressures and subsequent ulceration.[24] A unilateral, hot, swollen foot should be considered an acute presentation of Charcot foot until proven otherwise.[25] Early offloading and immobilization can prevent further damage and prevent a rocker bottom foot (Fig. 113.4). Acute Charcot foot can often be misdiagnosed as cellulitis, osteomyelitis, deep venous thrombosis, or gout.

Sensory testing using a Semmes-Weinstein monofilament (10 g) is a predictive and easily reproducible test to assess the neuropathic risk of foot ulceration and amputation in diabetic patients.[26] Failure of the patient to perceive more than four or more of the 10 test sites has been associated with a 15-fold increase in the risk of plantar ulceration.[27] Testing perception of vibration with a 128-mHz tuning fork is also predicative of ulceration risk, although this test is less reliable than the Semmes-Weinstein test.[14]

Lower extremity arteries, including the femoral, popliteal, and tibial arteries, should be palpated to detect a pulse. However, palpation is affected by factors such as the patient's body habitus, peripheral edema, and blood pressure fluctuations, as well as the examiner's level of experience. As such, clinical decision-making should not be based solely on the presence or absence of palpable pulses without further noninvasive vascular testing. An ankle-brachial index (ABI) measurement is often obtained at the time of the initial clinical evaluation but may be falsely elevated due to the prevalence of medial arterial calcinosis in the tibial arteries of the diabetic foot.[28,29]

Figure 113.4 Charcot foot; typical "rocker bottom" appearance (A), characteristic x-ray (B), and offloading with total contact cast (C).

Diabetic Ulcer Evaluation and Classification

The diabetic ulcer should be visually inspected for the presence of viable tissue, drainage, purulence, odor, and surrounding erythema. The wound dimensions, location, and the number of ulcers should also be carefully documented. Mixed arterial/venous ulcers should also be suspected with appropriate vascular lab testing. A sterile probe should be used to interrogate the wound for any abscesses, tendons, or bone. Encountering bone using the probe places the patient at a high index of suspicion for osteomyelitis.[30]

Numerous diabetic foot ulcer classification systems have been developed and used for clinical and research purposes. The Wagner Classification is the first such system and was initially developed for pressure wounds rather than diabetic ulcers. This system has limited sensitivity and specificity and has limited clinical application.[31] The University of Texas Classification System and the PEDIS ulcer classification were subsequently developed to correlate wound characteristics with clinical outcomes (Table 113.3).[29,30] The WIfI (Wound, Ischemia, foot Infection) classification system as advocated by the Society for Vascular Surgery is the most recent foot ulcer staging system that has been clinically validated by several investigators.[32-34]

Radiologic Investigations

Numerous imaging modalities are available for the workup of diabetic foot ulcers. Foot x-rays should be obtained to rule out

TABLE 113.3 Wagner and Texas Classification Systems of Diabetic Foot Ulcers

WAGNER METHOD (29)		UNIVERSITY OF TEXAS METHOD (30)	
Grade	Details	Grade	Details
0	No open foot lesion	0	Presence of preulcer or postulcer epithelization
1	Presence of superficial ulcer, partial or full thickness	1	Superficial ulcer not penetrating tendon, bone or joint
2	Ulcer extends to ligaments, tendon, joint capsule or deep fascia without abscess or osteomyelitis	2	Ulcer penetrating through to tendon or capsule
3	Presence of deep ulcer with abscess, osteomyelitis	3	Ulcer penetrating to bone or joint
4	Gangrene localized to the forefoot or heel	A	Noninfected and nonischemic ulcer
5	Extensive	B	Infection present
		C	Ischemia present
		D	Both infection and ischemia are present

bony deformities, and, if infection is suspected, evaluate for subcutaneous gas. When ulcer healing does not progress at a satisfactory rate, other imaging studies that should be considered include computed tomography (CT), magnetic resonance imaging (MRI), labeled white blood cell scans, single-photon emission computed tomography (SPECT), and positive emission tomography (PET) scans to rule out osteomyelitis or soft tissue infections. Although PET and labeled white blood cell scans have been shown to have the highest diagnostic accuracy in confirming or excluding the diagnosis of osteomyelitis, they are time-consuming and expensive tests and many clinicians will preferentially order MRIs first for the workup of osteomyelitis.[35]

MANAGEMENT

General Principles

The decision to treat a diabetic foot ulcer in an outpatient setting or as an inpatient in the hospital often hinges on the patient's presenting clinical status. Septic patients with severely infected wounds require admission for urgent surgical management to limit the spread of the infection and tissue destruction. Conversely, patients with stable, chronic issues can be managed in the outpatient setting. Outpatient care consists primarily of wound management through local wound care and coordination of appropriate diagnostic testing and consultations. Serial wound clinic visits for dressing changes and débridement of the wounds is often required for many patients. A myriad of topical dressings exists from which to choose based on the wound etiology, availability, and cost. In addition to débridement and maintaining a moist and healthy wound bed, diabetic foot ulcers should also be treated with culture-directed antibiotics, if infected. It is sometimes possible to accomplish these goals with a dressing that serves multiple purposes: control of infection and inflammation, moisture balance, and the provision of pressure relief.

Wound Débridement

The purpose of débriding a diabetic foot ulcer is to alter the environment of the wound and to promote healing by removing abnormal tissue, such as hyperkeratotic epidermis and necrotic dermal tissue, foreign debris, and bacteria.[36] In addition to removing nonviable tissue, débridement converts a stagnant wound into an acute healing wound by releasing platelet growth factors, inhibiting proteinases, and limiting the action of bacterial biofilm.[37] Different modalities for débriding a wound include sharp, surgical, enzymatic, autolytic, mechanical, and intraoperative with ultrasonic and hydrosurgical devices. Because the majority of these patients are neuropathic, aggressive débridement can usually be carried out with minimal discomfort. If the patient is anxious or an extensive débridement is required, a local anesthetic block or sedation in an operating room setting may be helpful.

Sharp débridement at the bedside may suffice for small wounds, but larger wounds often require repetitive débridement, with the goal of a well-perfused wound bed and quantitative cultures less than 10^5/g tissue before closure. In Sinkin's series of 193 wounds in Charcot foot patients, the average number of débridements prior to attempted closure was four.[38] Exposed bone needs to be débrided to stippled punctate bleeding, and bone cultures should be obtained. The bacteria most likely to be involved in diabetic osteomyelitis are skin organisms, frequently *Staphylococcus aureus* and sometimes resistant strains.[39] Copious pulse lavage irrigation should be performed at the end of each débridement.

Between débridements, wounds may be covered with moist dressings, silver-containing dressings, or creams or treated with negative-pressure therapy. Zhang and colleagues reported that negative-pressure therapy was more likely to shrink or heal ulcers compared with standard therapy and did so in a shorter period of time.[40]

Offloading

The foot must also be offloaded to minimize pressure on the wound and to prevent ulcers from recurring. The likelihood of healing increases with the effectiveness of offloading and the compliance of the patient.[41] Offloading modalities include postoperative shoes, wedge shoes, healing sandals, braces, boots, and total contact casting. Although level one evidence for these

individual modalities is sparse, a meta-analysis showed greater wound healing efficacy with the use of total contact casting and irremovable cast walkers.[42] Multilayer customized offloading orthoses and fillers at sites of partial foot amputation are available to stabilize the position of the foot within the shoe. It is necessary to balance and offload pressure from both prior and potential ulceration sites.[43] Referral to an orthotist for prescription footwear and orthoses is recommended because the at-risk patient will need monitoring and adjustment of the devices. The patient may also benefit from additional bracing or splinting to offload pressure and will need to have these devices replaced regularly for the rest of their lives.

Patient Education

Due to the initial indolent course of diabetic foot ulcers but their potentially devastating complications, it is advisable to educate patients and their families on the nature of the disease to maximize the likelihood of compliance with medical optimization and wound care. Patients should also recognize the reasons to seek urgent medical attention, should as a spreading soft tissue infection or gangrenous changes on the foot, because many patients with diabetic foot ulcers are insensate in their lower extremities because of diabetic neuropathy. The Society for Vascular Surgery has recognized the importance of involving patients in their plans of care, and its diabetic foot guidelines recommend that patients and their families be educated about preventive foot care.[44]

Advanced Wound Treatment Modalities

There is an ever-growing list of advanced wound treatment modalities such as bioengineered cultured cell grafts, allografts, collagen xenografts, and amniotic membranes. There is evidence to support the use of these products for wounds that have demonstrated a decreased rate of healing, but the quality of the evidence is variable, and the choice of product is often based on practitioner preference.[45,46]

There is also a role for negative-pressure wound therapy (NPWT) in the management of diabetic foot ulcers, as well as in the postoperative setting after amputation or delayed primary closure as a bridge to delayed grafting. A recent study reported that NPWT improved wound granulation, reduced the time to wound closure, and reduced the incidence of subsequent minor amputations.[47]

SOFT TISSUE SURGERY FOR THE DIABETIC FOOT

Diabetic patients with foot ulceration and tracking abscesses, wet gangrenous changes, gas in the tissue on plain film radiographs, or systemic signs of sepsis require urgent surgical attention. A thorough incision and drainage of any abscesses or infectious tracks must be aggressively performed in the operating room, along with an appropriate exploration of fascial compartments and layers of the foot, because abscesses originating from a forefoot ulcer can track up to the ankle or lower leg. Amputation of digits or portions of the foot may be necessary due to gangrene or to limit the advancement of infection. If the viability of any of the patient's foot tissue is questionable, then one might consider limiting the amount of tissue that is resected, to preserve later closure options. Any resected tissue or bone should be cultured and sent for a pathology evaluation. Patients will often subsequently require multiple procedures to resect necrotic wound edges and débride the wound to promote granulation.

After treating the foot infection, the focus of care should be directed towards the need for revascularization and primary or secondary wound closure. Because of the complex altered physiology of these wounds, as well as additional systemic issues in diabetic patients, wound closure is slow and multiple interventions are frequently required. However, with meticulous attention to detail, closure rates of up to 80% have been reported.[48] Defining principles of successful wound closure include infection control, wound débridement, adequate perfusion, offloading of pressure, and moisture balance. Small superficial wounds may heal either without additional intervention or with the application of cell-based materials such as Dermagraft, Apligraft, or keratinocyte allografts.[49] Antibiotic-impregnated bone beads might also be used to enhance the treatment of any residual osteomyelitis.[50]

Local Tissue Flaps

Local flaps for wound closure should be designed according to the foot's actual blood supply. A Doppler exam to determine areas of antegrade and retrograde flow is an important guide. Flaps should contain arterial perforators detected by Doppler signal, designed in the direction of antegrade flow to the local flap. The significant advantage of using local skin flaps is the concept of "replacing like with like": replacing defects with similarly specialized skin. The downside to local flaps is the limited amount of specialized skin available to close wounds, limiting the size of wounds that can be handled in this manner. If there is a bone abnormality causing the ulcer to form, the bone must be addressed and corrected to minimize the chance of recurrence. Blume described such an approach with 67 cases of one-stage ulcer débridement and closure together with correction of underlying bone abnormalities. Results with this single-stage approach included 97% healing, 54% without complication, and 88% without recurrence at 2.5 years. Forefoot wounds healed more quickly than midfoot or rear-foot wounds, and deep wounds healed slower than superficial wounds, with a longer hospital stay. This suggests that local skin flaps in selected patients can be very successful. Double plantar rotation flaps can also be designed to either side of the defect for closure of small (<2 cm) central plantar forefoot ulcers.[52]

Free (Microvascular Transfer) Flaps

Free flaps supply a large amount of tissue and can allow for aggressive débridement because the size of the wound is less constraining than with pedicled flaps. However, the flap should

not disturb the vascular supply of the foot, so arterial end-to-side anastomoses are a better choice than end-to-end anastomoses to maintain prograde flow in the native circulation. Microvascular transfers frequently require secondary procedures such as debulking and tissue re-inset to improve aesthetics and function. Because of flap bulk, getting shoes to fit can be very difficult. All successful series report aggressive débridement of nonviable tissue, revascularization when necessary to provide normal oxygen tension, control of medical problems, gradual protected weight bearing, correction of underlying bony abnormalities before or during the flap procedure, and control of infection. Deconditioned patients with multiple, poorly controlled medical problems are better treated with local tissue closure options.

Prevention of Recurrent Soft Tissue Defects

Prevention of wound recurrence is as important as the initial closure of the wound. Unfortunately, the risk of recurrent ulceration remains high despite improvements in diabetic foot management. The continued presence of those factors leading to initial ulcer formation such as neuropathy or arterial disease contributes significantly to this recurrence rate. Ulceration of the plantar surface correlates with increased sole and midfoot pressures with ambulation. Shortening of the Achilles tendon by contraction or chronic tightness can significantly contribute to increased plantar foot pressures. Diabetic Achilles tendons examined with electron microscopy demonstrate increased collagen density and structural disorganization.[53] Elevated glucose levels may lead to abnormal cross-linking between collagen fibrils and increasing tendon stiffness. Colen looked at diabetic wound closure comparing those that were done in conjunction with Achilles tendon lengthening versus those that did not have the tendon lengthened.[54] At nearly 3 years' follow-up, 2% of the patients with Achilles tendon lengthening recurred as opposed to 25% of those without tendon lengthening. Patients who cannot dorsiflex the ankle past neutral or have forefoot pressures of more than 100 lb/in.[2] are considered at increased risk of recurrent ulceration. Achilles tendon lengthening can often be performed percutaneously to achieve neutral or within 5 degrees of dorsiflexion in an effort to prevent recurrent foot ulceration.

AMPUTATION

When wound closure is not possible, because of the size and extent of the wound, location, or irreversible ischemia, then some variant of foot amputation may be required. Proper choice and optimal performance of amputation, such as partial or complete ray, transmetatarsal, midfoot amputations, are critical components of diabetic foot management (Fig. 113.5). With current advances in revascularization and wound care treatments, a partial foot amputation may be possible where a below- or above-knee amputation would previously have been thought more likely. Although amputations often carry a social stigma and are associated with significant psychological suffering to the patient, they may also result in rapid healing, shorter hospitalizations, lower risk of reinfection or recurrence of a wound, and an acceptable functional outcome. After the patient's amputation site is healed, the focus of treatment should become the prevention of ulcer recurrence at the site of amputation through appropriate offloading and patient education, as previously discussed.

Patients often benefit from a course of physical therapy postoperatively because many patients with advanced diabetic foot ulcer wounds demonstrate impaired ambulation in a prolonged non–weight-bearing state and are physiologically deconditioned. Outpatient or acute inpatient rehabilitation and physical therapy can be useful in helping patients regain muscle strength, improving gait and balance, and returning to an active lifestyle that is essential to controlling the patients' underlying medical and vascular pathologies. Finally, the patient will need ongoing care by multidisciplinary medical and surgical teams to mitigate the risk of future diabetic ulcer complications.

PERIPHERAL ARTERIAL DISEASE AND THE DIABETIC FOOT

Lower extremity arterial disease in diabetic patients is characterized by tibial artery involvement and the sparing of the microvascular circulation.[55] In the past, clinicians often discounted the utility of revascularization for diabetic patients with lower limb ischemia. It was reasoned that, because the etiology of diabetic arterial disease was secondary to the occlusion of the microvascular circulation, bypass surgery would not improve flow within the microcirculation and would undoubtedly fail. However, this belief has been discredited, and lower extremity revascularization with open or endovascular interventions can contribute in a significant way to limb preservation in this patient population. The indications for treating arterial occlusive disease in diabetics are similar to nondiabetic patients: lifestyle limiting claudication, rest pain, and tissue loss that is associated with nonhealing ulcers and gangrenous changes.

Vascular Lab Workup

Diabetic patients with tissue loss or nonhealing ulcers without palpable pedal pulses should undergo further testing for underlying arterial disease. Although ABI measurements are a standard component of the vascular workup, these values, as previously mentioned, are often unreliable in diabetics because of medial calcinosis of the tibial vessels. However, the digital arteries are often spared the heavy calcification that occurs in the tibial arteries, and their measurements of flow more accurately reflect foot perfusion. As such, toe-brachial index (TBI) measurements may be more useful in diabetic patients with a suspected falsely elevated ABI.[56] A TBI greater than 0.6 is predictive of tissue healing.

Alternative tests that might also be useful in the workup of diabetic foot ulcers include pulse volume recordings (PVR), photoplethysmography (PPG), and transcutaneous oxygen tension ($tcPO_2$), and skin perfusion pressure (SPP) measurements. Healing is unlikely to occur if the PVR amplitude is less than 5 mm or the PPG is less than 50 mm Hg.[57] Furthermore,

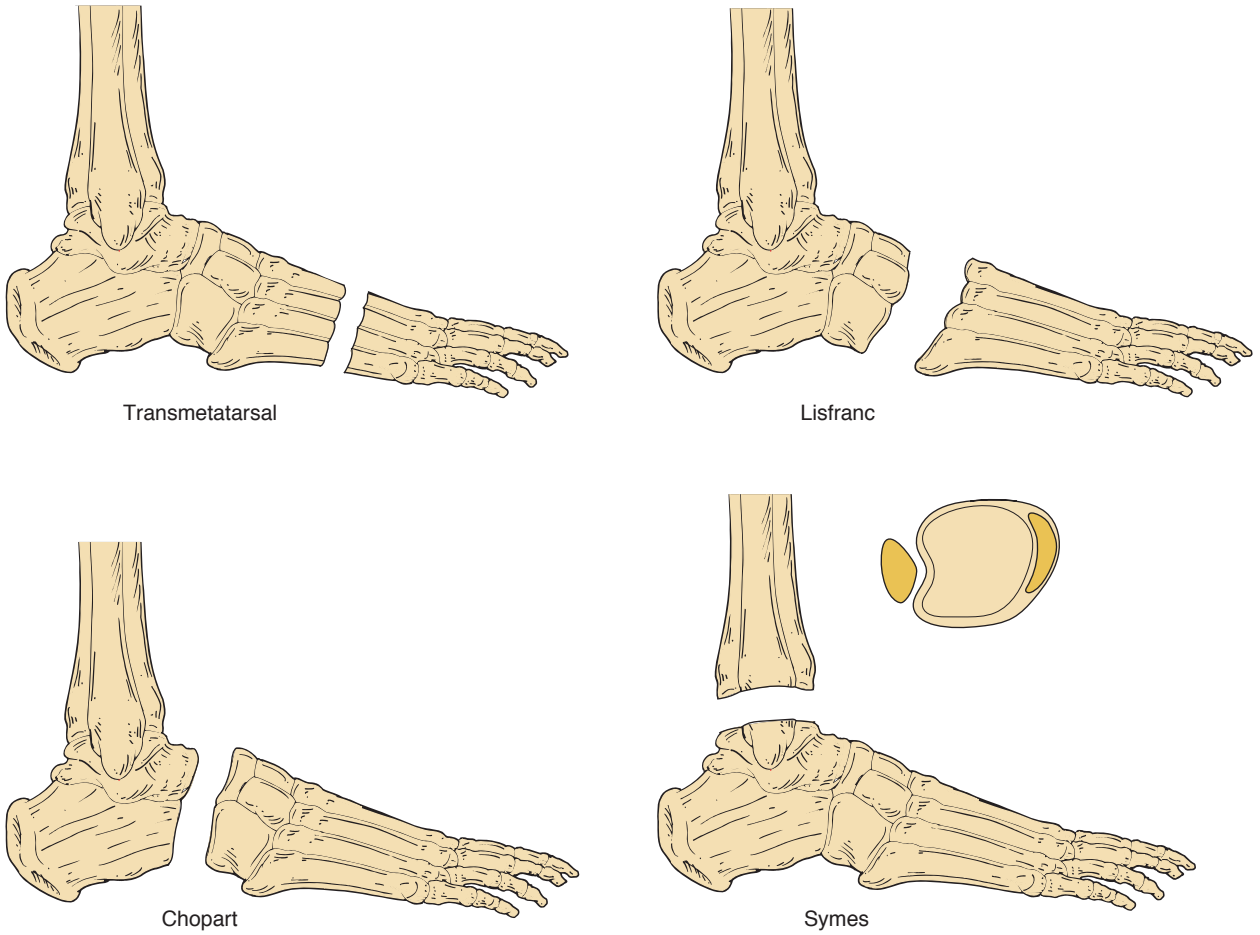

Figure 113.5 Types of midfoot amputation available for optimal maintenance of diabetic limb function: Lisfranc, Chopart, and Symes.

TABLE 113.4 Noninvasive Vascular Studies in the Diabetic Foot and Their Interpretations

Test	Normal	Mild Disease	Moderate Disease	Severe Disease
ABI	0.9-1.1	0.7-0.9	0.4-0.7	<0.4 or >1.1
TBI	>0.7	0.5-0.7	0.35-0.5	<0.35
PVR Waveforms	Triphasic	Biphasic	Biphasic	Monophasic
$tcPO_2$	>40 mm Hg	20-40 mm Hg	20-40 mm Hg	<20 mm Hg
SPP	>50 mm Hg	30-50 mm Hg	30-50 mm Hg	<30 mm Hg

ABI, Ankle-brachial Index; *PVR,* pulse volume recording; *SPP,* skin perfusion pressure; *TBI,* toe-brachial index; *$tcPO_2$,* transcutaneous oxygen.

wound healing is likely with a $tcPO_2$ greater than 40 mm Hg. A regional index can be calculated to account for variations in systemic arterial oxygen availability. To calculate this index, the foot $tcPO_2$ measurement is divided by a $tcPO_2$ reference point, usually chosen at the chest. A patient with a $tcPO_2$ index greater than 0.6 is likely to heal a wound, whereas a value less than 0.4 is unlikely to heal.[58] SPP measurements less than 30 mm Hg are predictive of nonhealing and greater than 50 mm Hg are predictive of healing. A summary of these noninvasive vascular studies and interpretive guidelines is presented in Table 113.4. Further noninvasive imaging, such as CTA and MRA, is often the next step for arterial imaging based on the vascular lab assessment. However, fine detail and definition of the tibial and pedal arteries is required to plan diabetic revascularization; therefore, arteriograms are often obtained to assist with operative planning, with CO_2 angiography considered in the setting of renal insufficiency (Fig. 113.6). Images from a CTA or MRA can allow a focused arteriographic approach that can often be combined with an endovascular therapeutic intervention if appropriate. In our experience, this occurs in approximately 60% of arteriographic studies performed for diabetic limb preservation.

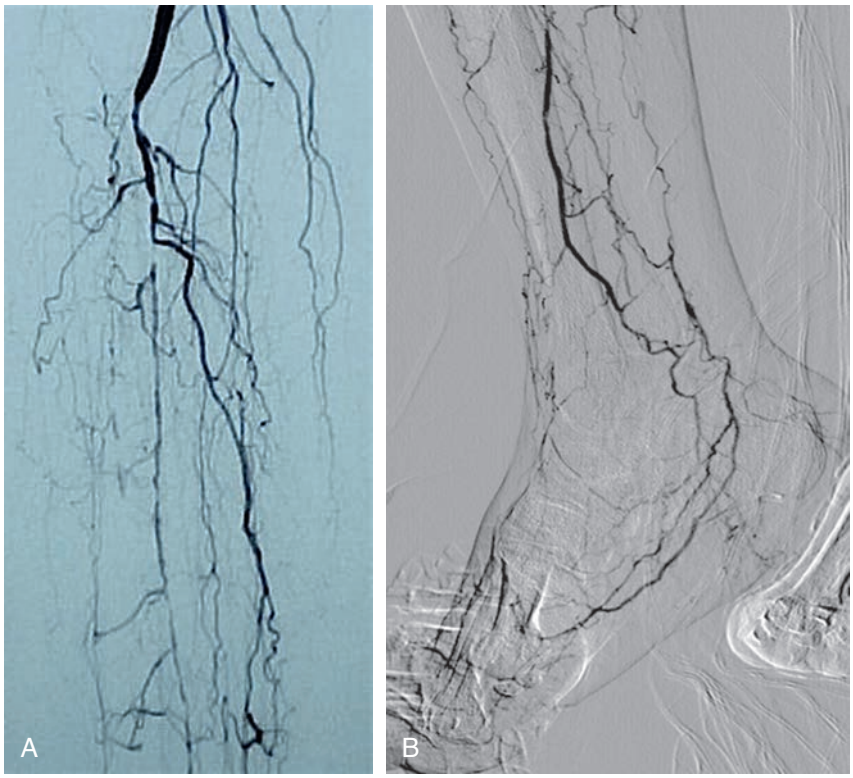

Figure 113.6 Lower extremity arteriogram with the tibial artery occlusive disease typical of a diabetic pattern (A) and the importance of adequate foot views to delineate distal targets for revascularization; in this case the distal peroneal and medial and lateral plantar branches (B).

Endovascular Interventions in the Diabetic Patient

Endovascular interventions continue to play an increasingly prominent role in the treatment of diabetic foot ulcer patients. However, tibial artery occlusive disease remains a challenge for a catheter-based approach. Several authors have demonstrated comparable outcomes after endovascular revascularization in diabetics and nondiabetics, with lower long-term primary patency rates in diabetic patients, but equivalent secondary patency and limb preservation rates.[59] Arterial runoff may be an important factor in determining the efficacy of endovascular interventions. Faglia and colleagues reported on 420 diabetic patients who underwent tibial angioplasty and found that the lack of a patent tibial artery at the end of the study resulted in a 62% amputation rate, compared with 1.7% in patients with at least one patent artery to the foot.[60]

Different modalities are available for revascularization, including standard tibial angioplasty with dedicated wires, standard balloons, and drug-eluting balloons, as well as pedal arch reconstruction with the "pedal loop" technique. The pedal loop technique involves traversing lesions in the pedal arch to establish blood flow to the foot in a prograde or retrograde manner.[61] Data of the role of stenting and drug-elution technologies in tibial artery revascularization remain limited. Although one study reported that infrapopliteal stenting can be successful, with restenosis rates of 20% at 1 year and greater than 70% primary patency, functional limb preservation was better for those patients undergoing proximal below-knee angioplasty compared with tibial stenting.[62]

SURGICAL BYPASS IN THE DIABETIC PATIENT

For diabetic ulcers to heal, it has been axiomatic to restore pulsatile blood flow to the foot. Although the femoropopliteal arterial segment is commonly affected in diabetics, tibial artery occlusive disease is the classic distribution in diabetic patients, leading to limb-threatening ischemia.[63] In our experience, functioning in a limb preservation program with a large volume of diabetic revascularization, approximately 25% of patients with limb-threatening ischemia who present with significant wounds and tissue loss are best treated by surgical bypass as the initial method of revascularization. We have found that diabetics with more extensive tissue loss (>2 cm^2) heal faster and more completely after bypass, compared with endovascular therapy. Due to the preponderance of tibial artery involvement, distal targets can include the medial and lateral plantar branches and other inframalleolar arteries (Fig. 113.7). Due to the patient's diabetic tibial distribution, a popliteal-distal bypass can often be considered because the proximal arterial tree is spared from flow-limiting occlusive disease. Use of the popliteal artery for inflow limits the length of the bypass to optimize long-term patency, as well as the length of the autogenous conduit needed for the bypass (Fig. 113.8).

Several investigators have established the superiority of lower extremity bypass with autogenous vein compared with other conduits. If vein can be used as a conduit for bypass in diabetic patients, then a patency and limb salvage rate similar to nondiabetic patients can be obtained.[64] Pomposelli and colleagues

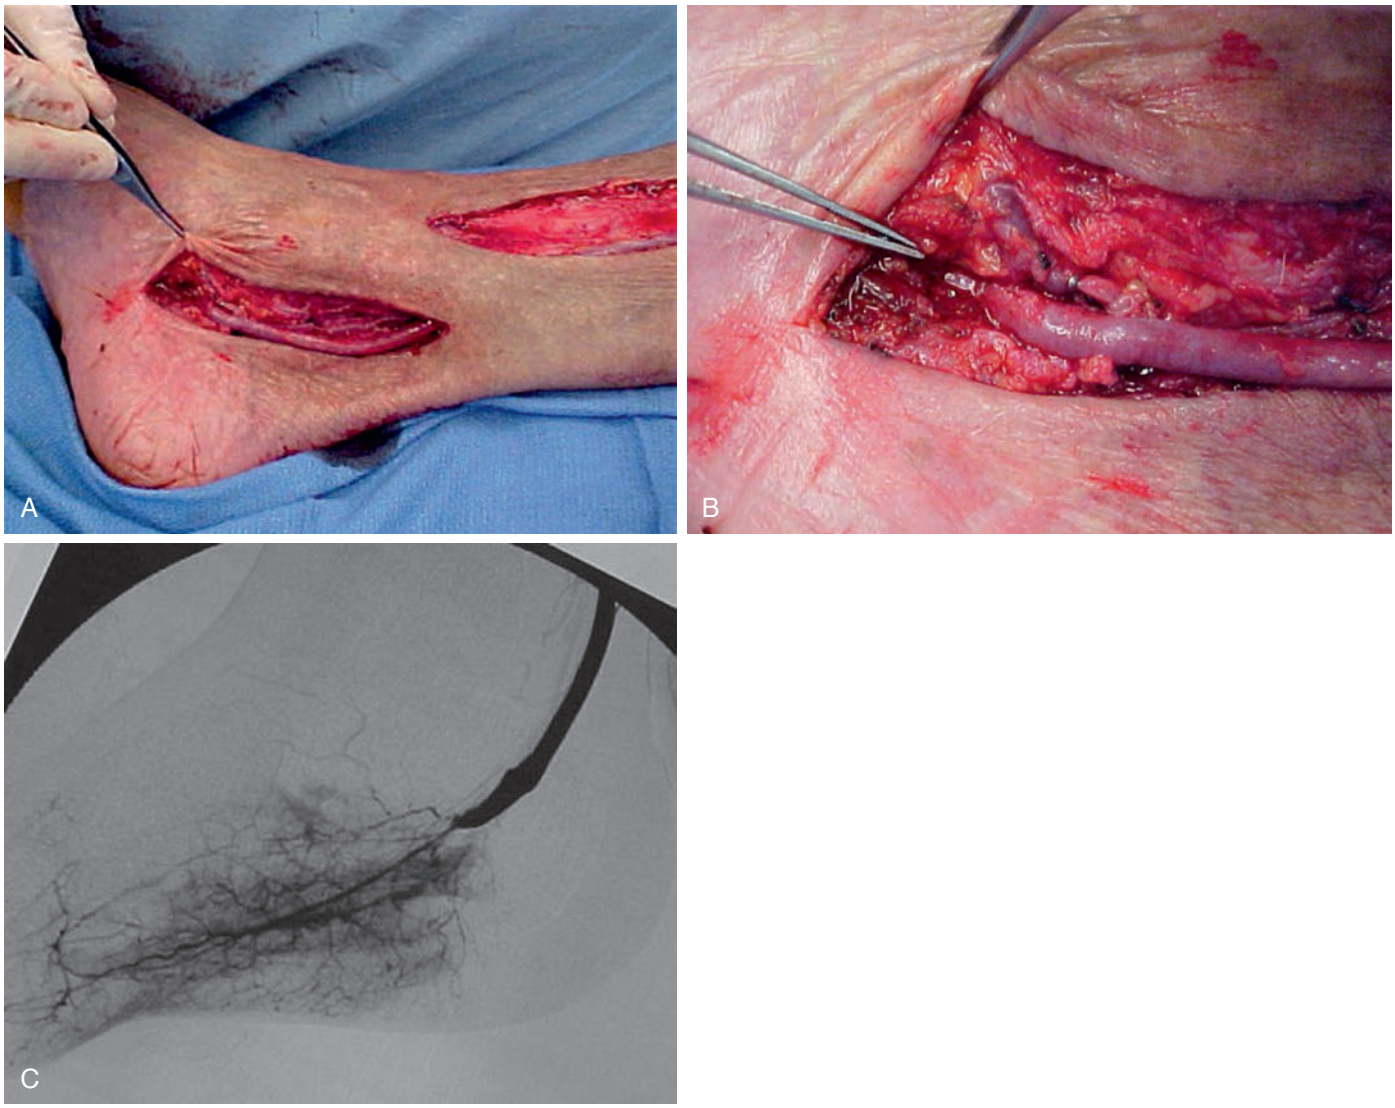

Figure 113.7 Distal bypass to the medial and lateral plantar branches of the posterior tibial artery as required in the diabetic patient (A) with the distal anastomosis (B), completion arteriogram (C).

Figure 113.8 Incisions associated with a popliteal-distal bypass in the diabetic patient with proximal extension of the skin incision to harvest optimal vein and limit the distal limb harvest incision through chronically ischemic tissue.

analyzed a cohort of 1000 bypasses, 92% of which were in diabetic patients, and reported a primary patency of 57% and 38% at 5 and 10 years, respectively.[65] A large prospective study of vein bypass grafts for critical limb ischemia (PREVENT III) evaluated bypasses in 1404 patients, 64% of who were diabetic and 75% of whom presented with tissue loss.[66] The authors reported a primary patency of 61% at 1 year and a reduced amputation-free survival at 1 year for a high-risk cohort, as determined by factors including age greater than 75 years and a history of dialysis, significant coronary artery disease, anemia, and tissue loss at presentation. However, up to 30% of diabetic patients do not have adequate saphenous vein for bypass to distal tibial targets. In reoperative patients, this figure increases to 50%.[67] In such patients, alternative conduits for bypass, such as the lesser saphenous vein, arm vein, composite veins, and a polytetrafluoroethylene (PTFE) graft with a distal vein patch with or without a distal arteriovenous fistula, should be considered. Furthermore, although these alternative conduits are

not equivalent to intact great saphenous vein for tibial bypass, they can be effective for limb preservation.[68-71]

Lower extremity bypasses in diabetic patients are not without risk. There is a certain perioperative morbidity associated with bypass surgery that approaches 20%, with a 10% incisional complication rate for vein grafts. These pulmonary, cardiac, and renal complications can delay recovery and add to hospital stay and cost. Indeed, although diabetes is not a risk factor for vein graft failure, it has been associated with increased risk of long-term mortality and limb loss in patients with critical limb ischemia when compared with nondiabetic patients.[72]

Endovascular Versus Bypass for Diabetic Revascularization

An appropriate revascularization strategy should be customized for diabetic patients according to their anatomy and comorbidities. The Bypass versus Angioplasty in Severe Ischemia of the Leg (BASIL) trial attempted to compare endovascular intervention with surgical bypass.[73] Among the 452 patients randomized to bypass or endovascular intervention, perioperative morbidity was higher with surgery, but amputation-free and overall survivals were similar in both groups at 1 year. However, at the 2-year interval, surgery was associated with a reduced risk of amputation and death. The authors concluded that angioplasty should be used first for patients with a life expectancy of 2 or fewer years and that bypass is preferred when a vein conduit is available. However, the generalizability of these results to diabetic patients is limited because only 42% of the patients in the study were diabetic. We hope that the ongoing BEST-CLI and BASIL 2 trials shed more light on the optimal revascularization strategy for diabetic patients.

Hinchliffe published a review of revascularization for the treatment of diabetic foot ulceration from 1980 to 2010.[74] Outcomes were similar, with a 1-year limb preservation rate of 85% after bypass and 78% following angioplasty. However, loss of patency was not always associated with amputation, because the initial intervention allowed for wound healing and sufficient collateralization to maintain tissue integrity, despite subsequent failure of the revascularization. Therefore although prospective, randomized data comparing surgical bypass with endovascular revascularization specifically for diabetic foot ulcer patients are lacking, similar limb preservation rates can be achieved when the physician's best judgment is used to develop an individualized revascularization plan for each patient.

MULTIDISCIPLINARY LIMB PRESERVATION PROGRAMS

A successful limb preservation program requires a coordinated effort of physicians, nurses, allied health professionals, and administrators dedicated to the preservation of functional limbs. Such a multidisciplinary approach should take advantage of protocol-driven care, involving a full complement of diagnostic and therapeutic modalities that combine revascularization with soft tissue reconstruction and medical support.[75] Unfortunately, there continues to be geographic and demographic variation in the care delivered to patients at risk of losing a limb from diabetes.[76] There are also a variety of approaches to diabetics with limb-threatening ischemia: approximately 25% undergo primary amputation, 25% receive medical therapy, and only 50% undergo any attempt at revascularization.

The Society for Vascular Surgery and the American Podiatric Medical Association have stressed the importance and prospective benefits of multidisciplinary care for diabetic foot ulcer patients.[77] Benefits to the patient include a reduction in time for vascular assessment, wound healing, and institution of treatment for infection, and the time to final correction of podiatric and orthopedic deformities. Enhanced follow-up and increased surveillance of revascularization procedures contribute to patient outcomes. Advantages for the physicians include the ability to efficiently manage complex patients with help from the appropriate medical specialties, an expected increase in patient referrals, the ability to obtain leadership roles both regionally and nationally, the development of an important clinical area to enhance the identity of the institution, and the infrastructure for clinical research and trials. Evidence is available that a multidisciplinary program can bestow these advantages, including a significant reduction in the incidence of major leg amputations (Box 113.1).[43,78]

BOX 113.1 Organizational Structure of a Multidisciplinary Team to Optimize Outcomes and Financial Viability in the Care of the Diabetic Foot

- Structure of a Limb Preservation Program

INTRODUCTION

Diabetes detrimentally affects almost every system in the body with the foot at particularly high risk for developing complications such as recurrent ulcers and infections that require surgical procedures, interventions, and hospitalizations. The cumulative incidence of developing a foot ulcer has been reported to be 5.8% to 7.1% per year.[1-3] Further, the sequelae may result in amputations with a relative risk of greater than eight at a rate of 9.9%.[4,5] Minority populations are twice as likely to undergo amputations as compared with Caucasians, and men have twice the incidence of amputations as compared with women.[6-8] Five-year mortality rates as high as 40% in high-risk populations have been reported.[8,9] Hospitalizations are common and often require readmission, with reported rates ranging from 18% to 49%.[10,11]

The economic impact of diabetic foot ulcers (DFUs) is substantial, with an average of three times higher expenditures as compared with people with diabetes without ulcers, with 77% of the overall cost of the treatment of a DFU involving hospitalization-related costs.[12,13] The annual cumulative costs continue to rise particularly in the areas of minor amputations and endovascular procedures.[14] The costs of care of diabetic limb complications exceed that of breast cancer.[15]

The care of a DFU involves a multidisciplinary approach with a core team composed of vascular surgery, podiatric surgery/orthopedic surgery, and plastic surgery. Other services including endocrinology, infectious disease, and orthotics/prosthetics also play a pivotal role. The multidisciplinary approach at specialized wound care centers has been demonstrated to provide improved clinical outcomes including a resultant decrease in major amputations as well as a cost savings, thus it is now considered the standard of care.[16-20]

It is important to have a fundamental understanding of foot and ankle anatomy and lower extremity function to appreciate the complications associated with the diabetic foot. The foot is a complex structure with small bones with multiple articulations; intrinsic and extrinsic tendon insertions; fascia and ligaments that are both flexible and rigid; and a redundant network of lymphatics, veins, arteries, and nerves, encased in a resilient soft tissue envelope. These structures work in concert for the purpose of providing a platform for efficient and durable ambulation. The foot is designed to propel the body forward against gravity and adapt to varying surfaces it encounters. The complications associated with diabetes impart a devastating toll on foot function.

Peripheral neuropathy, patho-biomechanics (e.g., joint immobility, structural abnormalities), and peripheral artery disease (PAD) can lead to ulceration (Fig. 114.1). These conditions are magnified in the environment of an immune-compromised host. DFUs lead the patient down a pathway that frequently results in infection, ischemia, amputation, and death. PAD is an extremely important consideration, for without adequate perfusion, the diabetic foot is at extreme risk of ulceration and amputation. Ischemia and its consequences will be discussed in a limited fashion in this chapter, as they are

Abstract

The remote anatomical location of the foot and its demands during weightbearing and ambulation creates an environment that makes it susceptible to ulceration in the environment of diabetes. The diabetic foot is at particular risk of complications and is a significant problem with extensive healthcare resource demands. Peripheral neuropathy, peripheral arterial disease, and biomechanical deformity contribute to the development and chronicity of a foot ulcer. As peripheral neuropathy progresses, the foot becomes insensate and the patient does not respond to acute or repetitive tissue stress. Detrimental changes to the soft tissue envelope in the presence of underlying bony deformity places the foot at great risk. In this environment, altered biomechanics during standing and ambulation accentuates the deleterious forces that contribute to ulcer development and its chronicity. Finally, ischemia and infection are pivotal events that can lead to amputation. This chapter reviews the important pathological processes of the diabetic foot and methods of prophylactic and interventional treatment of ulcers and the underlying deformities.

addressed in detail elsewhere in this book. The purpose of this chapter is to introduce the more important components related to the diabetic foot with a focus on the biomechanical considerations that play a critical role in the development and chronicity of a DFU.

PERIPHERAL NEUROPATHY

Peripheral neuropathy is a progressive pathologic process that develops in the environment of diabetes and prolonged poor glucose control.[21-23] Glycation-induced metabolic and vascular changes of nerve fibers result in sensory, autonomic, and motor neuropathy in the lower extremity, playing a devastating role in the cascade of events that lead to an ulceration.[24,25] Patients often present with small and large fiber neuropathy. Small fiber neuropathy is usually diagnosed based on symptoms of burning, tingling, and radiating electrical shock.[26,27] Clinical assessment of small fiber neuropathy is based primarily on history of the patient's reported inability to perceive temperature differences. Large fiber neuropathy generally presents with symptoms of numbness, tingling, and formication, and it can be easily assessed in the clinic with a 129-hz tuning fork, 10 g monofilament, or Achilles deep tendon reflexes.[28-30] Sensory neuropathy is very common and a key factor in the development of foot ulcers. Initially, diabetic peripheral sensory neuropathy with the "loss of protective sensation" (LOPS) begins distally in the toes and progresses to the ankle and legs. LOPS can lead to a 2.9 increase in the risk for an amputation and a 46-fold increase in the likelihood of hospitalization.[31,32] Large fiber sensory neuropathy is often so severe that patients lack sufficient peripheral sensation to protect their feet from injury. For example, in people with normal sensation, in response to a foreign body such as a thumbtack, the sharp object is reflexively identified and the foot spontaneously withdrawn from the noxious stimulus, thereby avoiding further injury. In an environment of sensory neuropathy with LOPS, the patient will not withdraw the foot, and the penetrated site is unrecognized by the patient. This often results in repetitive damage to the superficial and deep structures of the foot. DFUs usually develop at the site of pressure areas on the sole of the foot that are exposed to repetitive injury (walking activity) or at the site of pressure and shear forces where bony prominences (e.g., hammertoes or bunion deformities) are exposed to constant pressure from shoes. For example, tight-fitting shoes or an underlying bony deformity may cause a wound to develop over time and contribute to the ulcer's chronicity. As the nerve fibers continue to deteriorate, complete lack of sensation, lack of sympathetic vascular tone, and atrophy of the intrinsic muscles of the foot develop.

Autonomic peripheral neuropathy is related to the increase in sympathetic tone in the diabetic lower extremity.[33] A dysregulation can lead to arterial-venous shunting, small vessel ischemia, and changes in the soft tissue turgor.[34] The loss of soft tissue turgor is identified by xerosis with the loss of moisture balance and elasticity, which can lead to fissuring with subsequent ulcer formation.[35] Further, chronic edema applies tension on the compromised soft tissue envelope, increasing the susceptibility of minor tissue injury causing breaks in the skin leading to an ulceration.[36] These processes negatively impact the reparative capacity of the foot and place it at risk for ulceration. One devastating consequence of autonomic neuropathy is manifested in Charcot neuroarthropathy (CN), which will be discussed in further detail at the end of this chapter. Frequent moisturizing and edema control with compression garments are necessary to prevent ulcer formation.

Motor neuropathy in the lower extremity leads to muscle atrophy and imbalance of opposing muscle groups, and is especially apparent in the smaller intrinsic muscles of the foot. Even in people without diabetes, an imbalance of the extensors and flexors, evertors and invertors, and the abductors and adductors can cause capsular laxity and bony mal-alignment, joint subluxation, and structural foot deformity. Motor neuropathy contributes to the development of forefoot deformities such as hammertoe and hallux abductovalgus, which are reported to be major contributors of ulceration (92% related to neuropathy, and 77% related to deformities; Table 114.1; Fig. 114.2).[37] For example, the intrinsic flexors, interossei, and lumbricals in the foot normally stabilize the toes against the metatarsal heads in the stance and propulsive phases of the gait cycle. When the intrinsic muscles atrophy, the balance of the stronger long flexors and extensors causes the toes to contract and eventually to dislocate at the metatarsophalangeal joints. This imbalance and deformity can literally push the head of the metatarsals through the bottom of the foot.

Early detection and treatment of peripheral neuropathy is critical to ulcer prevention. Tighter glucose control is important for prevention and treatment for the symptoms of peripheral neuropathy. Peripheral neuropathy treatment options are largely focused on symptom management when the disease process is in its relatively earlier stages. The symptoms of peripheral neuropathy (paresthesias, burning, pins and needles, tingling, radiating pain) can be controlled through the use of oral medications including antidepressants, narcotics, antiarrhythmics, and the most frequently prescribed anticonvulsants such as gabapentin, which work through inhibiting the release of glutamate.[38] Vitamin supplementation with L-methylfolate, methylcobalamin, and pyridoxal 5′–phosphate has also been reported to be effective as well in the short term.[39] Topical medications including topical clonidine and capsaicin formulations have shown efficacy but may have limited utility.[40] Surgical decompression of the peroneal and tibial nerves may have a role if the disease is not advanced.[41,42]

TABLE 114.1 Common Biomechanical Abnormalities Encountered in the Diabetic Foot

Abnormality	Description	Problem
Digital contractures	Contracture of digit(s) at the interphalangeal or metatarsal-phalangeal joints	Causes ulcers from rubbing in shoe gear dorsally or at the distal tips of the toes
Hallux abducto valgus	Abduction frontal plane rotation of the hallux and medial deviation of the 1st metatarsal	Bony prominence causes ulcers to develop on the medial 1st metatarsal healed or medial or plantar medial hallux
Hallux rigidus	Degeneration of the metatarsal-phalangeal joint	Restriction of range of motion at 1st MTPJ causes increase in pressure un interphalangeal joint of the hallux
Tailor's bunion	Adduction of 5th digit and lateral splaying of the 5th metatarsal head	Lateral prominence of the 5th metatarsal causes rubbing in shoes as well as increased pressure on the lateral plantar aspect of the 5th toe, which results in an ulcer
Medial column collapse	Abduction of the forefoot and medial deviation of talus	Plantar and medial ulcerations develops with pressure with ambulation and shoe gear
Lateral column collapse	Subluxation of cuboid and/or base of 5th metatarsal	Plantar pressure along the lateral column of the foot
Equinus deformity	Limitation of dorsiflexion at the ankle joint	Plantar forefoot pressures increase
Calcaneal gait	Laxity to plantarflexion at the ankle joint	Plantar heel ulcerations develop due to increased and prolonged pressures
Ankle deformity	Medial or lateral deviation of the foot on the leg at the level of the ankle	Significant change in pressure distribution along medial or lateral columns as well as ulcers over the medial and lateral malleolus
Exostosis	Benign bony growth of bone which can be located anywhere on the foot or ankle	Focal areas of high pressure
Accessory sesamoids	Small cortical bone located in areas such as the plantar interphalangeal joint of the hallux	Increased focal pressure imparted on underlying tissue
Charcot neuroarthropathy	Subluxations, dislocations, fractures about joints in the foot or ankle	Most significant alteration to the biomechanics of the foot altering pressure and function throughout the foot or ankle

Figure 114.2 A photograph of a patient with type I diabetes with significant biomechanical deformities. Note the significant digital contractures as well as lateral and medial deviations of the digits which results in significant alterations in the pressure distribution across the plantar aspect of the feet. Calluses can be identified in these areas.

Appropriately fitting shoe gear with multidensity inserts (laminated layers of decreasing densities of materials), a seamless inner lining, and a wide toebox can also prevent ulcer formation. Eventually the patient will experience complete loss of sensation to the lower extremity with the sustained lack of glucose management. As this disease process progresses, the above treatment strategies become increasingly ineffective and the peripheral neuropathy is irreversible.

Preventing ulcer recurrence requires a multidisciplinary team that usually includes vascular surgery, podiatry, and a pedorthotist. The crux of prevention is understanding the role of biomechanics (joint range of motion and structural deformity), which can significantly reduce foot ulcer recurrence.[43-45] Appropriately fitting shoes and inserts as described previously can prevent ulcer reulceration. In randomized clinical studies, patients treated with "therapeutic shoes and insoles" who complied with prevention showed a two- to fourfold reduction in reulceration.[46-48]

BIOMECHANICS

Altered biomechanics of the diabetic foot are major contributors to ulcer development and chronicity. Foot biomechanics encompass the dynamics involved in ambulation. The foot must be both flexible and rigid, depending on the demands of the phase in the gait cycle. This intrinsic adaptability is maintained by the underlying bony architecture, as well the soft tissue attachments.

Structural changes occur in the diabetic foot that alter the underlying biomechanics. Stiffening of soft tissue structures, including tendons, ligaments, and joint capsules, leads to a limitation of range of motion across joints and joint subluxation, and dislocation.[49-51] The principal forces experienced by the

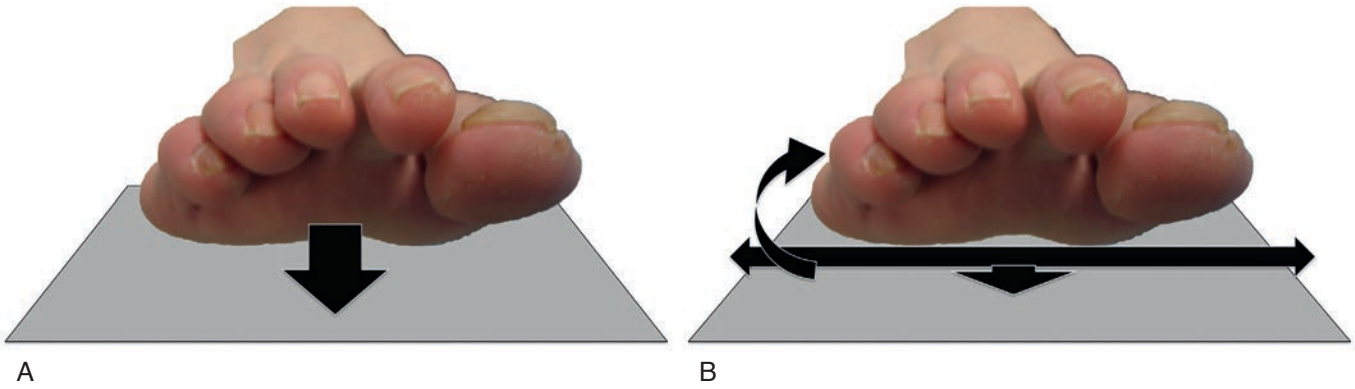

Figure 114.3 (A) A depiction of the sagittal plane forces *(arrow pointing downward)* experienced on the plantar aspect of the foot. The sagittal plane force imparts focal areas of peak plantar pressures that can lead to ulceration. (B) A depiction of the frontal *(curved arrow)* and transverse (*straight arrow* pointing from side to side of the page and arrow pointing towards the reader) plane forces experienced on the foot. These shear forces can lead to separation of the tissue thus leading to ulceration.

foot that can lead to ulceration are abnormal plantar pressures (sagittal plane) and shear (frontal, transverse plane; Fig. 114.3A, B). Shear forces experienced in the diabetic plantar soft tissue have been demonstrated to be 52% greater than in nondiabetic feet.[52] These forces are experienced between the bone-overlying soft tissue envelope, foot-ground, and foot-shoe. Both sagittal plane and shear forces are typically minimized in the sensate foot through compensation by subtle or overt changes in postural stance or positioning, but in the environment of peripheral neuropathy, compensation is compromised, leading to prolonged periods during which abnormal forces are applied until the skin and subcutaneous tissue fail.[53] Joint deviations and subluxations caused by the loss of structural integrity lead to further mal-alignment of the pull of the tendons further exacerbating biomechanical faults. Thus the stresses are magnified on the soft tissue envelope resulting in subsequent formation of calluses and blisters that lead to a separation of the epidermis from the dermis.

As an example, glycation-induced changes in the collagen of the Achilles tendon lead to shortening of the Achilles tendon with subsequent development of an equinus deformity.[54] An equinus deformity is an overpowering of the plantar flexors. Equinus results in overpowering of the Achilles tendon across the ankle joint and increased pressure and shear on the ball of the foot. This cascade of events results in plantar forefoot ulcerations under the metatarsal heads or an ulceration under the medial column of the foot caused by a collapse of the medial arch (Figs. 114.4 and 114.5).[30,55-57]

Alterations in lower extremity biomechanics are appreciated through gait analysis and biomechanical examination of the lower extremity on physical examination. Alterations in gait pattern (i.e., shuffling, antalgic, wide base, unsteady) imply an underlying abnormality.[58,59] Limited joint mobility (i.e., limitation of range of motion in the joints of the foot and ankle) and structural deformities (i.e., bony prominences or joint contractures) are signs of mal-alignment. Callus distribution is a reliable method of identifying areas of excessive sagittal plane and shear forces experienced due to the factors noted previously.[60,61]

Figure 114.4 A photograph of a sub third metatarsal head ulceration. This a typical presentation of a diabetic foot ulcer caused by plantar pressures.

Reducibility of any malaligned joint articulation is a key feature when examining the deformity. As the term implies, a reducible deformity is one that can be placed back into an anatomical position. A semireducible deformity can be somewhat reduced into an anatomical position, while a nonreducible deformity is fixed and cannot be placed into an anatomical position. This degree of reducibility is important when choosing a treatment option. Typically there is a progression from a reducible to a rigid deformity, and the options become more limited as the deformity progresses.

Figure 114.5 A photograph of a healing ulcer on the plantar aspect of the medial column of the foot. An underlying collapsed arch has increased the pressure in this area causing the wound to develop.

Biomechanics can be addressed through a combination of conservative and surgical methods (Table 114.2). Conservative methods focus on the concept of offloading focal areas of pressure and distributing pressure across a wider surface area. Offloading can be achieved through padding, multidensity orthotics, and braces, which may be helpful in ulcer prevention or recurrence.[62] Foot ulcer recurrence can be dramatically reduced when inexpensive, low-tech approaches are employed.[44,45] A multidensity accommodative insert, seamless inner, extra-depth, rocker-bottom shoe is ideal for the at-risk foot. A functional/accommodative device can also, depending on the degree of reducibility, realign the foot in a more anatomical position. Offloading is also used to treat an active ulcer. The total contact cast (TCC) is one such effective method of healing plantar forefoot ulcerations (Fig. 114.6).[63] Other methods, including a walker boot or healing shoe, are also utilized with a lesser degree of success.[64] Decubitus ulcers of the posterior heel should also be offloaded, especially when the patient is supine, utilizing a foam or airbladder filled device with complete relief of the posterior heel.

Offloading is the single most important treatment for the DFU. For instance, the proportion of DFUs that heal with silver dressings, bioengineered alternative tissues, and placental tissue products ranges from 30% to 56% in 12 weeks.[65] In comparative studies of offloading approaches for DFUs, among patients treated with TCCs, healing occurs 70% to 90% of the time.[63] A healing rate of 22% to 79% has been reported using removable cast boots compared with 21% to 58% for healing sandals or half shoes.[64,66-68] Regardless, the key to offloading treatment is patient adherence to actually wearing the device.

The goal of surgical biomechanical correction, whether it be a soft tissue or bony procedure, is to produce a rectus, balanced foot. Soft tissue corrections largely focus on tendon lengthening and rerouting and should be reserved for reducible or semi-reducible deformities. For example, Achilles tendon lengthening (TAL) has been demonstrated to reduce peak plantar pressures experienced in the forefoot by as much as 27%.[63,69,70] Randomized clinical studies and cohort studies of TAL report 93% to 100% DFU healing within 12 weeks.[63,71,72] Once the biomechanical abnormality has been addressed, not only is the ulcer healing rate high, but the incidence of reulceration is significantly less compared with patients treated with TCC alone. For the latter patients, the pressure and shear which caused the ulcer are only modified during the period of TCC therapy, remaining as pathologic forces to cause reulceration after TTC removal if no other means of offloading is utilized.

Digital flexor tendon releases have also been utilized as a simple method of relieving the pressure at the dorsal aspect of the interphalangeal joints or the distal aspects of toes.[73] Bony procedures include exostectomies (simple removal of bony prominences) and joint realignment through arthrodesis and/or osteotomies. Surgical correction can be conducted prophylactically (to prevent ulceration) or therapeutically (to heal an ulceration).[70,74,75] These surgical techniques are typically reserved for nonreducible deformities. Tendon balancing and skeletal reconstruction (e.g., TAL and midfoot arthrodesis) are often done in combination. Conservative offloading is still necessary after the surgical incisions have healed. The goal of all of these options is to optimize function while minimizing new ulcer formation or ulcer recurrence. This goal can be extended to amputations. Amputation is a viable option in maintaining or improving function. Major deformities that cannot be conservatively managed or surgically corrected, and for which the most functional option may be an amputation, will be discussed in further detail later.

ISCHEMIA

Perfusion is arguably the most critical element in DFU healing and must be addressed early. PAD is a major causative factor for amputation.[6] Referral to a vascular specialist to identify and treat vascular compromise is the first step to ulcer healing unless limb-threatening infection is present, in which case infection control is the initial priority. The assessment and treatment of PAD, or chronic limb-threatening ischemia, is beyond the scope of this chapter. However, there are a few important concepts that must be addressed.

One pertinent concept relates to angiosomes, blocks of tissue fed by a source artery, that correspond to different regions of the lower extremity. The three major vessels (posterior tibial, peroneal, anterior tibial arteries) feed specific areas of the lower extremity, and some have claimed that there is a correlation between the ulcer site and the angiosome that is compromised.[76] However, there are redundancies inherent in the

TABLE 114.2 Conservative and Surgical Strategies to Biomechanical Correction

	Method	Rationale	Limitation
Conservative	Diabetic shoe with custom inserts and rocker-bottom	Distribute areas of pressure more evenly Offload areas of pressure Reduce risk of new ulcer formation	Minor deformities
	Decubitus heel ulcer offloading device	Pressure relief of the posterior heel for prevention or treatment	Not to be used for ambulation
	Diabetic healing shoe	Multidensity insert to offload ulcers Accommodate dressings	Temporary Not meant for functional correction Not durable
	Walker boot	Multidensity insert to offload ulcers Accommodate dressings More rigid due to construct encompassing foot and ankle	Temporary Not meant for functional correction Not durable
	Custom brace (limited)	Realign single plane deformities	Moderate deformities that are reducible
	Custom brace (full)	Protect multiplane major deformities	Bulky, affects balance and contralateral limb trauma
	Total contact cast	Non-removable offloading device Healing of ulcers in forefoot and midfoot	Not a long-term solution due to need to replace weekly
Surgical	Tendon rebalancing/ lengthening	Reduce deforming force Augment the plane that is being overpowered	Reserved for reducible deformities May need to be repeated over time Immobility during healing period Rehabilitation
	Bony correction	Remove or realign bony segments through the use of hardware	Risk of associated surgical complications Immobility during healing period Rehabilitation
	Amputation	Reserved for nonsalvageble conditions	Loss of part of the foot or entire foot/ankle Can result in loss of function

Custom Brace (Limited): encompasses part of the foot and lower leg; Custom Brace (Full): encompasses the entirety of the foot/ankle, typically a clamshell design; Forefoot: toes and distal metatarsals; Midfoot: proximal metatarsals, cuneiforms, navicular, cuboid; Hindfoot: calcaneus, talus; Ankle: talus, distal tibia, fibula; Minor deformity: digital or forefoot with minor mal-alignment; Moderate deformity: midfoot, hindfoot with minor to moderate mal-alignment; Major deformity: hindfoot, ankle with significant mal-alignment; Nonsalvagable: deformity cannot be addressed through any other means.

Figure 114.6 A photograph of a total contact cast. A total contact cast provides effective immobilization and offloading for plantar forefoot ulceration and considered the gold standard in conservative diabetic foot ulcer management.

foot with arterial-to-arterial connections that may compensate for occlusive disease in one or more vessels. Successful healing of ulcers through indirect revascularization implies that in many cases, these redundancies exist and may be adequate.[77,78] Current consensus is that angiosome-targeted revascularization should be performed when possible, as it may enhance the wound-healing rate; indirect revascularization still provides benefit when it is the most practical or only choice.

Ischemic ulcers should not be debrided until revascularization has been performed. While necrotic areas or frankly gangrenous digits will ultimately require some sort of amputation, this must be performed at a level where perfusion is adequate for healing. As long as there is no significant infection, debridement and amputation for dry necrosis should also be delayed until after revascularization.

INFECTION

Infection is a significant complicating factor in the diabetic foot. Infection can be acute in nature with the classic signs of fever, erythema, edema, calor, and dolor. Infection may also be chronic or subclinical, as that seen with biofilm. Both types of infections are encountered in diabetic foot and must be addressed. Infection can lead to limb loss (42% higher risk) and will decompensate the wound and/or contribute to its chronicity.[79]

The acute infection in the diabetic foot typically enters through the ulcer or is seeded through a puncture wound. As the acute infection evolves, deep abscesses and/or osteomyelitis with possible sepsis may ensue. DFU infections are typically

bacterial and can be monomicrobial or polymicrobial, with the most common bacteria present being *Staphylococcus* and *Streptococcus*.[80,81] Fungal and yeast infections (23% of chronic wounds) can also be pathogens in the diabetic foot.[82]

Osteomyelitis has been identified in diabetics in up to 20% in an outpatient setting and 67% for hospitalized patients who require an amputation.[83,84] The majority of cases of osteomyelitis in the foot and ankle of diabetics are by contiguous spread, with the nidus being the ulcer. Thus, in many settings, there is a correlation of osteomyelitis with the clinical finding of a positive probe to bone.[85,86] The combination of clinical findings suggesting infection, bony fragmentation identified on plain radiographs, and focal areas of increased signal intensity on magnetic resonance imaging may all contribute to establishing the diagnosis of osteomyelitis.[87] The utility of laboratory biomarkers for the diagnosis of osteomyelitis is not been completely elucidated; however, they may be useful for infection monitoring.[88]

Treatment of an acute infection may include antibiotics as well as surgical decompression. Empiric antibiotic coverage is usually broad and then targeted therapy is implemented based on deep tissue and bone cultures and sensitivities. Surgical decompression may require multiple operating room visits until clean tissue cultures are obtained, at which point a plan for definitive procedure for closure or coverage can be conducted.

Biofilm are multispecies colonies of relatively senescent communities of bacteria that are encased in a glycocalyx shell that inhabit wounds, implantable medical devices, surgical material (e.g., suture), artificial joints, and orthopedic implants. Planktonic bacteria may leave the biofilm to begin other colonies or to seed acute infections. Due to the low metabolic activity of biofilm, antibiotic therapy is typically ineffective; thus disruption of the biofilm is often necessary.[89,90] Disruption can be accomplished through other methods beyond excisional debridement such as ultrasound, or antiseptics.[91-93]

THE DIABETIC FOOT ULCER

The soft tissue envelope of the diabetic foot cannot tolerate stress and has a compromised reparative process. Thus, the typical wound healing cycle is disrupted, prolonged, and the ulcer becomes chronic.[94] The reasons are multifactorial but include biomechanics, ischemia, and infection.

There are multiple DFU treatment strategies (Table 114.3).[65,95-103] Each treatment modality serves a purpose including: drainage control, edema management, infection/biofilm

TABLE 114.3 Diabetic Foot Ulcer Treatment Strategies

Method	Description and Example	Advantages	Limitations
Dressings	Materials that absorb, bolster, protect the wound and surrounding skin Example: alginates	Relatively inexpensive	Frequent dressing changes may be necessary
Compression	Edema control to decrease tension on the skin as well as emptying the venous system and the lymphatics Example: prepackaged multilayered compression dressings, sequential mechanical pumps	Provides a more predictable and reliable method of sustained compression	Weekly application with limited access to the wound Heavily exudative wounds may require additional absorptive dressings Patients may not tolerate
Topical drugs	Impart a drug directly to the surface of the wound May be antimicrobial, enzymatically debride or have other prohealing properties Example: collagenase, platelet derived growth factor	Concentrated and sustained delivery of medications directly to the wound site	Expense Frequent application Potential for adverse events
Bioengineered alternative tissues	Therapies that have viable cells or pro-healing factors imparted to the wound to stimulate healing Example: cell cultured lines of tissue, scaffold, amniotic tissue	Can directly expedite wound healing	Expense Frequent reapplication Technically more sophisticated
Sharp debridement	Regularly scheduled removal of nonviable tissue and biofilm Example: scalpel, curette, scissors	Can potentiate healing by removal of noxious factors Conversion of a chronic wound to an acute wound	Patient may not tolerate due to pain Technically more sophisticated
Advanced devices	Use of negative pressure though a foam or dressing interface Example: negative pressure wound therapy	Accelerate wound bed preparation and expedite closure	Expense Technically more complicated
Biophysical technologies	Acoustic energy or electrical current used to accelerate tissue repair Example: ultrasound, electrical stimulation	Generally well tolerated by patient Adverse events not common	Slow progression Frequent treatment Expense

This table is exclusive to outpatient treatment of the diabetic foot ulcer.

eradication, or direct wound-healing stimulation. Each modality has its own advantages and limitations with some level of evidence supporting efficacy or effectiveness. The number and diversity of treatment strategies reveal the lack of consensus for a singular algorithm. Further, the treatment rendered reflects the diversity of healthcare providers and their level of training and experience that care for DFUs (e.g., nurses, physical therapists, podiatrists, surgeons, and nonsurgical physicians). Regardless, certain fundamentals of wound care should be applied prior to implementation of any advanced therapies. These fundamentals include (1) ensuring or establishing adequate perfusion; (2) providing optimal offloading; (3) controlling/treating acute infection and biofilm formation; and (4) optimizing the patient's metabolic and nutritional status. It is also important to recognize that antibiotics and dressings serve to optimize the wound environment and do not directly heal wounds. In general, the chronic ulcer must be converted to an acute wound for healing to occur. Close monitoring is necessary including measurements taken at every clinic visit. Treatment strategies should be modified based on the changing quality of the ulcer. For example, if there is increased drainage a more absorbent dressing, compression dressings, and antibiotic/antiseptic therapy should be employed. Ulcers should be debrided regularly in clinic plans for definitive surgical closure or coverage once the ulcer is deemed "appropriately prepared" (i.e., not infected, perfusion maximized).

Minor or major amputation is a viable option for the treatment of chronic ulcerations. The decision for amputation is perhaps easier in the environment of infection and/or ischemia where there is an obvious need. However, an amputation performed to improve the *functional* ability of the patient and reduce the risk of ulceration is also acceptable.[104,105] Biomechanics must be appreciated prior to the performance of a functional amputation. For example, a transmetatarsal amputation (TMA) should be performed maintaining the anatomical parabola of the metatarsals. This allows for an even distribution of pressure at the plantar stump to prevent future breakdown. Further, an adjunctive TAL should be performed at the time of the TMA when an equinus deformity is present to compensate for the loss of the counterbalancing extension function of the long extensor tendons. The TMA results in a durable, functional foot with the addition of an accommodative shoe with a forefoot filler and a rocker-bottom shoe.[106-108] Regardless of the surgery performed, soft tissue coverage as well as the functional consequences of the procedure should always be considered.

CHARCOT NEUROARTHROPATHY

CN can be considered end stage sequela of a pathologic diabetic foot process with devastating economic and clinical consequences. CN has been reported to increase healthcare costs by 17.2% and results in an increase of hospital length of stay.[109] There is a paucity of published prevalence reports; however, an estimated less than 0.5% of patients with diabetes develop CN.[110] CN classically presents with edema, erythema, and calor with fractures and/or dislocations across joints of the foot or ankle. The prevailing theory involves demineralization of the bone, causing instability.

Figure 114.7 A lateral projection radiograph of a patient with Stage 1 Charcot neuroarthropathy. Note the significant soft tissue edema and the fracture dislocation of the talus and the joints of the midfoot.

In the environment of profound peripheral neuropathy where the patient bears weight and ambulates, fractures and dislocations occur in the joints of the foot and/or ankle (Fig. 114.7). An acute traumatic event or the cumulative effect of minor trauma can incite a CN episode. CN progresses through four stages: Stage 0—clinical stage presenting with warm, swollen, often painful foot; Stage 1—fragmentation/destruction, bony cysts, and erosion; Stage 2—joint subluxations; Stage 3—arch collapse and coalescence; and Stage 4—consolidation.[111] The key to the treatment of CN is early recognition and immobilization with non–weight-bearing. As it progresses through its stages, further destruction occurs. Once consolidation occurs, conservative management with custom molded braces/shoes can prevent ulceration and provided stability. Surgical reconstruction may be necessary to realign the foot and ankle into a rectus position. Surgical complication rates can be high with resultant major amputation rates as high as 32% (Fig. 114.8).[112] Chapter 116 discusses Charcot foot in more detail.

OTHER IMPORTANT CONSIDERATIONS

Other factors play a major role in the management of the diabetic foot. As diabetes progresses, every system in the body is detrimentally affected. Comorbidities such as end-stage renal disease and cardiac disease are particularly devastating.[113-115] Metabolic disturbances and immunologic depression impede healing that can lead to increased susceptibility to virulent and repeated infections. Other compromised host factors as well as emotional, mental, socioeconomic, and nutritional challenges make management of the diabetic patient extremely challenging.

CONCLUSIONS

Unfortunately, many complications of diabetes are manifested in the foot. The management of these complications follows a predictable course of multiple hospitalizations, operations, and progressive limb loss. Early recognition and identification of

Figure 114.8 A photograph of a custom molded, rocker bottom, clamshell, foot and ankle device that provides stability.

the at-risk diabetic foot can curtail this downward spiral by a specialized and dedicated diabetic foot team.

As the populations of developed countries age and become more sedentary, the incidence of diabetes and obesity increases, along with a dramatic increase in the incidence of chronic nonhealing wounds.[1] In most medical communities, surgeons are considered the local experts in the care of wounds and are expected to manage cases that do not respond to typical treatments recommended by primary care clinicians. This chapter focuses on the diagnosis and management of chronic wounds of the extremities that are typically referred to vascular surgeons for definitive management.

Abstract

Chronic non-healing wounds of the lower extremities most often occur due to vascular abnormalities of the arterial or venous system, often in association with diabetic neuropathy. The vascular specialist is a key member of multispecialty teams that are ideally suited to manage these wounds that are frequent causes of disability and limb loss. The vascular specialist must understand the differential diagnosis, diagnostic evaluation and complete care of these patients to achieve optimal outcomes. This chapter focuses on the aspects of care other than correction of the underlying vascular etiology which is a critical component of management. However, once the vascular etiology is treated, it is equally important that the other aspects of wound management, including wound bed preparation, debridement, and infection control are applied to support healing and prevent complications. Adjuncts to standard care including drug therapies, cell and tissue based products, and negative pressure wound therapy will also be considered.

Keywords

Chronic wound
diabetic foot ulcer
venous ulcer
bioengineered tissue

The most common etiologic factors in nonhealing limb ulcers are chronic venous insufficiency, arterial occlusive disease, and diabetic neuropathy. Most reports suggest that the most common cause is venous insufficiency, but patients with arterial insufficiency and diabetic neuropathy are at the highest risk of limb loss.[2] Accurate identification and treatment of these underlying disorders is the most important determinant of ulcer healing.

In many communities, specialized wound clinics have been developed, promising major benefits in wound healing, limb salvage, and quality of life. These centers, in optimal situations, are able to effectively coordinate the efforts of diverse specialists to improve the treatment of difficult patients with chronic wounds. It is clear that a vascular specialist is critical to the team managing these patients; no other specialist can provide the comprehensive management of arterial and venous insufficiency required by a high percentage of patients treated in wound centers. Similarly, a vascular surgeon participating in a multispecialty wound center can expect assistance from other valuable specialists, including endocrinologists, plastic or orthopedic surgeons, podiatrists, orthotists, and physical therapists, to maximize positive outcomes for their patients.

NORMAL WOUND HEALING

Healing of acute wounds normally proceeds through well-defined phases of hemostasis, inflammation, proliferation, and remodeling. Although these phases are typically described separately, the process is actually a gradual progression guided and regulated by the complex interaction of platelets, neutrophils, macrophages, and other cells that respond to and produce growth factors, cytokines, proteases, and inhibitors.[3] Although the effects of many of these proteins have been described, the deficiencies that lead to the failure of timely healing are not well described. It is clear that all of the common causes of nonhealing wounds, including venous hypertension, arterial insufficiency, chronic pressure, and chronic inflammation, inhibit this orderly healing process, usually in the inflammatory stage, with little meaningful tissue proliferation demonstrated.

Inflammatory Phase

The inflammatory phase of wound healing is critical to the normal healing process. Mediated by mast cells, neutrophils, and macrophages, inflammation develops within 24 hours of acute wounding and continues for up to 2 weeks. The involved cells produce chemokines, cytokines, and growth factors that mediate the inflammatory process.[4] Cytokines such as tumor necrosis factor-α (TNF-α), interferon-δ (IFN-δ), and the interleukins (ILs) are released by activated lymphocytes and macrophages into the tissue, resulting in further recruitment and activation of fibroblasts and epithelial cells in the wound.[5] Neutrophils following chemoattractant signals migrate into the wound, releasing concentrated matrix metalloproteinases (MMPs). The MMPs are responsible for clearing damaged tissue from the wound area by breaking down collagen (MMP-1 and -8), gelatin (MMP-2 and -9), and elastin (elastase).[6] The activity of MMPs is closely controlled by tissue inhibitors of MMPs (TIMPs), which are produced principally by macrophages.

Proliferative Phase

In the proliferative phase, growth factors, including platelet-derived growth factor (PDGF), transforming growth factor-β (TGF-β), and vascular endothelial growth factor (VEGF), are secreted by multiple cell types but primarily by macrophages. They are responsible for the recruitment of fibroblasts to commence the proliferative phase and for the initiation of angiogenesis required to support tissue generation and epithelial growth.[7] Fibroblasts responding to signaling growth factors and cytokines migrate into the extracellular matrix, synthesizing collagen and proteoglycans and developing granulation tissue to fill the wound. Orderly capillary growth and networking must occur to support the developing granulation tissue; this requires a complex interplay of growth factors, including multiple isoforms of VEGF, TGF-β, and hypoxia-inducible factor-1 (HIF-1).[8,9] MMPs are also required for the normal progression of angiogenesis and must be secreted at the correct time by budding capillary loops to allow them to degrade the existing capillary basement membrane as they sprout to establish a new capillary channel.[10]

Epithelialization and Remodeling

Epithelialization occurs most rapidly on a well-granulated, confluent tissue bed, in response to signals from growth factors, such as epithelial growth factor and keratinocyte growth factor. Epithelial cells migrate into the wound from the periphery by secreting MMPs to degrade the nonviable tissue at the wound edge, allowing migration into the wound. Normally epithelial migration should continue until other epithelial cells are contacted.[11]

Remodeling is a long-term process in which type III collagen is largely replaced by mature type I collagen. This process also requires the presence of MMPs to degrade the type III collagen in a controlled fashion mediated by TIMPs, facilitating its replacement with maturing type I collagen.[12]

MECHANISMS OF ABNORMAL WOUND HEALING IN CHRONIC WOUNDS

Chronic nonhealing wounds occur when the normal healing process is disrupted. This is most frequently the result of an underlying disorder that causes a prolonged, unchecked pro-inflammatory state. These disorders include venous hypertension, chronic pressure, bacterial colonization, inadequate tissue perfusion, and cellular senescence.

Inflammation

Recurrent or prolonged inflammatory stimuli result in chronic wounds that are characterized by persistent upregulation of proinflammatory cytokines and MMPs. Although this

environment is necessary for a brief period for acute wound healing, persistence of this environment has detrimental effects. Wound fluid collected from chronic nonhealing ulcers has been reported to inhibit DNA synthesis and mitotic activity of normal skin fibroblasts and keratinocytes.[13] In contrast, fluid collected from acute wounds stimulate these measures of cellular activity. Chronic wound fluid may contain high levels of MMP-2 and MMP-9 and abnormally low levels of TIMPs.[14] In venous ulcers, MMP levels decrease after compression treatment. In a study of 56 patients with pressure ulcers, Ladwig et al.[15] found that the ratio of MMP-9 to TIMP-1 was associated with wound healing outcomes: an elevated concentration of MMP-9 in relation to TIMP-1 was predictive of poor healing. Although this upregulation of protease levels might be expected to degrade endogenous growth factors, Drinkwater et al.[16] reported that the level of VEGFs in venous ulcer tissue was not decreased and was persistently high compared with normal tissue, and was equivalent to levels in tissue from acute wounds. In a separate study, these researchers found that fluid from venous ulcers inhibited angiogenesis, postulating that this effect must be caused by the presence of inhibitors or a lack of available receptors rather than an absence of stimulatory growth factors.[17] Patients with critical limb ischemia (CLI) also demonstrate deficits of growth factor function. Palmer-Kazen et al.[18] found that distal limb tissue in patients with CLI had lower levels of VEGF compared with nonischemic proximal tissue in the same limb.

Cytokines

Upregulation of proinflammatory cytokines, including TNF-α, IL-1, and IL-6, has also been described in chronic venous wound fluid.[13] These levels were found to improve when ulcers began to heal, with a decrease in size and improvement in granulation. Diabetic foot ulcers may also display proinflammatory upregulation and low expression of angiogenic factors.[19]

Cell Senescence

Cellular senescence has been reported in fibroblasts collected from chronic nonhealing ulcers. Lal and colleagues[20] found that fibroblasts from patients with increasing levels of venous disease by clinical class, etiologic, anatomic, and pathophysiologic (CEAP) criteria displayed a progressively diminishing response to agonist-induced proliferation. Fibroblasts from CEAP class 6 patients displayed severe inhibition of the proliferative response to TGF-β1. Mendez and colleagues[21] reported a series of studies of cultured fibroblasts from venous ulcers, indicating that these typically display phenotypic characteristics of cellular senescence, including slow growth and altered morphology. Stimulation of senescent fibroblasts may be a key target of therapy for improving the healing potential of chronic leg ulcers.

Therapeutic Targets

The development of therapeutic targets based on the known mechanisms of poor healing has been difficult, given its overall complexity. Initial strategies at modulating protease expression have not yielded major improvements in healing. A dressing composed of a combination of collagen and regenerated cellulose (Promogran, Systagenix, North Yorkshire, United Kingdom) has been developed, based on its ability to bind MMPs in wound fluid in vitro.[22] However, in a prospective randomized study of 276 patients with diabetic foot ulcers, treatment with this dressing for 12 weeks failed to result in a significantly higher incidence of complete healing (37%) compared with ulcers treated with saline-moistened gauze (28%).[23]

General treatments for the reduction of inflammation such as doxycycline and nonsteroidal anti-inflammatory drugs have been studied in animal models and considered for clinical use.[24] In a pilot study of chronic venous leg ulcers, high-dose doxycycline resulted in improvement of recalcitrant wounds and reduced wound fluid MMP levels.[25] These findings have not yet been confirmed in a larger patient cohort. Some researchers believe that the simple inhibition of upregulated proteases or cytokines is unlikely to yield significant gains in healing. As evidenced by the importance of MMPs in multiple aspects of the normal healing process, gross inhibition of their function impairs capillary development, epithelial migration, and collagen maturation. Beidler et al.,[26] in an analysis of cytokine levels and venous ulcer healing, found that untreated ulcers with higher levels of proinflammatory cytokines, including IL-1, IL-12p40, and IFN-δ, healed significantly better than those with lower levels of these cytokines before compression. It is clear that strategies to address the abnormal progression of healing in chronic ulcers must consider that inflammation is necessary at various points in the process and must be suppressed at other stages. Currently no diagnostic modalities are available to rapidly test the MMP or cytokine levels in wound fluid or tissue in a nonresearch setting, but clinically relevant testing strategies are under development.

ETIOLOGY OF ULCERATION

The successful treatment of patients with nonhealing leg ulcers requires that the underlying cause of ulceration be correctly diagnosed. Common differential diagnoses of leg ulceration are provided in Table 115.1. It has been reported that multiple causes are involved in more than 20% of leg ulcers, so it is clear that each potential diagnosis must be considered in every patient.[27] Based on the history and physical examination, the proper cause or causes of chronic ulcers can be defined in the majority of patients, but if doubt remains, confirmatory noninvasive testing should be performed.

Venous Leg Ulcers

The epidemiology and pathophysiology of venous leg ulcers are described in Chapter 156. Risk factors related to the development of venous ulcers are the same as those for the development of venous disease in general. It is important to understand that venous disease in any combination of anatomic sites may result in limb ulceration, including superficial venous insufficiency alone. The anatomic sites of venous reflux defined by duplex ultrasound examination in a series of 138 patients with venous leg ulcers are listed in Table 115.2.[28]

TABLE 115.1 Differential Diagnosis of Causes of Chronic Nonhealing Leg Ulcers

Etiology of Wound	Differential Diagnosis	Method of Investigation
Infectious conditions	Mycobacterial Fungal Bacterial Treponemal/spirochetal	Wound biopsy with special stains and cultures, VDRL, PPD, CBC, ESR, C-reactive protein, chest x-ray, wound x-ray
Malignancy	Basal cell carcinoma Squamous cell carcinoma Kaposi sarcoma Lymphoma Mycosis fungoides	Wound biopsy for pathologic evaluation
Macrovascular arterial insufficiency	Arteriosclerosis Posttraumatic Embolic Acute or chronic thrombosis	Noninvasive vascular studies Bidirectional color Doppler, $tcPO_2$, Contrast arteriography Computed tomography arteriography Magnetic resonance arteriography
Vasculitis/vasculopathy (microvascular arterial insufficiency)	Diabetic microangiopathy Hypertensive microangiopathy Thromboangiitis obliterans Raynaud disorder	$tcPO_2$ Laser Doppler Possible biopsy
Venous insufficiency (deep and superficial)	Deep venous thrombosis Extrinsic compression (tumors) Deep valve insufficiency Perforator valve insufficiency Superficial venous insufficiency	Strain gauge plethysmography (maximum venous outflow) Venous photoplethysmography Bidirectional color Doppler Air plethysmography
Lymphatic obstruction/ lymphedema	Venolymphatic disease (secondary to congestive heart failure, hepatic failure, renal failure, other overload states) Primary or secondary lymphatic insufficiency Lymphangiosarcoma	Clinical diagnosis, history, physical examination, chest x-ray, liver function tests, chemistries, lymphangiography
Hematologic abnormalities	Anemia (sickle cell) Polycythemia Dysproteinemia	CBC, iron studies (Fe, TIBC, folate, B_{12}) Sickle cell prep
Collagen vascular disorders	Systemic lupus erythematosus Scleroderma Polyarteritis nodosa Wegener granulomatosis	FANA Rheumatoid arthritis prep Serum complement Rheumatologic workup
Excessive pressure	Diabetic neuropathy Alcoholic neuropathy Decubitus ulcer Postoperative deformity Bone spurs	Monofilament (10 g) Vibratory sensation (>25 mV) X-rays

CBC, Complete blood count; *ESR*, erythrocyte sedimentation rate; *FANA*, fluorescent antinuclear antibody test; *PPD*, purified protein derivative; *$tcPO_2$*, transcutaneous oxygen tension; *TIBC*, total iron-binding capacity; *VDRL*, Venereal Disease Research Laboratory.

TABLE 115.2 Anatomic Distribution of Venous Reflux in 138 Patients[28]

Venous System	Limbs (%)
Deep alone	43.5
Deep and superficial	21.0
Deep, perforator, and superficial	6.5
Superficial alone	18.1
Superficial and perforator	10.9

The pathway between chronic venous hypertension and limb ulceration has been debated for years. In some patients persistent venous hypertension with chronic limb edema leads to the gradual development of skin changes. Chronic upregulation of pro-inflammatory cytokines appear to mediate the development of tissue fibrosis and the clinical appearance of lipodermatosclerosis (Fig. 115.1). This is believed to be a preulcerative condition that should stimulate treatment to correct the underlying venous pathology or eliminate edema to reduce the risk of future ulceration. Ulceration eventually occurs either spontaneously or due to minor limb trauma in the lower calf or ankle that then does not heal.

Figure 115.1 Limb with chronic venous insufficiency illustrating wound tissue scarring and lipodermatosclerosis.

Diabetic Foot Ulcers

The epidemiology and pathophysiology of diabetic foot ulcers are reviewed in detail in Chapter 116. For management purposes, it is critical to remember that the underlying causes of ulcers, such as polyneuropathy, vascular insufficiency, and infection, must be addressed before specific wound treatments can assist in healing. Inadequate pressure offloading is the most common cause of failure to heal, and no active wound therapy can overcome persistent pressure on a plantar ulcer. The assistance of an expert orthotist and consistent patient education to achieve compliance are far more important to the healing of diabetic foot ulcers than the specific dressing or agent selected.

Limb Ulcers Associated With Arterial Insufficiency

The treatment of patients with chronic nonhealing leg ulcers associated with arterial insufficiency involves a critical assessment of the patient's suitability for invasive procedures and the potential risk of limb loss based on ulcer characteristics. Data from several clinical trials studying CLI have identified a risk of major amputation in 25% to 40% of patients at 1 year if revascularization is not performed.[29,30] However, the hemodynamic criteria for CLI are broad and further evaluation of the specific level of perfusion to the wound bed is needed to predict which patients have a good chance of healing without revascularization. It appears clear that the severity of the wound itself is important, such that a superficial partial-thickness wound (Fig. 115.2) may not require the same level of perfusion as a deep, complicated leg ulcer involving tendon or bone (Fig. 115.3) to achieve healing. The WIfI classification system (see the section on Wound Classification later) was designed to capture the severity of wound tissue damage, arterial insufficiency, and infection as an aid to prediction of healing potential.[31]

The natural history of chronic wounds with AI that do not receive revascularization was reported in a study of 169 limbs.[32] At 1-year follow-up, 52% of limb ulcers were healed, and 23% required amputation (Fig. 115.4). Risk factor analyses revealed

Figure 115.2 Wagner grade 1 diabetic foot ulcer. The wound penetrates through the full thickness of the skin, involving the subcutaneous tissue but not the deeper tissue layers.

Natural history of limbs with arterial insufficiency and chronic ulceration treated without revascularization. *J Vasc Surg.* 2006;44: 108–114.)

Figure 115.5 Chronic wound with squamous cell malignancy (Marjolin's ulcer).

that the ankle-brachial index (ABI) and wound grade were associated with amputation at 1 year. In another study of nonrevascularized patients with CLI and wounds, limbs were separated into groups based on the toe pressure in the affected limb.[33] If the toe pressure was 20 to 50 mm Hg, 85% of patients were able to achieve limb salvage with wound management using standard multispecialty wound protocols, compared with only 60% in those with a toe pressure less than 20 mm Hg. Unfortunately, survival in these patients is poor, particularly in the patients with the lowest toe pressures less than 10 mm Hg, in whom only 8% of patients achieved amputation-free survival at 3 years. This is due to severe medical comorbidities affecting these patients, including a high prevalence of renal failure and cardiac dysfunction, which also lead to higher risks for efforts at revascularization.[34] This information suggests that some patients with AI and wounds who are at high risk for a poor outcome with revascularization can be reasonably treated without revascularization, and many will experience limb salvage. Revascularization should be considered early in those who have rest pain, those with more severe wound grades, and those with pedal gangrene. Wounds treated initially with wound management without revascularization should be monitored closely for progress, and if this does not occur within 4 to 6 weeks, revascularization should be considered. Arterial insufficiency is a common complicating factor for limb ulcers associated primarily with other causes, including venous insufficiency, diabetes, and rheumatoid arthritis. It is important that the status of the arterial supply be determined in every patient at the initial evaluation.

Other Causes of Limb Ulceration

Although the preceding causes are important factors in more than 90% of nontraumatic limb ulcers, other causes, including vasculitis, sickle cell anemia, malignancy, and dermatologic disease, are routinely seen by vascular specialists. It is beyond the scope of this chapter to review these leg ulcers in detail. The key to diagnosing these atypical causes is ulcer biopsy. Many of these conditions may be confused with venous ulceration and may coexist in a patient with chronic venous insufficiency. The most important diagnosis to make is Marjolin's ulcer, which may develop when squamous transformation occurs in a preexisting benign chronic wound (Fig. 115.5). This neoplasm is often not detectable by observation, so the physician must maintain a high index of suspicion. Whenever a wound does not respond to a comprehensive treatment plan as expected or a wound that has been healing ceases to progress for no known reason, a biopsy should be performed to rule out malignancy. Further information on the diagnosis and management of atypical wounds is beyond the scope of this chapter.

CLINICAL PRESENTATION AND INITIAL EVALUATION

The primary cause of most wounds can be identified after the history and an attentive physical examination. Fig. 115.6 contrasts common types of lower extremity ulcerations.

Wound Classification Systems

The most widely recognized system for classification of diabetic foot ulcers is the Wagner grading system. Limbs with higher Wagner grades, particularly grades 3 to 5, are at increased risk for limb loss (Table 115.3).[35]

Figure 115.6 (A) Leg ulcer associated with chronic venous insufficiency. (B) Diabetic neuropathic ulcer. (C) Plantar ulcer in a patient with diabetes and chronic Charcot neuropathy. (D) Leg ulcer in a patient with both arterial and venous insufficiency. (E) Leg ulcer in a patient with systemic lupus and venous insufficiency. (F) Squamous cell carcinoma arising in a chronic foot ulcer. (G) Leg ulcer associated with rheumatoid arthritis. (H) Bacterial biofilm covering the surface of a nonhealing venous leg ulcer. (I) Same ulcer depicted in (H) after elimination of the biofilm following débridement and 2 weeks of antibiotic therapy. (J) Chronic leg ulcer in a patient with sickle cell anemia.

However, the Wagner system only incorporates the extent of anatomic wound involvement. In an attempt to improve the predictive value of a wound classification system, the Society for Vascular Surgery Lower Extremity Guidelines Committee developed a new classification of the threatened lower extremity that also includes the presence and extent of wound ischemia and infection.[31] The WIfI classification (see Table 104.3 in Chapter 104) has been validated to correlate to the risk of amputation in several subsequent publications.[31,36,37]

Wound Size Measurement

At each visit, it is important to measure the wound size to document progress and alter the treatment plan if necessary.

Subtle changes in the wound itself, including the development of inflammation or bacterial colonization, may manifest only as the suppression of healing. Routine wound measurement allows the consideration of alternative treatment methods as soon as progress in wound healing ceases.

Numerous methods are available to document and follow wound size, including digital photography with computerized planimetry, direct planimetry, and simple measurement of dimensions. Software systems are also available to allow the determination of wound size from calibrated digital photography.

TABLE 115.3 Incidence of Limb Amputation in Patients Presenting With Limb Ischemia Based on Wagner Grade[a] at Initial Presentation

Grade	Criterion	Amputation at 12 Months (%)
0	Preulcerative lesion	
1	Superficial ulcer	12
2	Ulcer extending deep to tendon, bone, or joint	19
3	Deep ulcer with abscess or osteomyelitis	31
4	Forefoot gangrene	49
5	Whole foot gangrene	100

Wound Bed Assessment and Preparation

Once the history and physical examination are completed and a general idea of the underlying cause of the wound is determined, the wound itself must be assessed for local factors inhibiting healing. Numerous factors must be identified and corrected to optimize healing potential, a process termed "wound bed preparation." The components of this process include débridement of nonviable tissue, identification and correction of bacterial involvement, control of chronic inflammation, elimination of limb edema, and control of wound exudate. The first two components are addressed here.

Débridement

The majority of chronic limb ulcers are covered with nonviable tissue, including callus, eschar, fibrinous material, and slough. This tissue has no regenerative capability, harbors bacteria, and prevents the migration of healthy epithelium into the wound. Débridement is required to excise nonviable tissue and should be aggressive, particularly at the initial evaluation. Cellular senescence has been identified in wound tissue around diabetic foot ulcers and chronic venous ulcers of long duration, indicating the need for wound excision to remove all surrounding tissue in these cases (Fig. 115.7).[38] In a prospective multicenter study of becaplermin for the healing of diabetic foot ulcers, a secondary analysis suggested that centers employing more frequent wound débridement achieved better healing rates.[39]

In a retrospective review of 676 patients enrolled in clinical trials of novel therapeutic agents for venous or diabetic ulcers, the incidence of wound débridement was studied and correlated with wound closure.[40] Thirty-three centers where limbs were débrided more frequently were associated with higher rates of wound closure for both types of wounds, but an increased frequency of wound débridement per patient did not statistically

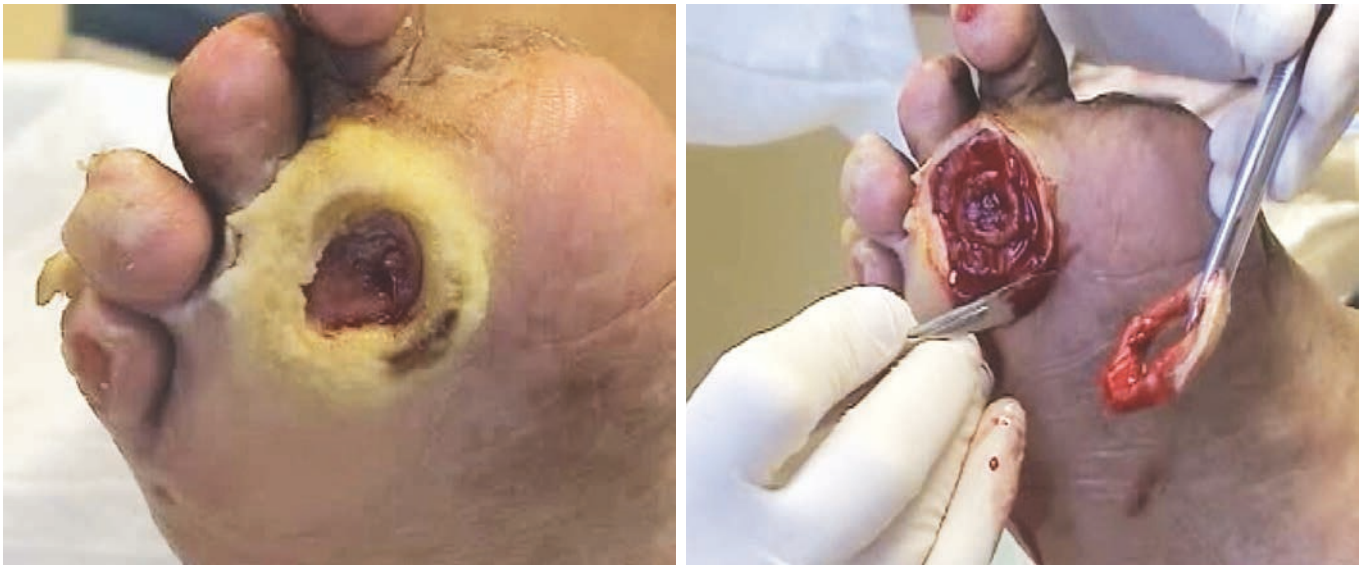

Figure 115.7 Example of aggressive débridement of senescent tissue in and around the wound bed to create an acute wound out of a chronic wound.

correlate with higher rates of wound closure. Using a large retrospective data set, Wilcox and colleagues (2013) documented faster healing with weekly débridement ($P < .001$) of a variety of chronic wounds.[41] Based on this information, it appears that débridement for chronic wounds is important to eliminate nonviable tissue, and may be required multiple times during the treatment course of the wound. However, the current body of evidence provides no definitive guidance on the question of how often chronic wounds should be débrided or the best timing.

Numerous alternatives to surgical débridement have evolved, including chemical débridement, ultrasound débridement, hydro-débridement, and larval therapy. In general, there are two situations in which alternatives to surgical débridement may be desirable: patients in long-term nursing facilities, and those who have difficulty traveling to wound or surgical clinics for surgical débridement when required. These patients may benefit from chemical débridement or some other method.

Chemical

Chemical débriding agents are typically composed of enzymatic agents, including collagenase (Santyl, Healthpoint Ltd., Fort Worth, Texas). Collagenase may be used as a maintenance débriding agent to remove moderate amounts of fibrinous slough from the wound surface, but it is usually ineffective against thick tissue or eschar.

Larval

Larval therapy using medical maggots has been studied as an alternative to conventional therapy in several nonrandomized studies. Sherman reported that 80% of maggot-treated pressure wounds achieved complete débridement, compared with 48% of conventionally treated wounds.[42] However, most of the studies evaluating maggot therapy have used autolytic or chemical débridement as comparators. A randomized study of larval therapy compared with hydrogel for the management of chronic leg ulcers was reported in 2009.[43] All other wound therapies were similar for each group. The study found that larval-treated wounds experienced significantly faster débridement than the hydrogel-treated group, but at the expense of significantly higher ulcer-related pain scores. No difference in ulcer healing or patient quality of life was demonstrated.

Ultrasound

Débridement using standard surgical techniques may be particularly painful, leading to interest in alternative methods that achieve wound débridement while increasing patient comfort. Several energy modalities, including ultrasound, have been investigated as adjuncts to débridement. Ultrasound may be used in conjunction with a surgical instrument: the instrument contacts the wound to deliver ultrasound energy to the tissue to loosen and remove nonviable tissue. Alternatively, the use of saline mist avoids the need for direct contact with the wound surface. In a study of the noncontact method of ultrasound treatment, mist ultrasound was compared with standard treatment of diabetic foot ulcers. Although there was no significant difference in the rate of ulcer healing based upon the intent-to-treat analysis, there was a significant increase in the rate of healing in patients who completed a course of properly applied mist ultrasound treatment.[44]

In summary, no other form of débridement has demonstrated superiority to standard surgical débridement, and most of these methods are less cost effective in the majority of cases. Alternative methods of débridement are generally recommended when surgical débridement is not possible or is not desirable.

Bacterial Colonization

Significant bacterial infection is a common complication in chronic wounds. In several prospective randomized clinical trials of therapies for diabetic foot ulcers, wound infection requiring systemic antibiotic therapy occurred in 20% to 25% of cases.[45,46] However, the treatment of bacteria in wounds that do not appear to be clinically infected is controversial. Moreover, it is believed that uninfected healing wounds are colonized with bacterial flora. Treatment with antibiotics is not indicated, so routine culturing of wounds in these cases is not recommended. The eradication of normal skin and nonvirulent wound bacteria is not desirable and may support the growth of more virulent and resistant bacterial strains. Of note, however, recent studies have identified an increase in the incidence of resistant organisms from cultures of chronic nonhealing ulcers that do not respond to standard treatment protocols.[47]

Biofilms harboring bacteria are well known to cover indwelling catheters, industrial surfaces, and dental structures. Bacteria in these situations secrete a polysaccharide substance that covers the colonies, which grow and interact to inhibit host-generated control mechanisms. Mechanical methods of cleansing these surfaces can minimize biofilms, but they typically repopulate rapidly after cleansing. In chronic wounds, biofilms appear to multiply to the point at which they inhibit healing by stimulating chronic inflammation, inactivating growth factors critical to the healing process, and preventing orderly angiogenesis required for healing (Fig. 115.8).[48] If untreated, it is believed that biofilms will continue to inhibit wound healing or may lead to more significant systemic infection.

Given the emergence of this clinical problem, wounds with poor progress and those demonstrating any evidence of enlargement or infection should be evaluated with quantitative cultures. If cultures demonstrate greater than 10^5 bacterial counts per cubic millimeter, the patient should receive systemic therapy guided by bacteria-specific sensitivities.[49]

In general, the management of bacterial colonization of chronic ulcers remains a controversial area with limited high quality research and contradictory results in the studies available for review. Although there is general agreement among experts that wounds with obvious signs of clinical infection should be treated with systemic antibiotics, there is no consensus on the management of wounds colonized with bacteria or bacterial biofilms without signs of systemic infection. Recent studies have described the types of bacterial biofilms that may develop in chronic wounds, with multiple species organized into colonies on the wound surface that are resistant to topical therapies. This adds complexity to treatment, and information on the clinical relevance of these biofilms and the best strategies to treat them is not yet well developed. Finally, the changing nature of

Figure 115.8 Examples of the appearance of biofilm covering chronic wounds.

bacterial behavior over time may render studies performed as recently as 5 to 10 years ago irrelevant at the present time. The importance of the bacteria affecting the wound bed remains controversial. Although some studies have reported that the information provided by wound cultures is of little prognostic significance,[50] others report improved healing with specific antibiotic treatment of cultured bacteria.[51] Diagnostic methods are becoming clinically available using polymerase chain reaction to provide more detailed descriptions of the bacteria existing in the wound bed.[52] This information may allow more specific tailored antimicrobial strategies to treat each individual wound. However, use of these methods has not yet been established to improve outcomes in the care of chronic wounds.

PROPERTIES AND CATEGORIES OF WOUND DRESSINGS

In general, the selection of a wound dressing should be based on wound characteristics, including location, inflammation, and amount of exudate. Moisture balance is important, and the dressing should maintain a moist environment conducive to tissue growth and epithelial migration. Based on the high concentration of inflammatory cytokines and proteases in chronic wound fluid, excessive fluid should be wicked away from the ulcer and the skin surface to prevent further tissue inflammation and damage from prolonged contact.

A multitude of agents with theoretical healing benefits have been added to wound dressings, including collagen, zinc, enzymes, copper, chlorophyll, honey, avocado oil, and others with little proof of benefit. Table 115.4 lists the common categories of wound dressings and their typical uses.

A common question concerning all these dressings is their worth in comparison to a simple regimen such as wet-to-dry saline gauze dressings. Although it is true that few wound products have been proved to heal significantly more wounds than saline-moistened gauze, other secondary benefits may be realized through the use of these dressings. Pain reduction, odor reduction, and longer wear time are important benefits. Also, it is assumed that wet-to-dry dressings are cost-effective because

TABLE 115.4 Dressing Categories and Primary Uses

Advantages	Disadvantages	Examples	Typical Uses
Gauze			
Mechanical débridement Permeable to gases Fills dead space Economical Readily available Absorptive	Can damage granulation tissue on removal May dehydrate wound Permeable to fluid and bacteria May require more frequent dressing changes	Kerlix Kling Nu-Gauze Sof-wick Tendersorb Mirasorb	Infected wounds Wounds requiring frequent dressing changes
Film			
Semipermeable Retains moisture Waterproof Allows wound visualization	Cannot be used on infected wounds May tear fragile skin May dislodge in high-friction areas	Bioclusive Flexfilm Tegaderm Opsite Polyskin II Cutifilm	Postsurgical wounds Partial-thickness wounds
Hydrogel			
May reduce pain Rehydrates wound Extends time between dressing changes Can fill dead space	Requires secondary dressing Sheets may be difficult to secure Can cause periwound maceration Minimal absorption	NU-GEL Curasol Safe-gel Carrasyn Hypergel Gentell Vigilon	Dry, minimally exudative wounds Diabetic foot ulcers
Hydrocolloid			
Impermeable to bacteria Facilitates autolytic débridement Water resistant Self-adhesive Reduces pain	Cannot be used in heavy exudate Cannot be used on infected wounds Softens and loses shape with heat and friction May cause skin tears	Duoderm Replicare Restore Tegasorb Cutinova	Partial-thickness wounds Low-exudative pressure ulcers
Foam			
Highly absorptive Nonadherent Conformable Protects wound from trauma Can be used under compression dressing	May require secondary dressing May macerate wound edge if dressing becomes saturated Not effective for wounds with dry eschar	Allevyn Flexan Lyofoam PolyMem	Highly exudative wounds Venous ulcers under compression
Alginate			
Forms moist gel in wound Highly absorptive Fills dead space Controls heavy exudate	Cannot be used in dry wounds with minimal exudate Can dehydrate wound bed Reports of burning sensation Requires secondary dressing	Sorbsan Kaltostat Curasorb Algisite Tegagen HG AlgiDERM	Heavily exudative, deep wounds Tunneling, draining wounds Venous ulcers under compression
Composite			
Combines two or more physically distinct products for better outcomes	Can be expensive Provider must have good understanding of dressing properties Generally requires intact skin border for anchoring dressing	Fibrocol (collagen and alginate) Versiva (foam and hydrofiber) Tielle (foam and polyurethane covering	Depends on specific composite

of the relatively low cost of the dressing materials compared with other products. However, proper utilization of wet-to-dry dressings requires dressing changes two or three times daily, resulting in increased cost of care. Particularly in situations in which skilled care such as home nursing is required, the cost efficacy of dressings with longer wear time is significantly better than that of wet-to-dry gauze dressings.[53]

Diabetic foot ulcers are typically treated with dressings that donate moisture to the wound bed, such as hydrogels, because the wound usually produces little exudative drainage. More

heavily draining wounds are better treated with alginates or hydrofibers with greater moisture removal capabilities. Venous leg ulcers are heavily exudative, with a high protease content to the fluid. This requires foam-type dressings that absorb and wick active exudate away from the wound and surrounding skin. Compression systems are placed on top of this primary dressing and should be changed as often as necessary to prevent saturation of the dressing, usually one to three times weekly.

As concern over resistant bacterial species has increased, a vast array of dressings containing antimicrobial agents has been developed. Employing these agents generally requires a balance between the positive antimicrobial effect and the inhibition of normal tissue proliferation and wound healing. The long-term use of iodine-based topical antibiotics in chronic wound healing fell out of favor after in vitro studies suggested the suppression of fibroblast function. Slow-release dressings containing cadexomer iodine were developed, designed to reduce the concentration of iodine limiting negative effects on wound healing while inhibiting bacterial growth. In a small multicenter randomized study comparing cadexomer iodine to wet-to-dry dressings in venous leg ulcers treated with compression, the cadexomer iodine treated wounds were found to heal more than twice as rapidly as the control ($P = .0025$).[54]

Silver and numerous other antimicrobial agents have been incorporated into dressing materials, many combined with other dressing characteristics that also permit moisture management in the wound bed. A Cochrane analysis of the benefit of silver-releasing dressings for the healing of chronic wounds found insufficient evidence to recommend their use for the treatment of infected or contaminated wounds.[55] In a randomized study of 129 patients with venous leg ulcers colonized with critical levels of bacteria and poor healing, a silver-containing foam dressing was compared with a non–silver-containing dressing; both groups received multilayer compression.[56] After 4 weeks, the silver-treated ulcers had closed an average of 45%, compared with 25% in the control group ($P < .05$). The wounds were not treated with the product to complete healing, so the rate of wound closure was not assessed. A prospective randomized trial performed in chronic venous leg ulcers evaluated the effect of routine use of silver-donating dressings compared with non–silver-donating dressings over a 12-week period.[57] All patients were treated with high-strength compression and primary dressings of similar absorptive capacity either with or without silver. No demonstrable effect on healing or quality of life was associated with the use of silver. Given the increased cost of these dressings, it was concluded that routine use is not indicated.

