Abstract

Reduced early mortality and simplicity of implantation have made thoracic endovascular aortic repair (TEVAR) the first-line approach for thoracic aortic aneurysm repair in suitable anatomy. This chapter summarizes the literature available on guidelines for thoracic endovascular repair, characteristics of thoracic devices, proper planning of the operative strategy, technical aspects of implantation, the main results, and complications.

INTRODUCTION

Morbidity and mortality remain high after open repair of thoracic aneurysm, so many high-risk patients are regularly excluded.[1] Stent graft placement first performed in abdominal aortic aneurysms has now been extended to thoracic endovascular aneurysms (thoracic endovascular aortic repair, or TEVAR). Reduced early mortality favors TEVAR as the first-line approach for thoracic aortic aneurysm repair with suitable anatomy.

INDICATIONS

Guidelines

Improvements in thoracic imaging and the availability of TEVAR have resulted in an increase in repairs of thoracic aneurysms, especially among patients older than 75 years. The 2010 American consensus guidelines establish that "for patients with degenerative or traumatic aneurysms of the descending thoracic aorta exceeding 5.5 cm, saccular aneurysms, or postoperative pseudoaneurysms, endovascular stent grafting should be strongly considered when feasible" (Level of Evidence: B).[2] The European guidelines state that "In patients with asymptomatic thoracic aortic aneurysm, TEVAR is indicated when the maximum diameter of the aneurysm exceeds 5.5 cm or if rapid expansion (>5 mm in 6 months) occurs." However, they also report that "comorbidities and patient age must be considered, and it may be appropriate to set a larger aortic diameter threshold in patients with increased operative risk" (Table 79.1).[3] There is inadequate evidence to support surveillance or TEVAR in patients with small aneurysms, and a reluctance to offer TEVAR to octogenarians and women, highlighting the need for stronger evidence in specific diameter thresholds.

Thoracic Endovascular Aortic Repair Versus Open Repair

The potential advantages of TEVAR compared with open surgical treatment include reduced procedure time and length of both critical care and hospital stay, avoiding thoracotomy and aortic

TABLE 79.1 Summary of Main Societies Guidelines

Guideline	Threshold for TEVAR	Provisos	Surveillance Imaging
STS[1] 2008	5.5 cm or twice the diameter of the normal contiguous aorta	Saccular aneurysm: width of 2 cm or total aortic size of 5 cm	/
American guidelines[2] 2010	5.5 cm	Endovascular stent grafting should be strongly considered when feasible	Annual basis if stable in size on the first follow-up. Every 2-3 years for relatively small stable aneurysms, especially in older patients
European guidelines[3] 2012	5.5 cm or rapid expansion (.5 mm in 6 months)	Larger diameter threshold should be considered in patients with increased operative risk due to comorbidities and age Saccular aneurysms: TEVAR may be justified at a diameter <5.5 cm	/
ESC[4] 2014	5.5 cm	>6 cm for open repair	<45 mm: annual imaging >45 to <55: imaging every 6 months unless stability confirmed by serial imaging
CCS[5] 2014	/	>6.5 cm for open repair or >0.5 cm/year increase in diameter	6-12 months after diagnosis, then every 6 or 12 months depending on aortic size and rate of change Intervals may be increased in patients with stable dimensions

cross-clamping, with potential reduction of renal failure and cardiopulmonary complications. Although several studies suggest that TEVAR is associated with early benefits compared with open repair, long-term benefits remain less clear.

In a study of 19 patients who underwent TEVAR between 1999 and 2000 compared with a historical cohort of 10 patients who underwent open repair, TEVAR was associated with a shorter operative time and hospital and ICU stay.[6] In a multicenter comparative trial including 140 patients who underwent TEVAR using the GORE TAG Thoracic Endograft between 1999 and 2001, at 30 days there was a significantly lower incidence of spinal cord ischemia (SCI; 3% vs. 14%), respiratory failure (4% vs. 20%), and renal insufficiency (1% vs. 13%) in the TEVAR group, and a significantly shorter hospital and ICU stay. However, at 2 years there were three reinterventions in the TEVAR group, none among the open repairs, and no difference in overall mortality.[7]

In the Nationwide Inpatient Sample (NIS) database, between 1998 and 2007 there were 8967 thoracic aneurysm repairs, including 8% TEVAR and 92% open procedures. On multivariate analysis, mortality in patients undergoing TEVAR was reduced by 46%, as well as postoperative neurologic, cardiac, and respiratory complications.[8] Using Medicare claims from 1998 to 2007, Goodney et al. reported a lower perioperative mortality with TEVAR, but a worse long-term mortality, suggesting that higher-risk patients were offered TEVAR, and the necessity to identify candidates unlikely to benefit from repair.[9]

Finally, a meta-analysis of 42 studies including 5888 patients suggested a reduced all-cause mortality at 30 days and paraplegia, as well as reduced cardiac complications, transfusions, reoperation for bleeding, renal dysfunction, pneumonia, and length of stay for TEVAR compared with open surgery, despite older patients. However, there was no significant difference in stroke, myocardial infarction, aortic reinterventions, and mortality beyond 1 year.[10]

DEVICES

History

Endovascular thoracic aneurysm repair was first described by Dake in 1994 in a cohort of 13 patients who had descending thoracic aneurysm disease. These early stent grafts were custom-designed for each patient, with a combination of Gianturco Z-stents and polyester fabric. The metallic framework was covered with Dacron graft (Meadox Medicals, Oakland, New Jersey) attached to the stent by interrupted 5-0 polypropylene sutures.[11] Stent-graft technology has evolved to standardize production and delivery systems that allow for more precise placement, with multiple manufacturers, and by 2005 there were several approved stent grafts commercially available. First-generation devices suffered initial drawbacks of large sheath size and rigidity, potential modular disconnection, decreased fabric integrity, and graft porosity. Technical refinements have led to second-generation devices with smaller, more flexible, and more accurate delivery systems, improved conformability, less porosity, and a greater variety of sizing options.

First Generation

GORE TAG thoracic endoprosthesis (W.L. Gore, Flagstaff, Arizona). This is the first thoracic stent graft commercially available in the United States, approved by the Food and Drug Administration in 2005 based on a multicenter, nonrandomized prospective trial comparing results of stent graft repair of thoracic aortic aneurysm (TAA) with those of open surgical repair in low-risk patients. TAG expands from the middle of the stent graft and progresses toward the ends to avoid the windsock effect and reduce device migration.[12]

Talent thoracic graft (Medtronic Vascular, Santa Rosa, California). The Talent stent graft with CoilTrac delivery system is the second-generation Medtronic stent graft introduced in 1999 offering an improved deployment. It is a polyester graft fabric sewn to a self-expanding nickel-titanium wire frame and a proximal bare spring. This device was used in the VALOR high-risk clinical trial for Food and Drug Administration (FDA) approval.[13]

Cook Zenith TX1 and TX2 thoracic endovascular grafts (Cook Inc, Bloomington, Indiana). These devices, commercially available in Australia since 2001, in Europe and Canada since 2004, and in the United States since 2008, are founded on the platform of the Zenith abdominal aortic stent graft. The TX1 design is a one-piece system with proximal and distal fixation, and the TX2 is a two-piece system, with proximal barbs oriented caudally and distal barbs cranially to reduce migration. This graft was later modified with the addition of ProForm, which allows improved conformability to the arch and limits the "bird-beak" effect.[14]

EndoFit Stent Graft (LeMaitre Vascular, Burlington, Massachusetts). This device is composed of self-expanding nitinol stents encapsulated in two layers of polytetrafluoroethylene (PTFE) fabric using a thermal process, available with or without an external fixation on the proximal end and in a tapered version. The sutureless design eliminates the potential for graft material tearing.

Modern Devices

Improvements in device and delivery system design include a decrease in caliber and improved conformability. Newer-generation stent grafts use a tip-capture mechanism to stabilize the proximal part, avoiding the windsock effect (downstream dislodgement of the partially deployed stent graft) and allowing for more accurate deployment.

Conformable TAG (W.L. Gore). This device provides a wider range of diameters and is designed to improve treatment of small-diameter, tortuous, and tapered aortic anatomy compared to the TAG stent graft.

Low-profile Zenith Alpha Thoracic Endoprosthesis (Cook Medical, Bloomington, Indiana). This latest generation graft has been designed to facilitate precise deployment, especially when the proximal landing zone is in the arch, with encouraging early clinical outcomes.[15]

Valiant thoracic device (Medtronic, Oakbrook, Illinois). First introduced in Europe in 2005 and available in the United

States since 2008, its design has been modified compared to the Talent stent graft to enhance conformability and distribution of radial force. The delivery system has also been improved to allow tip capture and more controlled deployment.[16]

Relay (Bolton Medical, Sunrise, Florida). This polyester/nitinol graft has a longitudinal nitinol bar for support and comes with either covered or bare metal proximal graft configuration. It is available in straight or tapered configurations.