Based on this information, it may be concluded that topical antimicrobial agents should not be used routinely to treat wounds for extended periods, but targeted use in well-defined wounds with critical levels of bacterial involvement may yield a benefit, but the level of evidence supporting this practice is poor.

VENOUS LEG ULCERS

All patients with venous leg ulcers who are candidates for corrective procedures should have diagnostic studies to determine their specific anatomy and physiology. Particular attention should be paid to correctable venous abnormalities, including saphenous reflux, perforator incompetence, and iliac outflow stenosis.

The American Venous Forum and Society for Vascular Surgery published treatment guidelines for venous leg ulcers in 2014. These comprehensive practice guidelines include recommendations on therapy to prevent ulceration, therapies to heal VLUs, and methods to prevent ulcer recurrence after healing.[58]

Compression

Sustained high-strength compression of the limb remains the basis of treatment for venous leg ulcers. Discussed in detail in Chapter 157, compression must be initiated before other therapies and throughout the treatment course to attain healing. Adjuvant therapies will uniformly fail if limb compression is not maintained during treatment in an ambulatory patient.

Pharmacologic Treatment

Pentoxifylline

In a review of randomized controlled trials, Jull and Arroll[59] found five trials in which pentoxifylline and compression were compared with placebo and compression. Pooling these data resulted in the conclusion that more patients in the pentoxifylline group achieved healing. In one of the studies, Falanga et al.[60] reported a median time to healing of 100 days for placebo, compared with 71 days for pentoxifylline at 800 mg three times daily.

Flavonoids

Flavonoids are a class of plant-derived compounds that display anti-inflammatory and antioxidant properties. Two randomized controlled trials studied the benefit of flavonoids in addition to compression for venous leg ulcer healing, and both found a significant benefit for flavonoid treatment.[61,62]

Anticoagulants

In an RCT on 284 patients with VLUs treated with compression therapy and surgical intervention, daily subcutaneous injection of LMWH for 12 months was found to accelerate wound healing.[63] Patients treated in the group randomized to receive LMWH experienced complete ulcer healing in 83.8% at 12 months compared with 60.6% at 12 months in those treated without LMWH. Although the cost and complications associated with daily LMWH use for a year may not warrant therapy for most patients with VLUs, this therapy may be considered for carefully selected recalcitrant ulcers not responding to other therapies.

Indications for Intervention

Gohel et al.[64] performed a randomized study comparing the efficacy of saphenous stripping plus compression with compression alone for the healing and prevention of venous leg ulcers in patients with superficial venous reflux. Significantly fewer

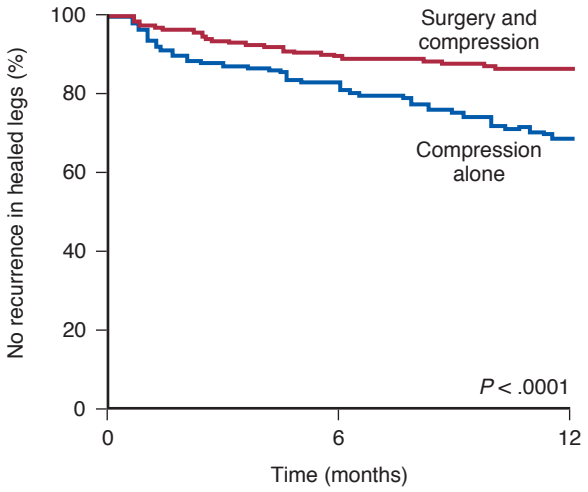

Figure 115.9 Incidence of ulcer recurrence in patients with chronic venous insufficiency due to superficial venous reflux treated with compression alone compared with compression plus surgical stripping of the saphenous vein. (Modified from Gohel MS, Barwell JR, Taylor M, Chant T, Foy C, Earnshaw JJ, Heather BP, Mitchell DC, Whyman MR, Poskitt KR. Long term results of compression therapy alone versus compression plus surgery in chronic venous ulceration (ESCHAR): randomized controlled trial. *BMJ.* 2007;335:83.)

patients in the surgery group experienced recurrent ulceration (15%) compared with the compression-only group (34%) at 1-year follow-up (Fig. 115.9). At 4 years of follow-up, 56% of patients treated with compression alone had developed recurrent ulceration compared with 31% of those in the surgery group ($P < .01$).

Based on the results of this trial, it is reasonable to recommend venous intervention to reduce the incidence of ulcer recurrence whenever superficial venous reflux is a prominent component of the abnormal venous function. This constitutes 30% to 50% of cases seen at most venous leg ulcers centers. However, intervention cannot be recommended for most patients to accelerate wound healing. The contribution of incompetent perforators to global venous insufficiency remains controversial and is discussed in detail in Chapter 158, but it is clear that some leg ulcers are associated with large incompetent perforators that should be ligated or ablated.

There is also limited evidence supporting the removal of varicose channels extending into the ulcer bed to eliminate the final channel of venous hypertension extending into the area of ulceration.[65] This may be done surgically or with sclerotherapy. Deep venous reconstruction can be considered in some cases (see Chapter 159).

Adjunctive Therapies to Accelerate Healing

Treatment of venous leg ulcers with compression bandaging using any number of systems results in healing in approximately 60% to 70% of patients after 4 to 6 months of consistent therapy.[26,66] Numerous adjunctive methods have been studied in an attempt to accelerate this healing process, including skin grafting, growth factors, living human skin equivalents, collagen matrices, platelet releasates, topical therapies, ultrasound, electrical stimulation, and other modalities. The majority of these therapeutic strategies have limited data supporting their efficacy.

Skin Grafting

Although split-thickness skin grafts have been employed for decades in an attempt to heal recalcitrant venous leg ulcers, there is little quality information supporting the benefit of this practice. There are no adequately powered randomized studies reporting the results of skin grafts versus compression therapy alone. The Cochrane Database recently reviewed the available clinical studies and concluded that further research is needed to assess whether skin grafting increases ulcer healing.[67] Although definitive evidence is lacking, some clinicians consider skin grafting in slow responding wounds or for patients with large soft tissue deficits that are able to granulate well to provide a clean healthy bed to support graft take. In a nonrandomized study of 111 patients, Jankunas demonstrated improved healing and durability with skin grafting compared with conservative therapy for large venous wounds that were present longer than 6 months, but only 65% of cases were judged to have good take of the split-thickness skin graft.[68]

For patients with large ulcers and extensive peri-ulcer lipodermatosclerosis, radical excision and free-flap tissue transfer have been described, with durable improvement in some cases.

Human Skin Equivalents

Apligraf (Organogenesis, Canton, Massachusetts) is a cultured bilayer cellular construct (BLCC) originating from neonatal foreskin. A bovine collagen lattice is used as a base to support the organization of dermal fibroblasts and epithelial cells. A layer of allogeneic keratinocytes is cultured over the fibroblast layer to form a stratified epidermis. The bilayer has a structure similar to human skin, with the absence of hair follicles or sweat glands (Fig. 115.10). The growth factors and cytokines secreted by the cellular components of BLCC include fibroblast growth factor (FGF), VEGF, PDGF, TGF-β, and multiple ILs, paralleling those secreted by healthy human skin.[69] The product requires a well-granulated wound bed in which exudate and bacterial levels have been controlled to yield positive results. The BLCC is easily applied in a clinic or operating room setting after aggressive wound débridement and hemostasis. Standard compression bandaging is then applied to maintain control of venous hypertension.

Apligraf was studied in a prospective randomized multicenter trial of 240 patients with nonhealing venous leg ulcers present for more than 1 month.[70] Patients were randomized to a standard compression bandaging regimen or compression bandaging plus BLCC. The primary study outcome measure was complete healing at 24 weeks of treatment. In the BLCC-treated group, 57% of venous leg ulcers closed at 24 weeks, compared with 40% in the control group ($P = .02$). For ulcers that had been present for more than 1 year, 47% healed at 24 weeks, compared with 19% in the control group ($P = .002$).

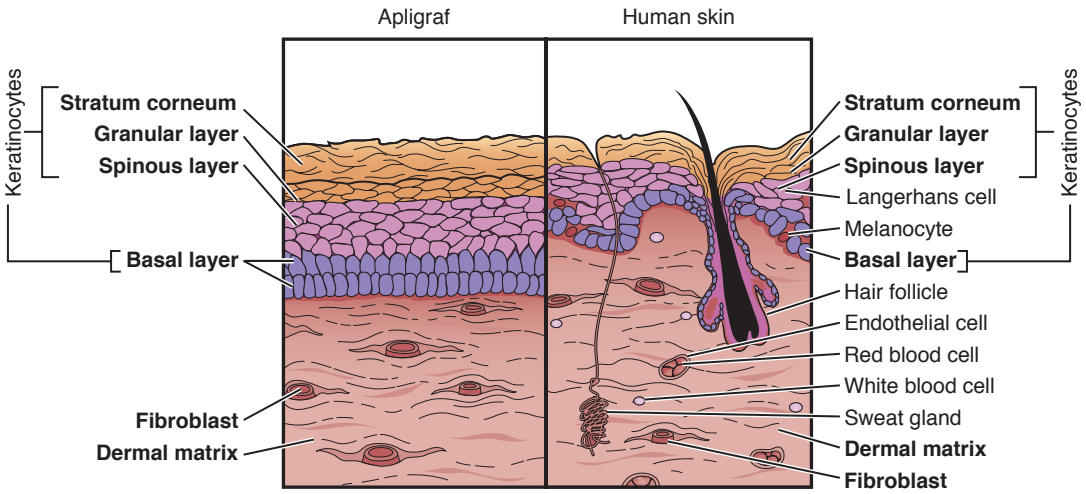

Figure 115.10 Comparison of the structure of Apligraf to human skin. (Courtesy Organogenesis Inc.)

Porcine small intestine submucosa (OASIS wound matrix, Healthpoint Ltd., Fort Worth, Texas) has been shown in a prospective RCT to accelerate healing of VLUs.[71] In a study by Mostow and colleagues, 2005 a total of 120 patients with VLUs were randomized to receive either weekly topical treatment of small intestine sub mucosa (SIS) plus compression or compression therapy alone. After 12 weeks of treatment, 55% of wounds treated with SIS healed versus 34% in the control group ($P = .0196$).

Using a large wound care-specific electronic medical record, the real-world effectiveness of BLCC and SIS for the treatment of VLUs over a 3-year period was assessed.[72] Although this method of comparison suffers from the inaccuracies of large EMR databases employed at a large number of treatment facilities, large numbers of treatment events may be captured for analysis. A comparison of 3702 VLUs treated with BLCC to 1143 treated with SIS indicated that significantly more patients treated with the BLCC achieved a healed wound. However, the overall rate of wound healing in both groups was disappointing (Fig. 115.11).

In summary, currently available adjunctive therapies for venous ulcers appear to provide only a modest benefit if used routinely to assist VLU healing. It is likely that use limited to patients with long duration wounds that are not responding well to standard treatment protocols is more cost-effective, particularly in wounds that are well prepared with good compression and little bacterial wound involvement.

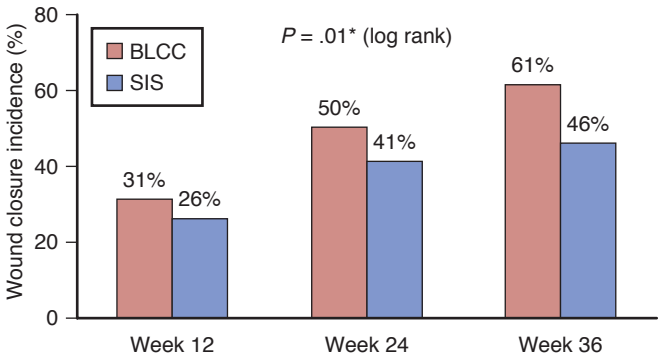

Figure 115.11 Estimated incidence of wound closure from Kaplan-Meier analysis of all available data up to 3 years. Bilayered living, cellular construct (BLCC). Apligraf, Small intestine submucosa (SIS), Oasis *P-value from a two-sided log-rank test.

DIABETIC FOOT ULCERS

See Chapter 114 for diagnostic modalities and a discussion of wound débridement, pressure offloading, and treatment of infection. The Society for Vascular Surgery also recently published comprehensive practice guidelines for the care of patients with diabetic foot ulcers in collaboration with the American Podiatric Medical Association and the Society for Vascular Medicine. The reader is referred to these guidelines for additional information on optimal management of DFUs.[73]

Adjunctive Therapies to Accelerate Healing

Vitamin D

In a recent randomized clinical trial, 60 patients with Wagner grade 3 DFUs were randomized to standard wound therapy with or without supplementation of 50,000 IU of vitamin D every 2 weeks.[74] After 12 weeks of treatment, the authors reported that the vitamin D treated patients had significantly greater reduction in wound size as well as significant reductions in HbA1c, LDL, high sensitivity C-reactive protein and erythrocyte sedimentation rate. Based on this study, many clinicians believe vitamin D supplementation to be reasonable in DFU patients.

Growth Factors

Although multiple growth factors have been studied in clinical trials, to date, only PDGF has been approved by the FDA for the treatment of diabetic foot ulcers. Becaplermin (Regranex, Ortho-McNeil, Raritan, New Jersey) is a recombinant human BB isoform of PDGF suspended in a gel designed for topical application. Becaplermin is applied daily to the diabetic foot ulcer and covered with saline-moistened gauze. It has been

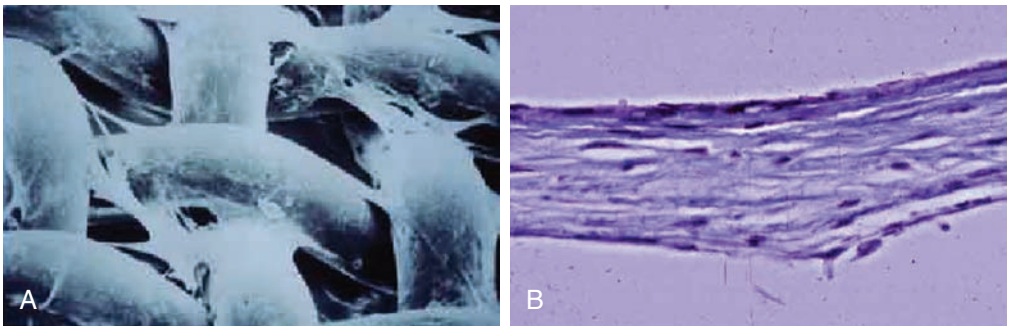

Figure 115.12 (A) Magnified view of Dermagraft showing polyglactin mesh with fibroblasts adhering to the surface. (B) Cross-section of the structure of Dermagraft with living dermal fibroblasts layered into a three-dimensional matrix. (Courtesy Advanced BioHealing, Inc.)

studied clinically in four prospective, randomized, placebo-controlled trials. In a meta-analysis of these studies, Smiell et al.[75] aggregated the 922 patients studied for analysis. Fifty percent of ulcers treated with the higher dose of becaplermin (100 mcg/g) for 20 weeks healed, compared with 36% treated with placebo gel ($P = .007$). Adverse events were rare, and the only medication-related event was local tissue sensitivity in 2%.

Kantor and Margolis[76] studied 26,599 patients from a clinical wound treatment database and reported effective wound closure at 20 weeks in 31% of those treated with standard care, compared with 43% treated with becaplermin. The incremental cost of increasing the odds of healing by 1% over standard therapy was $36.59 for becaplermin. In 2008 the FDA released a black box warning concerning the risk of fatal cancers in patients treated with becaplermin. Based on long-term follow-up studies of patients enrolled in randomized studies, there was no increased risk of malignancy in patients treated with becaplermin, but those who developed malignancies had a greater risk of dying from them.[77] This information is based on a small number of observations, so it should be interpreted with caution. It does emphasize, however, that the drug should be considered only in refractory diabetic foot ulcers failing to respond to standard therapy.

Living Tissue Substitutes

Apligraf

Described in detail earlier, Apligraf was also studied in a prospective randomized multicenter trial for the treatment of diabetic foot ulcers.[78] At 24 centers, 208 patients were treated with standard diabetic foot ulcer care (débridement, foot offloading) and saline-moistened gauze or standard diabetic foot ulcer care and Apligraf application. After 12 weeks of treatment, 56% of Apligraf-treated wounds were closed compared with 38% in the control group. The odds ratio for complete healing was 2.14 (95% confidence interval, 1.23 to 3.74). The incidence of osteomyelitis was significantly less frequent in Apligraf-treated patients (2.7%) than in controls (10.4%; $P = .04$). Ipsilateral toe or foot amputation was also significantly less frequent in the Apligraf group (6.3%) than in the control group (15.6%).

Dermagraft

Dermagraft (DG, Advanced BioHealing Inc., La Jolla, California) is an allogeneic dermal fibroblast culture derived from human neonatal foreskin samples and grown on a biodegradable scaffold.[79] The resulting three-dimensional matrix can be implanted into chronic nonhealing wounds to supply functional fibroblasts and their corresponding expressed proteins. A histologic cross-section of prepared Dermagraft is presented in Fig. 115.12. The scaffold biodegrades over a 1- to 2-week period, leaving behind only cellular components and proteins. Meticulous wound bed preparation and strict wound offloading are required for maximum benefit.

Several in vitro studies have evaluated the ability of DG to express clinically significant quantities of growth factors after cryopreservation and thawing. VEGF, PDGF-A, and insulin-like growth factor-I were all found to recover to significant levels, as measured by enzyme-linked immunosorbent assay, in wounds to which DG was applied.[80]

DG was evaluated in a single-blinded, randomized, controlled investigation in 314 patients comparing standard diabetic foot ulcer care to standard care plus a weekly application of DG for up to 8 weeks.[45] Standard care in both groups consisted of routine sharp débridement, pressure offloading, and saline-moistened gauze dressings.

Of the 314 patients enrolled, 245 evaluable patients completed the study. Results showed that treatment with DG produced a significantly greater proportion (30%) of healed ulcers compared with the control group (18%; $P = .023$). The number of ulcer-related adverse events (local wound infection, osteomyelitis, cellulitis) was significantly lower in the DG-treated patients (19%) than in the control patients (32%; $P = .007$). In a secondary analysis of risk factors related to healing, it was found that an initial ulcer size greater than 2 cm^2 was associated with a 1.5 times higher incidence of wound closure ($P = .02$).[81] Females were 2.0 times more likely to heal than males ($P = .009$). An episode of infection during the 12 weeks of treatment was associated with a 3.4 times increased risk of nonclosure ($P < .01$). Finally, patients with lower hemoglobin A_{1c} values throughout the study had significantly higher rates of wound healing with DG (Fig. 115.13).

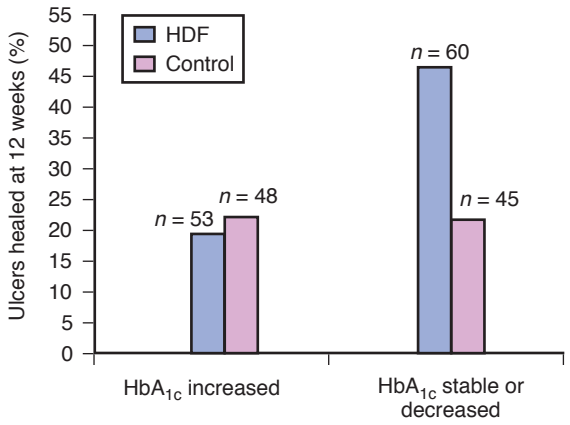

Figure 115.13 Comparison of healing rates in diabetic foot ulcers treated with standard care (control) or standard care plus Dermagraft (human-derived fibroblasts [HDF]), based on glycosylated hemoglobin A_{1c} (HbA_{1c}) levels during the 12-week study. If HbA_{1c} increased, suggesting poor glucose control, there was no difference in the healing rates in the two groups. If HbA_{1c} decreased, ulcers treated with Dermagraft healed significantly more often than did controls.

It must be stressed that DG and other active wound healing products are not substitutes for the standard principles of wound healing. If the wound is not well prepared before application of a growth factor or living tissue substitute, there is little potential for wound stimulation.

Acellular Dermal Matrix Products

Integra Dermal Regeneration Template

Integra dermal regeneration template (IDRT) is an acellular bilayer matrix designed to assist with dermal regeneration in multiple types of problem wounds. The bottom layer that is applied to the wound surface consists of a three-dimensional matrix of collagen and chondroitin-6-sulfate, a glycosaminoglycan. The top layer is a temporary layer made of silicone. This construct has been employed for years in burns, traumatic wounds, and other types of wounds with some success. The bottom layer is designed to incorporate into the wound and support tissue regeneration while the top layer provided a mechanical barrier to bacterial contamination. It is critical that the construct is applied to a clean wound that is free of bacterial that might lead to infection over time. This wound matrix has been adapted for use in diabetic foot ulcers in the outpatient clinic.

The benefit of IDRT in healing DFUs was studied in a prospective randomized study that enrolled 307 patients.[82] Complete wound closure occurred in 51% of patients treated with IDRT compared with 32% in the control group (P = .001). Assessment of quality of life indicated that patients treated with IDRT scored significantly better in physical functioning (P = .047) and bodily pain (P = .033) compared with the control group. Based on the results of this clinical trial, one of the largest prospective randomized studies of a therapy for DFUs, IDRT appears to be a useful adjunct to the care of DFUs, once excellent offloading and wound bed preparation have been achieved.

ULCERS ASSOCIATED WITH ARTERIAL INSUFFICIENCY

Patients with limb ulcers and associated arterial insufficiency should undergo diagnostic evaluation to attempt prediction of whether the ulcer can heal without revascularization. Potential studies include ABIs, toe pressures, transcutaneous oxygen/tension pressure ($tcPO_2$), and laser Doppler. These are reviewed in detail elsewhere in this text.

Local Wound Management

In general, principles of management are similar to those for diabetic foot ulcers, including pressure offloading, débridement of nonviable tissue, infection control, and moist wound healing. Close attention to the principles of wound bed preparation will maximize the wound's potential to heal, despite arterial insufficiency with success in some cases. Pressure offloading methods must be individualized, based on the specific location of the wound.

Sharp surgical débridement of nonviable or infected tissue should be performed as often as needed to maintain a clean wound bed. The primary exception is adherent eschar or dry gangrene. Most wound specialists recommend leaving this material in place (unless infected) until after revascularization is performed. The principles of moist wound healing are followed. Wounds of primarily arterial origin are typically dry, with little tissue edema or drainage. Hydrogels or similar hydrating agents should be applied to prevent desiccation of exposed layers after débridement is performed.

The need for revascularization is assessed using several variables. If the patient has severe pain at rest and is a good candidate for revascularization, this should be performed as soon as possible on an elective basis. Patients with diabetes and arterial insufficiency rarely have significant pain at rest, probably due to neuropathy. Wound size, depth, and character are all important measures. A small grade 1 ulcer on the dorsum of the foot is much more likely to heal without revascularization than is a large, complicated, deep wound on the plantar surface of the foot. The potential for healing based on noninvasive tests must be balanced with the risk of complications associated with the intervention required for revascularization. In patients in whom the risk-benefit assessment does not favor revascularization, the potential for healing should be optimized with standard wound care along with consideration of the modalities discussed next.

Pharmacologic Treatment

Pentoxifylline and Cilostazol

There is no high quality evidence suggesting that either pentoxifylline or cilostazol is able to accelerate wound healing in patients with ulcers associated with arterial insufficiency.

Prostaglandins

Prostaglandins, particularly prostaglandin E_2 and prostacyclin, in addition to their potent vasodilatory effects, can prevent

leukocyte activation and platelet aggregation. In some studies, treatment has resulted in significant improvement in patients with CLI.[83,84] However, a number of problems with prostaglandins have hindered their widespread use. Most are intravenous medications with short half-lives, requiring intravenous infusion for administration. Also, troubling side effects at clinically relevant doses, including headaches and dizziness, are frequent. Although available in other countries, no prostaglandin therapeutic agents have been approved by the FDA for the treatment of ischemic wounds.

Angiogenesis for Critical Limb Ischemia and Ischemic Wounds

Since the discovery of VEGF and techniques that allow it to be delivered to target tissue, there has been great enthusiasm for therapeutic strategies promising the development of new capillary beds to support blood supply. In numerous animal models, the transfer of VEGF to localized target tissues has resulted in angiogenesis, with the proliferation of blood vessels and increased tissue perfusion.[85] The application of this powerful technology to humans has been a long, arduous process because of concern over unintended adverse effects, such as tumor induction and the promotion of occult malignancies, resulting in accelerated growth and metastatic potential.

Local gene transfer to facilitate therapeutic angiogenesis has the theoretical advantage of producing protracted growth factor expression compared with single doses or direct applications of growth factors to wounds. Unfortunately, no angiogenic growth factor therapies have yet achieved FDA approval for use in patients with CLI and leg ulceration. Although several early phase clinical studies appeared promising, larger studies did not confirm that these therapies healed more wounds or prevented amputation. Similarly, investigations of progenitor cell therapies have also failed to demonstrate significant reduction in the incidence of amputation or improved wound healing in CLI patients. Clinical trials continue with various progenitor cell preparations in this patient population.[86,87]

Intermittent Pneumatic Compression

Numerous studies have documented the ability of various forms of intermittent pneumatic compression (IPC) to increase blood flow in ischemic limbs, suggesting that this modality may have a place in the treatment of CLI. Two general types of IPC have been described. In synchronized IPC, compression and deflation are gated to the cardiac cycle, with 55 to 80 mm Hg applied at end-diastole to maximize venous emptying. Pump decompression occurs before systole to reduce afterload and limit compression-related competition with systolic inflow to the limb.[88] Nonsynchronized IPC has been described in numerous protocols using various pressures, inflation durations, and deflation durations. Typical protocols involve an inflation pressure of 120 to 180 mm Hg, an inflation duration of 3 to 5 seconds, and a deflation time of 15 to 20 seconds. IPC of affected limbs is recommended for 2 to 4 hours daily.

There have been no direct comparisons of the beneficial effects of synchronized versus nonsynchronized IPC. Nonsynchronized IPC is generally less expensive and is more amenable to home use; this makes it attractive, given the length of therapy required in patients with CLI.

IPC reduces the edema that often occurs in patients with CLI. This, combined with improved venous emptying during IPC, may result in an increase in the arteriovenous pressure gradient in the limb. With less resistance to inflow, blood flow may increase, resulting in increased tissue perfusion, relief of rest pain, and improved ulcer healing. IPC also has been reported to increase the concentration of prostacyclin and nitric oxide in the treated limb.[89] These peripheral vasodilators in theory may stimulate improved tissue perfusion, despite the presence of large-vessel occlusive disease.

Several investigators have evaluated the hemodynamic effects of IPC on lower extremity blood flow. The velocity of blood flow in the popliteal artery increased after the initiation of IPC.[90,91] This increase was also noted in patients with significant arterial insufficiency.[92] Delis et al.[93] reported marked increases in popliteal artery blood flow during foot or calf compression, depending on the segments compressed (Fig. 115.14).

Delis et al.[94] studied 25 patients with claudication treated with nonsynchronized IPC of the foot and calf and 12 claudicants treated with an unsupervised exercise program. After 3 months of treatment, the IPC group had significant improvements in claudication distance, ABI, and mean popliteal artery blood flow. Control patients demonstrated no significant improvement. Of interest, 12 months after the cessation of IPC, the IPC group continued to demonstrate significant improvements over baseline in walking distance and ABI.

Using synchronized IPC, Vella et al.[88] reported on the treatment of 98 limbs with ulcers related to arterial insufficiency. These patients were not candidates for revascularization because of either inadequate outflow vessels or medical comorbidities. In limbs with an initial $tcPO_2$ <20 mm Hg, ulcer improvement

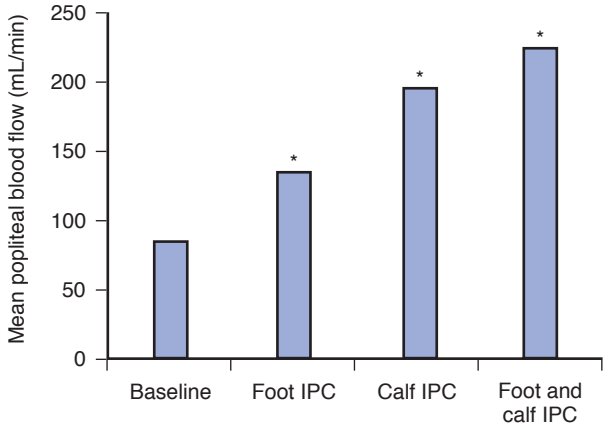

Figure 115.14 Mean popliteal artery blood flow in claudicants at baseline compared with claudicants using intermittent pneumatic compression (IPC) of various types. Each type of IPC resulted in significantly higher flows than baseline (*P < .001). (Mansbridge J, Liu K, Patch R, Symons K, Pinney E. Three-dimensional fibroblast culture implant for the treatment of diabetic foot ulcers: metabolic activity and therapeutic range. *Tissue Eng*. 1998;4:403-414.)

or healing was obtained in 19 of 29 limbs (65%); if the initial $tcPO_2$ was >20 mm Hg, 54 of 62 limbs (87%) healed or improved. From these data, the authors concluded that synchronized IPC is useful in a subset of patients with arterial insufficiency and nonhealing ulcers.

Case series of the clinical use of nonsynchronized IPC have also been published. Louridas et al.[95] reported on the use of IPC in 33 limbs with CLI, including 23 with nonhealing ulcers. Limb salvage was attained in 58%, and complete healing occurred in 26%. Chronic renal failure was a significant negative risk factor, with limb salvage attained in 86% of patients without chronic renal failure. Kavros and colleagues retrospectively compared the outcome in 24 patients with CLI and tissue loss treated with IPC compared with 24 patients treated without IPC.[96] All patients had no options for revascularization and were treated with standard wound care protocols. In the IPC treated group, 42% required amputation compared with 83% in the control group ($P < .01$).

The foregoing information is encouraging, providing a physiologic basis for IPC's positive effects in patients with arterial insufficiency and nonhealing ulcers. The question remains, however, whether the improvement in blood supply generated by this technique is sufficient to make a difference in the patient's wound-healing ability. No prospective randomized studies of IPC for ulcer healing have been performed.

Wound Management After Intervention

Management of the ischemic limb ulcer after revascularization is critical, because of the changes in the local environment that occur with a new blood supply. Limb edema after surgical bypass is common and may be severe, resulting in a breakdown of surgical incisions and worsening of ulcerated areas. Developing a strategy to combat limb edema is important in each patient, particularly at the time of hospital discharge, as the transition to the home environment may not be amenable to constant limb elevation and compression.

IPC devices are very useful for limiting limb edema in the early postoperative period. For patients with bypass grafts ending at the popliteal level, below-knee IPC for several hours a day reduces edema significantly. When the distal anastomosis extends to the lower leg or ankle, a pedal compression boot can be used, with reasonably good results.

Patients with dry gangrene of the digits or eschar over the heel or other ulcerated areas must be followed closely after revascularization. When the blood supply is successfully restored, these areas tend to heal under the eschar, and the eschar begins to separate at the interface between healing and necrotic tissue. Unfortunately, this is a favorable environment for infection, and it is common for these wounds to develop an increased bacterial load and frank infection if frequent débridement and careful wound management are not continued. Many surgeons prefer to amputate necrotic digits and perform wide débridement of eschar a few days after the arterial supply is improved to prevent further infection. After débridement, the remaining healthy tissue should be able to granulate, responding to standard wound-healing techniques.

SPECIALIZED TECHNIQUES

Negative-Pressure Wound Therapy

Negative-pressure wound therapy (NPWT) devices are designed to apply controlled suction to a wound bed at continuous or intermittent pressure settings to stimulate wound closure. Negative pressure can result in numerous alterations in the wound environment, including removal of excess exudate, stimulation of senescent cells, mobilization of macrophages, and stimulation of angiogenesis. NPWT has been used over uncovered bone, tendon, and other deep tissues, resulting in the clinical impression of a favorable response.

There are numerous reports in the literature concerning the use of NPWT for a wide variety of wound related conditions, including dehisced abdominal wounds, open infected sternotomy wounds, lymphorrhea, pilonidal cysts, and complex traumatic injuries. Little systematic study was available until 2005, when Armstrong and Lavery[97] published results of a prospective randomized study trial of NPWT for a specific indication. In this protocol, 162 patients with diabetic foot problems requiring partial foot amputation were randomized to standard moist wound care or NPWT after their surgical procedure. The primary outcome was complete healing after 16 weeks of treatment. In the NPWT group, 56% of wounds closed at 16 weeks, compared with 39% in the control group ($P = .04$). There was no difference in the incidence of adverse events between the two groups.

In another randomized multicenter trial, 342 patients with non-ischemic Wagner grade 2 or 3 diabetic foot ulcers were randomized to NPWT or moist wound therapy using hydrogels or alginates.[98] All patients were offloaded with devices specific to the wound location. At 16 weeks, 43% of wounds in NPWT patients were completely healed, compared with 29% in the moist therapy group ($P = .007$). No difference was noted in the incidence of infection or osteomyelitis in the two groups, but fewer secondary amputations (mostly digital) were required in NPWT-treated feet ($P = .035$).

NPWT has become a fixture in most hospitals and wound centers, and is a useful solution to some complex wound problems. However, the modality must be used carefully and with frequent evaluation to avoid complications. Bacterial colonization and biofilm generation may result in increased wound exudate that is not well managed by the NPWT system. Frank infection may occur if this problem is not identified early and treated appropriately, usually with wound culture, systemic antibiotics, and absorptive primary dressings changed frequently. Other complications include significant pain, particularly during dressing changes, and problems obtaining an adequate seal in irregularly shaped wounds.

The cost of adding NPWT to an outpatient wound treatment protocol can be significant, including the cost of device rental, wound dressings, and home nursing visits to perform dressings changes. Therefore utilization should be considered in patients with larger, more complex wounds who are more likely to benefit from therapy, and duration of use should be monitored carefully to maximize cost-efficacy.

In summary, NPWT has provided an alternative treatment modality for a wide variety of acute and chronic wounds. Although randomized studies are not available, it appears to be useful for complex traumatic and infected or dehisced postoperative wounds. There are prospective randomized studies that support its use in diabetic foot ulcers and postsurgical diabetic foot wounds.[97,98] It must be remembered that this modality is not a cure-all, and it must be used with a specific goal in mind rather than routinely for every wound.

Hyperbaric Oxygen

Hyperbaric oxygen (HBO) therapy involves treating the patient with 100% oxygen at elevated atmospheric pressures in a specially designed chamber (Fig. 115.15). The benefits of increasing the partial pressure of oxygen in the tissues may include improved oxygen supply, reduction of inflammation and edema, and inhibition of infection. HBO is reportedly useful in the treatment of a number of wound problems, including complex diabetic foot ulcers, osteomyelitis, necrotizing fasciitis, and the healing of tissue flaps. Typical treatment protocols for leg ulcers involve one or two treatments daily for a total of 20 to 40 treatments.[99]

HBO has long been considered a potential treatment modality for ischemic ulcers. Oxygen can stimulate angiogenesis, enhance fibroblast and leukocyte function, and normalize cutaneous microvascular reflexes.[100,101] Clinically HBO has been demonstrated to improve $tcPO_2$ in the limbs of some patients with ischemic ulcers. Significant side effects of treatment are uncommon but may be severe, including barotraumatic otitis, hyperoxic seizures, and pneumothorax.

The use of HBO in ischemic leg ulcers remains controversial. This is due to the difficulty in conducting large randomized blinded studies with HBO. The majority of the studies are small and not well controlled, leaving significant doubt concerning the validity of the findings.

Figure 115.15 Monoplace hyperbaric oxygen chamber.

Faglia and colleagues randomized 68 patients with ischemic diabetic foot ulcers to standard foot ulcer treatment with or without HBO therapy.[102] Amputation was required in 33% of the control group, compared with 8.6% of the HBO treated group ($P = .016$).

Abidia et al.[103] randomly assigned 18 patients with nonhealing ischemic diabetic limb ulcers to 100% oxygen or air at 2.4 atmospheres for 90 minutes in a hyperbaric chamber daily. In this double-blinded study, both groups received 30 sessions, after which the outcome was measured. In the oxygen group, five of eight ulcers were closed completely, compared with one of eight in the control group ($P = .027$).

In 2004, the Cochrane Collaborative reviewed HBO therapy for chronic wounds and concluded that HBO reduces the risk of amputation for patients with diabetic foot ulcers and increases the chance of healing at 1 year.[104] However, it noted that these findings were based on small, underpowered studies, and that further randomized studies are greatly needed to clarify the benefits of this costly therapy.

Since the publication of the aforementioned Cochrane review, several studies have focused on the use of $tcPO_2$ to select patients for HBO treatment. Grolman et al.[105] measured $tcPO_2$ in the ischemic limb of 36 patients breathing room air, followed by 100% oxygen. They found that a greater than 10 mm Hg increase in $tcPO_2$ in the ischemic foot was associated with a healing rate of 70%, compared with a healing rate of 11% in those with an increase of less than 10 mm Hg. Others have reported that the improvement in foot $tcPO_2$ obtained during a trial session of HBO is also predictive of wound healing.[106]

Recently, another study randomized 107 patients with Wagner grade 2–4 diabetic foot ulcers to comprehensive wound care with or without HBO therapy.[107] After 30 treatment sessions, the incidence of wound healing and freedom from criteria requiring amputation were assessed by a blinded vascular surgeon. Criteria for major amputation were met in 13 of 54 patients in the sham group and 11 of 49 in the HBOT group ($P = .846$). Twelve (22%) patients in the sham group and 10 (20%) in the HBOT group were healed ($P = .823$). All other indices of wound healing were also not statistically significantly different between groups.

Considerations of cost efficacy are important, given the effort and cost required to deliver HBO therapy. Patients often travel long distances for daily treatments at great cost to themselves and their families. Although protocols for the treatment of ischemic limb ulcers vary significantly, most involve a total cost of $15,000 to $40,000. In an assessment for the Canadian government, Chuck et al.[108] from the University of Alberta compared HBO and standard care for diabetic foot ulcers using a decision model and available outcome data. They found that the average yearly cost (in Canadian dollars) for HBO-treated ulcers was $40,695 compared with $49,786 for standard care. They concluded that adjunctive HBO was cost-effective compared with standard care alone.

Currently, HBO therapy, though controversial, is likely a useful option in a limited group of patients with complicated ischemic and diabetic limb ulcers. Unfortunately, it may be difficult to clearly identify patients who will benefit most from treatment. Until larger randomized studies are performed, HBO cannot be recommended as a primary treatment for patients with uncomplicated diabetic or ischemic ulcers. In selected cases, however, HBO may result in significant improvement, allowing healing of an ulcer in a limb that appeared to be destined for amputation.

Other Tissue/Matrix Products

Recently a proliferation of cellular- and/or tissue-based products have emerged, in part due to changes made in CMS coverage that have allowed reimbursement for a wide variety of human and animal based tissue products designed to assist with wound healing. These products are grouped together with living cellular constructs such as BLCC, DG, and IDRT into two buckets for reimbursement—one comprising a higher reimbursement value and the other a lower reimbursement value. This has resulted in broadly disparate products such as acellular porcine skin matrix, irradiated cadaver skin, and cryopreserved human fibroblasts receiving similar reimbursement despite different mechanisms of action and varying levels of supportive clinical data. One category that has emerged within this diverse group concerns wound therapies derived from placental membranes. The contents of the placenta have been described for decades as a source of regenerative materials to apply to problem wounds. Rich in progenitor cells, including mesenchymal stem cells (MSCs), placental tissue has been processed in varying ways to produce constructs that may be applied to nonhealing wounds. MSCs have been reported to have an important role in wound healing, reducing the proliferation of pro-inflammatory cytokines such as TNF-alpha and IFN-gamma that are believed to be upregulated in nonhealing wounds.[109] MSCs are also reported to have significant antibacterial activity and support upregulation of angiogenic growth factors.[110]

Numerous clinical preparations of placental contents are currently available for application to chronic wounds, but few have developed meaningful clinical data to support the theoretic benefits described previously. One strategy (Grafix, Osiris Therapeutics) is to cryopreserve living cells derived from the placental membrane, seed them into a three-dimensional cellular matrix, and apply these living cells to wounds to stimulate healing. This construct was studied in a prospective randomized clinical trial of 97 patients with recalcitrant DFUs, compared with standard DFU wound care.[111] At 12 weeks, 62% of the Grafix-treated wounds were healed, compared with 21% of controls ($P = .0001$). Wound infection occurred in significantly fewer patients in the Grafix group as well. To date, this is the largest reported prospective randomized study of a placental-derived therapy for treatment of chronic nonhealing wounds. Although this study is limited in power, the results are encouraging, and it is hoped that larger randomized studies will confirm its favorable results. If so, this will confirm the potential of this interesting adjunctive therapy for the treatment of chronic lower extremity ulcers.

SUMMARY 1572

A podiatrist is a doctor who practices medicine and surgery of the human foot and ankle. The scope of practice for podiatrists varies by state in the United States. When paired with vascular surgeons, podiatric surgeons are particularly well suited to augment the long-term medical, surgical, and functional care of the diabetic patient.

THE SPECIALTY OF PODIATRY

The history of podiatry is rich. The mention of foot specialists dates back to the Egyptians c. 1500 BC. Both Napoleon and Abraham Lincoln relied on the services of foot specialists. New York was the first state to license podiatrists in 1895. The *Journal of the American Podiatric Medical Association* was first published in 1907. One of the profession's early advocates, William M. Scholl, graduated from Illinois Medical College (now Loyola University) with an MD in 1904. His grandfather was a shoemaker in Germany, and Scholl was appalled by the lack of foot care in the United States. He invented several foot care products, resulting in the creation of a global company that was worth $77 million at the time of his death in 1968.

Education and Training

A candidate for podiatric medical school must first complete 4 years of undergraduate training. There are nine colleges of podiatric medicine in the United States, located in New York City, Philadelphia, Miami, Cleveland, Chicago, Des Moines, Phoenix, Oakland, and Los Angeles. Candidates must sit for the Medical College Admission Test (MCAT) to be considered for admission. Podiatric medical school consists of a 4-year program and includes course work in the basic sciences and clinical medicine. Graduates receive the Doctor of Podiatric Medicine (DPM) degree. All states require graduates to complete a residency in order to practice. Podiatric residencies are 3 years long and are accredited by the Council on Podiatric Medical Education. Some podiatrists complete additional fellowship training in diabetic limb salvage, trauma and reconstruction,

Abstract

An increase in the prevalence of diabetes and the associated peripheral complications has required more collaboration between vascular surgeons and podiatrists to prevent limb losses. Podiatric education, training, and experience is different, but no dissimilar to that of allopathic or osteopathic pathways. Limb salvage teams that include podiatrists and vascular surgeons have been successful at reducing amputations.

pediatrics, infectious disease, or research. The American Board of Podiatric Medicine now certifies podiatrists who meet certain qualifications and pass an examination in "amputation prevention."

Scope of Practice

The scope of practice for podiatric medicine is determined by state law, which accounts for geographic variations in practice. In most states a podiatrist can complete a history and physical examination, order laboratory work or imaging, and deal with a broad range of medical conditions and their treatment. Podiatrists are often allowed to perform partial foot amputations; in a few states they can perform below-the-knee amputations. In many states, podiatrists can harvest their own autologous grafts from areas proximal to the ankle if the graft is to be applied to the foot or ankle, and they can supervise the delivery of hyperbaric oxygen treatments. Privileges to perform what is within a podiatrist's scope of practice are up to each facility and its medical staff.

In practice, the podiatrist and the vascular surgeon often share patients. Podiatrists are trained to perform a clinical peripheral vascular examination and often order and interpret noninvasive vascular studies. They rely on the vascular surgeon for the treatment of impaired wound healing due to ischemic disease or when a patient as a candidate for surgery has marginal or poor perfusion—a frequent occurrence in the care of the diabetic foot.

DIABETES-RELATED AMPUTATIONS

The greatest area of overlap in which podiatrists and vascular surgeons collaborate is the foot complications of diabetes and amputation prevention. Fig. 116.1 illustrates the philosophy of cross referral. The sigmoid curve represents the probability of healing based on perfusion. When a patient is referred to a multidisciplinary team, the vascular team treats wounds that are profoundly ischemic, with the goal of improving flow and pushing the wound up the curve. Conversely, when flow is adequate, the podiatry team manages wound healing, off-loading, reconstruction, and prevention. Patients falling in the middle of the curve are frequently managed by both teams.

Epidemiology

The diabetic foot ulcer (DFU) is the most common pathway to amputation. Some 84% of amputated limbs have a foot ulcer at the time of amputation.[1] Up to 25% of patients with diabetes have a foot ulcer at some time during their lives.[2] Approximately 50% of such ulcers become infected, and in 20% amputation is required.[3] About 60% of all nontraumatic amputations occur in people with diabetes.[4] Roughly 75,000 major amputations are performed on individuals with diabetes in the United States annually.[5,6] After major limb loss, the contralateral limb will develop a serious lesion in 50% of cases.[7] The 5-year adjusted mortality rate after a major limb amputation is 70%,[8,9] which is higher than the mortality rate for many cancers (Fig. 116.2). The cost of treating DFUs and performing amputations was nearly $30 billion in the United States in 2007.[10]

Etiology and Natural History

The etiology of DFUs and their contribution to lower extremity amputation is well understood. Key factors leading to the development of DFUs are peripheral neuropathy, foot deformity, and trauma.[11] Neuropathy is the major component underlying all DFUs. A patient with a loss of protective sensation does not have the "gift of pain," as the late orthopedic surgeon and medical missionary Paul Wilson Brand wrote.[12] Pain warns of

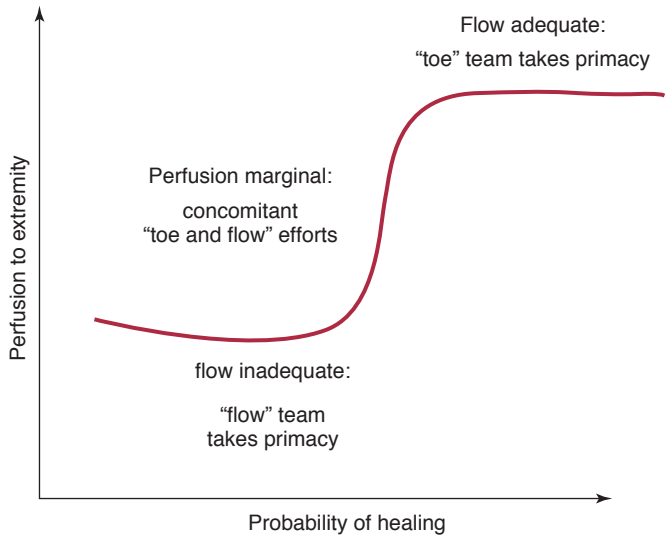

Figure 116.1 Team approach to diabetic foot care based on perfusion to the extremity.

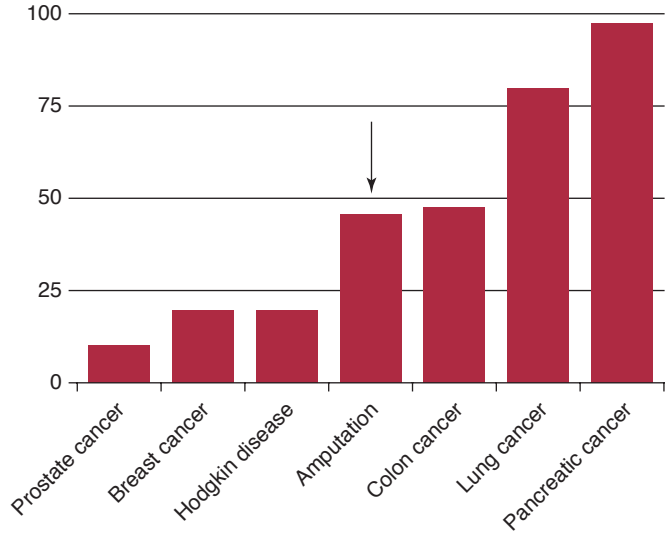

Figure 116.2 Five-year relative mortality rate for major lower extremity amputation compared with that for various cancers.[8,9]

impending tissue damage. In a sensate individual, when an area of the foot becomes tender, the gait is subconsciously altered to place less pressure on that area. Without this feedback loop, the tender area continues to receive pressure until tissue damage becomes irreversible. Trauma can be either high-pressure acute, such as that due to a puncture wound, or repetitive, due to low to moderate pressure. In an individual with peripheral sensory neuropathy, unopposed repetitive cycles of low to moderate stress first cause a callus, followed by a bulla and then a hematoma, until the skin envelope ulcerates. Foot abnormalities associated with DFUs can be visible or mechanical. Visible deformities include bunions, hammered or clawed digits, Charcot foot, or cavus foot. Mechanical deformities cannot be identified by superficial visual inspection and require an examination of joint motion.

Normal gait is divided into swing, contact, midstance, and propulsive phases. Peak pressure and the line of progression follow an orderly path from the heel, through the lateral aspect of the midfoot, coursing medially through the forefoot under the metatarsal heads, and eventually the push-off of the hallux. This allows a remarkable amount of force to be dissipated over a relatively large unit area. Diabetes, limited joint mobility, and aging alter this normal process and, in the presence of peripheral neuropathy, set the stage for the development of DFUs.

Limited joint mobility is as important as deformity in predicting ulceration.[13] If the extent of ankle dorsiflexion does not exceed 10 degrees, the abnormality is termed equinus (named after horses, which walk on their toes). In patients with diabetes, the tendons, including the Achilles tendon, become glycosylated and less elastic.[14] A less elastic Achilles tendon plantarflexes (or resists dorsiflexion) and concentrates plantar pressures under the forefoot. A neuropathic patient with ankle equinus has a risk ratio of 2.3 for developing a forefoot ulcer.[15] The most common location of a DFU is under the hallux.[16] Limited dorsiflexion at the first metatarsophalangeal joint (hallux limitus) increases plantar pressure under the distal hallux during toe-off. The hallux should normally be able to dorsiflex more than 45 degrees. Degenerative joint disease at this location is also common in people without diabetes, but the presence of pain prevents ulceration and causes them to change their gait and seek treatment. Hallux limitus in the presence of neuropathy has an associated risk ratio of 4.6 for ulceration.[15]

Foot ulceration is the main risk factor for limb loss in patients with diabetes.[1] The natural history of diabetes-related lower extremity amputation can be described as a staircase (Fig. 116.3). The first step is the diagnosis of diabetes, followed by the onset of neuropathy. If an ulcer occurs, it may be complicated by peripheral artery disease, which slows healing. The coup de grace is most often an ascending infection, leading to an urgent need for amputation. There are interventions to prevent each advancing "step" and, ultimately, to prevent major amputation. It is imperative that the ulcerated diabetic foot be free from infection and have adequate perfusion in order to heal in a timely fashion. If one can heal a DFU or at least prevent it from becoming infected, most amputations can be avoided.

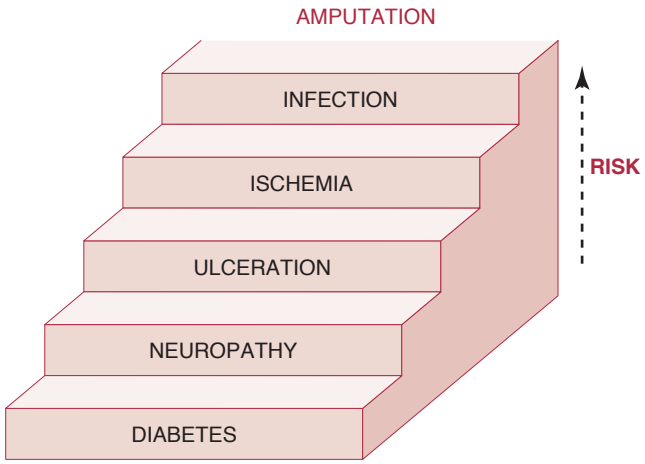

Figure 116.3 Common natural history of major lower extremity amputation. Each step in this "stairway to amputation" is a target for intervention to prevent the escalation to amputation.

Preventive Strategies

Podiatric Care

The education, training, and experience of a podiatrist can improve outcomes and reduce costs. A Duke University study of over 230,000 Medicare beneficiaries found that if a patient had visited a podiatrist in the year prior to developing a foot complication, his or her overall risk was reduced. Patients were 31% less likely to develop a foot ulcer and 77% less likely to develop cellulitis or Charcot foot when compared to visiting another health professional.[17] Another study found that patients who were under the care of a podiatrist had a 29% reduced risk of amputation and a 24% reduced risk of hospitalization, saving the insurer an average of $19,686.[18]

Team Approach

An effective means of amputation prevention is the formation of a multidisciplinary diabetic foot care team. The International Diabetes Federation has decreed that more than 85% of diabetes-related amputations are preventable and that this measure is attainable when podiatrists and vascular surgeons are partnered in cohesive teams.[19] A large population-based observational study reported a 69% reduction in the diabetes-related amputation rate over 5 years after the implementation of better organized foot care.[20] Our group was able to reduce amputations by 72% over 2 years by implementing a team concept for limb salvage that included both podiatrists and vascular surgeons.[21] Another study found that a multidisciplinary team consisting of physicians, podiatrists, and nurses led to a 51% reduction in ulceration in a high-risk population (previous ulcer history) over a 2-year period.[22]

Some 77% of the foot-related costs of a patient with diabetes are attributable to inpatient stays. Cohesive teams that follow guidelines can have an impact on the inpatient management of the patient with a complicated lower extremity. Wukich led a team of experts from the American Diabetes Association to create inpatient management guidelines[23] based on an outline developed by Fitzgerald and coworkers who identified seven

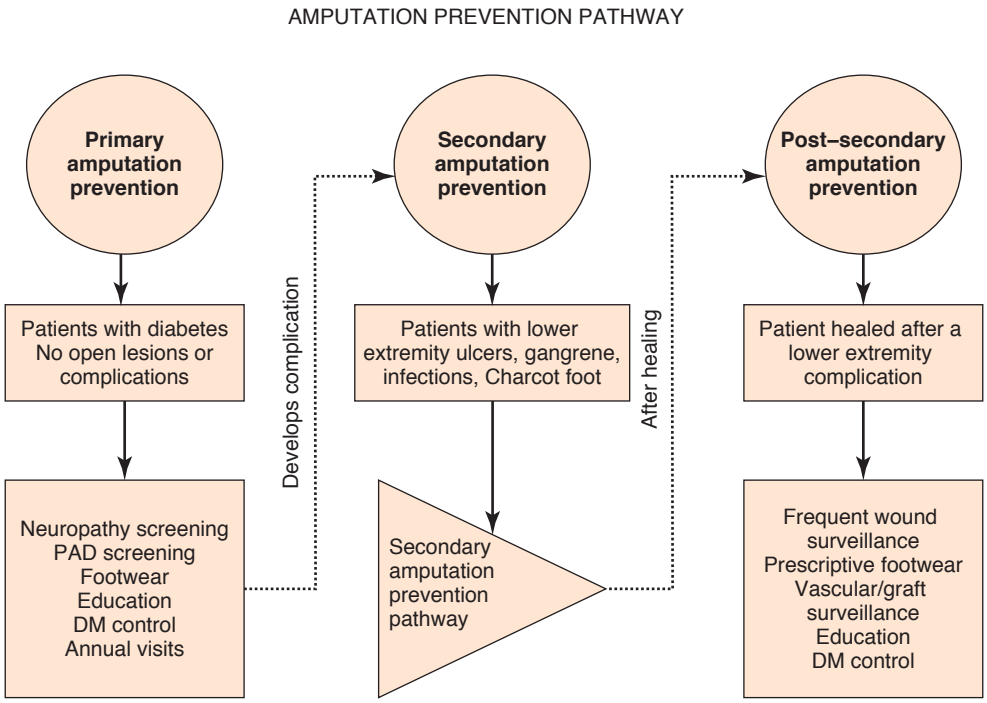

Figure 116.4 The three progressive categories of diabetic amputation prevention. *DM*, Diabetes mellitus; *PAD,* peripheral artery disease.

essential skills for limb salvage to be used by a "diabetic rapid response acute foot team."[24]

The prevention of amputations can be placed in three broad categories: primary prevention, secondary prevention, and post–secondary prevention (Fig. 116.4).

Primary Amputation Prevention

Patients in primary prevention have diabetes with or without neuropathy or mild peripheral artery disease but no open lesions or major lower extremity complications. These patients require neuropathy screening, peripheral artery disease (PAD) screening, special footwear, education, diabetes control, and annual visits for comprehensive diabetic foot exams. The primary focus in this category is to prevent lower extremity complications such as a DFU.

Neuropathy

The diagnosis of neuropathy is generally made by history and clinical exam. Neurophysiologic testing and skin biopsies to determine nerve fiber density can confirm the diagnosis. As many as 10% of patients with diabetes and neuropathy have a cause other than diabetes for their neuropathy[25]; therefore, it is prudent to seek alternate causes before making the diagnosis.[26] The Semmes-Weinstein monofilament,[27] Ipswich touch test,[28] and electronic tuning fork[29] are commonly used screening tools to determine if there is loss of protective sensation (LOPS), a more advanced neuropathy placing the patient at risk for foot ulcers.

Neuropathy can be reduced or delayed by precise glucose control. Both the Diabetes Control and Complications Trial[30] (type 1 diabetes) and the United Kingdom Prospective Diabetes Study[31] (type 2 diabetes) showed a reduction or delay in the onset of peripheral neuropathy when glucose was precisely controlled. However, there is no high-quality evidence that any treatment can *reverse* diabetic neuropathy. Some have proposed that it can be reversed by means of peripheral nerve decompression. Proponents of this approach generally cite trials that are poorly designed or use unaccepted diagnostic methods to demonstrate the restoration of sensation.[32] A position statement from the American Academy of Neurology cautioned against the use of this invasive procedure in the absence of sound evidence which are based on misconceptions regarding the pathophysiology of diabetic neuropathy.[33] Other methods have not proved effective. A double-blinded randomized controlled trial showed that monochromatic infrared light had no effect on peripheral sensory neuropathy.[34] Both alpha lipoic acid and aldose reductase inhibitors have been evaluated in well-designed trials for sensory neuropathy, with mixed results.[35,36] Additional trials are needed to determine whether the potential benefit of these treatments can translate into a restoration of sensation significant enough to reduce the incidence of DFUs. There have been single trials investigating B vitamins, magnesium, zinc, methylcobalamin, and vitamin E, but no consensus has been reached on their effectiveness.

Pressure Reduction

In individuals who already have sensory neuropathy, the focus should be on reducing areas of high plantar pressure and preventing trauma. Pressure reduction can include internal (surgical) and external (braces and shoes) approaches. Surgical reduction of pressure to heal or prevent DFUs is reviewed later in this chapter.

External pressure off-loading consists of the use of custom and noncustom devices and shoes. Abundant evidence proves that custom insoles and footwear reduce plantar pressure in diabetic patients with neuropathy.[37,38] Translating these data into clinical practice has been difficult, however. Custom-molded diabetic shoes reduced the rate of DFUs by 53% in one trial.[39] Another study showed little effect, but the control group in that study also received shoes (noncustom).[40] Shoes can prevent trauma, but proper patient education is required to ensure compliance. Such shoes should be worn at all times, including during ambulation at home.

Injection of silicone as a tissue filler to reduce pressure under bony prominences has been used with clinical success.[41] Our group has studied the injection of poly-L-lactic acid (Sculptra) to reduce pressure in areas of preulceration. The effect is determined by dynamic computerized peak plantar pressure and ultrasonic measurements of tissue thickness (unpublished data).

The home measurement of skin temperature has the most robust data of any prevention strategy. An increase in temperature is one of the cardinal signs of inflammation. Tissue inflammation increases the local temperature before dermal breakdown and can warn a patient of impending ulceration. Three randomized controlled trials have shown a reduction in the incidence of DFUs by 73% through the use of routine foot temperature monitoring.[42-45] Further study has been completed using a smart temperature-sensing mat, which was found to predict ulcers 31 days in advance (R.G. Frykberg and D.G. Armstrong, unpublished data). Thermometry as a preventive strategy is frequently not covered by payers; this is unfortunate in view of the considerable short-term financial benefit that may accrue from the prevention of DFUs.

Secondary Amputation Prevention

Once a patient develops a major complication such as a DFU, Charcot foot, gangrene, or infection, he or she is at risk for amputation; thus secondary prevention is necessary, as presented in Fig. 116.5.

Infection

First and most urgently, the diabetic foot must be inspected for signs of infection; if present, it must be managed appropriately. The diagnosis of diabetic foot infection is based primarily on the clinical presentation. Signs of infection include purulence, erythema, edema, and malodor. Because persons with diabetes may have a blunted immune response, laboratory testing should not be relied on to establish the diagnosis of infection; leukocytosis is present in only 46% of diabetic patients with moderate to severe foot infections.[46]

The Infectious Diseases Society of America (IDSA) has updated their guidelines for the diagnosis and classification of diabetic foot infection on the basis of clinical signs and symptoms (Table 116.1).[47] The IDSA divides infections into four categories: uninfected, mild, moderate, and severe. This classification system has been validated and is a good clinical predictor of the outcome of diabetic foot infection; it is also a component of the Wound, Ischemia, foot Infection (SVS WIfI) threatened limb classification.[48]

Vascular Care

Once any infection has been excluded or medical and surgical treatment started, it is important to assess the perfusion of the complicated foot. Although a clinical exam is useful and necessary, it is not sufficient in itself to rule out significant ischemia. All patients with diabetic foot ulcers require further investigation, such as ankle-brachial index (ABI), toe pressures, or skin perfusion pressure.[49] Caution should be used in interpreting the ABI result, since medial calcification, common in diabetes, can produce a falsely elevated or normal result.[50,51] Therefore toe waveforms and systolic pressures are preferred. These initial tests should be part of a foot ulcer workup, since ischemia in diabetes is often silent. The treatment of diabetic peripheral artery disease and critical limb ischemia is covered in many of the chapters of this book; it is not elaborated upon here. However, it is crucial that impaired perfusion be diagnosed promptly and staged based on the SVS WIfI classification. WIfI stage 3 and especially stage 4 patients most often benefit from revascularization; therefore, these patients should be identified early and treated aggressively. Delays result in loss of tissue and reduce the opportunity for salvage.[52,53]

Wound Care

Wound care has become exceedingly complex. However, by adhering to the important basic principles of wound inspection, ongoing reassessment, debridement, and the promotion of tissue substructure and granulation tissue as well as by applying a variety of closure techniques, healing can be achieved in most patients and accelerated in many.

Once infection and vascular insufficiency have been managed, a purely neuropathic wound should heal in a timely fashion with good wound care and off-loading. DFUs respond to debridement, promotion of granulation tissue, and closure. The modalities to achieve each of these treatment goals are displayed in Fig. 116.6.

Debridement removes devitalized tissue, bioburden, and senescent cells and promotes healing through bleeding. By debriding a wound, one transforms a chronic, slowly healing wound into one that is healthier and in a more acute state.[54] In debriding a wound, it is important to remove all necrotic and nonviable tissue. The surgeon should not be concerned about the defect caused by the initial debridement because the removal of such tissue is essential if closure is to be attained. Most wounds require serial debridements. Cardinal and coworkers found that DFUs that were debrided at each visit had a significantly greater chance of healing within 12 weeks than did ulcers debrided less often.[55] In a large retrospective analysis of almost 313,000 wounds, it was found that wound that were debrided on a more frequent basis (at intervals of 7 day or less) healed much faster than wounds debrided less frequently.[56]

There are five methods of wound debridement: mechanical, autolytic, enzymatic, surgical, and biosurgical. Mechanical debridement has fallen out of favor as a primary method; it consists of applying wet gauze dressings, allowing them to dry,

TABLE 116.1 Classification of Diabetic Foot Infections

Clinical Presentation	IDSA Infection Severity	Threatened Limb Class
Wound without purulence or inflammation	Uninfected	N/A
Presence of >2 manifestations of inflammation, cellulitis <2 cm surrounding ulcer, no systemic symptoms	Mild infection	Non–limb threatening
Infection with >2 cm of surrounding cellulitis; any infection with the presence of gangrene, abscess, deep involvement, or gas in the tissue; no systemic signs or symptoms	Moderate infection	Limb threatening
Infection as above with the presence of systemic signs or symptoms	Severe infection	Life and limb threatening

and then removing the dry gauze, thereby "ripping off" the surface layer (wet-to-dry dressing). Autolyic debridement is achieved by covering the wound with an occlusive dressing and allowing the wound's proteolytic enzymes to lyse the fibrotic or necrotic tissue. This is rarely recommended owing to the risk of infection and the availability of better methods. Enzymatic debridement uses a cream such as collagenase to remove devitalized tissue.

Surgical debridement is the most common and effective method.[55] It can be done simply by using a scalpel or a newer modality such as a hydroscalpel such as the Versajet (Smith & Nephew, Memphis, Tennessee), which allows for a precise depth of debridement.[57] The Versajet uses a handpiece that creates a Venturi effect and a stream of saline with a force up to 15,000 psi. It is typically performed in an operating room setting. Another recent development for wound debridement involves ultrasound. The SonicOne (Misonix, Farmingdale, New York) is a new device that combines ultrasound with an adjustable irrigation system to adequately debride a wound.

Once a wound has been thoroughly debrided, granulation tissue must form before the wound can close. This process, also called wound-bed preparation, starts by achieving an appropriate moisture balance in the wound. The principle of keeping wounds moist without maceration has been demonstrated to accelerate epithelialization.[58] Multiple dressing types and topical therapies exist (Fig. 116.7), and there is little unbiased evidence that any particular dressing is more effective than another. Most practitioners use multiple dressing types throughout the treatment cycle to adapt to the changing wound environment.

Few advances in wound healing have been as groundbreaking as negative-pressure wound therapy (NPWT). The Wound VAC (Kinetic Concepts Inc., San Antonio, Texas) is the only NPWT device with any evidence to support its use. The VAC uses a piece of foam in contact with the wound bed; it is covered with an occlusive dressing and placed under negative pressure (usually –125 mm Hg). The VAC produces high-quality granular tissue that has a characteristically rough appearance. It is essentially a wound simplification device, converting complicated (deep) wounds to simple (shallow) ones (Fig. 116.8). The VAC device can decrease the depth and area of large diabetic foot wounds, thus speeding closure.[59] In a recent randomized controlled trial evaluating its use after partial diabetic foot amputations, the VAC

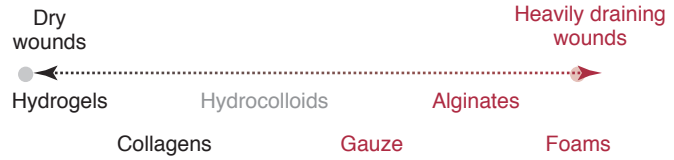

Figure 116.7 Dressings can be used to attain proper moisture balance in a wound. These dressings are categorized based on their effects on wound moisture.

was found to be more effective than the standard of care, and it limited the number of secondary amputations.[60] Because DFUs are so costly, the rapid response provided by the VAC lowers the cost of care delivered to those with chronic wounds.[61] Occasionally, in shallow DFUs, it is difficult to keep the VAC foam from shearing. To prevent this, one can reduce the thickness of the foam or bridge the track pad to the dorsal foot. Once a wound becomes shallow and covered in granulation tissue, it is time to consider discontinuing the VAC and progressing to wound closure.

Growth factor therapy has been theorized to speed the healing of chronic ulcers.[62] Recombinant human platelet-derived growth factor (PDGF) is available in the United States by prescription. Original trials reported a 32% decrease in the time to complete closure when combined with good wound care.[63] PDGF therapy is expensive and should be used only by those with experience in wound care. It has no effect on fibrotic or necrotic tissue and should be applied only to a thoroughly debrided wound. Aggressive serial debridements improve outcomes.[64]

Chronic diabetic ulcers exhibit cells that are phenotypically senescent, incapable of not only mitosis but also apoptosis. These cells may be unresponsive to growth factor application. Debridement of the superficial layer of the wound bed and margins aids in removing them. Bone marrow contributes to dermal wound healing by the mobilization and peripheral circulation of progenitor cells.[65] Direct application of autologous marrow-derived stem cells topically or by periwound injection may speed this process, resulting in robust granular tissue that will accept a skin graft or substitute.[66] Others have harvested and expanded marrow-derived stem cells in culture and reapplied them to chronic ulcers with success.[67-69]

In the diabetic foot, hyperbaric oxygen treatment (HBOT) has a role in the preservation of compromised flaps (as in the case of a partial foot amputation) and failing skin grafts. There

Figure 116.8 (A) Wound with fibrotic tissue in the base before debridement. (B) After proper debridement and promotion of granulation tissue with the Wound VAC, the wound bed is prepared for closure.

have been studies showing its use in Wagner grade 3 and 4 ulcers, leading to limb salvage.[70] A meta-analysis from the Society for Vascular Surgery concluded that there is low- to moderate-quality evidence suggesting a benefit for HBOT as an adjunct to standard treatment for DFUs.[71] HBOT is not a substitute for effective revascularization.

After preparing a vascularized wound bed, wound closure should be performed as rapidly as possible to avoid complications. Wound closure can be obtained by split-thickness skin graft, plastic surgical flaps, or bioengineered tissue.

Split-thickness skin grafting is a viable, minimally invasive, and cost-effective method for covering large granular defects.[72,73] Split-thickness grafts often perform best on non–weight-bearing surfaces of the foot, including the dorsal, medial, lateral, and arch areas; however, areas of traditional plantar weight bearing may also be considered if this process is combined with additional soft tissue or bone reconstruction.[72] Although meshed grafting can reduce the rate of seroma and hematoma formation, some have shown that unmeshed grafts perform equally well.[74] Another method to improve the adherence and survival of meshed split-thickness skin grafts is the use of NPWT as a bolster dressing,[75,76] which reduces seroma and hematoma formation and shear forces. A nonadherent interface must be interposed between the foam and the graft. The negative pressure can be used continuously for 4 to 5 days after grafting; then it is discontinued and standard dressings are applied.[75]

New technology, such as the CelluTome (Acelity/KCI, San Antonio, Texas), has made it simpler to harvest suction blister epidermal grafts (SBEGs) in the clinic without the need for anesthesia. Guidelines submitted for publication suggest that SBEGs can be used for a variety of ulcer types after the wound bed is adequately prepared. A few studies have evaluated the effectiveness of SBEGs for complex lower extremity wounds,[77,78] including our own preliminary work, which showed an 83% healing rate in 25 patients without any donor site morbidity.[79]

Large soft tissue defects and wounds with exposed deep structures such as bone require more aggressive measures to obtain closure. Multiple types of soft tissue flaps can be used to manage these defects. The flaps should be based on current vascular flow and not assumed anatomic flow because patients with diabetes may have segmental or regional arterial occlusions. With fasciocutaneous flaps, the fascia and superficial tissue are rotated into place to cover a defect. One of the more common fasciocutaneous flaps performed in the diabetic foot is a medial plantar artery flap, which can be rotated laterally to cover a subcuboid ulcer or proximally to cover a plantar calcaneal defect. The toe fillet flap can be used to cover submetatarsal head ulcers, but it requires the sacrifice of a digit.[80] For plantar central metatarsal head ulcerations, the attached toe can be filleted with a central plantar incision, the nail removed, and the skin advanced in a plantar direction to cover the ulcer site. In rare cases, the hallux may be sacrificed; however, this can have a deleterious impact on gait and plantar pressure. In these cases, the incision is made laterally between the dorsal and plantar digital neurovascular bundles; the flap is then lifted from the bone and advanced laterally (Fig. 116.9). Muscle flaps are used to cover exposed bone, such as the extensor digitorum brevis flap or the abductor hallucis (and digiti minimi) flap. The exposed muscle can be covered with a split-thickness skin graft. Free flaps involve the autotransplantation of a vascularized myocutaneous area to the recipient site and microvascular reanastomosis.[81]

In the case of shallow wounds without exposed deep structures, cellular and tissue-based products (CTPs) are viable options. Some tissues—such as Apligraf and Dermagraft (Organogenesis, Canton, Massachusetts)—are living and made from human dermal cells. Apligraf has been studied extensively and is approved by the US Food and Drug Administration (FDA) for use in DFUs and venous leg ulcers. It has a shelf life of approximately 10 days. It must be secured to the wound

Figure 116.9 Toe fillet flap of the hallux is lifted from the underlying bone. The incision is made laterally, and the soft tissue is lifted full thickness from the periosteum to ensure that the digital arteries are captured in the flap.

with sutures or another type of anchor. In a large multicenter trial, weekly applications (up to five) resulted in a 63% healing rate, compared with 38% among controls at 12 weeks.[82] Dermagraft (Advanced BioHealing, Inc., La Jolla, California) is a single layer consisting of living fibroblasts on an absorbable mesh that is FDA-approved for DFUs. It is cryopreserved and has a shelf life of 90 days. After thawing, it is applied to the ulcer and secured with a dressing. It is applied weekly for up to 8 weeks.[83] In a randomized controlled trial, Dermagraft resulted in a 30% healing rate over 12 weeks, compared with 18% in the control group. Dermagraft was also associated with a lower rate of ulcer-related adverse events.[84]

However, at the time of this writing, the living dermal-based CTPs have given way in the DFU market to amniotic membrane-based tissues. Studies have shown high healing rates with Epifix[85,86] (MiMedx, Marietta, Georgia) and Grafix[87] (Osiris, Columbia, Maryland). These tissues may not heal by engraftment, as originally thought, but rather by providing abundant growth factors to the wound, thus speeding granulation and epithelialization. In addition to good efficacy, amniotic tissues cost much less than the dermal-based tissues in a per-treatment analysis.[88] Bundled payments are creating pressure on providers to be more cost-conscious, leading to a faster adoption curve for amniotic tissues. Since amniotic tissues do not create an immune response risking host rejection, they have also found a place in the management of wounds with exposed deeper structures, such as tendon or bone.[89]

Mechanical Off-Loading

Effective pressure reduction is the cornerstone of treatment for DFUs. Repetitive trauma and pressure on the wound bed are two of the primary reasons for ulcer persistence.[90] Excessive plantar pressure and shear forces prevent the formation of adequate granulation tissue and result in undermining and hyperkeratotic tissue. The total-contact cast (TCC) has been shown to be the best practice for off-loading the ulcerated foot, and a consensus document published in the *Journal of the American Podiatric Medical Association* supports its use for all

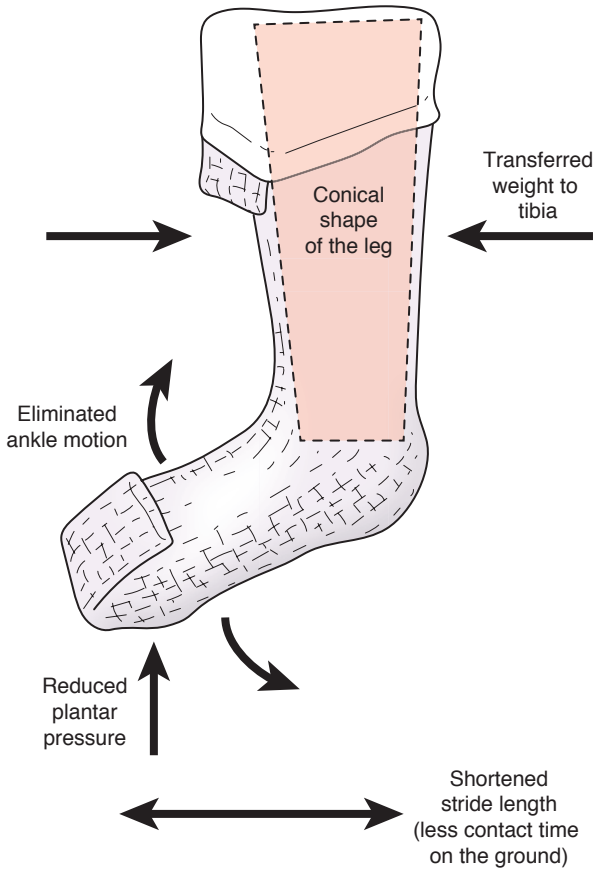

Figure 116.10 Image of a total contact cast (TCC) and the main principles by which it works.

appropriate plantar DFUs (Fig. 116.10).[91] However, the TCC is not standard practice, even in wound care centers.[92,93] The obstacles to use of TCC are multifactorial, consisting of provider-related barriers, patient-related barriers, and system-related barriers. The barriers and suggested solutions are presented in Table 116.2. Since the barriers are not often addressed, the use of noncustom off-the-shelf devices has become an alternative. In the laboratory, removable cast-walkers (RCWs) off-load the plantar foot as well as the TCC does, and they do so better than postoperative shoes and half shoes.[94] In clinical practice, however, TCCs are better at healing ulcers. This is explained by the removable nature of RCWs. Armstrong and colleagues concealed pedometers inside RCWs and also gave the same patients pedometers to wear on their hips.[95] Subjects were instructed to use the RCWs at all times while ambulating. The investigators found a significant discordance between the hip and RCW pedometers, indicating that the patients were not compliant with instructions to wear their off-loading devices at all times and suggested that improved outcomes would be achieved with a nonremovable device. The instant TCC (iTCC) is a removable walking cast-boot rendered nonremovable by applying a layer of adhesive bandage, plaster, or fiberglass. The iTCC is an effective, easy-to-use off-loading device that improves patient compliance.[96] The Society for Vascular Surgery recently published guidelines for off-loading the DFU which strongly recommend either a TCC or a fixed ankle RCW.[97]

TABLE 116.2 Barriers and Solutions to Usage of a Total Contact Cast

Barrier	Solution
Provider Barriers to TCC Usage	
Lack of proper training	Attend a training course or designate a trained staff member to apply
Timidity due to history of complications	Education about risks and benefits and improve training
Time for application	Enhance training or designate a staff member to apply
Misunderstanding of billing or global	Increase awareness of billing guidelines
Patient Barriers to TCC Usage	
Lack of desire to be in a cast	Patient education of the benefits of casting, including shorter healing time and cost
Claustrophobia	Psychologic counseling or medication
Driving with right extremity cast	Designate a family member or friend to drive, use a ride-share program
Fear of falling	Prescribe a gait aid, order physical therapy, counsel about common home environment risks
Process Barriers to TCC Usage	
Clinic/staff time for application	Improve clinic process by designating a trained staff person to apply casts, place patients in hallway or waiting area while cast dries, use a faster drying material
Misunderstanding of billing or global	Increase awareness of billing guidelines
Space to store the casts	Use cast kits to take less space and keep material in one place
Use in conjunction with HBOT	Remove cast after HBOT treatment and reapply, allowing almost 24 h prior to the next treatment

HBOT, Hyperbaric oxygen therapy; *TCC*, total contact cast.

Surgical Off-Loading

Surgical off-loading involves either an exostectomy to remove a plantar prominence or joint reconstruction to lower peak plantar pressure distal to the joint. Plantar hallux ulcers in the presence of hallux limitus respond well to a base resection of the hallux proximal phalanx (Keller arthroplasty; Fig. 116.11). This operation improves dorsiflexion and reduces plantar pressure on the distal hallux during toe-off.[98] Plantar forefoot ulcers can heal faster when a tendon of Achilles lengthening (TAL) is performed.[99] The standard TAL is accomplished through three stab incisions, posing minimal surgical risk (Fig. 116.12). Although this "lengthening" might be considered more of a "weakening" of the posterior muscle group, it results in muscle-tendon balancing and reduces forefoot pressures. This relatively short-lived pressure reduction can lead to ulcer healing and prevent recurrence (Fig. 116.13).[100] Possible complications of this procedure include Achilles tendon rupture, calcaneal gait (increased weight-bearing time on the calcaneus), and heel ulcer, which can lead to amputation in rare instances.

In a foot that demonstrates both equinus and varus—that is, the foot is inverted and pressure is placed on the plantar or lateral fifth metatarsal area—an additional tendon procedure might be of benefit. The tibialis anterior tendon transfer is performed through three anterior incisions. The tendon is transected from its normal insertion on the medial cuneiform and transposed laterally into the lateral cuneiform or cuboid; it is usually secured with a bone anchor. This eliminates the forces that pull up on the medial midfoot, transferring pressure laterally. The new function of the tibialis anterior is a more central dorsiflexory action.

With a single plantar metatarsal ulcer and no equinus, one might consider a metatarsal head resection. This procedure is commonly performed when osteomyelitis is present in the metatarsal head from a chronic ulcer tracking to bone. The incision is made dorsally over the metatarsophalangeal joint, and the head is removed by osteotomy of the neck of the metatarsal. Occasionally, when there are multiple foci of pressure or ulcerations under plantar metatarsal heads, a panmetatarsal head resection is indicated, which can significantly reduce plantar forefoot pressures (Fig. 116.14).[101] The heads of metatarsals 1 through 5 are removed through multiple dorsal longitudinal incisions or through one plantar transverse incision in the sulcus, distal to the metatarsal heads. Some surgeons prefer to perform a fusion of the first metatarsophalangeal joint instead of resecting it.

In persons with normal baseline circulation (or in those who have been revascularized), there has been increased interest in performing reconstructive diabetic foot surgery. However, this approach has led to an ill-defined mélange of indications and contraindications. To address this confusion, Armstrong and Frykberg proposed classifying nonvascular diabetic foot surgery into four categories based on indications and perceived risk: elective, prophylactic, curative, and emergency. This system, which focuses on historical variables such as neuropathy, presence of ulceration, and limb-threatening infection,[102] was validated in a study we reported in 2006.[103] Designed as a cohort model, the study involved abstracting medical records from 180 patients with diabetes requiring foot surgery and assigning them equally to the four classes. There was a strong and significant trend toward increasing postoperative infection, ulceration, reulceration, and amputation with higher surgical class (Fig. 116.15).[103]

Figure 116.11 (A) Preoperative view of limited mobility of the hallux (hallux limitus) with a distal hallux ulcer. (B) Intraoperative view illustrating an improvement in dorsiflexion after resection of the base of the proximal phalanx. (C) Hallux ulcer healed within 3 weeks of surgery.

Figure 116.12 Triple-hemisection approach to Achilles tendon lengthening. The linear markings connote the outline of the left Achilles tendon medially and laterally. Two transverse stab incisions are made medially and one is made laterally, all 1 cm apart, transecting slightly more than 50% of the tendon substance. The foot is then forcibly dorsiflexed to create a sliding effect of the tendon.

Class I: Elective

Elective diabetic foot surgery is performed on a sensate (non-neuropathic) patient to reduce pain or improve function.[102] Assuming good metabolic control, these patients are at no greater risk for the development of complications than corresponding patients without diabetes.[103]

Class II: Prophylactic

Prophylactic surgery is performed to alleviate deformity in a person with neuropathy but without an open ulcer. The goal of prophylactic surgery is to reduce plantar vertical and shear stress. Armstrong and coworkers compared postoperative complications in people with and without diabetes undergoing a single hammertoe correction (arthroplasty).[104] After a follow-up period of 3 years, there were no complications in either the neuropathic diabetic patients with no history of ulceration or the nondiabetic subjects. However, those with a history of ulceration were more likely to experience a postoperative infection (14.3%). Long-term outcomes after these procedures were uniformly good, with 96.3% of patients remaining ulcer-free

Figure 116.13 (A) Preoperative view of a plantar forefoot ulcer in the presence of Achilles contracture (equinus). (B) Three weeks after Achilles lengthening, the plantar ulcer has healed.

for a mean of 3 years. In a later work, we reported a postoperative infection rate of 6.7% following class II surgery.[103]

At least 4 in 10 people with Charcot arthropathy develop an ulcer, and their risk ratio for ulceration is up to 36-fold higher than normal.[15] Those presenting with an unstable foot secondary to this condition can often achieve bony fusion and limb salvage with surgical reconstruction; however, most people with Charcot arthropathy do not require surgical intervention.[105]

Limited joint mobility in the foot is essentially equivalent to overt deformity.[13] A common example is hallux limitus, in which limited dorsiflexion of the first metatarsophalangeal joint increases pressure at the distal hallux during ambulation, specifically during toe-off. This can lead to the formation of calluses and blistering under the great toe and the subsequent development of a wound. This is a clear indication for prophylactic surgery to increase motion and thereby reduce pressure.

Class III: Curative

Curative diabetic foot surgery is designed to heal the wound and reduce the risk of reulceration.[102] Rosenblum and colleagues reported their experience with hallux interphalangeal joint arthroplasty in 45 feet for chronic neuropathic ulcers of the great toe.[106] Overall, 41 feet (91%) healed and had no evidence of recurrence in the follow-up period. The authors reported an 11% postoperative complication rate and a 4% infection rate.

Ankle equinus (<10 degrees of dorsiflexion at the ankle joint) increases plantar forefoot pressures and may increase the risk of ulceration.[107] TAL has been shown to reduce plantar forefoot pressures by a mean 27% and is beneficial in preventing ulceration.[108] Lin and associates have reported there was more rapid healing of previously recalcitrant plantar wounds with a TAL procedure as well as a lower rate of recurrence.[109] Mueller and coworkers, in a randomized controlled trial, similarly reported a trend toward lower ulcer recurrence after performing TAL.[100]

Class IV: Emergency

Emergency surgery connotes procedures performed to reduce the risk of proximal spread of an acute infection. Patients who may require revascularization must be evaluated by a vascular surgeon in the immediate perioperative period. However, drainage or damage-control debridement of a limb- or life-threatening infection should not necessarily be delayed if the time to obtain consultation will be prolonged.[102] These procedures often include partial or whole-foot amputation.

The Charcot Foot

The Charcot foot ulcer can be particularly troublesome to off-load and deserves special mention. Charcot arthropathy or neuroarthropathy is a fracture and dislocation process of the foot and ankle that occurs in patients with sensory and autonomic neuropathy. Fracture is often associated with unrecognized injury or minor trauma that might otherwise appear innocuous.[110,111] Charcot arthropathy patients classically present with a painless, hot, swollen foot. Others may present with what initially seems to be a unilateral flatfoot deformity, with the arch of the foot "suddenly" collapsing. Patients generally have excellent arterial pulses and severe sensory neuropathy. Diabetic patients with sensory neuropathy and ischemia have been reported to

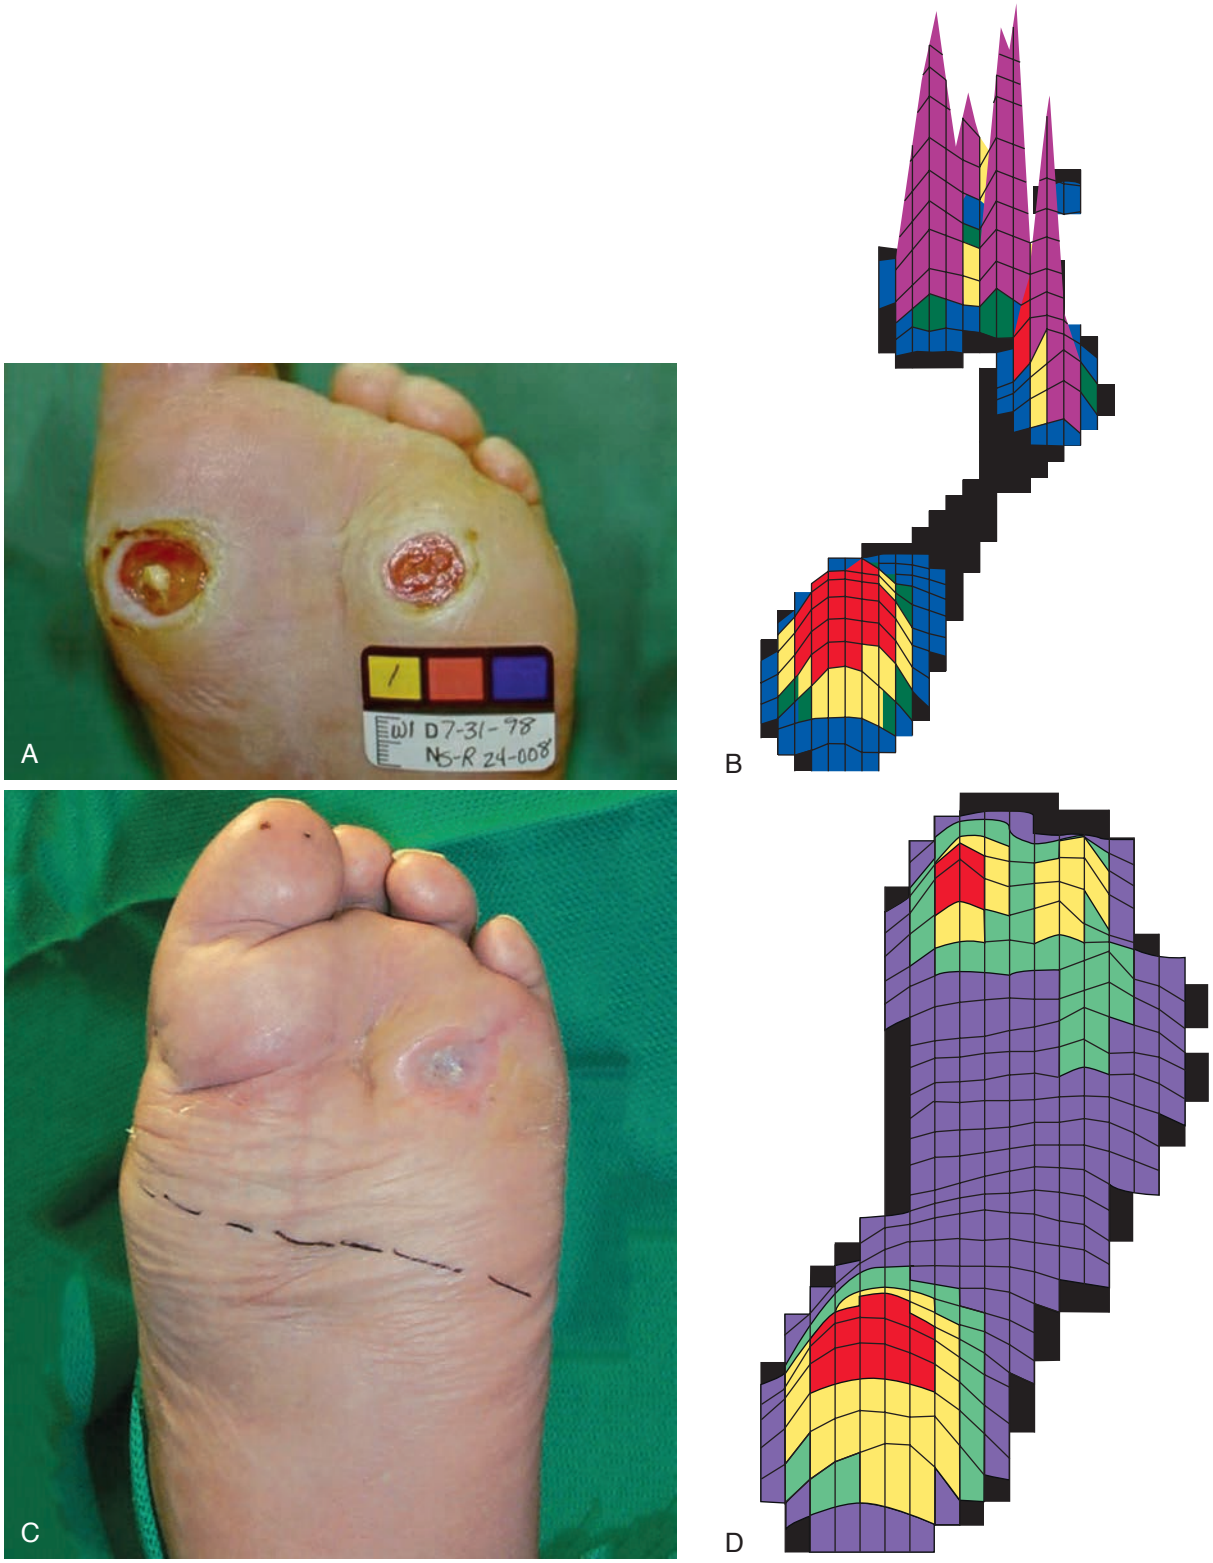

Figure 116.14 Clinical photograph (A) and peak plantar pressures (acquired using a pressure-sensitive mat) (B) of a foot with ulcers under metatarsal heads 1 and 5. After panmetatarsal head resection, the ulcers have healed (C) and the peak plantar pressures have been reduced (D). *Red color* connotes the zones of highest pressure, and the magnitude of this pressure is depicted by the height of the peaks.

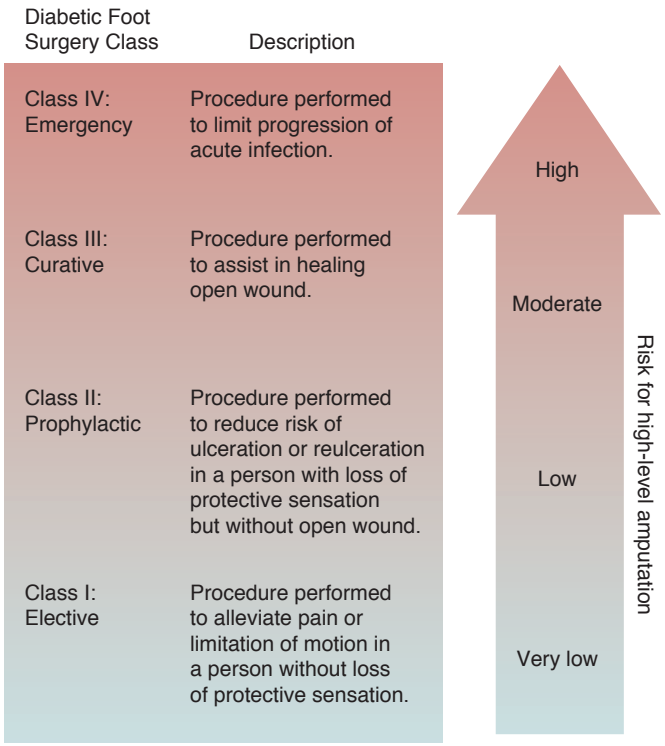

Figure 116.15 Armstrong-Frykberg classification of diabetic foot surgery. Risk of amputation increases as a function of complications and the indications for performing the given procedure.

develop Charcot arthropathy following in situ pedal bypass, after perfusion to the foot has been restored. Certain cases require surgical reconstruction and arthrodesis. In some cases, a simple exostosectomy can reduce pressure enough to heal an ulcer[112]; many others require complete foot reconstruction (Fig. 116.16).[113]

Charcot arthropathy is often misdiagnosed as an infectious process unless the treating physician has a high index of suspicion. The differential diagnosis includes infection, osteomyelitis, deep venous thrombosis, posterior tibialis tendon dysfunction, and even bone tumor. Imaging studies can be misleading, especially early in the course of the disease. Plain film radiographs often show periosteal elevation, multiple fractures, and, in some instances, osteopenia that may be misinterpreted as osteomyelitis by an inexperienced radiologist or surgeon. Many patients are treated for osteomyelitis even though they have never had a wound or injury. Bone scanning and magnetic resonance imaging are usually not reliable for differentiating bone infection, trauma, fracture, and postsurgical inflammation. The surgeon should have a clear diagnosis of bone infection before planning an amputation, especially in the absence of a wound. A bone biopsy is the "gold standard" to diagnose bone infection. A Jamshidi needle used under fluoroscopy permits the surgeon to obtain a bone specimen for a definitive diagnosis and minimizes the ambiguity associated with more expensive imaging techniques.

Figure 116.16 (A) Plantar diabetic foot ulcer under a Charcot foot deformity. (B) Healing of the ulcer 12 weeks after a midfoot reconstruction, medial plantar artery flap, and split-thickness skin grafting.

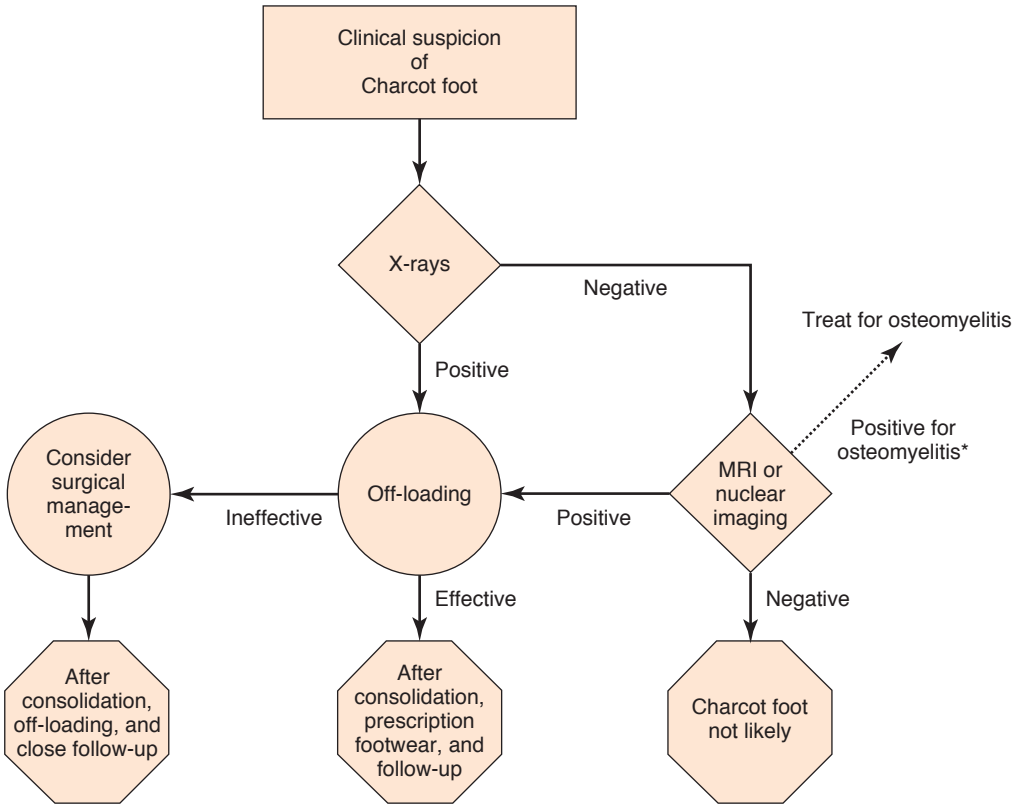

Figure 116.17 The Charcot Foot Joint Task Force basic treatment algorithm. (Reprinted with permission from Rogers LC, Frykberg RG, Armstrong DG, et al. The Charcot foot in diabetes. *J Am Podiatr Med Assoc.* 2011;101(5):437-446.)

The midfoot is the most common site of a Charcot fracture. The result is often a convex arch, with the head of the talus and navicular bones or the cuboid projecting from the bottom of the foot; in some cases, the talus bone may be destroyed, with the weight of the extremity borne by the malleolus, which easily ulcerates. Ulcers often occur because of the abnormal pressure and shear forces created by the collapse of the arch. When these wounds fail to heal, it is usually not due to ischemia but rather to a combination of neuropathy, bony abnormality, pressure, shear, and repetitive local trauma. The treatment for both ulcers and active Charcot arthropathy is cast immobilization. Charcot fractures may take 2 to 3 times longer to heal than fractures at the same site in persons without diabetes.

The American Diabetes Association and the American Podiatric Medical Association have created a joint task force on the Charcot foot which resulted in a consensus document publication in 2011[114] and the generation of a treatment algorithm (Fig. 116.17).

Metabolic Control

Chronic hyperglycemia leads to neuropathy[30,31]; but it is also associated with delayed wound healing and increases risk of postoperative complications in foot and ankle surgery.[115-118] A comprehensive management strategy for hyperglycemia should be initiated with a short-term goal of tight glycemic control and a long-term goal of a HbA_{1c} below 7.0%. Nutrition is a frequently overlooked facet of wound care. Among 478 patients with limb-threatening DFUs, 70% were at risk for malnutrition and 15% were malnourished.[119] Patients' nutritional status had a significant influence on outcomes for limb preservation.

Post–Secondary Amputation Prevention: Diabetic Foot Remission

After resolution of a lower extremity complication, patients are "in remission."[120] We find this an appropriate description and one that helps to convey the ongoing risk to patients, similar to cancer. Not only is the all-cause 5-year relative mortality rate high for those with diabetic lower extremity disease, but there is a high recidivism rate. Patients who heal from a DFU have 50% recurrence within 12 months.[121] After an amputation, there is also a 50% likelihood of a contralateral amputation within 2 years.[7]

The focus in the post–secondary prevention group is to prevent the recurrence of a diabetic foot complication or the onset of a new one. The target should be functional restoration and an increase in ulcer-free days. Strategies to achieve this include regular podiatric surveillance,[17,18] prophylactic foot surgery,[104,108] prescriptive footwear,[39] and thermometric analysis.[43]

SUMMARY

The podiatric and vascular surgeon must frequently cooperate in the care of the complicated lower extremity due to diabetes. Understanding each provider's role will streamline care. Pathway-driven teams can improve patient outcomes and reduce costs to the healthcare system. For a more complete description of such teams, we refer the reader to manuscripts outlining their components and structure.[24,122]

INTRODUCTION

Upper extremity ischemia accounts for less than 5% of patients presenting for evaluation of limb ischemia, with a vast majority of cases being caused by autoimmune/connective tissue diseases. In contrast to lower extremity, atherosclerosis is not a major contributor to upper extremity ischemia. According to a Dutch study, only 2.3% of diabetic patients and no nondiabetic patients were found to have abnormal Doppler waveforms in either of the upper extremities.[1]

This chapter provides an overview of upper extremity arterial diseases. Ensuing chapters will discuss in detail the diagnosis, pathophysiology, and treatment of specific vascular conditions that affect the upper extremity.

EPIDEMIOLOGY

A wide array of pathology may contribute to upper extremity arterial disease and, as a result, little comprehensive epidemiologic data is available. One exception is Raynaud's syndrome, which is characterized by intermittent digital ischemia in response to cold, caffeine, or emotional stress (see Chapter 141). Among people living in cold climates, up to 20% to 30% will complain of cold-induced digital pain.[2] In the United States, the prevalence

Abstract

Upper extremity ischemia is less common than lower extremity ischemia and is typically classified as vasospastic or occlusive. Occlusive disease is associated with worse prognosis for developing tissue loss. Most patients with occlusive disease have their most severe symptoms at the time of presentation. Surgical bypass is a viable option in patients with occlusive disease and is associated with excellent 1- to 3-year outcomes. Vasospastic etiologies are more responsive to pharmacologic intervention.

large vessel arteriopathy
hand ischemia

of Raynaud's syndrome in women is approximately 9% in the Northeast and 4% in the South. The prevalence in men is approximately 6% in the Northeast and 3% in the South.[3,4]

Most patients with Raynaud's syndrome have primary (idiopathic) *Raynaud's disease*. Patients with Raynaud's syndrome who have an identifiable arterial pathology or associated disease contributing to their condition are classified as having *Raynaud's phenomenon*. This distinction has prognostic implications as secondary Raynaud's phenomenon is more likely to progress to severe occlusive disease leading to digital rest pain, and ulceration. Diseases associated with Raynaud's phenomenon include scleroderma, mixed connective tissue disease (MCTD), systemic lupus erythematosus (SLE), and rheumatoid arthritis. Of these, scleroderma accounts for majority of Raynaud's phenomenon with 80% to 90% of patients presenting with Raynaud's symptoms.[5]

ETIOLOGY AND PATHOGENESIS

Upper extremity arterial disease can be categorized based on anatomic location (large vs. small vessel) and etiology (vasospastic vs. occlusive). Although the clinical appearance of occlusive and vasospastic disease may be similar, delineating between them is essential for appropriate treatment. Processes leading to upper extremity arterial disease are vast. Arterial vasospasm may occur with ergotism, vinyl chloride exposure, and idiopathic Raynaud's phenomenon.

Patients with vasospastic Raynaud's syndrome have normal digital artery pressure at baseline. In response to certain triggers (cold, stress, caffeine), they experience digital artery smooth muscle contraction leading to profound, albeit temporary, digital hypoperfusion. Upon relief of the trigger, the vasoconstriction ceases and normal flow is restored. Obstructive Raynaud's can have palmar and digital artery occlusive disease, proximal obstruction of the large arteries, or a combination of the two. They have lower resting digital blood pressure and may have symptomatic digital ischemia or tissue loss under nonstressed conditions. With cold or emotional stress, a vasoconstrictive response of the digital artery smooth muscle further causes arterial closure with resultant symptoms.

The pathophysiological mechanisms underlying Raynaud's syndrome remain poorly understood despite the fact that it has been more than a century since it was first described by Maurice Raynaud.[6,7] Multiple abnormalities including those of the sympathetic nervous system,[8,9] digital blood vessels, altered sensitivities, numbers of α-adrenoceptors,[10,11] and β-adrenoceptors,[12] and vasoactive peptides, including calcitonin gene-related peptide,[13,14] and endothelin[15] have been hypothesized. It is being increasingly recognized that the pathophysiology of Raynaud's syndrome is complex and that potentially more than a single factor might be at play.[16]

Small Vessel Arteriopathies

Numerous small vessel arteriopathies in the upper extremity, defined as those distal to the wrist, may lead to hand ischemia. The diseases leading to the most severe upper extremity arterial ischemia are autoimmune or connective tissue diseases such as scleroderma, rheumatoid arthritis, systemic lupus, and others.

Scleroderma

Scleroderma is the most common connective tissue disorder in patients with Raynaud's syndrome. It is a generalized disorder of connective tissue, the microvasculature, and the small arteries.[17] It has a female-to-male ratio of 3:1, and the incidence is approximately 10 per 1 million people in the United States. Cutaneous involvement is almost universal, and the clinical course is characterized by progressive scarring and small vessel occlusions in the skin, gastrointestinal tract, kidneys, lungs, and heart. Serology often reveals anti-centromere or anti-topoisomerase (anti-Scl-70) antibodies. It is postulated that damage seen in scleroderma is mediated through these cytotoxic antibodies to endothelium.