Custom-made proximal scalloped Relay Plus stent grafts (ABS Bolton Medical, Barcelona, Spain). This graft consists of a self-positioning system using a curved nitinol catheter along the length of the stent graft to allow the placement of the scallop systematically on the upper side of the aortic arch. The distal marker of the scallop is used to align the stent graft with the targeted supraaortic vessel.[17]

E-vita thoracic 3G (JOTEC GmbH, Hechingen, Germany). This device, not available in the United States, is a low-profile flexible third-generation stent graft that may also be part of a frozen elephant trunk repair using a graft combining a conventional vascular graft and an attached endovascular stent graft.[18]

TAArget Thoracic Stent Graft (LeMaitre Vascular). Introduced in 2008 to replace the EndoFit stent graft, it offers a new Tortuous Tracker Delivery System for more precise deployment and a new, optional uniform top stent design for improved external fixation.[19]

TECHNIQUE

Training

The implantation of thoracic stent grafts requires advanced endovascular skills, attention to both the process of implantation and specific bail-out techniques needed to rescue unintended events, but also attention to planning and sizing prior to implantation. The impact of training during residency and operative experience on clinical and hospital outcomes after TEVAR was assessed in a 3-year review of thoracic repairs in the NIS. Among 2531 procedures, vascular surgeons with more experience than other specialties had the lowest morbidity rate (stroke and cardiac event) and lower mortality.[20] Rehearsal of the TEVAR procedure on an endovascular simulator has also been associated with reduction of overall procedure and fluoroscopy time, and subjective measure of technical success.[21] However, operative mortality after TEVAR is not significantly different in high- (≥8 cases/year) compared to low- (<8) volume hospitals,[22] and has also been demonstrated during aneurysm repair for rupture,[23] contrary to open repair where results are closely correlated to hospital volume.

Sizing

High-quality (≤1 mm) computed tomography angiography (CTA) extending from the supraaortic vessels to the common femoral arteries, is recommended for the correct sizing of the thoracic stent graft (see Chapter 27). Use of postprocessing software that can facilitate curved planar reconstruction provides information about the sealing zones, coverage length, tortuosity and angulation of the aorta, involvement of the arch side branches, intraluminal thrombus and wall calcification, and iliac access.

Aortic diameter and length should be assessed by semiautomatic centerline reconstruction, which provides the least variable and fast diameter measurements in TEVAR patients with the same accuracy as the reference standard multiplanar reformations.[24] For most device platforms, the length of the sealing zones should be at least 2 cm and ideally larger, with a good wall apposition throughout without thrombus or dissection, and with a consistent diameter (parallel walled aorta). The maximum aortic diameter recommended is usually 38 mm, with clearly hostile neck above 42 mm. When multiple stent grafts are used, a minimum of 30 mm of overlap is required to prevent modular disjunction.

In a review of the M2S database including 899 patients who underwent TEVAR between 2004 and 2013, there was a higher sac expansion rate (>5 mm) at 3 years when the proximal or distal sealing zone was more than 38 mm in diameter or less than 20 mm in length, which reinforces the hostile neck as a predictor of advanced disease. At 5 years, 60.9% of patients were free from sac expansion, with significant influence of sealing zone morphologic features.[25] The authors advise a maximum diameter of 38 mm and length of 20 mm, clinical judgment, and postoperative imaging surveillance.

In addition to anatomic assessment, 10% to 20% oversizing at the proximal landing zone is recommended, and some authors use 10% to 15% oversizing for degenerative aneurysms to reduce the risk of retrograde aortic dissection and stent-graft collapse.[26] In the case of a proximal landing zone in a previous Dacron graft, a longer length (4-5 cm) and more aggressive oversizing is recommended to avoid type Ia endoleaks.[27] Applications are available to facilitate sizing.[28]

Access

The size of the delivery system remains an important challenge with significant coexisting occlusive arterial disease. Assessing vessel diameter, tortuosity, and calcification to avoid iliac rupture or aborting the procedure requires a dedicated 3D workstation.

Several techniques have been described to deal with poor iliac access. Balloon angioplasty or dilation angioplasty in limited stenoses of the iliac arteries is the first and earliest step. The use of a brachiofemoral through-and-through guidewire may allow graft insertion in highly tortuous arteries, but does not overcome the challenge of occlusive disease. Retroperitoneal access is used in cases of marginal common femoral arteries, or when external iliac arteries are highly tortuous with excess length to pull on the artery and straighten the vessel. In the case of small external iliac diameter, retroperitoneal access also allows a direct puncture of the common iliac artery to insert the graft,[29] or more commonly to perform an iliac conduit. The conduit usually consists of a 10-mm Dacron graft sutured to the common iliac, and used to insert the stent graft. Once the endovascular procedure is completed, the conduit is either

oversewn or anastomosed distally.[30] The last alternative is the "paving and cracking" technique, consisting of deploying a 10-mm or 13-mm self-expandable covered stent in the common and external iliac artery ("paving") and opening the access with a 10- to 12-mm balloon ("cracking"), through a femoral access.[31]

Management of Proximal or Distal Short Neck

Management of the proximal landing zone remains challenging in cases of short proximal neck or severe angulation of the arch. In these cases, if coverage of the left subclavian is not sufficient to deal with compromised proximal sealing, then development of alternative techniques, such as hybrid repair with debranching, chimneys, fenestrations and branches, or scallop should be considered.

In instances of planned left subclavian artery (LSA) coverage, the SVS suggests a routine preoperative LSA revascularization (GRADE 2, level C); strongly recommends revascularization when the perfusion to critical organs is compromised (GRADE 1, level C); and suggests an individualized approach in cases of life-threatening acute aortic syndrome, based on anatomy, urgency, and availability of surgical expertise (GRADE 2, level C).[32] Studies have reported a higher incidence of stroke among patients with LSA coverage (11% vs. 3%[33] or 25% vs. 2%[34]) and of upper extremity ischemia (15% vs. 0%[34]). Moreover, the LSA is one of the collateral beds for spinal cord network perfusion, and its preservation is of main importance to reduce neurovascular complications during extensive TAAA repairs. However, a systematic review pooling 5 studies and 1161 patients failed to demonstrate any significant reduction in neurovascular complications or mortality rate with LSA systematic revascularization. Future randomized trials are needed to elucidate the role of routine or selective revascularization in these cases.[35]

In every case of LSA coverage, the origin has to be occluded to avoid type II endoleak and secondary rupture.[36] This may be performed by coil embolization from the ipsilateral brachial artery after TEVAR deployment, or by occlusion plug positioning from femoral access before TEVAR insertion or from the left arm after TEVAR.

A proximal scallop may increase the proximal landing zone in the inner curvature of the arch without compromising the patency of supraaortic trunks. Although a scallop does not improve the distance for sealing, it may improve the conformability of the stent to the steepest portion of the arch and thus promote a better overall position of the graft. A few single-center series reported early and midterm experience with a Bolton device with 100% technical success, no proximal endoleaks, and acceptable rates of stroke and 30-day mortality.[17,37] However, longer-term outcome data is required. Newer off-the-shelf branched devices for the LSA are also currently under investigation.

In the case of a short distal landing zone, several alternatives have been described: a hybrid procedure with TEVAR and open bypass to the celiac artery, a custom-made stent graft with distal scallop or fenestration, and intentional celiac trunk coverage after confirmation of adequate collateral supply to the upper gastrointestinal tract. This latter alternative has been described with an intact superior mesenteric artery and gastroduodenal artery providing collateral flow to the celiac with a complication rate of 6% of mesenteric ischemia, 6% SCI, and 6% mortality in a series of 31 patients).[38] Preoperative angiography has to be performed through the superior mesenteric artery with temporary balloon occlusion of the celiac artery.

Perioperative Consideration

The advanced age and multiple comorbidities of patients with thoracic aortic aneurysms render these patients susceptible to a number of postoperative complications.

Preoperative Cardiac Workup

Recommendations for cardiac workup are generalized across all vascular disease (see Chapters 32 and 42). However, it has been suggested that a resting transthoracic ECHO and electrocardiogram should be performed, with subsequent invasive studies (exercise/pharmacologic stress testing, or coronary angiography) only if initial screening reveals cardiovascular abnormalities.[39] In addition, the frequent concurrence of bicuspid aortic valve with proximal aortic aneurysms suggests that echocardiography to assess structural valve disease may also have benefit.[40] There are data suggesting that the incidence of cardiac adverse events may be reduced with endovascular techniques compared with open surgery in abdominal aortic repairs.[41]

Antibiotic Prophylaxis

Intravenous antibiotics should be given prior to TEVAR to reduce the incidence of graft infection[42] including broad-spectrum coverage such as cefazolin 1000 mg intravenously or amoxicillin-clavulanic acid 1200 mg intravenously.

Implantation

Procedure

The procedure is generally performed under general anesthesia to allow respiratory control and more precise imaging. Ipsilateral femoral access is gained with open or percutaneous femoral artery exposure. An additional access for pigtail catheter placement is obtained percutaneously with a short 4 or 5 Fr sheath from the contralateral groin or from brachial artery access. From the ipsilateral access, a floppy guidewire is positioned into the ascending aorta and then replaced with a stiff 0.035-inch wire. Prior to surgery, the proximal and distal target landmarks are chosen: a supraaortic trunk or the celiac or superior mesenteric artery, are most common. Over the stiff wire, the stent graft is inserted to the approximate level, and then imaging is performed. The pigtail catheter is placed at the level of the aortic arch and the C-arm angulation is optimized to visualize the target vessel. A first acquisition is then performed with power injection of contrast during respiratory cessation. The stent graft is deployed gradually after ensuring controlled moderate hypotension (≤100 mm Hg systolic) to avoid downstream displacement due to the windsock effect. In the early experience, rapid pacing or other techniques to decrease cardiac output were performed to improve accuracy of deployment, but this is no longer mandatory when using advanced-generation devices.