Systemic Lupus Erythematosus

SLE occurs most often in young females, and damage to affected organs appears to be caused primarily by immune complex deposition.[18] The diagnosis is made clinically since the available laboratory tests, while quite sensitive, are not specific.[19] Clinical criteria include fevers, arthralgias, skin rash, Raynaud's syndrome, and nephritis. Raynaud's syndrome is present in as many as 80% of patients.

Rheumatoid Arthritis

While rheumatoid arthritis is primarily a chronic inflammatory joint disease, a subgroup of patients has extraarticular involvement of the skin, eyes, lungs, spleen, and arteries. Several types of vasculitis have been described in rheumatoid arthritis, the most severe of which is termed rheumatoid vasculitis, a systemic process that involves both arteries and veins.[20] The etiology of rheumatoid arthritis is unknown, but it likely results from immune-mediated damage. Most patients have the HLA-DRW-4 allele, and it has been hypothesized to mark a genetic predisposition that in response to an unknown stimulus such as infection leads to immune complex deposition and inflammation.

Sjögren's Syndrome

Sjögren's syndrome is characterized by dry eyes and mouth and may be primary or secondary to another connective tissue disease. It may be associated with small vessel arteriopathy, which can then be subdivided into acute necrotizing, leukocytoclastic, and lymphocytic vasculitis.

Mixed Connective Tissue Disease

MCTD is a group of disease states that are autoimmune diseases but do not fall into a named disease category. Patients characteristically have high titers of antibodies to an extractable nuclear antigen, which consists of ribonucleic acid and protein. MCTD clinically presents as an overlap syndrome with features of two or more connective tissue diseases, such as SLE, rheumatoid arthritis, or scleroderma.[21]

Buerger's Disease

Buerger's disease (thromboangiitis obliterans) is characterized by segmental thrombotic occlusions of the small- and

medium-sized arteries (see Chapter 138).[22,23] The disease most commonly affects lower extremities but upper extremity is involved in as many as 50% of these patients. It classically occurs in young male smokers and is often associated with both migratory thrombophlebitis and Raynaud's syndrome. Diagnostic criteria include age less than 45 years, tobacco abuse, exclusion of other diseases with similar clinical findings, normal arteries proximal to the popliteal or brachial arteries, and documentation by objective means of digital arterial occlusion.[24]

Hand-Arm Vibration Syndrome

Hand-arm vibration syndrome (HAVS) refers to the finding of Raynaud's syndrome after long-term use of vibrating tools.[25,26] The initial group of patients were stonecutters, but the disease has been described in various occupations, including welders or grinders in shipyards, timber fellers, and windshield replacement technicians in the auto-glass industry.[27] The exact pathophysiology of this condition is not known, but it is postulated that kinetic energy imparted to the small vessels and nerves of the hand by vibrating tools with power in certain frequency bands is harmful. The damage appears to accumulate over time. Early on, patients have vasospastic Raynaud's syndrome, which over a period of time, progresses to digital artery occlusive disease.[28] (Reference occupational vascular problems chapter here.)

Fibromuscular Disease

Fibromuscular disease involving the forearm, palmar, and digital arteries is rare.[29] Patients often present with finger ischemia because of arterial embolization and occlusion. It has been postulated that the condition known has hypothenar hammer syndrome, in which patients have the acute onset of hand ischemia after using the heel of their hand as a hammer, is actually due to trauma to a preexisting fibromuscular disease lesion.[30]

Hypersensitivity Angiitis

The term hypersensitivity angiitis describes a group of patients who present with acute onset of significant digital ischemia, usually with ulceration, but have no demonstrable underlying abnormality, such as connective tissue disease or embolic source.[31] An immune-mediated arterial wall injury has been hypothesized as the underlying etiology, although strong evidence is lacking in that regard. It is a benign condition that follows a course of progressive improvement.

Malignancy

Raynaud's syndrome has been reported in association with several malignancies.[32,33] The exact mechanism is unknown, but it appears related to tumor-based immunologic processes, including both small vessel arteritis and immune complex deposition, possibly including cryoglobulins.

Frostbite

Freeze injury of the small vessels of the digits results in Raynaud's syndrome. Mild frostbite usually results in vasospastic Raynaud's syndrome, while significant freezing injury may result in occlusive disease of the digital arteries.

Large Vessel Arteriopathies

The most common large vessel arteriopathy in the upper extremity is atherosclerosis. Risk factors are the same as those for occlusive disease elsewhere in the body. These include tobacco use, hyperlipidemia, hypertension, diabetes, male gender, and age. The most common mechanism via which atherosclerosis may cause upper extremity ischemia is occlusive disease, with involvement of the origin of the left subclavian artery being the most common location. Aneurysms are rare in the upper extremity but can occur in the subclavian or axillary arteries. Chronic trauma from arterial thoracic outlet syndrome can lead to subclavian artery stenosis, which is accompanied by digital ischemia due to embolic phenomenon (see Chapter 122).

Takayasu's arteritis is a common vascular condition mainly involving the aorta and its branches. Upper extremity ischemia may occur with disease within the subclavian arteries.[34] Giant cell arteritis mainly involves the walls of medium and large arteries. The temporal artery is the most commonly involved; however, upper extremity arteries are occasionally affected.[35] Embolic occlusion from atrial fibrillation or other sources is classically seen in the brachial artery before the bifurcation of radial and ulnar arteries.

Another well-described presentation of upper extremity ischemia occurs after placement of dialysis access. Steal syndrome refers to a distal hypoperfusion ischemic syndrome after dialysis access placement. It occurs in 5% to 10% of cases when the brachial artery is used.[36]

Iatrogenic injury to the radial and brachial arteries has increased in conjunction with increased use of upper extremity for coronary and peripheral catheterization access. Initial reports of brachial artery access revealed a complication rate as high as 17%, but this has since declined to 1% to 5%.[37,38] The median nerve lies in close proximity to the brachial artery in this location within the covering fascia, and at high risk for compression from hematoma formation. Therefore, evidence of an access site hematoma should be addressed immediately to prevent long term nerve injury. Occlusion of the radial artery is seen in 3% to 10% of interventions using radial access.[39] An intact ulnar artery and palmer arch can maintain collateral flow to the hand in cases of radial artery occlusion. An Allen test should be performed before any radial access procedure to confirm adequate collateral flow.

Box 117.1 below lists the causes of hand ischemia, and Table 117.1 details the portion of the arterial system affected by these etiologies.

Clinical Findings

Acute Ischemia

Patients with acute ischemia of the upper extremity are more likely to be females and tend to be older than those with lower extremity ischemia.[40] However, symptomatology remains the same: pain, paresthesias, and paralysis. Physical examination reveals diminished or absent pulses (brachial, radial, or ulnar); pallor, dependent rubor; and reduced temperature. As mentioned earlier, classic Raynaud's phenomenon is characterized by pain,

BOX 117.1 Causes of Hand Ischemia

Arterial Vasospasm
- Ergotism
- Idiopathic vasospastic Raynaud's syndrome
- Vinyl chloride exposure

Arterial Obstruction

Large-Artery Causes
- Atherosclerosis
- Thoracic outlet compression
- Arteritis
- Takayasu's
- Giant cell
- Fibromuscular disease
- Iatrogenic injury
- Dialysis steal syndrome

Small-Artery Causes
- Connective tissue diseases
- Scleroderma
- Rheumatoid arthritis
- Sjögren's syndrome
- Systemic lupus erythematosus
- Myeloproliferative disorders
- Thrombocytosis
- Leukemia
- Polycythemia
- Buerger's disease

color, and temperature changes in response to cold or emotional stress. Tissue loss is rare in cases of acute occlusion due to an abundant network of collateral circulation in the upper extremity. It has been reported that acute occlusion of the axillary artery results in limb loss in less than 10% of cases and that interruption of the brachial artery distal to the deep artery branch results in digital gangrene in less than 5% of cases.

Chronic Ischemia

Patients with chronic ischemia of the upper extremity tend to have all the symptoms of acute ischemia superimposed on chronic ischemic changes in skin and musculature. This may manifest as muscle pain with use, ulcers, or gangrene in the upper extremity. Findings on physical exam may be normal at rest, but the hand and digits are cool and brachial and wrist pulses are diminished or absent. Steal syndrome may manifest by onset of symptoms in conjunction with dialysis access and remaining asymptomatic between dialysis sessions.[36] In this situation, fistula compression usually is associated with an increase in wrist pulses, Doppler signals, or both.

Diagnostic Evaluation

Clinical Evaluation

Initial evaluation of patients with upper extremity ischemia starts with a detailed history and physical examination with specific attention to signs and symptoms of an underlying connective tissue disease. Pertinent historical information includes temperature sensitivity, dry mouth, dry eyes, arthritis, history of trauma or instrumentation, as well as occupational history to evaluate for vibration arterial injury.

A complete arterial examination should be performed in a warm room and patients should be allowed to rewarm before their examination, during cold weather. Brachial and forearm blood pressures are measured. In cases of suspected claudication, they should be measured at rest and after 2 to 5 minutes of exercise. A gradient of 20 mm Hg or more is considered significant when comparing sides. All pulses are palpated, and Doppler insonation of the radial, ulnar, palmar, and digital arteries is performed to evaluate the quality of Doppler waveforms. Auscultation of the supraclavicular and infraclavicular fossa may reveal a bruit, indicating possible subclavian artery stenosis.

The hands and digits should be examined carefully, with temperature, capillary refill, and ulcers noted. Fingers should be examined for clubbing, sclerodactyly, and telangiectasia; nail beds should be checked for splinter hemorrhages. Clubbing is seen in chronic pulmonary disease. Telangiectasia and sclerodactyly are seen in scleroderma among various other connective tissue diseases. Splinter hemorrhages in nail beds are seen in embolic disease. Finally, a complete upper extremity neurologic examination may give clues to external compression of neurovascular bundle.

Vascular Laboratory Evaluation

Basic vascular laboratory evaluation consists of segmental pressure measurements of the upper extremity and finger pressure measurements and waveforms (Fig. 117.1). This allows differentiation of large artery disease (reduced wrist arterial pressure with no further reduction at the finger level) from small artery disease (normal upper extremity examination, abnormal finger pressures). Duplex ultrasonography is also particularly useful in large vessel occlusive diseases, such as subclavian artery stenosis (Fig. 117.2).

The diagnosis of Raynaud's phenomenon is made clinically. However, qualitative testing for the severity of cold sensitivity in Raynaud's syndrome can be useful. The most basic test for cold sensitivity is finger temperature recovery after ice-water immersion. If the initial battery of tests is nondiagnostic and the patients have significant obstructive disease (by vascular laboratory criteria) or digital ulceration, further testing to determine the presence of a hypercoagulable state is conducted.

This screening battery consists of antithrombin III, protein C, and protein S levels, which are tests for the presence of anticardiolipin and antiphospholipid (lupus inhibitor) antibodies, Lp(a) levels in patients with hyperlipidemia, and tests for familial hypercoagulable states such as factor V Leyden (Table 117.2).

Other Imaging

Imaging can be extremely useful when the diagnosis cannot be established by clinical assessment and basic vascular laboratory studies alone. For embolic disease, both duplex ultrasound and echocardiography are recommended. If these do not reveal an embolic source, the aortic arch and intrathoracic upper extremity arteries should be imaged. Both computed tomographic arteriography (CTA) and magnetic resonance arteriography (MRA) provide excellent resolution and are less invasive than catheter-based arteriography.[41]

Finally, invasive arteriography is generally reserved for patients with unexplained digital artery occlusion in an asymmetrical distribution to rule out a surgically correctable proximal lesion where a CTA or MRA fails to reveal an etiology (Fig. 117.3). The entire upper extremity vasculature should be visualized. In addition, both upper extremities should be imaged. The presence of significant bilateral disease, even with unilateral symptoms, is an indication of a systemic disease.

Treatment

Medical

Most patients with idiopathic Raynaud's syndrome are best treated with cold and tobacco avoidance, with medication reserved for more severe cases. Several medications have been shown to be beneficial in the treatment of Raynaud's syndrome. The most effective drug to date has been the calcium channel blocker nifedipine.[42] Losartan has also been demonstrated to be effective in patients with Raynaud's syndrome in randomized trials.[43] Many of these patients are young women who do not tolerate year-round antihypertensive medications. Patients may take the medication from late fall to late spring or when they anticipate facing cold exposure. Fluoxetine, a selective serotonin uptake inhibitor, has also been shown to be effective in a double-blind, randomized, controlled trial.[44] Other drugs that have a modest clinical effect and have been used in the treatment of Raynaud's syndrome include prazosin,[45] sildenafil,[46] reserpine, cilostazol,[47] captopril.[48] Bosentan, an endothelin receptor blocker, appears to particularly benefit in patients with scleroderma.[49] These patients typically have a benign disease course and tissue loss is rare.

Unfortunately, the results in patients with obstructive Raynaud's syndrome are less satisfying. Pharmacologic

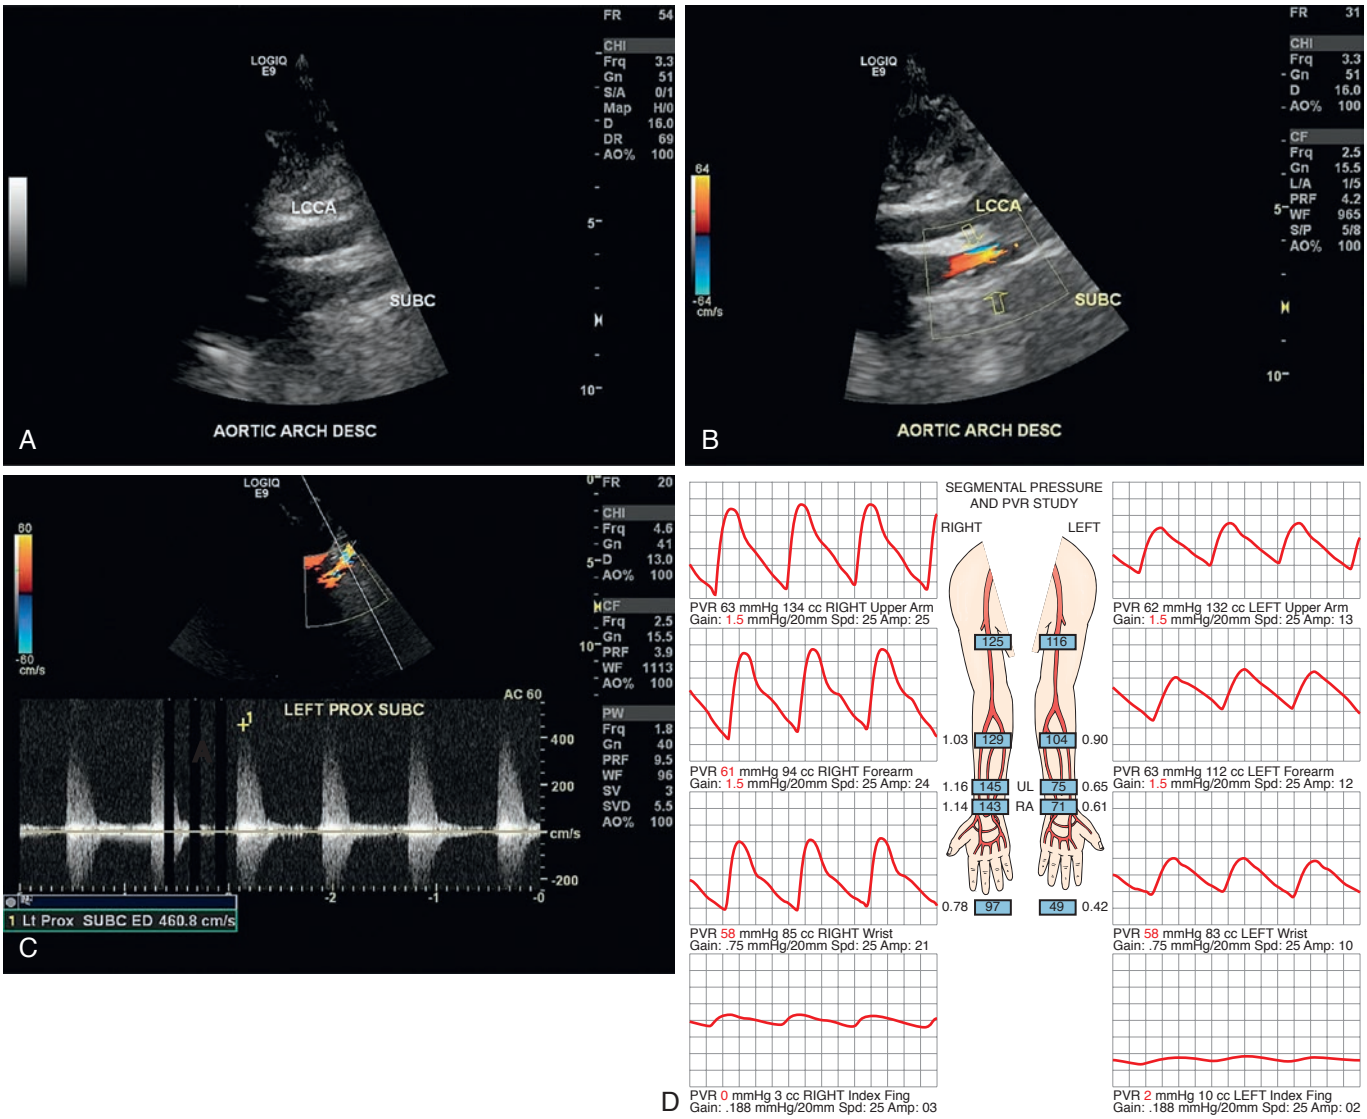

Figure 117.2 Left Subclavian Artery Stenosis Demonstrated on Ultrasound. (A) B-mode ultrasound image of the descending aortic arch with the left common carotid artery and left subclavian artery origins clearly visible. A bulky atherosclerotic plaque is narrowing the origin of the left subclavian artery. (B) Color Doppler image demonstrating arterial flow through the stenosis at the origin of the left subclavian artery *(yellow arrows)*. (C) Color duplex image with the velocity through the left subclavian artery stenosis dramatically elevated at 460.8 cm/s. (D) Segmental pressures and pulse volume recordings of the same patient identifying reduction in PVR amplitude and latency and reduced wrist and finger to brachial index.

intervention is less effective in these patients. About 20% to 30% of patients do not tolerate nifedipine because of ankle swelling, headache, or fatigue. This group has an intermediate risk for progression that is dependent on the natural history of the underlying cause of the obstruction.[5]

Patients with both arterial obstruction and an underlying disease have the worst prognosis and the highest risk for ulceration and tissue loss. These patients are likely to progress slowly over time. Of note, if ulceration is not present at the initial consultation, it is unlikely to develop in the future, and those with ulceration have only 50% chance of further ulceration developing.[5]

Surgical

Thoracic sympathectomy has been used both for treatment of digital artery vasospasm and as an adjunct for healing of digital ischemic ulceration. For vasospasm, thoracic sympathectomy is usually initially successful, but the symptoms invariably return, usually within 3 to 6 months.[50] The exact basis of this lack of durability is unknown but could be attributed to the rich network of collateral nerve pathways in the upper extremity. Alternatively, periarterial digital sympathectomy performed in the common digital arteries has been suggested as a superior strategy, and a number of small series claim long-lasting benefit from such a

procedure.[51] Thoracic sympathectomy as an adjunct measure for digital ulceration is unproven. In a study of 100 patients with digital ulceration, patient outcomes were independent of whether they underwent sympathectomy.[52] Patients with digital ulceration have obstructed digital arteries and are most likely already maximally vasodilated; thus, sympathectomy is unlikely to improve blood flow. Other treatments that have been reported include spinal cord simulation[53] and biofeedback.[54]

Thoracic outlet syndrome requires cervical or first rib resection. Large artery occlusion, arterial aneurysm, thoracic outlet syndrome with arterial damage or occlusion, fibromuscular disease, and upper extremity arterial trauma with symptoms are best treated by revascularization. Revascularization may be achieved via open bypass or by interventional techniques such as angioplasty with or without stenting.

Results for upper extremity bypass are excellent and even superior to those reported for lower extremity ischemia. Twenty upper extremity bypasses were performed for chronic upper extremity ischemia over a 13-year period at our institution with outstanding patency and limb salvage rates of 85% and 100% at 3 years.[55] Patients that underwent upper extremity bypass compared with those with lower extremity bypass were younger, less likely to be diabetic, and more likely to undergo surgery due to exercise intolerance (claudication equivalent). The inflow varied from brachial (65%), axillary (30%), and ulnar (5%). The outflow consisted of the brachial (60%), radial (25%), and ulnar (5%). The conduits used were great saphenous vein (55%), arm vein (35%), and prosthetic graft (10%). Excellent patency (90%-96%) and limb salvage rates (100%) of upper extremity bypass at 1 year have been reported by other groups as well.[56,57]

Revascularization options for the upper extremity are discussed in a separate chapter. If the revascularization is unsuccessful and the extremity is nonviable, amputation may be necessary. Fortunately, upper extremity amputation is rare.

SUMMARY

Upper extremity ischemia is less common than lower extremity ischemia. Possible etiologies could be vasospastic or occlusive. Occlusive disease is associated with worse prognosis for developing tissue loss. Most patients appear to have their most severe symptoms at the time of presentation. Vasospastic etiologies

Figure 117.3 A sample of an abnormal hand and forearm arteriogram (A, unsubtracted; B, subtracted) where the ulnar artery *(arrow)* is occluded from an embolus *(arrow)*.

are more responsive to pharmacologic intervention, with nifedipine and losartan the best studied medications. Sympathectomy does not confer a durable response in vasospasm and is of little to no use in occlusive disease. Finally, bypass is a viable option in patients with occlusive disease with excellent 1- to 3-year outcomes.

Upper extremity arterial occlusive disease is responsible for less than 5% of all cases of limb ischemia.[1] Even in high-volume centers, arm reconstructions account for only 3% of elective limb revascularizations. Palmar and digital artery occlusive disease is the most common cause of upper extremity arterial occlusive disease, whereas large-vessel disease, including arteries proximal to the wrist, account for less than 10%. The majority of arm emboli are cardiac in origin (75%). The most common site for emboli is the brachial artery (60%), followed by the axillary artery (26%). In situ thrombosis accounts for only 5% of episodes of arm ischemia.[2] This chapter deals with revascularization for both acute and chronic ischemia involving the intrinsic arteries of the upper extremities, including the axillary, brachial, radial, ulnar, and palmar arteries. Raynaud phenomenon (see Chapter 141), thoracic outlet syndrome (see Chapter 120), brachiocephalic artery disease (see Chapters 98 and 99), and Takayasu arteritis (see Chapter 139) are described elsewhere. Because the volume of these procedures is small, it is difficult to draw evidence-based conclusions on the optimal approach for patients with upper extremity ischemia. Upper extremity occlusive disease is far less prevalent than lower extremity peripheral vascular disease. Accordingly, research on lower extremity treatment strategies has far outpaced the upper extremity with relatively few reports added to the upper extremity revascularization literature over the last several years. Patients with diabetes mellitus and chronic renal failure make up a significant proportion of those with digital gangrene. Treatment presents a challenge that often involves difficult reconstruction, meticulous wound care, and patience.

Abstract

Upper extremity arterial occlusive disease is a relatively infrequent cause of limb ischemia. Palmar and digital artery occlusive disease is the most common cause of upper extremity arterial occlusive disease, whereas large-vessel disease, including arteries proximal to the wrist, accounts for less than 10%. The majority of arm emboli are cardiac in origin (75%), and the most common site for emboli is the brachial artery (60%) followed by the axillary artery (26%). This chapter deals with revascularization for both acute and chronic ischemia involving the intrinsic arteries of the upper extremities, including the axillary, brachial, radial, ulnar, and palmar arteries. Because the volume of these procedures is small, it is difficult to draw evidence-based conclusions on the optimal approach for patients with upper extremity ischemia. Upper extremity occlusive disease is far less prevalent than lower extremity peripheral vascular disease. Accordingly, research on lower extremity treatment strategies has far outpaced the upper extremity, with relatively few reports added to the upper extremity revascularization literature over the last several years. Patients with diabetes mellitus and chronic renal failure make up a significant proportion of those with digital gangrene. Treatment presents a challenge that often involves difficult reconstruction, meticulous wound care, and patience.

CLINICAL FINDINGS

Patients may have either acute or chronic ischemic symptoms, as discussed in detail in Chapter 117.

Acute Arm Ischemia

Arms with acute ischemia account for only one-fifth of all acutely threatened limbs. A recent systematic review found that out of 1326 acutely ischemic upper extremities, 92% were attributed to thromboembolic disease (usually of cardiac origin), with the second most common cause being iatrogenic (1.5%).[3] Women are affected more often than men, and patients are significantly older than those with acute symptoms in the lower extremity.[4] Most reports of acute arm ischemia generally involve those who required surgery; thus, the denominator is difficult to calculate. The classic symptoms involve the "six P's": pain, pallor, paresthesia, paralysis, pulselessness, and poikilothermia. The fingers and hand are often cool with obvious color changes. Numbness and tingling are common. Motor dysfunction may range from mildly diminished hand strength to paralysis. Wrist pulses are usually absent while axillary and/or brachial pulses may remain palpable. Doppler interrogation at these sites often produces an occlusive or "water hammer" signal.

Chronic Arm Ischemia

Whereas chronic leg ischemia is usually due to atherosclerosis, the causes of chronic arm ischemia are more diverse. Although atherosclerosis is still one etiology, consideration must be given to other pathologies, such as thoracic outlet syndrome, iatrogenic injury after arm catheterization, and less frequent causes, such as Takayasu or giant cell arteritis, and radiation-induced injury. Hand and finger ischemia has been reported with increasing frequency in patients with end-stage renal disease.[5,6] The etiologic backgrounds of this disease process are multiple and include thrombosis, accelerated atherosclerosis, and diffuse arterial calcification. The origin of this condition may well involve atherosclerosis, but there is a well-described association with calciphylaxis.[7]

Manifestations of chronic arm ischemia can include arm fatigue with activity, digital pain at rest, and tissue loss with ulceration or gangrene. Initial assessment is by noninvasive studies, such as pulse volume recordings or duplex ultrasound, followed by magnetic resonance angiography (MRA) or computed tomographic angiography (CTA). Confirmation of these findings can be obtained by aortic arch and arm catheter angiography. Occlusive lesions will be located in the axillary, brachial, or forearm arteries. Each requires separate treatment strategies.

Another clinical situation of hand ischemia encountered in patients with end-stage renal disease is that associated with an ipsilateral upper extremity arteriovenous fistula. The onset of hand ischemia is a devastating complication of upper extremity hemodialysis access. Arteriovenous shunts are almost always associated with some degree of reduced arterial flow to the distal circulation. Untreated, this may produce pain, ulceration, and gangrene in a previously viable extremity. Although prevention of this complication remains paramount, several techniques are available to manage this problem once diagnosed. Chapter 179 describes the diagnosis and management of steal-associated ischemia and critical upper extremity ischemia caused by infrabrachial disease in renal failure patients.

TREATMENT

Conservative Therapy

Between 9% and 30% of patients seen by vascular surgeons with upper extremity arterial occlusive disease are managed conservatively because of significant comorbid conditions or minimal symptomatology. Conservative therapy classically includes anticoagulation for acute or subacute ischemia. Adjunct therapies, such as calcium channel blockers, topical nitrates, and phosphodiesterase inhibitors, have also been used with variable success. Smoking cessation, optimizing cardiac output, avoiding vasopressors, and warming the upper extremity are also useful to obtain the best possible outcome.

Postoperative mortality rates for brachial embolectomy are as high as 12%.[8] However, after successful brachial embolectomy, 95% of patients will remain free of symptoms.[9] Patients managed conservatively are probably underreported in the literature. In the few reported series, assessment of symptoms and disability tends to be inconsistent. However, in a series of 95 patients described by Baird and Lajos in 1964 with arm ischemia managed without surgery, 32% were left with permanent disability in the arm.[10] In 1977, Savelyev and coauthors reported that 75% of patients managed conservatively had a poor functional outcome.[11] In 1985 Galbraith and associates confirmed that 50% of their conservatively managed patients had persistent exercise-induced forearm pain (a claudication equivalent).[12] Therefore, although conservative management is appropriate for some patients with acute ischemia, for those with a reasonable life expectancy, all efforts should be made to restore blood flow.

Endovascular Treatment

Endovascular therapies for the treatment of arterial occlusive disease have increased in popularity over the last decade with advancement in catheter, balloon, and stent technology. The majority of lower extremity revascularizations in contemporary vascular surgery practices are now done percutaneously. However, the upper extremity has not shared the same paradigm shift, possibly due to the relative infrequency of interventions or the underlying causes of the arterial disease. A recent Japanese multicenter study reviewed 553 patients undergoing primary endovascular therapy with angioplasty and/or stenting for subclavian artery occlusive disease, with a primary patency of 90% at 1 year and 81% at 5 years.[13] Most institutional reviews that describe treatment of occlusions in the axillary, brachial, radial, and ulnar arteries still involve surgical bypass or embolectomy.[14,15] There are scattered reports of emergency placement of covered stents in the axillary artery in trauma patients.[16] An example of such therapy is illustrated in Fig. 118.1. There are also reports of small series of patients treated by axillary artery angioplasty for radiation-induced occlusion, by brachial artery

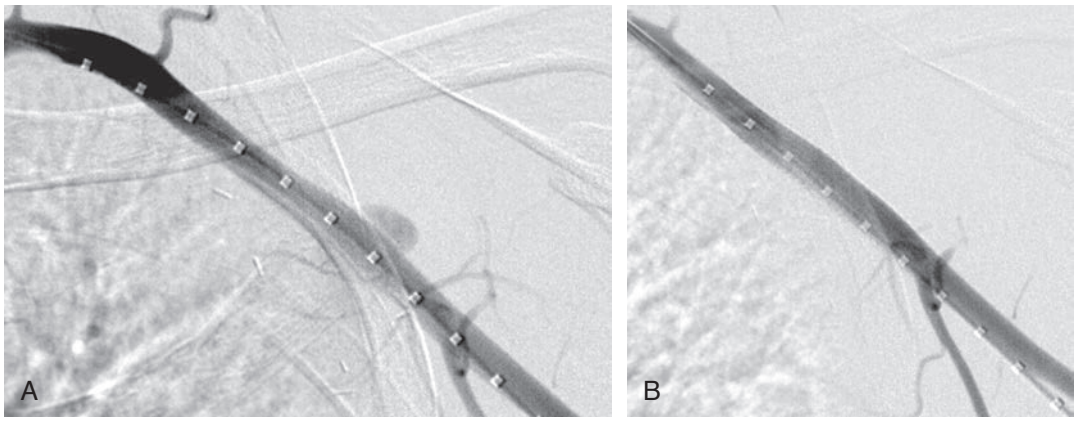

Figure 118.1 (A) Angiography of the left arm after penetrating trauma reveals a pseudo-aneurysm off the axillary artery (B). After deployment of a covered stent graft in the axillary artery, no further extravasation is seen.

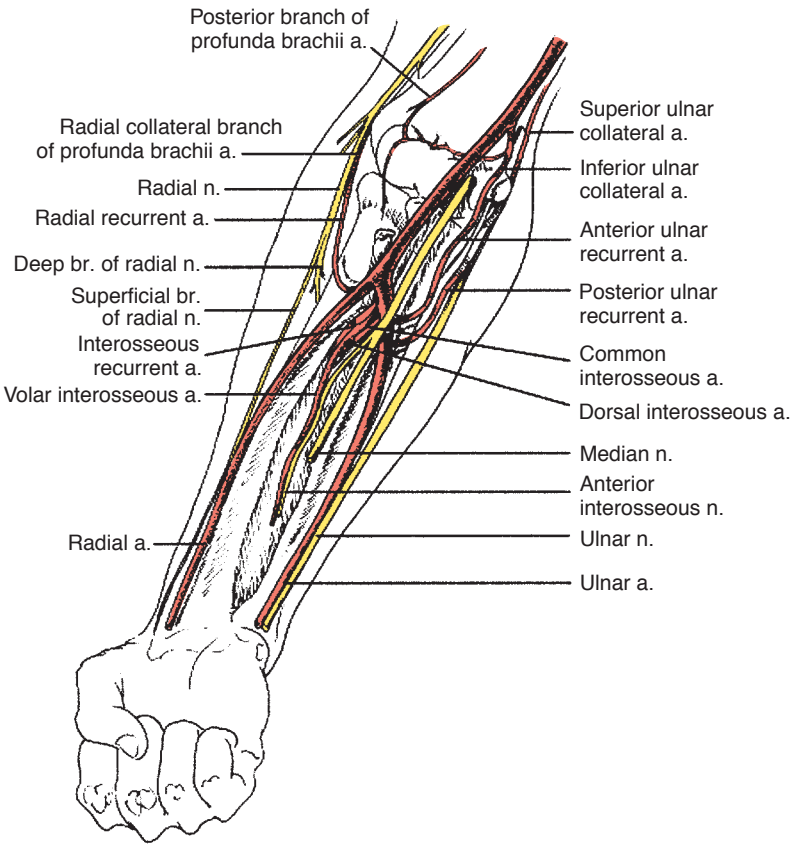

Figure 118.2 Forearm nerve and vessel anatomy. The brachial artery typically bifurcates just below the elbow. (From Valentine RJ, Wind CG. *Anatomic Exposures in Vascular Surgery*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2003.)

atherectomy, and by radial artery stenting for digital gangrene, but their numbers are low and follow-up is minimal.[17-20] Therefore, dissection and exposure of the arterial anatomy for revascularization will be described at the most common levels of intervention (Fig. 118.2).

SURGICAL TREATMENT

Arterial Exposure

Axillary Artery

The patient is positioned supine and the arm is draped circumferentially. The axillary artery is exposed with a transverse incision 2 cm below the middle third of the clavicle (Fig. 118.3). The underlying pectoralis major muscle is divided, when possible, in the decussation between the sternal and clavicular portions. Despite the descriptions found in most operative texts, this point is not always readily apparent. Division of the pectoralis major exposes the clavipectoral fascia, which is divided. The axillary artery is located cephalad to the vein. It is dissected carefully to avoid injury to the surrounding cords of the brachial plexus. The second portion of the axillary artery can be exposed by dividing the pectoralis minor muscle. If needed, the distal third of the axillary artery may also be exposed. An oblique incision is made along the lateral margin of the pectoralis major muscle with the arm abducted 90 degrees relative to the thorax.

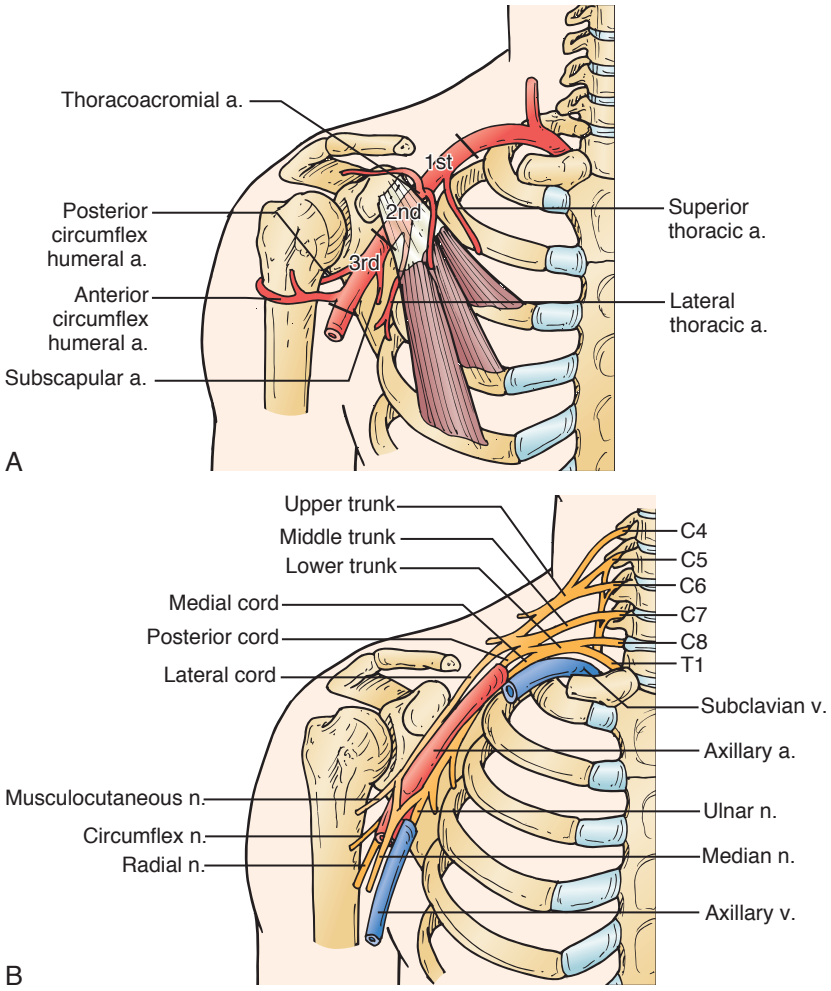

Figure 118.3 Exposure of the axillary artery. **A,** Segments of the axillary artery are defined by the relationship to the coracoid process and the pectoralis minor muscle. This muscle can be divided to provide full axillary artery exposure. **B,** The brachial plexus is intimately associated with the axillary artery at all levels and must be avoided during dissection.

Once the subcutaneous tissue is divided, the axillary sheath is located near the posterior and inferior border of the coracobrachialis. Careful dissection avoids injury to the medial and lateral cords of the brachial plexus medially and the median and ulnar nerves laterally.

Brachial Artery

The mid or distal brachial artery is exposed through a medial incision over the bicipital groove. This allows access to the proximal or middle third of the brachial artery. The basilic vein and cutaneous branches of the median nerve are located within the subcutaneous tissue and should be avoided during dissection. Traction or transection of the median antebrachial cutaneous nerve may lead to hyperesthesia or anesthesia along the medial dorsal surface of the forearm. This occasionally occurs after dialysis access (e.g., basilic vein transposition) and can be debilitating for the patient. In some cases, it can even preclude the use of a patent and mature fistula. The brachial sheath is then incised longitudinally. The median nerve is the most superficial structure encountered. The nerve is gently mobilized and retracted to allow access to the brachial artery. Crossing vein branches should be divided to minimize the risk of injury to the posteriorly located ulnar nerve.

The distal third of the brachial artery and its bifurcation, in contrast, are exposed in the antecubital fossa (Fig. 118.4). A lazy S–shaped incision is recommended to expose the origins of the ulnar and radial arteries. Sometimes a vertical incision is used. However, there is a legitimate concern about contracture of the elbow with vertical incisions. The skin and subcutaneous tissues are divided. Care is taken to preserve the superficial veins, especially the median antecubital vein, because it may be required for autogenous patch angioplasty closure. The bicipital fascia is incised and the brachial artery is seen coursing between the biceps tendon laterally and the median nerve medially. Dissection is continued distally until the ulnar and radial arteries are encountered. The radial artery is really a continuation of the brachial artery. The ulnar artery, on the other hand, comes off the brachial artery medially and, within 2 to 3 cm, dives beneath the pronator and epitrochlear muscles.

Radial Artery

The course of the radial artery in the forearm follows an oblique line from the brachial artery pulse medial to the biceps tendon to the styloid process of the radius. In the midforearm, the radial artery is medial to the brachioradialis and lateral to the flexor carpi radialis. A lateral longitudinal incision is made. The

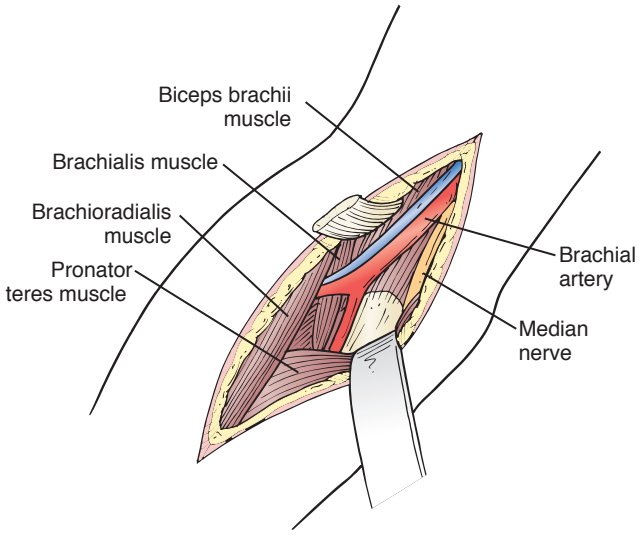

Figure 118.4 Exposure of the brachial artery at the elbow. The bifurcation of the brachial artery can be exposed by retracting the pronator teres and flexor muscle mass. The radial artery can be followed the length of the incision, but the larger ulnar artery dives between the heads of the flexor digitorum superficialis.

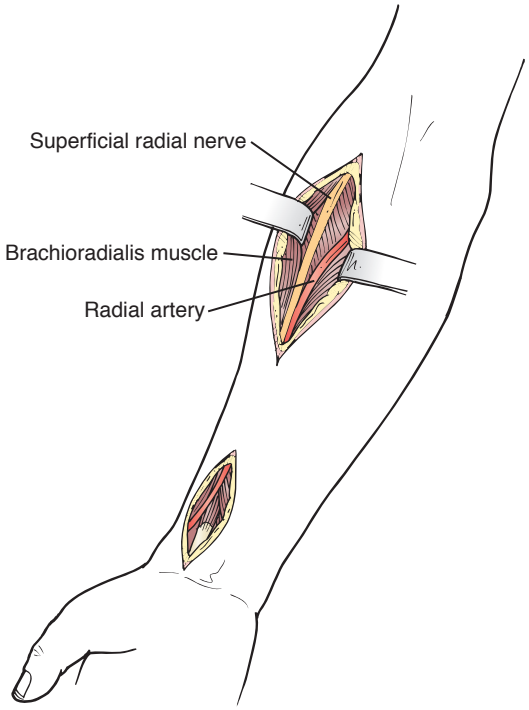

Figure 118.5 The radial artery in the midforearm can easily be exposed beneath the brachioradialis.

muscles are separated to reveal the radial artery as needed (Fig. 118.5).

At the wrist, the radial artery is exposed by a longitudinal incision between the tendons of the flexor carpi radialis and the brachioradialis muscles. This is the traditional site of the radial artery pulse in normal subjects. The artery is superficial and exposure is relatively straightforward. The superficial branch of the radial nerve is often located near the lateral aspect of the

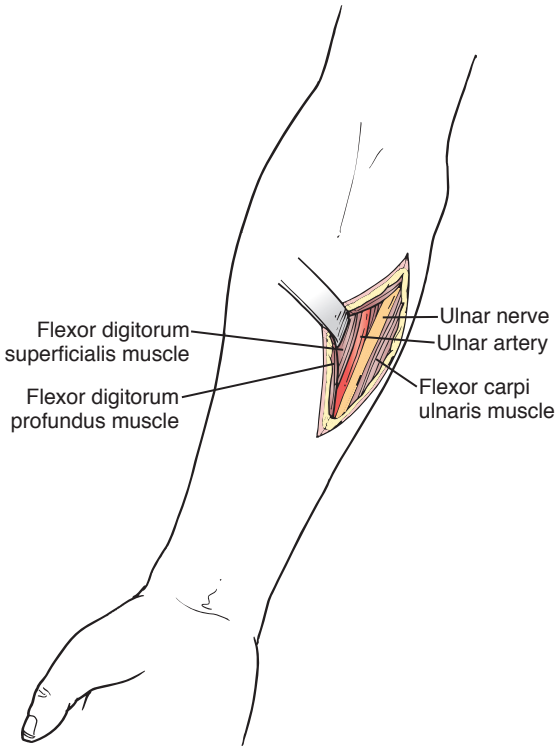

Figure 118.6 Exposure of the forearm ulnar artery. The ulnar artery in the midforearm is reached between the flexor carpi ulnaris and flexor digitorum superficialis.

artery. Injury can result in troublesome paresthesias along the lateral aspect of the thumb.

Ulnar Artery

The ulnar artery extends from the medial epicondyle of the humerus to the pisiform bone. In the midforearm, the ulnar artery lies beneath the deep fascia between the bellies of the flexor digitorum laterally and the flexor carpi ulnaris medially (Fig. 118.6). The ulnar nerve joins the artery on its lateral aspect for its distal two-thirds. It may be injured if not carefully identified and preserved.

At the wrist, the ulnar artery is lateral to the flexor carpi ulnaris (it is the most medial tendon palpable at the wrist). For exposure, this tendon is identified and a vertical skin incision is made lateral to it. The ulnar artery is relatively deeper than the radial artery at the wrist, but is just as easily exposed. The palmar cutaneous branches of the ulnar nerve are superficial to the artery here and should be preserved.

Interosseous Artery

The interosseous arteries of the forearm are naturally the smallest and most deeply situated of the forearm vessels. They are the embryologic analogue to the peroneal artery in the lower extremity, an artery of supply to the distal extremity musculature. The initial few millimeters of the common interosseous artery can be accessed by following the ulnar artery down from the brachial artery, dividing some of the fibers of the superficial flexor digitorum, and looking for the large branch going lateral and deep from the ulnar artery.

The common interosseous bifurcates into an anterior (or volar) interosseous and a posterior (or dorsal) interosseous just proximal to the forearm interosseous membrane. Exposure of the length of the anterior interosseous artery is best done through the same incision used to expose the midportion of the ulnar artery and then to separate the flexor carpi ulnaris from the superficial flexor digitorum. After an incision long enough to release the fascia is made, the superficial flexor digitorum is elevated along with the median nerve, and dissection is carried along the volar surface of the flexor digitorum profundus. Next, the flexor pollicis longus is elevated toward the radius to expose the anterior interosseous neurovascular bundle; some fibers of the flexor pollicis longus may partially cover the anterior interosseous artery and need to be divided. The posterior interosseous artery is best approached through a dorsal forearm skin incision along the medial aspect of the radius. This artery is usually smaller and less often used for revascularization.

Palmar Arteries

Exposure of the palmar arteries is not routinely performed in many vascular surgery centers. The blood supply of the hand is supplied by the superficial and deep palmar arches. The superficial palmar arch is supplied by a branch of the radial artery and the ulnar artery. The deep palmar arch is supplied by the radial artery itself and a deep branch of the ulnar artery. Exposure of the radial artery, ulnar artery, and superficial palmar arch is relatively straightforward, and these vessels match the distal tibial or pedal vessels in the leg in size. The deep palmar arch is much more difficult to expose and deeply located and thus is relatively inaccessible.

Exposure of the distal radial artery can be performed as described earlier. Alternatively, exposure can be accomplished by making a vertical incision over the anatomic snuff-box (the snuff-box lies between the extensor pollicis longus tendon posteriorly and the tendons of the extensor pollicis brevis and abductor pollicis longus anteriorly). After deepening the incision through subcutaneous tissue, the radial artery can be exposed in the floor of the snuff-box (Fig. 118.7). Because there are no significant nerves at this level, it is often chosen as a site for hemodialysis access.

Distal ulnar artery and superficial palmar arch exposure is best accomplished via a curved incision along the lateral border of the hypothenar eminence (Fig. 118.8). The aponeurotic layer is divided and the artery is then exposed in the upper part of the palm at the origin of the superficial palmar arch. No major nerves pass in the vicinity, and a reasonable length of artery can usually be exposed for an arterial anastomosis. Alternatively, the superficial palmar arch can be exposed in the palm by making an incision along one of the larger vertical or oblique skin creases.

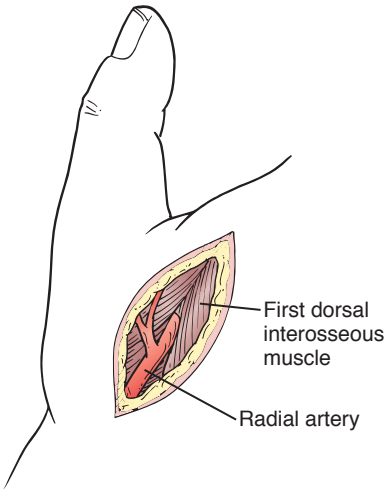

Figure 118.7 The segment of radial artery beyond the extensor pollicis longus tendon is exposed.

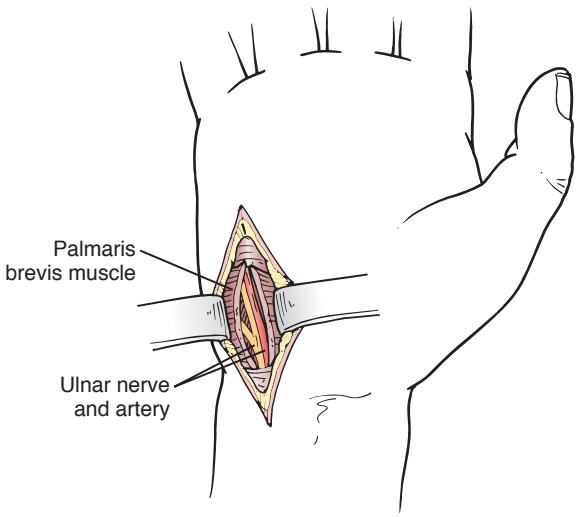

Figure 118.8 The ulnar artery and nerve beyond the tunnel of Guyon are exposed beneath the palmaris brevis muscle and the hypothenar fascia.

Bypass Conduit and Tunneling

The autogenous vein is the conduit of choice for upper extremity reconstructions. The great saphenous vein is preferable, although use of the in situ cephalic vein has been described.[21] The more joints that the bypass crosses, the lower the patency rate.[22] After systemic heparinization, the venous conduit is excised and its side branches ligated with fine polypropylene suture or silk ties. The vein is distended with a solution of dextran, heparin, and papaverine (500 mL bag of dextran 40 + 120 mg papaverine + 1000 units heparin). The excised conduit may be used in either reversed or orthograde (nonreversed) orientation, depending on the taper of the conduit. If orthograde orientation is used, the proximal anastomosis is performed, the conduit is distended, and the valves are rendered incompetent by the passage of a retrograde Mills valvulotome. Prosthetic reconstructions in this setting have lower patency rates than venous bypasses, and should be avoided.[14] The management of infection in prosthetic grafts also can be challenging.

Bypasses originating from the axillary artery are preferably tunneled anatomically along the axis of the axillary and brachial arteries because they are then less prone to movement or distortion. They may also be positioned anteriorly in the subcutaneous plane. However, superficial bypasses are more prone to distraction

Figure 118.9 Palmar artery bypass completion arteriogram.

Figure 118.10 Digital artery bypass completion arteriogram.

injuries from forcible abduction of the shoulder. Therefore, redundancy is paramount to avoid harming the conduit. As another alternative, there is at least one case report of a retrohumeral approach for tunneling.[23] This involves a more proximal reconstruction, which originates in the supraclavicular fossa and then traverses the subcutaneous plane inferior to the acromion process. The conduit continues from the posterior aspect of the upper arm around both medial and anterior aspects, where it descends through the fascia to the brachial artery.

Bypasses based on brachial artery inflow are most often tunneled in the subcutaneous plane. This facilitates physical examination for appropriate evaluation of bypass patency, ensures surveillance of the bypass with duplex if readily available, and avoids manipulation of the rich forearm nerve network. Alternatively, if good-quality basilic or cephalic veins are present, an in situ bypass may be performed.

In the case of distal radial sided reconstructions, the graft is tunneled subcutaneously over the extensor pollicis tendons toward the anatomic snuff-box onto the dorsum of the hand. The bypass ends between the thumb and index finger, where the deep palmar arch (Fig. 118.9), or even a digital vessel in the absence of a complete arch (Fig. 118.10), is exposed. In the case of ulnar-sided reconstructions, the course of the vein graft is more direct and it passes superficial to the flexor retinaculum in the subcutaneous plane at the wrist lateral to the pisiform bone to join the superficial palmar arch.

Transbrachial Embolectomy

When an embolectomy is planned, several considerations are essential. If preoperative imaging (usually duplex ultrasound) has demonstrated occlusion of the distal brachial artery, it is important to expose the origins of both forearm arteries because the embolectomy catheter must be passed down each artery. If the catheter is passed blindly down the brachial artery, it will most likely travel down the radial artery. This will probably reestablish flow to the hand in the majority of patients. However, it may fail to restore adequate flow if the ulnar is the dominant arterial blood supply or if the catheter passes down the common interosseous artery, which does not provide any direct flow to the hand. We usually make a transverse arteriotomy in the brachial artery. Clots, which are frequently encountered at the bifurcation, can be readily removed. The majority of brachial embolectomies are performed under local anesthesia with monitored anesthesia care. The brachial artery may be pulseless, indicative of an embolus lodged more proximally. However, one concern with proximal passage of an embolectomy catheter is dislodgment of debris that may embolize the vertebral artery near the origin of the subclavian artery. If there is any concern, contrast-enhanced angiography is warranted to define the anatomy. Once inflow is established, a size 2 or 3 French embolectomy catheter is passed distally down each forearm vessel. The arteriotomy can be closed primarily with running fine polypropylene suture if the artery is sufficiently large. If there is any doubt, the artery should be closed with a vein patch. Usually, a segment of vein can be harvested from the antecubital fossa.

After closure, an intraoperative continuous wave Doppler probe should be applied to each artery to ensure the presence of adequate flow. Immediate completion angiography is at the discretion of the surgeon, but should be performed if the hand still appears ischemic, especially if extensive thrombus has been extracted from forearm arteries. Occasionally, embolization may have been a chronic process and resulted in distal arterial occlusion that cannot be completely resolved with embolectomy, but arteriography can be used to detect residual fresh thromboembolic material. If there is any suspicion of an inflow lesion, intraoperative arteriography can be performed by either the femoral or brachial route to diagnose and treat such lesions. A recent Italian study by Zaraca et al. demonstrated a significant reduction in 2-year reocclusion rates in patients undergoing angiography after embolectomy (12% vs. 2% without angiography). After embolectomy, the rate of extension of the procedure was 26% in the angiography group versus 4% in the group without intraoperative angiography, suggesting that routine intraoperative angiography impacts outcomes and may be associated with a more thorough embolectomy.[24]

Postoperative Management and Follow-Up

Postoperatively, surveillance with pulse volume recordings or Doppler segmental pressure measurements can be used to document the adequacy of the bypass. Duplex ultrasonography is used to determine the patency of the reconstruction and allow early detection of stenoses during surveillance of the venous conduit. The number of series reporting long-term patency is limited. Roddy et al. identified a 90% primary patency and 100% limb salvage rate at 1 year in their cohort of 61 bypasses.[14] More recently, Spinelli and colleagues identified 23 patients with chronic ischemia that underwent upper extremity bypass.[25] At a mean of 34 months, primary patency was 83% with a limb salvage rate of 100%. Anticoagulation is essential after embolectomy. Recurrent embolization occurs in one-third of patients after successful embolectomy if systemic anticoagulation is not instituted. In an Edinburgh study, even in patients started on warfarin after embolectomy, 11% sustained a further embolus if they had ongoing atrial fibrillation.[4] In those patients without atrial fibrillation as the source of embolus and in whom no preoperative, intraoperative, or immediate postoperative angiography has been performed, formal diagnostic arteriography, CTA, or MRA should be considered to rule out alternate etiologies for thromboembolism. Intracardiac assessment with echocardiography is indicated if no arterial source is identified.

ALTERNATIVE THERAPY

Sympathectomy has been used with isolated reports of success,[26,27] but the experience in most centers has been less than optimal (see Chapter 194). Thrombolysis of acutely occluded axillary or brachial arteries has been described with reasonable outcomes.[26] However, in one large series, success was reported in just over half of the limbs treated, and 8 of 55 patients required surgical thrombectomy.[28] Thrombolysis has also been described as a treatment option for acute finger ischemia with disease distal to the wrist. In a small series, half the patients (8 of 16) experienced anatomic improvement on repeat angiography, but functional outcomes are less clear.[29]

TRAUMA

Upper extremity trauma is relatively frequent and can be iatrogenic or noniatrogenic (see Chapter 181).

Iatrogenic Trauma

Brachial Artery

Brachial artery pseudoaneurysm, or occlusion related to cardiac catheterization, is one of the most common indications for arterial surgery in the upper extremity.[30] The presence of a pseudoaneurysm may be suggested by a mass at the puncture site, evidence of distal occlusion or embolization, or neurologic complications related to median nerve compression within the sheath, usually manifesting as paresthesias. The diagnosis can generally be made with duplex ultrasonography (Fig. 118.11), and direct repair with evacuation of the hematoma compressing the median nerve can be performed under local anesthesia. Percutaneous thrombin injection is another therapeutic option described in the literature. In a report of 14 patients successfully treated with ultrasound-guided thrombin injection for iatrogenic upper extremity pseudoaneurysms, there was a low complication rate with no recurrences at 8 months.[31]

Occlusion of the brachial artery as a result of catheter insertion often requires more extensive reconstruction that usually involves a segmental bypass with either saphenous vein or cephalic vein from the ipsilateral arm. If recognized promptly, any propagated thrombus proximal or distal to the puncture site can be extracted

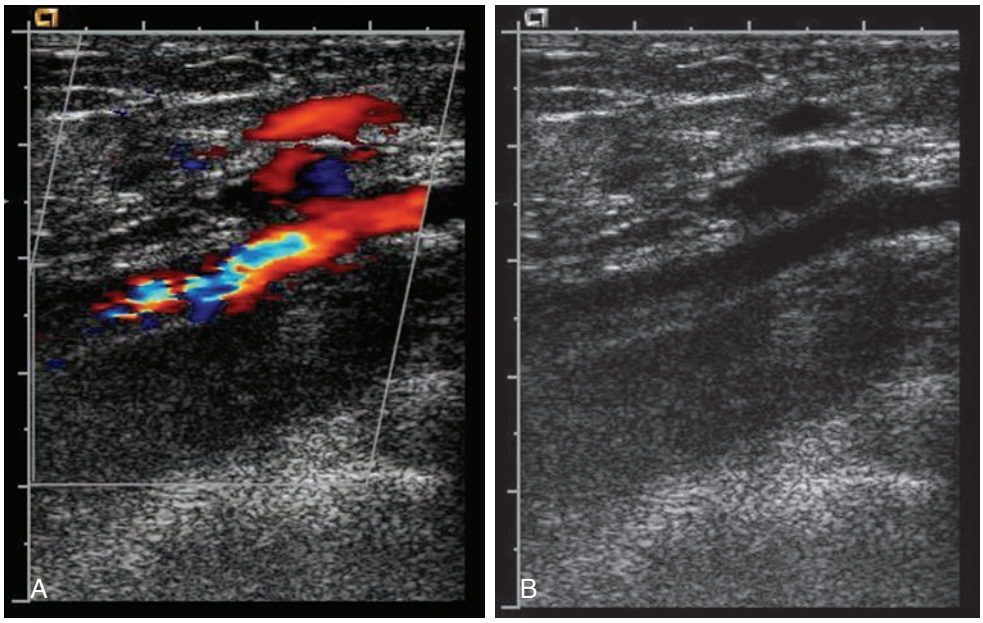

Figure 118.11 Brachial artery pseudoaneurysm after cardiac catheterization, as seen through color duplex (A) and B-mode (B) ultrasound imaging.

with a balloon embolectomy catheter. Delayed recognition of this problem will often necessitate a longer-segment interposition graft with autogenous vein.

Radial Artery

The radial artery is the second most common site of upper extremity iatrogenic arterial injury as a result of catheterization. Partial or complete occlusion of the radial artery after cannulation for monitoring purposes was apparent in 25% of 1699 patients undergoing cardiovascular surgery in a series by Slogoff and colleagues. None of these patients had hand ischemia.[32] Although the involved hand may be clinically pale, the fingers usually remain viable with intact neurologic function due to collateral filling across the palm from the ulnar artery. Unless there is some obvious evidence of severe cyanosis, demarcation, neuropathy, or sensorimotor deficit, we would generally recommend a period of observation after removal of the arterial catheter. Heparinization is desirable but not mandatory. Many of these cases will improve with conservative treatment. In the few cases in which the hand either acutely or subacutely appears to be severely ischemic, repair with a short autogenous bypass of the radial artery above and below the puncture site is usually sufficient to effect improvement. Radial and ulnar artery vascular access for cardiac catheterization using up to 6 Fr sheath systems, is increasing. Occlusion rates have been reported to be approximately 5% in either vessel,[33] and the overwhelming majority are asymptomatic and do not require reconstruction.

Noniatrogenic Trauma

Trauma related to blunt or penetrating trauma is, unfortunately, a common source of upper extremity arterial injury.[34] In civilian centers, these injuries are predominantly blunt or involve low velocity penetration. Military-associated upper extremity vascular injuries are complex because of the combined nature of the mechanism and significant multi-system injury.

Penetrating Trauma

Penetrating trauma is generally evident on evaluation in the emergency department. Repair of the injury is not usually complex, but obtaining proximal arterial control can be challenging. Injury to the subclavian arteries may require anterior thoracotomy or a trapdoor-type incision, or both (see Chapter 182). Injury to the axillary arteries is often best managed by initial proximal exposure of the subclavian artery from a supraclavicular approach. Proximal control of the brachial artery can usually be managed with a more proximal medial upper arm incision. Radial and ulnar artery injuries can often be managed with relatively local control, although exposure of the brachial artery at the elbow is always an option. Alternatively, application of a tourniquet may allow direct wound exploration. Patients with isolated radial or ulnar artery injuries and clinical evidence of satisfactory hand perfusion in all five digits can be managed by ligation of the affected artery. However, it is often not much more difficult to simply repair the involved artery with a local vein. Whether to ligate or bypass an isolated forearm arterial injury in a pink viable hand is still debated.

Delayed Recognition

Delayed recognition of arterial injury related to penetrating trauma may occasionally result in pseudoaneurysm formation, and sometimes arteriovenous fistulae are also formed by this mechanism. Consequently, there should be a relatively low threshold for obtaining arterial imaging for any penetrating trauma that may produce an arterial injury. Many forearm injuries related to broken glass may produce an occult radial or ulnar artery injury that is not identified at the initial inspection, but may result in further hemorrhage and even the development of compartment syndrome days later. Given the potential difficulty with the follow-up of these patients, imaging at the time of initial evaluation is recommended to avoid delayed recognition of these injuries. Once identified, arterial pathology, such as pseudoaneurysm, arteriovenous fistula, and compartment syndrome, should be promptly addressed. Alternatively, asymptomatic upper extremity arterial occlusions may be observed or reconstructed based on clinical condition paralleling treatment algorithms with the lower extremity.

Blunt Trauma

Management of blunt trauma producing arterial injury is somewhat more complicated because of the difficulty in diagnosing and localizing the injury. The force of an impact strong enough to injure the artery may result in associated neurologic compromise and long-bone fracture. Frequently, these patients benefit from preoperative arteriography. Ongoing hemorrhage is generally not the problem, and exposure can be directed at the injured site. However, it is also more likely that there will be associated extensive venous injury and the development of venous hypertension after reconstruction of the arterial lesion. In these cases, either direct repair of the vein or a short autogenous bypass of the injured venous segment is useful to decompress the venous hypertension in the affected arm, and thereby decrease swelling and continued hemorrhage from the wound, although this remains controversial.[35]

Pediatric Supracondylar Fractures

One area of controversy is the treatment of type III supracondylar fractures of the humerus in children who lack a palpable radial pulse after the injury. Long-term ischemia from arterial occlusion in a child may lead to Volkmann contracture, which results in permanent flexion and a claw-like deformity of the hand and fingers. The brachial artery may be pinched, avulsed, or thrombosed as it wraps around the fracture site. Orthopedic reduction is the accepted first treatment, with neurovascular reevaluation after stabilization. If the pulse returns, no further treatment is necessary besides observation. If it does not return, and the hand appears white, pale, and ischemic, operative exploration is preferred. Debate exists in the literature regarding the optimal treatment when the pulse is not palpable but the hand is pink and viable. Some describe a conservative approach with serial examination.[36] Others favor aggressive operative reconstruction whenever possible,[37] either direct arterial repair with patch angioplasty or bypass using the great saphenous vein around the area of injury. Care must be taken with arterial manipulation

in children to avoid spasm whenever possible. Fortunately, the incidence of this type of upper extremity ischemia is low. Multiple authors have found that additional imaging, such as contrast angiography or duplex ultrasonography, does not alter the course of treatment.[38,39]

Complications

Major complications that may occur after upper extremity arterial surgery include brachial plexus and median or ulnar nerve injury. Such injury is usually a result of traction and should be avoided by careful dissection during operative exposure. The use of electrocautery should be minimized to reduce the chance of direct thermal injury to the underlying nerves at all levels.

As with any arterial bypass, graft thrombosis can also occur. Some series found female smokers and patients with longer bypasses crossing multiple joints to have the lowest patency.[2,14] An inflow lesion in the subclavian artery can also cause acute arm ischemia (e.g., ulcerated plaque, thrombosed subclavian artery aneurysm, or arterial thoracic outlet syndrome). In such situations, even a technically perfect brachial embolectomy will fail to restore normal hand perfusion. Moreover, if the arteries are relatively free of atherosclerotic disease, embolectomy of the distal radial and ulnar vessels may result in arterial spasm. This problem is more commonly seen in women and children. However, it is a diagnosis of exclusion, and the first priority must be removal of retained embolic debris. If spasm is identified intraoperatively, topical or intra-arterial vasodilators, such as papaverine, warm saline irrigation and time should relieve the constriction and result in an adequately perfused hand.

Compartment Syndrome

As in the lower extremity, reperfusion of the arm may result in a significant inflammatory response and swelling. This response is more common with treatment of acute ischemia in an individual without long-standing collateralization, but overall it is a rare event. Decompressive fasciotomy is the mainstay of treatment. This involves incising the fascia on both the volar and the dorsal aspects of the arm. In severe cases, extension of the fasciotomy into the hand itself, through the carpal tunnel, may be required.

Upper extremity amputation remains infrequent in today's vascular surgery practice. Loss of a portion of the arm and hand is usually a devastating and life-altering event. Although surgical therapies may be aimed either at completing initial salvage attempts or, with reconstructive principles in mind, at maximizing function after amputation, such efforts are only the beginning of a life full of challenges for these individuals. Rehabilitative, social, financial, and psychological considerations are important and may be different from those of patients who have suffered lower extremity loss.

EPIDEMIOLOGY

In 2005, there were approximately 1.6 million amputees living in the United States, with upper extremity amputees accounting for 541,000 of this number; it is anticipated that these values will more than double during the next four decades.[1] Approximately 185,000 patients undergo amputation each year in the United States, and it is estimated that anywhere from 10% to 25% of these amputations involve the arm and hand.[1,2] It seems that this relative proportion remains constant as the overall number of amputations performed increases. Most amputations in the upper extremity (93%) involve minor amputation at the wrist or within the digits.

Etiology

The majority of upper extremities requiring amputation are the result of trauma (80%-90%).[1,2] It is not surprising, then, that upper extremity amputees are generally younger (20-40 years

old on average) and predominantly male. However, other etiologies do contribute. Vascular disease and tumors are the next most common indications and represent 7% and 0.6% of upper extremity amputations, respectively.[1,2] Even less frequent causes include infections, congenital anomalies, and iatrogenic reasons, such as complications related to catheterization, vasopressor administration, and vascular access. Thus, the general indications for amputation of portions of an arm or hand include tissue destruction, vascular compromise, and tumor development. This overall distribution is in contradistinction to that of lower extremity amputation, where vascular disease is the inciting etiology in nearly 80% of cases.[1,2]

Ischemia as the cause of upper extremity amputation usually results from trauma. Atherosclerosis is distinctly less common in the arteries of the arm and is a rare form of peripheral arterial disease.[3] Even in more chronic scenarios, the most frequent reason for upper extremity revascularization is traumatic injury.[4,5] (Even emboli from more proximal atherosclerotic or cardiac origins are much more common than chronic occlusive disease).[6] Such trauma may include vibration-induced white finger, hypothenar hammer syndrome, and athletic-associated conditions, such as quadrilateral space syndrome and arterial thoracic outlet compression resulting in subclavian aneurysm. Arterial trauma or embolization related to drug use has clearly been illustrated. Apart from atherosclerosis, a variety of arterial disorders leading to extremity arterial insufficiency may affect the arm, including vasospastic disorders (e.g., Raynaud disease), small-vessel diseases (e.g., Buerger disease), and radiation-induced arteritis.

Trauma and Military Injuries

The long-standing experiences from Operation Iraqi Freedom (OIF) and Operation Enduring Freedom (OEF, Afghanistan) have provided continued insight into traumatic vascular injury of the upper extremity and upper extremity amputation. Such insight is mostly due to the significance of extremity injury during this conflict and during war in general. Many of the principles of amputation were developed during the American Civil War and persist today. Stansbury and colleagues characterized the amputations that occurred in 8000 United States troops after injuries to extremities during the first 5 years of OIF/OEF.[7] They found that 7.4% of major limb injuries required amputation. However, this is not unique because a purported need for amputation occurred in more than 8% of extremities during the Vietnam War. In both wars, nearly 18% of amputees required multiple limb amputations.

Interestingly, the experience in the upper extremity is somewhat different from that in the lower one. With nearly 3400 major upper extremity injuries recorded, the arm amputation rate was 3.1%. This figure is in contrast to a rate of 8.5% in almost 4000 major lower extremity injuries, even though the incidence of neurovascular injury was similar in the two groups at approximately 15%. The authors surmised that this disparity could be related to several factors. Nearly 90% of extremity injuries were due to explosive mechanisms, which are most common at ground level, so the legs may sustain more significant destruction. Furthermore, the increased infection and nonunion rates cited in the lower extremities may have played a role. Finally, the surgical push for arm salvage because of limited functional prosthetic options for the upper extremity may have created a higher threshold for amputation.

Nevertheless, experience in Iraq clearly depicts the seriousness of arterial injury in the upper extremity during OIF.[8,9] At the 332nd Expeditionary Medical Support Group (EMDG), Air Force Theater Hospital in Balad, Iraq, almost 10% of patients with upper extremity arterial injury who underwent arm salvage treatment ultimately lost the limb during the early period. Yet if those sustaining upper extremity arterial trauma are able to be successfully revascularized, the prospect of limb salvage into the later phases of treatment and rehabilitation is excellent.[10] This reaffirms a small body of literature indicating that in those with significant neurovascular, bony, and soft tissue upper extremity injury, aggressive limb salvage attempts are often successful.[11-20] Moreover, even though disability after upper limb salvage is usual, intensive therapy can lead to improvement over the longer term. Thus, unless absolutely clear from a destructive or systemic indication, early amputation should be avoided. The extreme views on this topic are seen in communications by those espousing limb reimplantation techniques.[21,22]

Yet, the visibility of upper extremity amputation from OIF/OEF troops has led to an appreciation by society and produced an increasingly supportive environment. Recently, updated OIF/OEF data describing amputation trends from January 2001 through July 2011 using the Military Amputation Database were reported.[23] Specifically, upper extremity amputation has accounted for 14% of amputations performed, 18% of amputees, with bilateral upper extremity amputation in nearly 1% of amputees. Delayed amputation beyond 90 days has accounted for 10% to 15% of amputations per year. Our ability to address, improve, and provide newer prosthetic technologies, broadened therapeutic applications, and rehabilitative principles has been advanced for those missing a segment of an arm or hand. However, even with these advances the upper extremity amputees are unlikely to be found "fit for duty." In a series of 1315 service members that sustained 1631 amputations, 173 service members were found to have an upper extremity amputation, none were found fit for duty, and only 12 were allowed continuation on active duty. In addition, upper extremity amputees were more likely to have a disability from posttraumatic stress disorder (PTSD) versus the general amputee population. These findings underscore the complexity of patients suffering an upper extremity amputation.[24]

Nontraumatic Disease

When nontraumatic vascular compromise in the upper extremity is the pathologic pathway leading to a limb-threatening process, treatment should be directed at correction of the underlying condition. This may be relatively simple and systemic, such as cessation of smoking in those with Buerger disease; operatively straightforward, as with thromboembolectomy; or more complex and infrequent, such as sympathectomy for vasospastic diseases and bypasses, with or without thrombolytic therapy, for occlusive disease. Should the process affecting the upper extremity be focal, the surgical principles of treating limb-threatening conditions apply so that the best possible function can be provided

for the patient. Unfortunately, some diseases involving the arm and hand are more diffuse; they lead to regional pain syndrome, are difficult to treat, and have less clearly described therapeutic outcomes. All of this may proceed to a final pathway that simply requires some form of amputation. If this is the case, the principle of conservatism and conservation of parts is critical because aggressive surgical procedures may both aggravate the ischemic process and impede eventual function.

GENERAL OPERATIVE CONSIDERATIONS

Initial Management

As stated earlier, the majority of amputations are secondary to trauma and are usually managed in staged fashion to preserve as much of the arm as possible. This principle dates back to the care of battlefield injuries during World War II.[25] As opposed to the lower extremity, which requires only adequate soft tissue coverage in anticipation of a functional prosthesis, an upper extremity amputation must be both functional and cosmetically acceptable. With this in mind, definitive decisions on the level and length of amputation should not be made in the acute setting. In addition, as compared to the lower extremity, the majority of patients are less willing to lose a poorly functioning hand. Sequential stepwise debridement and later definitive closure are the keys to successful technical and functional results. One of the advancements over recent years is wound care and wound bed preparation before closure. The use of negative pressure therapy to promote granulation and assist in flap and graft coverage has become a mainstay in treatment. This technology is used even in the modern battlefield scenario, with multiple debridements and placement of these devices early after injury.[26] Although the basic techniques of surgery and debridement have not changed, emotional and functional rehabilitation has dramatically improved. Advancements in prosthesis design and functionality have allowed these patients to return to meaningful positions in today's society. Factors that play major roles in individualizing the surgical strategy for upper extremity amputation include etiology, age, handedness, occupation, associated injuries and physiologic state, accessibility to state-of-the-art occupational and physical therapies, and cultural settings.

Arterial Assessment

For both traumatic and nontraumatic indications, the level of upper extremity amputation fundamentally required depends on adequate arterial perfusion. The use of physical examination in conjunction with noninvasive studies, such as duplex ultrasound, segmental pressure measurement, pulse volume recording, infrared photoplethysmography, laser Doppler techniques, transcutaneous oxygen tension ($tcPO_2$) measurement, and, occasionally, even arteriography before amputation, can ensure that no ischemic component of the injury will prevent healing. Each evaluation technique has benefits and shortcomings. As described in Chapters 117 and 118, the use of noninvasive tests can be invaluable in facilitating success. This is no less true in amputation, and though rare when compared with lower extremity evaluation, low pressure, poor arterial waveforms, and low $tcPO_2$ measurements along the extremity must be recognized and the management appropriately altered.

Guidance suggesting the appropriate blood flow for healing at specific levels has largely been described for lower extremity amputation (see Chapter 111). Within the context of tissue perfusion, however, these same principles can be applied to the upper extremity. Generally, healing will occur at the hand level when digital pressure is 40 mm Hg or higher and wrist Doppler pressure is greater than 60 mm Hg. For hand-level procedures, healing is unlikely to occur when digital pressure is less than 20 mm Hg. At the forearm and arm levels, healing will almost always take place when wrist or brachial pressure is at least 60 mm Hg or when $tcPO_2$ is 40 mm Hg or greater. Healing is less predictable when $tcPO_2$ is between 20 and 40 mm Hg and wrist or brachial Doppler pressure is less than 50 mm Hg. Pulse volume recordings may provide evidence of collateralization and suggest a higher likelihood of success, yet they remain nonspecific when blunted. Once a level for amputation is chosen, simple ligation of blood vessels during the procedure is usually sufficient as long as tissue coverage of these structures can be obtained.

Preservation of Length

Although preservation of length is a fundamental principle of amputation surgery, length does not always correlate directly with function, depending on the type of prosthetic application contemplated. However, in general, it is important to retain and salvage as much residual stump as possible to maximize the ultimate functional outcome. To this end, several reconstructive techniques have been described to salvage stump length,[27-32] including plastic and orthopedic surgery techniques, such as bone and free tissue transfer. These techniques have been applied selectively and may be helpful in certain instances, particularly elective planned procedures when the cause is tumor resection or isolated traumatic injury and the procedures may need to be performed in a staged fashion. Length-preservation techniques have a limited role when the underlying pathology involves vascular insufficiency because of concern for viability and perfusion of the grafted tissue. Moreover, selective reimplantation methods and even hand transplantation have been suggested in an attempt to maintain viable, functional tissue and length for the upper extremity.[21,22,33] In fact, in select scenarios, such as clean traumatic severing without much tissue loss or associated trauma, these methods must be given initial consideration. However, in most acute trauma settings, this decision cannot be made, and minimizing loss of length should be the goal. One concept that should be considered is that longer length may result in poorer healing, whereas shorter length results in decreased function. Thus, acute amputation should be performed at a level at which healing is likely and function is maximized. Also, if at all possible, the elbow joint should be retained to facilitate later prosthetic function.

Soft Tissue Coverage

Historically, the maintenance of length depended on local soft tissue coverage; if soft tissue coverage was not adequate, one merely shortened the extremity until closure could be achieved. As mentioned earlier, skin grafts, free flaps, and composite tissue transfer have dramatically changed this approach. Skin grafts are applicable when the underlying soft tissue bed is acceptable, but one must be sensitive to the ultimate functional needs of the amputation site; in some cases, skin grafts may not be durable enough to tolerate therapy and the use of prostheses. Local flaps (see section "Fingertip Amputation") abound, but their applicability is limited because of the anatomy at more proximal amputation sites. Pedicled flaps (regional or distal) have a long, productive history in hand surgery; however, they have been increasingly replaced by free tissue transfers. This change is based on (1) better matching of the tissue transferred (in terms of thickness and ultimate functional performance), (2) avoidance of additional surgery (whether for division or thinning of the flap), and (3) lack of the joint limitations that result from the immobility that is typically necessary with pedicled flaps. Free tissue transfer is increasingly being accomplished at sites proximal to the hand to achieve more satisfactory results.

Nerves

Prevention of neuroma is the most difficult problem in upper extremity amputation. As in all of medicine, the existence of many methods of treatment usually indicates that none of them is exceptionally good. Such is the case with prevention of neuroma. Distal ligation, proximal ligation, coagulation, chemical ablation of the end, simple division, traction and division, nerve repair to other divided nerves, and immediate burial of the transected nerve end have all been attempted with varying degrees of success. The desire to eliminate painful focal sensation must be balanced against the secondary loss of sensibility induced by many of these techniques. A divided nerve always attempts to regenerate and, in so doing, produces a neuroma of variable clinical significance. Thus, in reality, the goal is not to prevent the formation of a neuroma altogether, but to prevent the patient from experiencing the pain or dysesthesias from the neuroma that will predictably develop. In general, locating the divided, free nerve end as far from external stimuli as possible and placing it in a healthy, nonscarred bed of tissue are the best preventive measures. In addition, early postoperative therapy (desensitization or sensory re-education) is an extremely important determinant of the patient's ability to tolerate the dysesthesias that result from an amputation. Centrocentral nerve union utilizes the technique of coapting severed nerve ends to form a loop and has been reportedly successful as well.[34] Targeted reinnervation by way of nerve transfer techniques has also been described as a means of improving residual muscle function and sensory aspects of the stump and thus prosthetic utility.[35] Such procedures can be performed in either a planned elective or a staged scenario.

Bone and Cartilage

Whatever length is ultimately chosen for the amputation, the bony prominences must be optimally contoured. Lack of attention to bony prominences or irregularities in bony contour lead to aesthetic abnormalities and difficulty in obtaining optimally fitting prostheses. Inadequate debridement of traumatized tissue and displaced bony fragments, improper initial contouring of bone, or failure to identify bone-producing periosteum, which must also be contoured, are the sources of such difficulties. Visual identification of the periosteum is easiest during initial management of the injury, and achievement of a natural bone contour is greatly assisted by palpating the end of the bone through the skin before closure. This is even more important in amputations through joints, where natural anatomic flares of the bone produce aesthetically unnatural contours and interfere with prosthetic fitting.

Tendons

The hand represents a very delicate balance between extensor and flexor forces. It is extremely difficult to duplicate the balance of these forces through myodesic methods (i.e., suturing of tendons or muscles to bones) or myoplastic techniques (i.e., suturing of tendons or muscles to tendons or muscles of the opposite functional group; for example, suturing an extensor tendon directly to a flexor tendon over a bony amputation site). In general, then, such techniques are not used distally in the fingers and hand because they often add to the functional deficit. However, they do have value proximally, where the balance is not as critical, and re-education and adaptation are easier.

SPECIFIC AMPUTATIONS

Fingertip Amputation

Distal finger amputations are extremely common. The most frequent mechanism causing such injuries is a crushing blow, such as from a closing door. Although many people arrive at the emergency department with the tip of the finger available for reattachment, the injury is usually too distal for microsurgical reattachment. Many surgeons have attempted composite reattachment (i.e., reattachment without specific revascularization) with generally poor results. At present, such composite grafts are not indicated except in young children (younger than 2 years), in whom there is an increased chance of graft survival.[36] Most composite grafts fail because (1) the amount of tissue is generally more than can survive the ischemia until new circulation develops and (2) the zone of injury is greater than the area of amputation (i.e., the tip is usually damaged and thus is not capable of surviving as a composite graft).

Technique

If the proximal portion of the distal phalanx is not severely injured so the insertions of the flexor digitorum profundus and extensor tendons are intact, preservation of that portion of

bone is indicated for functional length. If these areas are damaged beyond repair, disarticulation through the distal interphalangeal joint is indicated. The flexor digitorum profundus tendon should never be sutured over the tip or to the extensor tendon because this can weaken grip in the hand (the quadriga effect).[37] The bone of the distal phalanx should be of adequate length to support the nail bed and nail growth.[38] Generally, these amputations occur through a portion of the nail bed. If enough proximal nail bed (≈50%) is present to provide a functional nail, the bed should be repaired under optical magnification with absorbable 6-0 or 7-0 suture.

The distal phalanx is usually rongeured back so the end of the bone is not exposed. The digital nerves are identified, distracted distally, and divided so they will be at least 1 cm from the fingertip stump to avoid neuroma formation in this location. If the final cutaneous defect is then less than 1 cm^2, simply allowing the wound to close by secondary intention is acceptable. Other wound closure techniques have been attempted, including every conceivable type of local or regional flap. However, given the fact that flap closures are frequently insensate and do not reduce healing time, ultimate functional recovery appears to be better after secondary healing because the resulting scar contracture diminishes the size of the sensory defect.

Skin Grafts

If the cutaneous defect is greater than 1 cm^2, the amount of time needed for closure and the ultimate functional result may not warrant healing by secondary intention. If there is no exposed bone, a skin graft is possible. The temptation is to use the amputated part as a donor source for the skin graft. This practice should be avoided because the amputated portion has been traumatized and the overall success of such skin grafts is disappointing. However, one advantage of these grafts is that they may serve as temporary biologic dressings even if they do not survive.

Nontraumatized skin graft donor sites that may be considered are:

- The ulnar border of the palm (within the operative field and a good color match)
- The forearm (the medial portion of the forearm or the elbow crease, although hypertrophic scarring can lead to some cosmetic deformity)
- The groin (a well-hidden donor area, although the color match is not good and some unwanted hair may also be transferred)

Local Flap Closure

As mentioned previously, many alternative flaps are often useful for cutaneous defects of the fingertip; some of the more common local flaps include:

- The Kutler flap,[39] a lateral V-Y flap for closure of a central tip defect
- The Atasoy flap,[40] a palmar V-Y flap
- The palmar flap,[41] based on both digital neurovascular bundles in which the entire soft tissue coverage of the digit above the tendon sheath is elevated and advanced to cover the tip of the finger
- Radius- or ulna-based local flaps, which preserve cutaneous innervation on the appropriate digital nerve,[42] with skin grafting of the donor site as necessary

In addition to these local flaps, numerous regional flaps can be used, such as dorsal skin cross-finger flaps, palmar skin cross-finger flaps, and thenar flaps. Although it is sometimes necessary to use these regional pedicled flaps, they carry significant additional morbidity by creating joint stiffness because of the obligatory period of immobility needed for attachment of the flap. Even in young people who have had good physical therapy, long-term problems can result.

Digit-Level Amputations

Midfinger Amputation

Amputations that leave more than half the proximal phalanx may be functional for the patient. These amputations represent variations of fingertip amputations. First, the bone is rongeured back a short distance to allow soft tissue coverage. Tendons that have been separated from their bony insertions by the amputation are placed on traction, divided, and allowed to retract into the palm. Digital nerves are a potentially more difficult problem. It is preferable to divide them under mild traction and allow them to retract beneath healthy vascularized tissue. Excessive traction may denervate the new tip of the digit. However, if traction is not applied, the cut nerve remains adjacent to the amputation site, which can lead to postinjury trauma and produce significant pain. The associated soft tissue defect is managed in the same manner as a fingertip amputation.

Proximal Phalanx

Amputation proximal to the midportion of the proximal phalanx is not typically a functional amputation. If enough digit remains, it may be possible for patients to wear a cosmetic prosthesis that may allow some functional restoration; however, most patients find the remaining digit a nuisance (Fig. 119.1). The effects of proximal digital amputation vary with the finger involved. For example, an index finger, which is second in importance to the thumb, when amputated proximally can become a hindrance to function of the hand. Because the patient uses the middle finger for activities such as writing, the index finger stump becomes an obstacle. With middle or ring finger amputations, each time the person reaches into his or her pocket or purse for a small object, the object falls through the opening left in the hand by the remaining short digit. The small fingers play a role in gripping objects, and if the finger becomes immobile, it may become caught on objects. Because of these issues, patients frequently choose to undergo secondary ray amputation. Regardless of the certainty of this denouement, ray amputation should not be offered to the patient at the time of initial wound closure. Elective resection of the remaining portion of the digit is a decision that each patient should reach by experience.

Ray Amputation

Ray amputation, which includes removal of the injured finger to the metacarpal base, often provides a far more cosmetically

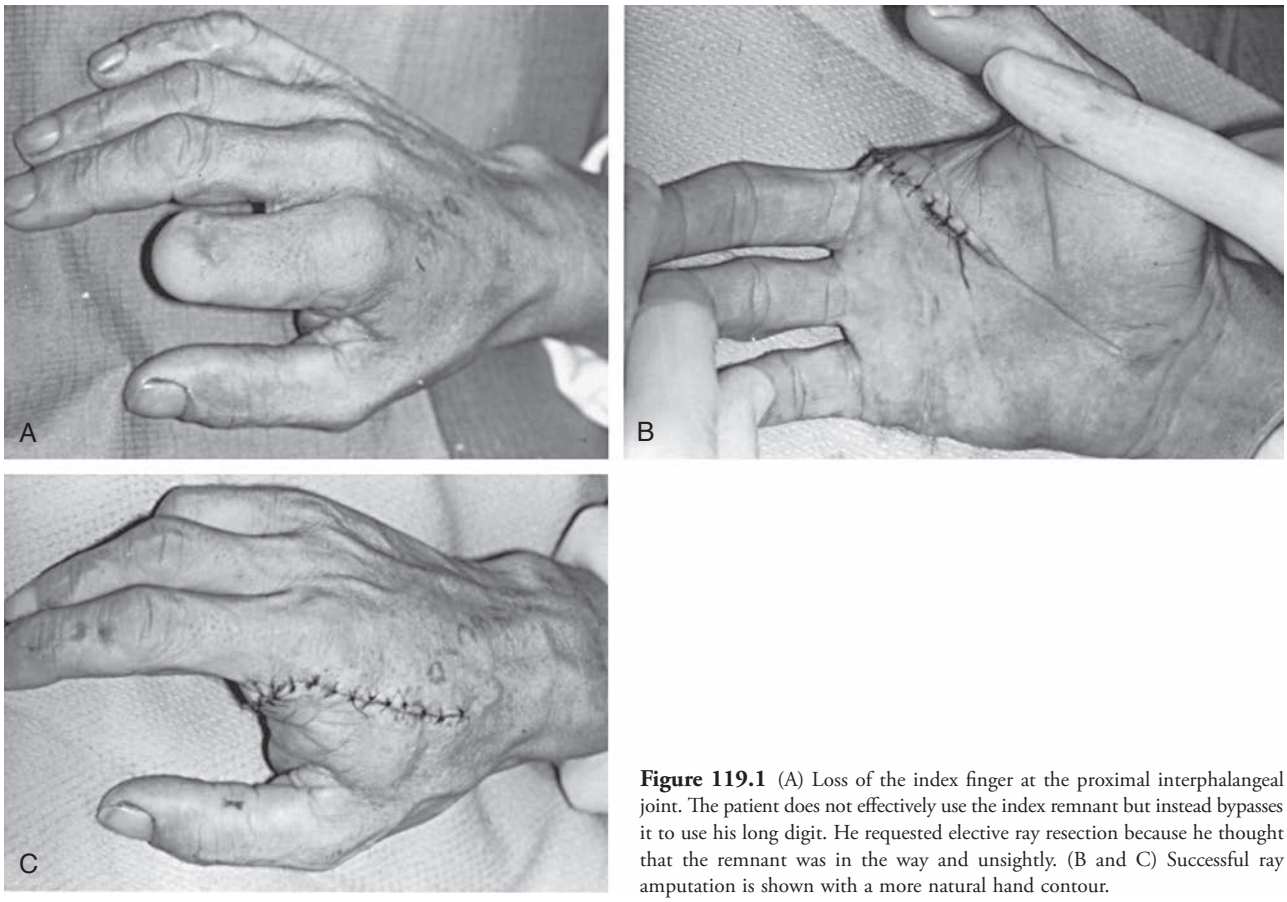

Figure 119.1 (A) Loss of the index finger at the proximal interphalangeal joint. The patient does not effectively use the index remnant but instead bypasses it to use his long digit. He requested elective ray resection because he thought that the remnant was in the way and unsightly. (B and C) Successful ray amputation is shown with a more natural hand contour.

acceptable hand, especially with an index ray amputation. This technique usually involves a dorsal longitudinal incision over the index metacarpal along with a palmar skin incision over the proximal phalangeal level. Alternatively, a circumferential racket incision may be used. Minimal digital nerve neurolysis should be done to prevent pain. Attention to myodesic and myoplastic techniques is critical because improper attachment of the remaining muscle and tendons to the lumbrical and interosseous muscle or nearby periosteum can significantly downgrade intrinsic hand function. In addition, care should be taken when performing a fifth ray amputation because the extensor carpi ulnaris inserts at the base and wrist function can be affected.

In most cases, the appearance of a three-fingered hand with normal border contours is so natural that it goes unnoticed. Nevertheless, the operation is not without its own set of risks. First, the procedure narrows the palm by 20% to 25%, which reduces the hand's ability to stabilize objects. Second, the operation is a more extensive procedure that produces more proximal postoperative pain, edema, and stiffness than that caused by the original injury to the digit. However, in the final analysis, ray amputation is very functional and cosmetically appealing, and there are few dissatisfied patients.

Thumb Amputation

Because it accounts for 40% of the function of the hand, the thumb deserves special attention in any amputation involving the hand. Clearly, the major emphasis is on reattachment of the thumb. However, the desire for reattachment has led some surgeons to attempt reimplantation in circumstances that would otherwise be considered contraindications (e.g., severe avulsion injuries). The standard of care is now to attempt reimplantation of the thumb if possible, and encouraging results have been achieved even after avulsion injuries.[43] Nonreimplantable amputations at the level of the interphalangeal joint are functional, and most patients do not request or require additional reconstruction. These stumps still provide the opposition function for the fingers. Revision of thumb amputations proximally to allow closure should not be performed as in the other fingers, and thought should be given to rotational, advancement, and free flaps.[44] More proximal thumb amputations can be reconstructed by pollicization (using a remaining finger, usually the index finger, and myodesic techniques to create a thumb), osteoplasty, bone-lengthening techniques, or toe-to-thumb transfer (great toe, second toe, or toe wraparound).

Hand-Wrist Amputations

Any tissue that can be preserved during hand amputation should be salvaged. A hand with a short palm may seem dysfunctional, but as an assist hand it may be preferable to a prosthesis. A transcarpal amputation allows supination and pronation of the forearm, as well as flexion and extension of the wrist. A prosthesis can be fitted for this type of amputation as well.

Wrist disarticulation is preferred to more proximal forearm amputation because it has the same advantages of a transcarpal amputation except that wrist flexion and extension are lost. Wrist disarticulation is performed by creating a long palmar and short dorsal flap; ligating the radial and ulnar arteries proximal to the wrist; identifying the median, radial, and ulnar nerves and distracting and dividing them; dividing all tendons; disarticulating the joint; and resecting the tips of the radial and ulnar styloid processes. The resultant smooth contour can easily be fitted for a prosthesis.

The radial, ulnar, and median nerves can present difficulties during hand-wrist amputation. The ulnar and median nerves are frequently avulsed at a more proximal level with these traumatic amputations; if they are apparent in the wound, they can be severed with mild traction and allowed to retract. Retraction of the ends usually positions the nerves away from contact with a prosthesis. The sensory branch of the radial nerve, however, is quite superficial throughout its course in the forearm (covered only by the brachioradialis muscle). Neuromas from this nerve are not uncommon, and division of the nerve in the proximal part of the forearm may be considered at the time of the initial amputation. Sensation of the forearm skin is not directly determined by these nerves but instead is controlled by the brachial cutaneous nerves, and improper management of the brachial cutaneous nerves can cause difficulties similar to those that occur with the superficial branch of the radial nerve. However, it is preferable not to divide these nerves far proximally because sensation of the forearm skin will be sacrificed.

Forearm Amputations

The optimal level for a forearm amputation is the junction of the middle and distal third of the forearm. The issue with the distal third of the forearm is the relative paucity of padding in this area because of the thin skin and subcutaneous tissue. This factor can be more evident in patients with ischemia because this area is notably prone to skin breakdown. So important is the elbow that the use of free-flap soft tissue coverage to preserve length or even distraction osteogenesis (Ilizarov technique)[29] is a viable consideration in the case of very short below-elbow amputations. However, with the exception of these very special cases, heroic efforts at preserving length are not usually indicated.

Heeding these caveats, the surgeon can trim the bony tissues adequately to permit soft tissue closure. The technique is as follows: creation of equal anterior and posterior skin flaps; ligation of the radial and ulnar arteries; distraction and division of the medial, radial, and ulnar arteries; transection of the muscle bellies; division of the radius and ulna; and closure of the deep fascia followed by the skin (Fig. 119.2). Reconstruction of the amputation is generally accomplished by means of a fitted prosthesis. However, as described by Tubiana, bilateral upper extremity amputations can be functionally improved with the Krukenberg procedure, in which a sensate pincer is created between the radius and ulna (Fig. 119.3).[45] The pincer is motorized by the pronator teres muscle, and this procedure allows preservation of proprioception and stereognosis. Although the cosmetic result is far from desirable, the functional improvement is great, and the procedure should be given serious consideration in the rare instances of bilateral injuries, in blind individuals, or when prosthetic reconstruction is not practical.[46]

Elbow Disarticulation

If the elbow joint is not salvageable, elbow disarticulation is preferred over distal humeral transection. In addition to maintaining length, humeral rotation can be transmitted to the elbow, and the broad flare of the condyles makes for a good prosthetic fit. When compared with the forearm, which has two bones with a functional noncircular cross-section and thin soft tissue coverage that allows transmission of rotational forces (pronation and supination), the upper part of the arm has a single bone with a relatively circular cross-section and less rotational stability because of its thicker soft tissue. The amputation technique is similar to that described earlier in that anterior and posterior skin flaps are created; the brachial artery is ligated; the median, ulnar, and radial nerves are distracted and divided; the joint capsule is opened and the forearm removed; and a muscle flap (brachialis or triceps) is then used to cover the humerus (Fig. 119.4). As noted, there has been an emphasis on retaining all of the humerus if possible. However, in so doing, the upper part of the arm may appear longer than the normal (unamputated) arm when fitted with an internal elbow joint prosthesis. It is possible to use an external elbow joint option, but these joints are substantially less durable. Another approach to this problem involves construction of an artificial asymmetry by means of angulation osteotomy in which bone is resected yet epicondylar stability is retained.[47] This method has gained popularity in Europe but is not routinely practiced in the United States because of the obvious cosmetic deformity in the proximal remaining stump.

Upper Arm Amputations

Surgical considerations for above-elbow amputations are essentially the same as those for forearm amputations with respect to the treatment of bone, muscles, tendons, nerves, and skin. A transcondylar amputation functions essentially the same as an elbow disarticulation. More proximal amputations must include an elbow lock mechanism to stabilize the musculature and future prosthetic joint in full extension or flexion, and a turntable mechanism that will serve as humeral rotation. Taking into account the location of the elbow lock, which extends 4 cm from the distal amputation site, the transhumeral amputation should be made 4 cm proximal to the elbow (see Fig. 119.4).[48]

Reimplantation remains a viable option, and Wood and Cooney have reported that reimplantation should be considered even with high amputations.[22] A multidisciplinary approach is required and involves early arterial and venous shunting followed by bony fixation, definitive vascular repair with attention to maximizing venous outflow, and finally nerve and soft tissue reconstruction. Functional recovery of the hand may not occur, yet it may be possible to convert an obvious above-elbow

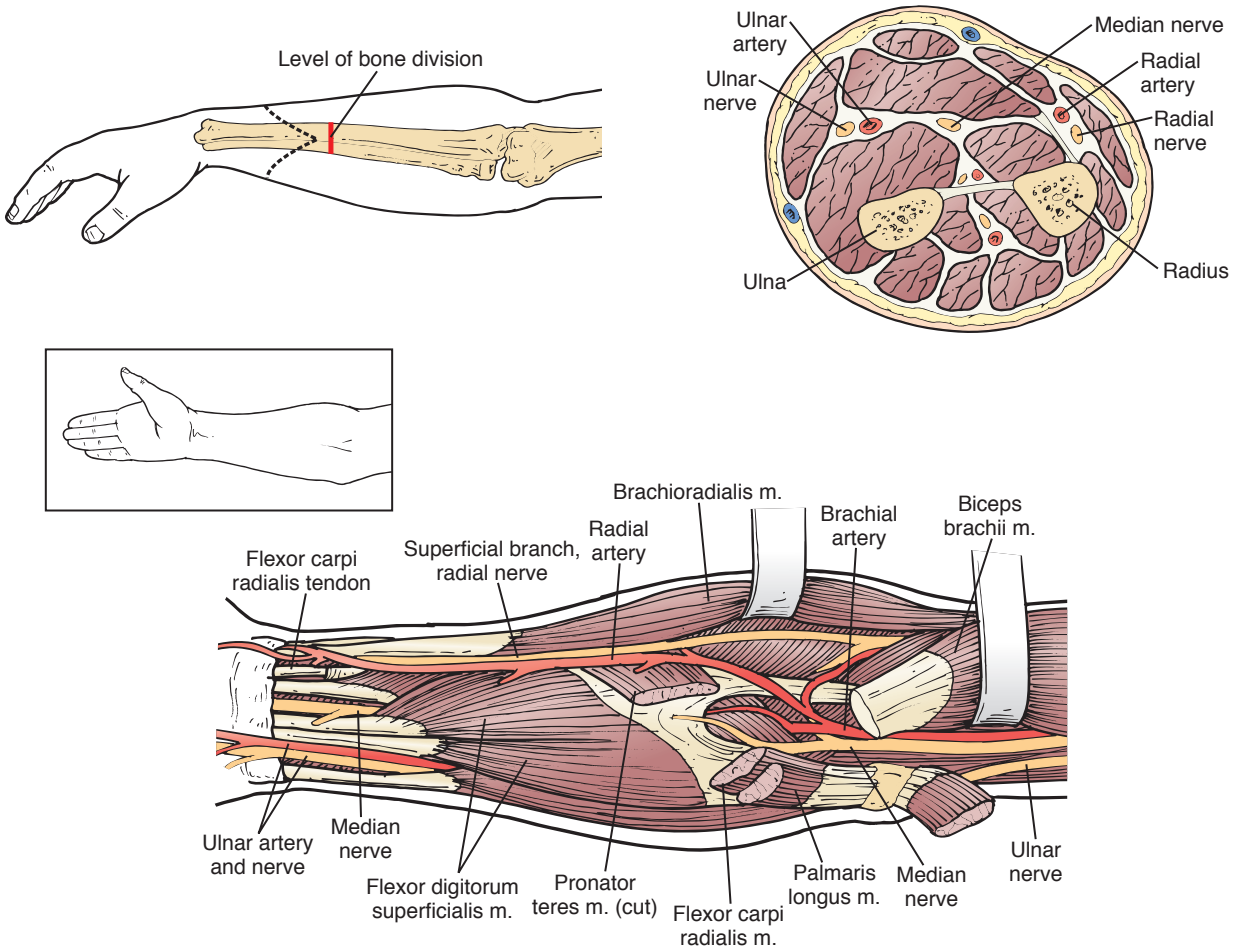

Figure 119.2 Forearm amputation is relatively straightforward: division of soft tissue at the junction of the distal third and proximal two-thirds of the forearm and several centimeters distal to the level of the bony division. Proper muscle coverage is achieved with myofascial closure. (Adapted with permission from Maxwell MC. Amputations in trauma. In: Thal ER, Weigelt JA, Carrico CJ, eds. *Operative Trauma Management: An Atlas,* 2nd ed. New York: McGraw-Hill; 2002:449.)

amputation to a below-elbow amputation, which is far more functional. The shorter the remaining stump, the more difficult the prosthetic fit and the less functional the prosthesis will be. As a result, several new techniques have been developed to facilitate this type of reconstruction. The use of free flaps can provide additional soft tissue and bone length for a short upper arm amputation. Functional restoration of the glenohumeral joint may be accomplished with a free fibular transfer. The proximal humerus can be replaced with the fibula and its proximal joint with reattachment of the muscular insertions.[27,28] Particularly in patients with malignant tumors, limbs that would otherwise have to be sacrificed can now be salvaged. Fibular flaps can also be used in conjunction with soft tissue coverage from a latissimus dorsi flap (pedicled or free) to provide acceptable upper arm length for fitting a prosthesis.

One final technique used to achieve adequate bony length is distraction osteogenesis, as mentioned previously.[29-31] Although this technique was developed in the 1960s by Ilizarov, it did not become widely recognized and used worldwide until the 1990s. The scattered reports of this method of treatment have been encouraging. As previously indicated, every effort should be made to avoid high amputations. Even when the amputation will be a functional shoulder disarticulation (amputation proximal to the insertions of the deltoid and pectoralis major muscles), maximal proximal length of the humerus should be sought for either prosthetic fitting or potential reconstruction by these complex plastic and orthopedic techniques.

Shoulder Disarticulation and Forequarter Amputations

Shoulder disarticulation and forequarter, or scapulothoracic, amputation are the most complex and difficult procedures from a prosthetic and functional standpoint. Considerations are (1) loss of potential motor units as drivers of the prosthetic device and (2) difficulty fitting the prosthesis to contours. The shoulder disarticulation (after rounding off any bony prominences that may cause wear) leaves a contour adequate to provide a snug fit for the prosthesis (Fig. 119.5). In addition, scapular function is retained and can be used (with some difficulty) as a motor

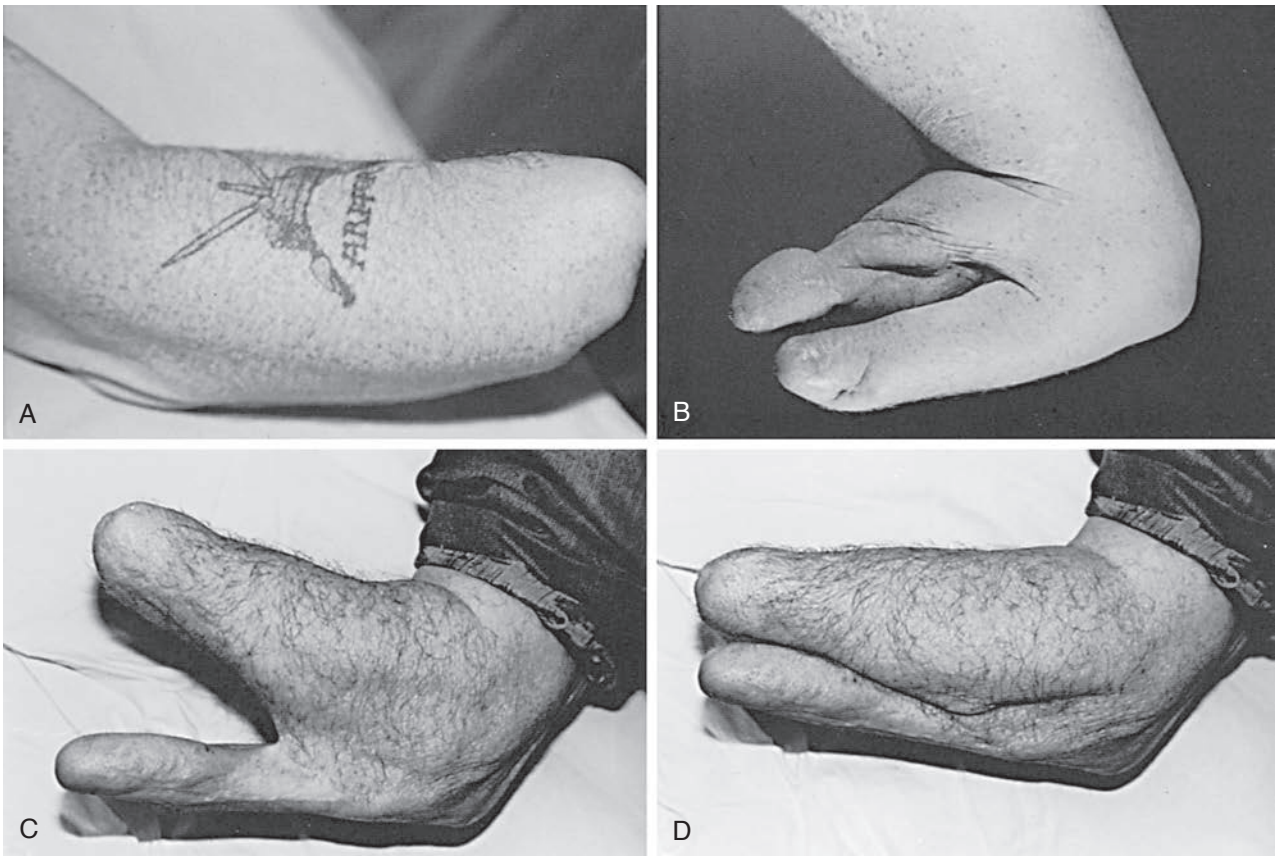

Figure 119.3 Classically, in a double-arm or blind amputee, the Krukenberg procedure has been performed. **A,** A typical below-elbow stump. **B,** The initial separation of the ulna and radius. **C,** The open and **D,** closed pincer grasp mechanism is preserved and controlled by the pronator teres muscle.

unit for the prosthetic device. However, a forequarter amputation (which is done almost exclusively for malignant processes), offers little hope for functional restoration of the limb, and prosthetic application is challenging.[49]

The surgical techniques for these amputations are well described in the literature. The shoulder disarticulation may be modified by retention of the humeral head to assist in contouring or may be a true disarticulation with complete removal of the humerus. Regardless, the deltoid and pectoral muscles, along with their overlying myofasciocutaneous tissue, provide the flap coverage. Occasionally, if the deltoid is not available, an inferior axillary fasciocutaneous flap may be necessary. The latissimus dorsi and pectoralis major are reattached to either the glenoid capsule or the humeral head remnant. The tendinous components of the rotator cuff are also attached to the glenoid capsule. In a modified technique, their insertions are undisturbed, which reduces movement and, thus, pain in the joint area. It also stabilizes the muscles for future myoelectric control points.

There are two approaches to forequarter amputation. The anterior approach, described by Berger,[50] and the posterior approach, described by Littlewood,[51] differ only in exposure of the vascular structures hidden behind the clavicle. Both approaches are well accepted. Any available remaining myofascial components are used to provide closure. The same principles that were previously described apply: removing the bony prominences, treating the nerves and muscles, and providing adequate soft tissue coverage.

POSTOPERATIVE MANAGEMENT AND COMPLICATIONS

Wound Treatment

Aside from the standard surgical principles of postoperative wound care and post-traumatic injury care, the principles of postoperative management after upper extremity amputation are supportive. There should be a low threshold for the use of drains in areas of potential space because hematoma and seroma formation is not uncommon and might not only delay rehabilitation and prosthetic placement but also place tissue viability at risk and increase the potential for infection. Drain removal as soon as possible is encouraged to reduce infection risk. Early physical activity and rehabilitation are encouraged. Compressive dressings are used immediately. The full range-of-motion exercises of the elbow and shoulder should be started immediately when these structures are preserved. Local amputation site concerns revolve around infection, wound healing, and the viability of specialized reconstructive methods, such as free flaps if used. Infection is rare, and, even when trauma is the indication for

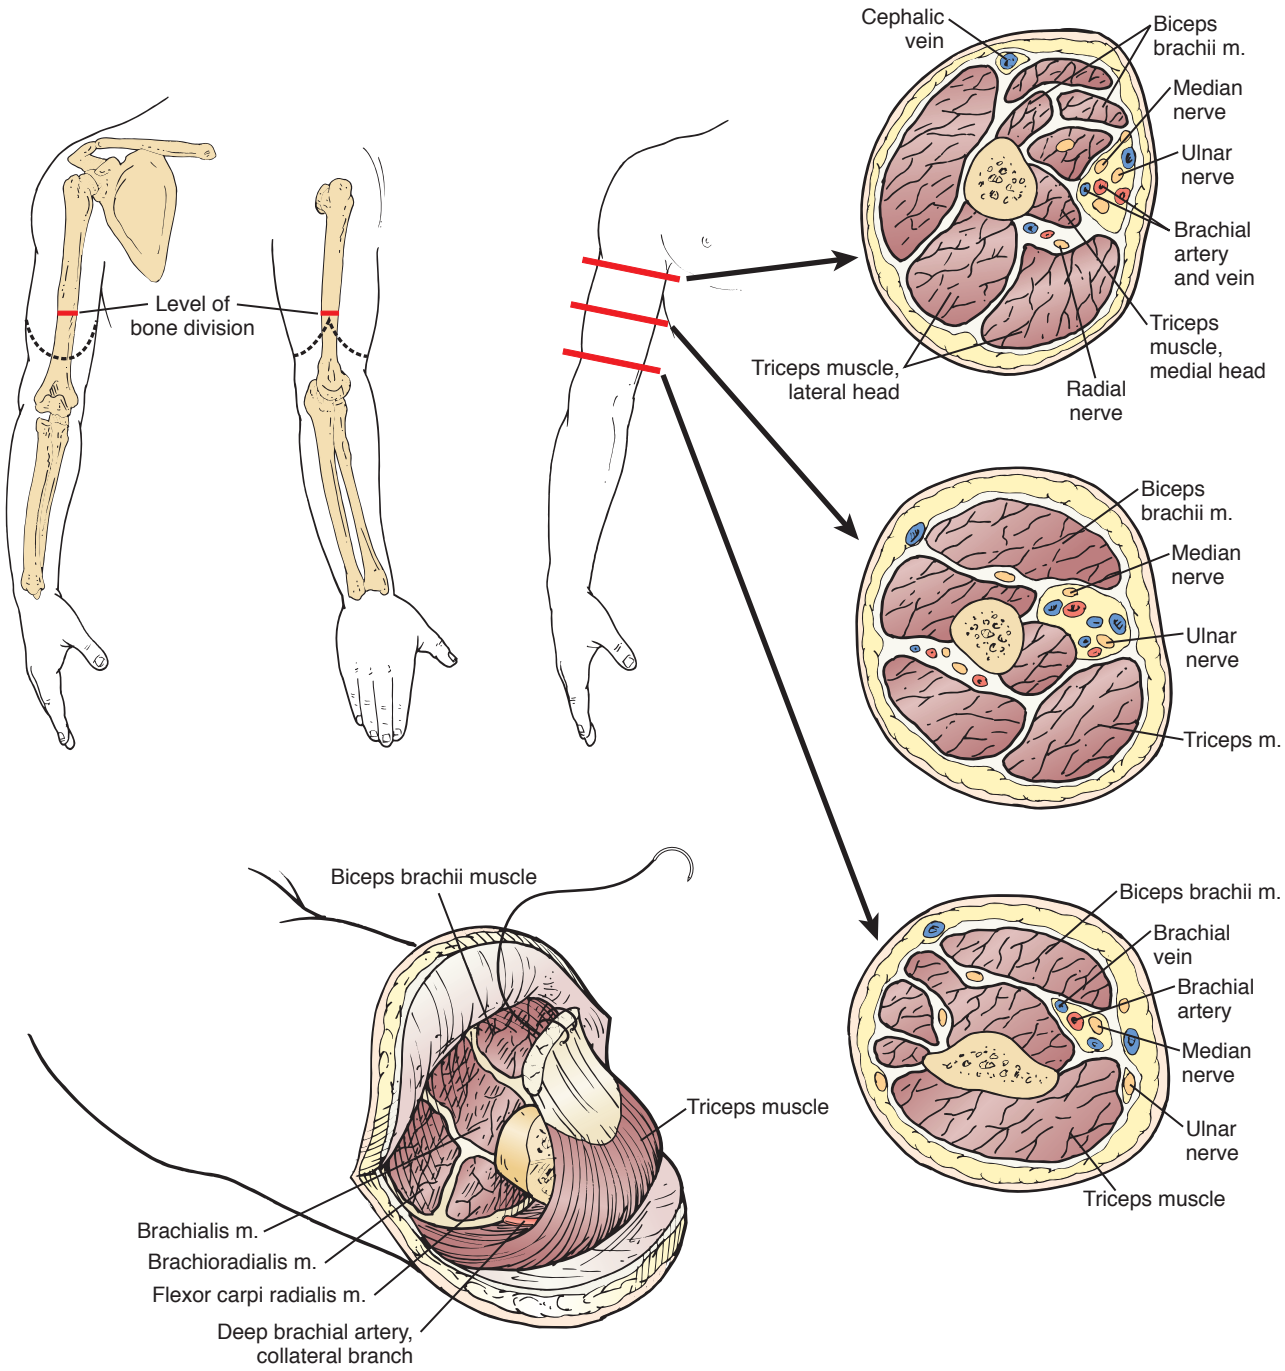

Figure 119.4 Upper arm amputation can be performed at several levels. The initial operation should be focused on maintaining as much humeral length as possible and the epicondyles, if salvageable. (Adapted with permission from Maxwell MC. Amputations in trauma. In: Thal ER, Weigelt JA, Carrico CJ, eds. *Operative Trauma Management: An Atlas,* 2nd ed. New York: McGraw-Hill; 2002:451.)

amputation, should generally occur in less than 5% of cases. Failure of complex tissue transfers, if performed, occurs in 3% to 8% of upper extremity reconstructions early and becomes even rarer in later evaluation.[52]

Poor wound healing and the concerns of flap ischemia and stump necrosis, which are well appreciated in lower extremity amputation, occur infrequently in upper extremity amputation but must be recognized if they do occur. Potential systemic complications of upper extremity amputation are related to septic events, associated traumatic injuries, or systemic consequences of either a global vascular process or an organ system comorbidity. As with treatment of any ischemic injury, should upper extremity amputation be performed subsequent to attempts at limb salvage and revascularization or after significant crush injury, one should be attuned to the potential for significant rhabdomyolysis and myoglobinuria. The threat of this problem

is usually less than in the lower extremity because of smaller muscle mass, shorter arm length, and, thus, attainment of collateral flow; yet it remains a possibility, and proper hydration and urine alkalinization should be instituted, if necessary.

Revision

Because the majority of upper extremity amputations are secondary to trauma, reoperations for residual limb revision are often required. Recently, a study describing a cohort of soldiers involved in OIF/OEF found that of 100 major upper extremity amputations, 42% required repeat surgical procedures. Interestingly, patients undergoing transradial amputation were 4.7 times more likely to have phantom pain. Revisions of these amputations resulted in an increase in prosthetic use from 19% preoperatively to 87% postrevision. Obviously, this underscores both the improved understanding and treatment of this complex patient population, as well as the complex and intensive care required to provide a reasonable endpoint for these patients.[53]

Phantom Pain

Phantom sensations occur over time in the majority of patients undergoing upper extremity amputation. Long-term phantom

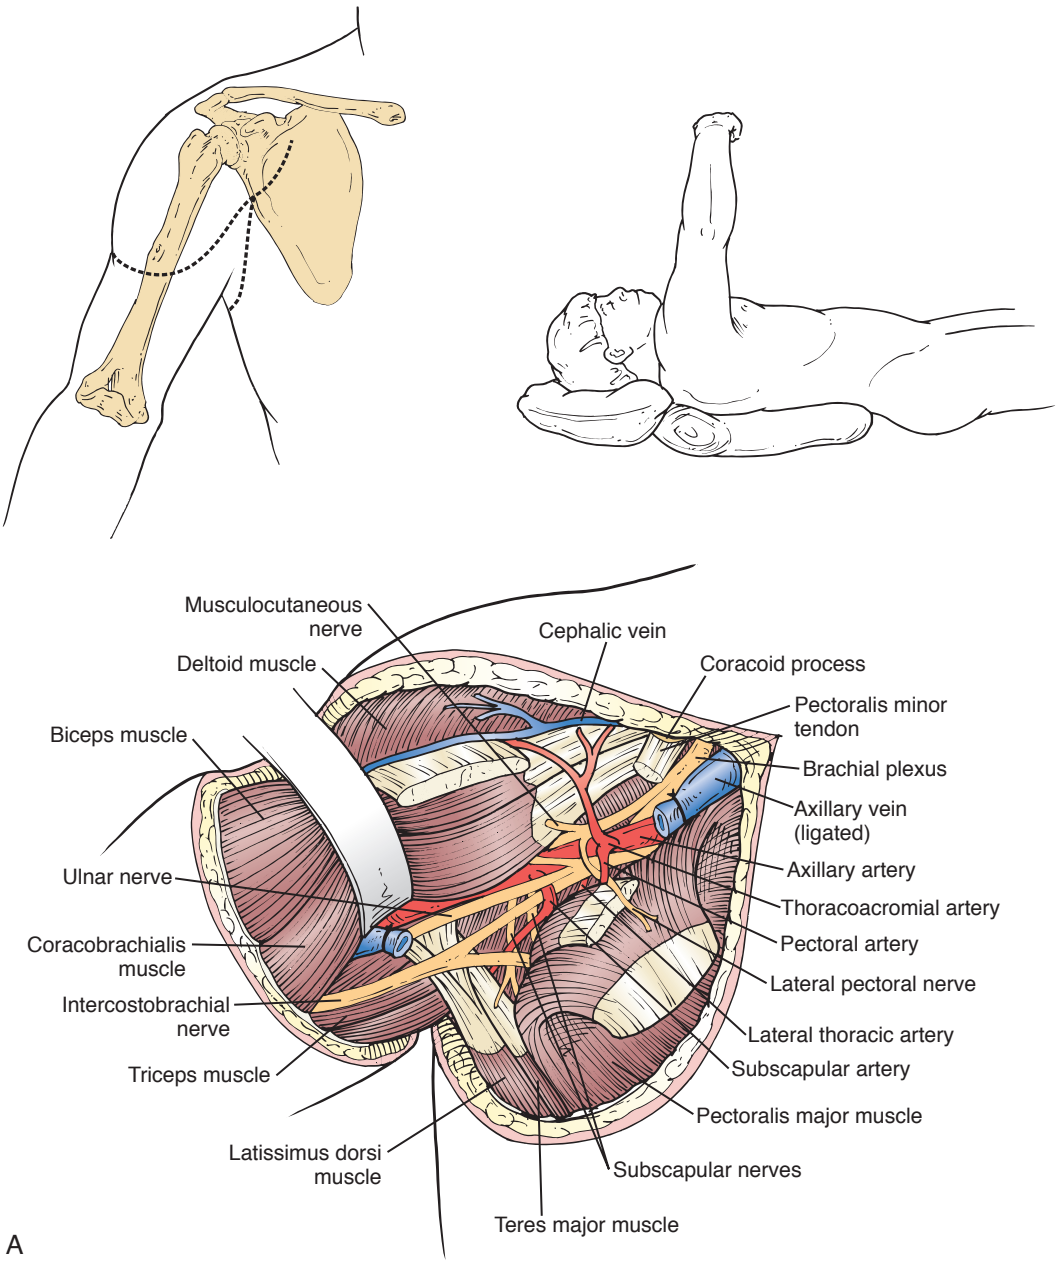

Figure 119.5 Shoulder disarticulation as classically described. (A) Skin incision and initial anterior approach with division of the anterior attachments, brachial plexus, and subclavian vessels. *Continued*

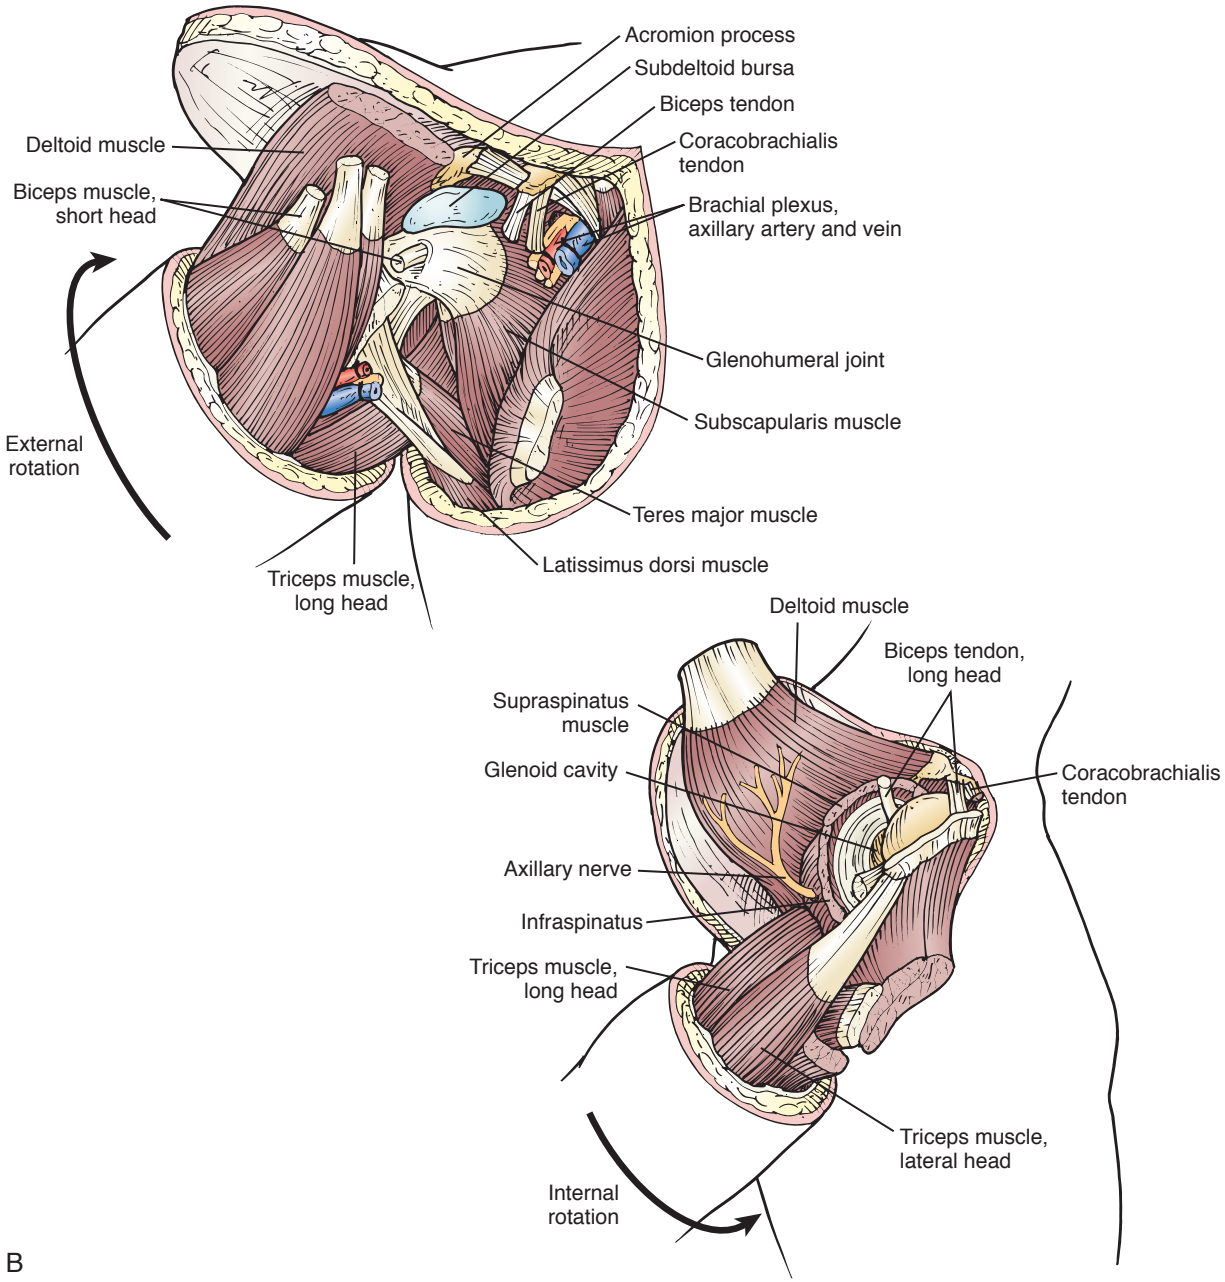

Figure 119.5, cont'd (B) Completion of all anterior and posterior attachment transections.

pain, in varying degrees, occurs in 40% to 80% of patients.[54,55] In an evaluation of upper extremity amputees from the Iran-Iraq War during an average of 17.5 years, phantom pain occurred in 32% of amputees.[56] Treatment methods for phantom pain are numerous and usually multidimensional, but can be generally categorized as pharmacologic, surgical, psychological, and neurostimulatory. Newer evaluations of motor cortical changes and alterations in hemispheric function after upper extremity amputation may, in the near future, lead to novel therapeutic methods to treat postamputation pain syndromes.[57] It has been suggested that loss of the dominant hand is an independent predictor for the development of more significant phantom limb pain.[58]

Psychosocial Rehabilitation

When compared with lower extremity amputees, those losing part of the arm or the hand suffer from a higher rate of psychological disorders, such as depression, anxiety, and PTSD. Although, overall, this area is relatively poorly studied, it appears that approximately 30% to 40% of upper extremity amputees will require psychological care afterward.[59] In a study by Desmond, it was noted that prevalence of significant depressive symptoms was 28.3%.[60] This finding is specifically related to the complex impact that the upper extremity and its components have on daily function. The effect that hand function has on both the patient's quality of life and his or her psychological

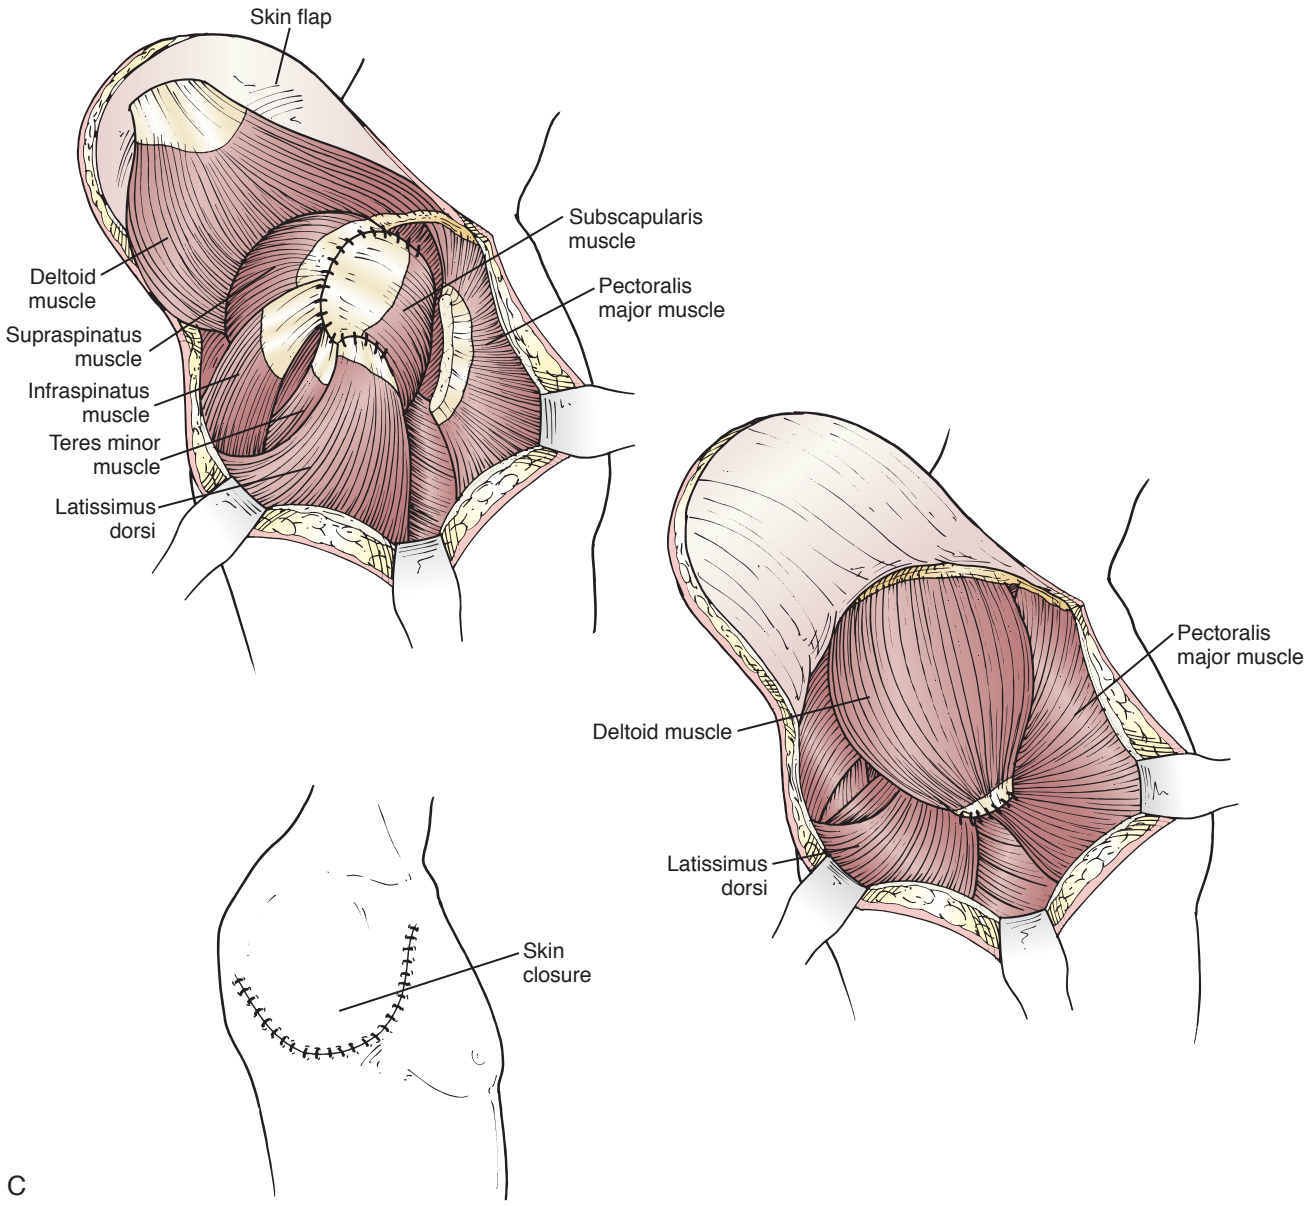

Figure 119.5, cont'd (C) Sequential closure over the glenoid of the scapularis muscle, other rotator cuff components, latissimus dorsi muscle, pectoral muscle, and deltoid muscle. (Adapted with permission from Maxwell MC. Amputations in trauma. In: Thal ER, Weigelt JA, Carrico CJ, eds. *Operative Trauma Management: An Atlas,* 2nd ed. New York: McGraw-Hill; 2002:452–457.)

well-being is recognized. It is therefore understandable that loss of hand function, not to mention the physical aspects of the hand and arm, directly leads to a grieving process and possibly longer term psychological disorders.

Physical Rehabilitation

Rehabilitation for those with upper extremity amputation is complex and onerous, and, to date, the technology and functionality of upper extremity prosthetics have lagged behind those of the lower extremity because of the intricate movements and fine sensorimotor function in the native arm and hand. Replicating these attributes has been difficult. The rehabilitative principles used for upper extremity amputees are not unique. They encompass residual limb soft tissue shrinkage and shaping, desensitization, maximization of range of motion, skin health and mobility, muscle strength, augmentation of self-reliance and daily activities, and, finally, exploration of prosthetic options.[61] These key features are focused on issues that provide a reduction in postamputation pain and maximize the potential for meaningful prosthetic use.

Prostheses

Prostheses used in the upper extremity fall into three categories: purely aesthetic, body powered, and myoelectrically powered.[62,63]

Figure 119.6 Aesthetic forearm and hand silicone prosthesis.

Aesthetic prostheses are simply that. They usually consist of silicone and are made to produce a lifelike appearance so the amputee can have a relatively normal body habitus (Fig. 119.6). They have very minimal function. Body-powered prostheses are simple mechanical devices that are controlled by residual body motion and function (Fig. 119.7). They are, in general, the most durable of prostheses and are used for most significant physical activity by amputees. Indeed, young upper extremity amputees use these types of prostheses for swimming, rock climbing, and performing most athletic activities.

Myoelectrically controlled prostheses use electrodes to convert the electrical stimulation of residual muscle groups into a current used to power the prosthesis. This has made movements, such as wrist rotation and finger movement, a reality, and many terminal devices may be attached to the prosthesis to allow various functions (Fig. 119.8). Although they permit greater degrees of freedom, these prostheses are much more complex, more expensive, and less durable for hard physical activity. Progress in myoelectric technologies continues at a rapid pace. In addition, the Defense Advanced Research Projects Agency, in affiliation with Johns Hopkins University, is now developing and testing an upper extremity prosthesis that is myoelectrically controlled with nearly all the degrees of freedom of a human arm (Fig. 119.9).[64] The residual muscles are surgically reinnervated, with or without splitting, for the maintenance of cortical functioning to enable muscle contraction and, thus, application of the myoelectric prosthesis. This technique, targeted reinnervation, has been clinically applied recently, and has improved the prosthetic function in a small number of patients. The results of this procedure have allowed this group of patients to simultaneously open and close the hand, and flex and extend the elbow.[33,65,66] Another complex, contemporary method of neural control of biomechanical upper extremity prostheses involves the placement of electrodes directly on the cerebral cortex.[67] As this technique continues to undergo study and improvement, integration of direct cortical signaling into mechanical endpoints is proving to be intricate. It is likely that in the near future a prosthetic mechanical arm controlled by the patient's own neurologic processes, and with almost normal function, may be an everyday reality.

Figure 119.7 (A) Body-powered left arm prosthesis in a young soldier after transhumeral amputation. Note the pincer terminal device, cable powered by proximal movements at the shoulder girdle harness. (B) Forearm sleeve body-powered golf prosthesis with a terminal device for the club handle.

Hand Transplantation

The first hand transplantation was performed in 1964 and it failed secondary to acute rejection. Since that time, over 70 transplantations have been performed as at 2013.[68] The improvement in surgical technique and decreasing rejection with better immunosuppressive medications has led to success in hand

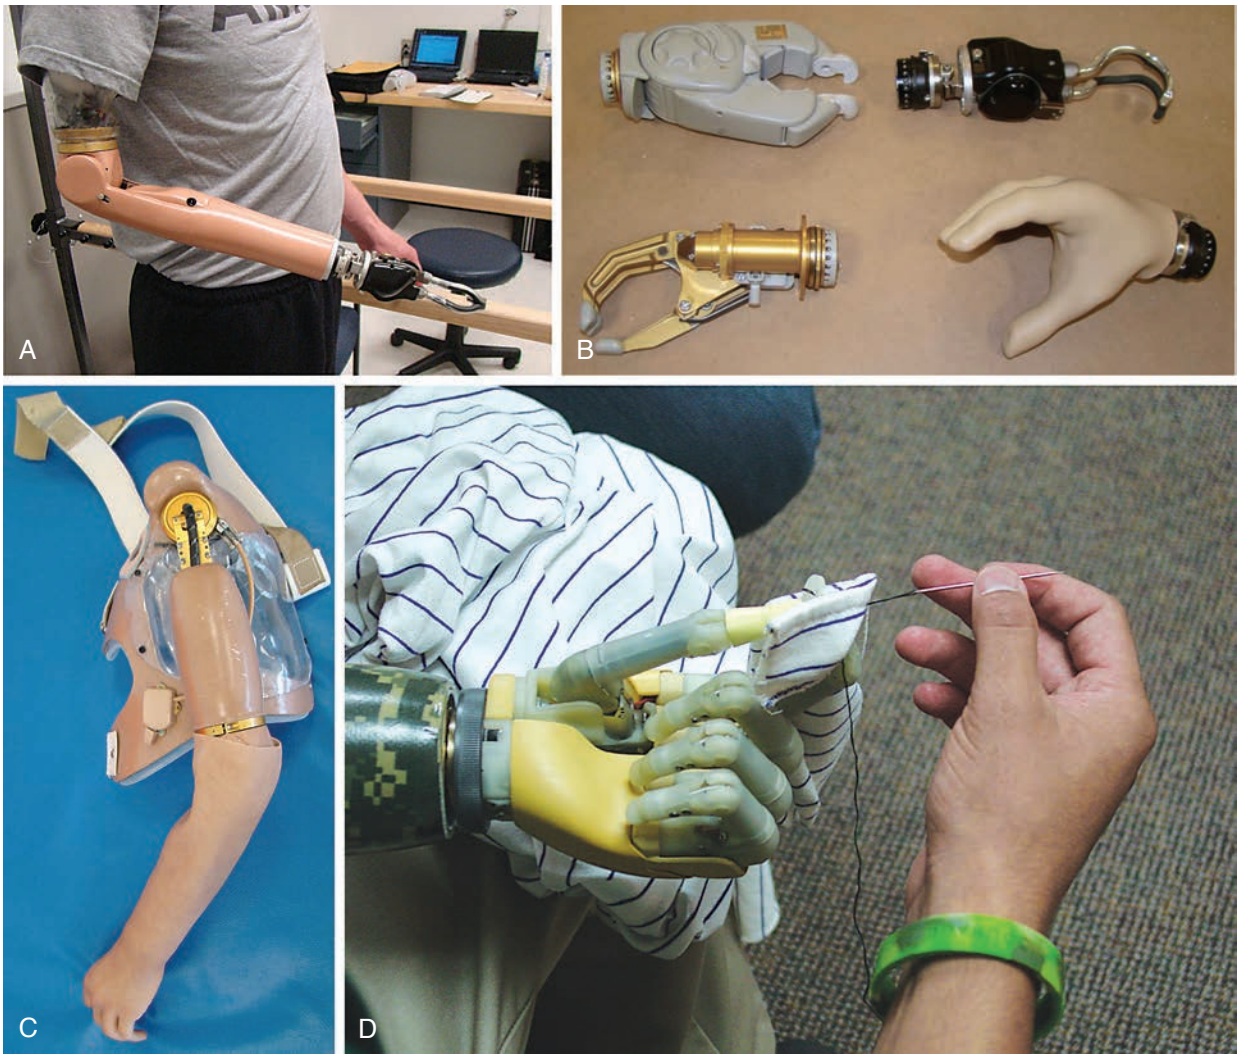

Figure 119.8 (A) Contemporary myoelectric arm prosthesis with a classic pincer terminal device. (B) Various detachable terminal devices used on myoelectric upper extremity prostheses for differing needs. (C) Shoulder girdle-mounted myoelectric arm prosthesis with a silicone aesthetic cover. (D) The i-LIMB hand (Hangar Orthopedic Group, Inc., Bethesda, MD) is a new hand prosthesis with myoelectric control that is able to simulate nearly normal hand motion.

transplantation. In a review of five bilateral hand transplant patients with a mean follow up of 7.6 years, Bernardon et al., found that the physical results achieved were considered "fair" and the functional results were considered "good," but the procedure is demanding for the patients and the rehabilitation team and carries the risk of chronic rejection.[69] Obviously, the success must be tempered by the continued need for lifelong immunosuppression. The ethical dilemma is weighing the perceived benefit of hand transplantation in regard to expected quality-adjusted life years (QALY) versus the effects of long-term immunosuppression. Alolabi studied the health utility of hand transplantation in the general public and a group of hand amputee patients and found that their results did not support a clear benefit to advocate for hand transplantation.[68] As this technique grows and more long-term studies are performed, we will identify whether it is a viable solution for patients with hand amputations.

LONG-TERM OUTCOMES

There are few reports of late outcomes after upper extremity amputation. Meaningful comparative information is difficult to obtain because of differing causes, levels of amputation, and amputee age, in addition to many other variables. The rate of late stump revision remains poorly defined for similar reasons, but late revision is not uncommon and is influenced by both disease and either prosthesis-induced or prosthetic technology–specific concerns. Such concerns may include late skin and musculoskeletal changes, and complications necessitating revision, such as ulcers, stump necrosis, dermatitis, infection, or disease recurrence in the stump, as with malignancy and vasculitis. In addition, revision of the bony and soft tissue stump components to allow the fitting and use of more modern prostheses may be chosen.

In general, attitudes toward prosthesis use in proximal upper extremity amputees are poor, and currently, as many as 40%

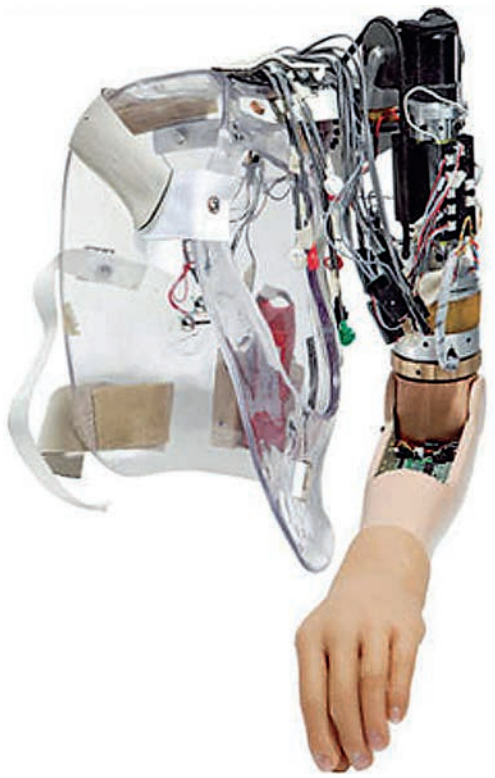

Figure 119.9 Complex myoelectric upper extremity prosthesis developed at Johns Hopkins in conjunction with the Defense Advanced Research Project Agency. Note the color-coded electrodes, which are placed on certain muscle groups for myoelectric control, or on various aspects of muscles after targeted reinnervation surgery, to allow areas of each muscle to independently transmit current.

would rather not use prostheses.[70] Even those with hand-based amputations can find the return to activities of daily living and job performance challenging.[71] Return to employment has a positive effect on prosthesis use.[72] However, the patient's education level appears to play an important role in postamputation employment. Weed and colleagues found that more than 70% of those with at least some college education were employed after amputation, whereas only 23% of those with a high school or less education were employed.[73] The potential for these long-term physical, socioeconomic, and psychological problems again reinforces the need for upper extremity amputees to have access to a multidisciplinary institution, regardless of whether they choose to seek contemporary rehabilitation and prosthetic options.

INTRODUCTION

Thoracic outlet syndrome (TOS) is a condition resulting from compression of the neurovascular structures traversing the thoracic outlet. The syndrome is divided into three types based on the symptoms and signs of neurovascular compression: neurogenic TOS (nTOS) results from brachial plexus compression, venous TOS (vTOS) results from subclavian vein compression, and arterial TOS (aTOS) results from subclavian artery compression. The distinct symptoms and signs of each of these syndromes are described in Table 120.1.

Most patients with TOS are 20 to 50 years of age. Fewer than 5% are teenagers, whereas 10% are older than 50 years. Seldom is any form of TOS seen in patients older than 65. Seventy percent are female. There is no explanation for the female predominance, but perhaps it is related to the observation that 70% of cervical ribs also occur in females. The exception to this is the subset of patients diagnosed with vTOS, as there is a 2:1 male predominance in this condition.

TOS is uncommon, but its true incidence is unknown because many people with upper extremity pain and paresthesias could have escaped diagnosis by healthcare providers who may have

TABLE 120.1 Comparison of the Three Subtypes of Thoracic Outlet Syndrome

	Neurogenic	Venous	Arterial
Incidence	95%+	3%	1%
Etiology	Neck trauma (i.e., auto accident with whiplash), RSI at work, falls on the floor or ice	Repetitive overhead shoulder movements and/or coagulopathy	Cervical rib or anomalous first rib; rarely, congenital band
Predisposing factors	Cervical rib, congenital band, scalene triangle muscle variations	Congenital narrowing of the costoclavicular space by the costoclavicular ligament or the subclavian tendon compressing the subclavian vein	Cervical rib or anomalous first rib eliminating space under the artery
Pathology	Scalene muscle fibrosis; occasionally anomalous first rib or cervical rib	Subclavian vein stenosis with or without thrombosis	Subclavian artery stenosis, thrombosis or aneurysm formation with mural thrombus and emboli
Symptoms	Extremity pain, paresthesia, weakness plus neck pain and occipital headache, Raynaud phenomenon, chest pain for pectoralis minor syndrome	Swelling of the whole arm, cyanosis, pain	Pain, paresthesia, pallor, coldness; digital ischemia; arm claudication; seldom are there neck or shoulder symptoms
Physical examination	Positive response to provocative maneuvers; tenderness over the scalenes, pectoralis minor	Arm swelling, cyanosis, pain	Those with arterial occlusion: decreased pulses at rest, perhaps color changes and ischemic fingertips, distal emboli
Diagnostic tests	Duplex scan, scalene muscle block, MRI to rule out other conditions, pectoralis minor block, EMG/NCV, MAC measurement[1]	Duplex scan, venogram	Neck radiograph, duplex scan, arteriogram, digital pressures and waveforms, arteriography

EMG, Electromyography; *MAC*, medial antebrachial cutaneous nerve; *MRI*, magnetic resonance imaging; *NCV*, nerve conduction velocity; *PTA*, percutaneous transluminal angioplasty; *RSI*, repetitive strain injury; *Rx*, treatment.

failed to recognize the diagnosis. Of the TOS subtypes, nTOS is by far the most common form, accounting for more than 95% of all TOS patients. vTOS occurs in 2% to 3%, whereas aTOS comprises fewer than 1% of patients.

These syndromes result from a combination of developmental and anatomic anomalies in the thoracic outlet, as well as physical activities and life events that predispose individuals to become symptomatic. A common initiating event is neck trauma, which causes symptoms in patients who may be predisposed to its development based on anatomic developmental anomalies of the thoracic outlet. In this chapter we will describe the relevant anatomy and then elaborate on the pathophysiology of each type of TOS, followed by a discussion of the diagnostic evaluation of TOS.

RELEVANT ANATOMY

There are three anatomic spaces that pertain to the thoracic outlet, including the scalene triangle, the costoclavicular space, and the pectoralis minor (PM) space (Fig. 120.1). The costoclavicular space is traversed by the subclavian vein and is the most common site of subclavian vein compression (see Figs. 120.1 and 120.2). The subclavian artery and brachial plexus traverse the thoracic outlet between the anterior and middle scalene muscles, also referred to as the scalene triangle (see Figs. 120.1 and 120.2). The scalene triangle is the most common site of brachial plexus compression. When present, cervical ribs and anomalous first ribs also compress the plexus in this location (Fig. 120.3).

Nerves

In addition to the brachial plexus, the phrenic and long thoracic nerves are seen during supraclavicular dissections. Very close to the area but rarely seen are the dorsal scapular nerve and cervical sympathetic chain.

Brachial Plexus

The brachial plexus arises from nerve roots C5 to T1. In the scalene triangle area the five nerve roots become three trunks. The anterior and posterior divisions and cords of the plexus are usually formed proximal to the PM space, so it is the branches of the plexus that lie under the PM muscle, along with the axillary artery and vein.

Phrenic Nerve

Arising primarily from C4, the phrenic nerve usually receives branches from C3 and C5. It is single in 87% and double or triple in 13% of individuals. The phrenic nerve descends 84% of the time from the lateral to the medial side of the anterior scalene muscle. In the other 16% of individuals, the phrenic nerve remains on the lateral side.[2]

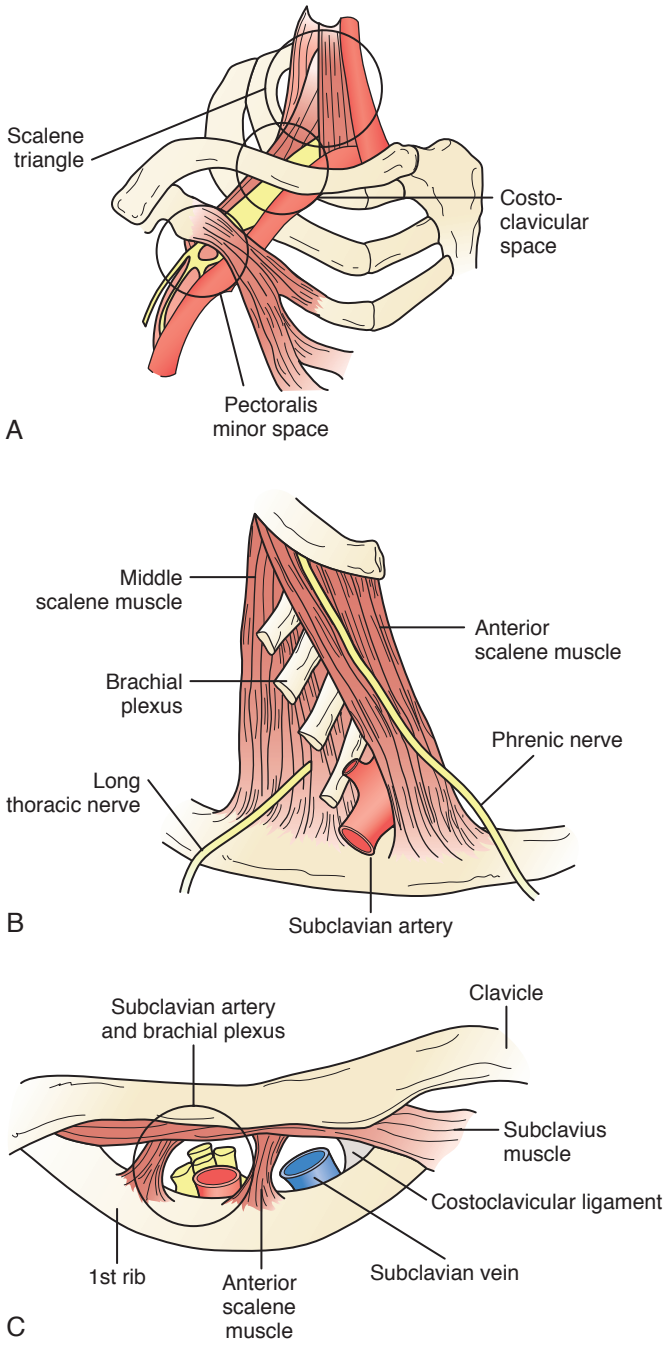

Figure 120.1 (A) Anatomy of the thoracic outlet with respect to the three major spaces. (B) Scalene triangle with the phrenic and long thoracic nerves located in the most common positions. (C) Costoclavicular space revealing the subclavian vein being separated by the anterior scalene muscle from the subclavian artery and brachial plexus.

Long Thoracic Nerve

The long thoracic nerve arises primarily from C6 and usually receives contributions from C5 and C7. The C5 and C6 branches run through the muscle belly of the middle scalene muscle, where they usually join. The C7 branch arises from the posterior aspect of the nerve root and often descends below the middle scalene before joining the other two branches.

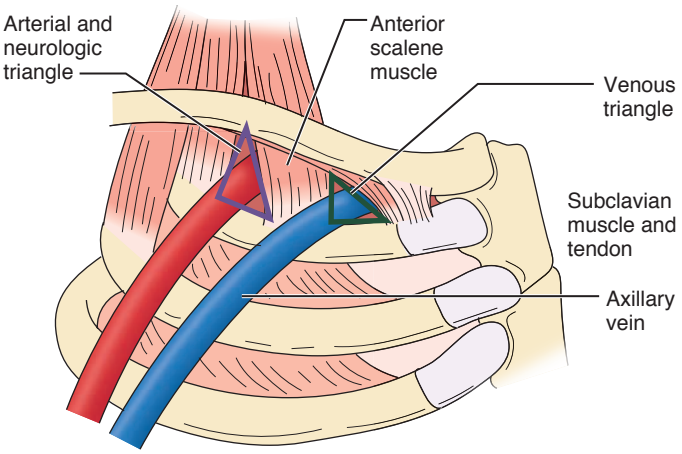

Figure 120.2 Anatomic triangles of the thoracic outlet highlighting the location of the neurovascular structures. The subclavian artery and brachial plexus traverse the thoracic outlet through the scalene triangle. The subclavian vein traverses the thoracic outlet anterior to this through the costoclavicular space. (Adapted from Moore R, Lum YW. Venous thoracic outlet syndrome. *Vasc Med*. 2015; 20:182-189.)

Dorsal Scapular Nerve

The dorsal scapular nerve, the first branch of C5, courses through the cephalic portion of the middle scalene muscle and then descends lateral to the muscle. However, it may course very close to the area of dissection in supraclavicular approaches to thoracic outlet decompression.

Cervical Sympathetic Chain

Though not usually in the operative field of supraclavicular procedures, the cervical sympathetic chain lies over the transverse processes of the cervical vertebrae and is therefore very close to the origin of the anterior and middle scalene muscles. As a result, when cautery is used to excise the scalene muscles at their transverse process origins, the current may reach and damage the cervical sympathetic chain. This is the probable explanation for the occasional case of Horner's syndrome observed after supraclavicular scalenectomy.

Variations and Anomalies of the Scalene Muscle

A significant number of anatomic variations in scalene muscles have been observed both in the normal population and in patients with nTOS. They are too common to be called anomalies. These variations might be regarded as anatomic and developmental variations predisposing to TOS, but are not regarded as causes.

Splitting of the anterior scalene around C5 and C6. Such splitting was noted in 45% of cadavers and in only 21% of nTOS patients.[3]

Scalene minimus muscle. This muscle arises from the transverse processes of the lower cervical vertebrae, runs in front of C8 and T1 and behind the subclavian artery, and inserts on the first rib or Sibson fascia. Its incidence is 25% to 55%.[4]

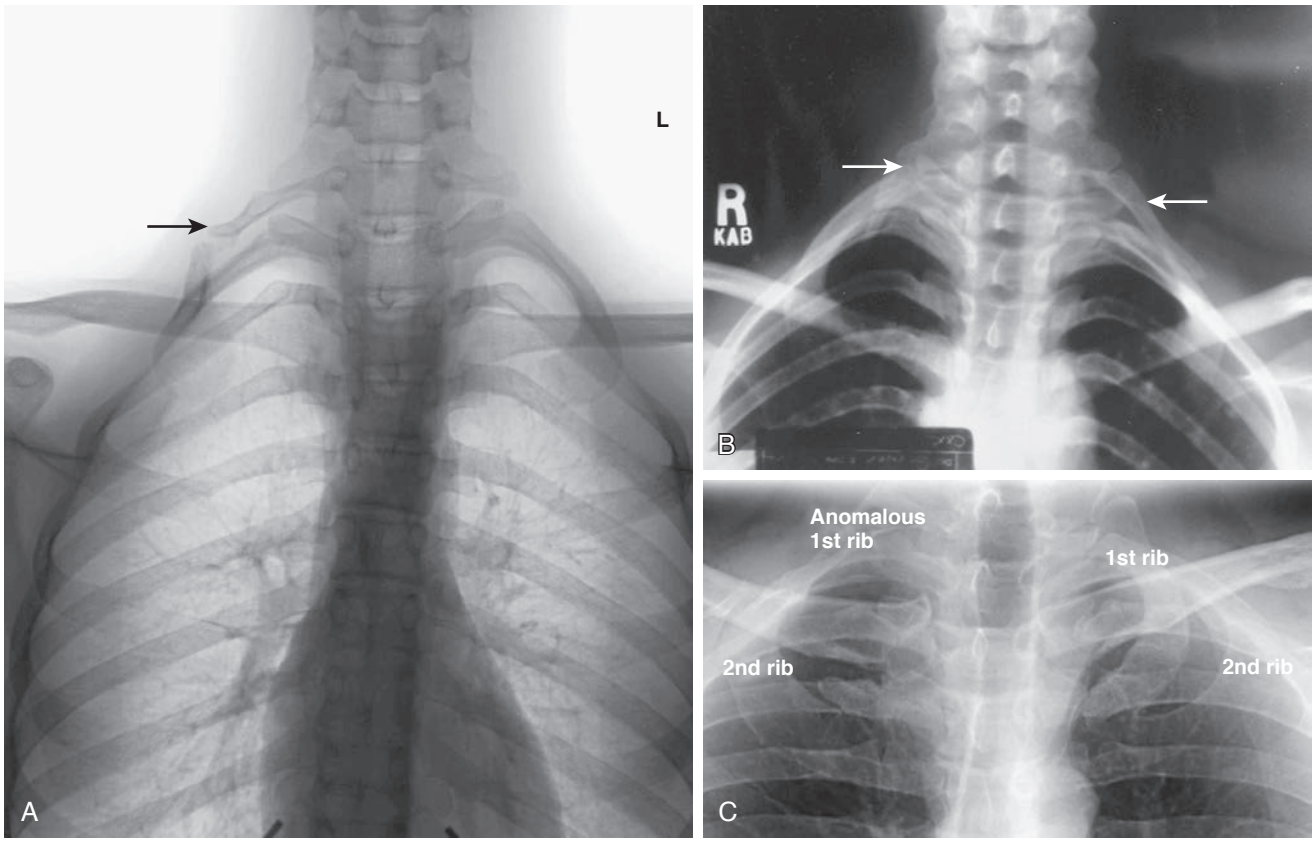

Figure 120.3 (A) Right complete cervical rib with a true joint between the cervical rib and a small process arising from the top of the first rib. (B) Bilateral cervical ribs, incomplete on the right and complete on the left. (C) Anomalous first rib.

Interdigitating muscle fibers. Such fibers commonly run between the anterior and middle scalene muscles. They were noted in 75% of nTOS patients and in only 40% of cadavers.

Scalene triangle width. The width of the scalene triangle varies from very narrow to quite wide, with the distance between the two scalene muscles at their insertion on the first rib ranging from 0.3 to 2.0 cm. The nerve roots emerge lower in a wide triangle compared with their pathway in a narrow triangle (Fig. 120.4). Observations during surgery have revealed that most nTOS patients have the narrower type of triangle.[2]

Congenital bands and ligaments. These structures are frequently observed in the normal population, with an incidence as high as 63%.[5] Although bands have been observed in almost every area of the scalene triangle and have been nicely classified,[6] their role is as a predisposing factor rather than a direct cause.

Relationship of the subclavian vein to the phrenic nerve. The phrenic nerve usually runs posterior to the subclavian vein. However, in 5% to 7% of individuals, the phrenic nerve runs anterior to the vein and in this position can be a rare cause of subclavian vein obstruction.[7]

Relationship of the subclavian vein and costoclavicular ligament. The subclavian vein passes cephalad to the first rib just before it is joined by the jugular vein. It is bounded medially by the costoclavicular ligament and superiorly by the subclavius tendon. A variation in the position of the vein is its position more medially on the first rib so that it is partially compressed by the costoclavicular ligament. Variations in the thickness of the subclavius tendon can also result in compression of the vein from above. These variations in position between the three structures predispose to the development of subclavian vein obstruction. Obstruction is then caused by excessive abduction of the upper extremity, which results in compression of the vein against the dynamic outlet created by the costoclavicular ligament, subclavius tendon, and the first rib.

Skeletal Abnormalities

As many as 29% of patients with TOS have been reported to have skeletal anomalies, including cervical ribs, clavicular anomalies, and isolated first rib abnormalities, the majority of which are congenital.[8] Anomalous or rudimentary first ribs are often overlooked on routine chest radiographs. In a study conducted in 1939, 5000 chest radiographs were reviewed, and it was found that the incidence of anomalous first ribs and cervical ribs in these subjects was 0.76% and 0.74%, respectively. Anomalous ribs occurred equally in women and men. In contrast, the female-male ratio of cervical ribs was found to be 7:3.[9] Cervical ribs and anomalous first ribs are both narrower and are positioned more cephalad than a normal first rib. The only difference between the two is that a cervical rib arises from the transverse process of C7, whereas an anomalous first rib arises from the transverse process of T1 (see Fig. 120.3).

Figure 120.4 Scalene Triangle Variations. (A) The usual relationship found in cadavers. The triangle is wider and the nerves emerge lower in the triangle than in most patients with neurogenic thoracic outlet syndrome. There is minimal contact between nerve and muscle. (B) Narrow scalene triangle in which the nerves emerge high and are touching the muscles as they emerge. Contact between nerve and muscle is more significant compared with A. (Adapted from Sanders RJ, Roos DB. The surgical anatomy of the scalene triangle. *Contemp Surg.* 1989; 35:11-16.)

About 30% of cervical ribs are complete ribs fused to the first rib by a true joint or a fibrous attachment. The other 70% are incomplete cervical ribs with no direct attachment to the first rib. However, most of these incomplete ribs have a tight fascial band extending from the tip of the cervical rib to the first rib.[6] The cervical rib and attached band lie within the middle scalene muscle, thereby narrowing the space within the scalene triangle through which the nerve roots of the brachial plexus course. Thus an incomplete cervical rib with associated band can behave like a complete rib. Cervical and anomalous first ribs can compress the subclavian artery and cause stenosis with or without poststenotic aneurysm formation. More commonly, these anomalous ribs compress the lower trunk of the brachial plexus and cause neuropathy. However, most cervical and anomalous first ribs remain asymptomatic throughout life.

When symptoms do develop, they are usually neurogenic (see Chapter 121). In a recent review of 47 nTOS operations involving abnormal ribs, 15% were performed in the setting of anomalous first ribs and 85% were performed in the setting of cervical ribs. Spontaneous onset of symptoms occurred in 50% of patients with complete cervical ribs versus only 20% with incomplete ribs. Neck trauma preceded the onset of symptoms in the other 80% with incomplete ribs and in the 50% with complete ribs.[10] All patients with cervical ribs are predisposed to the development of some form of TOS—most commonly nTOS. Cervical ribs or anomalous first ribs are almost always present in patients with aTOS. On the other hand, symptomatic cervical ribs are more likely to produce symptoms of nTOS than aTOS. Over a 28-year period during which more than 1000 nTOS operations were performed, there were 39 cervical ribs and 7 anomalous first ribs treated in this group of patients, with an incidence of 4%. Among the same group of TOS patients, there were only nine with aTOS—five with complete cervical ribs and four with anomalous first ribs, with an incidence of less than 1%.[10]

Contribution of the Pectoralis Minor

The PM can also cause compression of the structures of the thoracic outlet, leading to nTOS, vTOS, and aTOS in rare circumstances. Pectoralis minor syndrome (PMS) results when this muscle causes compressive symptoms in the subcoracoid or PM space. The PM space is actually outside the thoracic outlet area, but compression of the upper extremity neurovascular bundle can occur in this space between the PM muscle and ribs of the chest wall. Although this might better be termed "axillary compression syndrome," it is appropriate to consider the PM space as an extension of the thoracic outlet area, because compression here is common and the axillary and the thoracic outlet neurovascular bundles contain the same elements (see Fig. 120.1). The PM syndrome results from excessive trauma or exercise of the shoulder girdle caused by hyperabduction. The PM muscle becomes tight and hypertrophied and can compress the brachial plexus, axillary vein, and rarely the axillary artery. PMS is frequently responsible for recurrent nTOS after thoracic outlet decompression and can be responsible for up to 75% of cases of recurrent nTOS.[11] It is this PM space that should be evaluated more carefully, particularly in patients with recurrent or persistent symptoms after initial operation for nTOS.

Neurogenic Thoracic Outlet Syndrome

There are no established diagnostic criteria or reference standards for the diagnosis of nTOS (see Chapter 121).[12] Unlike the diagnostic algorithm for aTOS and vTOS, the diagnostic criteria for nTOS are highly disputed. Such extensive debate exists regarding nTOS being a nebulous diagnosis that there are even classifications by which nTOS is classified as "true" nTOS (with objective changes such as muscle atrophy) or "disputed" nTOS.[13] Regardless, a standardized approach in the diagnosis and workup of nTOS patients selects a group of individuals who have an excellent chance of symptomatic relief from thoracic outlet decompression.

Pathogenesis

In nTOS, predisposing factors include scalene muscle anomalies, narrow scalene triangles, congenital ligaments or bands, roots

of the plexus arising high near the apex of the scalene triangle, and cervical ribs. A common cause of nTOS is neck trauma that involves a hyperextension neck injury. Whiplash in a motor vehicle accident is the most common injury. Other frequent causes are repetitive stress injuries in the workplace and falls on slippery floors or icy walkways. The presence of a cervical rib predisposes to the development of nTOS. In such patients, neck trauma may precipitate symptoms, but in some patients with no history of trauma, activities of daily living can also cause nTOS when the anatomic relationships between the rib and arm cause nerve compression.

Pathology

The common pathologic findings in most patients with nTOS are (1) developmental anomalies of the thoracic outlet and fibrosis of the scalene muscle, and (2) conversion of muscle fibers from fast twitch to slow twitch.[14,15] The fact that transaxillary first rib resection for the treatment of nTOS has become popular since its introduction by Roos in 1966 has led some to believe that the first rib is the underlying cause of the pathology.[16] This is not universally believed to be true. Many think that the attachments to the first rib are the more likely cause of nTOS. Support for this theory is that there are reports demonstrating that the results of anterior and middle scalenectomy without first rib resection are similar to those of scalenectomy with first rib resection.[15]

Pathophysiology

Although the pathophysiology of nTOS may vary depending on the specific predisposing and causative factors, it is usually associated with a narrowed scalene triangle. These patients are asymptomatic until neck trauma stretches and tears some of the anterior and middle scalene muscle fibers. This mechanism explains the neck pain that usually appears within the first 24 hours of a neck injury. Over the next few days, swelling of the muscles from bleeding or inflammation, or both, results in compression against the nerve roots of the brachial plexus. This compression then causes upper extremity pain and paresthesias, the onset of which is usually delayed a few days or weeks after the initial trauma. As the muscle injury heals and the swelling subsides, scar tissue replaces the blood that collected within the muscle, which accounts in part for muscular fibrosis. The upper extremity neurologic symptoms persist due to compression of the nerves by scar tissue. This may manifest as persistent neck pain resulting from scalene fibrosis, and occipital headaches may occur as referred pain from scalene muscle spasm. When nerve compression involves the C8 and T1 branches of the lower trunk of the brachial plexus, the sympathetic nerve fibers supplying the extremity may also become irritated or compressed where they associate with the lower trunk of the brachial plexus at this location, traversing the scalene triangle. This may result in the development of a unilateral Raynaud phenomenon that manifests as intermittent subjective coolness and color change.[17]

Data supporting the scalene muscles as the site of pathology include (1) histologic studies of the scalene muscles that demonstrate an average of three times more scar tissue in the scalene muscles of nTOS patients compared with control patients, (2) the strong correlation between positive responses to scalene muscle blockade and positive responses to surgery, and (3) the fact that the rate of improvement after surgery for nTOS is the same as that for scalenectomy with or without first rib resection.

History

Obtaining a history of some type of neck trauma preceding the onset of symptoms is helpful for all types of TOS, but particularly when considering a diagnosis of nTOS. Although nTOS may occur spontaneously, more than 80% of patients have a history of some type of neck trauma, the most common being whiplash injuries from motor vehicle accidents, history of clavicular fracture, falls on slippery surfaces or down stairs, and repetitive stress injury from hours on keyboards, assembly lines, or in various other occupations. However, the absence of such a history should not exclude the diagnosis of nTOS.

The patient should be asked specifically about occipital headache and pain over the trapezius, neck, chest, and shoulder girdle. A patient who has symptoms confined to the forearm and hand is more likely to have carpal or cubital tunnel syndrome and not nTOS. A history of other interventions related to the musculoskeletal system associated with the cervical spine, shoulder, and upper extremity should also be documented in the medical history. Last, patients with nTOS should be asked about subjective coldness and color changes consistent with the Raynaud phenomenon, which may develop as a result of sympathetic nerve compression.[17]

Physical Examination

The standard neurologic examination often fails to detect nTOS. In addition to tenderness over the scalene muscles and reduced sensation to very light touch in the fingers, an examination for nTOS should include eliciting symptoms by a variety of provocative maneuvers. The three notable provocative maneuvers that should be executed and documented in patients with TOS, particularly nTOS, are as follows:

Adson test. The examiner palpates the radial pulse and then moves the patient's upper extremity into an extended, abducted, and externally rotated position. The patient is then asked to rotate and laterally flex the neck to the ipsilateral side while inhaling deeply. A positive test results in reduction in the amplitude or complete obliteration of the radial pulse.

Elevated arm stress test (EAST or Roos test). The patient is seated with arms abducted at 90 degrees in external rotation, with elbows flexed to 90 degrees and the head in neutral position. The patient is asked to open and close the hands for 3 minutes or until pain/paresthesia sets in and the patient is unable to continue. This test has a high negative predictive value for nTOS if the patient is able to perform the maneuver for 3 minutes.[18]

Modified upper limb tension test (Elvey test). The patient is asked to abduct both arms to 90 degrees with the elbows extended. The patient is then progressively asked to dorsiflex both wrists. The test is considered positive if symptoms are elicited on the ipsilateral side. A subsequent maneuver is carried out

by having the patient laterally flex the head on each side. The test is then considered positive if symptoms are elicited on the contralateral side.

Some authors believe that the most effective provocative test is the upper limb tension test of Elvey.[17,19] This test is analogous to the straight-leg raise test in the lower extremity for sciatica and is worth incorporating into every examination for upper extremity symptoms.[17] A positive response indicates compression of either the cervical nerve roots or brachial plexus at the level of the spine, thoracic outlet, or PM space. A negative response is usually adequate to rule out the diagnosis of nTOS.

The Adson test, however, is the most widely recognized of these maneuvers. In Adson's original description of his test, he noted "A decrease or obliteration of the radial pulse or blood pressure is a pathognomonic sign of scalenus anticus syndrome (this is one of the syndromes included in TOS)."[20,21] However, in 1947, the same year of Adson's last report, Gage and Parnell noted that 50% of normal individuals had a positive Adson test.[22] Subsequently others have demonstrated similar high rates of positive Adson tests in healthy volunteers.[1,3,18,23-25] Therefore the Adson test is unable to rule in or rule out a diagnosis of nTOS.[17] Despite the abundant evidence indicating its unreliability, the Adson test is still currently popular among many clinicians, probably because it is the only objective test available on physical examination.

These provocative maneuvers, while occasionally helpful in establishing the diagnosis of thoracic outlet compression, are neither highly sensitive nor specific for identification of thoracic outlet syndrome and are not reliable for identifying a specific anatomic region of pathology.[3,17] Indeed, positive findings on these maneuvers frequently lead to an erroneous diagnosis of vTOS or aTOS in patients whose symptoms and physical findings are typical of nTOS but who have no symptoms or physical findings of aTOS or vTOS. Many patients undergo electromyography (EMG) and nerve conduction velocity (NCV) tests in the course of workup for nTOS. These tests usually have normal or nonspecific results and do not play a helpful role in the diagnostic evaluation for nTOS, except to exclude other compressive neuropathic syndromes.[17]

Anterior Scalene Muscle Block

As elaborated previously, the diagnosis nTOS can be challenging based on history and physical examination alone. The anterior scalene muscle block (ASMB) is a useful adjunct in the diagnostic evaluation of this syndrome, and we have incorporated it into the diagnostic evaluation for nTOS.[17,26,27] ASMB involves injection of the anterior scalene muscle with 1% lidocaine.[12] The subsequent relaxation in the scalene muscle results in a change in configuration of the costoclavicular space, with a subsequent decompression of the thoracic outlet and relief of neurologic symptoms caused by neurovascular compression.[12] Symptomatic suppression subsequent to performing ASMB offers information that is helpful in localizing a pathologic process to a specific inciting anatomic site in the thoracic outlet that responds well to surgical decompression. Thus performing ASMB selects patients who have a high likelihood of responding to surgical management. In our practice, we rarely select patients for surgical thoracic outlet decompression for nTOS until they have symptomatically improved following ASMB.

VENOUS THORACIC OUTLET SYNDROME

vTOS is defined by the presence of compression and subsequent thrombosis of the axillo-subclavian vein (see Chapter 123). This condition is synonymous with Paget-Schroetter syndrome and "effort thrombosis," an older term originating before the pathogenesis of vTOS was understood. Primary effort thrombosis of the axillo-subclavian vein, also known as Paget-Schroetter syndrome, was first described by Paget in 1875[28] and subsequently by Von Schroetter in 1884.[29] There exists a further subset of patients who have symptoms characteristic of vTOS, but without the presence of venous thrombosis; it is a condition termed intermittent obstruction or McCleery syndrome.[30]

Pathogenesis

Venous TOS is most often the result of developmental anomalies of the costoclavicular space and repetitive arm activities such as throwing, swimming, or working with the arms overhead for long periods. In vTOS, the predisposition is the relationship of the subclavian vein to the subclavius tendon and costoclavicular ligament and dimensions of the costoclavicular space. In most patients with vTOS, the subclavian vein is situated closely adjacent to the costoclavicular ligament, and the subclavius tendon compresses the top of the vein within a narrowed costoclavicular space. With the vein in this compressed position, repetitive arm movements can easily traumatize the vein and produce fibrosis, stenosis, and eventually thrombosis. Therefore vTOS is a condition characterized by primary thrombosis of the axillo-subclavian vein secondary to compressive symptoms from thoracic outlet pathology and should be differentiated from secondary thrombosis. Secondary thrombosis of the vein may ensue following injury or iatrogenic causes, including central line or pacemaker lead placement.

Pathology

Many patients with vTOS have coexisting anatomic abnormalities. Some of the recognized anatomic anomalies include abnormalities of the scalenus minimus, pectoralis minor, subclavius, and anterior scalene muscles; ligamentous abnormalities of the costocoracoid ligament; and bony abnormalities of the clavicles and ribs.[31-37] In addition, as many as 43% of the patients treated for vTOS have been demonstrated to have evidence of occult first rib fractures.[38] A significant proportion also has osteophytic degeneration and costochondral calcification. The subclavian vein develops intimal injury and subsequent luminal narrowing. If thrombosis occurs, this event occludes the vein and precipitates acute symptoms of upper extremity deep venous thrombosis. Also characteristic of this condition is the formation of extensive venous collaterals when the occlusion is chronic.

Pathophysiology

Repeated compression injury of the subclavian vein is the inciting event leading to vTOS. As the vein traverses the thoracic outlet, the subclavian vein is in an anatomically tight space bounded by the subclavius muscle and costoclavicular ligament medially, the anterior scalene muscle laterally, the clavicle superiorly, and the first rib inferiorly (see Figs. 120.1 and 120.2).[30] Significant forces result from compression of the clavicle and first rib in a fulcrum-like effect during certain motions and maneuvers, particularly in young athletic males participating in activities that require repetitive overhead movement of the upper extremities. Cumulative trauma to the subclavian vein causes scarring, inflammation, and eventual thrombosis.[39] If left untreated, venous hypertension then ensues and prompts the subsequent development of venous collaterals. The symptoms of swelling and pain resulting from venous hypertension then subside once collaterals mature. Symptoms improve as a result of collateral formation and eventual recanalization of the vein in some patients, even in those untreated. However, thrombus may propagate into the venous collaterals and acute thrombosis of these vessels may occur, resulting in another relatively acute episode of arm swelling and pain characteristic of the presentation of Paget-Schroetter syndrome or vTOS.[40]

Clinical Findings

Consistent with the pathophysiologic mechanism leading to this condition, vTOS is most common in young athletic individuals who perform frequent repetitive overhead movement in the upper extremities, such as pitchers, weightlifters, and mechanics, to name a few.[30] Historical series have suggested a male preponderance, but the largest case series to date actually demonstrated an equal gender ratio.[41] Patients with vTOS are typically asymptomatic until the thrombotic event that results in pain, swelling, and cyanosis with a markedly blue appearance in the acute thrombotic episode. This acute episode is frequently preceded by intense physical exertion, exercise, or labor, and the arm may become severely swollen and edematous, enlarging up to double its normal size in a distribution from the shoulder extending distally to the hand.[42] Important elements in the history would be to rule out any secondary causes of upper extremity deep vein thrombosis such as upper extremity central venous catheters, pacemakers, or symptoms suggestive of malignancy (see Chapter 149).

A minority of patients develop pulmonary embolism, and this complication occurs in 12% or fewer of patients with axillo-subclavian venous thrombosis.[31,43-47] The surprisingly lower rate of venous thromboembolism in these patients is explained by the small clot burden present in vTOS, as well as the anatomic subclavian vein narrowing resulting from vTOS, which sequesters thrombus and prevents embolization.

Physical Examination

In a large case series of vTOS, 93% of patients presented with arm swelling, 77% presented with bluish cyanosis, 66% had worsening of aching pain with exercise, and 8% had minimal findings or symptoms.[41] In addition to pronounced swelling and edema of the involved arm, dilated subcutaneous veins may be present over the upper arm, neck, and chest, and herald chronic venous obstruction. On occasion a tender palpable cord can be appreciated on physical exam in the axilla.[30]

Diagnostic Evaluation

While the physical exam alone may be sufficient to reliably diagnose vTOS with a high degree of certainty in many cases, confirmatory testing is indicated. Duplex ultrasound is the imaging study of choice for the initial diagnosis of vTOS, as it is highly sensitive (78% to 100%) and specific (82% to 100%) for the diagnosis of venous thrombosis (Fig. 120.5).[48-54] Duplex evaluation of vTOS should encompass the entire length of the vein to avoid missing the presence of a subtle or short-segment thrombus and to evaluate the extent of vessel involved. In vTOS, duplex ultrasound typically demonstrates near-complete or complete occlusion of the subclavian vein with loss of flow. It is important to conduct the venous duplex in a variety of provocative maneuvers, with the arm in abduction with flow assessed through the axillo-subclavian vein with color Doppler in these various positions. In the absence of axillo-subclavian vein thrombosis, these maneuvers help establish the diagnosis of McCleery syndrome, which is characterized by intermittent compression of the subclavian vein resulting in upper extremity swelling without venous thrombosis.[55] This condition is diagnosed when significantly elevated velocities or flow occlusion are demonstrated at the thoracic outlet with these provocative maneuvers.

Venography is rarely necessary as an initial diagnostic maneuver, as ultrasound is both highly sensitive and specific for the diagnosis of subclavian venous thrombosis. In the rare instance that a negative duplex ultrasound result is obtained and the clinical suspicion remains high for venous thrombosis, contrast venography may play a helpful role (Figs. 120.6 and 120.7).[30] Contrast venography may also be utilized in the process of performing an initial endovascular intervention—most commonly thrombolysis.[30] Other imaging modalities described for venous imaging, including magnetic resonance venography (MRV) and computed tomographic venography (CTV), do not offer any advantages over venous duplex ultrasound, have equivalent sensitivity and specificity, are costly and time-consuming, and should generally be avoided in the diagnostic evaluation for vTOS.[56] In addition, thrombophilia may play a role in the pathogenesis of vTOS. Some series have documented that a significant proportion of patients presenting with vTOS have a contributory thrombophilia in the pathogenesis of their condition.[57] As such, when a family history or personal history of prior venous thrombosis is present, patients should also be evaluated for the presence of thrombophilia.

ARTERIAL THORACIC OUTLET SYNDROME

The least common form of TOS, aTOS, accounts for 1% of cases,[17] but represents the most firm indication for operative

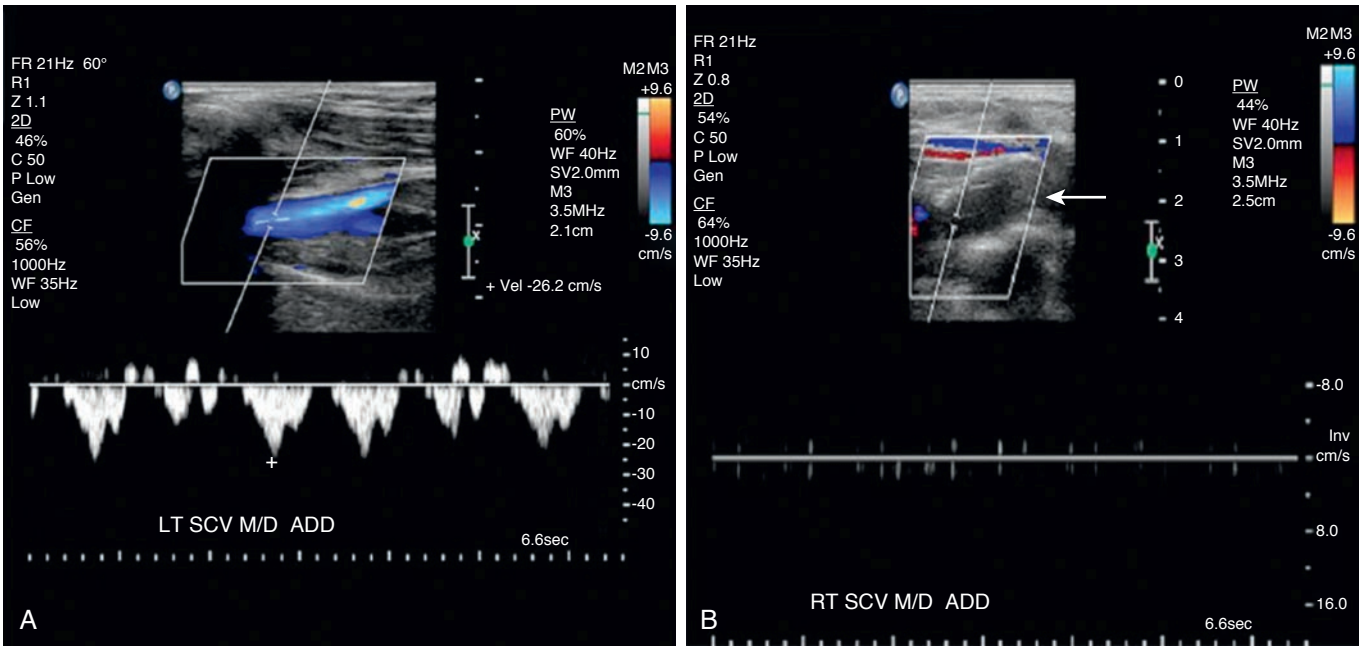

Figure 120.5 Duplex Ultrasound Images of the Axillosubclavian Vein. (A) Demonstrates a normal axillosubclavian vein. (B) Demonstrates a thrombosed axillosubclavian vein, as demonstrated by lack of both color flow and venous waveform, with the presence of an acute thrombus (see *arrow*).

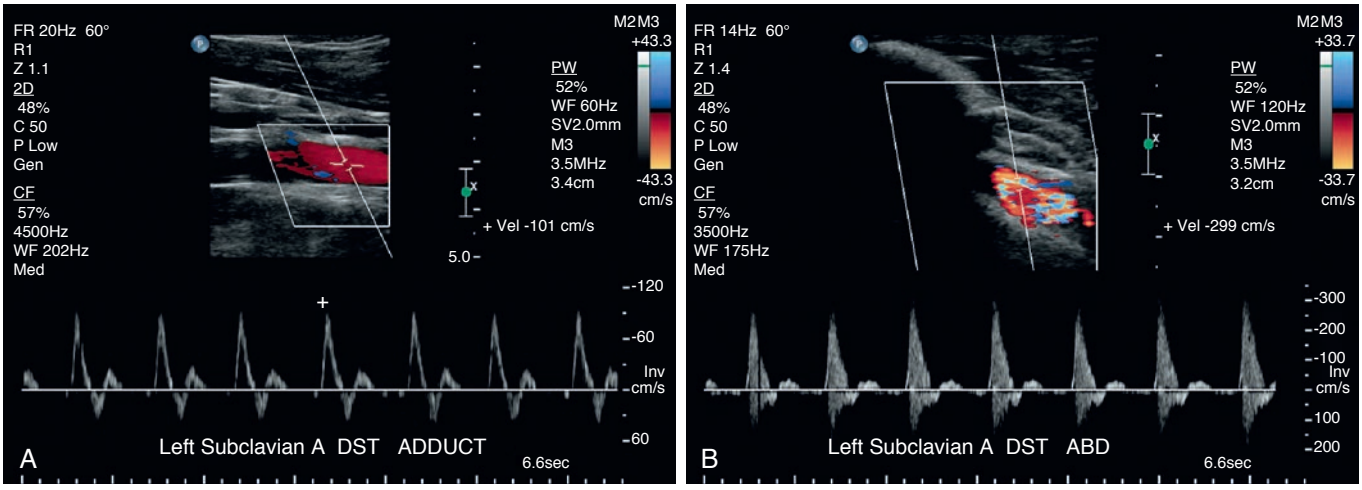

Figure 120.6 Duplex Ultrasound of the Subclavian Artery. (A) Normal arterial flow velocities at rest. (B) Abnormal (>50% increase) arterial flow velocities with provocative maneuvers.

intervention, as this condition confers the potential for embolic phenomena and ischemic complications (see Chapter 122).[58] The syndrome is characterized by a predictable course of events resulting from arterial compression, poststenotic dilation resulting in aneurysmal degeneration, and finally secondary embolism.

Pathogenesis

Arterial TOS is usually associated with a congenital or post-traumatic abnormality in the thoracic outlet. The inciting abnormality is usually a cervical or anomalous first rib, clavicular fracture, or rarely, an anomalous insertion of the anterior scalene muscle. Symptoms and signs are the result of arterial emboli arising from subclavian artery aneurysms or stenosis that resulted from the aberrant anatomy. In a compilation of case series representing 122 reported patients with aTOS, cervical ribs were present in 60%, anomalous first ribs in 18%, fibrocartilaginous bands in 15%, clavicular fracture in 6%, and an enlarged C7 transverse process in 1%.[59] The ensuing arterial compression results in subclavian artery stenosis accompanied by poststenotic dilation that causes the appearance of an aneurysm. Thrombus forms within the dilated portion of the artery just distal to the stenosis, as mural thrombus does in an aneurysm. The disease process is usually asymptomatic until emboli are dislodged.

The pathophysiology is based on the effects of arterial compression by an anomalous first rib, cervical rib, or anterior scalene muscle. Subclavian artery stenosis produces fluid hemodynamics that result in poststenotic dilatation or aneurysm

Figure 120.7 Subclavian venogram in a patient with venous thoracic outlet syndrome demonstrating subclavian vein narrowing due to compression *(arrow)* as the vein traverses the costoclavicular space.

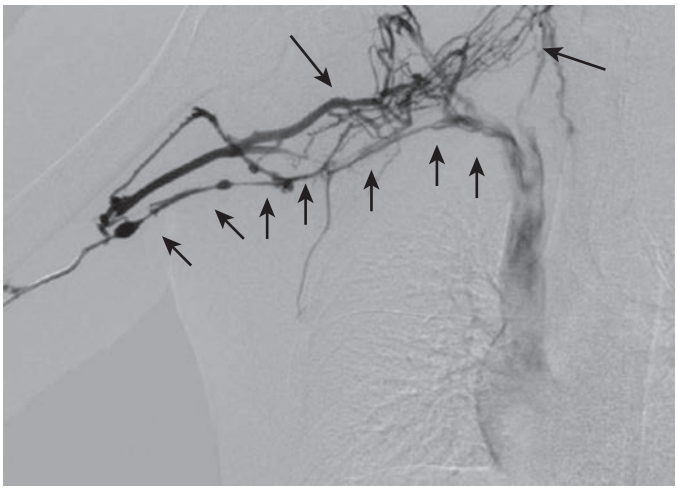

Figure 120.8 A contrast venogram demonstrating near-complete occlusion of the subclavian vein due to thrombus, prior to intervention, in a patient with venous thoracic outlet syndrome (TOS). *Large black arrows* indicate collateral venous drainage around thrombus. *Small black arrows* indicate the native axillary and subclavian vein.

formation, mural thrombus, and distal embolization. The most common presentation is microembolization to the hand, which causes ischemic symptoms.

History

Patients with arterial TOS are usually asymptomatic until arterial emboli occur. Symptoms include digital ischemia, claudication, pallor, coldness, and paresthesia and pain in the hand, but seldom in the shoulder or neck. Patients may complain of exertional pain, easy fatigability, or a "dead arm" sensation.[58] It is important to document if other systemic constitutional symptoms such as fever or malaise are present, which could suggest the possibility of vasculitis, particularly in younger patients. A history of an anomalous first rib or a cervical rib in any prior evaluation should also heighten the suspicion for arterial TOS.

Physical Examination

Evaluation for aTOS should focus on the presence of a subclavian aneurysm and on any signs of distal embolic phenomena. The supraclavicular fossa should be palpated for the presence of a cervical rib and for pulsatile mass. Auscultation should be performed to assess for the presence of a bruit. Additional abduction maneuvers may be employed to elicit a bruit or a pulsatile mass if there is not an obvious finding on exam in the seated position with arms relaxed. In addition, brachial blood pressure measurements should be recorded bilaterally.[58] Additional provocative maneuvers may be employed in the evaluation for aTOS. Obliteration of the radial pulse with the Adson test, costoclavicular maneuver, and hyperabduction maneuver may be observed in patients with aTOS. However, these tests are nonspecific, and many normal individuals have a positive result. The examiner should also pay particular attention to the fingers and hands, which should be inspected for skin changes consistent with thromboembolic or ischemic sequelae, including pallor, cyanosis, delayed capillary refill, mottling, discoloration, petechiae, and gangrene.

Diagnostic Evaluation

Duplex ultrasound should be performed in all patients presenting for evaluation of aTOS, with attention directed to the subclavian and axillary arteries and the presence of aneurysm, thrombus, turbulence, and elevated velocities consistent with luminal narrowing (Fig. 120.8). Duplex should be performed with the patient upright, and provocative maneuvers should be employed. In addition, chest radiography should be obtained on all patients presenting for evaluation of aTOS in order to identify the presence of bony abnormalities such as cervical ribs.

Spiral CT angiography may play a role in the diagnostic evaluation of patients with equivocal findings on duplex ultrasound (Figs. 120.9 and 120.10). Additional diagnostic information is obtained when the CT is performed with the arms at the sides, and again in a hyperabducted and externally rotated position in an effort to reproduce the arterial compression.[60,61] The advantage of CT in the evaluation of this condition is the ability of this modality to identify the relationship between the vasculature and the bony structures of the thoracic outlet.[58] CT is superior to conventional angiography for diagnostic purposes, as conventional contrast angiography has a high (32%) false negative rate when performed in the supine position.[62] Angiography can also play a role in the management of aTOS, and is mainly indicated when intervention such as thrombolysis is performed, or when planning for surgical revascularization.[17]

Figure 120.9 Three-dimensional–reconstructed computed tomography angiogram of patient presenting with arterial thoracic outlet syndrome and post-stenotic dilation of the subclavian artery.

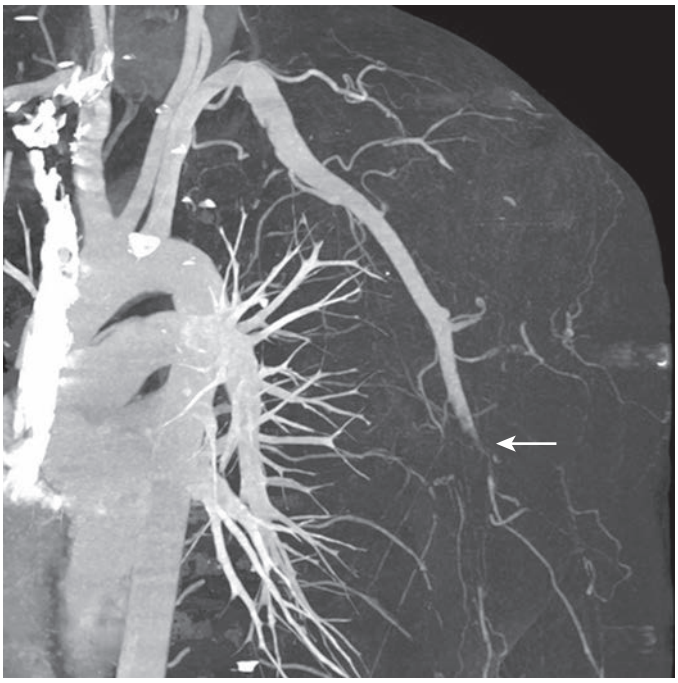

Figure 120.10 Three-dimensional–reconstructed computed tomography angiogram of patient presenting with arterial thoracic outlet syndrome, poststenotic dilation of the subclavian artery, and left arm ischemia resulting from thromboembolism to axillary artery *(arrow)*, with resulting intraluminal filling defect and distal outflow thrombosis.

Coexisting Thoracic Outlet Syndromes

Some patients being evaluated for TOS present with coexisting thoracic outlet syndromes as a result of the compression of multiple neurovascular structures traversing the thoracic outlet. For this reason, the workup of TOS should be broadly directed toward evaluating for the presence of neurologic, venous, and arterial TOS during the initial physical and diagnostic evaluation. It is our practice to obtain vascular duplex ultrasound on patients presenting with signs and symptoms of nTOS.[63] In our series from The Johns Hopkins Hospital, 5% of 423 patients presenting with nTOS were found to have coexisting aTOS.[64]

Challenges in Diagnosis

Several modalities of imaging and testing have been described for the evaluation of a patient suspected to have TOS. Occasionally, an anomalous first rib or cervical rib is overlooked during the workup. It is therefore important to obtain chest and/or neck radiographs to detect cervical and anomalous first ribs. Other tests that frequently accompany patients suspected to have TOS are noninvasive vascular lab studies such as photoplethysmography and duplex ultrasonography. It has been demonstrated that ultrasonography in combination with provocative maneuvers improves the specificity for diagnosis of TOS over either test alone.[65] Therefore patients with vTOS or aTOS should undergo duplex ultrasonography in conjunction with provocative maneuvers to evaluate for compression of the subclavian vessels in vTOS or aTOS. Patients being evaluated for nTOS have been shown to demonstrate vascular compression on duplex ultrasound in up to 50% of cases.[63] When this is demonstrated, the suspicion for nTOS being the primary cause of their symptoms should be heightened, and standard management for nTOS should ensue.

One might suspect that compression of the nervous structures in the thoracic outlet would lead to abnormalities in neurophysiologic tests such as EMG studies and nerve conduction studies (NCS). However, the results of EMG and NCS studies are often negative or inconclusive. While these results may seem superfluous in the diagnosis for nTOS, they are nevertheless still useful in excluding other nerve entrapment syndromes that can mimic nTOS.

Emerging Diagnostic Studies

Two additional studies have demonstrated promise in the diagnosis of nTOS: measuring the responses of the medial antebrachial cutaneous (MAC) nerve, and magnetic resonance (MR) neurography. The MAC nerve is the lowest branch of the inferior trunk of the brachial plexus and appears to be more sensitive to compression compared with other branches of the plexus. Abnormal measurements of MAC amplitude were recorded in patients with clinical signs of nTOS and normal electromyography/nerve conduction velocity studies.[66] In all patients, the amplitude of the symptomatic arm was lower than that of the asymptomatic arm. Another study of the MAC test was performed between 2004 and 2006 in 41 patients operated on for clinical signs of nTOS.[67] Although Seror's study measured only amplitude,[66] the later study found that latency was a little more helpful than amplitude. In applying these criteria, it is important that each electrodiagnostic laboratory establish its own diagnostic criteria in healthy volunteers, because precise technique and equipment may vary.[66,67]

There has been improvement in MR technology such that new 3 T MRI scanners can perform MR neurography by processing high resolution 2D STIR (Short Tau Inversion Recovery)

and isotropic three-dimensional (3D) T2 SPACE (Sampling Perfection With Application Optimized Contrasts Using Varying Flip Angle Evolutions, Siemens, Germany) imaging sequences. These processes result in imaging quality that can delineate subtle signal alterations, size changes, and mechanical course deviations of the brachial plexus within the thoracic outlet.[68]

As both these techniques gain further widespread usage and acceptance, they may offer further diagnostic options that could prove to be better objective tests compared with what is currently available to support the diagnosis of nTOS. Nevertheless, more studies are needed for confirmation before accepting their validity.[66-68]

An increasing body of experience demonstrates that excellent outcomes can be achieved by a comprehensive, multidisciplinary approach to neurogenic thoracic outlet syndrome (NTOS), including a prominent role for surgical treatment in well-selected patients.[1-3] Nonetheless, uncertainties in diagnosis and disappointing results of treatment have led some authorities to question the need for surgical management of NTOS, and even to challenge whether the condition actually exists.[4-6] The purpose of this chapter is to review current understanding of the diagnosis, optimal management, and surgical techniques for NTOS. Because the vascular (arterial and venous) forms of TOS give rise to distinct clinical syndromes and require variations in management, these conditions are covered in other chapters.

ANATOMY

As shown in Fig. 121.1, the anatomy of the thoracic outlet region is composed of several bony and soft tissue structures, as well as the nerves and blood vessels that pass through this area (see Chapter 120).

Nerves in the Thoracic Outlet

The space formed by the scalene triangle is traversed by the five nerve roots arising from cervical spine levels C5 through T1 that make up the *brachial plexus*. The three trunks of the brachial plexus include the *upper trunk* (formed by fusion of the C5 and C6 nerve roots), the *middle trunk* (composed of the C7 nerve root), and the *lower trunk* (formed by fusion of the C8 and T1 nerve roots). Further merging and branching of these trunks outside the thoracic outlet results in formation of the divisions, cords, and terminal nerves of the brachial plexus. Additional nerves of surgical importance pass through the thoracic outlet, including the phrenic nerve, the long thoracic nerve, and the cervical sympathetic chain. The *phrenic nerve* passes lateral to medial as it descends along the anterior surface of the scalene muscle, and then behind the subclavian vein into the mediastinum, where it innervates the diaphragm. The *long thoracic nerve* passes through the middle scalene muscle, where its three components typically fuse to form a single nerve. It then descends to supply the serratus anterior muscle. The *cervicodorsal sympathetic chain* lies along the posterior inner aspect of the ribs. At the level of the first rib, a fusion of several ganglia results in formation of the large stellate ganglion.

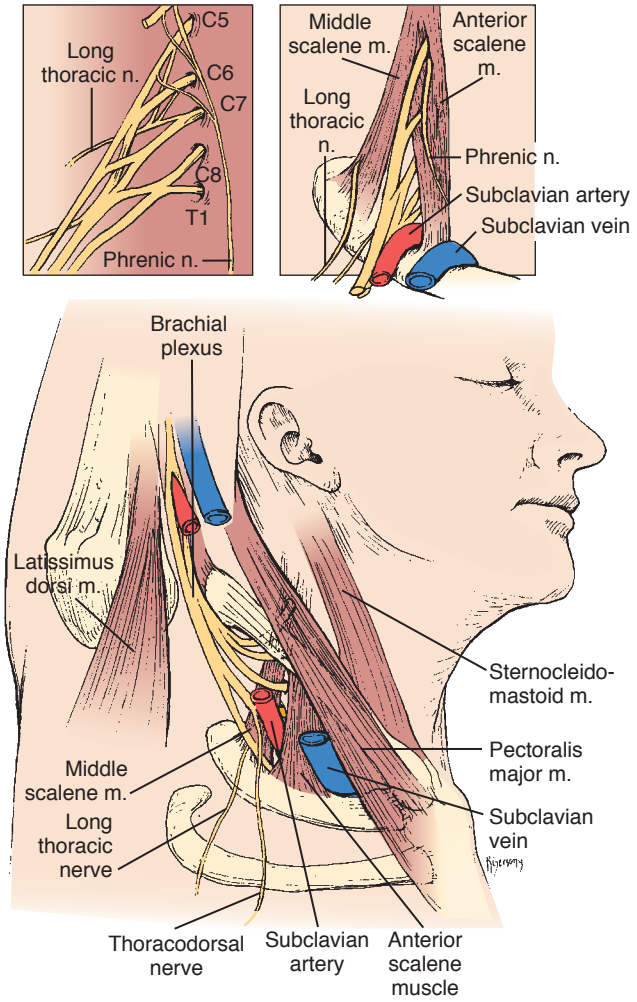

Figure 121.1 Anatomy of the Thoracic Outlet. The surgical anatomy of the thoracic outlet is centered upon spinal nerve roots C5 through T1, which interdigitate to form the brachial plexus as they cross under the clavicle and over the first rib. The long thoracic and phrenic nerves also arise within the thoracic outlet region. The brachial plexus nerve roots pass through the scalene triangle, bordered by the anterior and middle scalene muscles on each side and the first rib at the base. The subclavian artery also courses through the scalene triangle in direct relation to the brachial plexus nerve roots. The subclavian vein crosses over the first rib immediately in front of the anterior scalene muscle, before joining with the internal jugular vein to form the innominate vein. Symptoms of neurogenic thoracic outlet syndrome are often exacerbated by arm elevation, where greater strain is placed on the neurovascular structures passing through the scalene triangle. (Modified from Thompson RW, Petrinec D. Surgical treatment of thoracic outlet compression syndromes. I. Diagnostic considerations and transaxillary first rib resection. *Ann Vasc Surg*. 1997;11:315–323.)[67]

Musculofascial Variations

The conventional description of scalene triangle anatomy probably occurs in no more than one-third of individuals, with variations in the soft tissue structure of this region being very common.[7,8] The most frequent muscular variation in this region is known as the *scalene minimus muscle*, a structure that originates within the plane of the middle scalene muscle. This muscle passes between various nerve roots of the brachial plexus and inserts upon the first rib in conjunction with the anterior scalene muscle; thus it may contribute to nerve root compression when present. Additional soft tissue variations include fascial bands that pass across or between individual nerve roots, subsequently attaching to either the first rib or the extrapleural fascia. During operations for TOS, it is particularly common to encounter a dense fascial band crossing over the origin of the T1 nerve root, where it passes from underneath the first rib to contribute to the brachial plexus. A spectrum of other muscular and fascial variations in this region have been described and classified (Table 121.1).[9,10]

TABLE 121.1 Classification of Congenital Bands and Ligaments Within the Scalene Triangle

Type 1:	Extending from anterior tip of an incomplete cervical rib to the middle of the first thoracic rib; inserts just posterior to the scalene tubercle on the upper rib surface.
Type 2:	Arises from an elongated C7 transverse process in the absence of a cervical rib and attaches to the first rib just behind the scalene tubercle; associated with extension of the transverse process of C7 beyond the transverse process of T1 on AP spine radiographs.
Type 3:	Both originates and inserts on the first rib; starts posteriorly near the neck of the rib and inserts anteriorly just behind the scalene tubercle.
Type 4:	Originates from a transverse process along with the middle scalene muscle and runs on the anterior edge of the middle scalene muscle to insert on the first rib; the lower nerve roots of the brachial plexus lie against this band.
Type 5:	The scalene minimus muscle, arising with the lower fibers of the anterior scalene muscle, runs parallel to this muscle but passes deep to the muscle to cross behind the subclavian artery and in front of or between the nerve roots, and inserts on the first rib; any fibers passing anterior to or between the plexus but posterior to the artery.
Type 6:	Scalene minimus muscle inserting onto Sibson fascia over the cupula of the pleura instead of onto the first rib; labeled separately to distinguish its point of insertion.
Type 7:	Fibrous cord running on the anterior surface of the anterior scalene muscle down to the first rib, attaching to the costochondral junction or sternum; lies immediately behind the subclavian vein where it may be a cause of partial venous obstruction.
Type 8:	Arises from the middle scalene muscle and runs under the subclavian artery and vein to attach to the costochondral junction.
Type 9:	Web of muscle and fascia filling the inside posterior curve of the first rib, compressing the origin of the T1 nerve root.

Modified from Roos DB. Congenital anomalies associated with thoracic outlet syndrome. *Am J Surg*. 1976;132:771–778.

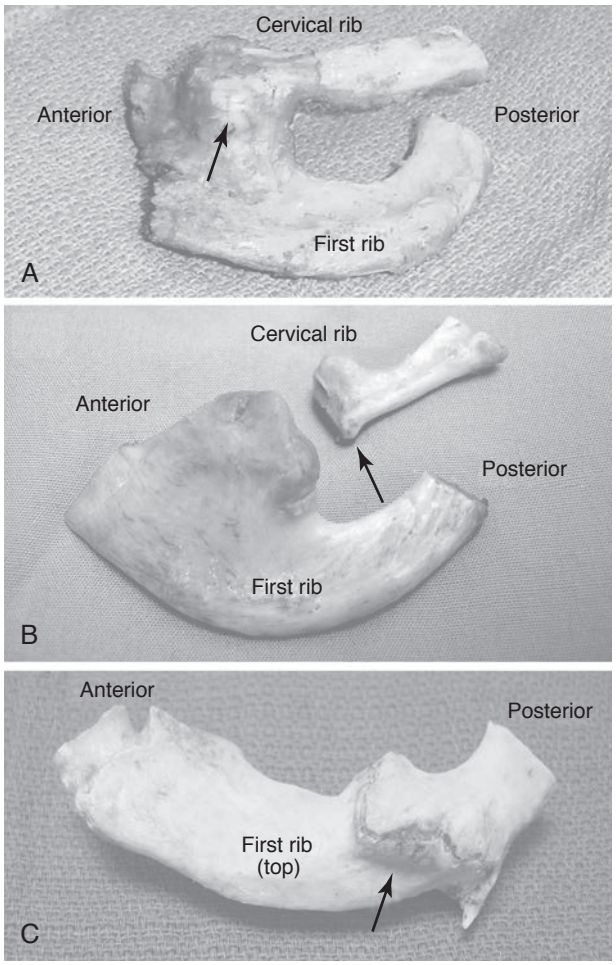

Figure 121.2 First Rib Anomalies. Operating room photographs depicting bony abnormalities associated with neurogenic thoracic outlet syndrome. (A) Resected specimen of cervical rib and attached first rib, exhibiting a completely formed joint *(arrow)*. (B) Resected specimen of cervical rib and accompanying first rib, with attachment through a fibrous connection and a large exostosis on the first rib *(arrow)*. (C) Resected specimen of a first rib that contained thickened callous associated with a healed fracture site from previous trauma *(arrow)*.

Bony Anomalies

Cervical ribs occur in approximately 0.45% to 1.5% of the population and in up to 5% of patients with TOS. They arise in the plane of the middle scalene muscle and typically attach to the midlateral portion of the first rib; the anomalous rib may join the first rib as an immobile bony fusion or as a fully developed joint (Fig. 121.2A).[11] *Incomplete cervical ribs* may also occur, arising as a bony or cartilaginous extension from the C7 cervical vertebrae without extension to join the first rib, and in some cases are attached to the first rib only by a band of cartilage or tendinous tissue (see Fig. 121.2B). *Rudimentary (hypoplastic) first ribs* are not as frequently recognized as cervical rib anomalies, and their actual incidence is unknown. These structures consist of a first rib that tends to lie higher in the neck than normal and often insert into the second rib rather than the sternum. *Previous trauma* may also result in abnormalities of the first rib, such as fractures with formation of thickened callous at the site of bony healing (see Fig. 121.2C).

Histopathology

Microscopic studies of the scalene muscles from patients with NTOS have consistently revealed two major abnormalities: (1) type I muscle fiber predominance and (2) endomesial fibrosis (Fig. 121.3).[12,13] Although the anterior scalene muscle normally exhibits an equal distribution of type I ("slow-twitch") and type II ("fast-twitch") muscle fibers, type I fibers compose up to 78% of the scalene muscle fibers in patients with neurogenic TOS associated with atrophy and pleomorphism of type II fibers. Alongside these changes there is marked thickening of the connective tissue matrix that surrounds individual muscle fibers, with a twofold increase in connective tissue content compared with normal scalene muscles, and in some cases there are mitochondrial abnormalities resembling those seen in

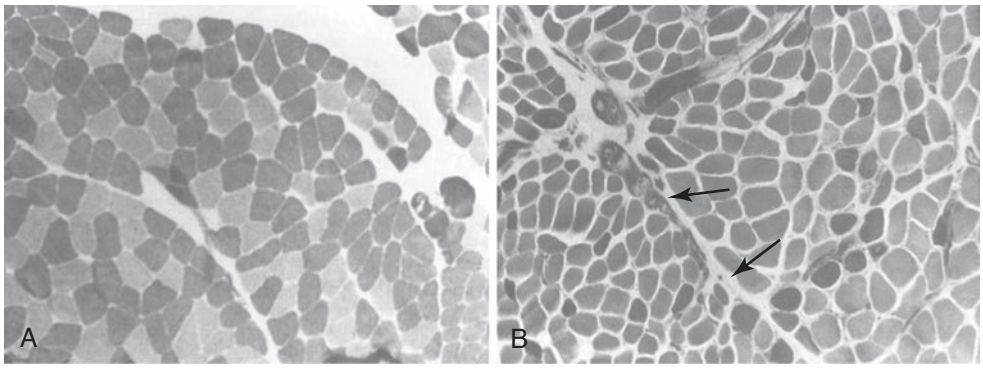

Figure 121.3 Scalene Muscle Histology in Neurogenic Thoracic Outlet Syndrome (NTOS). Muscle histopathology showing changes consistently observed in NTOS. Sections of the anterior scalene muscle were stained with myosin ATPase (pH 9.4) to visualize fiber types, with type I fibers staining lightly and type II fibers staining dark (original magnification 100×). Normal muscle has an equal distribution of type I and type II fibers *(left panel)*. The muscle from a patient with TOS *(right panel)* exhibits predominance of type I fibers, atrophy of type II fibers, and a significant increase in the connective tissue matrix between fibers *(arrows)*. (Modified from Sanders RJ. *Thoracic Outlet Syndrome: A Common Sequelae of Neck Injuries,* Philadelphia: J. B. Lippincott Company; 1991.)

muscular dystrophy. These changes do not represent a local abnormality, thought to reflect the histopathologic changes occurring after long-standing muscle injury, sustained muscle spasm, and abnormal tissue remodeling, and are therefore consistent with the frequent history of neck trauma that occurs in patients with NTOS.

ETIOLOGY

Predisposing Anatomic Factors

Current concepts indicate that NTOS is caused by a combination of predisposing anatomical factors and previous neck trauma. Indeed the normal anatomy of the thoracic outlet serves as a predisposing factor in the development of NTOS, since the neurovascular structures that traverse this region are prone to compression even during the course of regular daily activity. Activities involving sustained or repeated elevation of the arm or vigorous turning the neck may place additional tension on the scalene muscles, thereby potentiating any positional compression of the underlying nerve roots. This anatomical predisposition may be further increased by congenital structural variants, such as scalene muscle variations, abnormal tendinous bands, or cervical rib anomalies. However, because many individuals harbor such variations in the absence of neurogenic symptoms, anatomical factors are only considered a predisposing factor for NTOS rather than a distinct and separate cause, and they appear only to lower the threshold for the development of symptoms following injury.

Neck Trauma and Repetitive Strain Injury

Most patients with NTOS describe some form of previous trauma to the head, neck, or upper extremity, followed by a variable interval from days or weeks to several years before the onset of progressive upper extremity symptoms.[1] This is thought to reflect the variable time frame for scalene muscle injury to result in sustained compression and irritation of the brachial plexus nerve roots, and may obscure the relationship between a specific injury and development of NTOS. Persistent use of the upper extremity in activities that promote brachial plexus compression may further exacerbate symptom progression over time, resulting in progressive disability, and many patients do not seek medical attention until symptoms are well advanced. Not all patients with NTOS have their condition brought on by a specific traumatic event. In many cases, the injury may be the result of repetitive activities that inadvertently place strain on the scalene muscles over long periods of time, such as prolonged work at computer keyboards. TOS occurring in this circumstance is considered a form of repetitive strain injury (RSI). In these cases, it is likely that age-related changes in posture (e.g., slumping of the shoulders and stooping of the neck) may be significant factors leading to the development of extrinsic neural compression.