During deployment, respiratory cessation and repeated angiographies are performed to adjust the position of the stent graft to the optimal landing zone. Once the stent graft is partially deployed, only distal traction is possible (no advancement to a more proximal position), and even that is not advised with devices with barbs because of possible damage to the intima. The "jailed" pigtail catheter is withdrawn over a standard 0.035-inch guidewire under fluoroscopic vision. Once the stent graft is deployed, the delivery system is used to advance the sheath inside the graft to provide further support to the aortic occlusion balloon that is used in the sealing zone. Completion angiography is performed to assess for endoleak. Then the large sheath is withdrawn, leaving a stiff wire access in place until the hemodynamic stability of the patient is confirmed. At this point, the heparin is reversed before manual compression of the percutaneous access or closure of the arteriotomies.

Optimal C-Arm Angulation

A preoperative assessment of the ideal C-arm angulation should be performed on a dedicated 3D workstation to save time and radiation exposure, particularly in angulated views.[43] Moreover, it has been reported that at 20 degrees from optimal C-arm angulation, there is a 25% loss of available sealing zone (6.2 ± 2.3 mm), which may have an impact on successful seal and fixation.[44]

Staged Procedure

Any associated procedure (supraaortic trunk debranching or conduit) should be performed as a first stage to minimize blood loss and hemodynamic instability during the TEVAR.[45,46]

Fusion Imaging

Fusion imaging, which reduces contrast volume and radiation dose, should be considered.[47] The mask usually requires manual realignment after a first acquisition to be accurate enough to deploy the stent graft,[48] and reflects preoperative aortic shape, which may change once a stiff device is placed.

Radiation Exposure to Staff and Patient

The estimated dose received by the first operator during TEVAR is 0.06 ± 0.05 mSv, significantly correlated to procedural dose area product, iodinated contrast volume, and left anterior C-arm projections greater than 60 degrees (but weak correlation with fluoroscopy time).[49] As an average of the radiation exposure to the patient, the dose area product during TEVAR is reported to be 20 (11.4-30.0) Gy.cm^2 when performed on a mobile C-arm,[50] and 24.7 (22.0-28.7) Gy.cm^2 in an hybrid room (see Chapter 24).[51]

COMPLICATIONS

Intraoperative Complications

Iliac Rupture

The tortuosity and degree of calcification can impact the risk of iliac rupture as much as vessel diameter. Maintaining stiff wire access after the withdrawal of the large sheaths to assess hemodynamic stability before losing wire access can facilitate urgent endovascular rescue if an iliac artery is injured. In case of iliac disruption, the stiff wire access has to be maintained across the rupture for occlusion balloon placement and vessel control, while disruption is addressed through an endovascular or an open approach.[52]

Failure to Deliver the Device

In addition to rupture risk, severe iliac and aortic calcification, angulation, tortuosity, and small iliac diameter less than 8 mm, are predictive of deployment failure.[53] A meticulous analysis of iliac and aortic access on a dedicated workstation is mandatory to anticipate this complication. The presence of previous aortic repair, either open or endovascular, may also impede delivery of the device. Having low-caliber options available and using through-and-through access can sometimes overcome these challenges.

Device Distal or Proximal Device Migration

Device migration is more common when only one device is used, and the rate has been reported at 8.5% (3.6% of distal migration and 4.9% of supraaortic trunk covering) with a significant association with the use of a TAG or C-Tag device (Gore Medical, Flagstaff, Arizona).[26] The use of two devices allows for intercomponent movement, taking stress off of the sealing zones. Recent reports of the use of endostaples show some promise.[54] Care must be taken with aggressive proximal ballooning to avoid retrograde type A aortic dissection (RTAD). If a device migrates proximally, and a supraaortic trunk is covered, several rescue techniques have been described, including manual balloon traction, parallel stent placement (chimney or stenting of the target vessel), open conversion, or surveillance.

Perioperative Complications

Postimplantation Syndrome

Fever and elevated inflammatory markers with pleural effusion in the immediate postoperative period may be related to endothelial activation from the stent graft and aneurysm thrombosis. This syndrome is benign and does not require any medication with an otherwise negative infectious workup.[55,56] However it is imperative that this be a diagnosis of exclusion.

Spinal Cord Ischemia

SCI remains the most devastating complication after thoracic or thoracoabdominal repair. Its rate has not declined with the use of endovascular technology and ranges from 2% to 10% after TEVAR (3.89% in a review of 4936 patients).[57]

Pathophysiology

SCI is caused by ischemic injury and cellular damage secondary to reduction in proximal, medial, and distal direct and collateral arterial blood flow to the spinal cord. This risk is directly correlated with the location and extent of aortic coverage, as with the quality of the spinal cord network. In addition to the artery of Adamkiewicz, it is now understood that spinal cord circulation

is part of a continuous network that includes the intercostal, lumbar, subclavian, and hypogastric arteries, which provide flow to the anterior spinal artery. Common risk factors associated with SCI include aneurysm extent (number of segmental arteries compromised), location (aneurysms affecting the lumbar region have less robust collateralization), and perioperative hypotension.[58] Additionally, there is a risk of embolization from aortic atheromatous lesions.

NEUROPROTECTIVE STRATEGIES

Increasing Tolerance to Ischemia

Pharmacologic Neuroprotection

- ***Intrathecal papaverine:*** In vivo studies in nonhuman primates revealed that intrathecal papaverine injection prevented paraplegia through a mechanism of enhanced vasodilation and blood flow augmentation into the anterior spinal artery[59] and preservation of myelin integrity.[60] A prospectively randomized trial including open thoracic and thoracoabdominal repairs concluded that intrathecal papaverine injection in addition to modern neuroprotective adjuncts considerably diminished the occurrence of spinal cord injury.[61] Since then, it has been employed during endovascular thoracic or thoracic aneurysm repair, but results have not been published yet.[62]
- ***Additional measures***: Because steroids stabilize neuronal cell membranes damaged during ischemia and naloxone reduces the release of excitatory neurotransmitters that exacerbate injury in animal models of ischemia,[63-65] some surgeons administer naloxone (1 mg/kg/h intraoperatively and for 48 hours postoperatively), intraoperative mannitol (12.5 g), and steroids (30 mg/kg up to 2 g methylprednisolone) as an adjunct to other modern neuroprotective measures.[45]

Ischemic Preconditioning by Staged Repair

This strategy is based on the remodeling that occurs after the loss of elements of the collateral supply.[66] Whenever possible with a temporary landing zone, the completion of the repair in two temporally separate procedures allows maximizing collateralization and reducing SCI.[67]

Intraoperative Hypothermia (34°C)

Experimentally, hypothermia reduces the metabolism and oxygen requirement in nervous tissue and prolongs ischemic tolerance and reduces cell swelling after transient ischemia and injury. Similar to the experience with open repair of thoracic aneurysms, some surgeons use intraoperative hypothermia (34°C) with natural warming as an adjunct for spinal cord protection to reduce SCI in TEVAR.[45]

Augmenting Spinal Cord Perfusion

Deliberate Hypertension

The maintenance of a high mean arterial pressure (MAP) intra- and postoperatively is important, with a goal of 90 to 100 mmHg of MAP. Pharmacologic vasodilators may need to be held.

Cerebrospinal Fluid Drainage

Reducing intrathecal pressure improves spinal cord perfusion. A meta-analysis of open thoracic and thoracoabdominal aneurysm repairs demonstrated a decrease in SCI by nearly half using cerebrospinal fluid (CSF) drainage.[68] However in TEVAR, a recent meta-analysis of 46 studies comprising 4936 patients failed to demonstrate a benefit of routine prophylactic drain placement compared to selective use.[57] An alternative to preoperative prophylactic insertion is to wake up the patient even temporarily at the end of the operation to evaluate the neurologic status, and insert the CSF drain only if SCI occurs. Somatosensory evoked potential monitoring may also be used to initiate the drainage in case of intraoperative change. The lumbar drain is usually maintained for 48 hours postoperatively at 10 cmH_2O with coverage with a third-generation cephalosporin for a better CSF penetrance.[69] Monitoring and drainage by an automated system is described but has been associated with a higher rate of complications.[70]

Preservation of the Collateral Network Supplying the Spinal Cord

Every effort should be made to preserve direct perfusion (intercostal and lumbar arteries) and inflow of the alternate routes (left subclavian and internal iliac arteries) to the spinal cord.[62] Simultaneous closure of at least two supplying vascular territories (intercostal and left subclavian or internal iliac for instance) was highly correlated with development of SCI, especially if associated with hypotension.[71]

Maximize Oxygen Delivery

There is a consensus to maintain hemoglobin greater than 10 g/dL and oxygen saturation greater than 95% during and after surgery. Additionally, Maurel et al. described transfusion of 15 mL/kg of fresh frozen plasma and at least one pool of platelets after extensive aneurysm repair, with therapeutic targets of prothrombin time greater than 50%, plasma fibrinogen greater than 2 g/L, and greater than 100 G/L platelets.[46] Endovascular exclusion is associated with blood sequestration between the aneurysmal aortic wall and the stent graft, and results in an acute consumption of coagulation factors and platelets that seems to correlate with the amount of aneurysm thrombosis.[72] These coagulation disorders may induce severe bleeding and need to be corrected.

Recently, a novel approach to enhance collateralization consists of a selective segmental artery coil embolization as a first stage procedure before TEVAR (MISACE). More clinical work is needed before recommendation can be made.[73]

Complications Related to Cerebrospinal Fluid Drainage

Although CSF drainage improves outcomes, it may convey risks, including catheter fracture; postdural puncture headache; neuraxial hematoma; intracranial hemorrhage including subdural, cerebellar, subarachnoid, intraventricular and intraparenchymal hematomas; and meningitis.[74,75] Recovering the patient in a

unit familiar with CSF drainage and supervised by experienced individuals is imperative.