CLINICAL FINDINGS

The diagnosis of NTOS rests largely upon clinical pattern-recognition, with diagnostic suspicion raised by a stereotypical history and a description of symptoms typical of the disorder. The provisional diagnosis of NTOS is supplemented by physical examination and may be supported by a limited number of diagnostic studies. In most cases such studies are of value primarily in the exclusion of other (more common) conditions within the differential diagnosis. No single diagnostic test has a sufficiently high degree of specificity to completely prove or exclude the diagnosis of NTOS.[14]

Symptoms

Demographics

Neurogenic TOS most frequently occurs in individuals between 20 and 40 years of age, and approximately 70% of affected patients are women. Neurogenic TOS may arise in individuals

engaged in a variety of occupational or recreational activities, most often those involving heavy lifting or repeated use of the arm(s) in elevated positions, or following a spectrum of injuries to the head, neck, or upper extremity. Patients with no apparent predisposition, either due to anatomical variations or a history of trauma, may also develop NTOS. There are no medical conditions or known inherited patterns predisposing to NTOS.

Pain and Paresthesia

The primary symptoms of NTOS include pain, dysesthesias, numbness, and weakness. These symptoms usually occur throughout the affected hand or arm without any localization to a specific peripheral nerve distribution, and they often involve different areas of the entire upper extremity. Extension of symptoms from the hand to the shoulder, neck, and upper back is not infrequent, and in many patients the symptoms in the neck or upper back may be perceived as the most functionally disabling. Although most patients with NTOS have symptoms affecting just one upper extremity, bilateral symptoms are not uncommon; in such cases the dominant extremity is often more symptomatic at first presentation, but the opposite extremity may become involved over time, perhaps as a result of compensatory overuse. The lack of distribution of symptoms into patterns referable to a single peripheral nerve, and the frequent extension of symptoms to the shoulder, neck, and back, allows the distinction of NTOS from nerve compression disorders affecting the ulnar nerve at the elbow (cubital compression syndrome), the median nerve at the wrist (carpal tunnel syndrome), or other related conditions. Almost all patients affected by NTOS describe reproducible exacerbation of symptoms by activities that require elevation and/or the sustained use of the arms or hands. Positional complaints may also be brought on by lying supine, especially when the arms are positioned overhead, resulting in pain and difficulty sleeping at night.

Headache

Headaches are a common complaint associated with NTOS.[15] This most likely occurs as a result of referred pain to the occiput, due to secondary spasm within the trapezius and paraspinous muscles. Although NTOS and migraine headaches are often seen together, there is currently no evidence for a specific link between these conditions.

Weakness and Muscle Atrophy

Prolonged severe extrinsic compression of peripheral nerves can result in muscle weakness and atrophy, but such findings are actually rare in patients with NTOS, probably due to the intermittent nature of nerve compression in NTOS. Most commonly, hand or arm pain with use of the affected extremity may lead to the perception of weakness, causing the patient to avoid use of the arm or positions that exacerbate symptoms. This distinction should be sought during evaluation to help identify other conditions that may be responsible for symptoms of muscle weakness. The presence of authentic muscle weakness may therefore indicate particularly severe and long-standing compression of the brachial plexus nerve roots, either due to NTOS or another condition.

Disability

The majority of individuals with positional complaints related to NTOS are affected to only a mild and tolerable degree, usually due to transient irritation of the brachial plexus in certain positions of the arm or during certain activities. There is little risk of progressive injury in these situations, and no specific intervention is warranted. There remains a smaller subset of patients with clinically significant NTOS, however, who exhibit progressively disabling symptoms that effectively prevent them from working or carrying out simple daily activities. These patients often describe progressive disability and a long history of consultations with different physicians and partial or ineffective treatments. It is particularly helpful to obtain a detailed description from the patient of activities that exacerbate symptoms associated with NTOS, as well as those activities normally required in the workplace. Documentation of this assessment is often important if restrictions from work are necessary in the management of these patients and in guiding decisions about the role of surgical treatment.

Vascular Symptoms and Complex Regional Pain Syndrome

Vascular symptoms should be specifically sought in the history of patients with suspected TOS—particularly discoloration or coldness in the hands and fingers. It is important to note that ischemia is actually very unusual in such patients, whereas symptoms of vasomotor disturbance are not uncommon in those with longstanding or severe NTOS. Indeed, in some the symptoms of TOS may have progressed to resemble those of complex regional pain syndrome type I (CRPS-I; formerly known as reflex sympathetic dystrophy), with persistent vasospasm, disuse edema, and extreme hypersensitivity. The acuity of these symptoms often leads to avoidance and withdrawal from even light touch of the affected extremity. The diagnosis of CRPS-I can be supported by vascular laboratory studies revealing abnormal vasoconstrictive responses (cold-pressor tests) or imaging studies of the hand microcirculation, but in most cases the diagnosis is made on clinical grounds and the response to sympathetic blockade. The identification of this condition in patients with NTOS is quite important, because it may lead to an earlier recommendation for operative treatment and consideration of concomitant cervical sympathectomy.

When a history suggesting arterial insufficiency or thromboembolism exists, vascular laboratory studies and contrast-enhanced arteriographic imaging are necessary to exclude the presence of subclavian artery aneurysm or occlusive disease. Conversely, a history of arm swelling, cyanotic discoloration, and distended subcutaneous collaterals may indicate venous TOS due to obstruction of the subclavian vein, which requires contrast venography for full evaluation.

Physical Examination

Physical examination is initially directed toward eliciting the degree of neurogenic disability and identifying particular factors that exacerbate painful hand and arm complaints. The range

of motion of the upper extremity and lateral motion of the neck are assessed under both passive and active conditions. Pain and tenderness over the shoulder joint is evaluated as potentially related to rotator cuff pathology, and tenderness over the trapezius muscle may indicate fibromyalgia. A thorough peripheral nerve examination is performed to exclude ulnar nerve entrapment or carpal tunnel syndrome, two conditions that may mimic the symptoms of NTOS. The base of the neck is examined to identify the extent of any local muscle spasm over the scalene triangle itself, as well as over the trapezius, pectoralis, and parascapular muscles, and to localize specific "trigger points" to identify specific sites where palpation recreates the patient's typical symptoms of upper extremity pain and paresthesia. Localization of such trigger points over the scalene triangle or subcoracoid space serves to strongly reinforce the diagnosis of NTOS.

Perhaps the most useful component of physical examination is the 3-minute elevated arm stress test (EAST), in which the patient is positioned with the arms elevated in a "surrender" position and asked to repetitively open and close the fists. Most patients with NTOS report the rapid onset of their typical upper extremity symptoms with EAST, often being unable to complete the exercise beyond 30 to 60 seconds. When there is no difficulty performing the 3-minute EAST, the diagnosis of NTOS is suspect, and an alternative explanation for the symptoms should be sought more vigorously.

In some patients, compression of the neurovascular bundle as it passes underneath the pectoralis minor muscle tendon is a substantial factor contributing to NTOS. This situation is identified by localized tenderness and reproduction of upper extremity neurologic symptoms upon palpation over the pectoralis minor muscle. Given that pectoralis minor tenotomy may be an effective primary or adjunctive treatment in such individuals, it is important during the initial physical examination to identify this component of NTOS.

Vascular Examination

The Adson maneuver is commonly used to identify positional compression of the subclavian artery by detecting dampening of the radial pulse when the patient inspires deeply and turns the neck away from the affected extremity with or without elevation of the arm. Although this maneuver does not specifically reveal nerve root compression, positive findings may be associated with NTOS. However, a positive Adson sign is also quite common in the asymptomatic general population.

Patients presenting with symptoms of NTOS may on occasion have vascular findings related to either arterial or venous TOS (see Chapter 122 and Chapter 123).

Diagnostic Tests

Radiography

Plain radiographs of the neck are helpful in determining if an osseous cervical rib or abnormally wide transverse processes of the cervical vertebrae are present. Although either of these findings may solidify the diagnostic impression of TOS, neither of them is essential.

Cross-Sectional Imaging

The results of computed tomography (CT), magnetic resonance imaging (MRI), and other cross-sectional imaging examinations are usually negative in NTOS because the anatomical factors leading to intermittent or positional nerve compression are usually beyond the resolution of these studies. Even in situations where an apparent imaging abnormality exists in the region of the scalene triangle, it is usually impossible to prove the functional importance of such abnormalities with respect to the patient's upper extremity complaints. Imaging studies are nonetheless valuable to exclude other conditions that could be responsible for upper extremity symptoms, such as degenerative cervical disc or spine disease, shoulder joint pathology, or various forms of intracranial pathology.

In recent years, advances in MRI and data processing have led to higher resolution scans with three-dimensional reconstruction, along with the ability to detect localized abnormalities in nerve function (MR "neurography").[9,10,16,17] As this technique becomes utilized more frequently in patients with and without NTOS, it may provide a useful diagnostic tool to supplement clinical evaluation.

Neurophysiologic Testing

Electromyography (EMG) and nerve conduction studies (NCS) are often utilized in the evaluation of patients suspected of having NTOS, particularly when symptoms are suggestive of a specific radiculopathy, a peripheral nerve syndrome, or a general myopathy. Positive results of neurophysiologic testing are therefore quite useful, as they point to specific alternative conditions that must be evaluated further. Unfortunately, the results of conventional EMG/NCS studies are usually negative in NTOS, because nerve root compression occurs in an extremely proximal location, and is intermittent and not usually associated with permanent changes in motor nerve function.[18] Negative results from these studies nonetheless help exclude other conditions from further consideration. Positive EMG/NCS findings in patients with NTOS are a poor prognostic finding in the absence of an alternate explanation, indicating an advanced stage of neural damage that is unlikely to resolve despite adequate decompression. Recent evidence suggests that electrophysiologic testing of sensory nerve abnormalities may be more useful in the diagnosis of NTOS than conventional EMG/NCS. For example, Machanic and Sanders reported studies using the response to medial antebrachial cutaneous nerve (MAC) and C8 nerve root stimulation in patients with a clinical diagnosis of NTOS compared with asymptomatic controls, indicating that this form of electrophysiologic testing had a high degree of sensitivity and specificity.[19]

Scalene Muscle Blocks

Injection of local anesthetic into the anterior scalene muscle may be used as an adjunct to the clinical diagnosis of NTOS, particularly in predicting the potential response to surgical decompression.[20] Successful scalene muscle block is indicated by relief of symptoms in the hand or arm, along with a reduction in local tenderness over the anterior scalene muscle. Injection

of anesthetic to the level of the brachial plexus precludes accurate interpretation of this test, since there will be temporary numbness and weakness in the arm, making the assessment of pain relief unreliable. A scalene muscle block is not necessary in patients with clear-cut symptoms where the diagnosis is not questioned, but it can be useful in patients with an equivocal diagnosis of NTOS. Sanders and others have also reported a strong correlation between the relief of symptoms following scalene muscle block and the success of surgical decompression.[20-22] A variation of scalene muscle block as a treatment for NTOS is the use of locally injected botulinum toxin.[23] However, side effects of botulinum toxin may occur early after treatment (e.g., dysphagia); the duration of beneficial effects with botulinum toxin is often limited from 2 to 3 months, and repeated treatment effects are diminished by the systemic immune response to the injected protein. Thus botulinum toxin injections cannot yet be generally recommended.

Angiography and Vascular Laboratory Studies

Vascular laboratory studies and angiography are usually not necessary in making the diagnosis of NTOS, unless the patient presents with symptoms suggestive of an arterial or venous component.

Making the Diagnosis

The differential diagnosis may include a number of conditions (Table 121.2), and some of these entities can be distinguished by specific findings or diagnostic tests. The surgeon recognizing NTOS should not be dissuaded by the impression that these problems are frequently associated with psychiatric overtones, dependency on pain medications, and ongoing litigation. Careful evaluation using clinical diagnostic criteria can usually detect patients with strong clinical evidence of NTOS, as well as identify those most likely to respond to treatment (Table 121.3).[24] The evaluating surgeon must be willing to expend considerable time and energy to provide these patients with a thorough evaluation, detailed information, lengthy discussion, and ongoing support. The suspected nature of the condition is explained, the diagnostic and therapeutic uncertainties that surround NTOS are discussed, and an honest but reassuring outline of treatment expectations is presented. Surgeons making this effort are typically rewarded by grateful patients with renewed hope for long-awaited improvement.

TABLE 121.2 Differential Diagnosis of Neurogenic Thoracic Outlet Syndrome

Condition	Differentiating Features
Carpal tunnel syndrome	Hand pain and paresthesia in median nerve distribution; positive findings on nerve conduction studies.
Ulnar nerve compression	Hand pain and paresthesia in ulnar nerve distribution; positive findings on nerve conduction studies.
Rotator cuff tendinitis	Localized pain and tenderness over biceps tendon and shoulder pain on abduction; positive findings on MRI; relief from NSAIDs, local steroid injections or arthroscopic surgery.
Cervical spine strain/sprain	Posttraumatic neck pain and stiffness localized posteriorly along cervical spine; paraspinal tenderness; relief with conservative measures over weeks to months.
Fibromyositis	Posttraumatic inflammation of trapezius and parascapular muscles; tenderness, spasm and palpable nodules over affected muscles; may coexist with TOS and persist after surgery.
Cervical disc disease	Neck pain and stiffness, arm weakness, and paresthesia involving thumb and index finger (C5-6 disc); symptom improvement with arm elevation; positive findings on CT or MRI.
Cervical arthritis	Neck pain and stiffness; arm or hand paresthesia infrequent; degenerative rather than posttraumatic; positive findings on spine radiographs.
Brachial plexus injury	Caused by direct injury or stretch; arm pain and weakness, hand paresthesias; symptoms constant not intermittent or positional; positive findings on neurophysiologic studies.

CT, Computed tomography; *MRI*, magnetic resonance imaging.

CONSERVATIVE MANAGEMENT

Physical Therapy

Physical therapy serves as the initial treatment for almost all patients with NTOS.[25] It is important that the patient be referred to a therapist with experience, expertise, and interest in TOS, since the management of this condition is different from that of other disorders affecting the neck, shoulder, and upper extremity.[26] Many physical therapists do not have great experience with NTOS, and incorrect approaches to therapy can result in the worsening of symptoms and premature failure of conservative management.[27]

Evaluation

The physical therapist treating the patient with NTOS outlines a specific plan for initial treatment over a 4- to 8-week period, to be followed by reassessment of progress. Initial assessment includes evaluation of posture, alignment, and movement patterns of the patient, specifically focusing on areas of impairment that may contribute to compression of the brachial plexus. These areas include the slope of the shoulder girdle, the angle of the clavicle, the position of the scapula on the thorax, the position of the humerus in the glenoid, the posturing of the head and neck, and the alignment of the cervical and upper thoracic spine. The therapist also examines dynamic patterns, such as scapular mechanics and timing during upper extremity movements, as well as any changes in muscle length, strength, and/or recruitment that may put stress on the brachial plexus (Fig. 121.4).

TABLE 121.3 Clinical Diagnostic Criteria for Neurogenic Thoracic Outlet Syndrome

Upper extremity symptoms which extend beyond the distribution of a single cervical nerve root or peripheral nerve, have been present for at least 12 weeks, have not been satisfactorily explained by another condition, AND meet at least 1 criterion in at least 4 of the following 5 categories:

Principal Symptoms

1A: Pain in the neck, upper back, shoulder, arm and/or hand
1B: Numbness, paresthesias, and/or weakness in the arm, hand, or digits

Symptom Characteristics

2A: Pain/paresthesias/weakness exacerbated by elevated arm positions
2B: Pain/paresthesias/weakness exacerbated by prolonged or repetitive arm/hand use, including prolonged work on a keyboard or other repetitive strain tasks
2C: Pain/paresthesias radiate down the arm from the supraclavicular or infraclavicular spaces

Clinical History

3A: Symptoms began after occupational, recreational, or accidental injury of the head, neck, or upper extremity, including repetitive upper extremity strain or overuse
3B: Previous ipsilateral clavicle or first rib fracture, or known cervical rib
3C: Previous cervical spine or ipsilateral peripheral nerve surgery without sustained improvement in symptoms
3D: Previous conservative or surgical treatment for ipsilateral TOS

Physical Examination

4A: Local tenderness on palpation over the scalene triangle and/or subcoracoid space
4B: Arm/hand/digit paresthesias on palpation over the scalene triangle and/or subcoracoid space
4C: Objectively weak handgrip, intrinsic muscles, or digit 5, or thenar/hypothenar atrophy

Provocative Maneuvers

5A: Positive ULTT
5B: Positive 3-minute EAST

Exclusion of other conditions typically includes nonspecific or negative findings on physical examination (Spurling test, axial compression test, Tinel sign over the carpal tunnel or cubital tunnel, and Phalen test), imaging studies (MRI of cervical spine and shoulder), and conventional electrophysiologic tests (upper extremity electromyography and nerve conduction studies).
EAST, Elevated arm stress test; *TOS*, thoracic outlet syndrome; *ULTT*, upper limb tension test.
Modified from consensus diagnostic criteria developed by the Consortium for Research and Education on Thoracic Outlet Syndrome (CORE-TOS).

Treatment

The therapist utilizes the results of individual-based assessment to help educate the patient on specific faults that may be contributing to their condition, instruct them in an exercise program, and possibly implement the use of external devices, such as bracing or taping, to take stress off of the anatomical compression sites.[28] The principal areas addressed include the scalene triangle, the costoclavicular space, and the area between the pectoralis minor and the coracoid process. In addition, scapular mechanics may be at a disadvantage in patients with NTOS, leading to additional stresses with overhead motion.[29] The initial goals of physical therapy are therefore to maintain and improve the range of motion of the neck and affected upper extremity, using a combination of passive and assisted exercises.[30-32] In particular, exercises designed to relax and stretch the scalene muscle are used, combined with hydrotherapy, massage, and other techniques. These efforts may be accompanied by the use of nonsteroidal antiinflammatory agents, muscle relaxants, and nonnarcotic pain medications, as needed. Once initial improvement has been achieved, subsequent efforts can be focused on strengthening muscles of posture and increasing achievable levels of activity.

Results

Most patients with mild symptoms of NTOS, or those in whom therapy has been started early after the onset of symptoms, will exhibit significant improvement. Therapy is then continued with the expectation that continued benefits will preclude the need to consider surgical treatment. Although in our experience this outcome is obtained in only 20% to 30% of patients referred for management of NTOS, the proportion of patients responding to conservative treatment is much higher in a more general (nonreferral) population.[33] If progress with the initial course of conservative management has been unsatisfactory, the basis for the diagnosis of NTOS is reviewed, and any further testing thought to be appropriate is carried out. When the physician is confident of the diagnosis of NTOS, the level of symptoms is disabling, and the patient has not responded sufficiently to conservative management, surgical treatment is considered.[34]

SURGICAL TREATMENT

Historical Background

The first operations for thoracic outlet compression were focused on the treatment of subclavian artery aneurysms in patients with a cervical rib, as described by Coote in 1861.[35] By the turn of the century the "cervical rib syndrome" was widely recognized, and in 1927 Adson and Coffey described the use of anterior scalenotomy in treatment of this condition, including symptomatic patients without a cervical rib anomaly.[36] The term "thoracic outlet syndrome" was introduced by Peet in 1956,[37] and in the 1960s several new operative approaches to TOS were described, including posterior thoracotomy (Clagett) and transaxillary first rib resection (Roos).[38,39] Although transaxillary first rib resection became popular and widely used during the 1970s, disenchantment arose when results were found to be no better compared with scalenectomy and when a national survey indicated a significant incidence of permanent nerve injuries following this operation.[22,40] It also became appreciated that symptomatic recurrences following transaxillary first rib resection often involved reattachment of the unresected scalene muscles to the remaining end of the first rib or adjacent tissues,

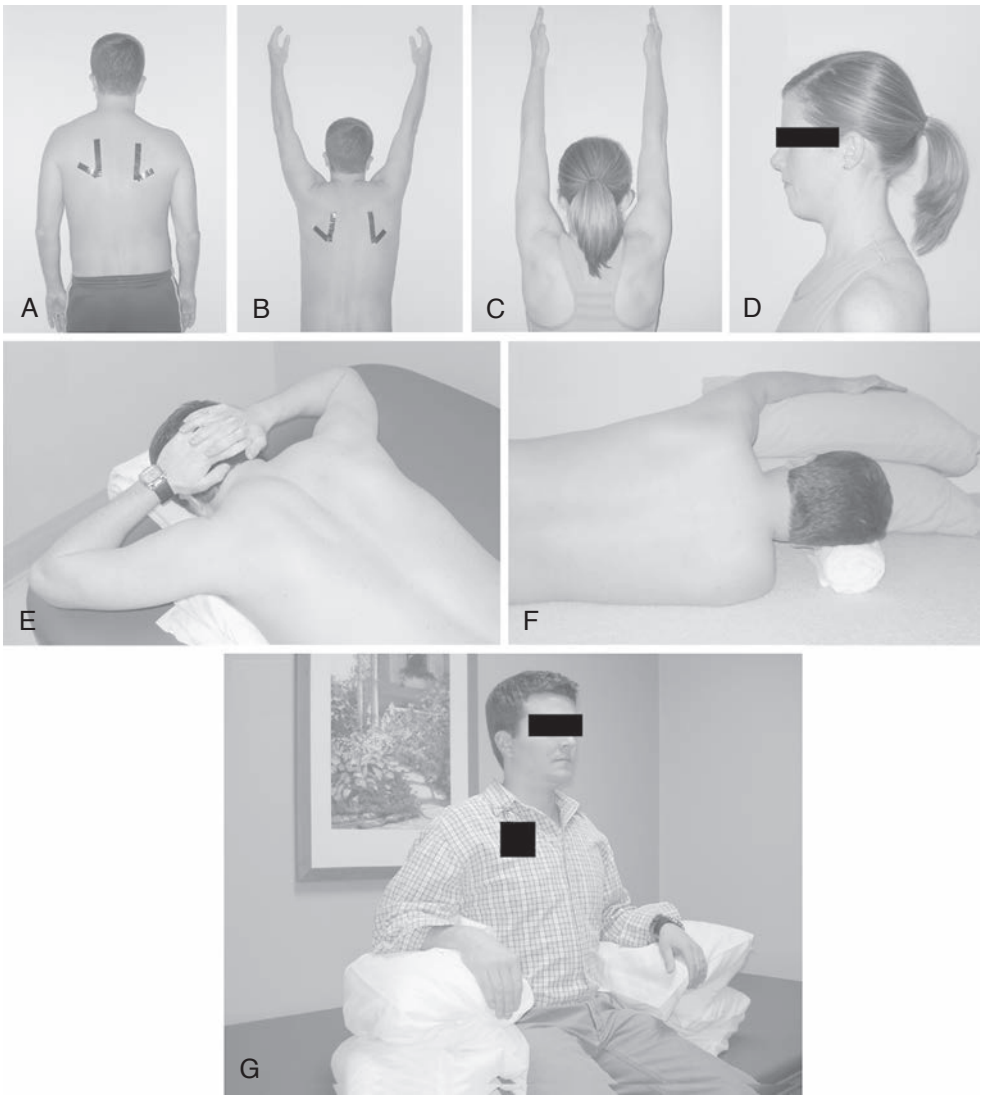

Figure 121.4 Physical Therapy for Neurogenic Thoracic Outlet Syndrome. (A) An example of postural assessment including scapular depression with an increased slope of the right shoulder girdle. (B) Implementing an exercise to improve a scapular depression fault. (C) Upper trapezius muscle recruitment in standing while facing a wall. (D) Addressing cervical spine alignment. (E) Strengthening the middle trapezius musculature. (F) Exercises addressing overhead mechanics are initiated in a gravity-lessened position. (G) Sitting with arms supported helps to take weight off the shoulder girdle.

leading to diminished enthusiasm for first rib resection and a reemphasis on complete scalene muscle resection.[41] The combined use of supraclavicular and transaxillary approaches was reported in 1984 by Qvarfordt et al.,[42] followed by further description of the supraclavicular approach by Sanders and Raymer and by Reilly and Stoney.[43,44] During the past decade the supraclavicular approach appears to have become the most commonly employed approach in current practice.

With regard to the selection of operative approach, it is now generally accepted that NTOS may arise from compression of the brachial plexus nerve roots at several different levels by different etiologic factors, not solely as a consequence of bony deformation by the first rib. Numerous soft tissue anomalies within the thoracic outlet have been described and classified, each of which can give rise to symptomatic neural compression. Significant factors playing a role in this process appear to include scalene muscle injury with spasm, scarring, and fibrotic inflammatory reactions surrounding the brachial plexus nerve roots, which may also be associated with pathologic changes in the scalene musculature. Current approaches to surgical treatment must take each of these potential contributing factors into account in selecting the optimal treatment for individual patients.

Transaxillary Approach

The primary advantages of *transaxillary first rib resection* include a relatively limited field of operative dissection, a cosmetically placed skin incision, and sufficient exposure to reliably accomplish resection of the anterolateral first rib. This approach also makes it possible to achieve at least partial resection of the anterior scalene muscle, as well as identification and removal of most anomalous ligaments and fibrous bands that may be associated with TOS. The disadvantages of the transaxillary approach include incomplete exposure of the structures comprising the scalene triangle, inability to achieve complete anterior and middle scalenectomy or brachial plexus neurolysis, and the necessity for first rib resection in all cases. This approach is also limited when vascular reconstruction is needed, and in such cases repositioning of the patient and the addition of a separate incision are required.

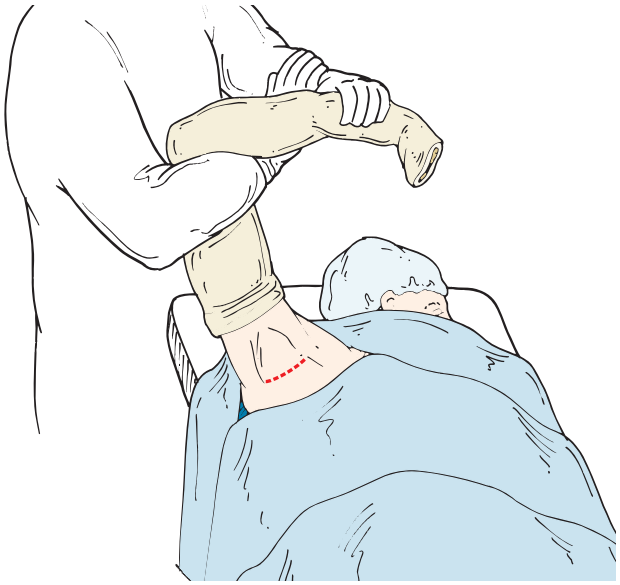

Figure 121.5 Positioning for Transaxillary First Rib Resection. With the arm carefully elevated by a reliable assistant, the initial skin incision is made at the lower edge of the axillary hair line. (Modified from Thompson RW, Petrinec D. Surgical treatment of thoracic outlet compression syndromes. I. Diagnostic considerations and transaxillary first rib resection. *Ann Vasc Surg.* 1997;11: 315–323.)[67]

Under general anesthesia, the patient is positioned supine with the back of the table raised about 30 degrees. A small towel pack is placed behind the shoulder to elevate the affected side. The arm is prepped circumferentially and wrapped in stockinette, and the sterile field includes the neck, upper chest, and posterior shoulder to the scapula. The arm is held and positioned by a reliable, flexible, and sturdy assistant (Fig. 121.5), or by a special retractor.

A transverse skin incision is made at the lower border of the axillary hairline, extending from the anterior border of the latissimus dorsi to the lateral edge of the pectoralis major (see Fig. 121.5). The long thoracic, thoracodorsal, and second intercostobrachial nerves are identified near the chest wall to avoid direct injury. Excessive elevation of the arm (unique to transaxillary exposure) is a potential mechanism of injury to the second intercostobrachial cutaneous nerve, resulting in postoperative pain and numbness along the medial aspect of the upper arm. The first rib is typically palpable at the upper reaches of the areolar tissue plane along the chest wall. Using a Deaver retractor to gently lift the subcutaneous tissues and axillary contents away from the chest wall, the first rib is more clearly exposed in the upper aspect of the wound. It is necessary to carefully lift the arm to facilitate this exposure, both at this stage and throughout the remainder of the procedure, and the operating surgeon should use a fiberoptic headlight to properly illuminate the operative field.

Exposure obtained during the transaxillary approach is generally limited to the operating surgeon. In order to avoid serious injury, the blades of the retractors must not apply excess traction to the neurovascular structures visible above the first rib. In addition to the nerve roots of the brachial plexus, proper attention must be given to avoid traction on the long thoracic nerve, which exits the plane between the middle and posterior scalene muscles before coursing over the first rib to the serratus anterior muscle. Periodic inspection of the retractors and relief for the assistants is recommended, using a staged approach to the operation as described by Machleder.[45]

Once the first rib is sufficiently exposed, the subclavian vein and subclavian artery are identified, along with the intervening anterior scalene muscle (Fig. 121.6A). These structures are carefully dissected such that the anterior scalene tendon can be encircled with a right-angle clamp just above its insertion onto the scalene tubercle of the first rib, which is typically palpable as a slight bony prominence. The anterior scalene muscle is exposed over several centimeters superior to the first rib, and while taking care to avoid the phrenic nerve, the muscle is divided using scissors at the highest level feasible. The importance of resecting a portion of the scalene muscle, rather than simply dividing it at the level of the first rib itself, has been underscored by analysis of the factors causing recurrent TOS.

The soft tissues attaching to the inferior and medial borders of the first rib are progressively divided with scissors, beginning with the attachments medial to the subclavian vein (the subclavius muscle tendon and the costosternal and costoclavicular ligaments). A periosteal elevator is used along the inferior border of the rib, extending underneath the rib from the vantage point of the exposure used. The intercostal muscle is fully divided, and the parietal pleura is pushed away from the deep aspect of the rib by blunt dissection. The middle scalene muscle is detached from the superior surface of the rib, posterior to the brachial plexus nerve roots (see Fig. 121.6B). Although the proximal aspect of the long thoracic nerve is not directly visualized during this maneuver, injury to this nerve must be prevented to avoid postoperative serratus anterior muscle weakness. This is best accomplished by keeping the periosteal elevator directly upon the rib during scalene muscle detachment, avoiding any tendency to stray laterally where the long thoracic nerve can be easily injured. The long thoracic nerve is thereby gently pushed away from the rib indirectly as the middle scalene muscle is detached, effectively protecting it despite the lack of direct visualization. Once the posterior surface of the first rib is exposed and the T1 nerve root is in full view to protect it from injury, a bone-cutting instrument is carefully applied across the neck of the rib. The lateral portion of the divided rib is pulled downward, and its anterior aspect is cut in a similar fashion, just medial to the subclavian vein at the costochondral junction. The first rib is then fully detached and removed from the operative field (see Fig. 121.6C). A bone rongeur is used to trim the remaining ends of the bone to a smooth surface well beyond the neurovascular structures. With an additional amount of extrapleural dissection, the same exposure can be used to perform adjunctive cervical sympathectomy for patients with neurogenic TOS complicated by reflex sympathetic dystrophy.

Any additional soft tissue bands found to be crossing the brachial plexus nerve roots are sought and carefully divided, particularly those that may insert upon Sibson's fascia, the thickened aspect of the apical pleural surface. After hemostasis is achieved, the wound is irrigated and the lung is inflated to detect any breaks in the pleural lining. If small air bubbles are

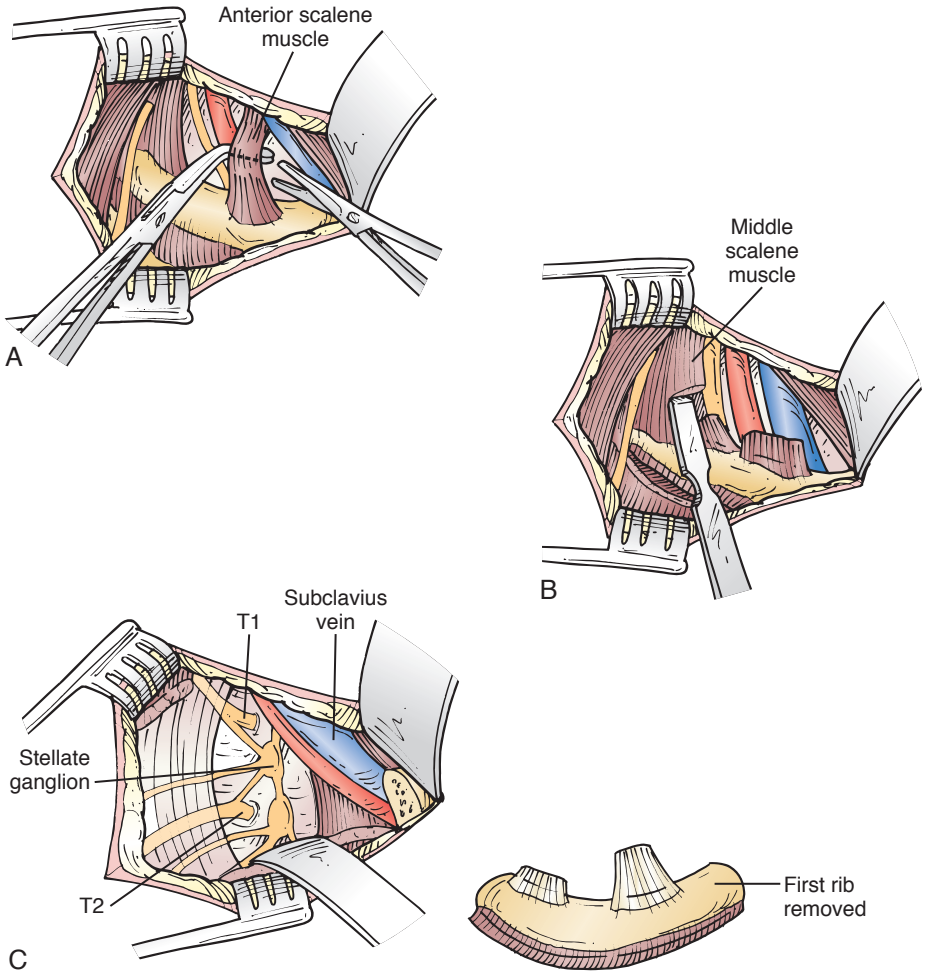

Figure 121.6 Transaxillary First Rib Resection. (A) Transaxillary division of the anterior scalene muscle. The tendinous insertion of the anterior scalene muscle onto the first rib is elevated with a right-angle clamp and divided with a scissors. (B) Detachment of the middle scalene muscle. After the intercostal attachments to the first rib are divided, a periosteal elevator is used to detach the middle and posterior scalene muscles. Injury to the proximal portion of the long thoracic nerve is prevented by staying directly on the rib. (C) Removal of the first rib. The anterior and posterior aspects of the first rib are divided, with the operative specimen including the resected portion of the anterior scalene muscle and the site of attachment of the middle scalene muscle. (Modified from Thompson RW, Petrinec D. Surgical treatment of thoracic outlet compression syndromes. I. Diagnostic considerations and transaxillary first rib resection. *Ann Vasc Surg*. 1997;11:315–323.)[67]

observed during positive-pressure ventilation or if the irrigation fluid appears to be lost into the pleural space, a small chest tube may be placed through a separate wound. The incisional wound is closed in two layers after placing a small closed suction drain in the operative field.

Supraclavicular Approach

The *supraclavicular approach* carries the major advantages of wider exposure of all anatomical structures associated with thoracic outlet compression. This allows complete resection of the anterior and middle scalene muscles to be achieved, as well as brachial plexus neurolysis with direct visualization of all five nerve roots. In many cases symptomatic relief of NTOS can be achieved by extended scalenectomy without the need for first rib resection, an option permitted by the supraclavicular approach. This approach also allows for resection of cervical ribs, anomalous first ribs, or the normal first rib. A further advantage is that all forms of vascular reconstruction can also be accomplished through supraclavicular exposure; although removal of the anteromedial portion of the first rib and distal control of the vessels may require addition of a second infraclavicular incision, this is performed without the need for repositioning the patient. The balance of advantages and disadvantages between these two operative approaches has led many groups to prefer the supraclavicular approach to TOS, with some adopting a highly selective approach in which resection of the first rib is reserved solely for patients with vascular complications.[46]

Under general anesthesia, the patient is positioned supine with the head of the bed elevated 30 degrees. The hips and knees are flexed and the neck is extended and turned to the opposite side. The neck, upper chest, and upper extremity are prepped into the field with the arm wrapped in a stockinette, then held comfortably across the abdomen. This allows for arm movement through an extended range of motion during the operation, when it may be necessary to assess any residual neurovascular compression following scalenectomy. A transverse skin incision is made two fingerbreadths above the clavicle, beginning at the lateral border of the sternocleidomastoid muscle (Fig. 121.7A). This incision is carried through the platysma muscle layer to expose the scalene fat pad, which is mobilized beginning at the lateral border of the internal jugular vein. As this tissue plane is entered, the fat pad is progressively dissected off the anterior surface of the anterior scalene muscle and reflected laterally (see Fig. 121.7B). The phrenic nerve is

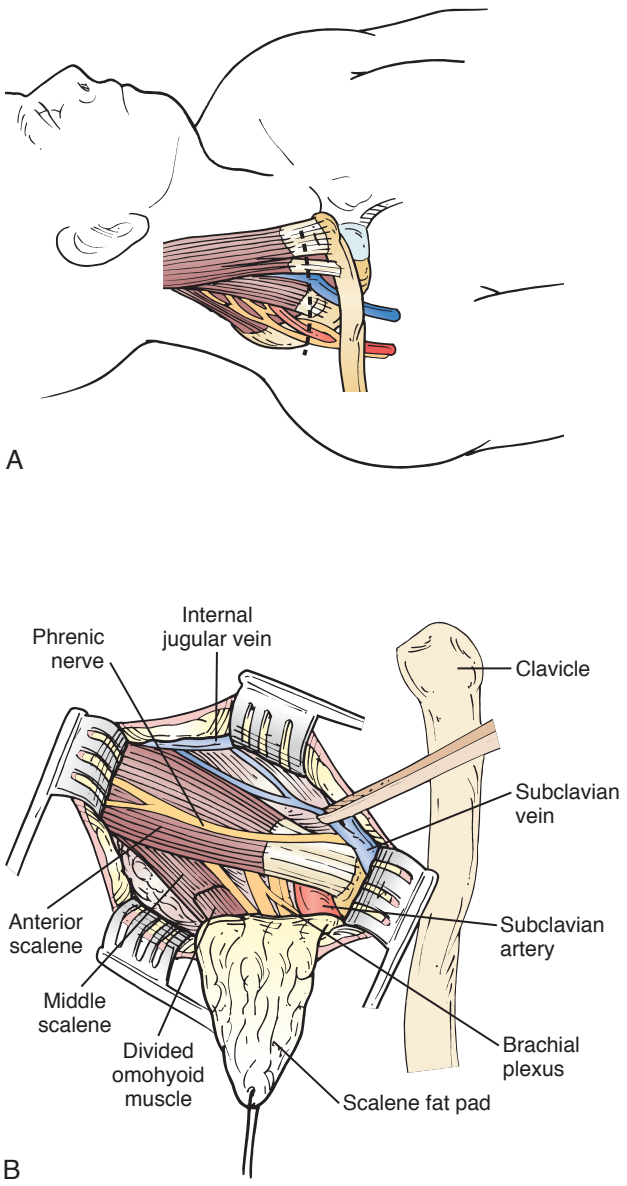

Figure 121.7 Positioning for Supraclavicular Thoracic Outlet Decompression. (A) A transverse skin incision is made two fingerbreadths above the clavicle to obtain full exposure of the structures associated with the scalene triangle. (B) The scalene fat pad is mobilized laterally to expose the underlying anterior scalene muscle, with identification and protection of the phrenic nerve. The omohyoid muscle is divided. The subclavian artery and the upper roots of the brachial plexus are identified behind the lateral edge of the anterior scalene muscle. (Modified from Thompson RW. Treatment of thoracic outlet syndromes and cervical sympathectomy. In: Lumley JSP, Hoballah JJ, eds. *Springer Surgery Atlas Series: Vascular Surgery*. London: Springer-Verlag; 2009:103–118.)[68]

identified within the investing fascia of the muscle, coursing in a lateral to medial direction ("lateral to medial" may be clearer to students and residents). Lateral retraction of the scalene fat pad then permits exposure of the underlying roots of the brachial plexus. The anterior scalene muscle is dissected, taking special effort to avoid excessive traction on the phrenic nerve (Fig. 121.8A). After circumferential mobilization of the anterior scalene muscle to its site of attachment to the first rib, a finger is passed behind the muscle and the muscle tendon is sharply divided at its insertion using a curved scissors (see Fig. 121.8B). There may be additional slips of muscle or tendon that must be divided more posteriorly, including direct attachments of the muscle to the thickened pleural lining behind the rib itself.

The anterior scalene muscle is lifted superiorly to detach it from the additional structures underneath, including the pleural apex, the subclavian artery, and the brachial plexus nerve roots (see Fig. 121.8C). This dissection is carried superiorly to the level of the scalene muscle origin on the transverse process of the sixth cervical vertebrae. Great care must be taken to avoid irretrievable neural injury while muscle fibers interdigitating with the proximal roots of the upper brachial plexus are removed. The entire anterior scalene is then removed, weighed, and sent to the neuromuscular pathology laboratory.

Following anterior scalenectomy and removal of any scalene minimus fibers, each of the nerve roots contributing to the brachial plexus is identified and meticulously dissected free of inflammatory scar tissue (see Fig. 121.8D). Moderately dense fibrotic tissue encasing the nerve roots is not uncommon in patients with neurogenic TOS, and failure to perform an adequate neurolysis may be one cause of persistent symptoms. This aspect of the operation is not complete until each nerve root from C5 to T1 is completely dissected throughout its course in the operative field.

Osseous cervical ribs or their soft tissue counterparts occur within the same plane as the middle scalene muscle. While the middle scalene muscle lies posterior to the roots of the brachial plexus, in some cases its insertion upon the first rib may occur as far anteriorly as the scalene tubercle (the site of attachment of the anterior scalene muscle). The attachment of the middle scalene muscle is divided from the first rib using a periosteal elevator or curved Mayo scissors, extending to a point posterior to the brachial plexus nerve roots (see Fig. 121.8E). If a cervical rib is present in the plane of the middle scalene muscle, it may also be detached from the first rib at this time. It is important to note the separation between the middle scalene and posterior scalene muscles, as defined by the oblique course of the long thoracic nerve. Muscle tissue anterior to this nerve is detached along the plane delineated by the long thoracic nerve while leaving the nerve intact. It is important to recognize that the long thoracic nerve may be represented by two or three branches at this level, rather than a single nerve, as often described.

Following resection of the anterior and middle scalene muscles and completion of a thorough brachial plexus neurolysis, an intraoperative decision is made regarding the potential role of the first rib in neurovascular compression. The surgeon's finger is placed alongside the brachial plexus nerve roots while the arm is elevated through a normal range of motion at the shoulder, allowing any residual compression to be detected during arm elevation. In many patients with NTOS, there is little residual compression by the first rib following adequate scalenectomy, and in these cases retention of the first rib may be considered. In contrast, the first rib should be removed if there is any question that it might contribute to residual neurovascular compression, as well as in all patients with arterial or venous TOS.

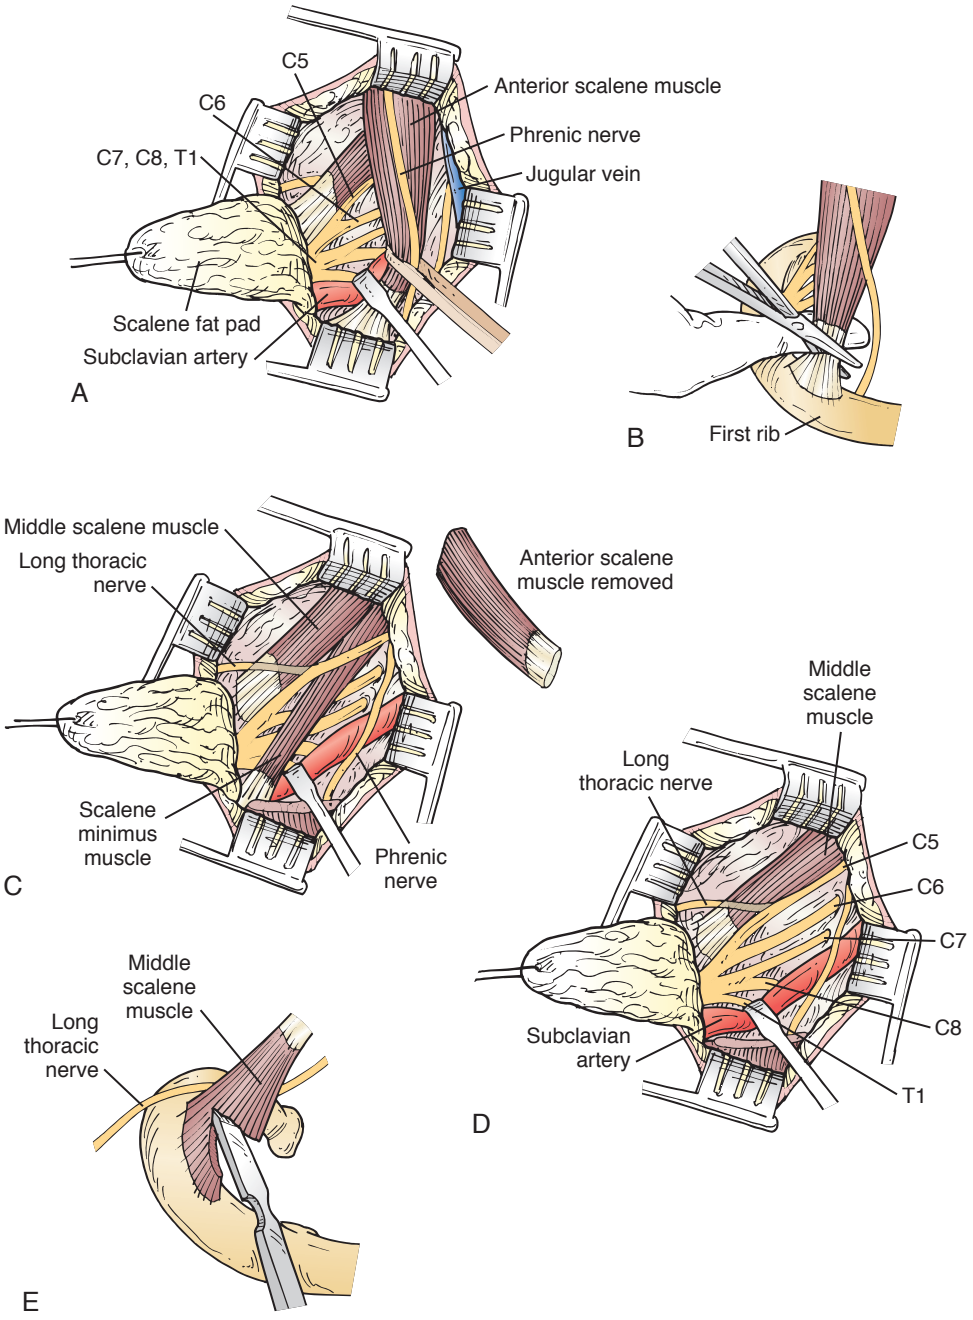

Figure 121.8 Supraclavicular Scalenectomy and Neurolysis. (A) The anterior scalene muscle is circumferentially mobilized from the underlying subclavian artery and roots of the brachial plexus. (B) The insertion of the anterior scalene muscle upon the first rib is sharply divided with scissors, with the surgeon's finger protecting the subclavian artery and the roots of the brachial plexus. (C) The anterior scalene muscle is reflected superiorly and dissected free of underlying structures to the level of its origin. Any muscle fibers passing between the upper nerve roots of the brachial plexus are also removed, including a scalene minimus muscle if present. (D) Complete dissection of the brachial plexus nerve roots from C5 to T1 is accomplished by resection of all perineural scar tissue. (E) The middle scalene muscle is detached from the first rib using a periosteal elevator, taking care to protect the long thoracic nerve. All muscle tissue lying anterior to the long thoracic nerve is resected. (Modified from Thompson RW. Treatment of thoracic outlet syndromes and cervical sympathectomy. In: Lumley JSP, Hoballah JJ, eds. *Springer Surgery Atlas Series: Vascular Surgery*. London: Springer-Verlag; 2009:103–118.)[68]

First, rib resection is readily accomplished through the supraclavicular approach, given the exposure already achieved at this stage of the operation (Fig. 121.9). Using a periosteal elevator, any remaining muscle fibers of the middle scalene muscle are detached from their insertion on the top of the posterior first rib. This dissection is always performed under direct vision, to protect the C8 and T1 nerve roots. Using a fingertip covered with gauze, the pleural membrane is bluntly dissected away from the inferior aspect of the first rib. Intercostal muscle attachments to the first rib are divided using a periosteal elevator, to relieve the posterior and lateral aspects of the first rib of all soft tissue attachments, and any remaining attachments are divided along the anterolateral aspect of the rib up to the scalene tubercle. The brachial plexus nerve roots are displaced anteriorly to expose the posterior neck of the rib. While the nerve roots are protected with a fingertip, a rib cutter is inserted over the neck of the isolated first rib and applied. A Kerrison bone rongeur is used to resect additional amounts of bone as needed to ensure that the end of the rib will not impinge upon the lower nerve roots and to create a smooth surface on the posterior stump of the first rib. The proximal portion of the rib is displaced inferiorly to open the anterior costoclavicular space, and a bone cutter is inserted at a level immediately medial to the scalene tubercle to divide the proximal rib. The first rib

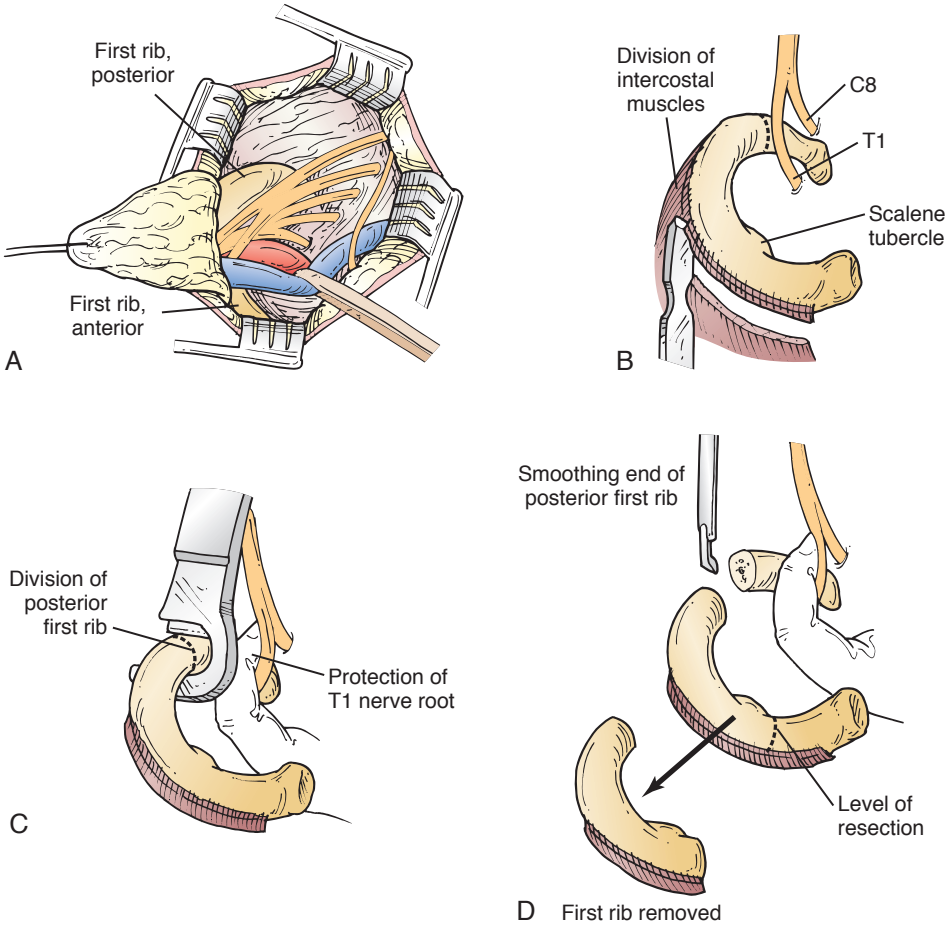

Figure 121.9 Supraclavicular First Rib Resection. (A) The first rib is shown in relation to the brachial plexus roots and the subclavian artery. (B) Intercostal attachments to the first rib are divided. (C) After division of the anterior first rib just proximal to the level of the scalene tubercle, the brachial plexus is reflected anteriorly to visualize the posterior neck of the rib. The T1 nerve root is displaced by a finger while the neck of the rib is divided. The anterior rib is cut and the specimen is removed from the field. (D) The remaining posterior edge of the rib is remodeled to a smooth surface using a Kerrison bone rongeur, ensuring that there is no residual impingement on the T1 nerve root. The anterior edge of the rib is similarly remodeled to a smooth surface (not shown). (Modified from Thompson RW. Treatment of thoracic outlet syndromes and cervical sympathectomy. In: Lumley JSP, Hoballah JJ, eds. *Springer Surgery Atlas Series: Vascular Surgery*. London: Springer-Verlag; 2009:103–118.)[68]

is then extracted from the operative field and discarded, and the proximal end of the rib is remodeled to a smooth surface with a bone rongeur.

Upon completion of the operation, the brachial plexus nerves may be wrapped with an absorbable film to act as a temporary barrier deterrent to the formation of perineural adhesions. A closed-suction drain is placed into the supraclavicular field, and the scalene fat pad is reapproximated over the brachial plexus prior to wound closure.

Pectoralis Minor Tenotomy

When there is evidence on physical examination for brachial plexus nerve root irritation at the level of the subpectoral space ("hyperabduction syndrome"), pectoralis minor tenotomy may be added to either transaxillary or supraclavicular decompression to ensure thorough relief of nerve compression. Pectoralis minor tenotomy may also be performed as an isolated procedure when this site is the dominant location of nerve compression symptoms, or when localizing findings are present in patients who have previously undergone thoracic outlet decompression by other approaches (persistent or recurrent NTOS). As illustrated in Fig. 121.10, a short vertical incision is made in the lateral infraclavicular space adjacent to the deltopectoral groove. The lateral edge of the pectoralis major muscle is gently retracted medially, and the underlying pectoralis minor muscle is encircled. The pectoralis minor tendon is then divided under direct vision, immediately inferior to its insertion on the coracoid process.

Postoperative Management

An upright chest x-ray is performed in the recovery room following all thoracic outlet decompression procedures, in part to detect residual pneumothorax or pleural fluid. Small air or fluid collections are carefully observed with the expectation of spontaneous resolution, although transthoracic aspiration may be necessary for a large or expanding pneumothorax. Postoperative pain medication is provided by intravenous opioids until adequate control can be achieved by oral medications, and we routinely prescribe oral narcotics, muscle relaxants, and nonsteroidal antiinflammatory agents for at least the first 2 to 4 weeks following surgery. The closed suction drain is removed 5 to 7 days after surgery unless there is persistent lymphatic fluid present, in which case the patient is discharged and the drain is removed in the outpatient office once the leak has subsided. In several hundred operations for TOS, we have only rarely had to perform a secondary procedure to control a persistent lymph leak.

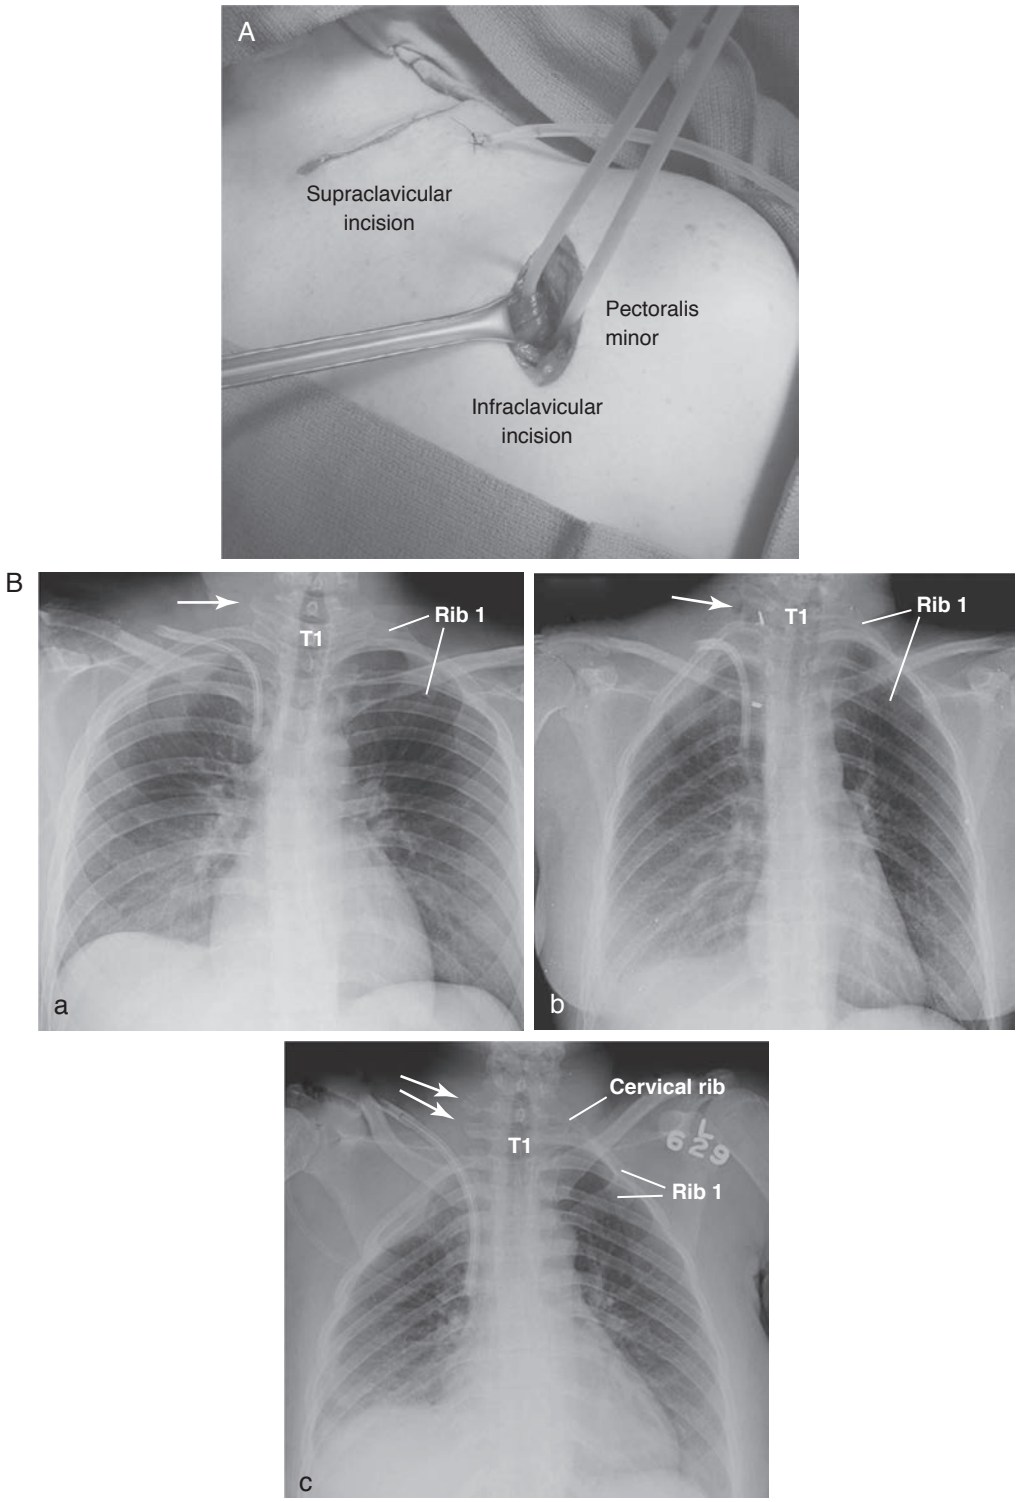

Figure 121.10 Pectoralis minor tenotomy and postoperative chest radiographs. (A) Operative view of left lateral infraclavicular incision used to isolate the pectoralis minor muscle tendon, performed in conjunction with a supraclavicular thoracic outlet decompression procedure. Operative view of left lateral infraclavicular incision used to isolate the pectoralis minor muscle tendon, performed in conjunction with a supraclavicular thoracic outlet decompression procedure. (B) Postoperative chest radiographs. *a*, Chest radiograph after right supraclavicular decompression. The closed-suction drain is seen extending from the neck into the pleural apex, and the posterior end of the resected first rib is indicated *(arrow)*. *b*, Chest radiograph after right supraclavicular decompression with an adjunctive cervical sympathectomy for reflex sympathetic dystrophy. The posterior end of the resected first rib is indicated *(arrow)*, with the extent of sympathetic chain resection demonstrated by the position of radiodense clips at the first and fourth thoracic levels. *c*, Chest radiograph after right supraclavicular decompression with resection of the cervical and first ribs. The posterior ends of the resected cervical and first ribs are indicated *(arrows)*.

There are no strict restrictions with respect to use of the upper extremity after operation, but patients are advised to avoid excessive reaching overhead or heavy lifting. Physical therapy is resumed as soon as feasible, usually upon discharge from the hospital or in the first postoperative week. Patients are cautioned against activities that can result in muscle strain, spasm, and significant pain in the trapezius and other neck muscles, and a gradual return to use of the upper extremity is encouraged. The majority of patients resume fairly regular activity within several weeks after the operation, and in most cases are permitted a cautious return to light-duty work by 4 to 6 weeks. Work restrictions are recommended to prevent heavy activity during the early stages of return to work, particularly to avoid excessive use of the upper extremity by lifting or repetitive activities that may contribute to postoperative complaints. It is important to recognize that patients with longstanding NTOS often display residual symptoms of dysesthesias, numbness, or other complaints that may not be eliminated by thoracic outlet decompression; while these symptoms may be tolerable, the surgeon must provide continuing support and reassurance during the period of recovery and rehabilitation. Physical therapy is continued for as long as necessary to allow the patient to return to an optimal level of function, and patients are seen at least yearly to assess the long-term results of operative intervention.

SURGICAL COMPLICATIONS

Nerve Injuries

The most serious complications associated with thoracic outlet decompression are injuries to the brachial plexus nerve roots. Although infrequent, the rate of nerve injuries reported to occur following transaxillary first rib resection was one of the factors leading many to diminish their enthusiasm for this procedure in the 1980s.[22,40] Although these factors are decreased in procedures done through the supraclavicular route given the improved exposure of the nerve roots, brachial plexus palsies can still occur secondary to retraction. In the absence of direct injury, however, these complications are temporary and will resolve within weeks to several months of the operation.

Temporary phrenic nerve dysfunction after supraclavicular thoracic outlet decompression occurs in approximately 10% of patients, is most often associated with retraction of the nerve necessary to accomplish anterior scalenectomy, and results in temporary diaphragmatic paralysis. Although most patients with phrenic nerve palsy are asymptomatic and only exhibit respiratory difficulty with extremes of exertion, patients with underlying lung disease prior to operation may have more significant symptoms. While these symptoms will typically resolve with recovery of phrenic nerve and diaphragmatic function within weeks to months of operation, in some cases full recovery may take up to 10 months. In patients with bilateral TOS requiring operation on the contralateral side, it is essential to ensure that any degree of phrenic nerve paresis has completely resolved prior to the second operation, since contralateral operation in this setting may result in a patient with complete diaphragmatic paralysis and severe ventilatory incapacity. We therefore routinely perform fluoroscopic visualization of diaphragmatic function to ensure complete return of innervation before planning any form of contralateral operation.

Lymph Leakage

It is not uncommon to observe minor postoperative lymphatic fluid collections in the area of the wound or emanating from the closed-suction drain, at least within the first week of operation. It is notable that this may occur despite ligation of the thoracic duct on the left side, usually due to lymph fluid leakage from small tributaries subjected to higher fluid pressures than normal. In the majority of cases, these lymph leaks will resolve spontaneously with time, usually within several weeks, and it is rare to encounter a patient in whom a secondary procedure is necessary for persistent lymph drainage.

RESULTS OF SURGERY

Outcome Measures

Since functional results depend in large part on the extent of disability existing prior to operation, reported results may vary considerably for patients with differing degrees or duration of disabling symptoms before surgical treatment. Unfortunately, there are no well-defined classification schemes in common use by which to stratify patients undergoing surgical treatment. A second difficulty in assessing the results of surgery remains the absence of well-established outcome measures or reporting standards for thoracic outlet decompression. Most authors describe results as divided into separate categories: (1) excellent, with complete relief of all symptoms; (2) good, with relief of major symptoms but some persistent symptoms; (3) fair, with partial relief but persistence of some major symptoms; and (4) poor, with no improvement. Another variable complicating the interpretation of outcomes for surgical treatment is the type of operation performed. It has been difficult to demonstrate a significant difference in outcome between the different procedures in common use. Further complicating these assessments is the fact that some reports do not distinguish between patients undergoing operations for NTOS versus arterial or venous TOS, making it impossible to separate the results for the treatment of NTOS alone.

It is recognized that the overall success of operations for NTOS can only be considered in the context of long-term outcomes. Most of these operations are performed in relatively young and active individuals, with the aim of improving function for many years. Because the degree of improvement obtained in the first few months after surgery may diminish with time, the durability of successful outcomes becomes another important measure of results. Unfortunately, many reports in the literature do not include follow-up or assessment of results beyond several months to a few years, making it difficult to assess differences that may exist between different operations over longer periods.

Finally, it is uncertain if the results reported by those regularly performing operations for NTOS can be extended to those who only perform thoracic outlet decompression on an occasional

basis, since these are technically demanding operations not often performed by the majority of vascular surgeons.

Operative Results

Anterior Scalenotomy/Scalenectomy

A summary of eight reports published between 1947 and 1987, describing results in a total of 241 patients undergoing anterior scalenotomy, indicates that the overall outcomes for this operation were good in 26% to 89% (mean 58%), fair in 0% to 39% (mean 9%), and poor in 7% to 60% (mean 33%).[47-54]

Anterior scalenectomy was popularized by Adson as a means to avoid potential injury to the brachial plexus in patients with cervical ribs. In six reports of this procedure published up to 1989, encompassing a total of 338 patients, there were good results in 26% to 89% (mean 56%), fair in 0% to 39% (mean 13%), and poor in 7% to 60% (mean 31%).[55-60] At present, neither of these operations are performed frequently for NTOS, in part because the long-term results do not appear as good as those achieved with approaches involving the resection of the first rib.

Transaxillary First Rib Resection

Since its introduction by Roos in 1966, transaxillary first rib resection has been one of the most frequently performed operations for NTOS. By 1989, more than 3000 of these operations were reported in 21 separate publications. The largest of these series included 1315 patients, with a successful outcome in 92% and a failure rate of 8%. As summarized in Table 121.4, the overall rate of good outcomes for transaxillary first rib resection has ranged from 37% to 100% (mean 80%), with fair outcomes in 0% to 14% (mean 6%) and failure of operation in 0% to 41% (mean 15%).

Supraclavicular First Rib Resection With Anterior and Middle Scalenectomy

Table 121.5 summarizes results of operation from seven different publications including a total of 1222 patients), the largest being the series reported by Hempel et al. (770 operations). Overall, the results for supraclavicular decompression were good in 59% to 91% (mean 77%), fair in 5% to 33% (mean 15%), and poor in 3% to 18% (mean 8%).

Comparison of Surgical Approaches

One of the most comprehensive analyses of results for NTOS has been presented by Sanders, in which the life-table method was used to compare outcomes for different operative procedures,[1,22,61,62] including patients undergoing transaxillary first rib resection (n = 112), anterior and middle scalenectomy (n = 286), or supraclavicular scalenectomy with first rib resection (n = 249); there was no difference in the initial success rate between these three procedures (91%, 93%, and 93%, respectively). As shown in Fig. 121.11, the percentage of patients with successful outcomes also declined over time with all three procedures. Although the long-term success with supraclavicular scalenectomy and first rib resection appeared somewhat better at 10 to 15 years (71%) than the results with either anterior scalenectomy (66%) or transaxillary first rib resection (64%), there was no statistically significant difference between these operations.

Predicting the Outcomes of Surgery

Franklin et al. examined injured workers in the state of Washington that had undergone an operation for NTOS between 1986 and 1991, finding that 60% of those with a work-related injury remained disabled 1 year after surgical treatment.[63] There appeared to be no differences in outcome based on the type of operation performed, the presence of any particular provocative test results, or the experience of the operating surgeon, but significant predictors of ongoing disability included the amount of work disability before surgery, longer time intervals between

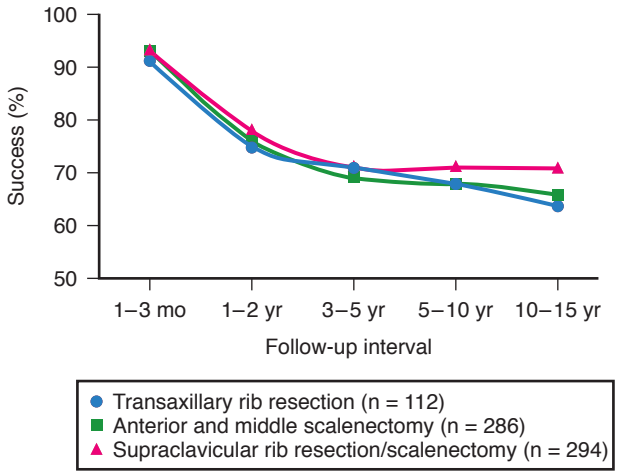

Figure 121.11 Long-Term Results of Three Operations for Neurogenic Thoracic Outlet Syndrome (NTOS). Outcome of 692 patients undergoing a primary operation for NTOS are shown in life-table format extending to follow-up intervals of 10 to 15 years. Data indicate results for patients having transaxillary first rib resection (circular symbols, n = 112), anterior and middle scalenectomy (square symbols, n = 286), or supraclavicular scalenectomy with first rib resection (triangular symbols, n = 249). There was no statistically significant difference between the three operations. (Modified from Sanders RJ. *Thoracic Outlet Syndrome: A Common Sequelae of Neck Injuries.* Philadelphia: J. B. Lippincott Company; 1991.)

injury and a diagnosis of NTOS, and older age at the time of operation. This study has been frequently cited to indicate poor outcomes for surgical treatment of NTOS in the presence of work-related injury and disability claims. However, the scope of its applicability is limited as a database study restricted to injured workers, and the results can be interpreted to suggest that better outcomes might be achieved with more accurate diagnosis of NTOS after work-related injury and earlier application of surgical treatment in this clinical setting. Axelrod et al. also examined potential associations between preexisting psychological factors and socioeconomic characteristics and the long-term outcomes of patients undergoing surgery for NTOS.[64] Supraclavicular thoracic outlet decompression in 170 patients was considered successful in 65%, with 35% remaining on medications and 18% reporting ongoing disability. Multivariate logistic regression models revealed several independent risk factors significantly associated with persistent disability, including major depression, not being married, and having less than a high school education. The authors suggest that further prospective studies are needed to address the potential impact of preoperative treatment for depression in patients undergoing operations for NTOS. In evaluating the potential role of specific anatomic factors in outcomes of surgery, Sanders et al. reviewed their long-term operative results in 54 patients with NTOS associated with a cervical rib or anomalous first rib.[11] While the overall success rate of operation was 72%, the etiology of symptoms was a significant variable in outcome, with failure in 42% of those with symptoms following a work-related injury or repetitive stress, 26% in those with symptoms following an automobile collision, and 18% in those with symptoms of nonspecific etiology. The failure rate was also substantially affected by the operation performed: 75% for those undergoing cervical rib resection without first rib resection in the work-related injury group (and 38% in the non-work-related group), compared with 25% for those undergoing cervical rib resection along with resection of the first rib in the work-related group (and 20% in the non-work-related group). The authors concluded that (1) the presence of a cervical rib or anomalous first rib in patients with NTOS does not improve the success rate from surgery compared with patients without rib abnormalities; (2) neck trauma is the most common cause for NTOS, even in patients with abnormal ribs; (3) cervical and anomalous first ribs are predisposing factors rather than the cause of NTOS; and (4) surgery for NTOS in patients with cervical ribs should include both cervical rib and first rib resection.

In a valuable study of 85 patients with NTOS treated with either surgery or botulinum toxin chemodenervation, Jordan et al. reported no differences between treatment-responsive and treatment-resistant patients with respect to work disability status or compensation claims, anomalous anatomy detected by ultrasonography, or subclavian artery flow alterations detected by duplex sonography.[24] They did observe, however, that treatment-resistant patients had a higher frequency of sensory complaints extending beyond lower trunk dermatomes (42% vs. 10%), weakness extending beyond lower trunk myotomes (19% vs. 2%), a history of previous non-TOS surgery of the neck or upper limbs (50% vs. 17%), and comorbidities of fibromyalgia or CRPS (81% vs. 12%), and depression (35% vs. 10%). Importantly, treatment-resistant patients also responded less frequently to scalene muscle test blocks compared with treatment-responsive patients (38% vs. 100%). This study thereby demonstrates the adverse effect on surgical outcomes associated with certain comorbid conditions and diffuse upper extremity symptoms, and highlights the clinical value of diagnostic scalene muscle blocks in the modern management of NTOS.

Freischlag and colleagues examined a series of 162 patients that had undergone transaxillary first rib resection using the

Short-Form 12 (SF-12), Brief Pain Inventory (BPI), and Cervical-Brachial Symptom Questionnaire (CBSQ) instruments, with a mean follow-up of 44.7 months.[65] They found no significant difference in QOL scores associated with long-term compared with short-term follow-up, but significantly poorer scores on all instruments associated with comorbid chronic pain syndromes, opioid use, and unfavorable clinical assessment. Significantly poorer scores on specific instruments were associated with smoking, age over 40 years, neck and/or shoulder pathology, and postoperative complications, but a positive preoperative scalene block was not significantly associated with long-term QOL scores. It was concluded that while clinical assessment can accurately reflect patient-reported outcomes and gauge postoperative improvement, patient factors are more predictive of long-term QOL than preoperative scalene blocks and should also be considered when selecting patients for surgical intervention.

Caputo et al. used the Disabilities of the Arm, Shoulder and Hand (DASH) survey, the CBSQ, and a 10-point visual analog scale (VAS) for pain, as well as a composite score combining these measures (the NTOS Index, scaled 0-100) to assess outcomes in a series of 189 patients at 3 and 6 month intervals after supraclavicular thoracic outlet decompression for NTOS.[66] Compared with adults (n = 154), adolescent patients (n = 35) had a significantly lower incidence of depression (11.4% vs. 41.6%), motor vehicle injury (5.7% vs. 20.1%), previous operations (11.4% vs. 29.9%), preoperative use of opiate medications (17.1% vs. 44.8%), and preoperative symptom duration greater than 2 years (24.2% vs. 50.0%). The mean preoperative NTOS Index (scale 0-100) was significantly lower in adolescents versus adults (46.5 ± 3.6 vs. 58.5 ± 1.7). Although both groups exhibited significant improvement in functional outcome measures at 3 and 6 months, the adolescent patients had a significantly lower mean NTOS Index (10.4 ± 3.1 vs. 39.3 ± 3.3) and less use of opiate medications (11.4% vs. 47.4%). This study demonstrates that adolescents undergoing supraclavicular decompression for NTOS had more favorable preoperative characteristics and enhanced functional outcomes than adults, and further illustrates the use of quantitative PROMs to help address factors that can improve surgical outcomes for NTOS.

It can be concluded from the studies cited here that certain preexisting clinical features appear to be associated with diminished success for operative treatment of NTOS, particularly work-related injury, longstanding symptoms, major depression, diffuse upper extremity symptoms, and lack of a response to anterior scalene muscle blocks.

Ongoing Symptoms

Persistent Neurogenic Thoracic Outlet Syndrome

Persistent symptoms are those that were not relieved even for a short period of time by the initial operation. In most cases, persistent symptoms are due to another condition, and the diagnosis should be completely reevaluated. If the symptoms cannot be attributed to another condition and they resist conservative management for at least several months, the possibility of persistent NTOS is then considered. If the initial operation was a transaxillary first rib resection, persistent symptoms may occur if there was inadequate relief of compression of the upper nerve roots, since scalenectomy was not performed. In these cases, a reoperative supraclavicular scalenectomy should be considered. Although it is unusual to observe persistent NTOS after supraclavicular scalenectomy, this may be considered if the procedure did not include first rib resection. In such cases it may be reasonable to consider reoperation to remove the first rib, by either the transaxillary or supraclavicular route.

Recurrent Neurogenic Thoracic Outlet Syndrome

The majority of such recurrences occur within the first 2 years of the primary operation. The symptoms are often the same as those present prior to the initial operation, and the diagnosis is made in the same manner as described earlier. If reoperation is considered, the choice of procedure again depends on the type of operation performed initially. If a transaxillary first rib resection was performed, reoperation should be through supraclavicular exposure to include scalenectomy, brachial plexus neurolysis, and resection of any remaining portion of the first rib. Experience with such operations shows that the stump of the anterior scalene muscle has often become attached to the extrapleural fascia or the brachial plexus nerve roots; it is also common to find a segment of the posterior rib still present, since this portion cannot be resected easily through the transaxillary approach. If the initial operation was a supraclavicular scalenectomy, a repeat operation should include first rib resection. Because the cause of recurrent NTOS following supraclavicular scalenectomy and first rib resection is usually the formation of perineural adhesions, reoperation through the supraclavicular route may still be of value since it permits a complete brachial plexus neurolysis to be achieved. Because reoperations are associated with a higher risk of nerve and vascular injury than primary procedures, the decision to reoperate should not be taken lightly, and the procedure should be performed by an individual with considerable experience in these operations.

Complications 1646

Arterial complications from subclavian artery compression represent the least common type of thoracic outlet syndrome (TOS) in adults, but they also represent the strongest indication for operative intervention. Arterial manifestations usually follow a progressive course characterized by extrinsic compression, poststenotic dilation, aneurysmal degeneration, thrombus formation, and secondary embolization. Because arterial TOS is typically associated with anomalous osseous structures, this form of TOS has a more easily definable clinical picture. In fact, arterial TOS was probably the first form to be described as early as 1831.[1] The first reported resection of a bone abnormality causing a subclavian aneurysm was by Coote in 1861.[2] Compression of the subclavian artery and brachial plexus was first termed Naffziger syndrome[3] and evolved to the modern term *thoracic outlet syndrome* after a 1956 publication by Peet and coworkers.[4]

PATHOPHYSIOLOGY

Arterial complications of TOS are associated with bone abnormalities in almost all cases. Cervical ribs that cause subclavian artery damage tend to extend beyond the transverse process with partial or complete fusion to the first rib by a bony pseudarthrosis.[5] This differs from the longer, thinner, and incomplete cervical ribs usually associated with neurogenic TOS. The cervical rib pushes the subclavian artery forward, angulating and compressing it between the first rib and the anterior scalene muscle. This compression causes injury to the inferior wall of the third segment of the subclavian artery, which may lead to localized intimal damage or poststenotic dilation. Less common causes of arterial TOS include anomalous first ribs, fibrocartilaginous bands associated with the anterior scalene muscle, muscular hypertrophy in athletes, and hypertrophic callus from healed clavicle or first rib fractures.[6-8] Poststenotic dilation associated with chronic arterial compression may progress to aneurysmal change, whereas localized intimal damage may lead to embolization or thrombosis. The relative frequencies of anatomic abnormalities are shown in Table 122.1.

EPIDEMIOLOGY

The frequency of arterial TOS in the general population is undefined. The largest single-institution experience of patients

TABLE 122.1 Relative Frequency of Anatomic Abnormalities Causing Arterial Thoracic Outlet Syndrome

Abnormality	Frequency (%)[a]
Cervical rib	60
Anomalous first rib	18
Fibrocartilaginous band	15
Clavicular fracture	6
Enlarged C7 transverse process	1

[a]Percentages represent a compendium of 122 patients from five large series (references 6, 7, 13-15).

treated for all varieties of TOS was reported by Urschel and Kourlis.[9] During 6 decades, the authors performed primary neurovascular decompression on 5102 patients, including 4183 (82%) for neurogenic TOS, 625 (12%) for venous TOS, and 294 (6%) for arterial TOS. In another series of 594 consecutive first rib resections performed at Johns Hopkins Medical Institutions, Orlando et al.[10] reported that 308 (52%) were performed for neurogenic TOS, 261 (44%) for venous TOS, and 25 (4%) for arterial TOS. In contrast, arterial TOS is a relatively more common form in children and adolescents, accounting for 20% to 38% of cases.[11,12]

Most patients presenting with symptoms of arterial TOS are young, active adults. The mean age in published series ranges from 32 to 37 years, with a similar proportion of men and women reported.[7,10,13-15] No familial predisposition has been described. The condition appears to be related to bone abnormalities or trauma in nearly every circumstance. Orlando et al. reported arterial TOS is significantly more likely to be associated with a cervical rib than either venous TOS or neurogenic TOS: in their series, 60% of arterial TOS patients had a cervical rib versus 2.3% of venous TOS and 9.4% of neurogenic TOS.[10] Cormier[13] has reported that only 5 (11%) of 55 patients with arterial TOS had fibrous bands without any definable osseous abnormality.

CLINICAL PRESENTATION

Patients with arterial TOS have a characteristic history and physical examination, but diagnosis requires confirmation with objective testing.

Signs and Symptoms

The most common presentation is hand ischemia due to microembolization. However, arterial TOS can be associated with less dramatic symptoms, and many cases go unrecognized because the condition tends to occur in young patients without atherosclerotic risk factors. Early in the disease process, patients may present with mild symptoms of exertional arm pain or unilateral Raynaud syndrome. Moderate to severe exertional pain may be associated with subclavian artery thrombosis. On occasion, a subclavian artery aneurysm may be palpable in an asymptomatic patient. Although rare, cerebrovascular accidents from retrograde propagation of subclavian thrombus have been reported.[16-20]

Clinical Assessment

Clues to the diagnosis of arterial TOS include the young age of the patient and the tendency for symptoms to be unilateral, which helps differentiate the condition from systemic pathologic states. The directed physical examination should consist of measuring blood pressure in both upper extremities and auscultating for bruits in the supraclavicular fossa. A bruit may be elicited on shoulder abduction or the overhead arm position if it is not present in the relaxed position. Specific findings on physical examination include a palpable cervical rib and a pulsatile supraclavicular mass. Evidence of microembolization to the hand, including digital ischemia and splinter hemorrhages, may also be present.

DIAGNOSTIC EVALUATION

Arterial TOS is a clinical diagnosis made by combining important elements from the history and physical examination. The following adjuncts may help support the diagnosis or suggest an alternative cause of the patient's symptoms.

Compression Maneuvers

Compression maneuvers such as the Adson test, costoclavicular maneuver (exaggerated military position), and hyperabduction maneuver (shoulder abduction beyond 90 degrees) have historically been used to aid in the diagnosis of TOS, but none is accurate. Ablation or reduction of the radial pulse with these maneuvers is considered a positive test result, but the incidence of false-positives in normal, healthy volunteers ranges from 9% to 57%.[21-24] Another compression maneuver is the abduction–external rotation test, also referred to as the elevated arm stress test popularized by Roos et al.[25] Development of hand pain or paresthesias within 60 seconds is considered a positive test result. This test is used in the diagnosis of neurogenic TOS but is not helpful in arterial TOS (see Chapter 121).[26]

Noninvasive Vascular Laboratory Studies

Duplex Ultrasonography

Duplex ultrasound examination of the subclavian and axillary arteries may demonstrate aneurysmal change or elevated flow velocities correlating with a compressive stenosis. The clavicle may interfere with complete ultrasound imaging of the subclavian artery, but significant ulcerations and intimal disruption may be visible. Compression maneuvers have been recommended during sonographic evaluation, with decreased subclavian artery diameter or changes in peak systolic velocity thought to be diagnostic of arterial TOS. One study evaluating multiple compression maneuvers and imaging locations found that arm abduction to 130 degrees while imaging in the costoclavicular space was the most discriminating technique.[27] However, as

with the pulse-monitored compression maneuvers described before, there are a high number of false-positives in normal, healthy volunteers. Studies have shown that compression maneuvers are associated with complete occlusion or significant stenosis of the subclavian artery in approximately 20% of normal subjects.[28,29] Therefore an abnormality detected on ultrasound during compression maneuvers should be used only to confirm a suspected diagnosis of arterial TOS.

Pulse Volume or Segmental Pressure Recording

Pulse volume or Doppler segmental pressure recordings taken at multiple levels in the upper extremities can help localize the level of arterial obstruction if embolization has occurred from arterial TOS. Diminished digital waveforms in the affected extremity coupled with normal findings in the contralateral extremity indicate arterial insufficiency consistent with stenosis or distal embolism.

Radiographic Studies

Radiography

The American College of Radiology recommends chest radiography as the initial imaging modality in patients suspected of having TOS, given that it is easy to perform, noninvasive, and a low-cost test that can assess for several potential abnormalities.[30] Chest radiographs including cervical spine views will often demonstrate the offending bone abnormality. Cervical ribs, elongated transverse cervical processes, and large clavicle fracture calluses are easily seen (Fig. 122.1). Soft tissue abnormalities such as Pancoast tumors can also be detected, but anomalous first ribs and fibrocartilaginous bands are not likely to be detected on plain radiographs.

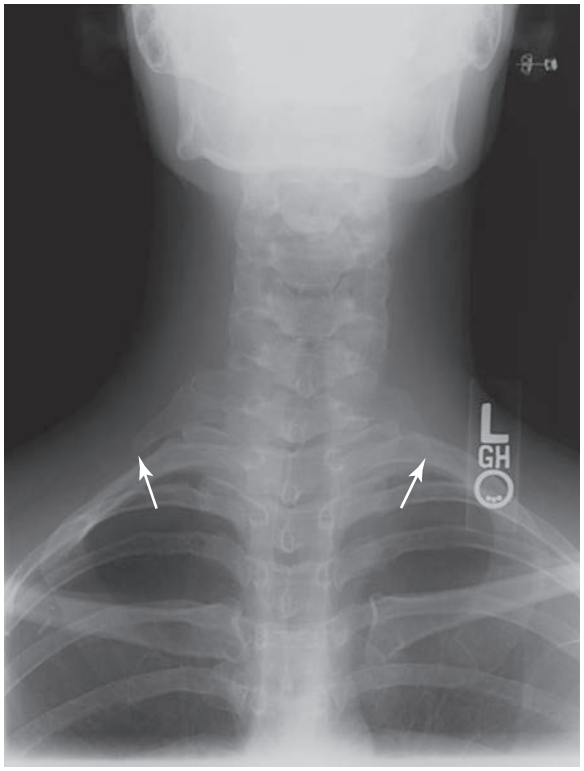

Figure 122.1 Chest radiograph demonstrating bilateral cervical ribs *(arrows)* in a patient with arterial thoracic outlet syndrome.

Computed Tomography

Computed tomographic angiography (CTA) with the intravenous administration of a contrast agent is a useful test to secure the diagnosis and to aid in surgical planning. CTA is typically performed in two views: one with the affected arm adducted, and the other with the arm abducted at 170 degrees or greater. CTA may identify the exact point of compression and the extent of arterial disease that requires treatment. According to American College of Radiology standards, an increase in arterial narrowing of 30% or more between the two views is considered significant.[30] With the ability to manipulate these images in three dimensions, there is usually no need for catheter-based arteriography (Fig. 122.2). In fact, CTA has replaced catheter-based angiography as the main radiographic test for diagnosis of arterial TOS at most centers. CTA can also be used to evaluate the distal arterial circulation, but catheter-based angiography may still be necessary to visualize the small arteries of the distal arm and hand. Because compression of the neurovascular structures in the thoracic outlet is common in normal, healthy subjects,[31] dynamic compression maneuvers should be used only to confirm the diagnosis in patients with suspected arterial TOS. In patients with arterial TOS, CTA findings show a strong correlation to both operative findings and success of operative decompression, in contrast to findings venous TOS, which are less predictive (see Chapter 123).[30]

Magnetic Resonance Angiography

Although magnetic resonance angiography (MRA) may be an acceptable substitute for CTA or catheter angiography in some centers, the sensitivity of MRA for diagnosis of arterial TOS appears to be low. Two reports of MRA in patients with arterial

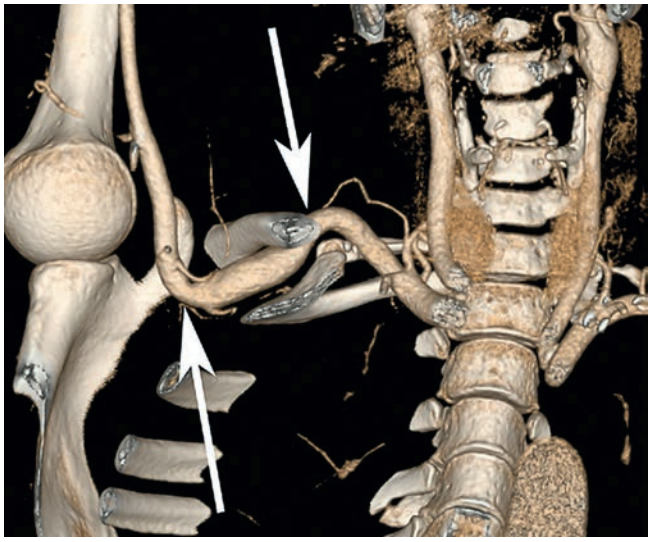

Figure 122.2 Three-dimensional reconstruction of a computed tomography angiogram showing compression of the right subclavian artery with poststenotic dilatation *(arrows)*. (From White P, Fox CJ, Feuerstein IM. Cervical rib causing arterial thoracic outlet syndrome. *J Am Coll Surg.* 2009; 209:148-149.)

symptoms had 37% and 42% incidence of false-negative findings, respectively.[27,32] Therefore a normal finding on MRA should not be used to rule out the diagnosis of a clinically suspected arterial TOS. To improve vascular imaging, a protocol of contrast-enhanced three-dimensional MRA with provocative arm positioning has been recommended.[33] However, further experience with the technique is needed before it can be recommended as more than a complementary test to diagnose arterial TOS.

Catheter-Based Angiography

Upper extremity arteriography was considered the "gold standard" for evaluation of arterial TOS. Compared to CTA, arteriography is less reliable in demonstrating impinging structures and other anatomic abnormalities. However, arteriography can localize the exact point of arterial compression, provide an assessment of the nature and extent of arterial damage, and permit evaluation of the distal circulation (Fig. 122.3). As noted before, CTA for operative planning is gradually replacing catheter-based arteriography. However, arteriography with magnified views remains the best method for demonstrating embolic occlusion of the small arteries of the hand and fingers (Fig. 122.4).

Laboratory Testing

There are no specific laboratory tests that are necessary to diagnose arterial TOS. However, specific laboratory assays are important to exclude systemic causes of upper extremity ischemia, such as vasculitis and connective tissue disorders (see Chapters 137 and 140).

DIFFERENTIAL DIAGNOSIS

Although arterial TOS has a characteristic presentation, other causes of upper extremity ischemia may be suspected from the history and physical examination (Box 122.1). A history of cardiac disease, particularly mitral valve stenosis or atrial fibrillation, supports a cardioembolic etiology. A family history of venous thromboembolic disease suggests an underlying hypercoagulable state, and further tests to exclude paradoxical embolus may be warranted. Risk factors for atherosclerosis, particularly heavy tobacco use, raise the possibility of atherosclerotic occlusive disease as the underlying etiology. Associated symptoms of polymyalgia rheumatica suggest the possibility of vasculitis, whereas symptoms of arthritis, dermatitis, and esophageal dysmotility warrant evaluation for connective tissue disease. Other possible causes include dissection, radiation injury, and trauma, all of which can be suspected from the history and evaluated with imaging studies discussed before.

Screening

There is no role for screening of asymptomatic patients to diagnose arterial TOS. As noted before, dynamic compression maneuvers are associated with a significant rate of false-positive results in asymptomatic patients; therefore, positive test results

should be viewed with caution. On the other hand, it is reasonable to evaluate the opposite side in a patient with symptomatic arterial TOS. The incidence of bilateral arterial TOS is not known. Among patients with cervical ribs, the prevalence of bilaterality has been reported to be 40% (Viertal). The reported frequency of bilateral TOS of all types is reported to be 9% to 26%.[10,34-36] Treatment may be indicated for evidence of arterial dilatation or severe intimal degeneration, even in asymptomatic individuals.

TREATMENT

Medical Treatment

Contrary to neurogenic TOS, there is no role for conservative treatment of symptomatic patients with arterial TOS. On the other hand, conservative treatment may be appropriate for some asymptomatic patients. Although the natural history is not well known, simple compression without evidence of arterial degeneration does not appear to carry a significant risk of complications in the asymptomatic patient. Therefore watchful waiting with use of serial noninvasive tests, such as duplex ultrasonography, may be a reasonable approach. In addition, every attempt should be made to reduce compression forces in the thoracic outlet. This is especially true for high-performance athletes engaged in repetitive overhead arm motion, such as professional baseball pitchers and tennis players. Aggressive physical therapy and modification of arm motion have been recommended in these cases.[37]

The natural history of arterial abnormalities in asymptomatic patients with arterial TOS is not completely understood. However, some patients present with profound hand ischemia as the first manifestation of arterial TOS. Therefore it seems reasonable to treat patients with subclavian artery compression and documented arterial disease, such as arterial dilatation or severe intimal disruption, before symptoms ensue, especially in young, active individuals. The role of anticoagulation in these circumstances is not known.

Surgical Treatment Principles

The three main components of treatment include relieving the arterial compression, removing the source of embolus, and restoring the distal circulation. At a minimum, relieving the arterial compression involves resection of cervical ribs and any other identified anomalies causing impingement in the thoracic outlet. As discussed later, most authors also recommend routine division of the anterior scalene muscle and resection of the first rib to avoid recurrence. Removal of the source of embolus involves resection of a subclavian aneurysm or repair of an arterial stenosis with intimal damage. The success of arterial reconstruction is usually related to the status of the arterial outflow in the limb. Restoration of the distal circulation may involve any combination of thrombolysis, thromboembolectomy, or bypass.

The decision to repair an artery after thoracic outlet decompression should be individualized. Resolution of poststenotic dilation after decompression of the thoracic outlet has been described,[6,38,39] but it is not certain that all lesions will heal spontaneously. Likewise, it is not known whether associated intimal damage will resolve after decompression. At some point, poststenotic dilation progresses to the point of being considered an aneurysm. Symptomatic patients with subclavian artery aneurysms tend to have recurrent thromboembolic complications that may lead to digit or limb loss. Because of the numerous collaterals around the shoulder, the natural history of a subclavian artery thrombosis is uncertain. However, arterial repair may be indicated in asymptomatic patients with subclavian artery thrombosis due to the reported risk of retrograde propagation with resultant stroke.[16-20] Further, most patients will have significant arm fatigue with exercise.

Treatment Selection

The appropriate treatment is dictated by the degree of arterial damage and the status of the distal circulation. Some definitions are important to consider here, as they differ from other anatomic sites. Aneurysm of the subclavian artery associated with TOS is defined as an increase in diameter of more than two times the diameter of the adjacent artery.[38,40] Poststenotic dilation associated with TOS is then defined as an increase in diameter of less than twice that of the adjacent artery.

Scher Classification

The Scher classification system for arterial TOS provides a guide to appropriate treatment and is summarized in Table 122.2.[40] Stage I describes compression of the subclavian artery with minor poststenotic dilatation and no intimal disruption.

TABLE 122.2 Scher Staging Classification of Arterial Thoracic Outlet Syndrome Complications

Stage	Arterial Complication	Treatment
Stage 0	Asymptomatic subclavian artery compression	No treatment indicated
Stage I	Stenosis of subclavian artery with minor poststenotic dilatation; no intimal disruption	Decompression of the thoracic outlet
Stage II	Subclavian artery aneurysm with intimal damage and mural thrombus	Decompression of the thoracic outlet Subclavian artery reconstruction
Stage III	Distal embolization from subclavian artery disease	Thrombolysis or thromboembolectomy Decompression of the thoracic outlet Vascular reconstruction

Modified from Matsumura JS, Rilling WS, Pearce WH, et al. Helical computed tomography of the normal thoracic outlet. *J Vasc Surg.* 1997; 26:776-783.

Appropriate treatment consists of decompression of the thoracic outlet including cervical or first rib resection, division of the anterior scalene muscle, and resection of any anomalous fibrous bands. Regression of poststenotic dilation after TOS decompression has been reported.[6,38,40] Scher stage II includes subclavian arteries with intimal damage, aneurysmal change, and mural thrombus. Appropriate treatment includes decompression of the thoracic outlet and subclavian artery reconstruction. Scher stage III includes those patients presenting with distal embolization. Treatment should include a combination of thrombolysis or thromboembolectomy, thoracic outlet decompression, and vascular reconstruction.

Surgical Treatment

Surgical treatment is indicated for all symptomatic patients with ischemia and for asymptomatic patients with aneurysmal degeneration or intimal damage. Asymptomatic individuals with compression of the subclavian artery at the thoracic outlet do not require surgical intervention, but they should be monitored because their natural history is unknown. There are no specific contraindications to repair of arterial TOS; however, a few patients may be unfit for open surgery because of severe uncorrectable comorbidities.

Relevant Anatomy

The most common offending osseous abnormality in arterial TOS is a cervical rib, accounting for about three fifths of cases (see Table 122.1). Multiple other abnormalities may be encountered, including abnormal first ribs, fracture calluses, fibromuscular bands, and soft tissue defects.[5-7] Fig. 122.5 demonstrates several of these abnormalities.

Operative Planning and Strategy

The first principle of treatment is decompression of the thoracic outlet. This may involve resection of a cervical rib, resection of fibrous bands, or anterior scalenectomy, but most experts agree that the first rib should usually be resected in addition to other associated disease.[13,14,36] The first rib is a fixed structure that maintains tension in the thoracic outlet, and once it is released, the neurovascular bundle is allowed to relax and fall inferiorly. More important, it represents a common insertion for fibromuscular structures that cause vascular compression but are not recognized at the time of operation.

There are two main approaches to thoracic outlet decompression: supraclavicular and transaxillary. Each has some advantage (see Chapter 124). Proponents of the transaxillary approach describe a more complete visualization of the first rib for resection. However, this approach is generally not suitable for vascular reconstruction and is therefore more commonly used to treat neurogenic TOS.[41] The supraclavicular approach facilitates removal of cervical ribs. This exposure allows identification of the cause of compression, visualization of brachial plexus trunks and scalene muscles, resection of the first rib, and subsequent vascular reconstruction. For this reason, we favor a supraclavicular exposure whenever an arterial reconstruction is necessary. A

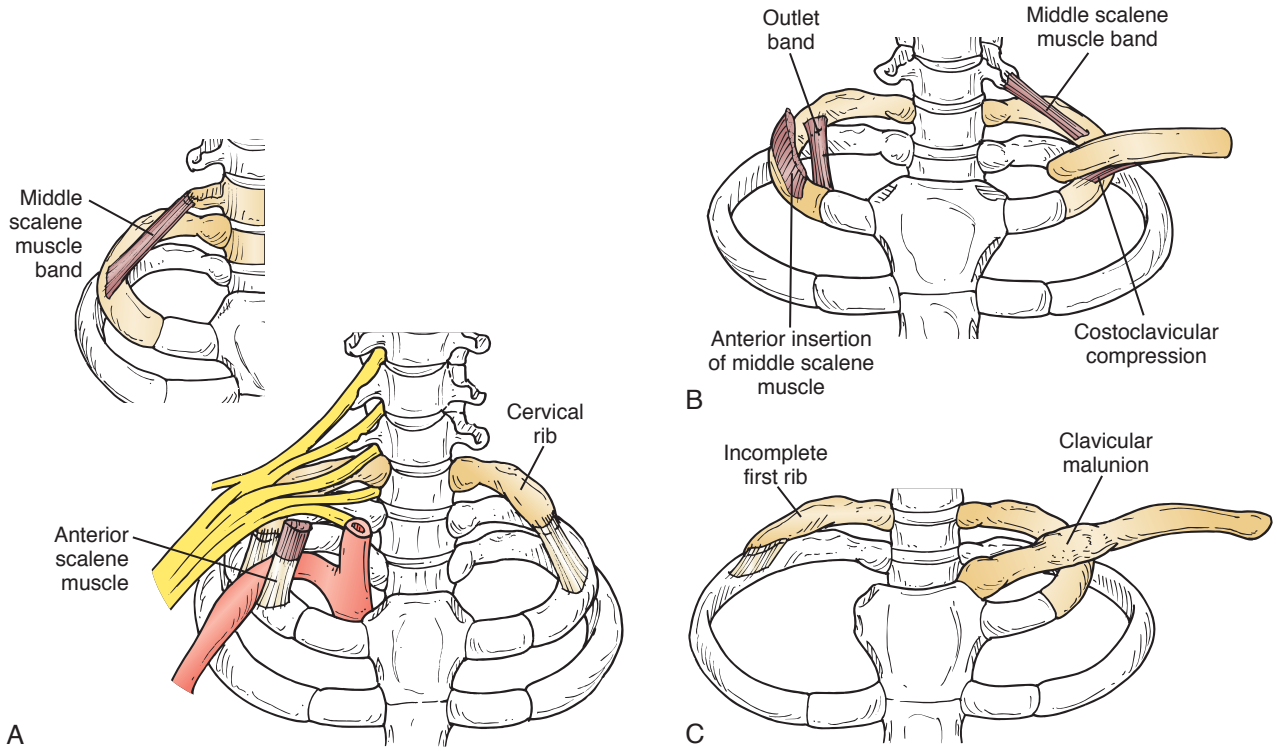

Figure 122.5 Pathologic Conditions Commonly Associated With Arterial Thoracic Outlet Syndrome. (A) Cervical ribs with associated fibrous bands and middle scalene muscle band. (B) Fascial bands and anomalous muscle insertions. (C) Incomplete first rib and clavicular fracture callus. (From Wind GG, Valentine RJ. *Anatomic Exposures in Vascular Surgery.* 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2013.)

large subclavian aneurysm or intimal damage that extends beneath the clavicle may require infraclavicular exposure in addition to the supraclavicular incision. This allows complete exposure of the subclavian and axillary arteries for vascular reconstruction. A single incision that affords both supraclavicular and infraclavicular exposure has been described.[42] Rarely, the subclavian artery has a focal abnormality that can be repaired with simple resection and primary anastomosis. More commonly, a conduit is required for replacement of the subclavian artery. Although some consider the great saphenous vein to be the conduit of choice, reconstruction can be accomplished with femoral vein, ringed polytetrafluoroethylene, or Dacron. Ringed polytetrafluoroethylene or femoral vein may offer some advantage in longer bypasses because these grafts resist kinking as they traverse under the clavicle. The femoral vein conduit also appears to offer superior patency.[43]

Description of Technique

The details of the supraclavicular exposure are presented in Chapter 124 and elsewhere.[44,45] However, a few technical points are worth additional emphasis. After the scalene fat pad is elevated, the phrenic nerve is mobilized off the surface of the anterior scalene before the muscle is divided (Fig. 122.6A). The subclavian artery is situated immediately behind the anterior

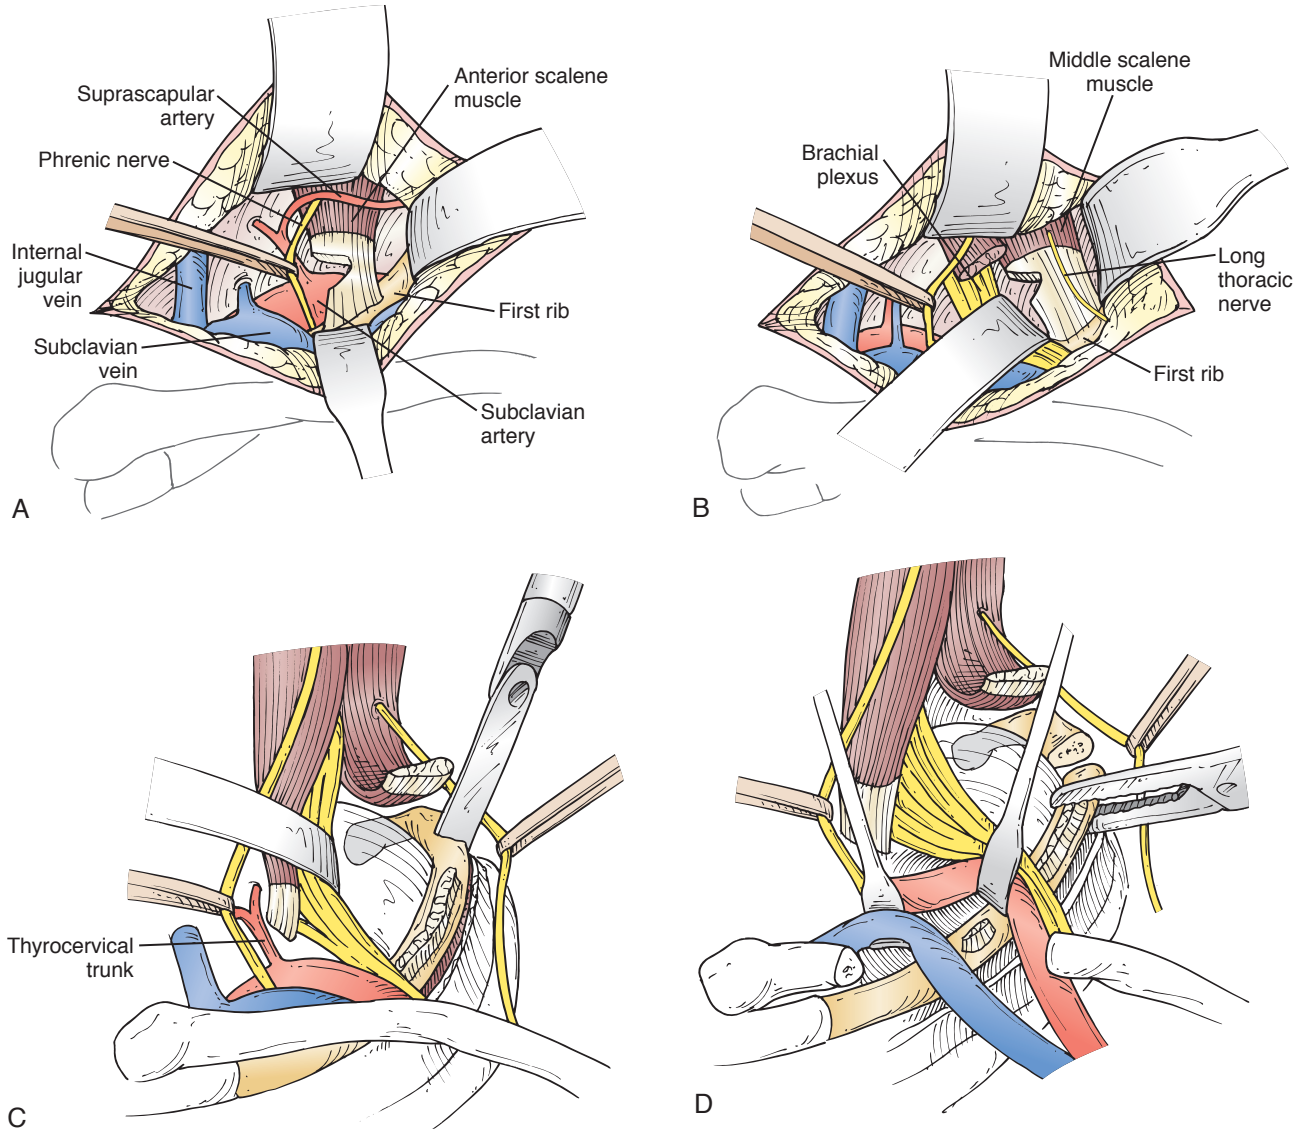

Figure 122.6 (A) Operative view of the supraclavicular approach to thoracic outlet decompression. After mobilization of the scalene fat pad, the phrenic nerve should be identified and carefully elevated before the anterior scalene muscle is divided. (B) The long thoracic nerve should be identified and protected during division of the middle scalene muscle. (C) Attachments are freed by an extraperiosteal approach to prevent recurrent symptoms from reossification of the periosteal bed. (D) Division of the first rib should be performed under direct vision to minimize the possibility of damage to the brachial plexus. After the first rib is divided just distal to the tubercle, the divided rib can be held as a lever to aid in clearing the overlying vessels. (From Wind GG, Valentine RJ. *Anatomic Exposures in Vascular Surgery.* 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2013.)

scalene muscle. The middle scalene muscle is then divided off the first rib, with care taken to avoid the long thoracic nerve that is located on the posterior aspect of the middle scalene (see Fig. 122.6B). Intercostal muscles are freed from medial and lateral edges of the first rib with a periosteal elevator, and the first rib is divided just distal to the tubercle (see Fig. 122.6C). The divided rib can then be used as a lever to assist with mobilization before it is divided anteriorly (see Fig. 122.6D).