In patients who experience headache after catheter removal, the first line of treatment is bed rest, hydration, and occasionally caffeine administration. If the patient does not improve within 24 hours, an epidural blood patch should be considered. In a review of 504 patients who underwent TEVAR with preoperative CSF, Youngblood et al. reported a 12.7% complication rate, including headache (9.7%), catheter fracture (0.2%), intracranial bleeding (2.8%), and subdural hematoma (1.9%) associated with a mortality rate of 14.3%. The clinical presentation of an intracranial hemorrhage after CSF drainage varies from severe headache and confusion to coma, motor deficit, or respiratory arrest,[75] but the patient may also be asymptomatic with only bloody spinal fluid that can be managed by immediately stopping drainage and correcting coagulopathy.[76]

Cerebral Infarction/Stroke

Stroke remains a major risk after TEVAR with an incidence of 2.3% to 8.2%, and is usually related to embolization. This has most frequently been associated with acute dissections,[26] the atheroma burden of the aortic arch, and a more proximal landing zone.[77] Risk factors also include hypertension, chronic renal failure, known cerebrovascular disease, increased aortic coverage (from LSA to computed tomography [CT]),[78] female gender, longer surgery duration, and occlusion of the LSA.[79] One high-volume center reported a 3.9% rate of perioperative stroke and multivariate analysis–identified risk factors of a history of ischemic heart disease or cerebral infarction, "shaggy aorta," the use of a pull-through wire, and intraoperative blood loss of greater than 800 mL.[80] Treatment should be focused on preventing secondary injury by providing supportive care (avoidance of hypoxia, hypercarbia, hyperglycemia, fever, and adequate airway maintenance), decreasing the risk of hemorrhagic conversion, minimizing cerebral edema, improving perfusion to the ischemic penumbra, and the treatment of acute complications.[81] An imaging study has also reported a high-incidence, silent, per-procedural embolization, with new foci of restricted diffusion on cerebral magnetic resonance imaging (MRI) in more than 60% of TEVAR patients free of neurologic deficit.[82]

Retrograde Type A Aortic Dissection

RTAD occurs in less than 2% of cases, is usually secondary to aortic wall damage, and is associated with high mortality up to 42% in several large series.[83-85] More than two-thirds of RTAD occurs within the perioperative period, but late presentations are also reported (up to 1050 days after procedure), including 25% asymptomatic presentations that underline the importance of lifelong surveillance of TEVAR. It mainly occurs after treatment of type B dissection and especially acute presentations, but also after thoracic aneurysm repair. It has been described with all commercially available stent grafts, regardless of the presence of a proximal bare stent. The MOTHER registry of 1010 patients identified several risk factors, including oversizing 24.4% versus 14.1% without oversizing;[83] post-ballooning; more proximal landing zone (from 6.8% risk in zone 0 to 1.3% in zone 3/4); manipulation of guidewire and sheaths; and progression of the underlying disease. RTAD carries a similar morbidity and mortality rate to de novo type A aortic dissection, so that emergent surgical repair is mandatory. Usually the repair should include a stent graft for the distal anastomosis, involving an aortic arch repair or a reverse frozen elephant trunk technique.[85]

Acute Kidney Injury

This complication is often multifactorial and may be related to preoperative dysfunction, exposure to iodinated contrast, involvement of the renal arteries in the aneurysm, renal macro/micro embolization, a high degree of inflammatory response, and prolonged procedure. Its management remains largely supportive, with hydration and adequate MAP, avoidance of nephrotoxic agents, and dialysis or continuous renal replacement therapy in case of refractory hypervolemia, hyperkalemia, or hyperphosphatemia.[81] The rate of post-TEVAR acute kidney injury has been reported as high as 17%, but with dialysis in less than 1% of cases.[86] Preoperative chronic renal failure has also been strongly associated with late complication and death.[78]

Cardiovascular Complications

Perioperative myocardial infarction is often related to ischemia and management includes hemodynamic stability, glucose control, and adequate oxygenation with consideration of coronary angiography.[81]

Thoracic Endovascular Aortic Repair Collapse

Collapse of a thoracic stent usually occurs where there is lack of apposition of the graft through the circumference of the first stent, causing a type 1 endoleak. This devastating complication is very rare using more flexible second-generation stent grafts. The few cases reported have occurred in young patients with traumatic transection with the underlying mechanism related to small aortic diameter and oversizing or tight arch curvature.[87]

Late Complications

Long-term results after TEVAR are affected by specific complications, such as late aortic ruptures and endoleaks, especially in patients with more challenging anatomy as part of a hybrid repair. Progression of aortic disease may affect the integrity of either the proximal or distal sealing zone, which is more common if small, contiguous aneurysms are present at the time of the index procedure. The rate of secondary procedures after TEVAR for aneurysms is estimated between 10% and 15%, and lack of operator experience may play a role in the development of complications.[88]

Endoleak

This is the main cause of procedural late failure, with an incidence ranging from 3% to 10% with current devices.[89] Similar to abdominal endovascular repair, major endoleak (type I or III) inducing reperfusion of the aneurysm sac is strongly associated with the risk of aneurysm rupture and requires repair. **Type I endoleak** is the main cause of late reinterventions mainly related

to degeneration of the landing zones over time. Distal migration related to stent-graft undersizing or progression of aortic disease may also be responsible. Reinterventions consist of proximal or distal extension of the main stent graft in association with hybrid debranching if necessary, and ultimately open conversion.[90] **Type III endoleak** is usually related to inadequate overlap between components and requires an additional component to bridge the defect with sufficient overlap (three stents). This may develop over time as the graft adjusts to the curvature of the descending thoracic aorta and intercomponent movement occurs. Conversely, **type II endoleak** coming from intercostal arteries may resolve spontaneously. In the setting of sac enlargement, embolization may be required, but it does not occur as frequently as in the infrarenal territory.

Device Migration, Component Separation, and Device Integrity Failure

These complications are linked to late failure and must be identified with high-quality imaging and 3D reconstruction surveillance and addressed before endoleak or rupture occurs. The definition of stent graft migration is a caudal or cranial movement of the stent graft with respect to the native vasculature of more than 10 mm or any distance that results in clinical sequelae or prompting a secondary intervention. Methods have been described to standardize imaging analysis during follow-up.[91]

Stent Graft Infections

The incidence of this complication is 0.2% to 5%. The patient may present with unexplained fever or sepsis. CTA findings suggestive of stent-graft infection include aortic-wall thickening, perigraft soft tissue greater than 5 mm between an adjacent organ and the stent graft, fluid collection, perigraft air (>6 weeks after surgery) or increasing amount of air on serial imaging examinations, adjacent soft-tissue stranding, abscess formation, and graft thrombosis or expansion.[92] Fistulization with either the airway or upper digestive tract can be both a cause and an effect of this process. It requires the complete removal of the infected stent graft and the wrapping of the replacement graft with pedicled omentum, in association with optimum antibiotic treatment. The Vascular Low-Frequency Disease Consortium reported 26 infected TEVARs at a mean of 22 months postoperatively. The clinical presentation included pain (66%), fever (66%), and fistula (27%). Five patients were managed medically and four of them died at a mean of 56 days. The other patients underwent in situ aortic replacement with cryoallograft, a neoaortoiliac system, or an antibiotic-soaked prosthetic. Thirty-day mortality was 11%. Prosthetic graft replacement was associated with higher reinfection and graft-related complications and decreased survival compared with autogenous reconstruction.[93] Medical management with antibiotics alone is not a durable option and only offered as a palliative option or bridging procedure for severely ill patients.[94]

Aorto-Esophageal/-Bronchial Fistulae

The European Registry of Endovascular Aortic Repair Complications (EuREC) estimated a 0.6% incidence of aorto-bronchial or aorto-pulmonary fistula and 1.5% of aorto-esophageal fistula, commonly associated with graft infection. The underlining mechanism is thought to be related to the external compression that the stent graft exerts on nearby structures, with endoleak playing a crucial role. This complication is encountered within 1 to 16 months after TEVAR, presenting as either hematemesis (massive or intermittent) or fever with elevated inflammation markers. CT may help to identify abnormalities in the descending aorta or secondary changes of the adjacent organs but extravasation is rarely seen.[92] Aggressive radical treatment, combining bronchial or pulmonary parenchymal repair or esophagectomy in combination with stent graft removal and aortic reconstruction, appears to be the most durable treatment strategy. A conservative approach resulted in 100% 1-year mortality.[95,96]

IMAGING SURVEILLANCE

Long-term surveillance is indicated after TEVAR, but there is little evidence to support annual surveillance for every patient. CTA is the most common imaging modality used, but is associated with radiation exposure, contrast-induced nephropathy, and cost. Indeed, assuming a preoperative CTA, the procedure, and three CTAs in the first year and yearly thereafter, Zoli et al. reported an estimated overall exposure of 89 mSv at 1 year and 161 mSv at 5 years. At 2 years of follow-up, these doses exceed the threshold of 100 mSv associated with a lifetime risk increase in radiation-induced leukemia and solid-tumor cancer greater than 2.7%.[97] MRI can be used for nitinol-based stent graft surveillance as an alternative to avoid radiation exposure. However, it lacks the ability to visualize metallic stent struts and should be supplemented by chest x-ray to assess metallic skeleton integrity. MRI is not compatible with stainless steel stent grafts due to large artifact.[98] A tailored approach to each patient, with closer monitoring for patients at risk of late stent graft failure has been proposed, as well as alternative imaging like noncontrast CT (maximum aneurysm diameter), plain radiography (integrity of the device and migration); intravascular ultrasound (endoleaks), intrasac pressure measurements, and magnetic resonance angiography.[99] Because late stent graft failure up to 10 years after the procedure is reported, there is no threshold for device-related complications and more long-term experience is needed to define optimal long-term surveillance.[100]

OUTCOMES

Reporting standards published in 2010 define primary and secondary outcomes, technical and clinical success, and how to report death and complications.[101]

Short- and Long-term Results After Thoracic Endovascular Aortic Repair (see Table 79.1)

In a systematic review and meta-analysis combining the results of 11 studies including 673 patients with thoracic aneurysms undergoing TEVAR published in 2016,[102] the technical success rate was 91% with access complications requiring repair in 9.1% of cases. Survival at 30 days, 1 year, 2 years, and 3 years was 96.0%, 80.3%, 77.3%, and 74.0%, respectively. The rate

of SCI was 3.2% (1.4% permanent) and stroke was 2.7%. Type Ia endoleaks occurred in 7.3%, type II in 2%, and type III in 1.2%. At 3 years, 90.3% of patients were free of reintervention. Aneurysm-related deaths occurred in 3.2% of patients. In a recent single-center 15-year experience including 223 patients (24 ruptures) undergoing TEVAR from 1998 to 2013, estimated survival rates were 73.6%, 58.2%, and 58.2%, at 1, 3, and 5 years, respectively.[26] In a series of 371 patients undergoing secondary procedures for thoracic stent graft complications (endoleaks [7.5%], organ malperfusion [2.4%], aorto-esophageal or bronchial fistulae [2.4%], stent graft infections [1.1%], aneurysm progression [0.8%], RTAD [0.5%] and aortic regurgitation [0.3%]), 15.1% required secondary open (44.6%) or endovascular (55.4%) procedures. In-hospital mortality was 16% after endovascular and 4% after open surgery (4%), with a cumulative rate of 80.4%, 73.5%, and 69.3% at 6 months, 1 year, and 3 years respectively. The main complications included stroke, SCI, renal failure, respiratory failure, organ malperfusion, and sepsis.[103]

Risk Stratification Scores

A preoperative all-cause mortality risk-stratification system using the formula 0.0398×(age)+0.516×(renal → insufficiency) + 0.46×(previous → cerebrovascular disease)+0.352×(prior tobacco use)+0.376×(number of devices >2)+0.016×(maximum aneurysm diameter), classified patients as low-, medium-, or high-risk groups, with a predicted survival at 5 years of 80%, 60%, and 40%, respectively.[104] The ATOM score has also been proposed to predict operative mortality among 2000 patients. Significant factors associated with operative mortality were age of 70 or more years, body mass index less than 30 kg/m^2, chronic obstructive pulmonary disease requiring total functional assistance, blood urea nitrogen greater than 25 mg/dL, white blood cell count greater than 12,000 cells/mL, emergency operation, left subclavian artery coverage, thoracoabdominal extension, and mesenteric debranching. Low- (ATOM < 5), moderate- (ATOM 5-9), and high- (ATOM ≥ 10) risk categories correlated with 1.3%, 6.6%, and 24% operative mortality, respectively.[105] Finally, a preoperative prediction score of SCI after TEVAR has been proposed, based on age, aortic coverage length, chronic obstructive pulmonary disease, chronic renal insufficiency, and hypertension.[106]

RUPTURED DESCENDING THORACIC AORTIC ANEURYSM

Ruptured descending thoracic aortic aneurysms (RTAAs) account for approximately 30% of all thoracic aortic ruptures and TEVAR is now considered as the first line option. In a 2010 review including 224 patients, the 30-day rates of mortality were 19% versus 33%, myocardial infarction 3.5% versus 11.1%, stroke 4.1% versus 10.2%, and paraplegia 3.1% versus 5.5% after TEVAR and open repair, respectively.[107] Jonker et al. reported 32% mortality, 24% strokes, and 40% pulmonary complication among patients older than 75 years, compared to 13%, 1.5%, and 9%, respectively, for younger patients. Thirty-day mortality was 40% among those older than 80.[108]

Five studies that compared the results of TEVAR after elective (n = 151) and urgent procedures (n = 77) demonstrated a 30-day mortality of 17.1% versus 1.8%, respectively.[102] This may be related to the rupture itself and an increased risk of device-related complication. Indeed, for an emergency procedure, the physician may have a restricted choice of device sizes, and inadequate sizing may occur due to hypovolemic shock or poor-quality imaging. Therefore, the durability of the repair has to be carefully checked by postoperative CTA surveillance. Device-related complications after TEVAR for RTAA include type Ia endoleak, perforation of the aortic wall by the bare portion of the stent graft, and infection.[107]

There is no recommendation concerning whether RTAA should be performed under local, regional, or general anesthesia. The overall intraoperative anesthetic goals should be focused on establishing a stable hemodynamic environment and maintaining good cardiac function and adequate blood flow to the spinal cord and abdominal vital organs.[109]

The use of proactive spinal cord protection protocols could lead to a decreased rate of paraplegia. In any case, every attempt should be made at the end of the procedure to obtain a neurologic assessment of the spinal cord and employ adequate treatment of SCI if necessary.

CONNECTIVE TISSUE DISORDERS

The Society of Thoracic Surgeons Endovascular Surgery Task Force stated that "stent grafting in patients with Marfan syndrome or any other known connective tissue disorder is not recommended [because] there is limited information regarding the impact of persistent radial forces of a stent graft in the abnormal and weak aorta."[1] The European Society stated that "TEVAR is not recommended in patients with connective tissue disease except as a bail-out procedure or bridge to definitive open surgical therapy, or as a procedure following prior aortic repair when both landing zones lie within previously sited prosthetic grafts."[5] The Canadian Cardiovascular Society reserves TEVAR in this population for patients in a complex repeat surgical setting or judged to have prohibitive open surgical risk, or as a life-saving bridge to a definite open repair in cases of severe bleeding or malperfusion.[110] Therefore, open surgery remains the treatment of choice. The role of TEVAR in these patients is unknown related to securing a device with radial force in a fragile aorta with potential long-term aortic dilation and subsequent endoleak or rupture.[111-113] Moreover, a higher risk of RTAD has been described in this population.[84] Further study is needed to refine the indications for endovascular surgery in the setting of genetic aortopathy (see Chapter 140).

METHODS FOR FAILURE TO RESCUE

Endovascular Rescue

Most secondary endovascular procedures for type I endoleak consist of additional TEVAR implantation in case of adequate

sealing zone (more than 2 cm), or in association with vessel debranching.[103] Alternatively, a custom-made device with branches or fenestrations may be used to maintain target vessel patency while achieving sealing, or snorkel/chimney techniques. In case of type II endoleak, coil embolization may be necessary in the setting of aneurysm growth (more than 5 mm).

Open Conversion

The incidence of open repair after TEVAR is estimated in large series (>300 patients) to range from 0.4% to 7.9%. Open conversion after TEVAR is classified as full extraction, partial extraction, or full salvage of the stent graft. The main reasons for open conversion are elective (type I endoleak, aortic fistula, endograft infection, device collapse or migration, continued expansion of the aneurysm sac) or emergent (rupture, RTAD, malperfusion, endograft infection). Open conversion for endoleak repair is the most common indication and is associated with the use of TEVAR outside of the IFU (shorter landing zone). It is indicated when associated with aneurysm growth after endovascular rescue. Hypothermic circulatory arrest is necessary when the graft impinges on the supraaortic trunks. Partial explantation is a useful strategy without infection when the stent graft is well incorporated and has not been associated with an adverse event during follow-up.[88]

In a recent series including 30 cases of late open conversion at an average time of 57 months after TEVAR due to progression of distal aortic disease (30%), stent graft infection/fistulization (33.3%), retrograde dissection (20%), endoleak (10%), and device migration (6.7%), the perioperative mortality rate was 16.6% (20% and 33% among the subgroups of infection and retrograde dissection, respectively). In most cases the proximal portion of the stent graft was left in place.[114]

Abstract

The goal of fenestrated and branched endovascular aneurysm repair (F/BEVAR) is to reduce the morbidity and mortality associated with complex aortic pathology. First described in 1999, F/BEVAR has been reported to treat juxtarenal, paravisceral, thoracoabdominal, and arch aneurysms. The need to maintain perfusion to aortic branch vessels had previously prevented the ability to repair these aneurysms via a total endovascular approach. A variety of techniques have been utilized to maintain patency of aortic branch arteries and these will be described in detail. In addition to advances in device design and availability, advances in patient selection, case planning, and intraprocedural imaging have supplemented the utilization of this technology and improved outcomes. Although Level I evidence for the efficacy of fenestrated and branched repair of thoracic and thoracoabdominal aneurysms in comparison to open repair does not yet exist, a growing body of literature has demonstrated high technical feasibility with excellent short-term outcomes. Encouraging midterm data has emerged, although, as with standard endovascular aneurysm repair, the need for re-intervention remains a concern. Long-term durability has not yet been established. Utilization of this technology is increasing worldwide which raises practice, training, and regulatory issues that will need ongoing attention.