Endovascular Options

Although the open surgical reconstruction is the standard approach to arterial complications of TOS, there have been scattered reports of endovascular repair of minor subclavian artery stenosis combined with surgical decompression of the thoracic outlet.[46,47] The importance of adjunctive decompression cannot be overemphasized because failure to decompress the thoracic outlet can lead to stent fracture or collapse, restenosis, and thrombosis.[48] However, at least one report has raised concern for stent fracture after decompression, casting doubt on the long-term outcome of endovascular therapy in these patients.[49] Longer term outcomes data are needed to determine the validity of this approach.

Distal Revascularization

Patients with Scher stage III present with upper extremity ischemia due to distal embolization. Any degree of motor deficit or a significant sensory deficit should be considered an indication for immediate operation including embolectomy. Brachial artery embolectomy does not always require a separate distal arm incision, as large emboli can be extracted through the subclavian artery in some cases. Although embolectomy is usually sufficient, distal bypasses are sometimes necessary in patients with chronic embolization. Patients who present with milder ischemia may be appropriate for thrombolysis before surgical repair.[50] This may be particularly important in patients who have complete thrombosis of the forearm and hand vessels on arteriography. Sympathectomy does not have a significant role in management of these patients.

Postoperative Management

In addition to supportive care, patients may benefit from physical therapy and range of motion exercises to shorten convalescence. Arterial repairs should be monitored with serial physical examinations and noninvasive studies such as duplex ultrasound. Examination intervals vary from institution to institution, but the Oregon group has recommended examinations at 3 months postoperatively and every 6 months thereafter.[15]

Definition of Success and Determinants of Outcome

Successful outcome after treatment of arterial TOS is determined by relief of symptoms, avoidance of recurrence, patency of arterial bypasses, and limb salvage. Published series report complete relief of symptoms in more than 90% of patients.[6,13,15] Gelabert and Machleder[51] have identified the following reasons for failed procedures: inaccurate diagnosis, failure to identify and correct the proximal embolizing lesion, and inadequate decompression. Unlike neurogenic TOS, recurrence of arterial TOS is very rare in patients who have undergone complete TOS decompression and adequate arterial reconstruction. Bypass patency is reported in the range of 90% to 100%, depending on the status of the outflow vessels.[6,13,50] Limb salvage should approach 100% in Scher stage I and stage II lesions; distal embolization may result in finger amputation in patients with Scher stage III lesions, but arm amputation is distinctly uncommon.[8,22,51]

Results

Long-term results are related to the status of the distal vasculature. For Scher stage I lesions, decompression of the thoracic outlet alone is sufficient, with excellent results and the expectation that poststenotic dilation will regress within a year.[6] Limbs with compromised outflow secondary to embolization have a poorer prognosis. One of the largest series examined 55 cases of arterial TOS.[13] The early results showed no mortalities and low rate of morbidity (7%). The long-term results (mean follow-up of 5 years, 8 months) of thoracic outlet decompression and vascular reconstruction were excellent, with 91% remaining asymptomatic and 9% experiencing exertional symptoms only. Of the four cases that were symptomatic at late follow-up, three originally presented with distal ischemia and required thromboembolectomy for brachial artery occlusions. There were no amputations in this series. In their series of 24 patients with arterial TOS, Orlando and colleagues[10] reported 100% positive results after 1 year of follow-up.

Complications

Operative mortality is negligible in these typically young patients. Morbidity is related to the closely related anatomic structures in the thoracic outlet and includes pneumothorax, hemothorax, chylous leak, brachial plexopathy, and vascular injury. Injury to the phrenic or long thoracic nerves is also possible. Rarely, injury of the cervical sympathetic chain may result in Horner syndrome. The overall morbidity rate in published series ranges from 7% to 40%,[6,15,52] with pleural entry and transient brachial plexus injury being most frequent.

Venous thoracic outlet syndrome (vTOS) is thrombosis or severe stenosis of the subclavian-axillary vein secondary to chronic extrinsic mechanical compression. The eponym Paget–von Schroetter syndrome was coined by Hughes in 1949 after a comprehensive review of the world's literature related to thrombosis of the subclavian and axillary veins.[1] Paget described the original disease process in 1875 as a syndrome of acute arm swelling and pain. He hypothesized the disease was due to vasospasm.[2] In 1884, however, von Schroetter described the symptoms of acute upper extremity pain and swelling as a result of subclavian and axillary vein thrombosis.[3] A final name for vTOS is *effort thrombosis*, which describes the association with young healthy individuals who engage in activities requiring repetitive arm and shoulder motion.[4-7]

EPIDEMIOLOGY AND ETIOLOGY

Primary Subclavian-Axillary Vein Thrombosis

Upper extremity deep venous thrombosis (DVT) represents approximately 9% of reported episodes of DVT.[8] Subclavian-axillary vein thrombosis in vTOS is a direct result of repetitive injury to the subclavian vein at the level of the costoclavicular space, the most anterior and medial aspect of the thoracic outlet (Fig. 123.1). The key anatomic structures resulting in compression of the subclavian vein are the first rib, the clavicle with its associated subclavius muscle and fibrous costocoracoid ligament, and the anterior scalene muscle/tubercle.[1,6] A cycle of alternating posttraumatic inflammation and quiescence leads to perivenous fibrosis, endothelial injury, stasis of blood flow, and thrombosis.[9]

Although vTOS has been reported to occur in the absence of any identifiable anatomic abnormality,[9,10] a diverse array of anomalies associated with the thoracic outlet has been reported at the time of surgery. These include abnormalities of the anterior scalene muscle and subclavius tendon, the presence of a scalenus minimus muscles, bone abnormalities of the clavicle and ribs, and ligamentous abnormalities of the costocoracoid ligament.[6,9-13] Frequently compression of the subclavian vein occurs at the costoclavicular space without the development of thrombosis. This point is underscored by venographic studies evaluating the contralateral subclavian vein in patients with confirmed subclavian-axillary vein thrombosis. Although narrowing of the contralateral vein with provocative measures is visualized in 56% to 80% of contralateral limbs, the incidence of bilateral thrombosis is markedly less, at 2% to 15%.[5,14-16]

McCleery Syndrome

Described in 1951 by McCleery and colleagues, this syndrome represents intermittent obstruction of the subclavian vein without thrombosis.[17] The pathology results from compression of the vein between the subclavius tendon and the anterior scalene muscle that is worsened with arm abduction (Fig. 123.2). This syndrome manifests with blue discoloration of the arm, superficial vein distention, and swelling. Despite the lack of venous thrombosis, these patients are usually limited in use of the affected extremity and should be treated with surgical decompression.

Abstract

Venous thoracic outlet syndrome is the thrombosis or severe stenosis of the subclavian-axillary vein. It may be caused primarily by chronic repetitive motion or secondary to trauma, indwelling catheters, pacemaker wires, or tumors. Treatment of vTOS is based on understanding the etiology and the functional goals of the patient. Controversies exist as to whether patients need to undergo surgical decompression, if pre-operative thrombolysis provides benefit, and how to manage venous stenosis after decompression. Here we present the most up to date data on management of patients with primary and secondary vTOS.

Secondary Subclavian-Axillary Vein Thrombosis

Although vTOS typically refers to primary subclavian-axillary vein thrombosis, the differential diagnosis should include secondary upper extremity DVT (see Chapter 149). Issues associated with secondary upper extremity DVT include nephrotic syndrome, mediastinal tumors, malignancy, local surgery or trauma, hypercoagulable states, renal failure requiring dialysis, long term use of peripherally inserted central catheters, and cardiac conditions requiring pacemaker placement. The two most common causes of mechanical secondary upper extremity DVT are the placement of central venous catheters and pacemaker wires.

Catheter-related venous thrombosis is suggested to occur in 5% or less of all inserted central venous catheters.[4,18] Risk factors associated with a higher rate of catheter-related thrombosis in adult patients are either catheter-related (malposition of the catheter, insertion of the catheter on the left, multiple catheter lumens), treatment-related (use of long-term antibiotics or total parenteral nutrition, bolus vs. dilute chemotherapy infusions), or patient-related (malignancy or hypercoagulable states).[19-22] Patients with catheter-related venous thrombosis can be

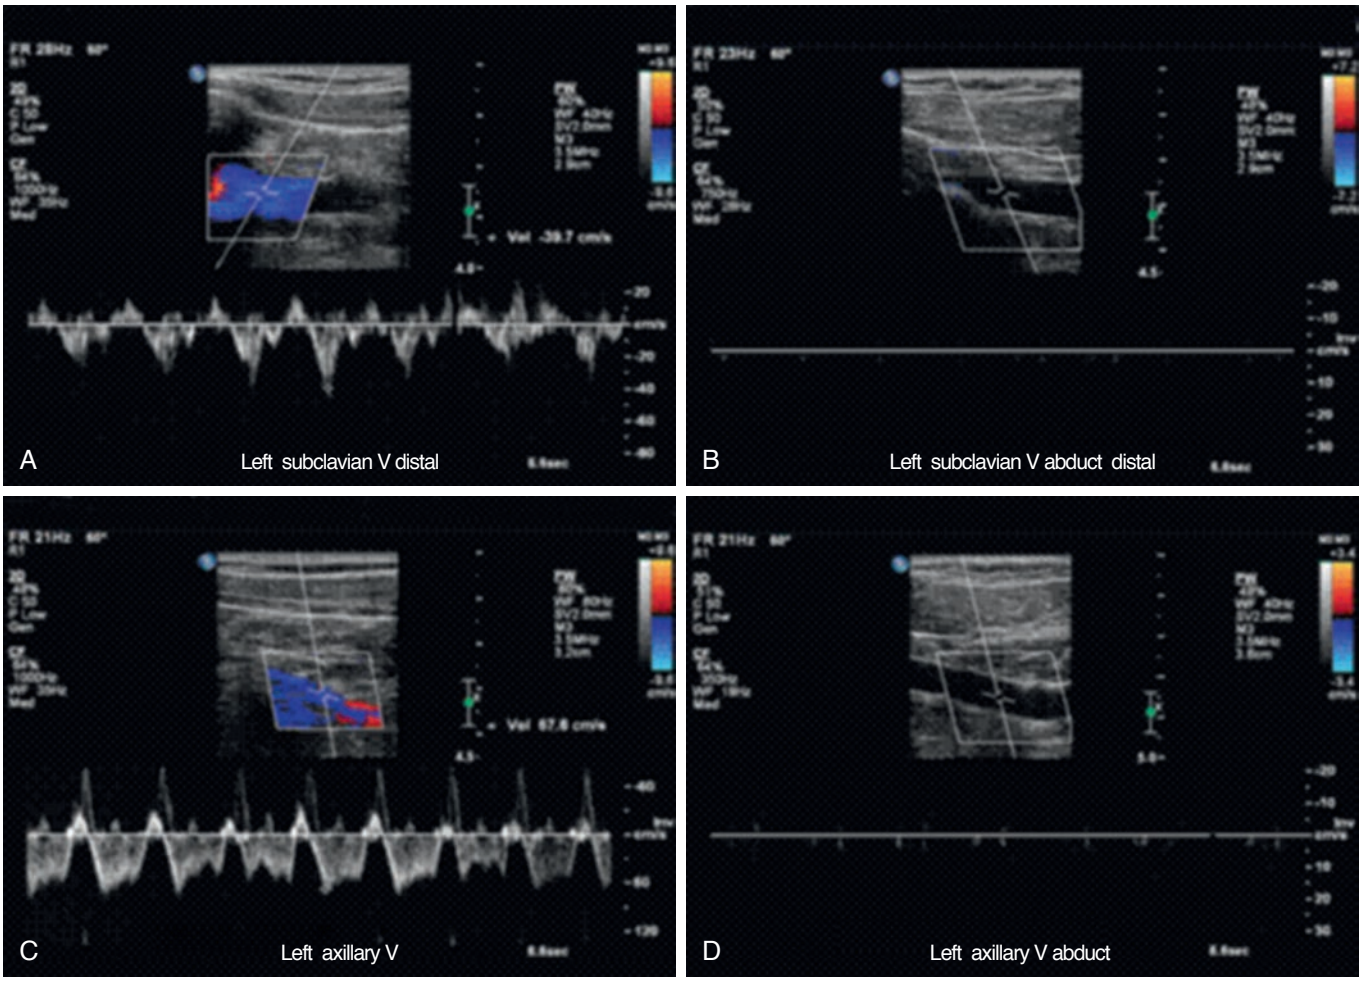

Figure 123.2 **Venous Compression of the Left Subclavian and Axillary Vein.** With the arm in the neutral position the subclavian **(A)** and axillary **(C)** veins demonstrate normal phasic flow. With elevation of the arm to 180 degrees, there is cessation of flow in the subclavian **(B)** and axillary **(D)** veins.

asymptomatic, but significant symptoms such as pulmonary embolism can be as high as 15% and 25%.[23] It is important to remember that the rate of thrombosis is not necessarily due to the duration of catheter placement.[24]

In addition to catheters, pacemaker wires are an increasing cause of secondary subclavian-axillary vein thrombosis. The number of leads, previous use of a temporary pacemaker, and left ventricular ejection fraction ≤40% are predictive of venous stenosis.[25,26] Infection of the pacemaker insertion site has also been shown to increase the risk of venous stenosis and occlusion.[27] The use of anticoagulation is protective against the development of occlusion of the subclavian vein, but has not been shown to prevent venous stenosis.[28]

Just as in the case of primary upper extremity vTOS, the pathophysiology of secondary upper extremity subclavian-axillary thrombosis is vein wall damage. In some cases, catheter removal causes the fibrin sheath to break loose and subsequently embolize into the pulmonary circulation.[29]

CLINICAL PRESENTATION

The mean age at diagnosis for vTOS is 32 years, with the majority of patients affected between the second and fourth decades.[15] Despite early reports showing a female predominance, more recent literature including the largest series published to date (312 affected extremities) have reported an equal gender ratio.[15,30] Individuals who perform strenuous or sustained upper extremity activities, whether athletic or occupational, are particularly prone to the development of subclavian-axillary vein thrombosis. The dominant arm is involved in the majority of cases.[16]

Upper extremity edema is the hallmark characteristic associated with subclavian-axillary vein thrombosis. The edema is often but not always accompanied by pain and cyanosis of the affected extremity. The edema usually involves the shoulder, arm, and hand, and is characteristically nonpitting. Dilated superficial veins over the shoulder, neck, and anterior chest wall can often be visualized as collateral veins try to accommodate the increased venous pressure (a pattern often referred to as *first rib bypass venous collaterals*).[31] A minority of patients may demonstrate symptoms resembling neurogenic TOS, such as numbness and tingling in the distribution of the inferior trunk of the brachial plexus (see Chapter 121). This association is likely due to the presence of muscular anomalies of the thoracic outlet anatomy and the performance of repetitive upper extremity arm activities.

Patients may report some degree of pain. The description can include aching, stabbing, or a feeling of tightness that worsens with exertion.[6] Extended use of the arm leads to increased arterial blood flow, for which the limited collateral venous bed is unable to compensate. The subsequent venous hypertension worsens symptoms of venous stasis and arm congestion. Urschel and Razzuk reported that out of the 312 patients with extremities with vTOS in their 30-year experience, 93% complained of arm swelling, 77% demonstrated bluish discoloration, 66% had aching pain with exercise, and 8% were asymptomatic.[15] Similarly, Van Rooden et al. reported that 52% of patients were symptomatic, 39% were completely disabled, and 9%, were asymptomatic.[28]

The two most potentially severe complications of subclavian-axillary vein thrombosis are pulmonary embolism and upper extremity phlegmasia cerulea dolens (venous gangrene). The reported incidence of pulmonary embolism due to subclavian-axillary vein thrombosis is less than 10%.[1,4,6,32,33] Compared with iliofemoral DVT, the small clot burden of upper extremity DVT may reduce the clinical impact of pulmonary embolism. Venous gangrene is exceedingly rare and has been limited to case reports in patients with malignant disease or an underlying hypercoagulable state.[34] No reports of venous gangrene occurring secondary to vTOS have been published.

DIAGNOSTIC EVALUATION

Duplex Ultrasound

Duplex ultrasonography is the most frequently used diagnostic modality for the evaluation of patients thought to have DVT of the upper limb. The study is noninvasive, does not require the use of a nephrotoxic contrast agent, and does not involve ionizing radiation. In addition, it can be performed at the bedside or in the emergency department. The use of diagnostic ultrasound in the upper extremity is different from that in the lower extremity. Overlying structures, such as the clavicle, make duplex interrogation of the vascular structures coursing through the thoracic outlet challenging. In the upper extremity, compressibility of the targeted vein is not possible beneath the clavicle, nor is it possible to compress the brachiocephalic vein or SVC. Therefore duplex examinations relying on B-mode ultrasound alone have historically demonstrated low sensitivity (54%) and high specificity (100%) for the detection of subclavian-axillary vein thrombosis.[35] The standard use of color-flow duplex imaging in conjunction with indirect criteria suggesting the presence of an occlusion (evaluation for phasicity of flow with respiration and augmentation with compressive maneuvers) have led to markedly increased sensitivity (81% to 100%) while maintaining high specificity (82% to 100%).[36,37,38]

Magnetic Resonance and Computed Tomographic Venography

Magnetic resonance venography (MRV) and computed tomographic venography (CTV) are additional noninvasive imaging modalities that have been used with increasing frequency for the diagnosis of vTOS.[39,40] The sensitivity and specificity of both modalities are comparable to those of duplex ultrasound.[23] CTV has the added advantage of being able to detect central vein thrombosis and the presence of pulmonary emboli, with appropriate arterial timed contrast. However, MRV and CTV are rarely necessary for patients with suspected vTOS. The cost and time required for completion of the examination are substantial. MRI is routinely used in patients with neurogenic TOS, as dynamic MRI has the ability to identify the location and etiology of brachial plexus compression, as well as associated vascular compression.[41]

Venography

Digital subtraction venography is considered the gold standard (Fig. 123.3). However, it is generally reserved for patients whose condition warrants an intervention. Venography is invasive and uses a nephrotoxic agent, in addition to requiring exposure of the patient to ionizing radiation. Up to 20% of patients do not qualify for venography because of a severe allergy to the contrast agent or the inability to cannulate the veins in the edematous extremity. The primary role of venography is in the patient whose duplex ultrasound findings are equivocal. In such patients, an additional objective study should be performed to confirm or to reject the diagnosis of upper extremity DVT.

When performed, venography should be done at rest and with positioning of the arm at 90 and 180 degrees (Fig. 123.4). These positional images are essential to confirm the presence of extrinsic compression of the subclavian vein at the level of the thoracic outlet. Evaluation of the collateral circulation is another important function of venography. The extent of collateralization provides information about the hemodynamic significance of the occlusion or stenosis and about the chronicity of the occlusion. Chronicity of the occlusion in turn plays a key role in dictating management. Patients may be classified into one of three categories on the basis of their history and venographic findings: (1) acute subclavian-axillary vein thrombosis, (2) chronic or recurrent subclavian-axillary vein thrombosis, or (3) high-grade symptomatic subclavian-axillary vein stenosis.

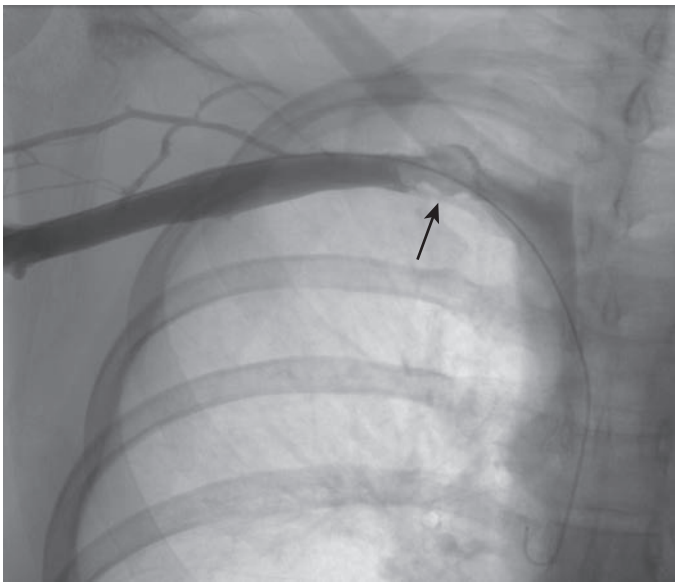

Figure 123.3 Venogram indicating an acute primary subclavian-axillary vein thrombosis *(arrow)*.

TREATMENT

Debate continues over the optimal treatment of vTOS. The disease has not been studied in a prospective fashion, and given the lack of consensus that experts in the field have over anticoagulation, thrombolysis, and surgical decompression, a prospective study is unlikely. Recently a collaborative national registry has been developed at the University of California-Davis. The registry has invited leaders in the field to add patients with both operative and nonoperative therapy in order to determine long-term outcomes for all patients with TOS.

Figure 123.4 Venogram of the subclavian-axillary vein after successful thrombolysis with the extremity in full adduction (A) and in full abduction (B).

Anticoagulation Alone

Historically, treatment of acute primary subclavian-axillary vein thrombosis consisted of rest, elevation of the affected extremity, and a variable duration of systemic anticoagulation. Retrospective reviews on this approach have demonstrated variable outcomes, but the initial report by Hughes on the conservative management of 320 patients with primary subclavian-axillary vein thrombosis found that 40% of patients had persistent symptoms or limited recovery.[1] More recent studies report the use of the objective Disability of the Arm, Shoulder, and Hand (DASH) questionnaire to assess quality of life after upper extremity venous thrombosis. In a retrospective review of patients treated with surgical decompression versus anticoagulation alone, patients that underwent surgical decompression had significantly improved quality of life and functionality DASH scores.[42] Specific factors contribute to failure and should be considered when devising a patient-centered treatment plan. Young age, active lifestyle, and participation in sports at a competitive level are all associated with the long-term failure of anticoagulation.[43-45]

The goals of treatment in secondary upper extremity DVT are to prevent pulmonary embolism and to achieve recanalization of the vein. Most patients with secondary upper limb DVT improve after removal of the venous catheter and institution of anticoagulation therapy. If a catheter causes extensive axillary vein thrombosis resulting in marked edema, thrombolytic therapy may be considered. If the catheter is nonfunctioning or no longer needed, it should be removed and the patient should be treated with 3 months of anticoagulation.[46] Patients with a functional catheter needed for ongoing treatment should be systemically anticoagulated. Anticoagulation should continue for the entire time the catheter is left in place.

Patients with secondary upper limb DVT who may have contraindications to systemic anticoagulation, such as concurrent gastrointestinal bleeding, recent neurosurgery, or the presence of pulmonary embolism despite anticoagulation, may be candidates for SVC filter placement. SVC filters are not used widely, but in small limited studies they have been shown to be effective in preventing recurrent pulmonary embolism. The long-term patency rates of the small number of SVC filters that have been placed are reportedly high.[47] Nonetheless, concerns persist about the risk of SVC filter migration or thrombosis resulting in SVC syndrome. Because fatal pulmonary embolism from upper extremity DVT has been documented to be very rare and evidence of the safety of filters is limited, clinical judgment must be used in recommending their deployment.[48]

Thrombolytic Therapy

Catheter-directed thrombolysis has emerged as an initial management strategy in the modern treatment paradigm of vTOS. The goal of catheter-directed therapy is to remove thrombus, restore the patency of the vein, and alleviate symptoms. Because subclavian-axillary thrombus is much more localized than lower extremity DVT, this approach usually lyses the subclavian-axillary vein thrombus quickly to restore luminal patency. In 1981, Zimmermann and associates documented, in a small case series, the successful use of systemic urokinase in 82% of patients with acute primary subclavian-axillary thrombosis.[49] Since this initial series, many authors have demonstrated high rates of success in reestablishing patency with catheter-directed thrombolysis (Fig. 123.5). Lee and colleagues reported their experience treating 64 patients with primary subclavian-axillary thrombosis. As the first step in their treatment algorithm, 54 patients with symptom onset within 7 days underwent attempted catheter-directed thrombolysis; 100% experienced successful restoration of luminal patency.[44] When thrombolysis is initiated within 14 days of the onset of symptoms, the results are generally

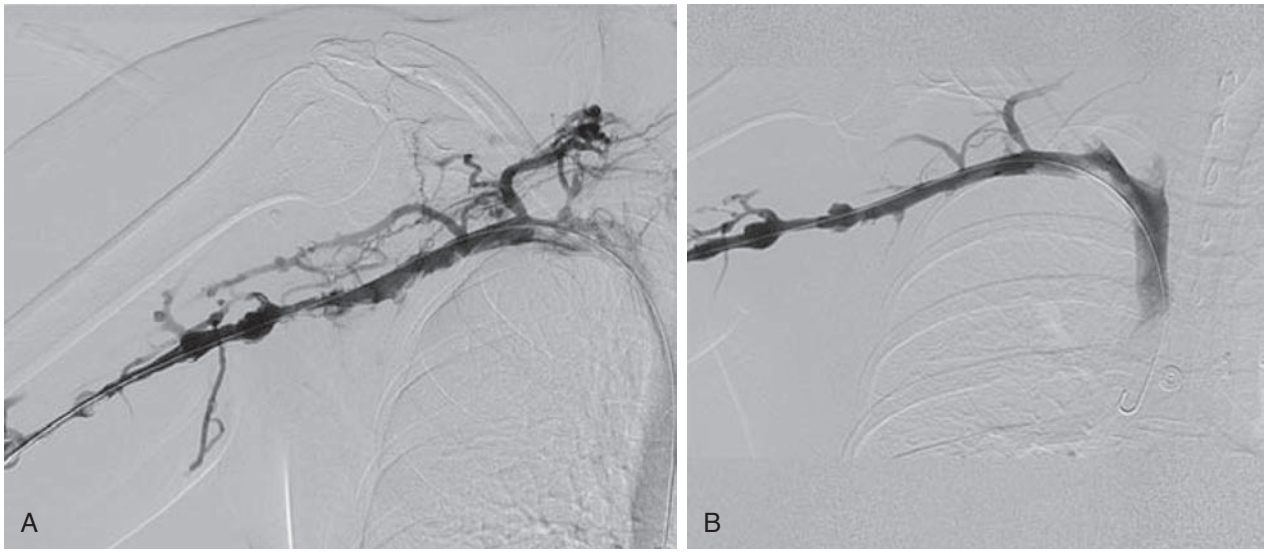

Figure 123.5 Venogram of the subclavian-axillary vein before (A) and after (B) thrombolysis.

reported to be excellent.[5] Treatment with thrombolysis in patients with more than 14 days of symptoms is possible, albeit with a decreased chance for successful reestablishment of luminal patency.[50,51] Technical aspects of thrombolysis performed prior to surgical decompression that are associated with poor long-term results include overly aggressive balloon venoplasty to achieve an optimal angiographic result and the use of venous stents.[44,52]

Despite the excellent results with thrombolysis, whether or not preoperative thrombolysis affords any benefit to long-term venous patency is questionable. In a retrospective review of a decade treating 34 patients with vTOS, primary subclavian-axillary vein patency at 5 years was 84% in patients who underwent thrombolysis followed by surgical decompression and 83% in patients who underwent surgical decompression without thrombolysis.[53] A second study by Guzzo et al. retrospectively reviewed 110 patients with vTOS. At 1 year they too found the primary patency was identical in patients treated by thrombolysis followed by decompression and those treated with anticoagulation followed by surgical decompression (91% vs. 91%, P = .99).[52] Given the risks of bleeding, procedural expense, and use of limited resources, the cost effectiveness of thrombolysis deserves future study.

Post-Thrombolysis Management

Patients with unsuccessful thrombolysis, defined as persistent total occlusion of the subclavian-axillary vein, should receive anticoagulation and measures aimed at control of local symptoms, such as rest, compression, and elevation. Unsuccessful thrombolysis of acute subclavian- axillary vein thrombosis is rare, and almost always seen in patients who have had repeated episodes of lysis with overly aggressive venoplasty or long-standing symptoms treated only with anticoagulation.

Whether or not these patients benefit from surgical decompression has only been reviewed in small series. In a group of 42 patients, Urschel and Razzuk reported a 57% rate of recanalization and resolution of symptoms with surgical decompression and extended length anticoagulation.[15] In a second series of 16 patients with chronic venous occlusion due to vTOS reported by Chang et al., first rib resection followed by anticoagulation resulted in 88% recanalization at 6 months. The mean duration of anticoagulation in this study was 3 months.[54] Given the potential for recanalization, high volume centers do offer first rib resection to select patients with chronic occlusion.

Patients in whom thrombolysis was successful, defined as those with reestablishment of subclavian-axillary vein patency, can be further classified on the basis of completion positional venography, according to the absence or presence of demonstrable extrinsic compression at the thoracic outlet. Patients without extrinsic compression will not benefit from thoracic outlet decompression and should be treated with 3 to 6 months of systemic anticoagulation.[46]

In patients found to have extrinsic compression, no effort should be made at the completion of successful thrombolysis to dilate a persistent subclavian vein stenosis. The resultant intimal injury of angioplasty without addressing the extrinsic compression results in inflammation and decreases the likelihood of reestablishing long-term patency of the vein.[55] Also, in no case should a patient that has not undergone surgical decompression have a stent placed in the subclavian vein. Multiple studies have documented the dismal results of subclavian vein stents.[56-58] Immediate thoracic outlet decompression and subsequent subclavian-axillary vein venography/angioplasty should be performed early to decrease the risk of rethrombosis (discussed later).

Surgical Decompression of the Thoracic Outlet

Technical details of surgical decompression are reviewed in Chapter 124. The decision to perform surgical decompression should be considered in all patients with persistent stenosis or signs of extrinsic compression on positional venography after thrombolysis. These patients remain at significant risk of recurrent thrombosis with anticoagulation alone.[50] When the underlying pathophysiologic process is not appropriately addressed, adjunctive therapies such as balloon angioplasty or stent placement may provide satisfactory immediate results but lack sufficient durability to be accepted as definitive therapy.[44,51,56-58] Multiple reports have confirmed that the radial force associated with either a self-expanding or balloon-expandable stent is not adequate to compensate for the compressive force between the first rib and clavicle; stent deformation, fracture, and thrombosis in this setting are the norm rather than the exception (Fig. 123.6). Therefore stents have no role in the treatment of vTOS before surgical decompression.

To alleviate extrinsic compression, first rib resection with external venolysis should be performed. Early studies advocate deferring surgical decompression for 1 to 3 months after thrombolysis to allow healing of the venous endothelium and

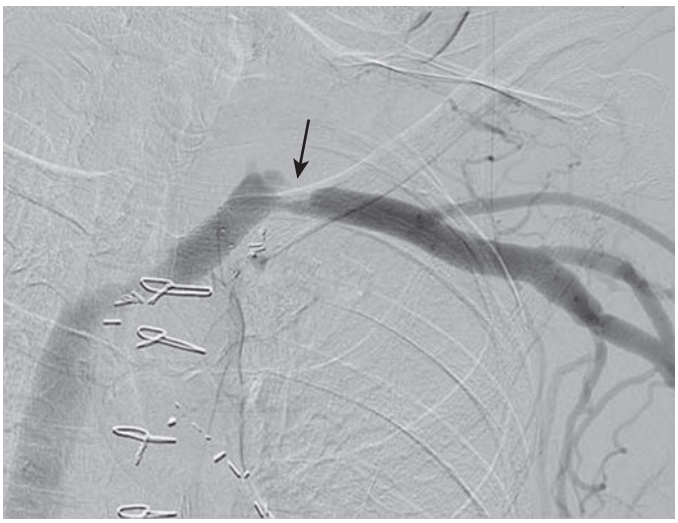

Figure 123.6 Deformed balloon-expandable stent *(arrow)* 6 weeks after treatment of primary subclavian-axillary thrombosis.

resolution of the acute inflammatory process.[59,60] However, early decompression, even during the same hospitalization as the thrombolysis, has been shown to significantly decrease the risk of reocclusion that may occur between thrombolysis and deferred surgery.[5,15,50,51,55,61,62] The shift to immediate surgery has virtually eliminated the vein rethrombosis rate of 6% to 18% that has been reported to occur during the waiting period.[5,60]

Vein Treatment After First Rib Resection

The optimal management of the subclavian-axillary vein after surgical decompression of the thoracic outlet remains open for debate. The presence of residual subclavian-axillary vein stenosis, even after relief of the extrinsic compression, is not uncommon (Fig. 123.7). Recommended strategies to deal with these intrinsic lesions have spanned a diverse spectrum, ranging from completion venography and angioplasty with or without stenting to extensive venous reconstructions including thrombectomy, patching, or bypass. No direct comparisons between these strategies have been performed to date, but it is clear that extensive venous reconstructions are accompanied by a higher complication rate. This issue is underscored by the experience of Melby and colleagues, in which 44% of their 32 patients underwent direct subclavian-axillary vein reconstruction and 100% experienced resolution of their symptoms (no patency data reported).[51] However, 22% of their patients required secondary operations for complications. Furthermore, if closure of adjunctive radiocephalic fistulae is also included as a secondary procedure, the overall rate of secondary procedures increases to 53%. In this experience, no intraoperative venography was used to assess the status of the subclavian-axillary vein after decompression of the thoracic outlet. Consequentially, no attempts at intraoperative angioplasty of residual lesions were undertaken.

Most groups favor an endovascular approach after thoracic outlet decompression. Endovascular treatment can occur during the surgical rib resection case, or within 2 weeks of the initial surgery. Advocates of the intraoperative strategy believe this approach can direct the surgeon to the most appropriate treatment of a residual stenosis before the patient leaves the operating room. In a study of the intraoperative strategy, 25 patients routinely underwent completion venography, with angioplasty as necessary, at the time of thoracic outlet decompression. Their overall results demonstrated 100% technical success, 100% resolution of symptoms, and 1-year primary and secondary patency rates of 92% and 96%, respectively.[50] Proponents of the delayed approach consider the possible complications with venoplasty and the need for immediate anticoagulation as risky. Routine postoperative venography within 2 weeks after thoracic outlet decompression was studied in 84 patients. Although technical success of 100% was not achieved in this cohort, 1 year primary and secondary patency rates were 94% and 98%, respectively.[54] Until a prospective comparison of the two strategies is undertaken, at this time the best recommendation is to evaluate and address any residual venous stenosis with intravascular imaging after surgical decompression.

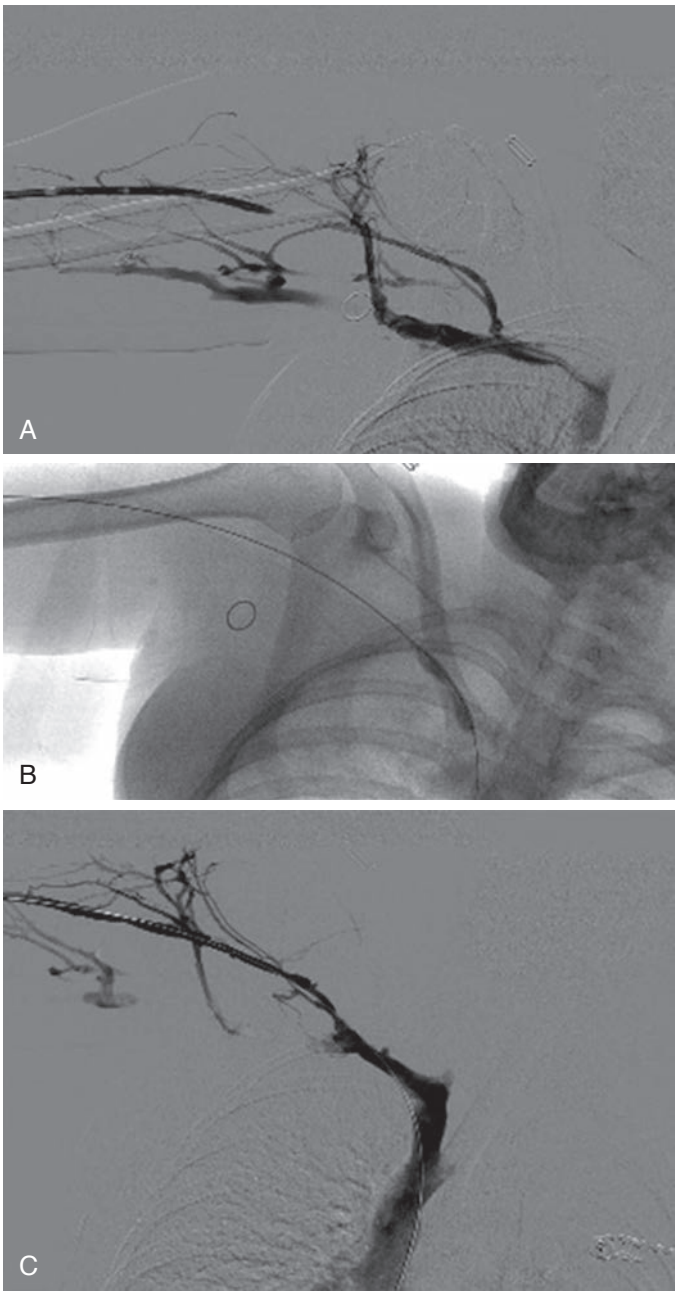

Figure 123.7 Venogram of the subclavian-axillary vein demonstrating (A) a fixed filling defect (B) treated by angioplasty after first rib resection (C) and demonstrating resolution.

Postoperative Care

Patients who undergo surgical decompression of the thoracic outlet for vTOS should start physical therapy after complete postoperative treatment of the subclavian-axillary vein. The physical therapy should be tailored for patients with TOS. This protocol should address soft tissue mobilization of the scar as well as restoration of movement of the entire shoulder girdle; improved function and flexibility to the upper cervical spine; activation and strengthening of the anterior, middle, and posterior scalene muscles (especially focused on maintaining

posture throughout the day); stretching of the trapezius, the sternocleidomastoid, the levator scapular, and the pectoralis minor muscle; and finally graduated resistance shoulder elevation exercises. The minimum duration of physical therapy should be 6 weeks. It is important to have a strong working relationship with the physical therapist and understand that patients should not be "fast tracked" through physical therapy. Severely fibrotic scarring develops in the surgical field without adequate physical therapy. This results in the tethering of the brachial plexus and can result in neurologic symptoms. Patients should not be released from physical therapy early simply because they demonstrate the ability to have full range of motion. This cannot be overly stressed in young high-level athletes. In order for them to return to full function in their sport, a slow and consistent approach to recovery is essential.

Recurrence

Recurrent thrombosis after first rib resection is most likely due to residual anterior rib left in place at the initial operation or inadequate cutting of the subclavius tendon to free up the vein. When rethrombosis is identified early, thrombolysis should be considered. The patient should be maintained on anticoagulation and undergo a workup to determine the cause. Plain radiographs can identify residual anterior rib that was left behind at the first operation. If the cause of recurrent thrombosis is scaring of the subclavian-axillary vein, an infraclavicular incision with repair of the vein can be considered. When thrombosis is thought to be due to inadequate first rib resection, either a supraclavicular or transaxillary approach may be used. Care must be taken when operating in a redo field, especially in the small space of the thoracic outlet. Injury to the vein, artery, or nerve can easily occur when the patient has large amounts of residual scar tissue.

Results

For the most part, reports on the treatment of vTOS are limited to case series, often with relatively small sample sizes. Nonetheless, in aggregate, the overwhelming evidence suggests that in properly selected patients, restoration of subclavian-axillary vein patency and decompression of the thoracic outlet result in excellent and durable outcomes. Table 123.1 summarizes the results of multiple series that have been used, albeit with varying techniques, strategies to achieve the goal of vein patency and decompression of the thoracic outlet in patients with vTOS. It should be mentioned again that although subclavian vein occlusion after abduction can be documented in a high percentage of the contralateral limbs of these patients, the risk of thrombosis has proved to be low. For this reason, prophylactic procedures should not be considered for routine patients with vTOS. In specific cases of high functioning athletes, contralateral surgical decompression should be considered in order to maintain full function and performance.

SELECTED KEY REFERENCES

Molina JE, Hunter DW, Dietz CA. Paget-Schroetter syndrome treated with thrombolytics and immediate surgery. *J Vasc Surg*. 2007;45:328–334.

This study reports one of the largest series of patients to undergo treatment of venous thoracic outlet syndrome. The outcomes were excellent, and the discussion emphasizes many key issues that are central to the management of this challenging syndrome.

Sajid MS, Ahmed N, Desai M, Baker D, Hamilton G. Upper limb deep vein thrombosis: a literature review to streamline the protocol for management. *Acta Haematol*. 2007;118:10–18.

Comprehensive review of key studies describing the etiology, diagnosis, and management of upper limb venous thrombosis.

Schneider DB, Dimuzio PJ, Martin ND, et al. Combination treatment of venous thoracic outlet syndrome: open surgical decompression and intraoperative angioplasty. *J Vasc Surg*. 2004;40:599–603.

This study describes the first significant series of patients who underwent venothrombolysis, immediate surgical decompression of the thoracic outlet and intraoperative venography, and definitive treatment of residual stenosis. The outcomes indicate that it is unnecessary to delay surgical decompression in most patients, and the study emphasizes the importance of intraoperative venography to determine the optimal strategy for treating any residual stenosis.

Pain Management 1660
Physical Therapy 1661
Follow-Up 1661
PITFALLS AND COMPLICATIONS 1661
General 1661
SPECIFIC SURGICAL COMPLICATIONS 1662

Although there is little debate over treatment of arterial thoracic outlet syndrome (aTOS), treatment for venous thoracic outlet syndrome (vTOS) and especially neurogenic thoracic outlet syndrome (nTOS) remains highly controversial. Because subjective findings are utilized in developing the diagnosis, nTOS is best treated at specialized centers where large numbers of patients are seen yearly and standard treatment protocols are in place. Not all patients with nTOS will require surgical treatment, so the surgical option should be reserved for patients who will most benefit and only after a complete trial of nonoperative treatment.

INDICATIONS

Indications for decompression of the thoracic outlet in patients with aTOS are the most clear, and the Scher criteria for treatment have been established based on the pathology of the subclavian artery (Table 124.1; see Chapter 121).[1] Because the subclavian artery cannot be adequately controlled and repaired through the transaxillary approach, Scher class 2 and 3 disease should be approached through a supraclavicular or a combination of supra- and infraclavicular incisions.

There are no absolute indications for surgical treatment of nTOS and vTOS. However, nTOS patients who have improvement with a TOS-specific physical therapy protocol but have residual symptoms or those with recurrent symptoms when physical therapy ends may obtain long-term relief with surgical decompression. In the case of vTOS, the likelihood of recurrent thrombosis must be balanced with the risks of surgical decompression. Indications for surgery can be anatomic or lifestyle-related. Patients with persistent stenosis or signs of extrinsic compression on positional venography after thrombolysis remain at significant risk of recurrent thrombosis with anticoagulation alone and should be considered for decompression.[2] In high-performance athletes, body builders, patients that perform repetitive movements during work using the affected extremity, or those with recurrent episodes of thrombosis, thoracic decompression provides the best long-term outcomes.[3]

In the past authors have advocated for deferment of surgical decompression for 1 to 3 months after thrombolysis to allow healing of the venous endothelium and resolution of the acute inflammatory process.[4,5] Now most agree that decompression should take place during the same hospitalization as the thrombolysis so as to decrease the significant risk of reocclusion that may occur between thrombolysis and deferred surgery.[2,3,6-8] Immediate operative decompression, even as early as 4 hours after thrombolysis, has been demonstrated to be safe and effective.[9] This shift to immediate surgery has decreased the venous rethrombosis rate of 18% that has been reported to occur during the waiting period.[5,6,10]

TABLE 124.1 Scher Classification of Surgical Treatment for Subclavian Artery Pathology

Stage	Arterial Pathology	Treatment
0	Asymptomatic subclavian artery compression	No surgical treatment except in high-performance athletes or patients required to perform repetitive movements with the affected arm. Should be monitored intermittently for arterial wall degeneration and injury.
1	Subclavian artery stenosis with mild dilation but no intimal injury	Decompression of the thoracic outlet and reimaging of the subclavian artery.
2	Subclavian artery aneurysm with mural thrombus	Decompression of the thoracic outlet and reconstruction of the subclavian artery.
3	Arterial thrombosis or distal embolization with occlusion	Thrombectomy vs. thrombolysis Decompression of the thoracic outlet and reconstruction of the subclavian artery.

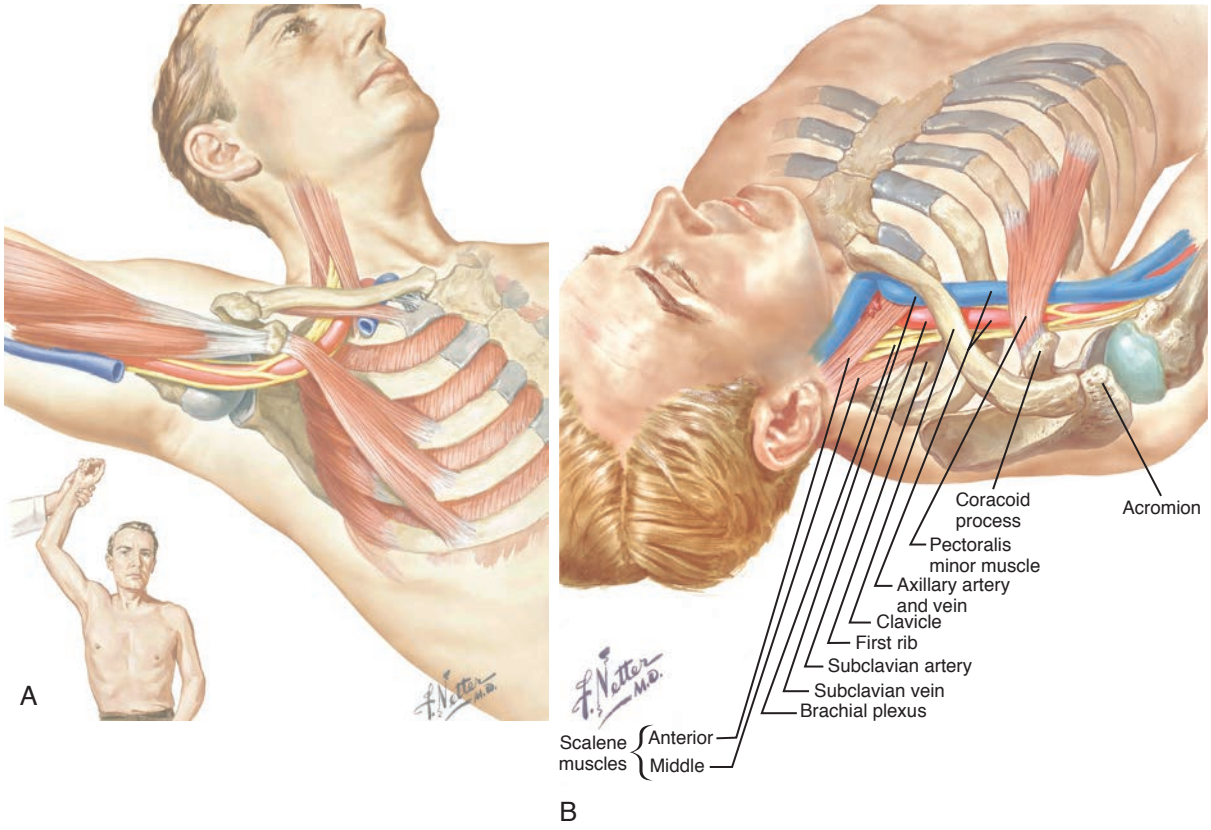

Figure 124.1 (A and B) Two views of the thoracic outlet area, demonstrating the pectoralis minor space in the foreground. The axillary artery and vein are continuations of the subclavian artery and vein. At the axillary level the brachial plexus has already formed its cords, so it is the branches that are seen under the pectoralis minor. (From Lord JW, Jr., Rosati LM. Thoracic outlet syndromes. *Ciba Symp.* 1971;23:1-13.)

PREOPERATIVE PLANNING

Appropriate preoperative planning is the core of successful surgical treatment. An understanding of the anatomy is critical to any surgical treatment (Fig. 124.1), but specific attention should be paid to prior injuries and daily activities in the patient's history. Knowledge of any prior surgical treatment in the vicinity of the surgical field is essential, as this may change the approach. Documentation of the complete preoperative vascular and neurologic examination is critical. A chest x-ray should be performed to evaluate for anomalous first ribs or a cervical rib. In patients with aTOS, imaging of the subclavian artery should be performed to evaluate for aneurysmal degeneration or intravascular thrombus. If reconstruction is planned, appropriately sized prosthetic grafts should be available or vein mapping should be performed if autologous conduit is being considered. Patients with vTOS do not necessarily need a hypercoagulable workup prior to surgery, but they will need to be bridged from oral anticoagulants with the last dose the night prior to surgery.

Selection of Arterial Conduit

Single-segment autologous great saphenous vein (GSV) is the preferred conduit for vascular bypass in the lower extremities due to its ability to resist infection and superior patency over

prosthetic grafts, but it is not the optimal conduit for subclavian artery bypass. Unlike long infrainguinal bypass grafts, subclavian reconstructions are shorter. Because the subclavian artery is subjected to forces of compression, elongation, and twisting, the selected conduit must be able to perform well under these challenging conditions. Prosthetic options include externally supported polytetrafluoroethylene (PTFE) or Dacron. Small single-institution retrospective reviews of patients who have undergone arterial bypass after TOS decompression show 96% patency at 5 years with PTFE and 94% patency with GSV at 12 years.[11,12] However, a larger series of 51 patients undergoing bypass grafting from the carotid artery to the subclavian artery beyond the clavicle indicates that PTFE had better 5 year patency (96%) compared with Dacron (84%) and saphenous vein (65%).[13] Because of the small numbers in these series, a definitive recommendation on choice of conduit cannot be made at this time.

SURGICAL TECHNIQUES

Removal of the first rib can be performed through a supraclavicular, infraclavicular, or transaxillary incision. Cervical ribs, however, may only be reached through the transaxillary or supraclavicular approach. As already mentioned, repair of the subclavian artery requires a supraclavicular approach to obtain control of the vessel. Venous repair may be performed through a supraclavicular or infraclavicular approach. Regardless of which approach is ultimately chosen, the procedure should be performed under general endotracheal tube anesthesia. The tube should be secured on the opposite side of where the surgeon will be working, and the use of neuromuscular blocking agents should be avoided because of the numerous nerves within the surgical field.

Supraclavicular Approach

The patient is placed on the operating room table in the semi-Fowler position. A small roll is placed transversely just below the shoulders. The head is extended and rotated away from the operative site. The neck, chest, and affected extremity are prepped and draped sterilely. The arm, forearm, and hand are wrapped in a stockinette or towel and secured with a towel clamp. Prepping the entire arm allows it to be moved if needed for additional exposure. During the procedure, the arm is maintained in the adducted position. The elbow may be flexed at 90 degrees and the arm secured to the abdomen or left straight at the patient's side. Both positions prevent tension on the brachial plexus.

External landmarks are identified and marked on the skin. These include the sternocleidomastoid muscle, sternal notch, and clavicle. A transverse incision is made 2 cm above the clavicle beginning at the lateral border of the sternocleidomastoid muscle and extending just beyond the external jugular vein. The platysma muscle is incised and inferior and superior subplatysmal flaps are created. Flaps should be created as widely as possible to provide adequate exposure. Portions of the clavicular head of the sternocleidomastoid muscle can be divided to provide exposure. The scalene fat pad is dissected along the medial, inferior, and superior borders, which allows it to be retracted laterally. This mobilization is initiated by taking down the medial attachments of the fat pad at the level of the internal jugular vein. The tissue should be tied with 3-0 sutures to prevent postoperative lymph leakage. Alternatively, a Ligasure (Medtronic, Minneapolis, Minnesota) or harmonic scalpel can be used. The dissection is carried down to the junction of the internal jugular and subclavian veins and extended laterally to the insertion of the external jugular vein into the subclavian vein. Finally, the fat pad is mobilized superiorly until the cutaneous nerves of the chest and shoulder region are encountered. Self-retaining retractors—Omni-Tract, Weitlaner, or cerebellar—are put into position to maintain exposure.

The medial and lateral borders of the anterior scalene muscle are mobilized, and the phrenic nerve is identified (Fig. 124.2A). The phrenic nerve is never directly grasped with an instrument. Rather, a generous length of fascia on either side of the nerve is incised and used to retract the nerve and expose the anterior surface of the anterior scalene muscle. The nerve may also be encircled with a vessel loop and the loop used to retract it, with care taken to avoid excessive retraction. Mobilization of the phrenic nerve is continued down to the thoracic inlet. The anterior and posterior borders of the anterior scalene muscle are dissected. A right-angle clamp is passed behind the muscle, which is divided sharply at least 1 cm off the first rib. Bipolar cautery may also be used to divide the muscle and maintain hemostasis. If a portion of the anterior scalene muscle or a separate scalenus minimus is present behind the subclavian artery, it should be divided as well. The anterior scalene muscle is dissected proximally as able and then excised. The plane in the deep cervical fascia is developed laterally with a moistened sponge or Kittner to expose the brachial plexus and the middle scalene muscle. After the long thoracic nerve is located, the middle scalene muscle is mobilized (see Fig. 124.2B). A periosteal elevator is used to dissect the attachments of the middle scalene muscle from the first rib. Often, some of the fibers of the middle scalene muscle extend to the second rib and may be incised with Metzenbaum scissors if needed. The intercostal fibers are taken off the first rib with the elevator (see Fig. 124.2C). The first rib is resected with a bone cutter or a Kerrison rongeur just proximal to its articulation with the vertebra (see Fig. 124.2D). Similarly, it is excised as medially as possible near its junction with the sternum. The subclavian vein is inspected and dissected from any surrounding perivenous fibrosis if present.

It is critical that the first rib be resected at its junction with the sternum. To accomplish this, it is sometimes helpful to make a small counterincision just beneath the clavicle. The pectoralis major and minor fibers are separated and the rib is identified. The remainder of the surface of the rib is then dissected with a periosteal elevator while care is taken to note the location of the subclavian vein. This requires resection of a portion of the subclavius muscle. After the rib is dissected thoroughly, it is resected up to the sternal junction. The scalene fat pad is reattached with interrupted 3-0 Vicryl suture. A Blake drain is placed routinely because of lymphatic leak, and the platysma and skin are closed.

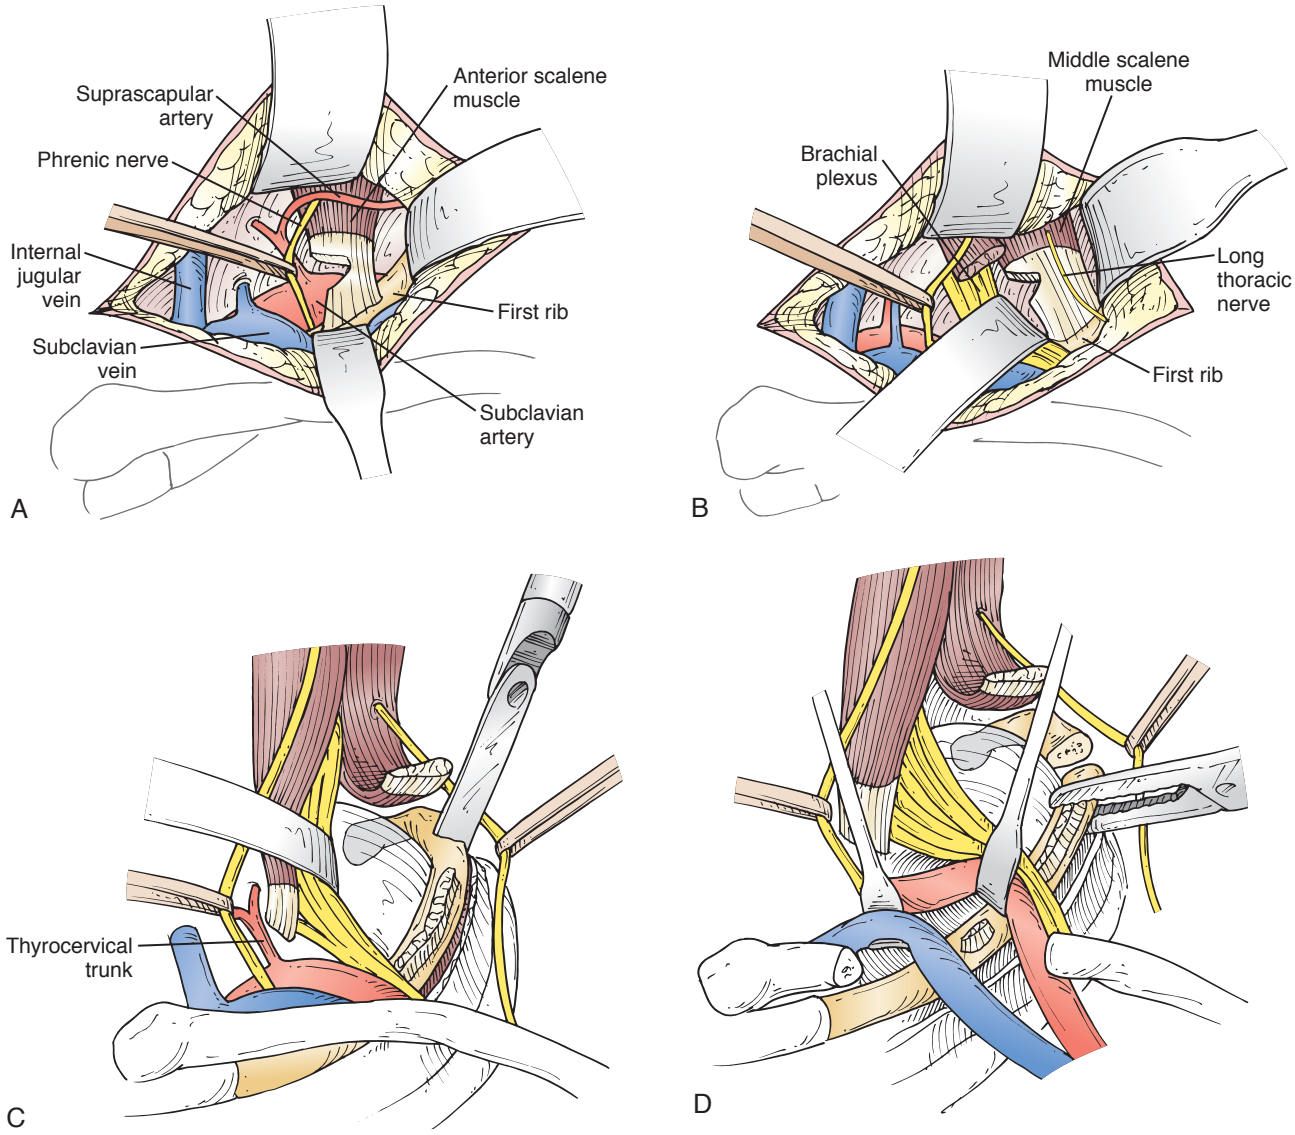

Figure 124.2 (A) Operative view of the supraclavicular approach to thoracic outlet decompression. After mobilization of the scalene fat pad, the phrenic nerve should be identified and carefully elevated before the anterior scalene muscle is divided. (B) The long thoracic nerve should be identified and protected during division of the middle scalene muscle. (C) Attachments are freed by an extraperiosteal approach to prevent recurrent symptoms from reossification of the periosteal bed. (D) Division of the first rib should be performed under direct vision to minimize the possibility of damage to the brachial plexus. After the first rib is divided just distal to the tubercle, the divided rib can be held as a lever to aid in clearing the overlying vessels. (From Valentine RJ, Wind GG. *Anatomic Exposures in Vascular Surgery.* 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2003.)

Transaxillary Approach

Several groups prefer the transaxillary surgical approach and have reported excellent results when it was used for first rib resection, scalenectomy, and venolysis.[7,14,15] The patient is positioned in the lateral decubitus position with a beanbag used for support. The legs and body are padded accordingly. An axillary roll is created and positioned under the patient.

The axillary hair is clipped and the entire arm, axilla, and shoulder are prepped into the field. The hand is placed in a stockinette that is extended just above the level of the elbow. The arm is wrapped with two Kerlex gauze wraps to provide additional padding. White terry cloth towels are placed in the Machleder retractor to pad it (see Fig. 121.5). The arm is then secured to the retractor using a Coban wrap. If a Machleder retractor is not available, a strong assistant at the 90-degree angle can hold the arm. To open the axillary space during dissection, the assistant should be placed on two steps (see Fig. 121.5).

The external landmarks are identified and marked on the skin, including the pectoralis major and latissimus dorsi muscles. A transverse incision is made just above the inferior aspect of the hairline between the two muscles. The subcutaneous tissue is dissected down to the chest wall. Placement of a Weitlaner

or cerebellar retractor allows the field to be held open during the dissection down to the chest wall. Once the avascular space over the chest wall has been entered, the arm is elevated with the Machleder retractor or by the assistant. The connective tissue over the thoracic outlet is bluntly dissected with a Kittner. A lighted retractor and a Dever are used to open up the anterior and posterior aspects of the field.

The subclavian vein, anterior scalene muscle, subclavian artery, and inferior nerve root are dissected in that order, using a Kittner. A large periosteal elevator is used to free up the intercostal muscle fibers along the lateral aspect of the rib and lift the middle scalene muscle fibers off the first rib. A smaller periosteal elevator is used to separate the pleura from the inferior aspect of the rib. A right-angle clamp is passed posteriorly to the anterior scalene muscle and the muscle is divided sharply as high as possible (see Fig. 121.6A). The phrenic nerve is rarely encountered through the transaxillary approach because it typically separates from the anterior scalene muscle and enters the chest above where the anterior scalene muscle inserts on the first rib. The entire anterior scalene muscle does not have to be divided at once and dividing the muscle slowly allows the surgeon to make sure that no surrounding structures are injured. The subclavius tendon is divided sharply, with care taken not to injure the subclavian vein.

If a cervical rib is present, the periosteal elevator is used to remove any muscle fibers from the rib. A right-angle clamp is passed under the rib and used to separate any additional medial attachment to the first rib. The anterior aspect of the first rib is transected with a Bethune rib cutter; this allows the rib to lift up from the pleura and act as a lever for cutting the posterior aspect. The rib is then cut posteriorly (see Fig. 121.6C). It is important that the rib be cut behind the nerve root but that the nerve not be injured during the cutting of the rib. This may require the rib to be cut more than once. The cervical rib is also cut with the rib cutter. A first-rib rongeur is used to remove any residual rib anterior to the sternum and posterior to the vertebra. Sterile saline is instilled into the wound and a Valsalva maneuver is performed to test for a pleural leak. The axillary space is closed in two layers of absorbable suture. The skin is also closed with absorbable suture.

Infraclavicular Approach

The infraclavicular approach is used to treat vTOS only. Only the anterior portion of the rib is removed during this approach, which enables control of the vein for patch venoplasty. In Molina and colleagues' relatively large series of 114 patients who underwent treatment for venous TOS, all thoracic outlet decompressions were performed through an infraclavicular-only approach.[8] This approach is well described and involves partial resection of the anterior half of the first rib, removal of the subclavius tendon, and division of both the anterior scalene tendon and part of the middle scalene muscle to the level of the subclavian artery. In this series, all patients underwent vein patch angioplasty of the subclavian vein with a segment of harvested great saphenous vein (Fig. 124.3). Of note, in 12 patients found to have long (>2 cm) stenoses, transmanubrial extension of the incision was performed. This consisted of extending the incision medially across the sternum to the midline and then angling 90 degrees up toward the sternal notch. These select patients were then managed with 6 weeks of postoperative arm immobilization. Angioplasty plus stent placement was used as an alternative strategy in seven patients with residual stenoses not amenable to local patch angioplasty. In this small group of patients, all stents were reported to remain patent on duplex follow-up (mean follow-up of 14 years). To date, this remains the largest published experience of central vein stenting after thoracic outlet decompression.

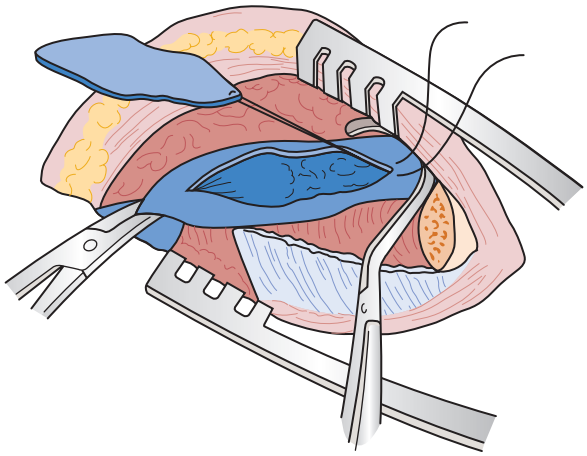

Figure 124.3 Infraclavicular Approach. The saphenous vein patch is laid over the strictured segment of the vein. The key to success is complete mobilization of the subclavian vein by detaching it anteriorly from the sternum until the vein is easily exposed in the operative field. This allows sufficient margin for placement of the medial clamp between the site of the stricture and the normal innominate vein. (From Molina JE, Hunter DW, Dietz CA. Paget-Schroetter syndrome treated with thrombolytics and immediate surgery. *J Vasc Surg.* 2007;45:328-334.)

POSTOPERATIVE CARE AND REHABILITATION

The type of TOS that is treated dictates the postoperative course regardless of which surgical approach is chosen, and appropriate physical therapy after surgery can prevent many long-term complications, such as brachial plexus entrapment in scar tissue.

Pain Management

Prior to surgical closure, the area is generously anesthetized with local anesthetic. A combination of long-acting bupivacaine and shorter-acting lidocaine is used. The addition of ketorolac can greatly improve patients' postoperative pain as well. Narcotic pain medication may be required for a short time in patients with arterial or venous TOS.

Patients with nTOS may have been treated with narcotics prior to surgery and therefore have a higher tolerance to pain. These patients may require narcotic pain relief through their physical therapy as well. The addition of gabapentin may help some patients, but overall it has not been effective at relieving symptoms in these patients long term.

Physical Therapy

Patients with aTOS and nTOS who undergo surgical decompression should start physical therapy (PT) within 7 to 10 days. Patients with vTOS should start PT after complete postoperative treatment of the subclavian vein. The same TOS-specific preoperative PT protocol used in patients with nTOS may also be used postoperatively for all types of TOS with the addition of soft tissue mobilization of the scar. The minimum duration of PT should be 6 weeks; however, this may extend to several months in nTOS patients with longstanding preoperative symptoms. It is important to have a strong working relationship with the physical therapist and an understanding that patients should not be "fast tracked" through the 6-week protocol. Without adequate PT, severely fibrotic scar develops in the surgical field. This results in tethering of the brachial plexus and the development of recurrent symptoms.[16] Patients should not be released from PT early simply because they demonstrate the ability to have full range of motion. This cannot be overly stressed in young high-level athletes. In order for them to return to full function in their sport, a slow and consistent approach to recovery is essential.

Follow-Up

Routine follow-up for all patients is 7 to 10 days after surgery. At this time the wound should be checked for adequate healing without infection. Patients with drains left in place should have them removed. Patients who have undergone venous or arterial bypass with a prosthetic conduit should have a duplex ultrasound of the graft. This serves as a baseline of comparison for identifying any subsequent stenosis in the graft. Finally, patients should be evaluated for adequate postoperative pain control in anticipation of PT.

Further follow-up is tailored to each patient's condition. VTOS patients who do not require vascular reconstruction or venoplasty are asked to return should their symptoms recur. When mild venous dilation is required, patients are left on anticoagulation for an additional 4 weeks and brought back for duplex ultrasound of the vein at that time. If the vein is patent without thrombosis or stenosis, anticoagulation may be stopped and follow-up is required only for recurrent symptoms. In patients who have extended residual subclavian vein thrombus and stenosis on postoperative venography, anticoagulation is continued for 6 to 8 weeks and patients are brought back at that time for duplex ultrasound. If the ultrasound shows persistent stenosis and thrombus, anticoagulation is continued and the patient is reevaluated at 2-month intervals with duplex ultrasound to assess patency of the vein. Again, even in patients with thrombosis, continuous anticoagulation for up to 1 year may allow for favorable recanalization and patency of the vein. If patency is not established in this time frame, the likelihood of the vein opening is less than 10%.[17]

Patients with aTOS who undergo subclavian artery bypass should be followed long term for possible graft stenosis. Although a specific regimen for upper extremity duplex ultrasound graft surveillance has not been established, acute occlusion of bypass grafts due to unrecognized stenosis can be devastating. In the first year, patients are seen at 3- to 6-month intervals to discuss symptoms of arm claudication or pain with use, and a duplex ultrasound is performed to evaluate for possible stenosis. With normal ultrasound findings, surveillance can be extended to longer intervals from 12 to 18 months.

PITFALLS AND COMPLICATIONS

Complications are best avoided with a solid patient selection algorithm, meticulous surgical technique, and appropriate postoperative treatment protocols.

General

Appropriate patient selection for surgical treatment, especially in nTOS, cannot be overemphasized and plays a central role in achieving successful outcomes. Although decompression surgery can be relatively straightforward, it should be avoided at all costs when a patient is not likely to have improvement in symptoms. Studies comparing outcomes for nTOS have found that older patients with longer preoperative symptomatology are more likely to have unresolved symptoms postoperatively. In addition, patients who smoke, have concomitant neck and shoulder injuries, and have other chronic pain syndromes are more likely to have residual symptoms after surgery.[16] Although many patients come with the mindset that surgical treatment will completely relieve their symptoms, a step-by-step approach for each patient should be carried out. This is especially true when patients have been seen by multiple specialists or have had numerous outside treatments. In all patients, reasonable activity expectations should be set. Patients with the previously mentioned comorbidities should be counseled to understand that surgery will not return them to a prior "normal" state. It is also important for patients with long-term nTOS to understand that even after surgery, activity limitations must be observed in order to prevent recurrent symptoms. This includes limitations of heavy lifting or strenuous upper extremity physical activity. When expectations and future limitations are explicitly laid out, patients will hopefully better understand the chronicity of nTOS and the dedication to long-term treatment that is needed.

Scar tissue after surgery is inevitable, but in some patients the scar becomes the nidus of postoperative pain. This is especially true for patients that do not undertake appropriate postoperative PT. It is imperative for patients to understand that there is no quick return to activity after surgery. Because vTOS patients may be healthy and athletic, therapists will occasionally "fast track" them through the 6-week protocol after surgery. This should be avoided, as patients may be noncompliant with the performance of therapy and exercises on their own. Supervised therapy for at least 6 to 8 weeks ensures the best possible outcome for all patients and improves their ability to return to activity as pain free and symptom free as possible. In patients with nTOS who have had long-term symptoms, the postoperative protocol may have to be extended to make sure that the neck and shoulder muscles previously injured for years are adequately worked and loosened.

Specific Surgical Complications

Meticulous operative technique and an understanding of anatomic aberrations help to avoid complications. Injury to the neurovascular bundle of the thoracic outlet is avoided by meticulous dissection in an anterior-to-posterior fashion and additionally by making sure that each structure is identified prior to cutting the muscles or the rib. Small arterial or venous branches can easily be injured with aggressive blunt dissection. Use of sharp dissection with Metzenbaum scissors around the artery and vein can help to avoid this. If a small vessel is avulsed or cut, closure should be accomplished with a 5-0 or 6-0 nonabsorbable monofilament suture.

Nerve injury after first rib resection is devastating. Rarely are the brachial plexus nerves cut during dissection if all structures are identified early, but stretch on the inferior nerve can occur with aggressive retraction in order to visualize the posterior aspect of the first rib. The risk is less severe with the transaxillary approach but injury still can occur. Postoperative pain from nerve stretch after surgery can last 3 to 9 months and be severely debilitating. From the supraclavicular approach, this is avoided by retracting the middle scalene muscle in order to visualize the posterior rib. The transaxillary approach is less likely to cause a stretch type of injury since the nerve is elevated off the rib but not retracted during rib cutting. Visualization of the tips of the rib cutter in the transaxillary approach by the surgeon ensures that the nerve is not inadvertently cut. If the nerve is cut during the surgical rib resection, intraoperative consultation should be obtained. Outcomes are best if the repair is performed early, although this can still be devastating. Stretch neuropathy after surgery can be managed with oral analgesia and should resolve in time.

When the rib is adherent to the pleura, a small pleural tear may result in a pneumothorax. If there is an injury to the visceral pleura, a small 12-Fr chest tube can be placed and left in place until any air leak resolves. If only the parietal pleura is injured, a flat Jackson-Pratt or round Blake drain may be inserted through the pleural tear and connected to a pleural vac. This is left in place overnight and removed the next day. If the patient is seated in the upright position (as in the supraclavicular approach), a red rubber catheter can be placed into the pleural tear with the opposite end placed under water. The air can be evacuated by Valsalva maneuvers prior to allowing the scalene fat pad to drop down and seal the pleural tear, thus avoiding the need for a chest drain.

Lymphatic leak may occur with the supraclavicular and infraclavicular approaches. Injury to the thoracic duct as it enters the posterior aspect of the subclavian vein can result in a leak of several hundred milliliters per day. Again, meticulous dissection and attention to the posterior vein can help to prevent this. Avoiding blunt dissection in this area is also essential. Repeat exploration to repair the lymph leak can be difficult. The application of a sealant product at reexploration is not usually effective when the lymphatic leak is large. Keeping the drain in place, making the patient NPO, and placing him or her on parenteral nutrition for high-output leaks allows the area to scar down over a period of 7 to 14 days.

Renovascular disease (RVD) encompasses a range of disorders that affect renal artery structure and kidney blood flow. The primary importance of RVD relates to associated hypertension (HTN) and loss of renal excretory function, which in turn contribute to cardiovascular morbidity, dialysis dependence, and death.[1-5] The most common pathology and major focus of the present chapter is atherosclerotic renal artery stenosis (RAS), which can be found in up to 7% of elderly individuals in the United States (Fig. 125.1).[1] Less common etiologies include renal artery fibromuscular dysplasia (FMD)[6] (see Chapter 142); dissection, aneurysms, and trauma (see Chapters 128 and 129)[7]; arteritis (see Chapter 139); and developmental abnormalities of the middle aorta and its branches (see Chapter 130).[8,9]

HISTORICAL PERSPECTIVE

Late in the 19th century Tigerstedt and Bergman isolated a substance from rabbit kidneys they called "renin" that when infused into control animals elevated their blood pressure (BP).[10] Decades later experiments would link reduced kidney blood

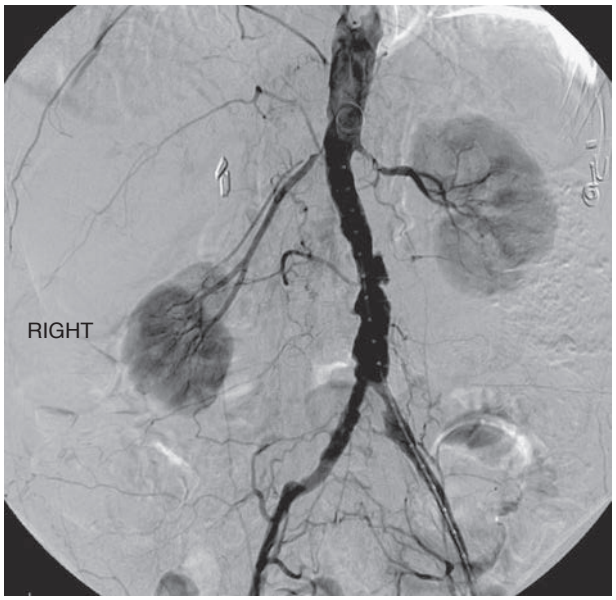

Figure 125.1 Digital subtraction angiogram illustrating bilateral atherosclerotic renal artery stenosis.

flow to elevated BP, and Goldblatt's landmark experiments in the 1930s would show that HTN from RAS could be reversed by correcting the stenosis or by removing the ipsilateral kidney.[11] These studies laid the foundation for research that would eventually define components of the renin-angiotensin-aldosterone system (RAAS) as biochemical mediators of BP regulation.

In 1938 Leadbetter reported that removing an ischemic ectopic kidney normalized BP in a child with severe HTN.[12] Nephrectomy was later popularized for the treatment of adults with uncontrolled HTN attributed to RVD, but results were inconsistent, as it was difficult to predict the impact of nephrectomy on BP control and on renal function.[13]

Successful renal artery reconstruction was first reported by Freeman in 1954, who treated a patient with bilateral ostial RAS and uncontrolled HTN, and in whom the BP normalized following endarterectomy.[14] As surgeons gained experience with open renal artery reconstruction for HTN, reports emerged that revascularization could also improve renal excretory function.[15-20] Dean and others coined the term *ischemic nephropathy* to describe renal insufficiency resulting from RAS or occlusion and explored the limits of renal salvage with provocative reports of patients removed from dialysis after revascularization.[15-20] As open renal revascularization was refined, the use of nephrectomy was largely abandoned.

Open revascularization proved effective at improving HTN, but not every patient benefited. Surgery carried significant risk, particularly in the elderly, with advanced atherosclerosis and ischemic nephropathy. In a series of 500 patients undergoing open renal reconstruction for atherosclerotic RAS at Wake Forest, the 30-day mortality was 4.6% and was 7% in the subset with ischemic nephropathy.[21,22] Mortality for 6608 renal bypass patients across a broad range of hospitals was 10% based on the U.S. National Inpatient Sample from 2000 to 2004.[23] Surgery improved BP in up to 85% of patients but in 15% BP was no better or worse.[21] Greater experience with open revascularization demonstrated that the major benefit in terms of improving survival related to the impact of surgery on renal function rather than HTN.[21,22] If estimated glomerular filtration rate (eGFR) stabilized or improved after surgery, then patients demonstrated improved dialysis-free survival, independent of the impact on HTN.[21,22]

Less invasive approaches to the management of RVD were developed in parallel with the emergence of new classes of antihypertensive agents that greatly reduced the number of patients requiring revascularization for refractory HTN.[24,25] Balloon angioplasty catheters were first used to treat RAS by Gruntzig et al. in the 1970s.[26] An increase in the number of patients treated for atherosclerotic RAS followed, but results were tempered by high rates of restenosis. Within a decade, however, balloon-expandable stents were developed that reduced renal restenosis rates substantially.[27-29] What followed was an explosion in renal stenting that rapidly reduced the number of open renal reconstructions. Statistics in the United States from 2000 showed that 21,000 renal revascularization procedures were performed under Medicare,[30] while the number of open reconstructions fell by 30% from 2000 to 2004.[23] As a result, open renal artery reconstruction has become uncommon in contemporary vascular surgery practice, except in centers with a particular interest in RVD.

Novelty often drives application of new technology, and renal stenting was employed enthusiastically prior to rigorous studies.[30] Only recently have large prospective randomized clinical trials compared stenting with medical management in atherosclerotic RAS, and have found no clear advantage for stenting.[31-34] These trials have shortcomings, and many patients included in these trials (e.g., ASTRAL and CORAL) would not have met the threshold for intervention at our center and others (see Chapter 127), but the impact of these trials has been to appropriately (in our opinion) limit application of stenting to select subsets of patients with atherosclerotic RVD. Few studies have directly compared open renal revascularization with medical management, angioplasty, or stenting, and all were too small to provide meaningful guidance.[35-37] Therefore the application of open surgery in RVD is guided largely by single center cohort studies and expert opinion (discussed later).

PATHOGENESIS OF RENOVASCULAR DISEASE

Etiology of Renal Artery Lesions

More than 90% of patients referred for renal artery stenting have atherosclerotic lesions.[38,39] In 840 patients undergoing open renal revascularization at our institution, 81% had atherosclerotic lesions, 14% FMD, and 1% dissection. The other 3% were children with hypoplastic renal arteries, midaortic syndrome, or dissection.

Atherosclerotic RVD is typically most severe at the renal artery ostia, but stenosis may occur at any level, including small

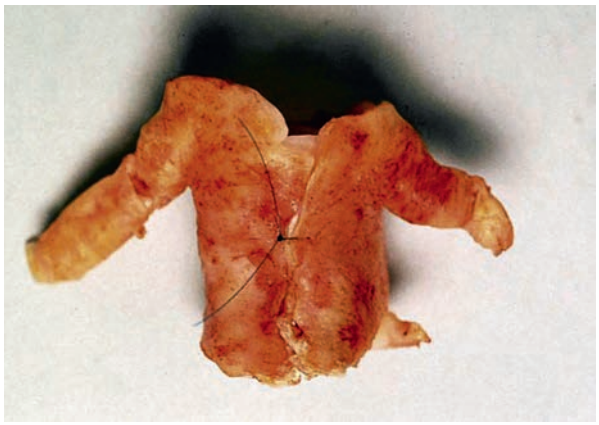

Figure 125.2 Operative specimen from transaortic sleeve endarterectomy illustrating ostial renal artery plaque extending perpendicular to a contiguous sleeve of calcified aortic plaque.

intraparenchymal branches.[40,41] Ostial lesions are typically contiguous with a sheet of aortic plaque oriented perpendicular to the renal artery (Fig. 125.2). This sheet is often heavily calcified and resistant to simple balloon dilation and more effectively overcome with balloon-mounted stents, which have become the standard endovascular approach.[28,38]

FMD in contrast typically affects the main renal artery and its branches away from the ostia (see Chapter 142).[6] In adults, FMD often creates a series of web-like stenoses, alternating with segments of normal or dilated lumen caliber, giving rise to the classic "string of beads" morphology typical of the medial fibroplasia subtype. Renal FMD in children is more often the intimal fibroplasia subtype and less likely to cause this stereotypical angiographic appearance.

Dissection of the renal arteries can be spontaneous or caused by blunt or penetrating trauma, endovascular manipulation (e.g., guide wires and catheters), severe HTN, or by renal artery wall pathology, such as FMD. Renal dissection often originates from aortic dissection that can obstruct the ostia with flaps or extend out the renal artery and branches. Dissection can result in acute occlusion or thrombosis of the renal artery with infarction of the kidney. Dissections may extend into the kidney parenchyma, limiting options for revascularization, and as they heal, dissections may create stenosis or aneurysmal degeneration (see Chapter 128).

Less common renal artery pathologies include the various arteritides and congenital syndromes covered elsewhere in this text (see Chapters 130 and 137, Chapter 139, Chapter 140, and Chapter 142).

Pathophysiology of Renovascular Hypertension

HTN in response to RVD results from a complex cascade of molecular and cellular events precipitated by hypoperfusion of one or both kidneys. A flow-limiting RAS creates a pressure drop sensed downstream by juxtaglomerular cells that then respond by releasing renin into the systemic circulation in an attempt to normalize sensed BP.[42] Renin catalyzes cleavage of angiotensinogen to form the decapeptide angiotensin I, which is then cleaved in the pulmonary circulation by angiotensin converting enzyme (ACE) to form the octapeptide angiotensin II (Ang II).[43] Circulating Ang II is then the primary effector of renin-mediated increases in systemic BP, promoting peripheral vasoconstriction and blood volume expansion.[43,44]

Ang II acts on a variety of cell-types through specific G protein–coupled receptors designated ATR1 and ATR2.[45] Ligation of ATR1 activates intracellular pathways that promote vasoconstriction and mitogenic responses within the vessel wall and myocardium.[43-46] In addition to direct vasoconstrictor activity, Ang II indirectly promotes vasoconstriction by upregulating expression of norepinephrine and endothelin-1.[45] ATR1 signaling also leads to formation of reactive oxygen species that can inactivate the vasodilator nitric oxide. Cross-talk between ATR1 and other receptors (e.g., growth factor-activated receptor tyrosine kinases) amplifies smooth muscle cell vasoconstrictor and proliferative signaling pathways.[45,46]

Fluid retention also contributes to renovascular HTN. Ang II acts directly on renal tubules to promote sodium and water reabsorption[47] but also stimulates adrenal release of aldosterone, a potent mediator of renal tubular sodium reabsorption.[48] Adaptive responses can limit volume expansion in patients with unilateral RAS as the contralateral normal kidney mounts a compensatory natriuresis.[11,49,50] Patients with bilateral RAS or RAS in a solitary kidney cannot compensate, resulting in so-called Goldblatt "volume-dependent" renovascular HTN, which can be severe.[11] The RAAS also contributes to HTN by acting on specific regions of the brain responsible for autonomic control of BP or by release of vasopressin from the pituitary to promote thirst and water reabsorption.[50,51]

While renovascular HTN is initially mediated by activation of the RAAS, chronic structural changes sustain and amplify the problem.[52,53] Longstanding HTN causes chronic tangential vessel wall strain that promotes hypertrophic remodeling in the myocardium and resistance vessels, a response likely amplified by mitogenic effects from Ang II excess. Wall thickening, stiffening, and amplified mechanical leverage in constrictor function characterize a remodeled vasculature that promotes cardiovascular embarrassment, even after RAS is corrected.[52-53] Structural changes in RVD are distinct from those observed in essential HTN in which resistance vessels exhibit eutrophic remodeling, with little change in wall mass. Hypertrophic remodeling in RVD may be reversed over time with inhibition of the RAAS (e.g., ACE inhibition).[52]

Pathophysiology of Ischemic Nephropathy

Ischemic nephropathy refers to loss of renal excretory function attributed to RVD, but its molecular and cellular basis are incompletely understood.[53,54] The kidney lacks significant collateral arterial flow, so acute renal artery occlusion generally leads to kidney infarction within minutes to hours. In contrast, the kidney adapts to a broad variation in pressure, preserving parenchymal oxygenation and glomerular filtration. Chronic hypoperfusion eventually impairs kidney function through a number of mechanisms, some of which are irreversible. Severe

hypoperfusion drops glomerular filtration pressure and leads to ischemic damage.[53,54] Chronic excess Ang II and aldosterone promote expression of profibrotic cytokines and growth factors, including transforming growth factor-β, a master regulator of extracellular matrix production, and platelet-derived growth factor, a potent mitogen for smooth muscle cells, renal fibroblasts, and glomerular mesangial cells.[53-55] Ang II also induces nuclear factor-κB, a potent master switch for proinflammatory pathways. Each of these contributes to glomerulosclerosis and tubulointerstitial injury.[53-57] Atherosclerotic lesions themselves may contribute to loss of excretory function by chronically releasing microembolic debris.[58-61] If perfusion is severely compromised, the renal parenchyma will become hypoxic, with resulting ischemic injury and inflammatory infiltration associated proinflammatory cytokine release, but the contribution of frank ischemic necrosis to renal parenchymal atrophy is less well-established.[53,54]

In the setting of unilateral RAS, the opposite kidney may suffer injury directly from compensatory systemic HTN, which persists despite medical control of HTN or renal revascularization. The etiology of chronic kidney disease is often complex and multifactorial, particularly in patients with established atherosclerosis[53,54,62] where risk factors overlap significantly with those for medical renal disease, including diabetes, hyperlipidemia, essential HTN, smoking, and others. So as with HTN, many patients with atherosclerotic RAS may have other factors contributing to renal insufficiency.

EPIDEMIOLOGY

While animal experiments and clinical experience have proven that reduced kidney blood flow can cause renin-mediated HTN, loss of excretory function, kidney atrophy, and even infarction, many individuals found to have RAS on imaging will be asymptomatic or have minimal change.[1-3] These individuals have "anatomic" disease that is "functionally" silent, because their lesions are hemodynamically inconsequential, their intrinsic adaptive responses are robust enough to maintain BP and glomerular filtration, or the ipsilateral kidney may be so damaged that it is incapable of significant renin release.[3,53]

Attributing clinical impact to a particular renal artery lesion is further confounded by the high prevalence of essential HTN and intrinsic kidney disease among individuals with atherosclerosis.[1,3] Provocative tests and chemical assays have been of limited value in helping prove a particular renal lesion is driving HTN or renal dysfunction. This creates the awkward dilemma that in order to prove a particular RAS will respond to reconstruction with improved BP and renal function, one often has to first do the reconstruction. Thus the prevalence of RVD defined by imaging alone overestimates the prevalence of a disease that will benefit from intervention.

Prevalence of Renovascular Disease

No studies have measured the prevalence and natural history of RAS in the general population, and the majority of estimates come from screening of high-risk cohorts (see below and Table 125.1). To address this, Hansen and colleagues used renal duplex ultrasonography (RDU) to screen 870 individuals for RAS without regard to BP or renal function.[1] Subjects were recruited within the Community Health Study (CHS), an NIH-sponsored prospective analysis of individuals 65 and older living independently in the community. Subjects were screened for CV disease at enrollment and then monitored for incident disease over time. The prevalence of a hemodynamically significant RAS at baseline was 7%, of which one in eight had bilateral disease, so a significant number of relatively healthy older individuals in the United States have undiagnosed RAS.[1] This study also highlights the high rate of essential HTN found in older adults, as 50% with normal RDU had elevated BP versus 72% of those with RAS. Therefore many individuals with RVD likely had HTN unrelated to their stenosis, and 28% were normotensive.[1,3] The vast majority of subjects in both groups had normal renal function, but creatinine was more likely elevated in those with RAS (16% vs. 8%).[3,62]

The prevalence of RAS has also been estimated from autopsy series. Schwartz and White examined 154 consecutive cases and reported RAS in 6% of individuals <55 years of age and 40% of those >75. Approximately half had bilateral lesions.[40] In another series of 295 autopsies, Holley reported 22% had

TABLE 125.1 Prevalence of Renal Artery Stenosis in High-Risk Populations

CAD, Coronary artery disease; *RAS*, renal artery stenosis.

significant RAS.[41] The high prevalence of atherosclerotic RVD in autopsy series is certainly impacted by bias toward atherosclerosis as the leading cause of death in developed countries.

Angiographic series have screened for RVD in patients with coronary, carotid, and peripheral artery disease (PAD; see Table 125.1).[63-71] RAS was found in up to 22% of patients undergoing heart catheterization,[63,66] 27% with carotid stenosis,[67-70] and up to 40% with PAD (see Table 125.1).[67,71]

Given the impact of RAS on BP and renal function, its prevalence will be higher in cohorts prescreened for HTN[72] or renal failure. We used RDU to evaluate 629 adults with newly diagnosed HTN and found 25% had significant RAS. This doubled in patients with severe HTN who were over 60 years old. RAS has been reported in 9% to 41% of patients requiring dialysis, but prevalence varies significantly by age, gender, and ethnicity. It is highest in the elderly and surprisingly infrequent among African Americans with end-stage renal disease.[73-77]

Natural History of Renal Artery Stenosis

Anatomic Progression

Understanding the natural history of RAS is critical in order to properly balance risks and benefits of various treatment options. Older studies used serial arteriography to monitor the severity of stenosis and reported progression in 11% to 35% of lesions managed medically.[78-81] Arteries with severe baseline stenosis went on to occlude in 10% of individuals.[78,80] Zierler employed serial RDU to follow 80 patients with established renovascular HTN after classifying baseline stenosis for each artery as >60%, <60%, or normal.[82] After 3 years, 8% of normal arteries and 43% with <60% stenosis had progressed to a high-grade stenosis, and 7% with >60% stenosis at baseline went on to occlude. Factors associated with progression included age, systolic BP, smoking, female gender, and poorly controlled HTN.[82]

Functional Progression

Chronic activation of the RAAS, severe HTN, and impaired renal excretory function each contribute to cardiovascular morbidity, dialysis, and death. This relationship provides the rationale for treatment of RAS.

Loss of functioning nephrons is accompanied by a rise in serum creatinine and fall in eGFR, although an individual must lose more than half of functioning nephron mass before creatinine rises. So surrogates for loss of kidney function, such as kidney shrinkage, can be valuable in understanding the progressive impact of RVD. Kidney atrophy can be assessed with RDU and cross-sectional imaging as loss of kidney length, cortical thickness, or volume. Schreiber reported a significant loss of renal function over time in patients with RAS, regardless of whether the degree of stenosis progressed,[79] and Dean randomized 41 patients with RAS and severe HTN to medical management and found 46% had a significant rise in serum creatinine while 37% showed loss of kidney length on follow-up.[78] In a prospective study of 122 patients with renovascular HTN, Caps reported that 21% of kidneys ipsilateral to >60% RAS lost more than 1 cm in length at 2 years with an increase in creatinine, and that atrophy correlated with degree of stenosis and systolic BP.[83] Others have also documented shrinking kidneys and loss of excretory function in patients with RAS,[84,85] and progression to dialysis has been reported in 7% to 12% of patients managed medically within 3 to 4 years.[84,85]

In contrast, none of the subjects that had >60% RAS at baseline that were followed prospectively in the CHS substudy (described previously) progressed to complete occlusion at a mean follow-up of 8 years.[86] However, nine kidneys with normal renal arteries at baseline went on to develop critical RAS, including one complete occlusion. In this relatively healthy cohort, enrolled independent of HTN or renal dysfunction, the rate of progression was 4%, far below the previously mentioned series in patients preselected for severe concomitant HTN.

Taken together, these studies demonstrate that progression of RAS is less likely in low-risk patients in whom lesions are found incidentally,[1,3] but that loss of renal mass and function are common in older patients with high-grade RAS and severe HTN.

Associated Morbidity

RAS has been associated with cardiovascular morbidity and mortality, and progression to dialysis. Risk of end-organ damage is much higher in patients with atherosclerotic RAS compared with patients with essential HTN, as measured by left ventricular hypertrophy, elevated serum creatinine, and proteinuria.[87] Mailloux projected that RVD accounts for 10% to 18% of incident dialysis dependence among the elderly,[75] and others have associated RAS with cardiovascular events, including stroke and perioperative complications.[71,87,88] Conlon showed that among 1235 patients with coronary artery disease (CAD) on angiography, the 4-year survival was significantly lower in those with concomitant RAS (67% vs. 88%). Increased mortality was attributed mostly to excess cardiovascular events.[89] Edwards reported that the incidence of new coronary events among 870 CHS participants was twice as high in those with RAS after only 14 months follow-up, and the association remained significant after controlling for HTN and preexisting cardiovascular disease.[2]

CLINICAL PRESENTATION

History and Physical Examination

The high volume of cross-sectional imaging employed in contemporary medicine has resulted in a large number of patients being referred for RAS found incidentally. The most common indications for referral to our vascular laboratory for RDU screening are severe HTN (e.g., resistant to three or more medications); unexplained renal insufficiency in patients with risk factors for RVD; and regular surveillance of patients with known RVD or for patients with prior renal revascularization. In addition, all children with unexplained HTN should be screened for RVD, and practitioners should be reminded that definitions of HTN in children are far lower than in adults (e.g., a systolic BP of 110 mm Hg is 99th percentile for a 1-year-old child).[90,91]

TABLE 125.2 Demographics of Patients Undergoing Open Renal Revascularization

Parameter	Value
Age	65 ± 9 years
Gender	49% male, 51% female
Systolic BP	200 ± 35 mm Hg
Diastolic BP	104 ± 21 mm Hg
Number of antihypertensive medications	2.6 ± 1.1
Creatinine concentration (mean)	2.6 mg/dL (230 µmol/L)
Comorbid extrarenal atherosclerosis	90%
Coexisting coronary artery disease	70%
Diabetes	16%

BP, Blood pressure.

HTN associated with critical RAS is typically more severe and refractory to medical therapy than essential HTN.[3,21] For example, in 500 patients with atherosclerotic RAS treated with open renal revascularization at Wake Forest, the mean preoperative systolic and diastolic pressures were 200 mm Hg and 104 mm Hg, respectively, on an average of three antihypertensive medications (additional demographics in Table 125.2).[21]

Advanced age, atherosclerosis risk factors, or a history of coronary, carotid, or peripheral arterial disease should raise suspicion in adults with severe HTN. Patients with RAS can have impaired renal function, but the etiology is often multifactorial. Ischemic nephropathy caused by RAS in our experience is nearly always associated with severe HTN.[20,21] Renal insufficiency in patients with only mild or moderate HTN typically have medical disease unlikely to stabilize or improve with renal revascularization.[20] Patients who demonstrate acute renal insufficiency after starting an ACE inhibitor or angiotensin II receptor blockers (ARB) should be screened by RDU for bilateral RAS where both kidneys rely on efferent arteriolar tone mediated by Ang II to maintain glomerular filtration.[92,93]

Individuals with unrecognized or poorly controlled renovascular HTN may present in "hypertensive crisis" with neurologic or cardiovascular embarrassment when HTN is severe (e.g., systolic BP >200 mm Hg).[94] Long-standing HTN leads to left ventricular hypertrophy and abnormal diastolic relaxation. A stiff ventricle then predisposes patients to "flash pulmonary edema" after relatively minor changes in volume status or further increases in BP. Severe HTN also drives fluid into the extravascular space, causing edema and inflammation of various tissues, including the brain. Neurologic manifestations may include headache, visual disturbance, mental status change, acute stroke, or intracranial hemorrhage. HTN can also damage the opposite kidney in patients with unilateral RAS, resulting in proteinuria and elevated serum creatinine that corrects as BP is normalized.[54,94] It is important to allow a patient in this setting to recover before imaging or intervention with iodinated contrast.

On physical examination patients may manifest severe systolic and diastolic HTN, peripheral edema, abdominal bruits, and nonspecific stigmata of atherosclerotic heart and vascular disease. Diminished lower extremity pulses can be found in adults with associated atherosclerotic PAD, Takayasu arteritis, and aortic dissection, while in children decreased lower extremity pulses may indicate aortic coarctation or midaortic syndromes. Differential diagnostic considerations are provided in Table 125.3.

TABLE 125.3 Differential Diagnosis in Patients Evaluated for Renovascular Hypertension

Essential hypertension	Hyperthyroidism
Glomerulonephritis	Coarctation of the aorta
Nephrotic syndrome	Hyperparathyroidism
Primary aldosteronism	Sleep apnea

Laboratory Findings

Laboratory testing in individuals being evaluated for HTN may include urinalysis, blood chemistries, fasting blood glucose or hemoglobin A1c, lipid panel, and 12-lead EKG.[95] Although nonspecific, blood urea nitrogen and creatinine concentrations may be elevated in patients with RVD. An electrocardiogram may show a strain pattern and increased voltage consistent with left ventricular wall thickening. Echocardiography can confirm ventricular hypertrophy with impaired diastolic relaxation, and in the pediatric patient can also exclude aortic coarctation. Measuring systemic renin levels in patients with RVD is rarely useful unless combined with invasive selective renal vein renin sampling (see the Renal Vein Renin Assays section that follows). In patients with diabetes, urinary albumin excretion should be measured to assess the extent of intrinsic kidney damage.

Spontaneous hypokalemia (<3.5 mmol/L) or severe hypokalemia after initiating diuretics should raise suspicion for primary hyperaldosteronism (Conn syndrome), which can be confirmed by measuring plasma aldosterone (see Table 125.3).[48,96] These patients also typically manifest a metabolic alkalosis and depressed or unmeasurable plasma renin activity. An incidental finding of adrenal adenoma on abdominal imaging in a patient with refractory HTN should prompt screening for hypersecretion of aldosterone and catecholamines. Patients with catechol-excreting adrenal tumors (pheochromocytoma) may have episodic HTN associated with headache, palpitations, sweating, panic attacks, and pallor. In these patients, paroxysms of HTN can be triggered by starting β-blockers or MAO inhibitors, or by micturition and other activities that increase intraabdominal pressure.[97] Patients with MEN2, neurofibromatosis type-1, and von Hippel-Lindau are also at risk for pheochromocytomas. Diagnostic algorithms are influenced by local expertise, and our preferred screen is a 24-hour urine assay

for fractionated metanephrines and catecholamines. Fractionated plasma metanephrine assays are also commonly employed.

Diagnostic Imaging

Renal Duplex Ultrasonography

RDU is an excellent screening test for RAS (see Chapter 21). When performed by an experienced technologist, a typical study is rapid, noninvasive, accurate, and reproducible. RDU avoids ionizing radiation and iodinated contrast material, does not require intravenous access, is safe in patients with medical implants, and is relatively inexpensive. Thus RDU has become the primary tool in most centers for screening and following patients with RAS.[98] Limitations include that it is technically demanding relative to other studies performed in the average vascular laboratory and thus somewhat operator-dependent, and RDU is also of limited use in characterizing other manifestations of RVD (e.g., aneurysm, dissection, FMD, etc.). Patient factors that can interfere with renal artery insonation include obesity, bowel gas, and excessive resistance from advanced disease within the kidney parenchyma.

In our laboratory the exam begins after an overnight fast with the patient supine. Imaging from the anterior approach, the perirenal aorta is examined for aneurysmal change, stenosis, or occlusion and a peak systolic velocity (PSV) is recorded. Each renal artery is then imaged and velocities and waveforms recorded from proximal, mid-, and distal segments. Patency and phasicity of the renal veins is evaluated using color flow and Doppler. Velocity profiles are recorded within the kidney parenchyma at the superior, mid-, and inferior pole to calculate resistive index (RI) and acceleration times. The exam concludes with the measurement of pole-to-pole kidney lengths.

The accuracy of RDU in detecting significant RAS (e.g., >60%), validated against conventional arteriography, can exceed 90% in experienced hands.[99-102] Criteria used to define a critical stenosis vary, but in our hands a PSV of >200 cm/s in the main renal artery when associated with poststenotic turbulence has proven accurate in defining a >60% stenosis.[99,103,103] Other centers rely on the ratio of renal artery to aortic PSV (RAR) to define a critical RAS (e.g., >3.5),[99,103,104] but in our hands the RAR has been unreliable.[103] Others have proposed different criteria for their laboratories, including slightly higher PSV cutoffs (e.g., 285 cm/s) and higher RAR (e.g., 3.7).[102]

Hilar and parenchymal analyses have been proposed as less complicated approaches to identify an RAS. Blunted waveforms with delayed systolic upstroke are indicative of proximal stenosis. Acceleration times estimate delay in systolic upstroke from onset of systole to its peak, with values exceeding 100 ms, suggesting flow-limiting RAS.[100,103,105] In our hands acceleration time provides a positive predictive value of 97%, but sensitivity is too low to be used alone for screening.[103] The RI has been proposed to screen for RAS but is best suited to identify patients with intrinsic kidney disease. A normal value is <0.7. Values >0.8 may indicate a critical RAS but more often are nonspecific, frequently caused by intrinsic medical parenchymal kidney disease. Radermacher measured RI in 131 patients undergoing renal revascularization and found a value >0.8 predicted a poor BP response and likely progression of renal insufficiency after surgery, consistent with irreversible medical renal disease.[100] In contrast, 94% of patients with a RI <0.8 showed improved BP and freedom from dialysis after reconstruction. The role of the RI in managing RVD is controversial, and we place little emphasis on RI in guiding treatment decisions.[104]

Computed Tomographic Angiography and Magnetic Resonance Angiography

Advances in speed, resolution, and postprocessing have contributed to the widespread application of computed tomographic angiography (CTA) for vascular imaging (see Chapter 27). Modern multichannel scanners provide precise three-dimensional visualization of vascular abnormalities not possible with digital subtraction angiography (DSA) alone.[106-109] CTA is noninvasive and widely available, and image acquisition and formatting are less technically demanding than for RDU or for contrast-enhanced magnetic resonance angiography (MRA) of the renal arteries. Disadvantages of CT include exposure to ionizing radiation and iodinated contrast. CTA delivers 87 to 260 times more radiation to the patient than a chest x-ray,[107] and a typical renal CTA uses 120 to 140 mL of contrast, often a problem given renal insufficiency in many patients being evaluated for RVD.[108,109] Studies comparing CTA with DSA report a sensitivity, specificity, and accuracy approaching 100% for defining significant lesions of the main renal artery (Table 125.4). CTA also provides detailed information about surrounding tissues and organs, such as kidney length and parenchymal thickness and quality of the adjacent aorta and visceral arteries. The latter

are helpful when planning surgery, identifying locations suitable for cross-clamping and inflow sources for bypass.