HISTORY OF FENESTRATED AND BRANCHED ENDOVASCULAR AORTIC ANEURYSM REPAIR

Fenestrated and branched endovascular aortic aneurysm repair (F/BEVAR) uses customized, patient-specific, endovascular devices with potential to significantly reduce morbidity and mortality associated with open repair of complex aortic pathology. The first publications describing F/BEVAR were reported in 1999 and involved the treatment of short-neck infrarenal abdominal aortic aneurysms (AAAs), using fenestrations for the renal arteries to extend the effective seal zone into the pararenal aortic segment.[1,2] Over the past two decades, the use of F/BEVAR has steadily increased.[3] In the early experience, uncovered stents were used to bridge fenestrations in the aortic endograft to target arteries to maintain target artery patency and aid in endograft alignment. Subsequently, covered stent-grafts have become preferred due to their superior ability to supplement aortic seal at the fenestration site and to improve long-term branch patency. Stented fenestrations are suboptimal for anatomic conditions in which the aortic diameter at the level of the target branch artery is significantly larger than the diameter of the aortic endograft.[4,5] In these cases, side arm branches sewn to the aortic endograft have emerged as an alternative approach to stented fenestrations. Side arm branches can be attached to the aortic endograft in an orientation that is proximal (antegrade) or distal (retrograde) to the level of the target branch artery origin. These side arm branches are then bridged to the target branch artery with a stent-graft as fenestrations are bridged to target branch arteries. Consensus has not emerged regarding the superiority of branches versus fenestrations, and most high-volume users would agree that there is a role for both methods of including target arteries into a complex endovascular repair.

Since its inception, F/BEVAR has been primarily performed in large-volume tertiary care centers. This reflects not only the complexity of the technology, but also the investigational nature of these devices. In the United States, F/BEVAR was initially confined to centers with access to company-manufactured devices through industry-sponsored clinical trials or to centers with an FDA-approved physician-sponsored investigational device exemption (PS-IDE) to study physician-modified devices and/or custom-made devices (CMDs). However, since FDA approval of the Zenith Fenestrated Device (Cook Medical, Bloomington, Indiana) in 2012, fenestrated technology has been made more broadly available for its application to short-neck and juxtarenal AAA in the United States.[6] Additional off-the-shelf devices for TAAA and aortic arch aneurysms are currently in or entering clinical trials in the United States.[7–13]

DEFINITIONS

Techniques for Incorporating Branch Vessels

It is important to differentiate the nomenclature used for F/BEVAR from two other common approaches to aortic branches during endovascular aortic aneurysm repair, "debranching" and "parallel stent-grafting." The term "debranching" refers to the use of open surgical bypass to an aortic branch artery from a location proximal or distal to the intended placement of the aortic endograft. In "parallel stent-grafting," grafts are aligned alongside the primary aortic endograft in a variety of configurations (chimney, snorkel, periscope, sandwich graft) to allow blood flow to aortic branches which are otherwise covered by the aortic endograft. Blood flow to the parallel grafts can originate from the aorta or iliac arteries either above or below covered portion of the aorta.

Standard definitions and terminology for F/BEVAR have been defined in the SVS TEVAR reporting standards document (Fig. 80.1).[14] A scallop refers to a semicircle cut-out of the endograft fabric involving the proximal or distal edge of the endograft which allows filling of an aortic branch. Scallops can vary in width and depth. A fenestration indicates the presence of an opening in the endograft fabric which allows perfusion of an aortic branch vessel which would otherwise be covered. They can vary in diameter in both the major and minor axis. If stents (or stent-grafts) are placed through the fenestration into the target vessel, this is described as a stented fenestration. Even when this stent-graft is not required to achieve a seal, the term "stented fenestration" is still used. A branch is a cylindrical tube of fabric, which may be placed either internally or externally on the aortic endograft; branches may have varying lengths and orientations. Its origin can be located on the endograft proximal or distal to the origin of the target vessel. Just as with a fenestration, a stent-graft is required to bridge the branch to

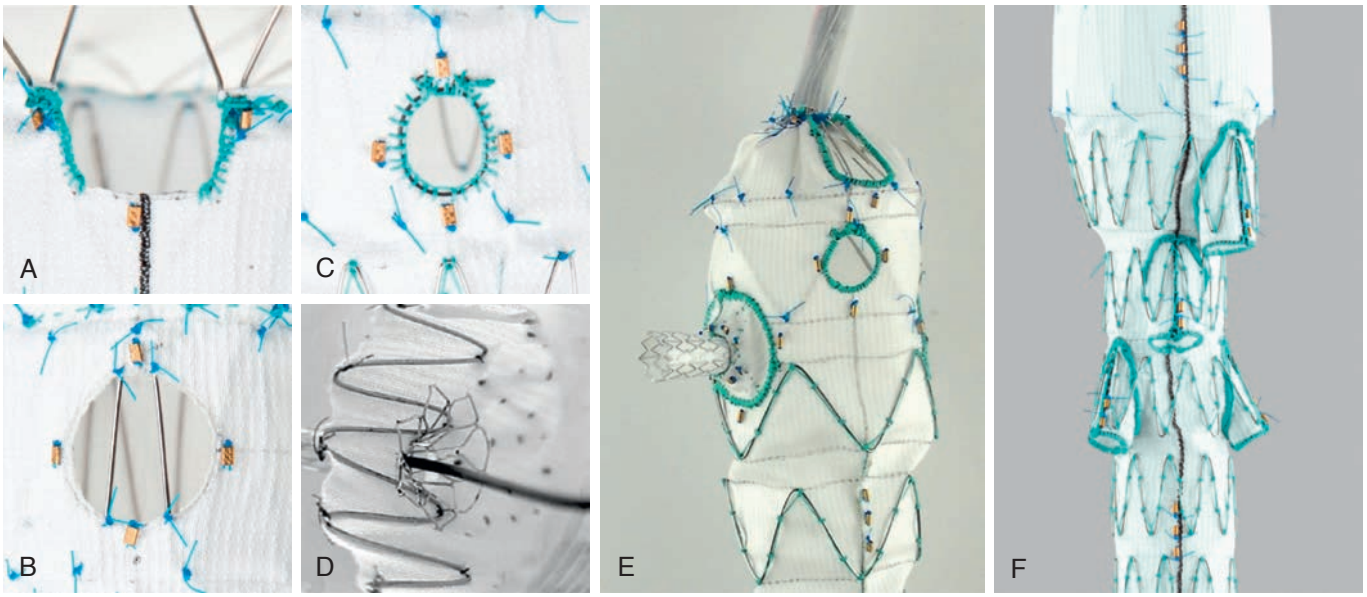

Figure 80.1 Illustrations of (A) scallop, (B) fenestration, (C) reinforced fenestration which is more suitable for stenting or fenestrated branches. (D) Stented fenestration, (E) fenestrated branch, and (F) side arm branch, as defined by the SVS TEVAR Reporting Standards.

the target artery origin to maintain target artery perfusion and to prevent flow into the aneurysm sac.

Device Availability

As previously alluded to, F/BEVAR devices can be obtained in a variety of ways. These are generally grouped into physician-modified endografts (PMEGs), custom-ordered patient-specific devices (CMDs), or off-the-shelf designs which have been tested to be applicable to a variety of anatomic configurations. There are a number of pros and cons associated with each type.

Physician Modified Endografts

In this approach the physician deploys a standard endograft on the back table under sterile conditions and creates modifications by hand to accommodate branch vessels at locations specific to the patient's anatomy based on preoperative imaging (Fig. 80.2). The modified endograft is then resheathed for insertion and deployment in the patient. The rationale for such an approach is twofold: (1) many institutions do not have access to CMDs and, (2) in urgent or emergent situations, there may not be time to wait the 6 to 8 weeks typically required for the manufacturing of a CMD.

Numerous reports have described techniques for modifying nearly all of the devices that are presently commercially available.[15–17] PMEGs have been used for the treatment of short-neck infrarenal to large extent thoracoabdominal aneurysms. Expertise and experience in planning and executing graft modification, as well as the implantation itself, is crucial. Although the planning techniques for PMEGs are similar to those for CMDs, PMEGs do not have standard measurement forms or manufacturer support. There are also some design

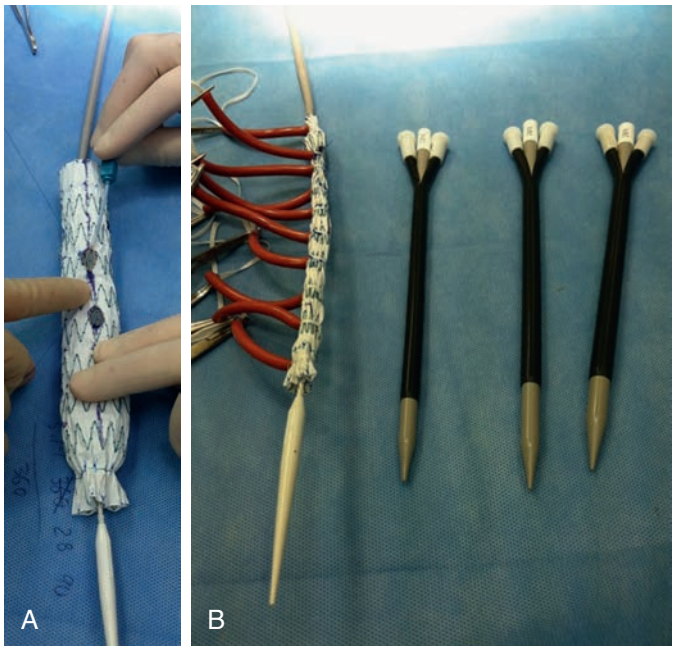

Figure 80.2 Physician-Modified Endovascular Graft. Commercially available device modified by the implanting surgeon with fenestrations on an operating room back table (A). The modified device is then reconstrained, and using a set of serial dilators, resheathed into the delivery system for implantation (B).