MRA has also proven useful for imaging RVD and has the advantages that it avoids ionizing radiation and iodinated contrast.[109-112] As with CTA, data sets can be extensively postprocessed and viewed from virtually any projection. Limitations include long scan times subject to motion artifact and a lower spatial resolution than for CTA or DSA. Patients can become claustrophobic in typical closed scanners and many have metal implants incompatible with the magnetic field.[111] Contemporary ceMRA protocols typically employ gadolinium contrast, which cannot be used in patients with significant renal impairment because of the risk for nephrogenic systemic fibrosis, a scleroderma-like syndrome most commonly affecting the extremities that may also involve the lung, diaphragm, esophagus, heart, and vasculature.[113-115] The pathogenesis is ill-defined, but most patients have end-stage renal disease, and a dose-effect is likely.[115] The Food and Drug Administration has issued a black-box warning to avoid the administration of gadolinium to patients with eGFR less than 30 unless it is absolutely necessary. If exposure is unavoidable, patients should be dialyzed immediately afterward, but this may not provide complete protection. When comparing MRA with DSA, accuracy in defining critical RAS is similar to CTA but MRA can overestimate degree of stenosis, although negative predictive value of a normal study is excellent (see Table 125.4).

Digital Subtraction Angiography

DSA remains the gold standard for renal imaging, providing lumen morphology in high resolution and allowing for endovascular treatment. DSA does not provide three-dimensional information on vessel wall structure or adjacent tissues and organs, as seen on axial imaging (Fig. 125.3), and image quality can be degraded by a number of patient factors, including obesity, bowel gas, heavy calcification, retained gastrointestinal contrast material, and movement (see Chapter 25). DSA is invasive, with risk of access site bleeding and other complications that are higher than generally appreciated (e.g., 13% in the roll-in phase of CORAL),[33] and it exposes patients to nephrotoxic contrast and patients and operators to heavy doses of ionizing radiation. DSA is also labor-intensive, requiring a team of trained specialists, and is expensive.

Given these issues, and noninvasive alternatives outlined previously, DSA is generally reserved for patients undergoing planned renal artery reconstruction (see Chapters 126 and 127). In this group, it is important to define accessory renal arteries, branch vessel disease, blood supply to the contralateral kidney, and status of the adjacent aorta and visceral vessels as potential inflow sources. In patients with renal insufficiency it is important to provide preprocedural hydration and strategies to limit volume of contrast, such as using carbon dioxide to reduce risk of contrast-induced nephropathy (Fig. 125.4; see Chapter 60).

Functional Studies

A pervasive problem in caring for patients with RVD has been a lack of practical screening tests to identify patients who respond to revascularization.[55,116] Each imaging modality described previously can detect anatomic RAS, but none can link a particular lesion to HTN or impaired renal function that will correct after revascularization. To address this, a number of adjuncts to imaging have been developed, including direct pullback pressure measurements to define gradients during DSA[33] and loss of kidney length on RDU[82,83] as a surrogate for ischemic nephropathy, indicating severe kidney hypoperfusion more likely to progress without intervention. Split renal function studies using radionuclide renography can screen for loss of excretory function ipsilateral to a RAS that can be compared with an opposite normal kidney in patients with unilateral disease. While each of these methods can help support or refute functional impact to a known RAS, none has proven reliable in identifying patients who respond to revascularization.[116] New

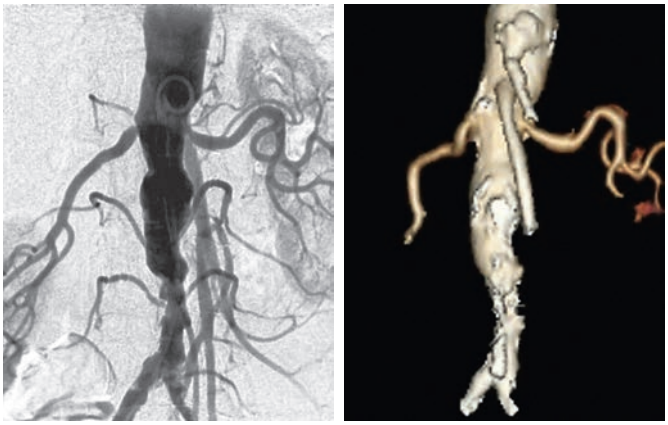

Figure 125.3 Comparison of digital subtraction angiography *(left)* and volume-rendered computed tomographic angiography *(right)* in a patient with bilateral proximal renal artery stenosis.

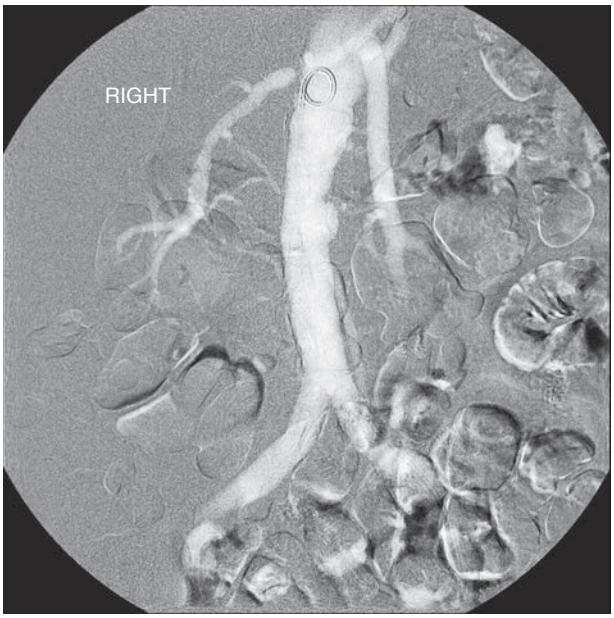

Figure 125.4 Strategies to limit exposure to nephrotoxic contrast material during renal angiography include the use of alternative contrast agents, such as carbon dioxide (shown) and gadolinium.

tools to define renal parenchymal ischemia are being tested but have yet to be validated for clinical decision-making.[53,54,116] Two older functional assays that have been studied extensively and remain in use in some centers today are captopril renography and selective renal vein renin sampling.

Radionuclide Renography

Split renal function can be measured by quantifying the uptake and excretion of radiolabeled molecules, such as technetium Tc 99m–labeled mercaptoacetyltriglycine.[117-120] Abnormal uptake and excretion by a kidney downstream of a RAS suggests a causal relationship, but renography is often normal in patients with RAS. In patients with unilateral RAS and renal insufficiency, a defect on renography is as likely to be in the contralateral kidney.[120]

ACE inhibitor renography, commonly called "captopril renography," uses pharmacologic inhibition of Ang II or its ATR1 receptor to unmask intrinsic renal compensation to RAS, creating a pressure drop that impacts glomerular filtration (see the Pathophysiology section noted previously). With unilateral critical RAS, the affected kidney will show an acute decline in excretion of the radiolabel after inhibiting Ang II with an ACE inhibitor or ARB.[117,118,120] The contralateral kidney may show enhanced excretory function after ACE inhibition, as efferent arteriolar dilatation leads to increased glomerular filtration in the setting of a normal perfusion pressure.[120]

In patients with unilateral RAS, ACE inhibitor renography may distinguish between renovascular and essential HTN, and thus identify patients more likely to benefit from revascularization.[118] A normal study effectively excludes renovascular HTN. The assay is inaccurate in patients with severe azotemia or small, poorly functioning kidneys. In these settings, an abnormal baseline renogram is less likely to change significantly with ACE inhibition, causing false-negative or indeterminate results. However, Erbsloh-Moller studied 20 azotemic patients with serum creatinine levels greater than 1.8 mg/dL (159 μmol/L) and reported that sensitivity and specificity of a positive study exceeded 90% in predicting BP response to revascularization.[120]

Renal Vein Renin Assays

Renovascular HTN is mediated by excess renin production. Thus documenting excess renin production by the affected kidney should support a functional link between RAS and HTN. Selective renal vein renin assays can be used for this purpose, but the complexity and invasive nature of the procedure limit its use as a screening tool. Renin levels can be altered by a number of variables unrelated to RAS, so careful patient preparation and standardization of the procedure are essential.

We start patients on a low-sodium diet and attempt to stop all antihypertensive medications except diuretics and calcium channel blockers 5 days before the assay. Furosemide (40 mg, PO) is given the evening before. The following morning patients are kept supine at strict bed rest 4 hours before and during the assay. Separate catheters are placed percutaneously under fluoroscopy into the inferior vena cava and each renal vein. A reference systemic sample is drawn from the cava, followed by simultaneous aspiration of right and left renal vein catheters. Sampling is repeated two or three times at 5-minute intervals and then a final systemic caval sample collected.

Reporting standards vary, but a ratio of renal vein renin to systemic renin of 1.5 times or higher is typically considered positive, linking RAS to excess renin production.[95,121] Lateralizing renins are generally informative, predicting a BP benefit from open revascularization,[95,121] but failure to lateralize has a low negative predictive value. The ratio for the opposite uninvolved kidney may be low because of compensatory suppression of renin release in response to HTN.[121]

Renin assays are of little use in patients with bilateral RAS, with solitary kidneys, or with RAS in accessory renal arteries. The value of renin ratios in predicting a positive response to revascularization in patients with ischemic nephropathy is also unclear. In these circumstances, decisions regarding intervention are left to clinical judgment factoring in degree of stenosis, severity of HTN, and trajectory of any decline in eGFR. Presently in our practice we only occasionally obtain renin assays, but they can be useful when making decisions about open revascularization in patients with unilateral RAS.

TREATMENT OF RENOVASCULAR HYPERTENSION

A diagnosis of RAS is associated with a high risk of cardiovascular morbidity and mortality[2,4]; significant risk of lesion progression and loss of kidney mass, particularly in cohorts with severe RAS and HTN (Table 125.5)[82,83]; and risk of progression to dialysis and death.[2,4,75] Despite these compelling statistics, the

benefits of renal revascularization have been challenged by better medical treatments,[97] an evolving experience with open renal revascularization,[20,21,122] and by a growing body of Level I data contesting the value of renal stenting for many patients with atherosclerotic RAS.[34] As a result, many centers are now appropriately limiting revascularization to patients with severe manifestations of atherosclerotic RAS and those with nonatherosclerotic RVD.

No large prospective randomized trials have compared open renal artery reconstruction to medical management, angioplasty, or stenting in patients with atherosclerotic RAS.[35-37] However, multiple randomized trials comparing renal artery stenting with medical management for atherosclerotic RAS and a meta-analysis summarizing these data,[34] including the recent CORAL trial,[33] have concluded that stenting provides no advantages over medical treatment alone (Fig. 125.5). The strengths and weaknesses of these studies are discussed in detail in Chapter 127. However, it is worth pointing out that patient demographics in ASTRAL[32] and CORAL[33] differ substantially from the average patient undergoing revascularization at our center.[21,22] Consider the baseline systolic BP in CORAL, which was only 150 mm Hg, and for ASTRAL mean BP was only 149/76 or 152/76 for the stent and control groups, respectively.[32,33] The number of antihypertensive medications taken by patients to achieve these values averaged 2.1 and 2.8 in CORAL and ASTRAL, respectively.[32,33] Contrast these values with baseline BP in 500 patients undergoing open repair of atherosclerotic RAS at our center that averaged 200/104 mm Hg on a mean of 2.6 antihypertensive medications. These differences suggest major variation in criteria used to select patients for revascularization, and we would argue that we could have predicted that many of the patients enrolled in these trials would not have shown a response to stenting.

Despite these criticisms, we agree that most patients with RVD can be approached conservatively. Interventions should be reserved for those with severe disease that fails to respond to aggressive medical therapy, or patients with nonatherosclerotic RVD. Clearly, the days of "drive-by" or "prophylactic" renal stenting in patients with atherosclerotic RVD are over.

Medical Management of Atherosclerotic Renovascular Disease

Mounting Level I data from randomized trials support a recommendation that most patients with atherosclerotic RAS should receive medical therapy without intervention.[34,97,116,122-124] Risk factors for atherosclerosis and renal impairment should be aggressively controlled.[33,97,122-124] Patients should be provided resources to help promote healthy lifestyles, including smoking cessation, regular exercise, and appropriate nutrition. Lipid levels should be monitored, and if high, lowered to accepted targets for secondary prevention in cardiovascular disease (e.g., LDL <100 mg/dL).[124] Patients should receive antiplatelet and statin therapy regardless of baseline lipid levels, unless there is a specific contraindication.[124] Statins may reduce progression of RAS[125] and inhibit restenosis after renal stenting,[126] and they clearly protect from cardiovascular morbidity and mortality in patients with established atherosclerosis. The protocol for medical treatment in CORAL included statin therapy adjusted to achieve these targets,[33] which along with aggressive protocol-driven BP treatment likely contributed to low rates of RVD progression, cardiovascular events, and death.

As mentioned previously, renal dysfunction in RVD patients is often multifactorial, given the overlap in risk factors for medical renal disease and atherosclerosis. Renal function should be monitored regularly, and patients with abnormal eGFR should be evaluated for common causes of chronic kidney disease and treatment tailored to limit further injury, generally in concert with a nephrologist. Individuals with a BMI >25 should be encouraged to lose weight, and those with diabetes should carefully manage glucose.

In centers experienced with RDU, patients with RAS and those with prior renal revascularization should be studied annually to assess patency and kidney length, particularly after stenting, given high rates of restenosis.[29,33] RDU should also be considered for sudden worsening of HTN or renal impairment to assess for progression.[127]

HTN should be treated aggressively, and BP goals for adults with RVD are the same as for essential HTN. Current consensus recommendations in the United States[97] and Canada[123] include a systolic BP of <140 mm Hg and diastolic BP <90 mm Hg. These targets drop to <130/80 for patients with concomitant diabetes or renal insufficiency.[97,123] Hypertensive patients should avoid excessive salt intake, limit alcohol consumption, reduce stress, and get regular exercise.

Renovascular HTN typically requires multiple classes of antihypertensive medications to achieve BP goals, and a number of individuals will never reach consistent control without revascularization.[21] There are no large randomized trials comparing efficacy of different combinations of antihypertensive medications in RAS, but given the central role of the RAAS, ACE inhibitors and ARBs should be among first-line choices.[97,123] The safety of these agents in RVD has been demonstrated in a number of studies, including CORAL,[33] but when initiating treatment in patients with bilateral RAS or solitary kidneys, the creatinine should be monitored for a sudden decline in eGFR. If this occurs, the offending medication should be promptly discontinued and renal function typically returns to baseline.[92,93] Other first-line agents for treating renovascular HTN include thiazide diuretics, calcium channel blockers (dihydropyridines; e.g., amlodipine), and beta blockers.[97,123] Diuretics are often helpful in RVD because of associated volume excess, particularly in patients with bilateral lesions, but patients should be monitored to avoid hypokalemia. Spironolactone should be used with caution with ACE inhibitors or in the setting of impaired renal function to avoid hyperkalemia. In patients intolerant or refractory to first-line agents, second-tier agents can be considered with caution (e.g., hydralazine, clonidine, etc.).[97,123]

Renal Revascularization

When an intervention is deemed appropriate, the approach should be tailored to the patient's anatomy and clinical status with consideration to local expertise, as described in Chapter 126 and Chapter 127. Fewer open surgical procedures are being

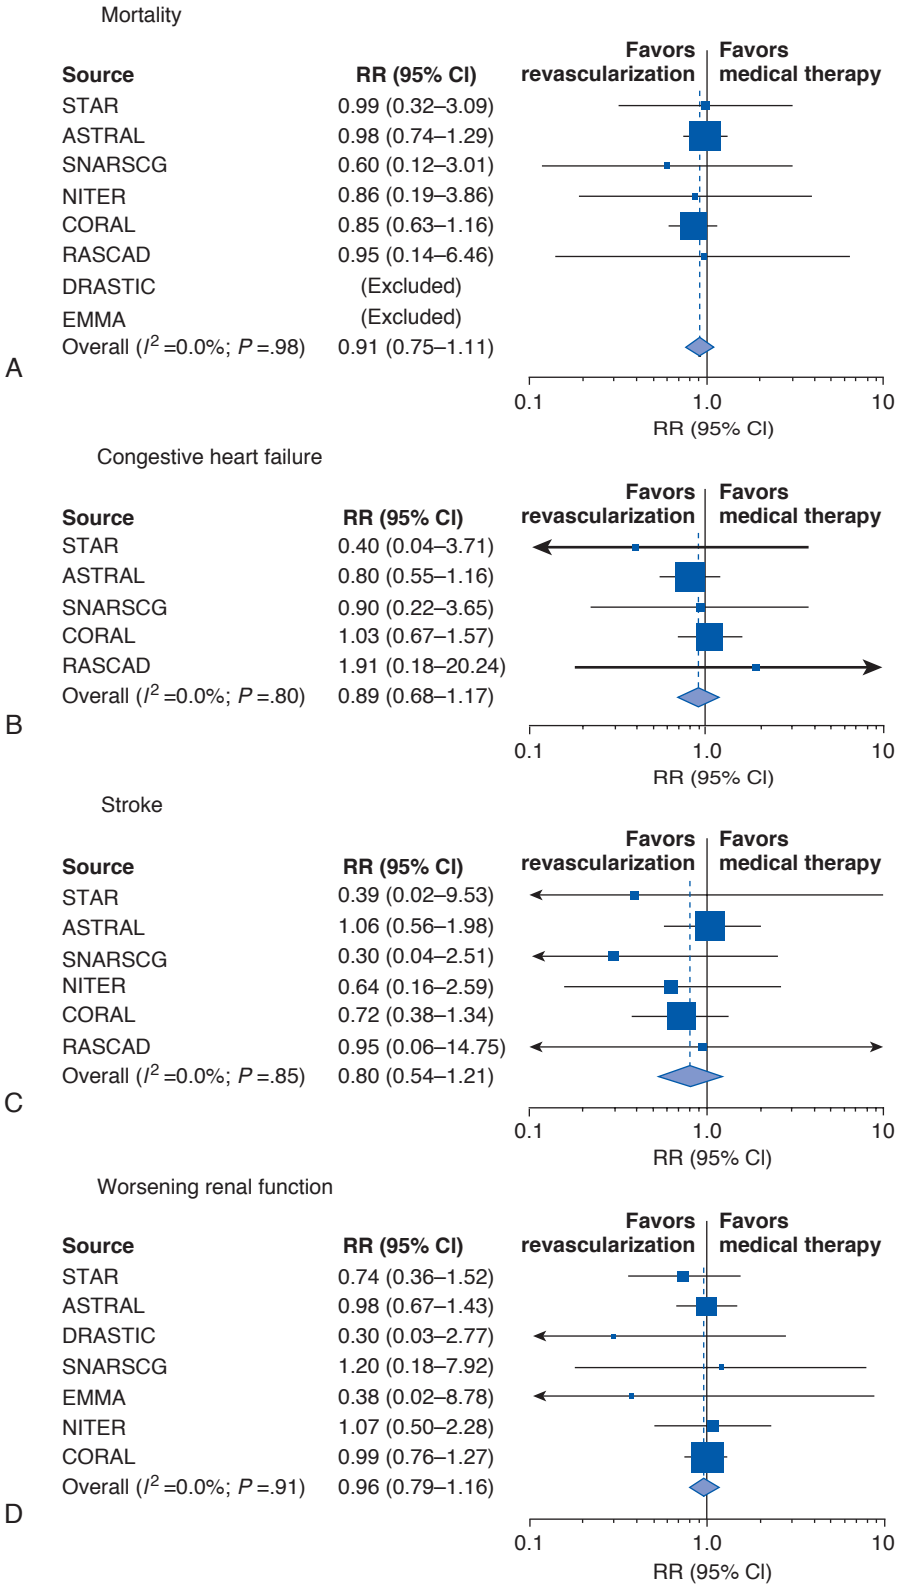

Figure 125.5 Histogram summarizing data from randomized trials of renal revascularization.

performed for symptomatic RAS because of a better understanding of the natural history of RAS without intervention, the availability of less invasive alternatives, refinements in patient selection,[21,22,116] and improved outcomes with medical management.[33,34] Results from prospective series by our group and others have helped shift the focus of surgery in RVD away from BP control to preservation of excretory renal function.[22] We consider open repair in good-risk patients with bilateral RAS or branch vessel disease who have failed to respond to medical treatment and for children with developmental RVD. Other

select populations in which the risks of open repair are justified are discussed in detail in Chapter 126. Open repair of atherosclerotic RAS is much more durable than stenting, with patency rates well over 90% on long-term follow-up, but carries a higher mortality.[21,22,128-130] Restenosis rates for stenting have declined over time, but in recent prospective trials were still >10%.[33,34] BP responses vary in the literature, but in our experience 85% of patients with successful open repair of all hemodynamically significant renal lesions improve or are cured of HTN,[21,22] which is much higher than for our results with stenting.[130,131]

At Wake Forest we reserve renal artery stenting or open renal revascularization in atherosclerotic RAS for patients that have failed aggressive medical management with severe refractory HTN; those with a recent significant decline in eGFR without another explanation with concomitant severe HTN, particularly when RAS is bilateral; and those with hypertensive crises precipitating cardiopulmonary or neurologic embarrassment (e.g., flash pulmonary edema).[97,116] Our threshold for renal revascularization is much lower for children with severe RVD[8,9,132] (see Chapter 130) and for adults with FMD complicated by severe HTN.[6,133]

Consequence of Failed Open Renal Artery Repair 1685

Following Goldblatt's innovative work defining the causal relationship between renovascular disease and hypertension in 1934,[1] the surgical management of renovascular disease evolved through three eras; nephrectomy, open surgical correction, and finally renal artery angioplasty with or without stenting (Fig. 126.1). Each era was met with initial enthusiasm, which was soon tempered by the modest results of each treatment. Nephrectomy is now rarely indicated in the management of renovascular disease, and recent randomized clinical trials comparing renal artery stenting with best medical management have demonstrated no advantage of catheter-based intervention (see Chapter 127). This chapter reviews patient selection for open repair of renovascular disease and then describes specific surgical approaches and their expected outcomes in contemporary practice.

INDICATIONS FOR SURGICAL REPAIR

The rationale for the treatment of renovascular disease by any method is to improve event-free survival. Our experience with 500 consecutive patients treated for atherosclerotic renovascular disease suggests that severe hypertension can be viewed as a key preoperative characteristic favoring clinical benefit, whereas renal function after operation can be considered the key clinical response.[2] An early incremental increase in excretory renal function has been the primary determinant of dialysis-free survival for all atherosclerotic patients.[3,4]

Unfortunately, once renovascular disease is identified in combination with severe hypertension, discriminating predictors of blood pressure and renal function response are lacking. Lateralizing renin assays have predicted blood pressure benefit but not blood pressure cure.[5,6] Moreover, renal function response in patients with ischemic nephropathy is uncertain after renal artery intervention.[4] Studies have also described a significant correlation between parameters derived from segmental renal artery Doppler spectral analysis (i.e., resistive index) and response to intervention as well as progression to dialysis dependence.[7,8] However, we have not been able to reproduce these results for open operative management of renal artery disease.[9] Rather, in

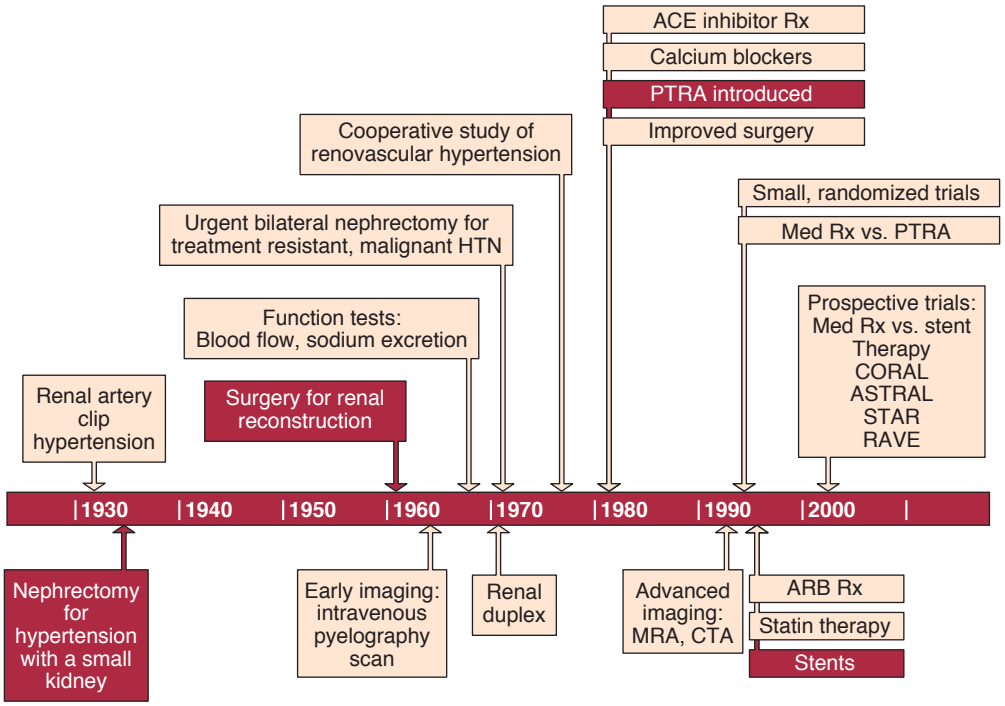

Figure 126.1 Time line showing evolution of the surgical management of renovascular disease through three eras. *ACE,* angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *CTA,* computed tomographic angiography; *HTN,* hypertension; *MRA,* magnetic resonance angiography; *PTRA,* percutaneous transluminal renal angioplasty; *Rx,* therapy.

our clinical experience with more than 1000 patients with atherosclerotic renal artery disease submitted to open operative repair, factors favoring the recovery of renal function after operation have included severe preoperative hypertension, bilateral or global atherosclerotic renovascular disease due to high-grade (>90%) stenosis or renal artery occlusion, and rapidly deteriorating renal function before surgery.[4,6,10-13] When each of these favorable features was expressed in patients considered permanently dialysis dependent, 70% of those submitted to open operative repair were permanently removed from dialysis.[4,13]

The quality of studies designed to define the natural history of the atherosclerotic renal artery has varied widely.[10,14-23] Most commonly authors have considered anatomic progression of atherosclerotic renovascular disease a certainty, one associated with an inevitable decline in kidney size and kidney function. This view has been cited to support intervention for renal artery disease whenever it is discovered, even in the absence of hypertension or renal insufficiency.

On the basis of a recent prospective, population-based study of progression of atherosclerotic renovascular disease in the elderly, we do not favor "prophylactic" intervention for asymptomatic renovascular disease.[24] This longitudinal cohort study included 119 Cardiovascular Health Study participants, with 235 kidneys for study, and no kidney progressed to a renal artery occlusion during a mean follow-up of 8.5 years. Among participants with mild to moderate hypertension in the Cardiovascular Health Study, progression to hemodynamically significant renal artery stenosis was observed in only 4%, or an annualized rate of 0.5% per year.[24]

When a patient has bilateral renal artery stenosis and severe hypertension, the decision for empiric open renal reconstruction is based on the severity of the hypertension and the renal artery lesions. When disease consists of severe stenosis of one renal artery and only mild to moderate contralateral disease, it is treated as a unilateral lesion. If both renal artery lesions are moderately severe (60%-80% diameter-reducing stenosis), revascularization is undertaken only if associated hypertension is severe. In contrast, if both renal artery lesions are severe (>80% stenosis) and the patient has severe hypertension, bilateral simultaneous renal revascularization is performed, especially when excretory renal insufficiency is present. However, because the degree of azotemia usually parallels the severity of hypertension, a patient who presents with severe excretory renal insufficiency but only mild hypertension usually has concomitant renal parenchymal disease from another cause (e.g., diabetes). Characteristically, renovascular disease contributing to severe azotemia or dialysis dependence is associated with severe hypertension and severe bilateral stenosis or renal artery occlusion.[3,4,10,13]

Open Operative Strategy

The presence of severe hypertension is considered a prerequisite for renal artery intervention, and functional studies are used to guide the management of unilateral lesions. Empiric renal artery repair is performed without functional studies when hypertension is severe, renal artery disease is bilateral, or the patient has ischemic nephropathy.[3,6,25] Prophylactic renal artery

repair in the absence of hypertension, whether as an isolated procedure or in combination with aortic reconstruction, is not recommended. During surgical reconstruction, all hemodynamically significant renal artery disease is corrected in a single operation with the exception of disease requiring bilateral ex vivo reconstructions, which are staged. Nephrectomy is reserved for a nonfunctioning kidney (i.e., ≤10% function by renography) with unreconstructable renal artery disease.[4,10,18] Direct aortorenal reconstructions are preferred to indirect methods because concomitant disease of the celiac axis is present in 40% to 50% of patients and bilateral repair is required in half.[4,6] Failed renal artery repair is also associated with a significantly increased risk of dialysis dependence.[25] To minimize these failures, intraoperative duplex ultrasonography is used to evaluate the technical results of surgical repair before closure.[26]

Our experience with percutaneous management as a substitute for open operative repair has demonstrated only modest hypertension and renal function response.[27-29] Consequently we continue to advocate open operative repair for select patients. These include children with hypoplastic lesions,[30] adults with dysplastic lesions other than medial fibroplasia, and patients with medial fibroplasia involving branch and segmental renal arteries complicated by a renal artery aneurysm.[31] We advocate open operative repair for atherosclerotic renovascular disease in good-risk patients, younger than 65 years of age, who demonstrate global renal ischemia manifested by critical renal artery stenosis or occlusion, especially when severe hypertension is associated with excretory renal insufficiency and rapidly deteriorating excretory function.[3,4,13] Selection criteria for the repair of renal artery aneurysms are discussed in Chapter 128, but we have continued to favor open operative repair as opposed to coiling, stenting, or stent-grafting of these lesions.[31]

MANAGEMENT OPTIONS

Certain measures are used in almost all open renal artery operations. Mannitol is administered intravenously in 12.5-g doses early in the operation during aortic and renal artery dissection. Repeated doses are administered before and after periods of renal ischemia, up to a total dose of 1 g/kg of patient body weight. Just before renal artery cross-clamping, 100 U/kg of heparin is given intravenously, and systemic anticoagulation is verified by activated clotting time. Unless it is required for hemostasis, protamine is not routinely administered for reversal of heparin at completion of the operation.

Mobilization and Dissection (see Chapter 58)

Midline Exposure

A midline abdominal incision is made for operative repair of atherosclerotic renal artery disease when bilateral renal artery repair or combined aortic and renal repair is planned. The patient is positioned supine with the umbilicus at the level of the table break, with the operating table flexed 10 to 15 degrees. To obtain full exposure of the upper abdominal aorta and renal branches, it is important that the last 1 or 2 cm of the proximal incision be made coursing to one side of the xiphoid (Fig. 126.2A). Some type of fixed mechanical retraction is also advantageous, particularly when combined aortic and renal procedures are required. Otherwise, extended flank and subcostal incisions are reserved for correction of unilateral branch renal artery lesions or splanchnic-renal bypass.

When the midline xiphoid-to-pubis incision is used, the posterior peritoneum overlying the aorta is incised longitudinally and the duodenum mobilized at the ligament of Treitz (see Fig. 126.2B). During this maneuver, it is important to identify and spare the meandering mesenteric vessel that may be found at this level. Finally, the duodenum is reflected to the patient's right to expose the left renal vein. By extending the posterior peritoneal incision to the left along the inferior border of the pancreas, an avascular plane posterior to the pancreas can be entered (see Fig. 126.2B) to expose the entire left renal hilum. This exposure is of special importance when there are distal renal artery lesions to be managed (Fig. 126.3A). The left renal artery lies posterior to the left renal vein. In some cases, the

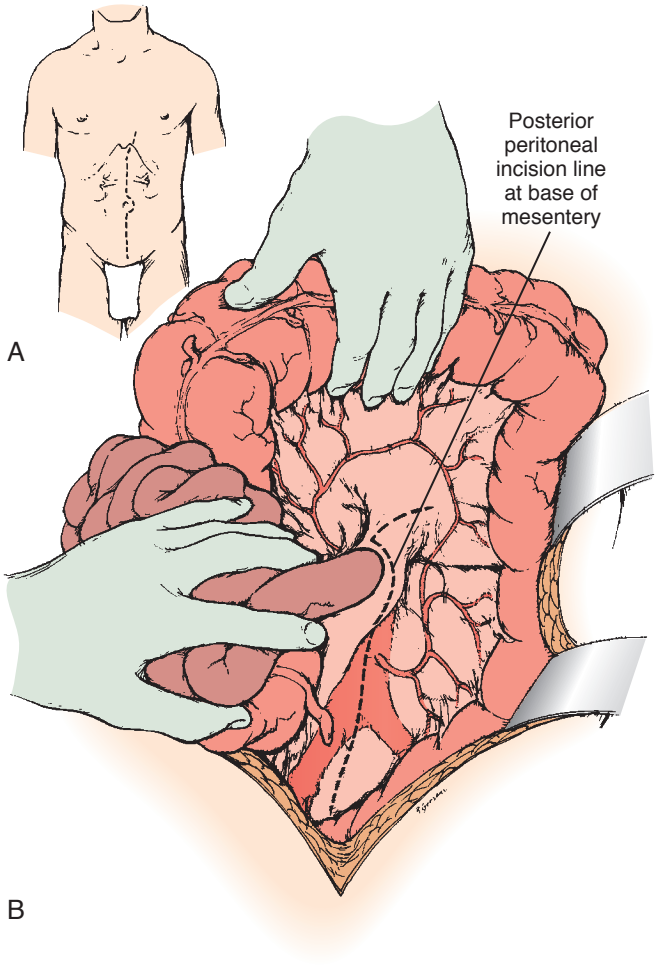

Figure 126.2 (**A** and **B**) Exposure of the aorta and left renal hilum through the base of the mesentery. Extension of the posterior peritoneal incision to the left, along the inferior border of the pancreas, provides entry to an avascular plane posterior to the pancreas. This allows excellent exposure of the entire left renal vein and hilum as well as of the proximal right renal artery. (From Benjamin ME, Dean RH. Techniques in renal artery reconstruction: part I. *Ann Vasc Surg.* 1996;10:306–314.)

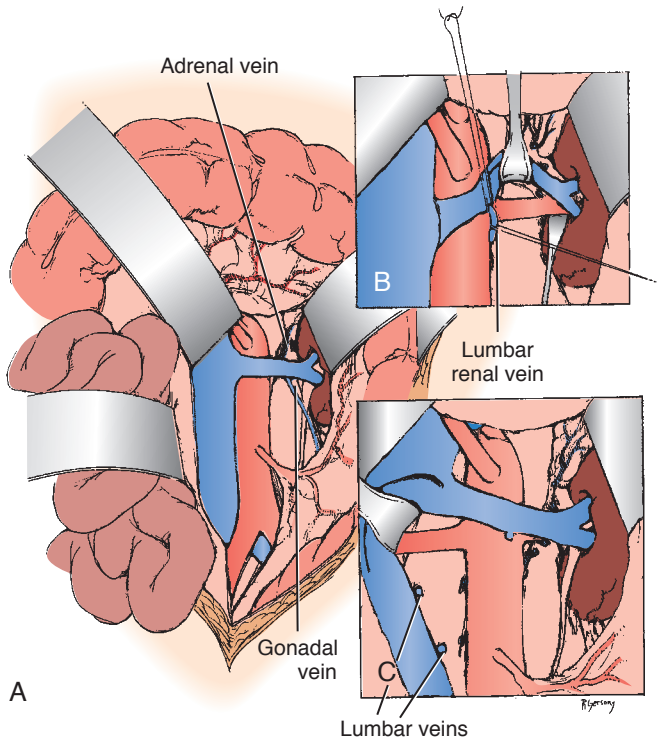

Figure 126.3 **(A)** Exposure of the proximal right renal artery through the base of the mesentery. **(B)** Mobilization of the left renal vein by ligation and division of the adrenal, gonadal, and lumbar-renal veins allows exposure of the entire left renal artery to the hilum. **(C)** On occasion, lumbar veins are ligated and divided to allow retraction of the vena cava to the right. Often, adequate exposure of disease of the proximal renal artery can be obtained without this maneuver. (From Benjamin ME, Dean RH. Techniques in renal artery reconstruction: part I. *Ann Vasc Surg*. 1996;10:306–314.)

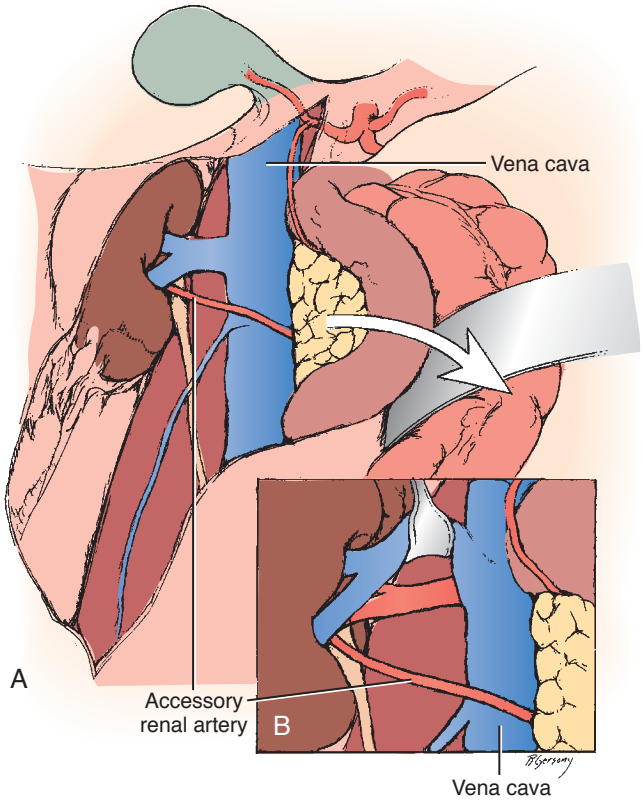

Figure 126.4 **(A)** Arteries encountered anterior to the vena cava should be considered accessory renal arteries and preserved. **(B)** The right renal vein is typically mobilized superiorly for exposure of the distal right renal artery. (From Benjamin ME, Dean RH. Techniques in renal artery reconstruction: part I. *Ann Vasc Surg*. 1996;10:306–314.)

vein can be retracted cephalad to expose the artery; in other cases, caudal retraction of the vein provides better access. Usually, the gonadal and adrenal veins, which enter the left renal vein, must be ligated and divided to facilitate exposure of the distal artery. Frequently, a lumbar vein enters the posterior wall of the left renal vein; it can easily be injured unless special care is taken (see Fig. 126.3B). For full mobilization of the left renal vein, ligation and division of the lumbar branch is also required. The proximal portion of the right renal artery can be exposed through the base of the mesentery by retracting the left renal vein cephalad and the vena cava to the patient's right (see Fig. 126.3C). However, mobilizing the duodenum and right colon medially best exposes the distal portion of the right renal artery; the right renal vein is mobilized and usually retracted cephalad to expose the artery.

Flank Exposure

When a branch renal artery repair is required, especially when ex vivo technique is used or when the supraceliac aorta is used as an inflow source for aortorenal bypass, an extended flank incision is useful. With the ipsilateral flank bumped, the incision extends from the opposite semilunar line into the flank, bisecting the abdominal wall between the costal margin and iliac crest. A left or right visceral mobilization allows access to the renal vasculature and the aortic crus. The crus can be divided, and an extrapleural dissection of the descending thoracic aorta can provide access to the T9–10 thoracic aorta for proximal control and anastomosis.[32,33]

Whether right or left branch renal artery exposure is required, the key is creation of the correct dissection plane between the mesentery anteriorly and Gerota's fascia posteriorly. The renal vein is identified first and mobilized from caval origin to renal hilum. On the right, small venous branches at the junction with the vena cava require ligation. The adrenal, gonadal, and lumbar branches on the left may be sacrificed to facilitate exposure.

Branch renal artery exposure on the right is achieved by colonic and duodenal mobilization. First, the hepatic flexure is mobilized at the peritoneal reflection (Fig. 126.4). With the right colon retracted medially and inferiorly, a Kocher maneuver mobilizes the duodenum and pancreatic head to expose the inferior vena cava and right renal vein (see Fig. 126.4A). Typically, the right renal artery is located just inferior to the accompanying vein, which can be retracted superiorly to provide the best exposure. Although accessory vessels may arise from the aorta or iliac vessels at any level, all arterial branches coursing anterior to the vena cava should be considered accessory right renal branches and carefully preserved (see Fig. 126.4B).

DIRECT SURGICAL TECHNIQUES

A variety of open operative techniques have been used to correct renal artery disease, but three basic operations have been used most frequently: aortorenal bypass, renal artery thromboendarterectomy, and renal artery reimplantation. No single approach provides optimal repair for all types of renovascular lesions in all patients. Aortorenal bypass using saphenous vein is probably the most versatile technique; however, transaortic thromboendarterectomy is especially useful for orificial atherosclerosis involving multiple renal arteries. On occasion, the renal artery will demonstrate sufficient redundancy to allow reimplantation; this is probably the simplest technique and one that is particularly appropriate to hypoplastic renal artery lesions in children.[29,30]

Aortorenal Bypass

Three types of materials are available for aortorenal bypass: autologous saphenous vein, autologous hypogastric artery, and synthetic graft. The decision as to which graft should be used depends on a number of factors. In most instances, the authors prefer the saphenous vein for older adults. However, if the vein is small (<4 mm in diameter) or sclerotic, the hypogastric artery or a synthetic graft may be preferable. In addition, vein enlargement can be anticipated in virtually all young adults. Although structural immaturity has been cited[30] for enlargement and aneurysmal degeneration when saphenous vein is used for renal artery reconstruction in children, the normal renal blood flow in the young resembles that of an arteriovenous fistula with continuous forward flow. This fact alone may account for vein enlargement in the young patient with normal renovascular resistance. In lieu of vein, a 6-mm thin-wall polytetrafluoroethylene (PTFE) graft is satisfactory when the distal renal artery is of sufficient caliber (≥4 mm). Hypogastric artery autograft is preferred for aortorenal bypass in children when reimplantation is not possible.[27,30,34,35]

End-to-side distal anastomoses are occasionally used to include polar renal arteries. In this instance, an end-to-side anastomosis between the polar renal artery and the graft is performed after the proximal aortic anastomosis. After the end-to-side anastomosis has been completed, the most distal main renal artery reconstruction is made in an end-to-end fashion (Fig. 126.5).

In creating the distal anastomosis, the length of the arteriotomy should be at least three times the diameter of the renal artery so as to guard against late suture-line stenosis. An anastomosis with 7-0 monofilament polypropylene as a continuous suture is created with loupe magnification. Just before completion of the renal artery anastomosis, the occluding clamps are temporarily removed to flush air and small debris. When renal artery bypass can be accomplished rapidly enough so that cold perfusion preservation is not required, the aortic anastomosis is performed first, removing an ellipse of the anterolateral aortic wall. This is especially important when the aorta is relatively inflexible because of atherosclerotic involvement. A 4.0-mm aortic punch applied two or three times creates a satisfactory ellipse in most instances. In combined aortorenal reconstructions, the proximal anastomosis is performed first with a thin-wall 6-mm PTFE graft for renal artery bypass attached in end-to-side fashion to the larger polyester aortic graft. The distal aortic reconstruction is completed, and the distal renal anastomosis is created as the last step.

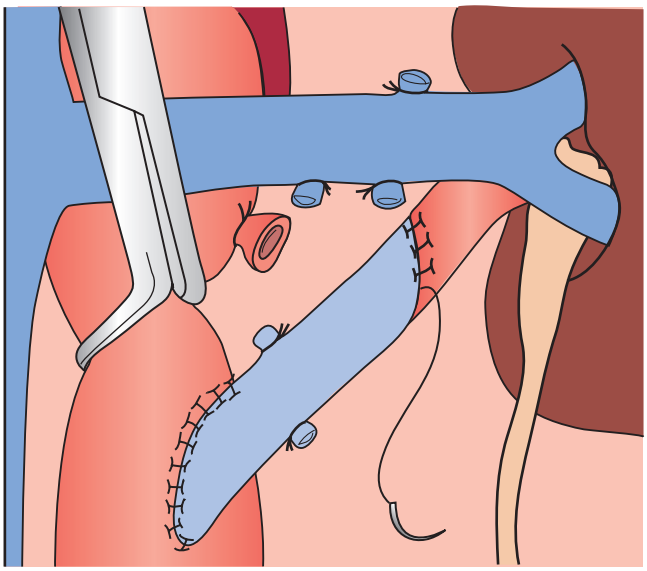

Figure 126.5 Technique for end-to-end aortorenal bypass grafting. The length of arteriotomy is at least three times the diameter of the artery so as to prevent recurrent anastomotic stenosis. For the anastomosis, 6-0 or 7-0 monofilament polypropylene sutures are used in continuous fashion with loupe magnification. If the apex sutures are placed too deeply or with excess advancement, stenosis can be created, posing a risk of late graft thrombosis. (From Benjamin ME, Dean RH. Techniques in renal artery reconstruction: part I. *Ann Vasc Surg*. 1996;10: 306–314.)

Thromboendarterectomy

In cases of ostial atherosclerosis of both renal artery origins, simultaneous bilateral endarterectomy may be the most suitable procedure. Endarterectomy may be either transaortic or transrenal.

For the majority of renal endarterectomies, the transaortic technique is used.[3] This method is particularly applicable in patients with multiple renal arteries that demonstrate ostial disease. In this instance, all visible and palpable renal artery atheromas should end within 1 cm of their aortic origin. Transaortic endarterectomy is performed through a longitudinal aortotomy with sleeve endarterectomy of the aorta and eversion endarterectomy of the renal arteries (Fig. 126.6). The aortotomy is closed with 5-0 polypropylene as a continuous suture. When combined aortic replacement is planned, the transaortic endarterectomy is performed through the transected aorta. Whether a longitudinal aortotomy is used or an endarterectomy is performed through the divided aorta, it is important to mobilize the renal arteries extensively to allow eversion of the artery into the aorta. This allows the distal endpoint to be completed under direct vision. When the aortic atheroma is divided flush with the adventitia by the use of scissors, tacking sutures are not usually required.

As is the case for thromboendarterectomy at all sites, the procedure is contraindicated by the presence of preaneurysmal degeneration of the aorta and transmural calcification. Transmural calcification can be subtle and may be missed unless careful attention is given to gentle palpation of the aorta. Aortic atheroma complicated by transmural calcification resembles fine-grade sandpaper on palpation of the outer surface of the aorta. Endarterectomy in this setting is characterized by numerous sites of punctate bleeding after blood flow is restored.

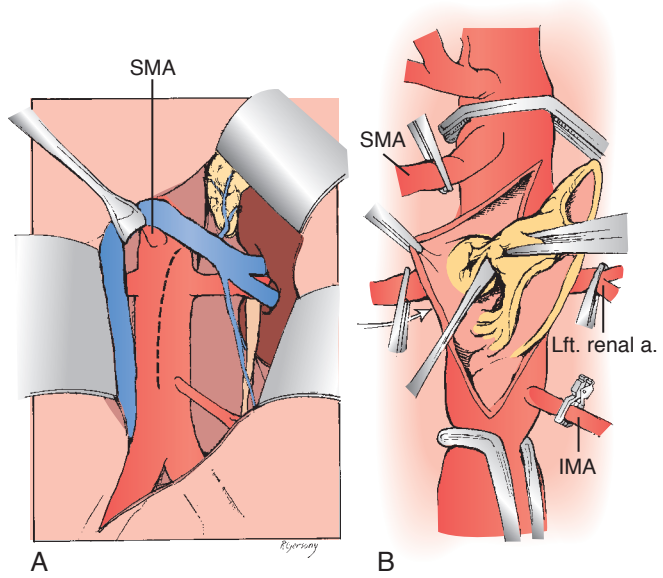

Figure 126.6 Exposure for a longitudinal transaortic endarterectomy is made by the standard transperitoneal approach. The duodenum is mobilized at the ligament of Treitz in standard fashion, or for more complete exposure, the ascending colon and small bowel are mobilized. **(A)** The dotted line shows the location of the aortotomy. **(B)** The plaque is transected sharply, and with eversion of the renal arteries, the atherosclerotic plaque is removed from each renal ostium. The aortotomy is typically closed with a running 4-0 or 5-0 polypropylene suture. *IMA,* inferior mesenteric artery; *SMA,* superior mesenteric artery. (From Benjamin ME, Dean RH. Techniques in renal artery reconstruction: part I. *Ann Vasc Surg*. 1996;10:306–314.)

Reimplantation

After the renal artery has been dissected from the surrounding retroperitoneal tissue, the vessel may be somewhat redundant. When the renal artery stenosis is orificial and there is sufficient vessel length, the renal artery can be transected and reimplanted onto the aorta at a slightly lower level. The renal artery must be spatulated and a portion of the aortic wall removed, as in renal artery bypass (Fig. 126.7). This technique has particular application to children with orificial lesions, avoiding the need for graft material[30]; however, it is suitable for selected atherosclerotic lesions as well.[36] Unlike prosthetic bypass performed during combined aortic replacement in adults, anastomosis from the renal artery to the graft is usually performed immediately after the proximal aortic anastomosis, followed by distal aortic reconstruction.

INDIRECT SURGICAL TECHNIQUES

Splanchnic-Renal Bypass

Splanchnic-renal bypass and other indirect revascularization procedures have received increased attention as alternative methods for renal revascularization.[37] The authors do not believe that these procedures demonstrate durability equivalent to that of direct aortorenal reconstructions, but they are useful in a highly select subgroup of high-risk patients.[3,38]

Hepatorenal Bypass

A right subcostal incision is used to perform hepatorenal bypass.[37] The lesser omentum is incised to expose the hepatic artery both

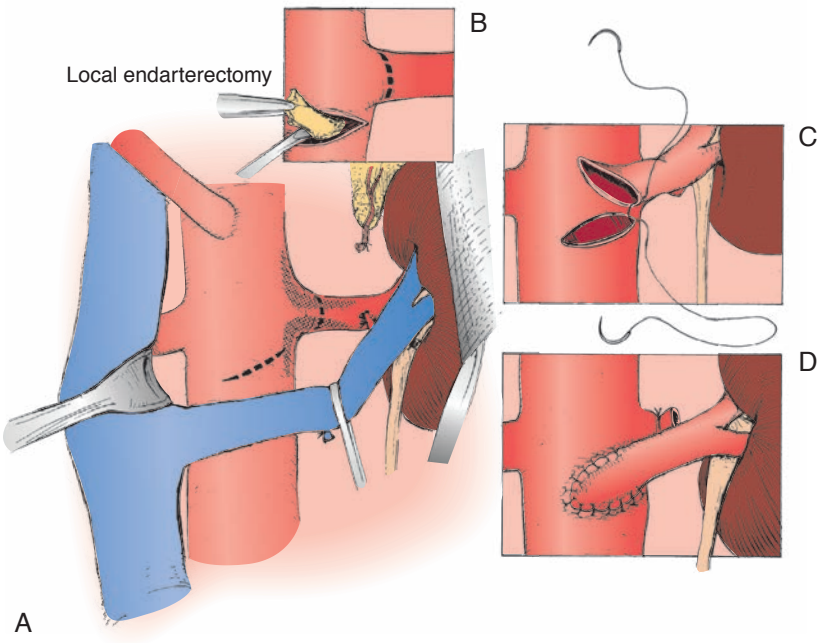

Figure 126.7 When the renal artery is redundant, the vessel can be reimplanted at a lower level **(A)**. Local endarterectomy **(B)** allows placement of the monofilament suture in the aortic wall **(C)**. The native renal artery is then ligated, proximally spatulated, and reimplanted **(D)**. (From Benjamin ME, Dean RH. Techniques in renal artery reconstruction: part II. *Ann Vasc Surg*. 1996;10:409–414.)

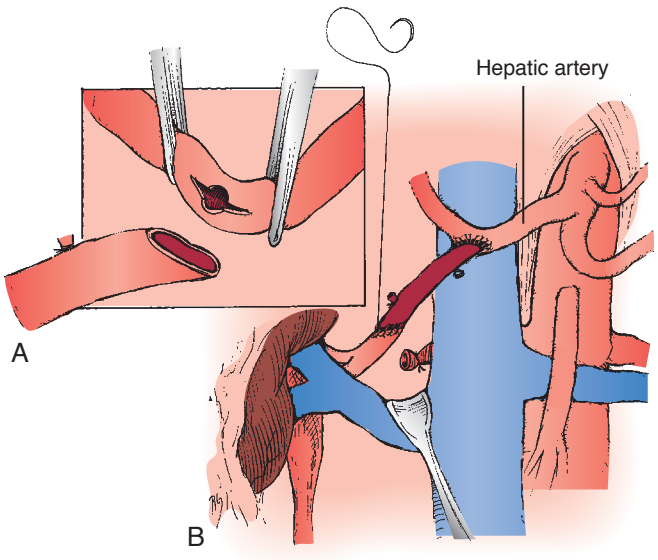

Figure 126.8 The reconstruction is completed with a saphenous vein interposition graft between the side of the hepatic artery **(A)** and the distal end of the transected right renal artery anterior to the vena cava **(B)**. (From Benjamin ME, Dean RH. Techniques in renal artery reconstruction: part II. *Ann Vasc Surg*. 1996;10:409–414.)

proximal and distal to the gastroduodenal artery (Fig. 126.8). Next, the descending duodenum is mobilized by a Kocher maneuver, the inferior vena cava is identified, the right renal vein is identified, and the right renal artery is exposed either immediately cephalad or caudad to the renal vein.

A greater saphenous vein graft is usually used to construct the bypass. The hepatic artery anastomosis of the vein graft can be placed at the site of the amputated stump of the gastroduodenal artery (see Fig. 126.8A). However, this vessel may serve as an important collateral for intestinal perfusion. Therefore the proximal anastomosis is usually made to the common hepatic artery, routing the graft through the foramen of Winslow. The renal artery is then transected and brought anterior to the vena cava for anastomosis end to end to the graft (see Fig. 126.8B).

Splenorenal Bypass

Splenorenal bypass can be performed through a midline or a left subcostal incision.[37,38] The posterior pancreas is mobilized by reflecting the inferior border cephalad. A retropancreatic plane is developed and the splenic artery mobilized from the left gastroepiploic artery to the level of its branches. The left renal artery is exposed cephalad to the left renal vein after division of the adrenal vein. After the splenic artery has been mobilized, it may be divided distally, spatulated, and anastomosed end to end to the transected renal artery (Fig. 126.9). Alternatively, a segment of saphenous vein may be used as a bypass.

Ex Vivo Reconstruction

Because of the widespread use of percutaneous techniques for main renal artery diseases, a significant proportion of open renal artery reconstructions require branch exposure and branch reconstruction. These procedures may require a complex repair,

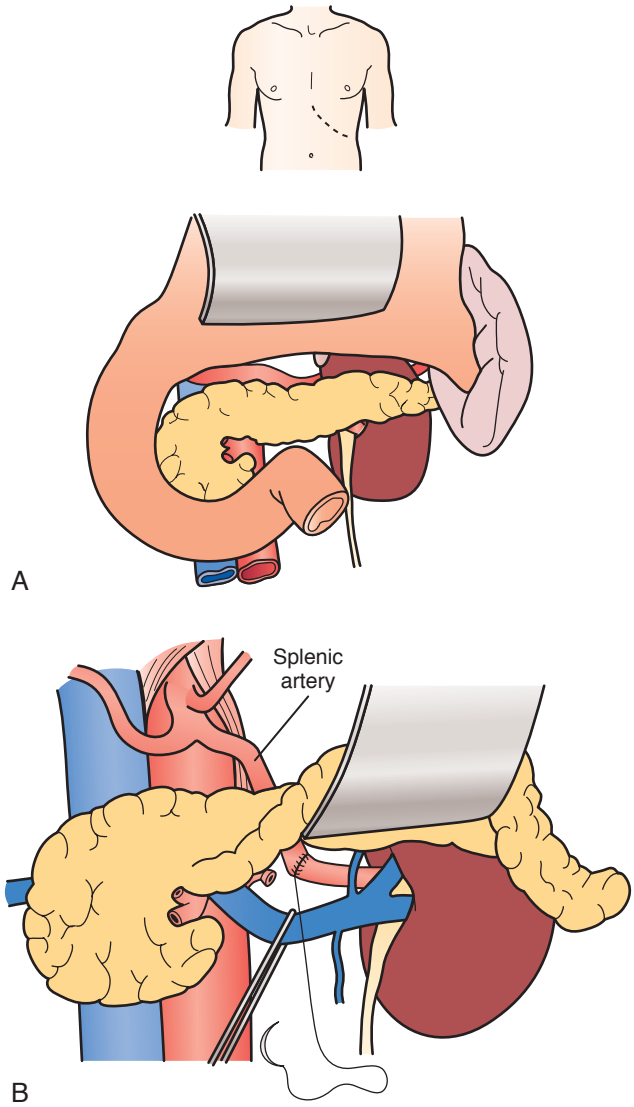

Figure 126.9 Exposure of the left renal hilum in preparation for splenorenal bypass **(A)**. The pancreas has been mobilized along its inferior margin and retracted superiorly **(B)**. The transected splenic artery may be anastomosed end to end to the transected left renal artery. A splenectomy is not routinely performed. (From Benjamin ME, Dean RH. Techniques in renal artery reconstruction: part II. *Ann Vasc Surg*. 1996;10:409–414.)

culminating in prolonged renal ischemia. Available data suggest that when more than 40 minutes of warm renal ischemia is required for renal revascularization, measures to protect renal function should be instituted.[39-42]

Several pharmacologic therapies have been promoted to provide protection during renal ischemia; however, no therapy to date has surpassed hypothermia for protection when renal ischemia exceeds 1 hour.[41,43-46] Surface cooling and hypothermic perfusion have been proposed, but the advantages of each are not well defined. Renal tolerance to ischemia is, in part, related to the duration of ischemia, the adequacy of collateral circulation, and the method of vascular control. Unprotected warm renal ischemia is best tolerated when only the renal artery is controlled.[41] In a similar manner, intermittent renal perfusion is associated with greater dysfunction than is isolated arterial control.[9]

Numerous methods for renal cooling and hypothermia during branch renal artery repair have been described. Our preference has been intermittent hypothermic perfusion and topical ice slush. Otherwise, several steps are common to each branch renal artery reconstruction. To promote renocortical perfusion, small doses of mannitol are administered intravenously throughout renal artery exposure and reperfusion.[46-48] Prior to division of the renal artery, heparin (100 U/kg) is administered intravenously and monitored, as described earlier.

Hypothermia appears to be more important than the composition of the perfusate; however, our preference is a perfusate with an intracellular composition of electrolytes. This composition theoretically limits ion exchange and intracellular volume shifts that contribute to organelle dysfunction associated with decreased activity of membrane-bound sodium-potassium adenosine triphosphatase.[41,49,50] Regardless of whether the renal vein is divided and reattached, branch renal artery repairs with use of cold perfusion preservation are made in an orthotopic fashion, with the kidney returned to the renal fossa rather than autotransplanted into the pelvis.

Several exposures for hypothermic branch renal artery reconstructions are available. When isolated branch renal repair is performed with orthotopic replacement, an extended flank incision is made from the midline to the posterior axillary line, as described earlier. This method is the authors' preferred approach for ex vivo reconstruction. The ureter is mobilized to the pelvic brim along with a large amount of periureteric soft tissue. A Silastic sling is placed around the ureter to control ureteric collaterals and to prevent subsequent renal rewarming.

Gerota's fascia is opened with a cruciate incision; the kidney is completely mobilized, and the renal vessels are divided. Hypothermia may be accomplished by topical ice slush placement, as illustrated in Fig. 126.10. To perform hypothermic perfusion, the kidney is placed in a plastic sling and the renal artery perfused with a chilled renal preservative solution. Continuous perfusion during the period of total renal ischemia is possible with perfusion pump systems, and this may be superior for prolonged renal preservation.[51] However, simple intermittent flushing with a chilled preservative solution provides equal protection during the shorter periods (2-3 hours) required for ex vivo dissection and branch renal artery reconstruction. The chilled (5-0°C) solution is hung at a height of at least 2 m. Immediately after its removal from the renal fossa, the kidney is flushed with 300 to 500 mL of solution until the venous effluent is clear and all segments of the kidney have blanched. As each anastomosis is completed, the kidney is perfused with an additional 100 to 200 mL of chilled solution. In addition to maintaining satisfactory hypothermia, periodic perfusion demonstrates suture-line leaks that are repaired before reimplantation. With this technique, renal core temperatures are maintained at 10°C or below throughout the period of reconstruction.

Even though it is an accepted method after ex vivo reconstruction, autotransplantation to the iliac fossa is unnecessary for most ex vivo reconstructions. This technique was adopted from renal transplantation. Reduction in the magnitude of the operative exposure, manual palpation of the transplanted kidney, and ease of removal when treatment of rejection fails are all practical reasons to place the transplanted kidney into the recipient's iliac fossa. However, none of these advantages applies to the patient requiring autogenous ex vivo reconstruction. Because many ex vivo procedures are performed in relatively young patients, the durability of the operation must be measured in terms of decades. For this reason, attachment of the kidney to the iliac arterial system within or below sites that are susceptible to subsequent atherosclerosis subjects the repaired vessels to disease that may threaten their long-term patency. Moreover,

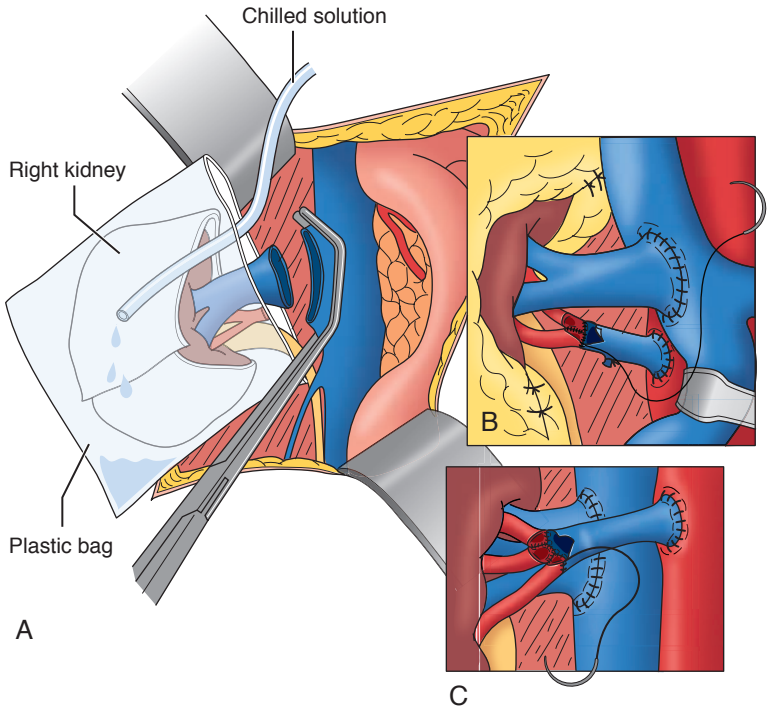

Figure 126.10 An ellipse of the vena cava containing the renal vein origin is excised by placement of a large partially occluding clamp **(A)**. After ex vivo branch repair, the renal vein can be reattached without risk of anastomotic stricture **(B)**. The kidney is returned to its native bed after ex vivo repair. Gerota's fascia is reapproximated to provide stability to the repaired kidney. Arterial reconstruction can be accomplished by end-to-end anastomoses after syndactylizing the distal branch or combined with end-to-side anastomoses **(C)**. (From Benjamin ME, Dean RH. Techniques in renal artery reconstruction: part II. *Ann Vasc Surg*. 1996;10:409–414.)

subsequent management of peripheral vascular disease may be complicated by the presence of the autotransplanted kidney. Finally, if the kidney is replaced in the renal fossa and the renal artery graft is properly attached to the aorta at a proximal infrarenal site, the result should equal those of the standard aortorenal bypass and thus carry a high probability of technical success and long-term durability.

INTRAOPERATIVE ASSESSMENT

Provided that the best method of reconstruction is chosen for renal artery repair, the short course and high blood-flow rates characteristic of direct renal reconstructions favor their patency. Consequently, flawless technical repair plays a dominant role in determining postoperative success.[52-59] The negative impact of technical errors unrecognized at operation is implied by the fact that we have observed no late thromboses of renovascular reconstructions free of disease after 1 year.[60]

Intraoperative Duplex Sonography

The risks and inherent limitations of completion angiography are not shared with intraoperative duplex sonography.[26] Because the ultrasound probe can be placed immediately adjacent to the vascular repair, high carrying frequencies may be used to provide excellent B-scan detail sensitive to 1.0-mm defects. Once defects are imaged, they can be viewed in a multitude of projections during conditions of uninterrupted pulsatile blood flow. In addition to excellent anatomic detail, important hemodynamic information is obtained from the spectral analysis of the Doppler-shifted signal proximal and distal to the imaged defect.[26] The freedom from static projections, absence of potentially nephrotoxic contrast material, and hemodynamic data provided by Doppler spectral analysis make duplex sonography a useful intraoperative method to assess both renovascular and mesenteric repairs. For these advantages of intraoperative duplex sonography to be realized, close cooperation between the vascular surgeon and the vascular technologist is required for accurate intraoperative assessment.

Currently, we use a 5/7.0-MHz compact linear array probe with Doppler color flow designed specifically for intraoperative assessment. The probe is placed within a sterile sheath with a latex tip containing sterile gel. After the operative field has been flooded with warm saline, B-scan images are first obtained in longitudinal projection. Care is taken to image the entire upper abdominal aorta and renal artery origins along the entire length of the repair. All defects seen in longitudinal projection are imaged in transverse projection to confirm their anatomic presence and estimate associated luminal narrowing. Doppler samples are then obtained just proximal and distal to the imaged lesions in longitudinal projection, determining their potential contribution to flow disturbance. The author's (K.J.H.) criteria for major B-scan defects (>60% stenosis) of a peak systolic velocity greater than 2.0 m/s associated with a distal turbulent waveform have been validated in a canine model of graded renal artery stenosis.[26] They have also proved valid in a retrospective study when preoperative radiographic studies were compared with intraoperative duplex images before surgical repair.[19] In more than 1000 open renal artery repairs, intraoperative duplex sonography has been 86% sensitive and 100% specific for technical defects associated with postoperative stenosis and occlusion of direct aortorenal reconstruction.[3,4,13]

Designation of B-scan defects according to Doppler velocity criteria provides accurate information to guide decisions about intraoperative revision. However, there are special circumstances that deserve comment. Unlike the case in surface duplex sonography, in which the Doppler sample volume is large relative to the renal artery diameter, a small Doppler sample volume can be accurately positioned within midcenter stream flow. Despite a small, centered Doppler sample, renal artery repairs demonstrate at least moderate spectral broadening. Transaortic endarterectomy gives the audible Doppler signal an oscillating characteristic, which is normal and not associated with anatomic defects. In addition, an infrequent intraoperative study will demonstrate peak systolic velocities that exceed criteria for critical stenosis when no anatomic defect exists. In these cases, the peak systolic velocities will be elevated uniformly throughout the repair, there will be no focal velocity change, and there will be no distal turbulent waveform. This scenario is most commonly encountered immediately after renal artery reconstruction for nonatherosclerotic renovascular disease. Moreover, renovascular repair to a solitary kidney will frequently demonstrate increased velocities throughout. Finally, an increase in peak systolic velocity is observed in transition from the main renal artery to the segmental renal vessels after branch renal artery repair; however, no distal turbulent waveform will be observed.

Finally, there are B-scan abnormalities observed in conjunction with renal endarterectomy that deserve comment. Infrequently, an irregular B-scan abnormality will evolve during performance of a completion scan. This B-scan finding may be associated with either increased or decreased (blunted) peak velocities but reflects formation of intra-arterial thrombus. Unlike acute venous thrombus, which is usually echolucent, acute arterial platelet aggregates are characterized by irregular echogenic material. Regardless of the associated velocity estimates, the endarterectomy site should be reopened and revised immediately. Last, a B-scan defect otherwise minor by velocity criteria may be revised according to its location and appearance. A mobile flap longer than 2 mm at the distal endpoint of an endarterectomy site is usually revised on the basis of its mere presence and potential for dissection or thrombosis.

RESULTS OF OPEN OPERATIVE MANAGEMENT

Anatomic Results

Our center's cumulative open operative experience from January 1987 through January 2012 has included more than 1700 renal artery repairs in more than 1000 patients. Our consecutive operative experience for atherosclerotic renovascular disease from January 1987 through June 1997 is described in Table 126.1.[25] During this 10.5-year period, 720 renovascular reconstructions

TABLE 126.1 Summary of Operative Management (n = 534 patients)

Total renal reconstructions				720
Aortorenal bypasses			445	
Vein		288		
PTFE		127		
Dacron		19

and 57 primary nephrectomies were performed in 534 patients. Postoperative stenosis or thrombosis occurred in 3.3% of renal artery repairs, resulting in recurrent hypertension and declining renal function in 3.7% of patients during a mean follow-up of 36 months.[3] However, because complete anatomic failure of repair (i.e., thrombosis) may result in blood pressure benefit equivalent to nephrectomy, anatomic failure is potentially more common than the rate of recurrent hypertension or reoperation.[26] To examine the authors' rate of anatomic failure, the results of 277 postoperative duplex studies in 128 consecutive patients were reviewed.[25] During a mean follow-up of 22 months, 6 of 177 (3.4%) operative renal artery repairs developed stenosis.[3]

Operative Morbidity and Mortality

Perioperative morbidity accounting for prolonged hospital stay has been observed in 15% to 20% of patients.[3,4] Less than half of 1% of patients with ischemic nephropathy have undergone operation resulting in permanent dialysis dependence within 1 month of repair.[4] Perioperative mortality within 30 days of surgery has demonstrated significant and independent association with advanced age and depressed left ventricular systolic function (i.e., ejection fraction <25%).[3] Overall, during the past 10 years, mortality after isolated renal artery repair has averaged 0.8%, compared with 1.6% for bilateral renal artery repair and 3.3% for bilateral repair combined with aortic repair for correction of atherosclerosis. This compares with 6.9% when visceral, renal, and aortic repairs are combined as one procedure.[61]

Blood Pressure Response

Considering open renal reconstruction for atherosclerotic renal artery disease and criteria for response including both blood pressure measurements and medication requirements at least 2 months after operation, 85% of surgical survivors had been cured or improved and 15% had no blood pressure response.[3]

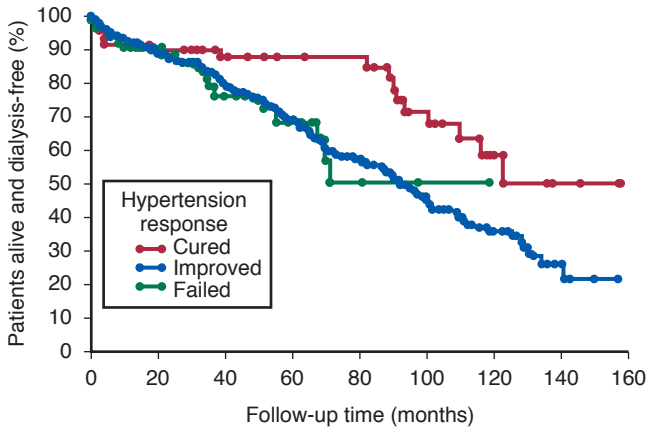

Figure 126.11 Product-limit estimates of time to death or dialysis according to blood pressure response to operation. (From Cherr GS, Hansen KJ, Craven TE, et al. Surgical management of atherosclerotic renovascular disease. *J Vasc Surg*. 2002;35:236–245.)

When patients with atherosclerosis were stratified according to blood pressure response and dialysis-free survival, only blood pressure cured was significantly associated with improved estimated survival.[3]

Renal Function Response

Considering renal function response in consecutive patients treated for atherosclerotic renovascular disease, renal function improved significantly when all patients are considered. In patients with atherosclerotic renovascular disease and ischemic nephropathy, defined by a preoperative serum creatinine concentration above 1.8 mg/dL, 58% demonstrated improved renal function at 3 weeks after repair.[3,4] When 45 patients considered permanently dependent on dialysis were examined, 70% were permanently removed from dialysis dependence after open operation.[4,13] Although other authors have considered that recovery of renal function is limited by elevated serum creatinine concentration, when patients are selected on the basis of severe hypertension and rapidly deteriorating renal function, the proportion of patients improved increases with increasing severity of preoperative renal dysfunction. This association between increased preoperative serum creatinine concentration and improved postoperative renal function is independent and highly significant ($P < .0001$).[3,4]

Hypertension and Renal Function Benefit: Clinical Outcome

Progression to death or dialysis among patients with atherosclerotic renovascular disease has demonstrated significant associations with both preoperative parameters and postoperative blood pressure and renal function response. Preoperative factors that have demonstrated a significant association with death or dialysis include the presence of diabetes mellitus, severe aortic occlusive disease, and poor renal function.[3] Postoperatively, significant associations were noted for blood pressure cured compared with blood pressure improved or worsened (Fig. 126.11).

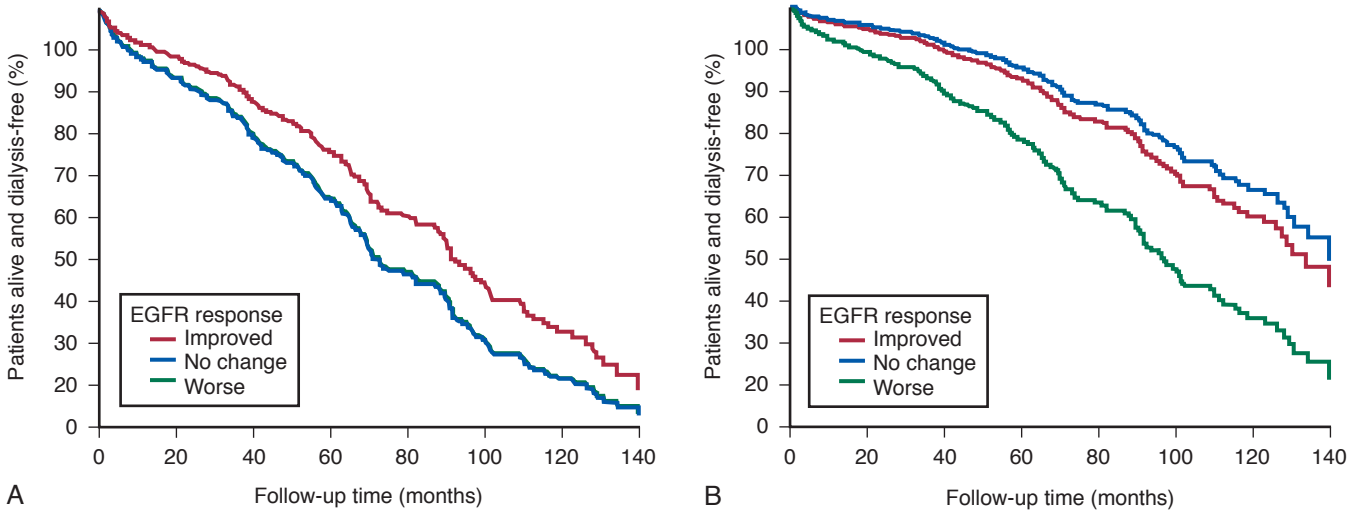

Figure 126.12 Predicted dialysis-free survival according to postoperative renal function response for patients with a preoperative estimated glomerular filtration rate *(EGFR)* of 25 mL/min per m^2 (25th percentile, **A**) or 39 mL/min per m^2 (median value, **B**). The interaction between preoperative EGFR and renal function response for dialysis-free survival was significant and independent. (From Cherr GS, Hansen KJ, Craven TE, et al. Surgical management of atherosclerotic renovascular disease. *J Vasc Surg*. 2002;35:236–245.)

Moreover, improved postoperative renal function demonstrated significant associations with increased dialysis-free survival compared with renal function unchanged. The relationship between each category of renal function response and dialysis-free survival demonstrated significant interaction with preoperative renal function. For patients with renal function unchanged, an increased risk of death or dialysis was observed for those with poor preoperative renal function.[4] For patients who worsened, an increased risk of death or dialysis was significant for those with preoperative renal function at median values of estimated glomerular filtration rate or greater. These significant interactions are shown for predicted dialysis-free survival according to preoperative renal function in Fig. 126.12.

Consequence of Failed Open Renal Artery Repair

Our secondary management of surgical repairs has included 10 repeat reconstructions and 10 nephrectomies for unreconstructable renovascular disease.[25] Regardless of the type of management (repeat reconstruction versus nephrectomy), and regardless of the blood pressure or renal function benefit after reintervention, the product-limit estimates for dialysis-free survival for patients experiencing failure of open operative renal artery repair were decreased compared with patients with primary patency. Patients requiring secondary intervention also demonstrated a significant and independent risk of eventual dialysis dependence (relative risk: 12.6; confidence interval: 4.5, 34.9; $P < .001$) and decreased dialysis-free survival (relative risk: 2.4; confidence interval: 1.1, 5.4; $P = .035$).[25] Whether failed balloon angioplasty with endoluminal stenting demonstrates significant associations with eventual dialysis dependence or death is not known.[29]

This experience with failed open renal artery repair reinforces two management strategies. First, irretrievable loss of excretory renal function observed after failed renal artery repair supports the view that renal revascularization should be performed for clear clinical indications, not as a prophylactic procedure in the absence of either severe hypertension or renal insufficiency.[3,6,61] Second, the direct aortorenal reconstruction used in the majority of these patients is durable.[25] The short length and high blood flow characterizing aortorenal repair has favored prolonged patency.

Management of atherosclerotic renovascular disease has focused solely on hypertension. Along with the article by Hansen and colleagues (later in this list), this work establishes an incremental increase in excretory renal function as the dominant determinant of dialysis-free survival on follow-up. Among patients with severe hypertension and renal insufficiency, changing renal function at 3 weeks predicts dialysis-free survival—a relationship that is stable at 10 years of follow-up.

The endovascular treatment of renovascular disease is controversial. Several adequately powered randomized trials have failed to support the efficacy of renal artery stenting. Nonetheless, renal revascularization remains a commonly used treatment option for selected patients who have clearly failed adequate medical therapy.[1-4] Endovascular techniques offer the benefits of decreased morbidity, mortality, patient recovery time, and hospital resource utilization compared with conventional open surgical revascularization.[5-10] This chapter provides an overview of the technical aspects involved in the performance of endovascular renal revascularization as well as current data concerning the technical results, clinical outcomes, and associated complications.

INDICATIONS AND CONTRAINDICATIONS

Indications

The indications for renal artery revascularization are controversial in light of the absence of level I data demonstrating the efficacy of such therapy in improving adverse event–free survival in patients with renovascular disease. Two clinical trials conducted in Europe, the Angioplasty and Stenting for Renal Artery Lesions (ASTRAL) trial[11] and the stent placement and blood pressure and lipid-lowering for the prevention of progression of renal dysfunction caused by Atherosclerotic Ostial Stenosis of the Renal Artery (STAR) trial,[12] and the more recent North American Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL) trial[13] demonstrated no evidence to support the widespread application of renal stents to patients with renovascular hypertension or ischemic nephropathy. Both of the European trials have been criticized for methodologic shortcomings that limit the generalizability of their results and conclusions. Those limitations aside, the data presented in ASTRAL strongly suggest that the application of renal revascularization therapy to patients without strong clinical indications (i.e., prophylactic or "drive by" revascularization) lacks demonstrable benefit for the patient. The results from the CORAL trial, which was more scientifically rigorous and robust, also demonstrate no clinical benefit for the widespread application of revascularization to patients with renal artery stenosis and significant hypertension

with or without associated renal dysfunction. Furthermore, no interactions were observed for bilateral renal stenosis, degree of stenosis, or other clinical factors in terms of clinical benefit. Subsequent secondary analyses of the CORAL data and other reports have directly examined the prognostic value of translesion pressure gradients, baseline blood pressure, stenosis severity, and fractional flow reserve; no evidence of prognostic value for these parameters was observed.[14,15] Additional secondary analyses are planned for the CORAL data, which may be of assistance in identifying patient subgroups more likely to benefit from RA-PTAS, and CORAL-2 is being planned to try to address these remaining questions as well. In the meantime, guidance can be provided by existing consensus documents for severely affected patients or patients not representative of the CORAL study population. In general, those documents recommend renal revascularization based upon the presence of hemodynamically significant renal stenosis in the setting of severe, difficult-to-control hypertension with or without associated renal dysfunction or in instances of hypertension-associated cardiac disturbance syndrome.[16]

Hypertensive indications and manifestations of renovascular disease include a spectrum of clinical presentations, such as chronic, severe hypertension that is refractory to pharmacologic management; renovascular hypertension associated with cardiovascular disturbance; and more acute hypertensive emergencies, which refer to acute blood pressure elevations associated with target organ damage, including flash pulmonary edema, hypertensive encephalopathy, myocardial infarction, and acute renal failure. Given the recent findings of ASTRAL and CORAL,[11] which demonstrated no reduction in adverse cardiovascular or renal events despite significant blood pressure decreases after RA-PTAS, as well as other large case series demonstrating a lack of survival benefit in association with blood pressure improvement alone,[5,7,8,17,18] many authorities on renovascular disease are advocating the application of renal revascularization only to cases of truly refractory hypertension and those cases of hypertension complicated by defined end-organ effects.[14,19,20]

Renal dysfunction in patients with hemodynamically significant atherosclerotic renovascular disease is commonly referred to as ischemic nephropathy,[3,21] although definitive establishment of a causal relationship between anatomic renovascular disease and renal dysfunction can be challenging in an individual patient despite extensive diagnostic testing. The diagnostic evaluation and pathophysiology of atherosclerotic renovascular disease are discussed in detail in Chapter 125. Conditions that would support a causative relationship between anatomically defined renal artery stenosis and disease manifestations are primarily based on reported predictors of response to intervention and include a significant observed decline in renal function over a short period of time and the presence of anatomic disease affecting perfusion to the entirety of the functioning renal mass (i.e., bilateral renovascular disease or renovascular disease affecting a solitary kidney).[7,22-26] In truth, though, a causative relationship can be proved only by a physiologic response after revascularization. Available data from numerous authors indicate that documented improvement in renal function after renal revascularization is the most important predictor of clinical benefit, suggesting that renovascular disease associated with renal dysfunction may represent the most appropriate contemporary indication for RA-PTAS.[5,7,27-29]

Contraindications

Contraindications to the treatment of renovascular disease by endovascular means can be broadly classified into anatomic reasons, cases in which open revascularization is optimal, and prophylactic treatment. Anatomic contraindications involve situations in which the disease exists in renal arteries not easily treated with currently available endovascular devices or, more commonly, those arteries unable to be treated with any reasonable expectation of durable result. Renovascular disease extending into the terminal portion of a main renal artery and that involving a very short main renal artery represent two instances in which treatment with currently available technology may be a problem (Fig. 127.1). Renovascular disease existing in the branch arteries beyond the main bifurcation, lesions in multiple small renal arteries (Fig. 127.2), and lesions in children (most commonly hypoplastic lesions) are poor candidates for endovascular treatment because of durability concerns. When encountered, these situations are likely best treated with open surgical revascularization unless the patient represents a prohibitive surgical risk. Surgical revascularization should also be considered in patients with indications for renal revascularization who require open aortic surgery for other reasons.

With regard to prophylactic revascularization, the high rate of technical success and low incidence of periprocedural complications associated with endovascular renal artery revascularization have led to increasingly aggressive application of this technique, with rapid growth in utilization in recent years.

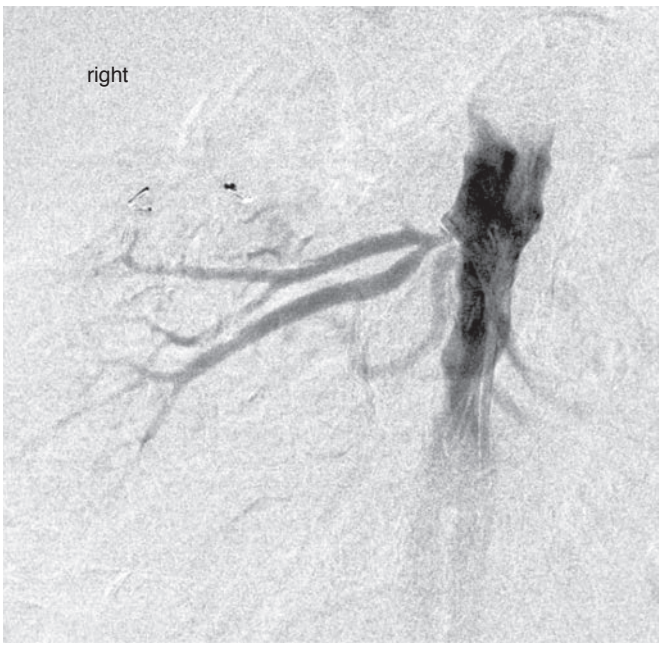

Figure 127.1 Arteriogram demonstrating early bifurcation of the *right* main renal artery.

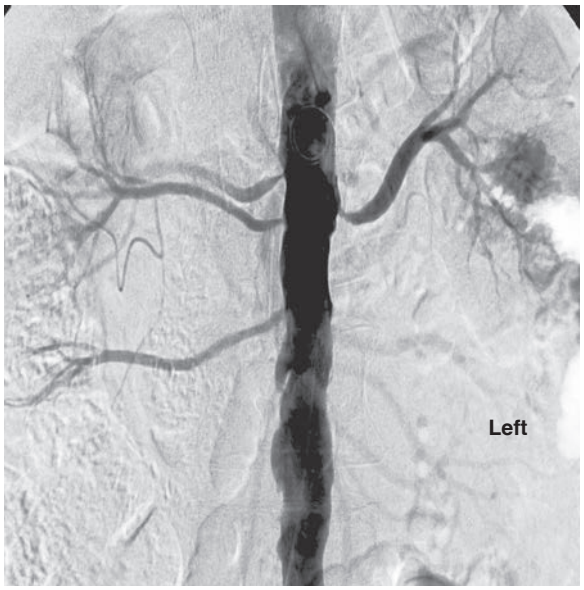

Figure 127.2 Abdominal aortogram demonstrates hemodynamically significant stenosis involving multiple renal arteries.

There is currently no evidence supporting prophylactic renal revascularization (i.e., endovascular treatment of renal artery stenosis in patients with normal renal function and hypertension that is well controlled with conventional medical therapy). Furthermore, the results of ASTRAL,[11] the conduct of which approximated prophylactic treatment in a large percentage of its participants, confirmed the lack of efficacy for such an approach in terms of blood pressure control, protection of renal function, reduction of cardiac events, or improved survival.

The natural history of atherosclerotic renal artery stenosis is associated with anatomic progression in only 10% to 30% of patients and progression to occlusion in 0% to 7%.[30-34] When anatomic disease progression does occur, it is not consistently associated with increases in blood pressure or serum creatinine concentration.[32] Considering the benign clinical course of asymptomatic renal artery stenosis in the majority of patients together with the risk of procedure-associated deterioration in renal function with intervention (see later) and the recent results from the CORAL trial, we support a nonoperative, noninterventional management strategy for asymptomatic patients with anatomic renovascular disease, normal or well-controlled blood pressure, and normal renal function.

RESULTS

Definitions of Success

Criteria for procedural technical success include reduction in stenosis as assessed by completion angiography and, when endoluminal stenting has been performed, complete coverage of the stenotic lesion by the deployed stent. Postintervention residual stenosis of less than 30% has been suggested as a threshold for technical success versus failure.[35] When contrast angiography demonstrates anatomically successful treatment of the stenotic lesion, these findings should be further confirmed with transduced pressure measurement immediately proximal and distal to the treated lesion. We consider a persistent systolic pressure gradient of 10 mm Hg or more to be suggestive of inadequate treatment and will repeat angioplasty in this setting in the absence of a significant residual stenosis on the completion angiogram.

Whereas technical success implies delivery of the intended treatment with satisfactory anatomic and hemodynamic results, determination of whether patient benefit has been derived requires consideration of the indications for intervention and the clinical responses observed. Approaches to the assessment of hypertension response have evaluated systolic, diastolic, and mean blood pressure and number of antihypertensive medications (both as continuous outcome measures and in a categorical fashion) using a combination of blood pressure and medication criteria.[35] The categorical definitions generally describe hypertension responses as cured, improved, or failed. Serum creatinine, cystatin C, estimated glomerular filtration rate (eGFR), and renal length and volume all represent continuous outcome measures indicative of renal function response to intervention. Categorization of renal response based on these measures has generally been determined as improved, unchanged, or worsened on the basis of postintervention change within a predefined range. We have generally used an increase or decrease of 20% or more in eGFR to define improvement or worsening in renal function, respectively, with all other patients categorized as unchanged. Alternative analytic approaches have evaluated the impact of renal revascularization on the rate of decline in renal function, defining worsened or unchanged rates of eGFR decline as failure and attributing procedure-related benefit to patients experiencing improvement, stabilization, or slowed rate of decline in eGFR.

Unfortunately, none of the previously discussed parameters assesses the impact of intervention on patient morbidity or survival. Survival free from dialysis, renal death, or cardiovascular morbidity represents an outcome that provides the most direct means of assessing the true benefit of intervention and likely represents the outcome of greatest importance in measuring the true value of renal revascularization to the patient.

Early Outcomes

A large body of literature exists reporting results of RA-PTAS in adult patients.[22,24,25,28,29,36-65] Technical success rates ranged from 88% to 100% and periprocedural 30-day mortality was 0% to 5%. Procedure-related complications associated with RA-PTAS occurred in 0% to 43% of patients. In general, these early results mirror those of ASTRAL and STAR.[11,12] In CORAL, technical success rates exceeded 95%, with no early patient deaths. Procedural complications were rare (less than 5% of cases) with the most common being dissection of the treated artery.

Late Outcomes

Late outcomes associated with endovascular renal artery intervention may be considered in terms of hypertension control, renal

function change, anatomic durability, and survival free of dialysis or cardiovascular morbidity.

Hypertension Response

Long-term hypertension response to RA-PTAS performed for atherosclerotic renovascular disease is most often improvement or failure, whereas cure (defined as normal blood pressure off all antihypertensive medications) is very uncommon. In the case series data,[22,24,25,28,29,36-65] hypertension improvement was seen in a majority of patients, but failure to improve blood pressure control was also a common outcome. In ASTRAL, no significant improvement in systolic blood pressure was observed when stenting was directly compared with medical therapy. A modest decrease in diastolic blood pressure was observed, and a statistically (although probably not clinically) significant decrease in the number of antihypertensive medications administered was also observed.[11] In CORAL, a small but significant decrease in systolic blood pressure was observed with no resultant decrease in medications.[13]

Reported predictors of hypertension response have included severity and duration of preoperative hypertension,[22,24,25] age of the patient,[66] percentage angiographic stenosis,[22] bilateral disease,[24] female gender,[25] and preoperative brain natriuretic peptide level,[67] although the brain natriuretic peptide finding is now in question.[68] Durable hypertension responses have been reported by several authors,[41,48,49,60] but others have observed a loss of initial hypertension response at 6-month post–RA-PTAS follow-up associated with a return to the preoperative number of blood pressure medications.[64,69] Given the data from ASTRAL[11] and CORAL[13] and the lack of association between blood pressure improvements and improved adverse event–free survival reported by multiple authors, there is increasingly limited enthusiasm for RA-PTAS for management of hypertension in the setting of normal renal function. For hypertensive indications, we would recommend limiting intervention for patients with truly uncontrollable and severe hypertension (which is increasingly uncommon given the potency of contemporary antihypertensive medications) and severe hypertension associated with target organ damage.

Renal Function Response

Although several case series have reported improvement as the most frequent categorical renal function response to RA-PTAS,[25,54,61] others have observed postoperative deterioration with a frequency equal to or greater than that of improvement,[40,45,47,48,53,60,62,63] and renal function was unchanged in the majority of patients after intervention. Reported rates of postintervention improvement versus deterioration in renal function vary widely in these series. The heterogeneous results may be partly attributable to differing patient selection criteria, particularly regarding the percentage of patients with baseline renal dysfunction (because patients with normal baseline renal function have no prospect for improvement through intervention). Weighted averages across series of unprotected RA-PTAS (see Table 146.1) demonstrate renal function improvement in approximately 25% of patients, with a roughly equal proportion experiencing postinterventional decline.

Rather than assessing renal function response as mean or categorical change in outcome measures, several studies have instead analyzed renal responses to RA-PTAS using breakpoint analysis based on the slope of either eGFR or reciprocal of serum creatinine concentration, with categorization of effect as improvement, stabilization, or failure.[35] Whereas these studies have demonstrated that RA-PTAS can reduce the rate of renal function decline,[36,55,61,69] interpretation of clinical benefit based on breakpoint analysis is controversial. Reciprocal creatinine analysis was employed in ASTRAL,[11] and RA-PTAS demonstrated no benefit in slowing the rate of renal function decline relative to the use of best medical management alone. One interesting finding from ASTRAL that deserves to be stressed was the observation of a much lower rate of renal function decline in the medical therapy arm than expected. This most likely represents the effects of ever-improving medical management on the natural history of atherosclerotic renovascular disease.

Case series data do suggest that improvement in renal function after renal revascularization is associated with improved survival. Hansen et al.[7] observed improved dialysis-free survival after open surgical revascularization in patients with early postoperative improvement in renal function, but no similar survival effect was noted in patients with unchanged renal function. Similar associations with improvement in renal function have also been demonstrated after RA-PTAS.[27,28,36,70] Although patients with increases in postoperative eGFR (or decline in serum creatinine concentration) appear to experience a survival benefit, clinical benefit resulting from stabilization of renal function or reduction in rate of decline is not clear. We therefore believe that in interpreting either categorized change in eGFR or breakpoint analysis data, patient benefit can be assumed only for patients with improvement, whereas presuming benefit in patients with unchanged or stable renal function may be conceptually flawed. Reported predictors of renal function response to RA-PTAS have included bilateral disease,[29] elevated baseline serum creatinine concentration,[25,29] higher levels of chronic kidney disease,[7,27] rapid preoperative decline in renal function,[23,36] impaired left ventricular function,[25] absence of metabolic syndrome,[71] smaller prerevascularization renal parenchymal volume,[72,73] and improved renal volume after revascularization.[73,74]

Renal Artery Restenosis After Intervention

Restenosis after RA-PTAS has been defined on the basis of angiography,[40,45,64] duplex ultrasound,[60] or both.[53,62,75] Reported rates of restenosis after RA-PTAS range from 5% to 66% and vary with duration of follow-up and criteria for repeated imaging.[37,39-41,45-48,53-55,62,64,65,75] Restenosis is more common in women and in patients exhibiting metabolic syndrome[76] and less common in patients treated perioperatively with statins.[6] Other factors that may occasionally contribute to restenosis include misplacement of the stent, most frequently inadequate proximal coverage of an ostial lesion, stent fracture, and severe calcification resulting in stent compression.

Anatomically identified recurrent stenosis must be considered in combination with clinical manifestations in formulating a management strategy. Conversely, acute worsening of hypertension or decline in renal function should prompt suspicion of

disease recurrence. Lederman et al.[40] identified recurrent disease twice as frequently when anatomic imaging was performed in the setting of clinical suspicion as opposed to routine postintervention screening (42% vs. 21%, respectively). The relatively frequent occurrence of recurrent disease should be considered when primary intervention is being contemplated, particularly in asymptomatic patients, and raises additional concerns about the long-term benefits achieved in patients with unchanged renal function after RA-PTAS.

Survival

Long-term survival data for patients undergoing RA-PTAS are presently limited to retrospective studies, ASTRAL, and CORAL.[11] Dorros et al.[49] observed a 74% 3-year survival rate after RA-PTAS; although renal failure was not a frequent cause of death, they observed decreased survival among patients with both baseline renal dysfunction and bilateral disease. Similar overall survival was reported by Kashyap et al.,[36] who also observed a 63% rate of dialysis-free survival; lack of postintervention improvement in renal function was associated with subsequent dialysis in that series. Similar relationships between baseline renal dysfunction, renal function response, and survival have been described by Kennedy et al.[28] Survival benefit associated with angiotensin-converting enzyme treatment[77] and statin use after RA-PTAS has also been described,[28,78] whereas preoperative congestive heart failure, coronary artery disease, and chronic obstructive pulmonary disease are additional factors that adversely affect postintervention survival.[28,40,78]

Similar data have come from ASTRAL and STAR.[11,12] In ASTRAL,[11] 5-year survival was 58% for the entire study sample, with no improvement demonstrated for those undergoing RA-PTAS. Improvement in diastolic blood pressure and reduced medication use observed for the stent arm participants were not demonstrated to have any effect on survival. As previously stated, no differences were observed in renal function, rate of renal function decline, or systolic blood pressure. In the results from STAR,[12] 2-year survival was slightly in excess of 80%, with no differences observed according to postrevascularization blood pressure control or renal function.

DESCRIPTION OF TECHNIQUE

Relevant Anatomy

The renal arteries originate laterally from the abdominal aorta and commonly assume an oblique orientation in their proximal course relative to the aortic axis (Fig. 127.3). Because aortography performed in a straight anteroposterior position can produce contrast overlap between the aorta and proximal renal arteries, resulting in inadequate visualization of ostial disease, oblique imaging is frequently necessary for renal arteriography and intervention. Multiple renal arteries are present in 18% of patients and may not be accurately characterized with renal artery duplex ultrasound.[32,79] Accessory arteries may therefore be an unanticipated finding in patients imaged with duplex ultrasound alone before intervention and must be assessed for occlusive disease during procedural planning. Distal renal artery diameter in patients undergoing endovascular intervention is usually 5 to 6 mm.[38,40] Poststenotic renal artery dilatation is common[40] and may result in size mismatch between the luminal diameter and stent or protection device; small-diameter arteries (<4 mm) increase the technical difficulty of ostial engagement and endovascular treatment. Endovascular treatment of atherosclerotic disease is most often performed for lesions of the ostial and proximal main renal artery. Branch vessel atherosclerosis is less frequently encountered and is seldom ideal for endovascular management.

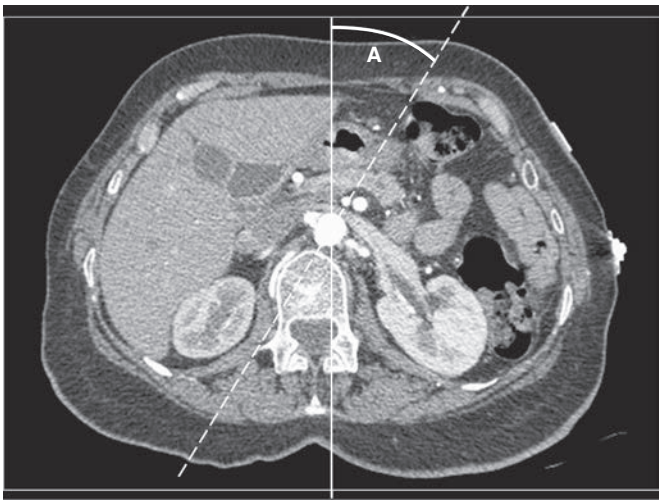

Figure 127.3 Oblique orientation of proximal renal arteries. Computed tomographic angiography demonstrates the axis perpendicular to the proximal renal arteries *(dashed line)* relative to the axis perpendicular to straight anteroposterior imaging *(solid line)*. The resulting angle *(A)* indicates the oblique correction needed to avoid artifact resulting from contrast overlap between the aorta and the proximal renal artery, which could result in underestimation of the degree of renal artery stenosis.

Operative Planning and Options

Contrast Considerations

Angiographic visualization of arterial anatomy is a fundamental element of both diagnosis and endovascular treatment of atherosclerotic renovascular disease. In addition to associated renal dysfunction and hypertension, common conditions among patients with renovascular disease that may predispose to contrast-induced renal function impairment include diabetes mellitus, congestive heart failure, and anemia.[40,80-85] Chronic volume depletion may represent an additional risk factor in patients taking diuretic medications. Procedure-related factors affecting risk of contrast-induced nephropathy include the volume, osmolality, and viscosity of the contrast agent administered.[83,86,87] Accordingly, procedural planning should incorporate assessment of the likelihood of contrast-induced nephropathy and implementation of protective measures for high-risk patients. Prophylactic strategies for the prevention of contrast-induced nephropathy have included a variety of measures directed toward maximizing renal perfusion, reducing oxidative stress, and inhibiting vasoconstriction. Hydration is a generally accepted

prophylactic measure, but evidence supporting the routine use of additional measures such as *N*-acetylcysteine, sodium bicarbonate, and ascorbic acid is inconsistent.[84,88] Currently, we prepare all patients for aortorenal arteriography with preoperative hydration using isotonic saline (reduced in the setting of significant congestive heart failure), administration of *N*-acetylcysteine, and routine use of iso-osmolar, nonionic contrast material at the lowest volume possible. For patients with renal dysfunction, we also administer sodium bicarbonate. In the setting of severe renal dysfunction (eGFR <30 mL/min per 1.73 m^2), carbon dioxide can be used as the primary contrast agent or as an adjunct during initial aortography and selective cannulation to reduce the administered volume of iodinated contrast material.[89,90]

Medical Management

In the setting of acute symptomatic presentations of renovascular disease (i.e., hypertensive emergency and acute renal failure), clinical stabilization is usually possible through medical management, making it possible to perform intervention in a lower-risk elective setting. Acute renal failure in the setting of renovascular disease can be precipitated by the initiation of angiotensin-converting enzyme inhibitors or angiotensin receptor antagonists in patients with bilateral disease or hypovolemia.[91,92] Deferring renal intervention until functional recovery is complete in these patients avoids additional renal insult from the administration of nephrotoxic contrast material. For elective revascularization, nonsteroidal anti-inflammatory drugs, diuretics, metformin, and warfarin are withheld during the periprocedural period. Preoperative antiplatelet and statin therapy is initiated in all patients unless contraindicated. Routine antihypertensive medications are taken with a sip of water on the morning of the procedure.

Primary Angioplasty Versus Angioplasty and Stenting

Whereas primary angioplasty is currently considered appropriate endovascular management for renal artery fibromuscular dysplasia, primary endoluminal stenting for the treatment of ostial atherosclerotic renovascular disease is associated with superior technical success and a lower incidence of recurrent stenosis versus angioplasty alone.[9,37] Primary angioplasty is still commonly used for the management of recurrent disease. Nonostial atherosclerotic lesions may also respond well to angioplasty alone, but secondary stent placement should be considered if primary angioplasty is unsuccessful.

Bilateral Atherosclerotic Renovascular Disease

In patients with bilateral, hemodynamically significant atherosclerotic renovascular disease and significant renal dysfunction, one can initially proceed with unilateral treatment. If the clinical response is inadequate and there is no evidence of recurrent stenosis, contralateral RA-PTAS can be performed in a staged fashion. Compared with simultaneous bilateral RA-PTAS, a staged management approach can reduce the volume of contrast material administered during a single procedure setting and decrease the likelihood of acute renal injury. Downsides to this approach include the additional costs of two separate procedures, the incremental risk of vascular access complications, and patient inconvenience. However, this strategy may be useful in patients who are at a high risk for contrast-related complications.

Access

Common femoral artery access is safe, versatile, and our preferred access method for RA-PTAS. When selective renal artery cannulation is planned, selection of the femoral location contralateral to the targeted renal artery for access facilitates ostial cannulation through a tendency for the catheter to preferentially track along the contralateral aortic wall (Fig. 127.4). The brachial artery is an alternative access site that may be preferred in patients with aortoiliac occlusive disease, in patients with renal arteries with significant inferior angulation, or when selective cannulation through a femoral approach has been unsuccessful. Compared with the femoral artery, disadvantages of brachial access include higher incidence of access-related complications and limitations of the catheter or sheath diameter.[44,93] Recently, successful use of radial artery access for RA-PTAS has been described, although the technical challenges can be formidable.[94]

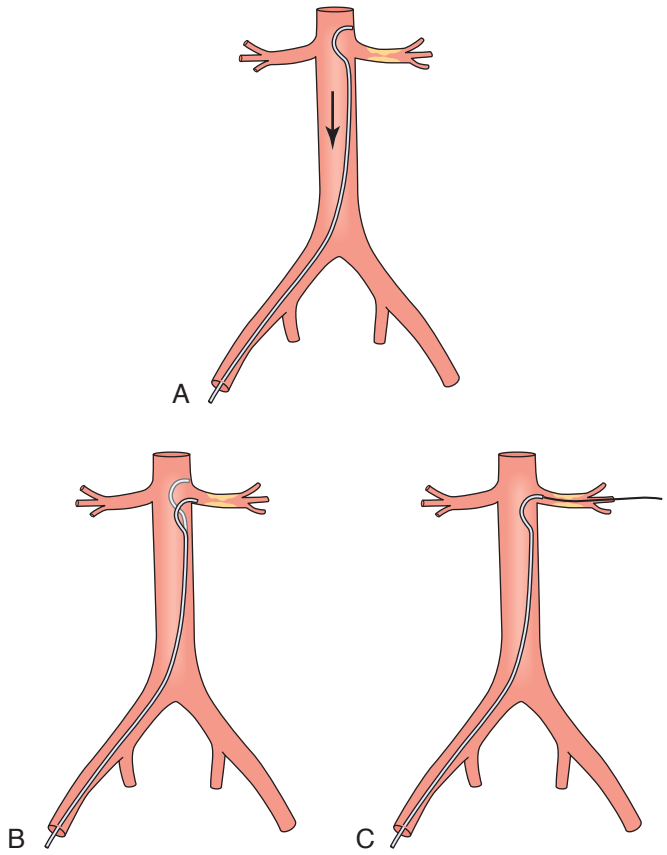

Figure 127.4 (A–C) Contralateral femoral access often facilitates selective renal cannulation. (From Schneider PA. More about how to get where you are going: selective catheterization. In: Campbell B, ed. *Endovascular Skills: Guidewires, Catheters, Arteriography, Balloon Angioplasty, Stents.* St. Louis: Quality Medical Publishing; 1998:71.)