aspects (such as aggressive tapering) that cannot be achieved with commercially available endografts. Physician modification thus requires a much more detailed knowledge of devices and deployment mechanisms, and acceptance of some design limitations. It is imperative to note the serious responsibility assumed by the implanting physician, particularly if the procedure is not performed in the context of an investigational device exemption study.[18]

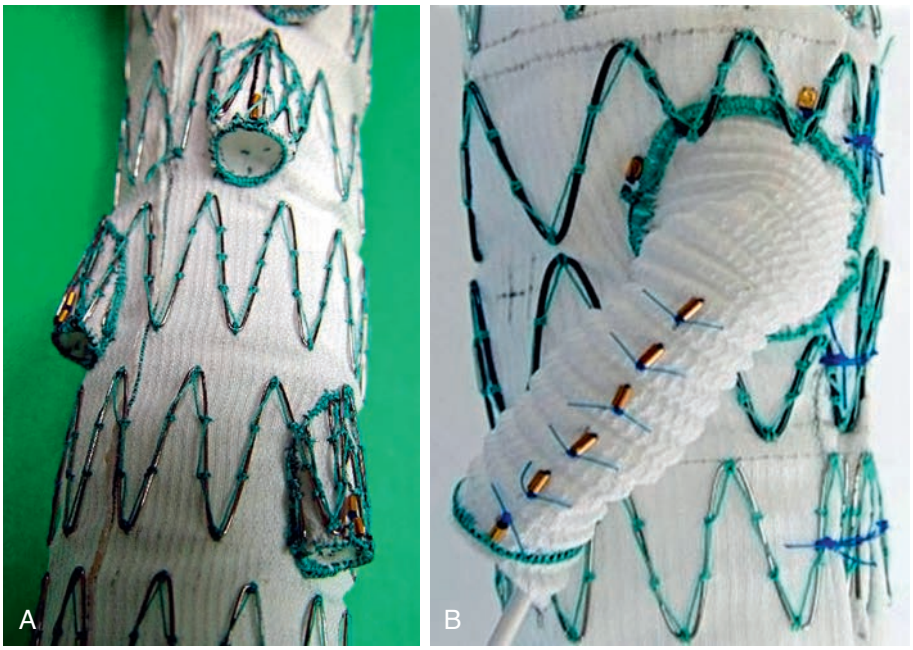

Figure 80.3 Visceral artery branched devices, showing both straight cuffs (A) and helical branches (B).

Company-Manufactured Custom-Made Devices

The majority of the experience accumulated to date with F/BEVAR is through the use of CMDs based off of the TX2 and Zenith platforms (Cook Medical). These devices can include any combination of fenestrations and/or branches. Branches have varied in configuration but have generally involved straight axial cuffs, directional cuffs, and helical limbs (Fig. 80.3). Often the device is "preloaded," whereby a catheter and wire is threaded through the delivery system and then through the fenestration and/or branch (Fig. 80.4). Preloaded catheters/wires can be used to facilitate F/BEVAR in one of two ways: (1) snared from above to facilitate target artery cannulation from the brachial or axillary approach or (2) loaded from below to guide a sheath through the transfemoral ipsilateral delivery system and out the fenestration (Fig. 80.5). Although these CMDs are commercially available throughout much of the world, they have limited availability in the United States. To date, other than the FDA-approved Zenith Fenestrated Device (Cook Medical), all CMDs that have been implanted in the United States have been done so as part of an industry-sponsored clinical trial or at a center with an ongoing PS-IDE trial.[16,19–22]

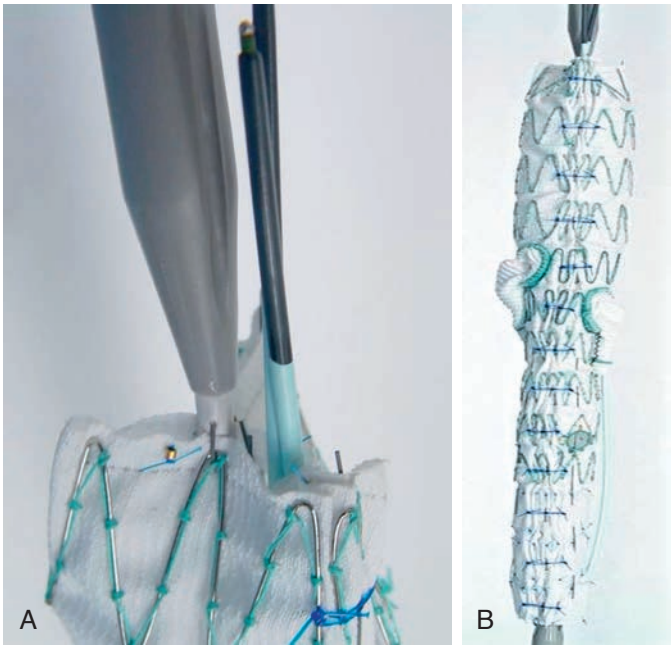

Figure 80.4 (A and B) A preloaded, two-branch, two-fenestration device. In this device the preloaded catheters and wires are threaded through the visceral branches, with a proximal exit as depicted in B. This design facilitates cannulation of the branches during the operation.

Company-Manufactured Off-the-Shelf Devices

Off-the-shelf devices have been developed to overcome the limitations of custom-made CMDs requiring several weeks of manufacturing time. Off-the-shelf designs take advantage of the fact that branch vessel anatomy varies within a defined range for the majority of patients.[23–26] Pivoting fenestrations and downgoing axial side branches have both been used to create different off-the-shelf devices applicable to different types of aneurysms. There are currently three different off-the-shelf F/BEVAR devices in trial in the United States: Cook "p-Branch" (Cook Medical), "t-Branch" (Cook Medical), and Gore Excluder Thoracoabdominal Multibranch Endoprosthesis (W.L. Gore and Associates, Inc., Flagstaff, Arizona). Each of these designs is specifically engineered to allow for more degrees of freedom for cannulation of target vessels within a set range of positions. While these devices are more versatile than custom-made CMDs, off-the-shelf designs are not able to accommodate all extremes of anatomy.