Angioplasty and Stenting

After initial aortography, the patient is systemically heparinized and the target renal artery is accessed. Access can be gained by use of a selective catheter in the form of a guide catheter or a diagnostic catheter (Fig. 127.5). If a diagnostic catheter is used for engagement, the selective catheter and sheath are exchanged over a 0.014- to 0.035-inch guidewire for a guide sheath, which is advanced to the origin of the renal artery. Guide sheath and guide catheter access platforms both provide mechanical support during guidewire exchange and facilitate delivery of therapeutic devices to the targeted lesions. The choice of platform type is a matter of preference. Multiple device configurations are commercially available, and a luminal diameter of 6F will accommodate the majority of angioplasty and stenting systems. The tip of the guide sheath or catheter is positioned at or within the orifice of the targeted renal artery, and then a guidewire is passed across the stenotic lesion. We believe that smaller wire systems minimize renal artery trauma and are associated with technical advantages in crossing critical lesions. We prefer a 0.14-inch guidewire with a floppy, radiopaque tip for lesion passage. Once guidewire access across the stenotic lesion has been obtained, care must be taken to avoid advancement of the nontapered guide sheath or catheter, which could potentially result in injury to the luminal surface of the renal artery.

If renal artery distal embolic protection is being used, a wire system incorporating a distal renal artery occlusion balloon or filter is used for crossing the lesion and is subsequently deployed distally. If an occlusion balloon device is used, complete renal artery occlusion is confirmed by hand injection of contrast material (Fig. 127.6). Angioplasty with stenting is then performed, followed by aspiration of the static column of blood distal to the treated lesion, irrigation with heparinized saline, and repeated aspiration. The distal occlusion balloon is then deflated, and completion angiography is performed. Filter devices permit ongoing distal renal artery flow in their deployed configurations and use a porous membrane to trap embolic material. After angioplasty and stenting, the filter is collapsed to trap any captured embolic material before device withdrawal.

Both coaxial and monorail systems are available for RA-PTAS. For critical lesions, initial predilatation angioplasty may be necessary to permit subsequent endoluminal stenting. Angioplasty balloon diameter should be selected on the basis of quantitative angiography measurements; we select angioplasty balloons sized to the adjacent normal artery for primary RA-PTAS and select smaller balloons if predilatation is required (we commonly use a 2- to 4-mm × 20-mm low-profile balloon for predilatation). For predilatation, the angioplasty balloon should be inflated to nominal pressure for 15 to 30 seconds before deflation; noting the location of the balloon's "waist" before full inflation is helpful for subsequent endoluminal stent positioning. Patients may experience pain or discomfort during angioplasty that resolves with balloon deflation; symptoms persisting after deflation suggest renal artery injury; in the worst cases, they coincide with renal artery rupture. Guidewire access is maintained during balloon deflation and removal.

RA-PTAS is most commonly performed with balloon-expandable stents that have greater radial strength and can be deployed with precision; self-expanding stents offer greater flexibility but are used less frequently. Stents are placed with 1 to 2 mm of extension into the aorta for treatment of ostial or proximal disease; more distal stent placement frequently fails to support the true renal artery orifice; it is associated with increased risks of both technical failure and recurrent stenosis[41,42,46,95] and also increases the technical difficulty of subsequent surgical revascularization.[96] The shortest stent that will adequately cover the lesion should be used, and positioning can be guided by frequent hand injection of small volumes of contrast material into the guide catheter or sheath. A balloon-expandable stent is deployed by fully inflating the angioplasty balloon. Currently available stents are supplied premounted on low-profile delivery systems that often permit primary RA-PTAS without predilatation. If a residual waist is visible on fluoroscopy or completion angiography after stent deployment, the narrowed area can be postdilated with an appropriately sized angioplasty balloon (Fig. 127.7). However, dense calcifications sometimes preclude full stent expansion, and overly vigorous attempts to fully dilate the vessel can lead to the risk of vessel rupture. In all

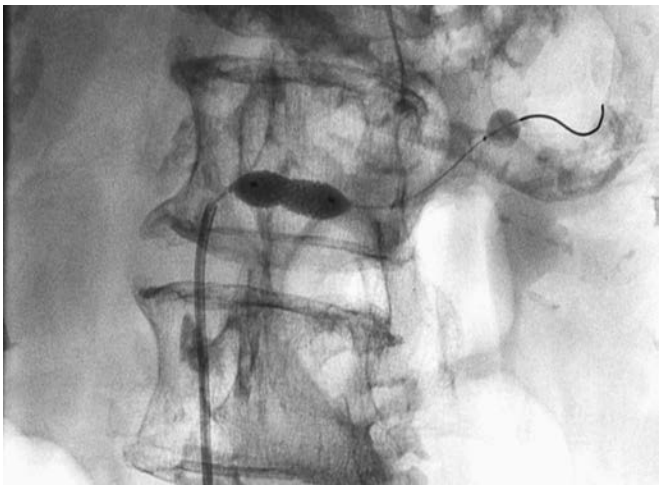

Figure 127.7 "Waisting" of an endoluminal stent being treated with postdeployment dilatation. The distal renal artery occlusion balloon is also visible.

cases, the vessel should be dilated only to the diameter of the nondilated segments, not to the diameter of areas of poststenotic dilatation.

After RA-PTAS, technical results may be assessed by completion angiography, intravascular ultrasound, or measurement of the pressure gradient. When RA-PTAS has been performed with protection of the distal renal artery by balloon occlusion, we find it useful to measure pressure gradients through the aspiration catheter, which has already been positioned distal to the treated lesion before balloon deflation. Use of the aspiration catheter to check pressure gradients during its withdrawal therefore avoids the need for passage of an additional catheter past the newly stented lesion, which could potentially lead to stent deformation or migration. Pressure gradients of the renal artery to the aorta can also be measured by pressure-sensing guidewires,[96,97] which also afford the advantage of allowing both pre- and postrevascularization pressure measurement without catheter exchanges. Once a satisfactory result has been obtained, the guidewire and sheath are removed and hemostasis is obtained. An adequate result includes a residual stenosis of less than 30% on angiography and a pressure gradient of less than 10 mm Hg between the distal renal artery and the aortic lumen. Intravascular ultrasound can also be used as an adjunct measure to assess lesion coverage, stent extension into the aorta, and patency.

Embolic Protection

Atheroembolization during RA-PTAS may occur, with the liberation of an alarming amount of debris of a size sufficient to occlude the arterioles of the kidney.[51,98] Embolic protection devices can be used during RA-PTAS, although none is currently approved by the U.S. Food and Drug Administration for such a purpose. Case series data have been published demonstrating infrequent deterioration of acute renal function and higher rates of renal function improvement after RA-PTAS when embolic protection devices were used.[50,51,56-58,99] One prospective randomized trial of the use of an embolic protection device has been published, the Randomized Comparison of Safety and Efficacy of Renal Stenting (RESIST) trial.[100] RESIST demonstrated an improvement in the rate of adverse renal events by embolic protection with the Angioguard filter device (Cordis Johnson & Johnson, Bridgewater, New Jersey), but only when the filter device use was combined with the potent glycoprotein IIb/IIIa inhibitor abciximab. The beneficial effects were most pronounced in those patients with greater degrees of renal dysfunction.[101]

Postoperative Management

After intervention, patients are monitored overnight for access site problems and hemodynamic instability. We routinely check a serum creatinine concentration the day after the procedure, before hospital discharge. Clopidogrel is continued after intervention for a minimum of 30 days; aspirin and statin therapy is continued indefinitely. Clinical follow-up with surveillance renal duplex ultrasonography is performed within the first month after intervention and subsequently at 6-month intervals for 2 years and annually thereafter. We consider a renal artery peak systolic velocity of more than 180 cm/s suggestive of disease recurrence[102] and consider all anatomically identified recurrent lesions in combination with their clinical manifestations. For patients experiencing anatomic recurrence in the setting of maintained blood pressure or renal function response to intervention, we increase the frequency of clinical follow-up and imaging surveillance but do not intervene unless clinical manifestations occur. When repeated intervention for recurrent disease is required, an endovascular approach is most often used.[76] In-stent stenosis due to intimal hyperplasia should be suspected with early disease recurrence; this pathologic process is difficult to manage with routine balloon angioplasty alone; technical results may be improved by initial dilatation with a cutting balloon[103] or by the use of a balloon-expandable covered stent.[104]

COMPLICATIONS

Reported major complications include hemorrhage, access site pseudoaneurysm, bowel or extremity ischemia, myocardial infarction, renal artery thrombosis, and acute renal failure.[105,106] Hemodynamic instability after endovascular renal intervention must be presumed to be hemorrhagic in etiology until proven otherwise, and computed tomography scanning is a useful tool for the identification and localization of bleeding. Hemorrhage is most commonly related to bleeding at the site of arterial access, but potentially fatal bleeding can also occur at the site of renal artery rupture secondary to angioplasty balloon, or guidewire perforation[107] of the parenchyma of the kidney, resulting in a perinephric hematoma. Retroperitoneal or perinephric hematoma accumulation that is undetectable on physical examination may be identified by non–contrast-enhanced computed tomography (Fig. 127.8); if no apparent bleeding is identified, other causes (such as myocardial infarction, heart failure, or reaction to the contrast agent) should be investigated. Bleeding due to renal artery perforation may be managed most commonly with endovascular techniques; surgical

exploration is rarely required. A perinephric hematoma due to guidewire perforation is a medical emergency and should be treated immediately and definitively with either endovascular embolization, coiling, or open surgical treatment. Successful endovascular treatment of procedure-related renal artery thrombosis by thrombolysis has also been described.[106]

RENAL ARTERY ANEURYSMS

Epidemiology

Even in referral centers, few vascular surgeons have extensive experience with the clinical management of renal artery aneurysms.[1,2] Autopsy studies have revealed an incidence of 0.01% to 0.09%, which is probably an underestimation because renal artery aneurysms may be small, intrarenal, or not specifically sought.[1,3] In two angiography studies, renal artery aneurysms were documented in 0.73% (7-965) to 0.97% (83-8525) of arteriograms; in a computed tomographic (CT) angiography study, the incidence was 0.7% (6-862).[4-6] Conversely, these reports might overestimate the prevalence of these lesions. At Pennsylvania Hospital (Philadelphia, Pennsylvania), we documented renal artery aneurysms in only 0.12% (1-845) of abdominal aortograms. Renal artery aneurysms are bilateral in about 10% of cases.[1,5] If fibrodysplastic cases are omitted, there is an equal incidence in males and females.[1,2,7]

Pathogenesis

Types of renal artery aneurysms include true (saccular and fusiform), false, dissecting, and intrarenal aneurysms.

True Aneurysms

More than 90% of true renal artery aneurysms are extraparenchymal.[2,8-10] The peak incidence is in patients between the ages of 40 and 60 years. Stanley[2] and Stanley et al.[10] have suggested that true aneurysms are probably due to either atherosclerosis or a congenital defect. Although arteriosclerotic changes have been identified in most aneurysms in patients with multiple lesions, these aneurysms are more likely due to a congenital medial degenerative process with weakness of the elastic lamina.[7,10] Lesions typically occur at the primary or secondary renal artery bifurcations and are rarely confined only to the main trunk of the renal artery.

Approximately 75% of true renal artery aneurysms are saccular. Saccular aneurysms occur almost invariably at the main renal artery bifurcation.[11] Fusiform aneurysms are usually associated with atherosclerosis or are a result of a poststenotic dilatation distal to a hemodynamically significant renal artery stenosis, the latter of which results from atherosclerosis or fibromuscular disease.[7,8,11,12] Fusiform aneurysms usually affect the main renal artery trunk.[8]

Arterial fibrodysplasia is often a direct contributor to the development of an aneurysm.[2,10] Medial fibroplasia is typically associated with multiple stenoses and poststenotic dilatation of

Abstract

Renal artery aneurysms and arteriovenous fistula are rare conditions, but indications for treatment need to be understood by vascular surgeons. Asymptomatic renal artery aneurysms in men and in women not of childbearing age can generally be followed until they are more than 3 cm in diameter because of the low risk of rupture. However, any size renal artery aneurysm needs to be repaired in women of childbearing age. Treatment includes insertion of a stent graft, embolization, or open surgical repair. Renal arteriovenous fistulae (AVFs) are usually asymptomatic, but when symptomatic or causing hypertension, can usually be treated by coil embolization.

Renal artery aneurysms and renal AVFs are rare entities but are encountered frequently enough that vascular surgeons need to be well-acquainted with the natural history, diagnosis, and management of these lesions. Endovascular interventions represent the newest advances in the treatment of these problems. Aneurysms and AVFs are discussed separately because they rarely occur concomitantly, and their clinical course and treatment differ.

Keywords

Renal artery aneurysms
renal artery arteriovenous fistula

the distal two-thirds of the renal artery. Renal artery aneurysms in association with fibromuscular dysplasia are generally only a few millimeters in diameter. The typical angiographic appearance of a renal artery involved with medial fibroplasia is a "string of beads." Larger aneurysms can also occur, however, and in one study, renal artery microaneurysms were found in 9.2% of adults with fibromuscular dysplasia.[10]

A rare cause of renal artery aneurysms is Ehlers-Danlos' syndrome. This disorder is associated with extreme arterial fragility and spontaneous rupture.[13]

False Aneurysms (Pseudoaneurysms)

False aneurysms of the renal artery arise from blunt or penetrating trauma and occasionally from iatrogenic causes such as renal artery catheterization or after nephrectomy. They represent contained ruptures of the renal artery, with only inflammatory and fibrous tissue encasing the leak.

Dissections

Spontaneous dissections confined to the renal artery that do not arise from the adjacent aorta are rare. However, primary dissections causing pseudoaneurysms affect the renal arteries more than any other peripheral artery.[2,11,14-17] Poutasse[11] and Stanley et al.[10] reported that 14 of 57 cases of renal artery aneurysms were due to spontaneous dissection. An intimal defect of the renal artery due to atherosclerosis is probably the underlying cause of spontaneous renal artery dissection causing aneurysms, along with dysplastic renovascular disease and trauma.[8] The incidence of dissection in patients with fibrodysplastic renal arteries ranges from 0.5% to 9.0%.[2,14] Dissection often extends into the branches of the renal artery and may pose particularly challenging reconstruction problems.

Traumatic renal artery dissection can occur secondary to blunt abdominal trauma or catheter-induced injury. Blunt trauma accounts for the higher prevalence of dissection in men and is more likely to result in right-sided injuries, possibly because of ptosis-related physical stresses affecting the renal pedicle.[2] Blunt trauma can cause renal artery dissection by either severe stretching of the artery, with fracture of the intima, or compression of the artery against the vertebra. Renal artery dissection caused by guide wires or catheters can occur, but is rare, having been observed in only 4 of 2200 selective renal artery arteriograms.[14]

Intrarenal Aneurysms

Less than 10% of renal artery aneurysms are intraparenchymal.[9,10] Intrarenal aneurysms are usually multiple and may be congenital, are associated with collagen vascular disease, or are posttraumatic. They may be associated with arteriovenous fistulae (AVFs), possibly as a result of spontaneous closure of a fistula. Intrarenal aneurysms can occur with polyarteritis nodosa and are usually in the renal cortex.[18,19]

Clinical Manifestations and Diagnosis

Most renal artery aneurysms are asymptomatic and are found on imaging studies, such as arteriography, ultrasonography, magnetic resonance angiography (MRA), or CT performed to investigate other intraabdominal pathology.[2,20,21] Clinical manifestations of renal artery aneurysms include rupture, hypertension, pain, and hematuria.

The most dreaded complication of renal artery aneurysm is rupture. Typical associated findings include acute abdominal pain and distention and hypotension. Intuitively, a stable renal artery aneurysm should not cause pain or symptoms, similar to a stable abdominal aortic aneurysm, so the clinician should hesitate to attribute chronic abdominal pain to a stable, noninflammatory renal artery aneurysm.

Renal artery aneurysms may be associated with severe hypertension. Macroaneurysms were found in 2.5% of arteriograms performed for the evaluation of hypertension.[10] Renal artery aneurysms may cause renovascular hypertension by distal embolization with segmental hypoperfusion, renin-mediated vasoconstriction, and fluid retention. Compression of an adjacent renal artery branch or luminal stenosis due to extensive thrombus may also lead to renin-mediated hypertension. Frequently, significant renal artery stenosis causes a poststenotic fusiform aneurysm, and the renal artery stenosis is responsible for the hypertension. Saccular and intrarenal aneurysms are much less likely to be associated with hypertension. We urge that caution be exercised in attributing the cause of hypertension to a renal artery aneurysm, especially if intervention is being considered. Just as renal artery stenosis without an aneurysm is currently less likely being treated with intervention and more likely treated with medical management, the clinician should hesitate to recommend endovascular or surgical intervention to treat hypertension potentially due to a renal artery aneurysm.

Patients with renal artery aneurysms caused by dissection may present with severe flank pain, hematuria, or acute hypertension, although most dissections are asymptomatic. CT angiography or MRA is essential to detect dissection.

Intrarenal aneurysms may rupture into calices.[3] In addition to pain, microscopic or gross hematuria may occur. Similarly, renal artery aneurysms may rarely cause obstruction of the collecting system.

Indications for Intervention

Indications to repair a renal artery aneurysm are related to the risk of rupture, hypertension, acute dissection, and other clinical symptoms. Because of the lack of controlled data, controversy persists regarding indications for repair of asymptomatic renal artery aneurysms. The optimal method of repair is also controversial.

Rupture and Prevention of Rupture

Rupture of a renal artery aneurysm is an indication for emergency intervention, as it is for virtually any arterial aneurysm. Probably less than 3% of renal artery aneurysms rupture.[2,10] This complication is associated with a mortality rate of approximately 10% in men and nonpregnant women.[2,10,22,23] In a hemodynamically stable patient, an emergent CT scan may reveal the pathology and allow the surgeon to plan the operative repair.

Prevention of rupture is the most common indication for intervention in cases of asymptomatic renal artery aneurysms.

Traditionally, repair has been recommended for renal artery aneurysms greater than 2 cm in diameter.[8,12] We strongly believe this recommendation is overly aggressive, and more conservative guidelines for intervention based on more recent studies with longer follow-up have been suggested.

Older series suggested higher rates of rupture. Harrow and Sloane[24] reported one of the highest rates of rupture of renal artery aneurysms, noting 14 ruptures in 100 cases. In another series of 126 renal artery aneurysms, six ruptured.[25] However, most other series of asymptomatic renal artery aneurysms in men and nonpregnant women report a much lower incidence of rupture. Only 1 of 62 patients with aneurysms 4 cm in diameter or smaller ruptured after follow-up from 1 to 17 years.[26] None of 19 small aneurysms in another series ruptured.[22] A group of 21 patients was observed for an average of 3 years without rupture.[21] In another series of 18 patients, no renal artery aneurysms ruptured that were less than 2.6 cm who were followed for 1 to 16 years.[1] There were no ruptures in a series of 32 patients (who eventually underwent surgery) with renal artery aneurysms that ranged from 0.7 to 9 cm.[13] Of 83 renal artery aneurysms found on arteriography and followed without surgery,[27] none ruptured or became symptomatic after a mean of 4.3 years.[5] In a pooled analysis, there were no ruptures in more than 200 renal artery aneurysms observed for up to 17 years.[7] Because of the very low risk of rupture and the relatively high rate of significant postoperative complications, especially with open surgery, we recommend that a more conservative approach be used for these cases and that a 2-cm guideline for intervention is too aggressive and unwarranted.

Besides size, other factors may play a role in the consideration of elective surgery for asymptomatic renal artery aneurysms. Calcification of the aneurysm has been thought to protect against rupture. Poutasse[12] suggested that a heavily calcified renal artery aneurysm may be less likely to rupture than a noncalcified or minimally calcified one. In a review of cases through 1959, 14 of 100 noncalcified aneurysms ruptured.[24] In a more recent series, 15 of 18 ruptured renal artery aneurysms were noncalcified.[28] However, in a series of 62 solitary aneurysms less than 4 cm in diameter, one-third were not calcified, and only one aneurysm in the entire series ruptured after 1 to 17 years of follow-up.[23] Because of these conflicting data, some authorities believe that the presence or absence of calcification is not relevant when predicting the risk of rupture.[2]

Most authorities agree that pregnancy is associated with a significantly increased risk of rupture for renal artery aneurysms.[2,10,20,29] Pregnancy may increase the risk of rupture because of a hyperdynamic state with increased blood volume and cardiac output, hormonal influences, and increased intraabdominal pressure due to the gravid uterus.[1,10] Cohen and Shamash[29] reported 18 cases of rupture during pregnancy. In another series of 18 patients who underwent surgery for renal artery aneurysms, the only two ruptures were in women at childbirth; both of these aneurysms measured only 1 cm in diameter.[1] In a review of 43 ruptured renal artery aneurysms, 81% occurred in women; 21 of the 35 women in this series were younger than 40 years old, and 18 were pregnant. Of the 18 aneurysms of known size, three ruptured when they were less than 2 cm.[30] Rupture of renal artery aneurysms in pregnancy has been associated with a maternal mortality rate of 55% and a fetal death rate of 85%.[29,31] Vascular surgeons should maintain an aggressive surgical or endovascular approach for pregnant women with renal artery aneurysms of any size, namely more than 1.5 times the diameter of the normal adjacent artery.

It seems prudent to recommend repair of renal artery aneurysms in men and women older than childbearing age when the diameter is at least greater than 3 cm in good-risk patients when there is reasonable certainty that nephrectomy will not be required.[24,27] In a recent review of 865 renal artery aneurysms from 16 institutions, the authors concluded that these aneurysms rarely rupture when asymptomatic (even if >2 cm), major complications occurred in 10% of patients postoperatively, and recommended repair for renal aneurysms greater than 3.0 cm in asymptomatic patients of non-childbearing age (Klausner et al., 2015). An even more conservative approach reserving repair for aneurysms greater than 4 cm has been suggested; in our opinion, this is not unreasonable.[32] As previously mentioned, any renal artery aneurysm in women of childbearing age should be repaired—namely, more than 1.5 times the diameter of the normal adjacent artery.

Hypertension

Although the prevalence of hypertension in patients with renal artery aneurysms is approximately 80%, there is no conclusive evidence that the aneurysms themselves are the direct cause of hypertension, unless there is an associated stenosis or compression of an adjacent artery.[1,10,20] In a series of 39 patients with renal artery aneurysms, 26 had diastolic hypertension, but only nine (23%) patients had hypertension that was of renovascular origin.[1] The indication for intervention for renovascular hypertension due to renal artery stenosis continues to be failure of medical management. The same criterion should be applied when a renal artery aneurysm is present (if large size alone is not otherwise an indication for repair). If the primary indication to repair a renal artery aneurysm is poorly controlled hypertension, a nephrology consult should be routinely obtained to be sure there are firm indications for intervention for this reason. Both the stenotic artery and the aneurysm should be repaired.

Dissection

Emergent intervention is required for dissections that cause renal artery aneurysms and threaten the viability of the kidney. Nephrectomy is frequently required because of the extensive damage to the renal branch vessels and the limited time available to salvage a previously healthy kidney that cannot tolerate prolonged periods of ischemia. If hypertension is the only manifestation of a chronic dissection and the hypertension is well controlled by blood pressure medications, or if the patient is asymptomatic and a renal artery dissection is found incidentally (without an associated aneurysm), endovascular or surgical repair is not justified.[10]

Other Clinical Manifestations

If a patient with an intact renal artery aneurysm as documented by CT or magnetic resonance imaging (MRI) is symptomatic,

repair may be indicated. Acute onset of symptoms is more worrisome than a patient referred for months of abdominal pain or fullness, unless the renal artery aneurysm is very large. Symptoms may be a harbinger of impending rupture. Embolization of mural thrombus from the aneurysm to the renal parenchyma may also account for these symptoms.[9] Nonetheless, it is difficult to attribute chronic abdominal pain to an intact 2-cm diameter renal artery aneurysm. Other causes need to be thoroughly investigated.

Treatment: Medical, Endovascular, Surgical

Repair of a Ruptured Renal Artery Aneurysm

If emergent surgery is required for a ruptured renal artery aneurysm, a sizable juxtarenal hematoma may not allow safe exposure of the proximal renal artery or even of the aortic immediately above the renal arteries for clamping to obtain proximal control. Therefore, in many cases, a midline approach and supraceliac aortic control may be temporarily required. If the bleeding is quickly controlled, the patient is hemodynamically stable, and the proximal and distal renal arteries lend themselves to a relatively quick and straightforward bypass, consideration can be given to reconstruction. In most cases, however, nephrectomy is required because of the instability of the patient or the limited warm ischemic time of the kidney (less than 30-60 minutes in healthy patients). The prolonged ischemia of the kidney and the technical and time-consuming nature of surgical repair with a bypass generally result in a nonsalvageable kidney.[2,10,11,26] If the aneurysm extends into the renal parenchyma or if a "bench" repair of the kidney is required, the patient is generally best treated by nephrectomy, as long as the contralateral kidney is intact with normal function.

A stable patient with a ruptured renal artery aneurysm may be treated with endovascular techniques. The use of a stent graft may be the preferred treatment for lesions not involving the distal renal branches, as reported by Bloemsma et al.,[33] and Routh et al.[34] reported thrombosis of a leaking saccular aneurysm using Gianturco coils, thrombin, and bucrylate.

Elective Repair of Renal Artery Aneurysm

Elective repair of a renal artery aneurysm is usually more challenging than revascularization for renal artery stenosis. Most renal artery aneurysms extend past the bifurcation of the main renal artery and frequently extend into the renal parenchyma. For in situ repairs of a renal artery aneurysm, the left kidney can be exposed through a left retroperitoneal or midline transperitoneal approach. The right kidney can be exposed through a midline transperitoneal approach with a Kocher maneuver to reflect the right colon and duodenum medially or with a right subcostal incision.

Several methods have been used to repair renal artery aneurysms. The most straightforward technique for saccular aneurysms involves aneurysmorrhaphy with primary repair or patching. In three combined series of patients who underwent surgical repair of renal artery aneurysms, approximately one-third (6/18, 3/10, and 6/23) of the aneurysms were able to be repaired in this manner.[1,9,20] A common renal arterial reconstruction is an end-to-side anastomosis of a small renal artery branch to the main renal artery or a side-to-side anastomosis of two small renal arteries to create a common inflow channel with a single, larger diameter lumen, which can then be anastomosed to the more proximal renal artery (or to the distal end of a bypass). Because the small branches of the main renal artery are often involved with the aneurysm, a branched autologous graft is preferred to reconstruct these lesions. The internal iliac artery is an excellent choice in these reconstructions because of its multiple small side branches.[27,35] Alternatively, the saphenous vein is preferred.[8,20] The proximal anastomosis of the graft is usually the infrarenal aorta. Useful alternative reconstructions include a splenorenal bypass for a left-sided renal artery aneurysm and hepatorenal bypass for a right-sided aneurysm.

If multiple branch vessels are involved and renal ischemic time is expected to exceed 30 to 60 minutes, and especially if the cause of the renal artery aneurysm is dissection resulting in a friable vessel, extracorporeal or bench surgery may be required.[36,37] Ex vivo surgery requires nephrectomy, followed by hypothermic perfusion of the kidney with a heparinized renal preservation solution. The kidney can then be autotransplanted to its original bed, as Dean et al.[38] and Crutchley et al.[39] prefer, or to the iliac fossa. For renal autotransplantation into the iliac fossa, a flank incision with a retroperitoneal approach is used for exposure of the kidney, ureter, and iliac artery. Gonadal and adrenal veins are divided to obtain an adequate length of renal vein. If the reconstruction can be safely performed by placing the kidney on the anterior abdominal wall, the ureter does not need to be divided. The procedure is occasionally best performed at a separate table after dividing the ureter and removing the kidney from the operative field. Perfusion is carried out through the main renal artery to preserve the kidney, while selected branches are individually repaired and other branches are perfused. The kidney may be perfused with a heparinized crystalloid solution, such as Collins solution or lactated Ringer's solution with heparin 1000 U/L with 12.5 g of mannitol, while the kidney is wrapped with gauze and placed in a chilled solution at 4°C.[8,34,40] The use of continuous pulsatile perfusion is controversial.[34]

When performed for proper indications by well-trained vascular surgeons, elective repair of renal artery aneurysms has been associated with very low mortality.[2,9,40,41] English et al.[42] reported a 1.7% perioperative mortality rate in 62 patients with 72 renal artery aneurysms with a 4-year patency of 96% and cured or improved hypertension in three quarters of patients. Pfeiffer et al.,[43] from Germany, reported similar excellent long-term surgical results in a series of 94 patients. A series of 26 renal artery aneurysms that required reconstruction of first- or second-order branches were repaired primarily with in situ techniques. Autogenous vein bypasses resulted in a mortality of 0%, with long-term patency of 95% at an average follow-up of 99 months (range, 1-300 months).[44] Ex vivo repairs have been shown to be safe and effective by Dean et al.,[38] Crutchley et al.,[39] and others.[36] In a review of ex vivo repairs, postoperative mortality rates ranged from 0% to 9.6%.[45] The use of bifurcated internal iliac artery autografts was also highly successful in a

series of 11 patients, most with fibrodysplastic aneurysms who were treated by in situ or bench repair.[35]

Recent technologic and surgical developments have allowed less invasive surgical repair of complex renal artery aneurysms. Both laparoscopic and robot-assisted techniques have been described.[46-48]

An alternative approach to the treatment of renal artery aneurysms includes the use of endovascular techniques.[27,49-51] Degenerative renal artery aneurysms have been treated with transcatheter embolization with detachable platinum coils that occlude the aneurysms but maintain renal flow.[50-52] In a small series of endovascular repairs, Klein et al.[50] treated 12 renal artery aneurysms using selective endovascular embolization with nondetachable microcoils or Guglielmo's detachable coils. In another series, 13 patients with renal artery aneurysms were successfully treated using a variety of endovascular techniques with combinations of coil embolization, liquid embolization, stenting, and stent grafts, with no complications after an average follow-up of 43 months (range, 13-103 months).[53] A series of 18 renal artery aneurysms were also treated with endovascular intervention.[54] Sixteen of the 18 aneurysms were embolized utilizing adjunctive techniques to protect embolizing into the main renal artery. There was a 100% technical success rate, with only one aneurysm showing residual minor flow into the sac and with no long-term complications. Alternatively, several authors have recently reported using ethylene vinyl alcohol copolymer to ablate renal artery aneurysms.[55-57]

Endovascular stent graft exclusion as a definitive treatment for renal artery aneurysms has been widely reported. Many aneurysms extend to branch vessels, making this approach risky or ill-advised, but it may be ideal for aneurysms of the main renal artery not involving branches. Advances in stent graft technology, with smaller diameter devices and lower profile delivery systems, have made definitive treatment of renal artery aneurysms feasible. A review of the English literature analyzing the use of stent grafts to treat renal artery aneurysms up to 2010 yielded 22 cases with a technical success rate of 91% (20 cases), without any deaths or significant morbidity reported.[58] Although most published series have been small, results have been excellent, and this approach will undoubtedly become more common as technology improves.[59-63]

A nationwide inpatient sample of 6234 isolated renal artery aneurysms from 1998 to 2011 revealed an increase in endovascular repairs without a decrease in open repairs (Buck et al., 2016). Although the in-hospital mortality was low for both endovascular intervention (1.8%) and open repair (0.9%), complication rates were greater than 10% for both. The authors concluded that indications for repair of renal artery aneurysms should be re-evaluated and possibly be less aggressive.

Fibromuscular Dysplasia

Poststenotic dilatation causing hypertension resulting from fibromuscular disease can be treated by balloon angioplasty of the stenotic lesion. When the lesion extends into the branches of the main renal artery, surgery can yield excellent results. Dean et al.[38] reported 24 patients with fibromuscular disease, many of whom had branch aneurysms; all but one did well.

Intrarenal Aneurysms

Intrarenal aneurysms represent particularly challenging lesions. Frequently, a partial nephrectomy is required.[45] Intrarenal aneurysms in association with polyarteritis nodosa have also been successfully treated with renal artery embolization, with preservation of the kidney.[64]

RENAL ARTERIOVENOUS MALFORMATIONS AND FISTULAE

Arteriovenous malformations (AVMs) and AVFs are uncommon lesions that can be associated with hematuria, hypertension, renal dysfunction, high-output congestive heart failure, and even rupture. More than 200 cases have been reported since the first description in 1928.[65] Fistulae may be congenital or acquired. Multiple diagnostic modalities are now available, although conventional selective arteriography remains critical in therapeutic interventions. Many asymptomatic lesions do not require treatment. In the past, symptomatic lesions were treated surgically, but endovascular treatment has now supplanted surgery in most cases.

Epidemiology and Pathogenesis

Congenital Arteriovenous Malformations

True congenital AVMs of the kidney are rare, with an incidence of only 0.04%.[66] In a large series, only 1 congenital AVM was noted in 30,000 autopsies.[67] These lesions represent approximately one-fourth of all renal AVFs.[68,69] The right kidney is involved more often than the left, and although multiple lesions can occur, a single focus is more common.[36] The angiographic appearance of the lesions is similar to that of AVMs elsewhere, with large coils of dilated vessels. An early "blush" is noted and correlates with the degree of arteriovenous shunting.

These lesions have been described as cirsoid or varix-like, and are generally focal and located in the renal medulla. AVMs are not neoplastic, but enlargement presumably can occur because of vessel dilatation and hypertrophy associated with high-flow volume from arteriovenous shunting. Symptomatic AVMs have been reported in pregnancy,[65,70] and it is thought that the hyperdynamic state of the gravida leads to increased AVM flow and symptoms. Histologically, involved vessels have irregular fibrosis or intimal hyperplasia, as well as medial hypertrophy.

Acquired Arteriovenous Fistulae

Acquired AVFs may occur spontaneously. Spontaneous AVFs have been documented in association with fibromuscular dysplasia[71] and are thought to develop when a dysplastic or aneurysmal renal artery erodes into a neighboring vein.[72] This may also occur with renal malignancy, and significant arteriovenous shunting is a hallmark of renal cell carcinoma.[73] With arteriography, it can be difficult to differentiate a renal malignancy from a congenital or acquired AVF, although CT and MRI generally reveal a mass distinct from the renal parenchyma in malignancy.

Traumatic AVFs are the most common lesions, accounting for more than 70% of all renal AVFs.[65] These lesions may occur after nephrectomy, and are related to the erosion of the arterial stump into the vein with mass ligature,[67,74,75] after renal artery angioplasty,[65] after blunt[76] or penetrating[74] trauma, after nephrostomy,[76] and most commonly, after percutaneous renal biopsy. With the routine use of needle biopsy for the diagnosis of rejection in renal allografts, the incidence of acquired AVFs has grown, although only 1% to 2% of patients who undergo needle biopsy develop symptomatic AVFs.[77,78] However, the true incidence of AVF is 15% to 18% when arteriography is routinely used.[79,80] Similarly, Ozbek et al.[81] found AVFs in 8 of 64 patients (12.5%) monitored by color duplex ultrasonography, whereas only 5% developed AVFs in the study of Rollino et al.[82] In the prospective study of Merkus et al.,[79] who used routine color duplex surveillance, 10% of patients who underwent biopsy developed AVFs.

Clinical Presentation

The majority of both congenital and acquired AVFs do not produce clinical symptoms, and many lesions are noted incidentally in studies done for other reasons. The most common symptom of congenital AVM is hematuria, which occurs in 72% of cases.[67] Hematuria occurs when subepithelial varices erode transitional epithelium into the collecting system. A dramatic presentation with massive hematuria can occur,[70,83,84] although minor or microscopic hematuria is more common. Hypertension occurs in congenital AVMs and is also the primary abnormality in most acquired AVFs that are described as symptomatic. The hypertension is renin-mediated, based on diminished glomerular filtration pressure distal to the fistula because of arterial "steal."[69,85,86]

Although AVFs are generally painless, intermittent perilumbar discomfort has been reported in some patients.[73,75] This discomfort is generally associated with hematuria and may re-present as renal colic. In addition, dyspnea and other symptoms of congestive heart failure may be the primary complaint in some patients; this is more common with acquired lesions, and only with those having a large communication between the artery and vein. This "high-output" type of heart failure manifests as tachycardia, left ventricular hypertrophy, and cardiomegaly, and a palpable thrill in the flank. A continuous abdominal bruit is a hallmark of acquired AVFs and is frequently noted with congenital AVMs as well. Retroperitoneal or intraabdominal hemorrhage rarely occurs with AVMs and AVFs.[83,87] However, patients with rupture present with severe abdominal and flank pain and shock, a clinical picture indistinguishable from ruptured abdominal aortic aneurysms.

Diagnosis

Excretory urography is performed in many patients presenting with hematuria or flank pain. A filling defect may be noted in the kidney, and dilated vessels can compress the collecting system, although these findings are not specific.

CT can usually define AVFs and AVMs within the kidney, but it is not always possible to differentiate these lesions from other hypervascular abnormalities (e.g., renal cell carcinoma). Similarly, radionuclide imaging can demonstrate early augmented perfusion, but differentiation from malignancy is not possible.[88] In contrast, CT angiography has significantly improved the noninvasive imaging of AVFs and AVMs.[89] Likewise, contrast-enhanced MRA allows three-dimensional reconstruction that can provide visualization not possible with conventional angiography.[90]

Color duplex imaging is also of growing importance in the diagnosis of AVMs and AVFs. Because it is inexpensive and noninvasive, it is the ideal study for screening purposes. Color duplex imaging has been used liberally to assess for AVFs after percutaneous renal biopsy.[79,91,92] Marked turbulence is noted on color examination, and Doppler spectral analysis reveals an elevation of peak systolic flow velocity and a larger increase in end-diastolic flow velocity compared with the normal renal artery, with a resultant low resistive index.[81,91]

In the past, contrast arteriography was the definitive diagnostic modality for renal AVMs and AVFs. Rapid opacification of the inferior vena cava is noted. Depending on the size of the fistula, the nephrogram may be diminished distal to the AVF. With congenital AVMs, multiple segmental and interlobar arteries communicate with varix-like veins, whereas a single arterial communication is generally present with acquired AVFs.[67]

Treatment: Medical, Surgical, Endovascular

The majority of both congenital and acquired AVFs do not cause symptoms and do not require treatment. However, patients may become symptomatic, and even if asymptomatic, should be closely observed for the development of hypertension, hematuria, or high-output cardiac failure. Most AVFs occurring after percutaneous renal biopsy close spontaneously.[79,81,85,92,93] Periodic duplex surveillance, along with clinical follow-up for the development of hypertension or renal insufficiency, is indicated. If a postbiopsy AVF persists at 1 year, it is not likely to close spontaneously,[77] although intervention should still be delayed until the development of symptoms.[79,86] Spontaneous regression of AVMs unrelated to trauma has also been reported.[94,95] Although hypertension related to an AVF may be readily controlled with angiotensin-converting enzyme inhibitors,[71] the long-term effect on renal function is not known. In most published reports, patients with hypertension have undergone surgical or endovascular therapy; thus the natural history of medically treated patients with hypertension secondary to AVFs remains undefined.

For patients with symptomatic AVFs, surgery remains an option, although a declining one (Chimpiri and Natarajan, 2009).[96,97] Except for very peripheral lesions, a transperitoneal approach is preferred to establish proximal arterial and venous control at the renal pedicle. Because of the frequent presence of thin-walled dilated veins and channels, surgery can be challenging. With surgery, ligation of the feeding vessel or vessels alone is often not possible, and partial or total nephrectomy is often required. The resultant loss of functional renal mass, as well as the morbidity of the operation itself, makes endovascular treatment an attractive approach.

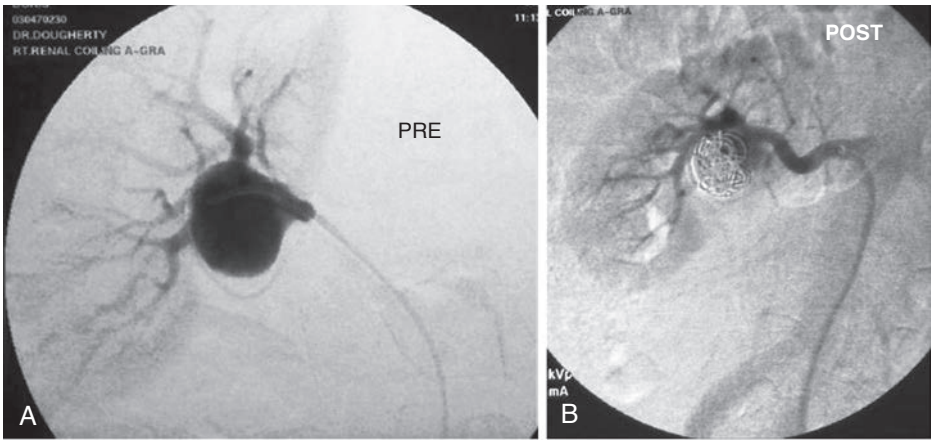

Figure 128.1 (A) Arteriogram showing a post-traumatic arteriovenous fistula. This patient experienced a stab wound to the flank and presented with hematuria. (B) After Gianturco coil embolization of multiple arterial branches, venous communication is no longer present. Hematuria resolved, and the patient recovered uneventfully.

There are now more than 3 decades of experience with percutaneous arterial embolization therapy for congenital and acquired AVFs.[98] Because renal arteries are "end arteries," they are especially amenable to therapeutic occlusion using gelatins, glues, alcohols, silicon, steel and platinum coils, and detachable balloons.[23,68,87,92,99,100] The development of co-axial catheter systems has allowed highly selective embolization, which can preserve renal function; loss of functional renal parenchyma is reportedly between 0% and 30% with modern techniques. In general, smaller AVFs are treated with glues or macroparticles, whereas coils and balloons are used for larger vessel fistulae (Fig. 128.1; Wetter et al., 2012).[101] Because Gelfoam (Pfizer, New York) and autologous clot resorb, recanalization with recurrence of symptoms can occur in up to 50% of cases.[102,103] For this reason, and because of the perception that microcoils are associated with less indiscriminate embolization than glues and alcohols, recent trends favor the use of microcoils even for smaller AVFs and AVMs[23,87,92]; however, the success rate has been reported to be higher if liquid agents are used in addition to coils (Murata et al., 2014).

For very large AVF, covered stent exclusion has been described,[104] and others have utilized bare metal stents to provide a barrier to coil extrusion.[105] Radiofrequency ablation has recently been described as well (Kwak and Shim, 2008).

Very large AVFs may present a technical challenge because of the risk of central embolization. Some authors recommend surgery in this setting.[96,97,106,107] Others have reported success in this setting using the Amplatz spider device (Cook Medical, Bloomington, Indiana) to provide a scaffolding that can then engage other embolic materials.[68,74] Staging the procedure—beginning with large coils, followed weeks later by smaller coils and other materials to close off persistent flow channels, may also be an effective strategy.[108] Because very large arteriovenous communications tend to be at the renal pedicle rather than intraparenchymal, surgical treatment is feasible and probably preferable for good-risk patients. In the case of surgical therapy, ex vivo techniques may be of value.

Complications of embolization are unusual but not insignificant. In addition to arterial access site morbidity and contrast agent toxicity, pulmonary or peripheral arterial embolization can occur. Large AVFs require large devices such as coils or detachable balloons, but even these can embolize centrally. Gelfoam, alcohol, and various glues may be more appropriate for very small communications, but the delivery is less precise, and renal parenchymal infarction seems to be greater with these materials.[85] It is common for patients to have transient fever, leukocytosis, and even hypertension after embolization.[80] With modern techniques, endovascular treatment is successful in more than 80% of patients, although repeat treatments are sometimes necessary (Eom et al., 2015)[109] and is clearly the treatment of choice for symptomatic congenital and most acquired AVFs.

Acute renovascular ischemia is defined as a sudden interruption of arterial and/or venous renal blood flow; it may involve either partial or complete ischemia of one or both kidneys. Because the renal arteries are considered "end arteries," acute ischemia can rapidly progress to irretrievable loss of renal function if it goes unrecognized or untreated. Appropriate clinical management of acute renal ischemia is therefore quite time-sensitive; the duration and severity of ischemia are therefore key considerations for decision making related to both medical and procedural intervention. In the setting of acute renal ischemia, salvage of a functioning kidney requires a high index of suspicion, rapid diagnosis, and quick implementation of a definitive treatment plan.

Causes of acute renal ischemia include renal artery thrombosis, embolism, trauma, aortic or renal artery dissection, iatrogenic injury, and renal vein thrombosis (Table 129.1). Evidence supporting specific management strategies for acute renal ischemia is limited and primarily comes from case reports and small cohort studies, perhaps because of the relative rarity of this diagnosis.

Main renal artery occlusion occurring during endovascular aortic aneurysm repair is discussed in Chapter 72. Similarly, other iatrogenic injuries of the renal artery, including complications occurring during angioplasty and stenting, are specifically covered in Chapter 127. Acute renal ischemia associated with aortic dissection is covered in Chapter 81; and detailed discussions of open surgical revascularization are found in Chapter 126. Further discussion of the management of renal artery trauma, including penetrating injury, can be found in Chapter 183.

PATHOPHYSIOLOGY

Renal ischemic injury is characterized by glomerular collapse and tubular necrosis, resulting in reduced glomerular filtration and loss of tubular function.[1] Reperfusion further induces endothelial dysfunction in acute ischemic renal failure, resulting in excess cytokine secretion and the expression of adhesion molecules that promote leukocyte influx. Reperfusion injury also leads to excessive production of nitric oxide and reactive

TABLE 129.1 Causes of Acute Renal Ischemia

Renal artery thrombosis
Atherosclerotic disease
Aneurysmal disease
Dissection (aorta or renal artery)
Fibromuscular dysplasia
Arteritis (e.g., Takayasu)
Stent thrombosis
Hypercoagulable state
Renal artery embolism
Chronic atrial fibrillation
Valvular heart disease
Aortic plaque
Paradoxical embolism in setting of patent foramen ovale
Cardiac tumor
Trauma
Iatrogenic
Direct injury or embolization
Ostial occlusion by aortic endograft
Renal vein thrombosis
Hypercoagulable state
Mechanical obstruction
Malignancy

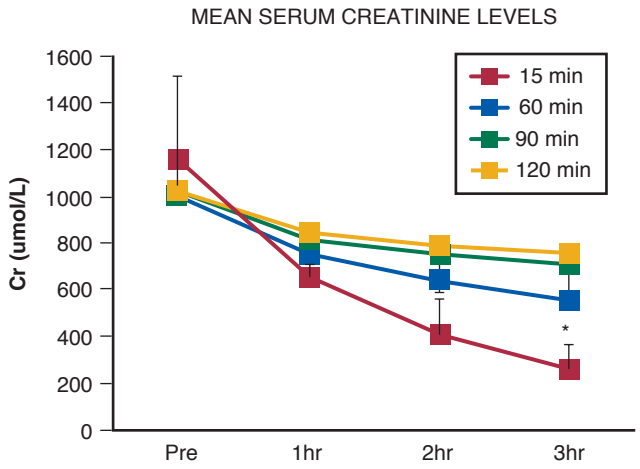

Figure 129.1 Duration of Warm Ischemia and Mean Serum Creatinine. Mean serum creatinine levels following 15, 60, 90, and 120 minutes of warm ischemia and 2 hours of static cold storage. (From Hosgood SA, Shah K, Patel M, and Nicholson ML. The effect of prolonged warm ischaemic injury on renal function in an experimental ex vivo normothermic perfusion system. *J Transl Med.* 2015;13:207).

oxygen species, which result in additional parenchymal damage and impaired autoregulation of renal blood flow.[2]

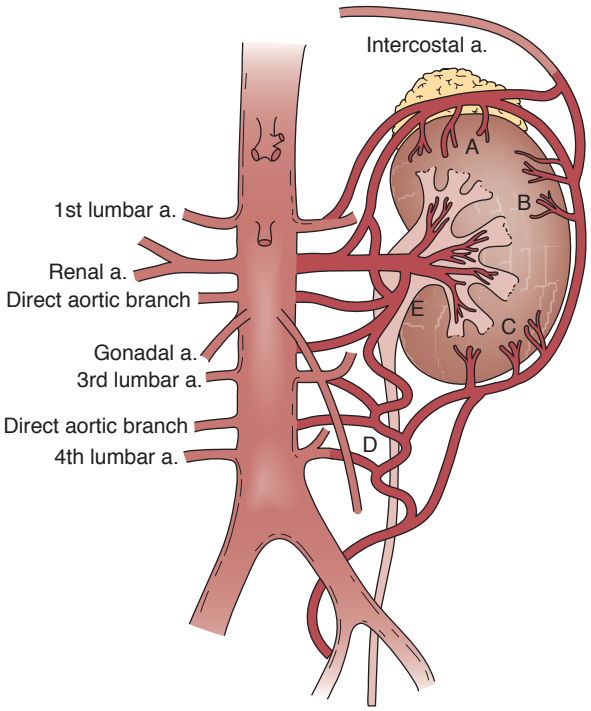
The baseline kidney function and duration of acute warm renal ischemia affect the potential for recovery of renal function and are therefore important considerations when revascularization is being considered. Age and diabetes have been identified as patient-specific risk factors associated with increased susceptibility to injury from acute renal ischemia in experimental models.[3,4]

Duration of Ischemia

In a normal kidney, 1 hour of warm renal ischemia is associated with loss of 70% to 80% of renal function, but complete recovery can occur within weeks; increasing the duration of ischemia to 2 hours diminishes long-term recovery to 30% to 50% of baseline.[5] In vivo models of acute, total renal artery occlusion have demonstrated irreversible ischemia after a period of 3 to 4 hours, but this varies substantially by species.[6,7] Figure 129.1 shows serum creatinine levels in a porcine model following periods of warm renal ischemia lasting 15, 60, 90, and 120 minutes.[8] Prolonged ischemia time (>45 minutes) has been identified as a predictor of poor early graft function following living donor kidney transplantation,[9] and more than 90 minutes of acute warm ischemia has been suggested as a cut point for the retrieval of renal function.[10] Technically successful revascularization performed after longer durations of acute ischemia therefore may not be followed by functional recovery, especially when overt renal failure or anuria is already present.[10,11]

Gradual Versus Acute Renal Occlusion

In contrast to acute renal artery occlusion, gradual main renal artery occlusion (e.g., main renal artery stenosis, which progresses in severity over months or years) may result in the development of collateral circulation, which may lessen the severity of



A. Superior capsular complex
B. Lateral capsular complex
C. Inferior capsular complex
D. Periureteric complex
E. Peripelvic complex

Figure 129.2 Collateral Circulation of the Kidney. (From Flye MW, Anderson RW, Fish JC, Silver D. Successful surgical treatment of anuria caused by renal artery occlusion. *Ann Surg.* 1982;195:346-353.)

the ischemic insult. Renal artery collaterals originate from the inferior adrenal, gonadal, ureteral, internal iliac, lumbar, intercostal, and capsular arteries (Fig. 129.2).[12-15] Less commonly, collaterals may also originate from the inferior mesenteric artery.[16] Prerenal communication may exist at the hilum, while intrarenal

communication occurs through capsular perforating arterioles. As much as 80% of renal arterial collateral communication may be independent of the main renal artery,[7] potentially allowing maintained kidney viability in the setting of main renal artery occlusion (particularly in the setting of acute thrombosis of a chronic critical stenosis).[14,17] Extrarenal arteries (alternatively referred to as accessory, aberrant, or duplicated renal arteries) may also preserve direct arterial flow from the aorta and have a reported prevalence of 24% to 42% based on imaging and cadaver studies.[18-21]

Glomerular collapse and tubular necrosis occur following acute reduction of renal perfusion pressure; in the setting of gradual reduction of renal perfusion, however, maintained tubular function (reflected by low fractional excretion of sodium and normal *N*-acetyl-glucosaminidase excretion) has been observed despite reductions in both glomerular filtration rate and filtration fraction.[1] In a canine model of gradual renal artery occlusion induced incrementally over a period of 7 weeks, collateral circulation developed, which was sufficient to maintain both renal viability and life.[22] Reports of functional recovery following periods of main renal artery occlusion exceeding 24 hours underscore the importance of collateral perfusion and demonstrate that the potential for kidney salvage is not a function of warm ischemia time alone.[23-31] Main renal artery occlusion accompanied by the visualization of good renal vein flow on duplex ultrasound suggests the presence of collateral arterial flow.[31]

Renal Vein Thrombosis

Renal vein thrombosis, which may occur primarily or in association with thrombosis of the inferior vena cava, can also produce acute renal ischemia. Renal vein thrombosis may be unilateral or bilateral; as with acute arterial ischemia, the degree of functional impairment and severity of clinical presentation are related to the acuity of venous occlusion and presence or absence of collateral flow.[32] When renal vein thrombosis occurs rapidly in the absence of developed collaterals, congestion and edema of the affected kidney can produce pain due to capsular distension as well as hemorrhagic infarction.[33,34] Experimental models have demonstrated that renal injury and blood flow reduction are both more severe with acute venous versus arterial occlusion.[35]

CLINICAL PRESENTATION

Symptoms and signs of acute renal ischemia include abdominal or back pain, dyspnea, nausea, vomiting, hematuria, anuria, and acute hypertension.[24,26,29,30,36-39] Since many of these symptoms are relatively nonspecific, the differential diagnosis for acute renal ischemia is broad and includes a variety of nonrenal pathologies. Renal colic with nephrolithiasis is a common initial presumptive diagnosis owing to the similarity of presenting symptoms, and several reports have recommended that absence of renal calculi on an unenhanced computed tomography (CT) scan performed for suspected renal colic should prompt a contrast-infused study to rule out acute ischemia.[40-43] Other diagnoses with symptoms similar to renal ischemia include pyelonephritis, renal carcinoma, mesenteric ischemia, cholecystitis or biliary colic, gastritis, splenic infarction, myocardial infarction, and pulmonary embolism.[24,30,37,40,44]

The presentation of acute renal ischemia is often delayed for hours or days after symptom onset, adversely affecting the possibility of functional salvage through revascularization. In a series of patients with embolic renal artery occlusion secondary to atrial fibrillation described by Hazanov et al., the majority of patients presented more than 24 hours following the onset of symptoms[40]; Huang et al. reported a median time of 31 hours between symptom onset and presentation to the emergency department for acute renal infarction.[36]

Renal vein occlusion may also present with unilateral renal congestion and tenderness, although the enlarged kidney is rarely palpable in adult patients.[33] In a retrospective cohort study of neonates with renal vein thrombosis, the "classic triad" of flank mass, gross hematuria, and thrombocytopenia was identified in only 13% of patients.[45]

DIAGNOSTIC EVALUATION

Laboratory Tests

Because no single laboratory test is diagnostic of acute renal ischemia, tests must be selected and interpreted in combination with the clinical presentation and findings on physical examination.

Laboratory findings associated with acute renal ischemia include leukocytosis, elevated lactate dehydrogenase (LDH), microscopic or gross hematuria, proteinuria, elevated D-dimer, and eosinophilia.[26,28,30,36,40,41,46,47] Eosinophilia may be indicative of atheroembolism.[47,48] In a series of 20 patients with acute renal ischemia, 19 patients had an elevated serum LDH, while 16 had the triad of flank/abdominal pain or tenderness, elevated serum LDH, and proteinuria.[36] Only half of patients presenting with acute renal ischemia have an elevated serum creatinine,[41] so a normal serum creatinine does not exclude this diagnosis. In the setting of a contralateral kidney with normal function, asymptomatic unilateral renal ischemia may be identified as an incidental imaging finding, the acuity of which cannot be determined.

Imaging Tests

Imaging plays a critical role in the diagnosis of acute renal ischemia because of the frequently nonspecific nature of the presentation, physical examination, and laboratory findings. The ideal diagnostic imaging test for renal ischemia would be rapid, widely available, noninvasive, inexpensive, and with no need for either radiation exposure or contrast administration. Although no imaging technique has all of these characteristics, consideration of these attributes can be helpful in choosing the most appropriate study based on the clinical presentation.

Computed Tomography Angiography

Computed tomography angiography (CTA) is a widely available imaging technique that is rapid and useful for ruling out other soft tissue abnormalities when acute renal ischemia is being considered. Although CTA results in radiation exposure and requires contrast administration for definitive diagnosis, it is

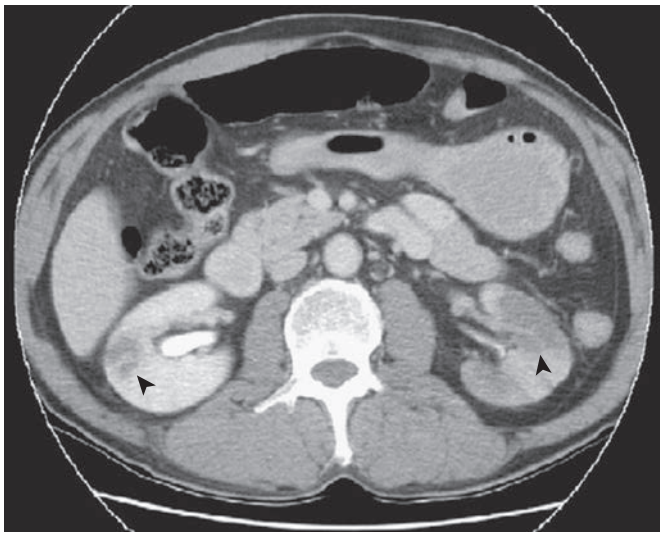


Figure 129.3 Computed Tomography Angiography Demonstrating Bilateral Renal Infarcts. Patient had sudden onset bilateral flank pain with a history of atrial fibrillation. Bilateral wedge-shaped, hypodense lesions (arrowheads) are consistent with embolic renal infarcts. (From Huang C-C, Lo H-C, Huang H-H, et al. ED presentations of acute renal infarction. *Am J Emerg Med*. 2007;25(2):164-169.)

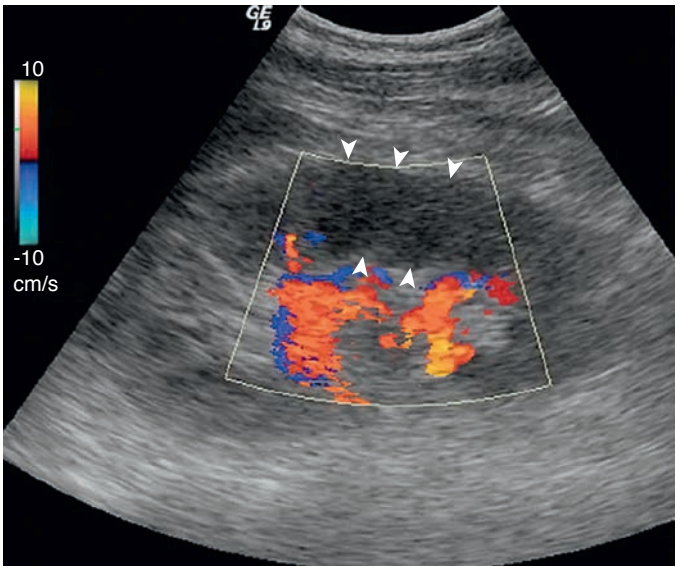

Figure 129.4 Renal Infarction Demonstrated by Duplex Ultrasound. Renal infarction caused by arterial embolism appears as a wedge-shaped hypoechoic area with absence of blood flow signal (arrows). (From Cai S, Ouyang YS, Li JC, et al. Evaluation of acute renal artery thrombosis or embolism with color Doppler sonography. *Clin Imaging*. 2008;32(5):367-371.)

more sensitive than ultrasound and less time consuming than magnetic resonance angiography (MRA), with a reported sensitivity of 80%.[40] CTA also provides a thorough evaluation of aortic and iliac anatomy and/or disease, which may be useful when revascularization is being planned. CTA, which should routinely include both noncontrast and venous phase images, has also been suggested as the diagnostic imaging study of choice for renal vein thrombosis, with a sensitivity and specificity that both approach 100%.[34] Features of a renal infarct on CTA imaging include areas of hypoattenuation with associated mass effect (Fig. 129.3) or a "cortical rim sign," described as a rim of functioning nephrons supplied by capsular collaterals surrounding an otherwise nonfunctioning kidney.[40,41,49,50]

Magnetic Resonance Angiography

Renal MRA is capable of the anatomic evaluation of renal artery disease with the additional capability of physiologic assessment through flow-dependent imaging.[51] Unenhanced MRA is capable of characterizing renal artery disease with a reliability similar to that of CTA; its distinct advantages for evaluating renal segmental arteries and parenchymal disease[52] make it a potentially valuable technique when contrast imaging is contraindicated due to renal dysfunction. Although these advantages have resulted in the increasing utilization of MRA for the evaluation of chronic renal artery occlusive disease, MRA has not been utilized extensively as a first-line imaging modality for acute renal ischemia. This may reflect the practical limitations of MRA when rapid imaging assessment is required because it is more time-consuming and may require extensive image postprocessing prior to interpretation. Compared with CTA and/or ultrasound, rapid access to MRI is often relatively limited within emergency department and hospital environments, where acute renal ischemia is commonly evaluated.

Ultrasound

By comparison, ultrasound requires neither contrast nor radiation exposure but is less sensitive than CTA for renal ischemia. Renal infarcts typically appear as wedge-shaped, hypoechoic lesions with absent blood flow on duplex ultrasound (Fig. 129.4). Ultrasound imaging is also technician-dependent and may be challenging in patients who are obese or have excessive bowel gas. In a series of 44 patients with renal embolism, only 3 of 27 (11.1%) ultrasound studies were positive. In a retrospective review of 10 patients with renal artery thrombosis or embolism, Cai et al. concluded that color Doppler ultrasonography was useful for the detection of large infarcts resulting from main renal artery occlusion but that other imaging modalities were needed to confirm smaller infarcts.[53] They also reported decreased renal artery peak systolic velocity as a finding that may be associated with intrarenal embolism. In addition to renal vein thrombus, other ultrasound findings indicative of ischemia due to venous thrombosis may include unilateral kidney edema or congestion.

Nuclear Renal Scan

Nuclear renal isotope scanning has been suggested as the most sensitive imaging technique for the diagnosis of acute renal ischemia, but this modality is seldom practical because it is time-consuming and less widely available. The reported sensitivity of nuclear imaging for acute renal ischemia is 97%,[40] and infarcts are characterized by a marked reduction of renal blood flow with preserved kidney size.[54]

Angiography

Although catheter angiography potentially allows endovascular treatment of renal ischemia during the same procedure when

anatomically suitable disease is identified, use of this method for diagnostic purposes should be limited to situations where other imaging studies are equivocal or the index of suspicion is especially high (e.g., suspected iatrogenic injury).

RENAL ARTERY EMBOLISM

Epidemiology

Risk factors for renal artery embolism include atrial fibrillation, ischemic heart disease, cardiomyopathy, previous arterial thromboembolism, mitral or aortic valve disease, cardiac tumor, atherosclerotic aortic plaque, and paradoxical embolism in the setting of a patent foramen ovale (Fig. 129.5). Renal artery embolism is uncommon, with an incidence among hospitalized patients of 0.007% (or 6.1 per million per year).[55]

Renal artery branches are more commonly occluded by emboli than the main renal artery, making it challenging, unless a proximal source can be found, to distinguish between embolism and thrombosis when branch occlusion with a partial infarct is identified.

Cholesterol crystal embolization (CCE) is a distinct type of embolism characterized by multiple small renal emboli comprising cholesterol debris. Chronic CCE has an incidence of 6.2 per million people per year; risk factors include male gender, hypertension, and atherosclerosis.[56] CCE may also occur during arterial catheterization and/or procedural intervention, especially with repeated instrumentation of a diseased thoracic or abdominal aorta. CCE is associated with a 30% incidence of progression to dialysis within 2 years and increased mortality.[57] Additional discussion of CCE can be found in Chapter 103.

Treatment

Once embolic renal artery occlusion is established or strongly suspected, heparin anticoagulation should be initiated immediately to prevent local propagation of renal artery thrombus as well as additional embolic events at other anatomic locations.

Besides anticoagulation, patients with renal embolism also require thorough evaluation for the embolic source to determine whether additional treatment (such as repair of proximal aneurysmal disease, thrombectomy, repair of patent foramen ovale, or heart valve replacement) is warranted for definitive management and reduction of the long-term risk of repeat embolism. Among patients presenting with renal artery embolism, over 20% have a history of previous thromboembolism.[40,55,58]

Although successful management with anticoagulation alone has been described,[12,40] revascularization may be considered in patients presenting with acute ischemia and potentially salvageable renal function, especially in the setting of bilateral embolism. Conversely, anticoagulation alone can be used for definitive management in patients with unilateral embolism and limited potential for renal salvage (e.g., patients with preexisting chronic kidney disease or other renal pathology). In the report of Hazanov et al., over 80% of patients presenting with renal embolism were managed using anticoagulation alone, without procedural intervention.[40] One-month mortality was 11% in this series; 61% of patients had normal renal function at long-term follow-up, and only 8% required dialysis.

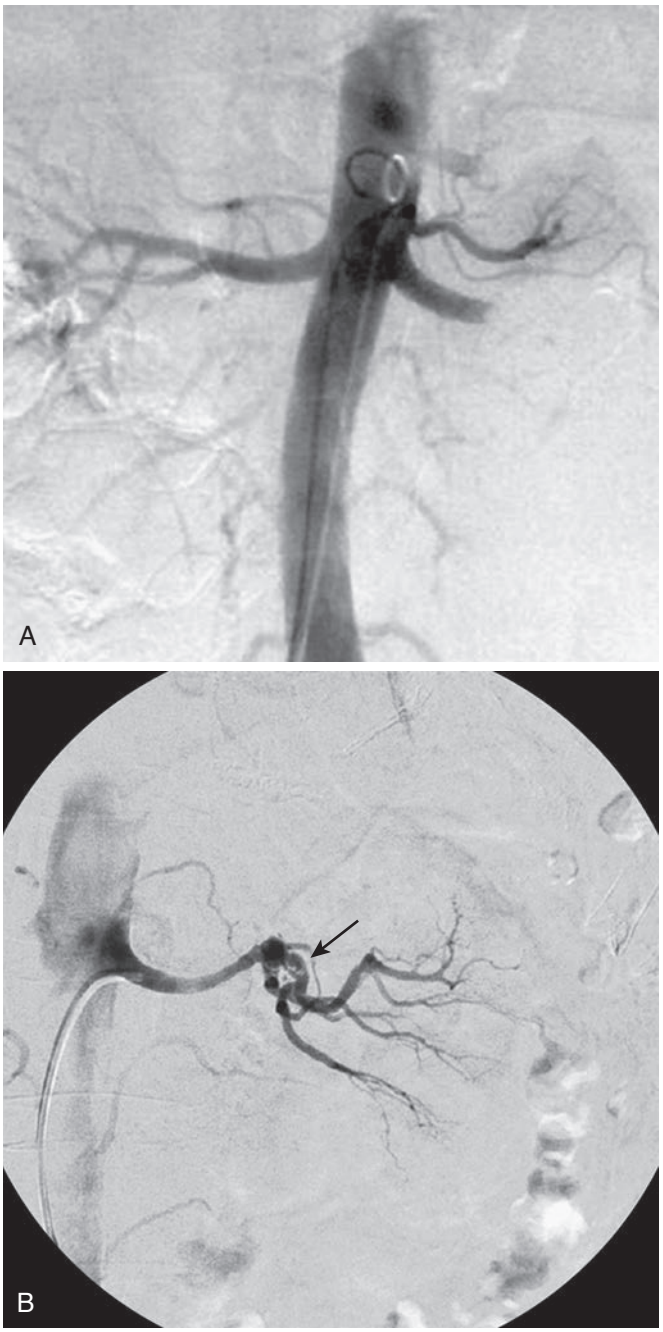

Figure 129.5 Renal Artery Embolism. (A) Contrast angiogram demonstrating left main renal artery occlusion resulting from embolism in a patient with atrial fibrillation (From Syed MI, Shaikh A, Ullah A, et al. Acute renal artery thrombosis treated with t-PA power-pulse spray rheolytic thrombectomy. *Cardiovasc Revasc Med.* 2010;11(4):264.e1-7.) (B) Contrast angiogram demonstrating branch renal artery thrombosis resulting from cardiac tumor embolus. (From Boggetto-Graham L, Chavanon O, Hacini R, et al. An uncommon cause of renovascular hypertension. *Can J Cardiol.* 2012;28(3):397.e1-3.)

Endovascular Treatment

Catheter-directed thrombolysis can be a valuable treatment strategy in the setting of acute renal ischemia resulting from

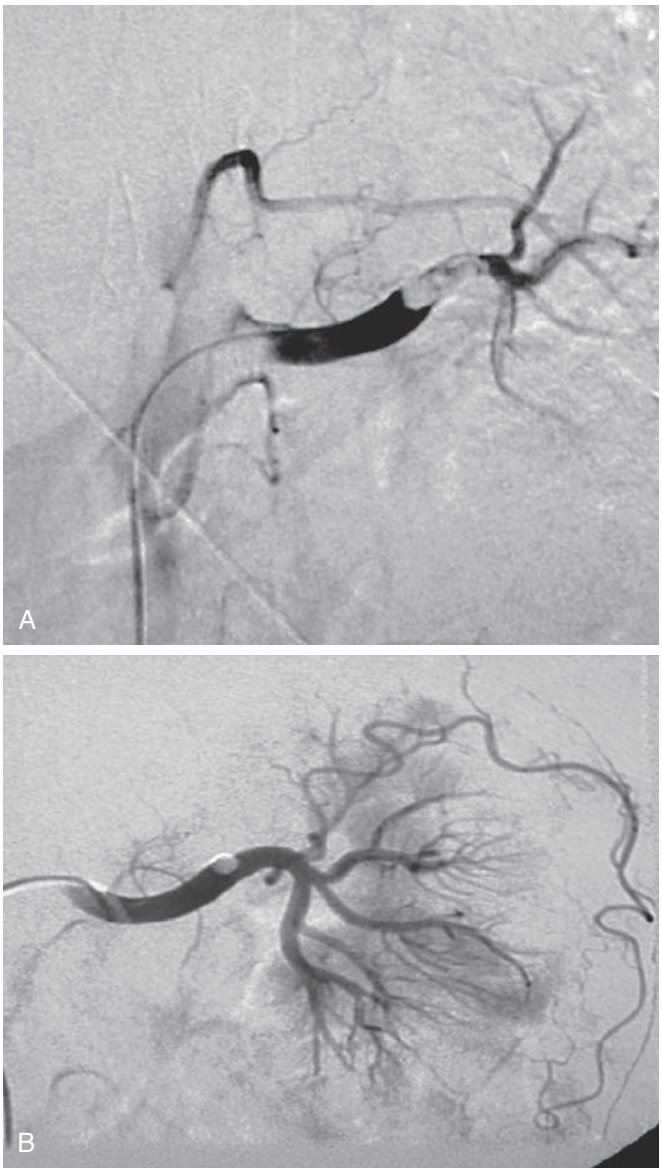

Figure 129.6 Management of Renal Artery Embolism With Catheter-Directed Thrombolysis. (A) Distal left renal artery embolus demonstrated by angiography. (B) Patent left renal artery demonstrated following catheter-directed thrombolysis. (From Robinson S, Nichols D, Macleod A, et al. Acute renal artery embolism: a case report and brief literature review. *Ann Vasc Surg.* 2008;22(1):145-147.)

arterial embolism, where the occlusion is typically located at the renal artery bifurcation or distal segmental branches (Fig. 129.6).[11,37,59,60] Rheolytic thrombectomy can be used in combination with thrombolysis and may permit definitive intraprocedural management with no need for placing a catheter for extended thrombolytic infusion.[28,38] Aspiration thrombectomy, angioplasty, and stenting may also be utilized as adjuncts to thrombolysis in the setting of embolic renal artery occlusion.[30] In a series of 14 patients with acute embolic renal artery occlusion, Blum et al. did not observe recovery of renal function in any patients presenting with complete main renal artery occlusion, whereas partial functional recovery was observed in the setting of either segmental branch or incomplete main renal artery occlusion.[10]

Open Surgery

Surgical embolectomy can be performed through a midline or flank incision[61,62]; following renal artery exposure, the artery and vein are mobilized and encircled with vessel loops. Embolectomy can then be performed through either a transverse or longitudinal incision in the renal artery, with removal of thrombus using forceps and a Fogarty catheter. Suprarenal control of the aorta should be obtained if thrombus extension into the aortic lumen is suspected. Following removal of the embolism and associated thrombus, the arteriotomy can be closed either primarily or with a patch angioplasty.

Intraoperative completion duplex ultrasound should then be considered to evaluate patency and rule out residual stenosis or other technical complications. Lacombe et al. reported a 25% mortality associated with surgical management of renal artery embolism; these authors noted a similar mortality but a lower rate of renal function recovery among patients managed medically.[63]

At present, surgical embolectomy is infrequently utilized for acute renal embolism because it is relatively invasive and time-consuming compared with endovascular treatment.

RENAL ARTERY THROMBOSIS

Epidemiology

Nonembolic renal artery thrombosis may result from a variety of both renal and extrarenal disease processes, including atherosclerotic renal artery stenosis, distal aortic occlusion from aneurysmal or atherosclerotic disease with proximal thrombus propagation, aortic or renal artery dissection, renal artery aneurysm, fibromuscular dysplasia, arteritis (e.g., Takayasu), stent thrombosis, hypercoagulable state, or trauma. Iatrogenic thrombosis may also result from renal artery coverage or injury during endovascular procedures. Other less common causes of renal artery thrombosis include antiphospholipid antibody syndrome,[64] factor V Leiden mutation,[65] heparin-induced thrombocytopenia,[66,67] and Beçhet disease.[68]

Thrombotic occlusion of preexisting atherosclerotic disease is most common among individuals over age 55 (Fig. 129.7). Although atherosclerotic renal artery stenosis has an incidence of 7% among elderly individuals,[69] progression to thrombosis is uncommon in the absence of other contributing factors, such as dehydration or hypotension.[54,70] In a study by Caps et al., the 5-year incidence of renal artery thrombosis in the setting of known stenosis was less than 5%; risk factors for thrombosis included systolic blood pressure greater than 160 mm Hg, diabetes mellitus, and the presence of high-grade (≥60%) stenosis.[71]

Spontaneous renal artery dissection leading to thrombosis is rare. In contrast to atherosclerotic renal artery stenosis, renal artery dissection commonly occurs in younger patients and has similar incidence in men and women. An intimal flap is the most characteristic imaging finding associated with renal artery dissection (Fig. 129.8), but diagnosis may be challenging in the setting of false lumen thrombosis; other findings may include

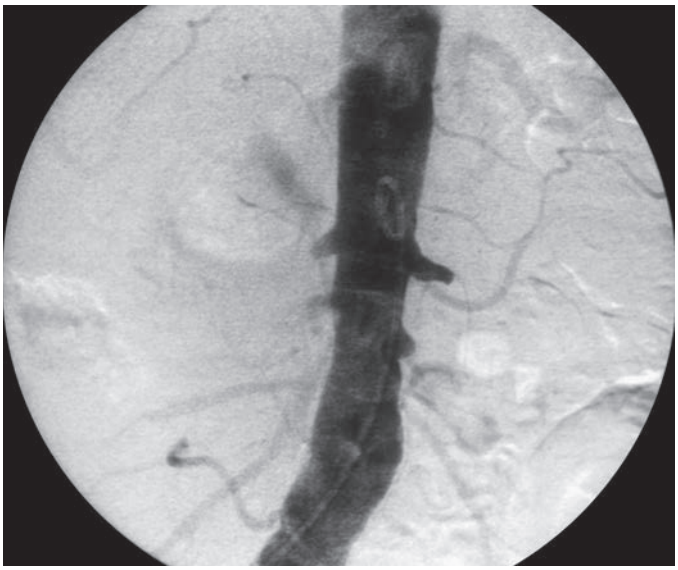

Figure 129.7 Thrombotic Bilateral Renal Artery Occlusion. The patient presented with acute renal failure and anuria. Nuclear medicine study demonstrated renal perfusion by collateral vessels and indicated viable kidneys.

an enlarged renal artery or a long, tapered stenosis. Dissection may be unilateral or bilateral at the time of diagnosis, therefore potentially affecting the entire renal mass.[72] Risk factors include fibromuscular dysplasia,[73-75] Ehlers-Danlos syndrome,[76] cocaine use,[77] and strenuous exercise.[78,79] Iatrogenic renal artery dissection has been reported following a variety of procedures including diagnostic angiography,[80] peripheral or aortic endovascular intervention,[81,82] and extracorporeal shock-wave lithotripsy.[83]

Treatment

Medical treatment—including systemic anticoagulation, control of hypertension, and assessment and management of intravascular volume status—is an important component of the management of acute renal ischemia regardless of whether revascularization is undertaken. Systemic anticoagulation should be initiated in the setting of acute presentation to prevent propagation of thrombus and preserve collateral flow.

Endovascular Treatment

Endovascular options for the management of acute renal ischemia include angioplasty and stenting, thrombolysis, mechanical catheter thrombectomy, and aspiration thrombectomy; these treatments are frequently used in combination with one another depending on the angiography findings and suspected etiology.

Angioplasty and stenting are useful for the treatment of ischemia resulting from thrombosis of a critical primary renal artery or in-stent lesion.[26,31,84] Use of catheter-directed thrombolysis in combination with angioplasty and stenting is frequently described for restoring the patency of thrombosed distal branch vessels in the setting of main renal artery occlusion.[85] Alternatively, aspiration thrombectomy combined with angioplasty and stenting plus intraoperative bolus thrombolytic administration

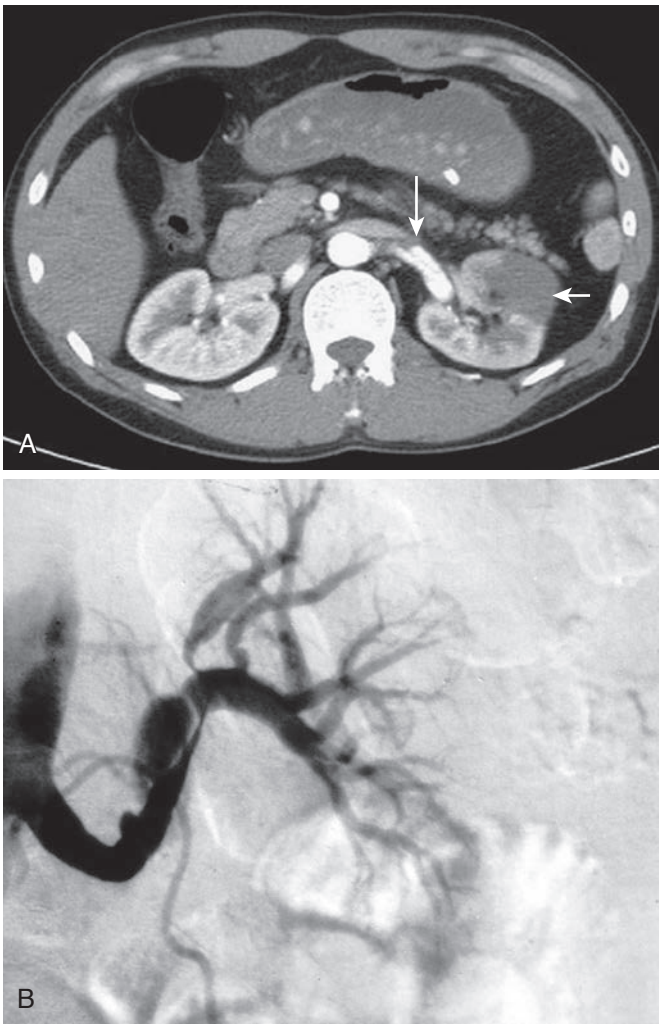

Figure 129.8 Spontaneous Renal Artery Dissection. (A) Axial computed tomography angiographic image shows left renal artery dissection (long arrow) with ipsilateral upper pole renal infarction (short arrow). (From Tsai TH, Su JT, Chao CC et al. Spontaneous renal artery dissection complicating with renal infarction. *Urology*. 2010;76:1371-1372.) (B) Contrast angiogram demonstrating spontaneous renal artery dissection extending into the hilar branches of the left kidney. (From van Rooden CJ, van Baalen JM, van Bockel JH. Spontaneous dissection of renal artery: long-term results of extracorporeal reconstruction and autotransplantation. *J Vasc Surg*. 2003;38(1):116-122.)

may also restore renal perfusion with no need for continuous infusion.[30] Use of catheter-directed thrombolysis to reestablish patency in the setting of an acutely thrombosed renal artery aneurysm has also been reported, permitting subsequent treatment of the aneurysm in a staged fashion.[59] Systemic thrombolysis prior to angioplasty and stenting has also been described as a means of reestablishing renal artery patency in the setting of acute bilateral occlusion.[86] In a series of 10 patients with renal artery thromboembolism from a variety of causes treated by Salam et al. with catheter-directed thrombolysis, adjunctive angioplasty and/or stenting was necessary in half of the procedures and the rate of anatomically successful revascularization (defined by completion angiography) was 70%.[11] In this series of patients presenting with acute renal failure, however, only one of four recovered renal function after intervention.

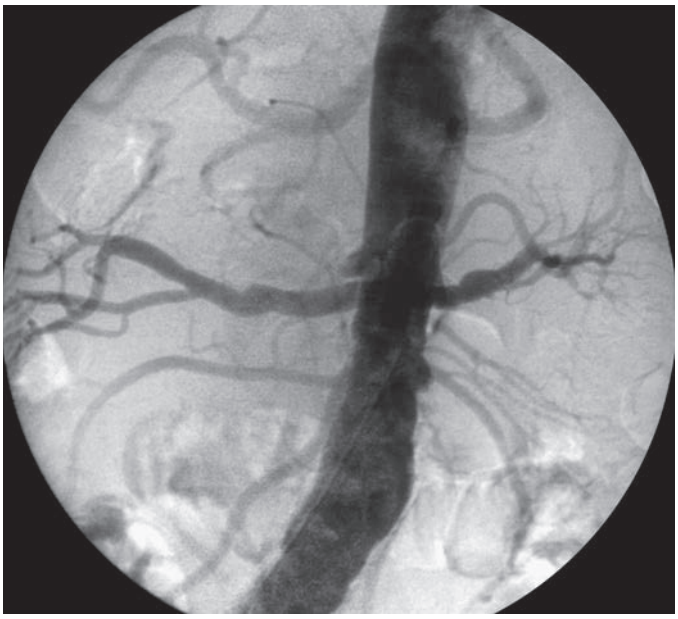

Figure 129.9 Bilateral Aortorenal Vein Graft Bypasses Performed for Thrombotic Occlusion. (Preoperative angiogram is shown in Fig. 129.7.) Renal biopsy showed partial infarction, but renal function recovered immediately following revascularization and gradually returned to normal over several months.

Open Surgery

Surgical revascularization options include renal artery thrombectomy, bypass, and/or endarterectomy (Fig. 129.9).[61,62] Because surgical revascularization is more invasive and time-consuming (therefore necessitating a longer duration of ischemia), these procedures are typically reserved for situations where the chance of renal salvage is deemed substantial (limited ischemia, normal preexisting kidney function, acute thrombosis of preexisting chronic stenosis with existing collaterals, etc.) and where endovascular treatment has failed or may be ill advised owing to technical or anatomic considerations.

Surgical exposure for renal artery revascularization is similar to that described earlier for embolectomy. Revascularization techniques—including endarterectomy, aortorenal bypass, and extra-anatomic bypass—are described in detail in Chapter 126. Renal artery bypass for ischemia resulting from delayed thrombosis after renal artery angioplasty and/or stenting has been described by several authors, with successful salvage of renal function.[87,88] As with endovascular treatment, the maintenance of collateral perfusion is critical to renal salvage in the setting of acute ischemia. In a series that included 16 patients treated with surgical revascularization, Ouriel et al. noted that renal salvage with thrombectomy and aortorenal bypass was dependent on a distally reconstituted renal artery regardless of the duration of ischemia; recovery of renal function among patients with embolism or traumatic injury in this series was less common.[89]

Perioperative mortality associated with surgical revascularization for acute renal artery thrombosis is 15% to 25%, with salvage of renal function in approximately 65% of patients.[90,91] Surgical management may also be preferred over endovascular therapy in situations where the thrombus burden is extensive or thrombolysis is contraindicated. Chevalier et al. described complete recovery following surgical thrombectomy in a patient with acute aortic and renal artery thrombosis due to heparin-induced thrombocytopenia.[66]

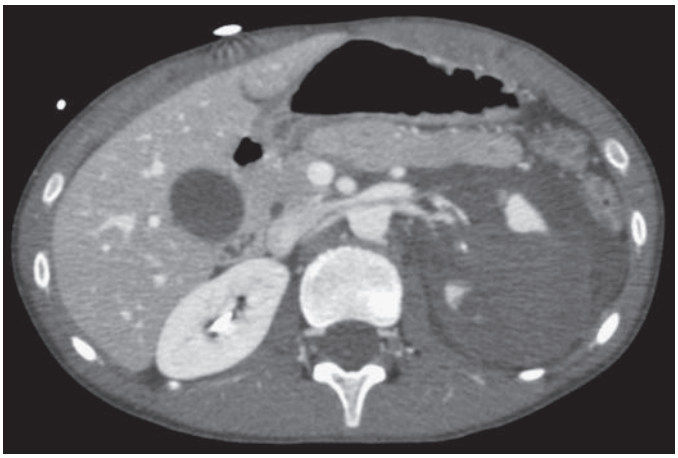

Figure 129.10 Traumatic Injury to the Left Kidney. Contrast CT demonstrates large left renal perfusion defect caused by acceleration-deceleration trauma of the renal pedicle, resulting in vascular injury and kidney rupture as well as injury of the urinary collecting system.

There is inadequate evidence to support a particular management strategy for spontaneous renal artery dissection. Reported outcomes associated with surgical revascularization are predominantly derived from series of elective procedures performed for hypertension associated with dissection-related stenosis rather than acute thrombosis.[92,93] Resolution of symptoms with preservation of renal function has been reported in patients presenting with dissection and segmental renal infarction managed nonoperatively with antihypertensive agents and/or anticoagulation.[94,95]

RENOVASCULAR TRAUMA

Epidemiology

Renovascular injury has a prevalence of less than 1% in the setting of blunt abdominal trauma.[96,97] In addition to renovascular injury, approximately 75% of patients also have an abdominal solid organ injury involving the kidney, liver, or spleen, and over 17% have multiple abdominal vascular injuries (most commonly to the renal vein or inferior vena cava).[97] Acute ischemia resulting from traumatic renal artery injury frequently involves rapid deceleration or compression between the abdominal wall and vertebral bodies, resulting in subintimal tears and/or dissection in addition to thrombosis. Renovascular injury may also be associated with injury to the urinary collection system (Fig. 129.10).[98-100]

Treatment

A selective approach to revascularization in the setting of renovascular trauma is warranted. Factors that should prompt consideration of revascularization in the setting of traumatic injury include bilateral injury or injury to a solitary functioning kidney.

As with nontraumatic etiologies, the duration of ischemia and baseline kidney function prior to injury influence the

potential for kidney salvage. In contrast to nontraumatic renal ischemia, where the time of symptom onset may be ill defined and patients often present more than 24 hours later, the duration of ischemia is often known with some degree of accuracy in the setting of traumatic injury, thus facilitating relatively informed decisions regarding revascularization. In addition to prolonged warm ischemia, other factors favoring management without attempted revascularization include hilar injury, extensive kidney injury, and a normal contralateral kidney in a patient with multiple other injuries and/or hemodynamic instability.[101,102] A thorough evaluation for other injuries is also important to determine whether intraoperative anticoagulation can be safely administered during revascularization.

Selection of a revascularization approach requires consideration of renal and other solid organ injuries, hemodynamic stability, and anatomic characteristics of the vascular injury.

Management options for blunt renovascular injury other than revascularization include nephrectomy, embolization, and observation with or without anticoagulation. Even complex blunt injuries have a potential to heal without revascularization (Fig. 129.11).

Results

In a review of 517 renal artery injuries from the National Trauma Data Bank by Sangthong et al., 73% of patients were managed nonoperatively, whereas 18% had immediate nephrectomy, 9% underwent surgical revascularization, and 1.5% were treated with stenting.[97] Surgical revascularization approaches in this series included both direct repair and well as autotransplantation. Overall mortality was 21%, the majority of which occurred within 24 hours of admission; these deaths were attributed to other associated injuries. Mortality among patients without other major abdominal injuries was 10.3%. Despite similar injury severity scores, patients who underwent revascularization or nephrectomy had longer stays in the intensive care unit or hospital, leading the authors to conclude that revascularization should be undertaken only to avoid long-term dialysis in the setting of bilateral injury or a solitary kidney. A similar conclusion was reached by Haas and Spirnak, who reported a kidney salvage rate of approximately 25% in the setting of unilateral traumatic renal artery injury.[103]

A multicenter study by Knudson et al. of severe kidney injuries (defined as American Association for the Surgery of Trauma as grade IV/V injuries) identified blunt mechanism and severity of injury as predictors of poor outcomes (defined as renal failure requiring dialysis, serum creatinine >2 mg/dL, <25% function of the injured kidney on renal scan, postinjury hypertension, or nephrectomy). Interestingly, neither physician specialty nor time to definitive surgery were associated with the composite outcome.[104] Ten percent of patients in this study developed renal failure or hypertension postoperatively, and arterial repairs had inferior outcomes when compared with repair of isolated venous injuries.

Lopera et al. reviewed eight consecutive patients presenting with renal artery occlusion or dissection following blunt abdominal trauma who underwent endovascular treatment.[105] Intervention resulted in contrast extravasation requiring embolization of the main renal artery in two patients in this study. Of the remaining six patients who underwent a technically successful renal artery recanalization and stenting, half required nephrectomy or underwent subsequent embolization during a follow-up period ranging from 2 to 24 months.

RENAL VEIN THROMBOSIS

Epidemiology

Renal vein thrombosis has an incidence of less than one case per million annually among adults and is the most common

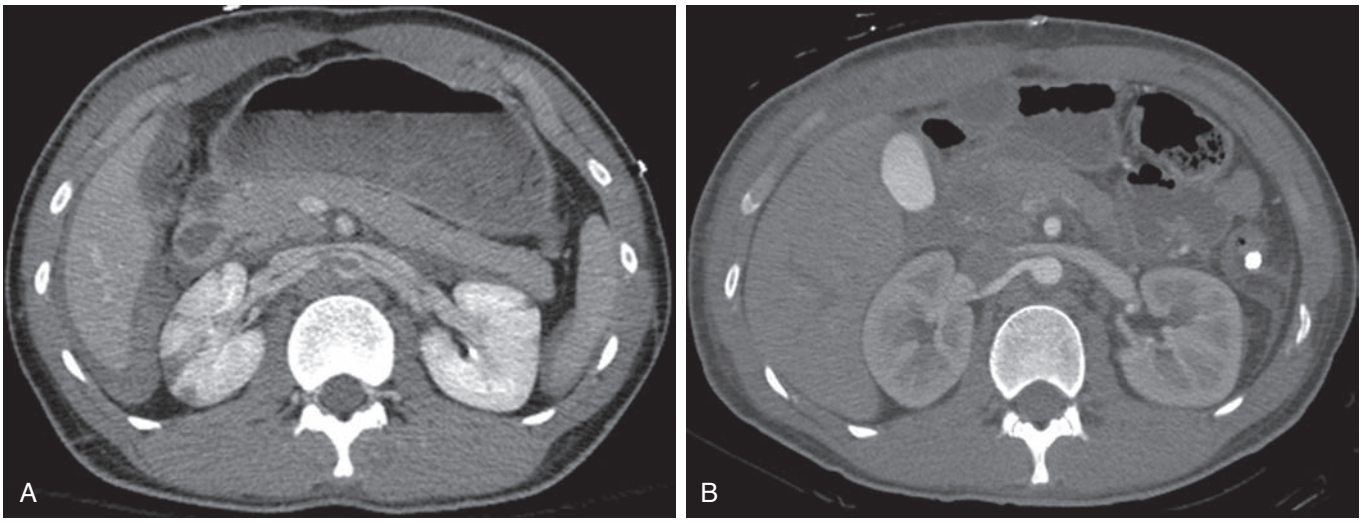

Figure 129.11 Renal Artery Dissection and Infarcts Associated With Blunt Traumatic Injury. Renal artery dissection associated with aortic dissection and multiple right renal infarcts visible on contrast computed tomography at the time of initial presentation (A). Follow-up scan 1 month later, after initial management with observation and anticoagulation, demonstrates healed dissection without residual perfusion defects (B).

non–catheter-related thrombosis in neonates.[106,107] Risk factors for renal vein thrombosis include malignancy (especially renal cell carcinoma, lymphoma, and other retroperitoneal tumors), nephrotic syndrome, inherited thrombophilia, local surgery or inflammation, oral contraceptive use, pregnancy, and infection.[32] Malignancy and nephrotic syndrome were identified as the underlying cause of renal vein thrombosis in 66% and 20% of patients, respectively, in a single-center review of 218 adult patients by Wysokinski et al.[108] Mean age at presentation in this cohort was 55 years, and 35% were women. Iatrogenic renal vein thrombosis may also occur in the presence of a vena cava filter or central venous catheter. Among children, more than 80% of renal vein thrombosis is diagnosed during the first month of life; risk factors include central vein catheters, dehydration, inherited hypercoagulable state, and prolonged hypotension.[45,107]

Treatment

Although treatment of renal vein thrombosis once centered on thrombectomy and/or nephrectomy, anticoagulation is now recognized as the treatment of choice in the majority of patients. As with treatment of renal artery embolism, goals for the treatment of renal vein thrombosis include both preservation of renal function and prevention of additional thromboembolism.[33]

Anticoagulation

Therapy should be initiated with unfractionated or low-molecular-weight heparin at the time of diagnosis; the duration of long-term anticoagulation depends on the presumed etiology and identified risk factors for venous thromboembolism. Patients with a temporary or modifiable risk factor (such as infection, hormone use, pregnancy, or immobilization due to surgery) can be treated for 3 to 6 months with a vitamin K antagonist or other oral anticoagulant, while those with idiopathic thrombosis or ongoing long-term risk factors (such as inherited thrombophilia or malignancy) should be managed, in the absence of contraindications, with lifelong anticoagulation.[32]

The overall incidence of recurrent renal vein thrombosis is 1% per patient year of follow-up, and survival following renal vein thrombosis is inferior to that of individuals with deep venous thrombophlebitis of the lower extremity.[108] Laville et al. reported a 6-month mortality rate of approximately 40% following diagnosis of acute renal vein thrombosis.[109] Active malignancy and infection affect survival negatively, whereas warfarin therapy is associated with a survival advantage.[108]

Anticoagulation is also considered the definitive treatment for renal vein thrombosis in neonates. Zigman et al. observed long-term renal functional impairment in one third of patients treated with heparin anticoagulation versus 100% of those who were not anticoagulated.[45] No patients in this study required dialysis or surgical intervention for renal salvage.

Thrombectomy

Use of thrombectomy or thrombolysis in the setting of acute renal vein thrombosis should be reserved for select situations, including failure or complication of oral anticoagulation (such as thrombus propagation or pulmonary embolism), bilateral thrombosis or thrombosis of a solitary kidney, associated caval thrombosis, acute renal failure, or persistent severe symptoms (most commonly flank pain).[34,110,111] Thrombectomy should be considered in the setting of a contraindication to anticoagulation, failure of thrombolysis, or when nephrectomy for an associated renal malignancy is anticipated. Nephrectomy has a limited role but may be the treatment of choice in the setting of postinfarction hemorrhage.

Developmental abdominal aortic disease is complex and can be associated with stenotic lesions of the aortic branches to the kidneys and splanchnic organs. The etiology and clinical spectrum of this disease have been well defined in past decades.[1,2] A variety of interventions exist with the expectation that the majority of patients will benefit from appropriately planned and conducted vascular reconstructive procedures.

DEVELOPMENTAL ABDOMINAL AORTIC COARCTATION AND HYPOPLASIA

Classification

Descriptions of abdominal aortic narrowings are varied in the existing literature. Abdominal aortic coarctation or segmental aortic hypoplasia accurately describes the majority of these lesions. The pattern of aortic narrowing distinct from isthmic coarctation involving the pediatric population was first categorized in 1963 by Sen et al.,[3] who used the phrase "middle aortic syndrome" to describe 16 patients, although the majority of patients included in this original report were actually older than 20 years of age. In this work, a distinction was made between coarctations arising above the diaphragm and those that were infradiaphragmatic, which many refer to as midaortic syndrome.

A more contemporary classification of developmental aortic narrowing is based on the most cephalad extent of the involved aorta, which distinguishes suprarenal (69%) from intrarenal (23%) and infrarenal (8%) narrowings (Figs. 130.1-130.3).[1] Diffuse hypoplasia of the abdominal aorta is included in the spectrum of disease, but is often considered separately.[1,4]

Etiology and Pathogenesis

Embryology

Overfusion of the two dorsal aortas during the fourth week of gestation is thought to be the cause of most developmental abdominal aortic narrowings. Prior to this event, both dorsal aortas extend along the entire length of the embryo, with each segment of the paired aortas containing dorsal intersegmental, lateral segmental, and ventral segmental branches. As the two dorsal aortas fuse, these branches persist, involute, dilate, or

Abstract

Developmental abdominal aortic disease is complex and is often associated with stenotic lesions of the aortic branches to the kidneys and splanchnic organs of which renovascular hypertension is a common manifestation. The etiology and clinical spectrum of this disease have been previously well defined and a variety of surgical interventions exist with the expectation that the majority of patients will benefit from appropriately planned and conducted vascular reconstructive procedures.

Abdominal aortic coarctation: surgical treatment of 53 patients with a thoracoabdominal bypass, patch aortoplasty, or interposition aortoaortic graft. *J Vasc Surg*. 2008;48:1073–1082.)

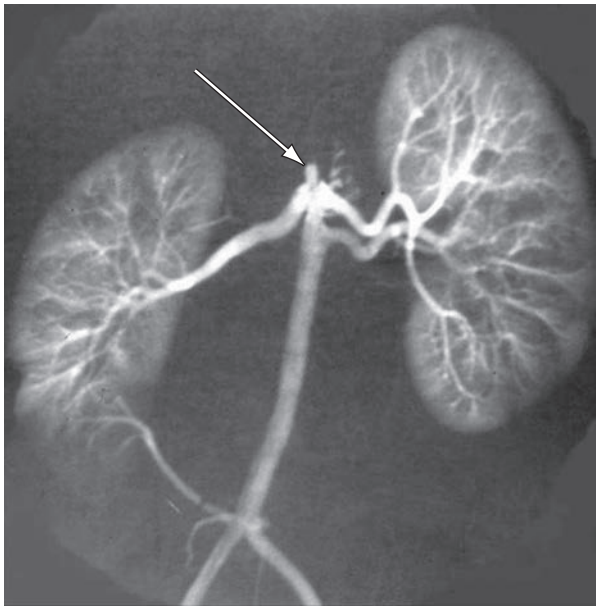

Figure 130.4 Multiple bilateral renal arteries in a patient with a near-occlusive coarctation of the suprarenal aorta *(arrow)*.

join together to form the named branches found at birth. A clinical finding supporting the overfusion theory of segmental aortic hypoplasia is the loss of paired lumbar arteries within a hypoplastic aortic segment, with only a single lumbar artery trunk exiting the dorsal aorta.[5] A developmental etiology for aortic hypoplasia is also supported by the observation that multiple renal arteries to one or both kidneys occur in these patients, with nearly twice the frequency that occurs in the general population.[1,6,7] Aortic development occurs concurrent with the involution of multiple metanephric arteries to leave a single renal artery to each kidney in the majority of fetuses. It is plausible that developmental aortic narrowings result in flow disturbances near what would usually be the principle renal artery; this diminishes its hemodynamic advantage and allows adjacent metanephric channels to persist as multiple or accessory renal arteries (Fig. 130.4).

Associated Genetic Syndromes and Infectious-Inflammatory Disorders

Certain genetic diseases or in utero events have been associated with abdominal aortic coarctations. The most frequent is

neurofibromatosis-1 (NF-1).[1,7-11] Others include William syndrome, Alagille syndrome, and tuberous sclerosis.[12-18] It is theorized that each of these diseases results in the interference of cell growth in vascular tissue or cellular death during development. The NF-1 phenotype deserves particular note. It is highly variable, and a wide spectrum of vascular involvement exists. Although aneurysms, arteriovenous malformations, cardiac valvular anomalies, and direct neural tumor invasion or compression of vascular structures have been reported, hypertension due to renal artery stenotic disease or abdominal aortic narrowing is the most common presentation of NF-1, reflecting vascular involvement.[19-22] It is difficult to find a unifying cause for this phenotype of NF-1, although the variable influence of modifying genes in addition to a primary NF-1 mutation, as well as alterations in the tissue specific elastin gene transcription, may play a role.[23,24] In our experience, more than 25% of patients with abdominal aortic coarctation or segmental aortic hypoplasia carry a confirmed diagnosis of NF-1.[1] In another large series of patients who had NF-1–related vascular involvement, only 13% exhibited abdominal aortic coarctations.[22]

Maternal rubella during the first trimester is an infectious-inflammatory disorder that has been associated with abdominal aortic hypoplasia.[25-27] Takayasu aortoarteritis is another recognized cause of abdominal aortic coarctation that must be differentiated from developmental narrowings, although this disease is more likely to involve the aortic arch and proximal descending thoracic aorta.[28] Such an active or latent arteritis may be the most common cause of abdominal aortic narrowings encountered in the subcontinents. Nondevelopmental abdominal aortic coarctation has been associated with umbilical artery catheterization during the neonatal period, although aortic thromboses and mycotic aneurysms have been reported more frequently than aortic narrowings.[29,30]

DEVELOPMENTAL RENAL AND SPLANCHNIC ARTERIAL STENOSES

Abdominal aortic coarctations are associated with stenoses of the splanchnic and renal arteries, in 87% and 62% of cases, respectively.[1] Similar to abdominal aortic coarctation, pediatric renal artery stenoses represent a spectrum of diseases. Etiology of pediatric renal artery stenosis is most commonly developmental in North American Caucasian children,[2,7] compared with more common inflammatory aortoarteritis and Takayasu-related stenoses that dominate reports from Asia, Africa, and South America.[31-34] Large clinical reports suggest that the causes of most developmental renal occlusive lesions are the same as those causing abdominal aortic coarctations,[1,2] and that many of these patients have NF-1.[2,22,35-37] The majority of renal artery narrowings are ostial in location, representing true hypoplastic stenoses. The affected arteries are very small, with derangements of all three vessel wall elements, including intimal proliferation, medial thinning, and excessive adventitial elastin (Fig. 130.5).

Similar ostial stenoses of the celiac artery (CA) and superior mesenteric artery (SMA) also occur in areas of abdominal aortic coarctations (Fig. 130.6). These stenotic narrowings usually are incidentally recognized most often during studies for suspected aortic or renal artery pathology. Developmental lesions appear related to embryonic phenomena similar to those causing aortic and renal artery narrowings. These events likely affect the reorganization of the ventral segmental vessels associated with the cephalic roots of the vitelline arteries that form the CA and SMA. This results in an ostial stenosis or occlusion. Minimal CA and SMA narrowings at a young age may not increase in diameter as the child grows. In these circumstances, the artery's origin becomes proportionately narrower as the adjacent artery

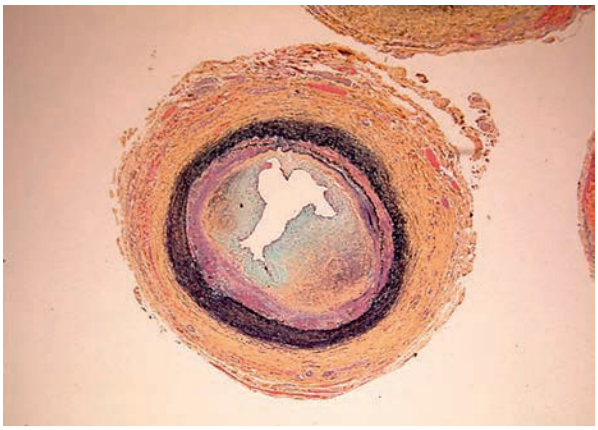

Figure 130.5 Typical developmental renal artery ostial stenosis exhibiting proliferation of intimal tissues, medial thinning, and excessive adventitial elastin (Movat stain).

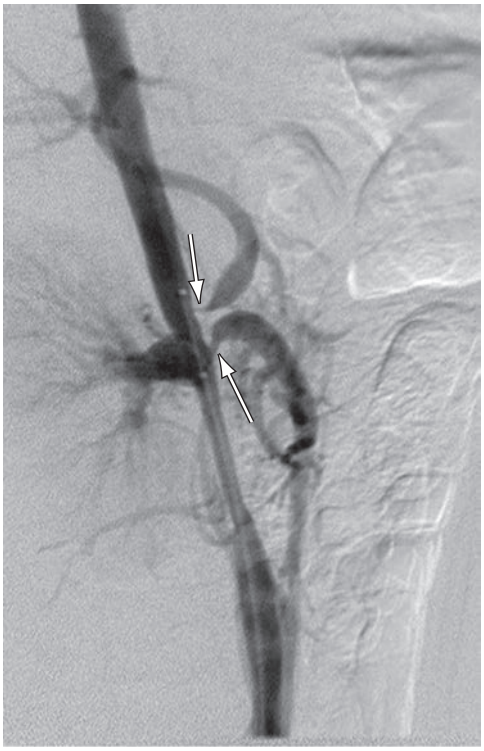

Figure 130.6 Severe celiac artery and superior mesenteric artery ostial stenoses evident on a lateral aortogram *(arrows)*. (From Stanley JC, et al. Pediatric arterial disease. In: Coran AG, Caldamone A, Adzick NS, et al, eds. *Pediatric Surgery*, 7th ed. Philadelphia: Elsevier Saunders; 2012:1631–1645.)

becomes bigger, until the narrowing becomes a critical stenosis. This entire process suggests a major growth arrest of the aortic origins of these splanchnic arteries.

CLINICAL MANIFESTATIONS