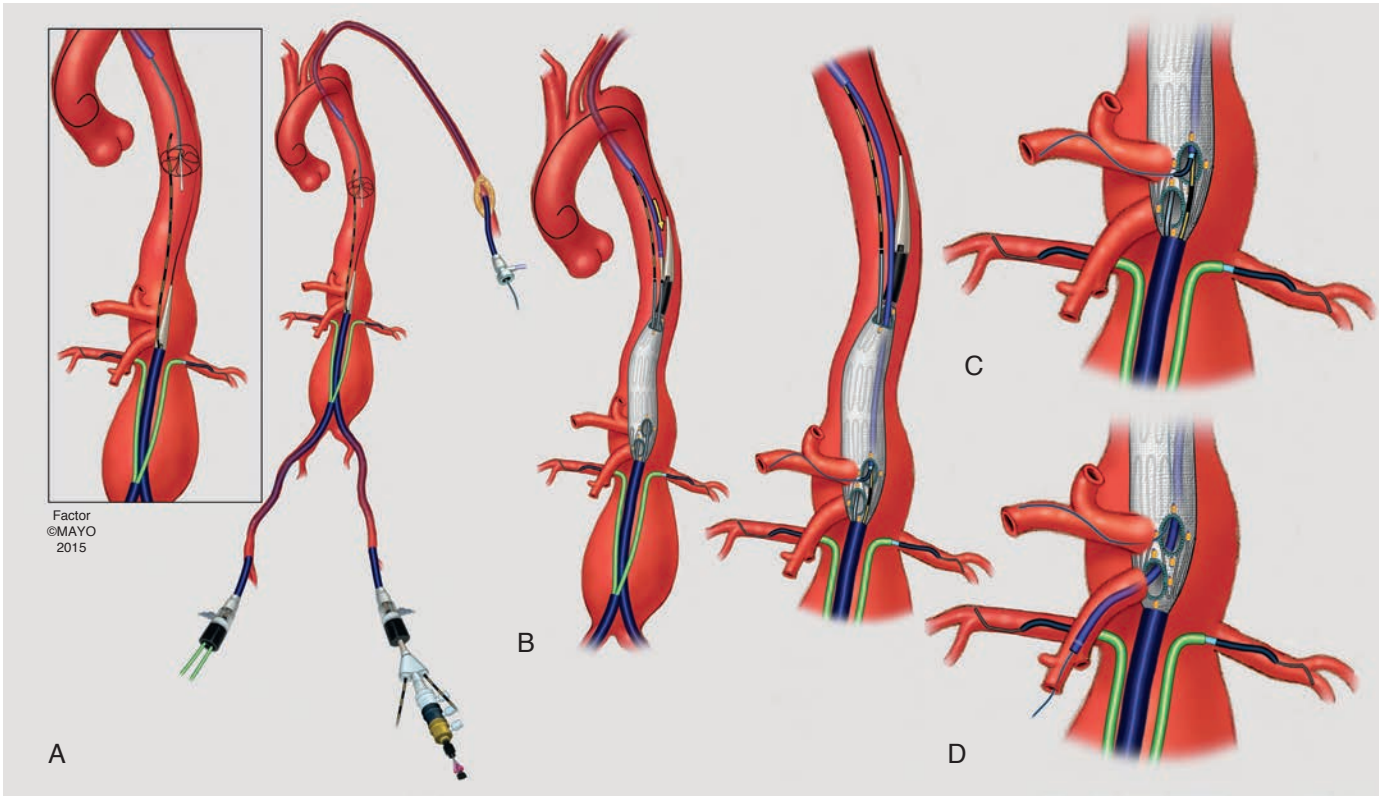

Figure 80.5 Demonstration of the Use of Preloaded Catheters During Fenestrated and Branched Endovascular Aortic Aneurysm Repair. Preloaded catheters are loaded through the graft and ipsilateral device delivery system in the left groin and emerge through the top of the endograft. The catheters are snared from a left axillary approach (A). After unsheathing of the proximal endograft, catheters and sheaths can be advanced from the axillary artery over wires placed through the preloaded sheaths, which have been threaded through the fenestrations for the celiac artery and superior mesenteric artery (B). After sheaths have been advanced from above through the graft fenestrations, wire and catheter selection of the branch arteries is performed (C). Sheaths are subsequently advanced over wires through the graft fenestrations and into the branch vessels which will allow placement of covered stents into the branch vessels after deployment of the aortic endograft (D). (Figures courtesy of Gustavo Oderich, MD, Division of Vascular and Endovascular Surgery, Mayo Clinic, Rochester, MN.)

OVERVIEW OF CURRENT DEVICES BASED ON ANEURYSM LOCATION AND EXTENT

Juxtarenal Abdominal Aortic Aneurysm

The commercially available Zenith Fenestrated Endovascular Graft (Cook Medical) also known as the "Z-Fen" device, is intended to treat "short-neck" infrarenal and juxtarenal AAA and is the only fenestrated device currently FDA-approved (Fig. 80.6). The proximal main body graft is a tube graft which utilizes a combination of fenestrations and/or a scallop to accommodate the superior mesenteric artery (SMA) and renal arteries; these are custom-made to the patient's specific anatomy. The most common graft design employs either a scallop or a large fenestration for the SMA and two small fenestrations for the renal arteries. There are several restrictions on how scallops and/or fenestrations can be placed due to specific engineering constraints. As a result, not all branch vessel anatomy can be accommodated. The proximal main body is deployed with the fenestrations appropriately aligned with their target arteries. After deployment of the proximal main body device, the fenestrations and branch arteries are selected from inside the proximal main body endograft and sheaths are advanced into the target arteries to allow deployment of bridging stent grafts. The proximal main body is subsequently mated to a distal bifurcated endograft which can be designed to extend into the ipsilateral iliac artery or from which standard iliac limbs can be extended bilaterally.

Pararenal Abdominal Aortic Aneurysm

There are currently no commercially available devices intended available in the United States to treat pararenal AAAs. The Cook "p-Branch" (Cook Medical) device, so named for the ability of the renal fenestrations to "pivot," is currently in clinical trial within the United States. This is an off-the-shelf device which incorporates fenestrations for the SMA and bilateral renal arteries and a scallop for the celiac artery, thereby allowing more proximal extension of the aortic endograft seal zone in comparison to the "Z-Fen" device. As an off-the-shelf device, it is currently manufactured in two configurations which, in combination, are anticipated to accommodate the aortic branch anatomy in approximately 70% of pararenal aneurysms.[26] There

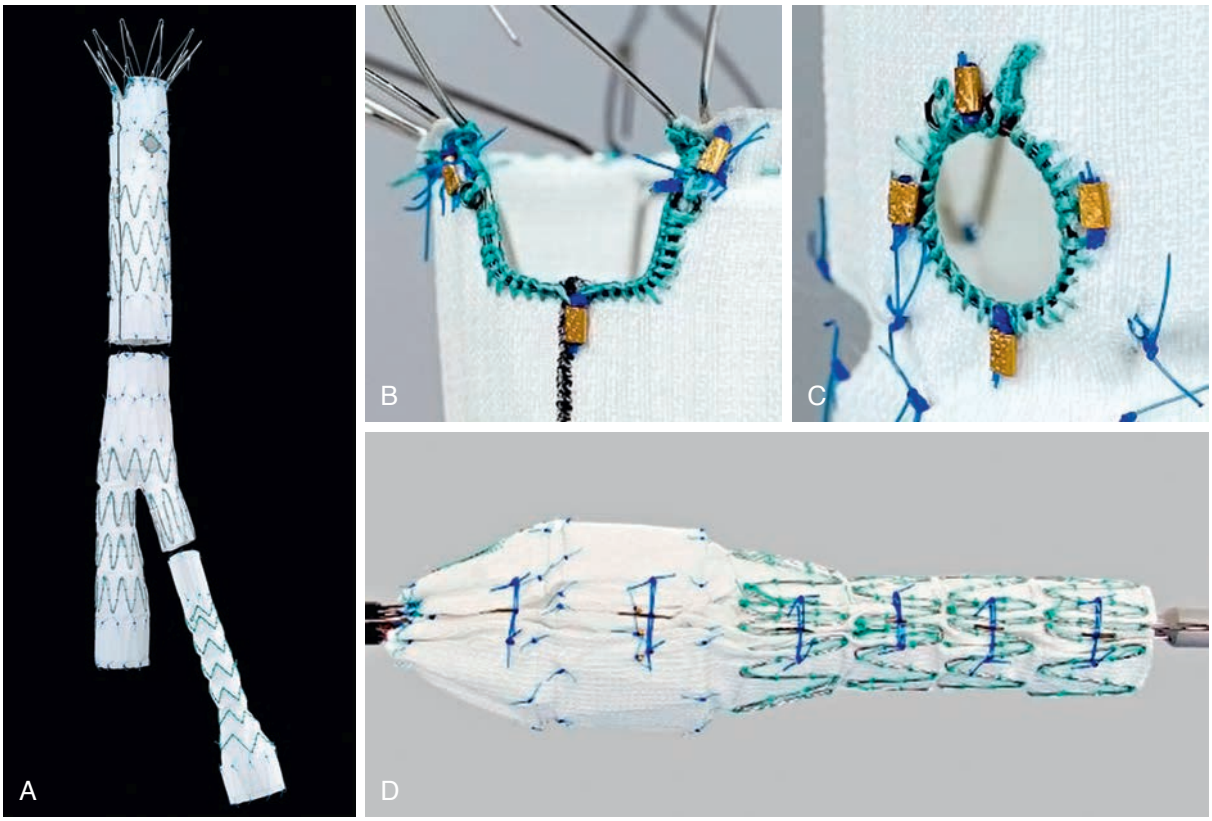

Figure 80.6 **The Zenith Abdominal Aortic Aneurysm Fenestrated System (Cook Medical, Inc., Bloomington, Indiana).** (A) The device is a modular bifurcated device. (B) Nitinol-reinforced scallop with three gold radiopaque markers. (C) The fenestrations are reinforced with nitinol rings and radiopaque gold markers to aid with orientation of the graft during deployment. (D) Constraining ties which reduce the diameter of the proximal main body help to allow rotation of the graft which is necessary to achieve alignment.

are two notable features of this device (Fig. 80.7). First, the renal fenestrations are created within a pocket of redundant fabric which can "pivot" and thereby allow selection of the renal artery and extension with a stent graft into the renal artery in a myriad of directions. Second, the proximal main body of the "p-Branch" device has preloaded wires and catheters specifically designed to cannulate the renal arteries without the need to select via contralateral femoral access. Both aspects of this graft are designed to facilitate selection of the renal arteries. After proximal main body deployment and target vessel selection and stent graft placement, the remaining graft deployment proceeds similarly to the "Z-Fen" device.

Thoracoabdominal Aortic Aneurysms

There are currently no commercially available devices intended to treat thoracoabdominal aortic aneurysms (TAAA) in the United States. As a result, options for the F/BEVAR of TAAA are limited to PMEG or custom-made patient specific (CMDs) available through an industry-sponsored clinical trial or physician-sponsored IDE study.

Custom Made Devices

CMDs can be custom-manufactured to include any combination of fenestrations and/or branches. On average, these devices require 6 to 10 weeks of time for manufacturing. These devices are available with standard fabric and stainless steel stents that require delivery systems ranging from 22 to 26 French or with low-profile fabric and nitinol stents that require delivery systems ranging from 18 to 22 French. As mentioned previously, a diverse array of preloaded wires and/or catheters can be incorporated into the endograft design to ease target artery cannulation from either below or above.

Thoracic Branch or "t-Branch" (Cook Medical)

Based upon the experience with custom-made CMDs, Thoracic Branch or "t-Branch" (Cook Medical) is an off-the-shelf device based on the Cook TX2 platform which uses four downgoing axial branches sewn to the thoracic component which allow extension of stent grafts into the visceral vessels (Fig. 80.8). The thoracic endograft is mated with a standard modular infrarenal bifurcated graft distally and can be extended proximally with a thoracic endograft. This device, available in Europe, is scheduled to enter a clinical trial in the United States in the near future.

Gore Excluder Thoracoabdominal Multibranch Endoprosthesis (W.L. Gore and Associates)

The Thoracoabdominal Multibranch Endoprosthesis, or "TAMBE" graft, is an off-the-shelf device designed for the

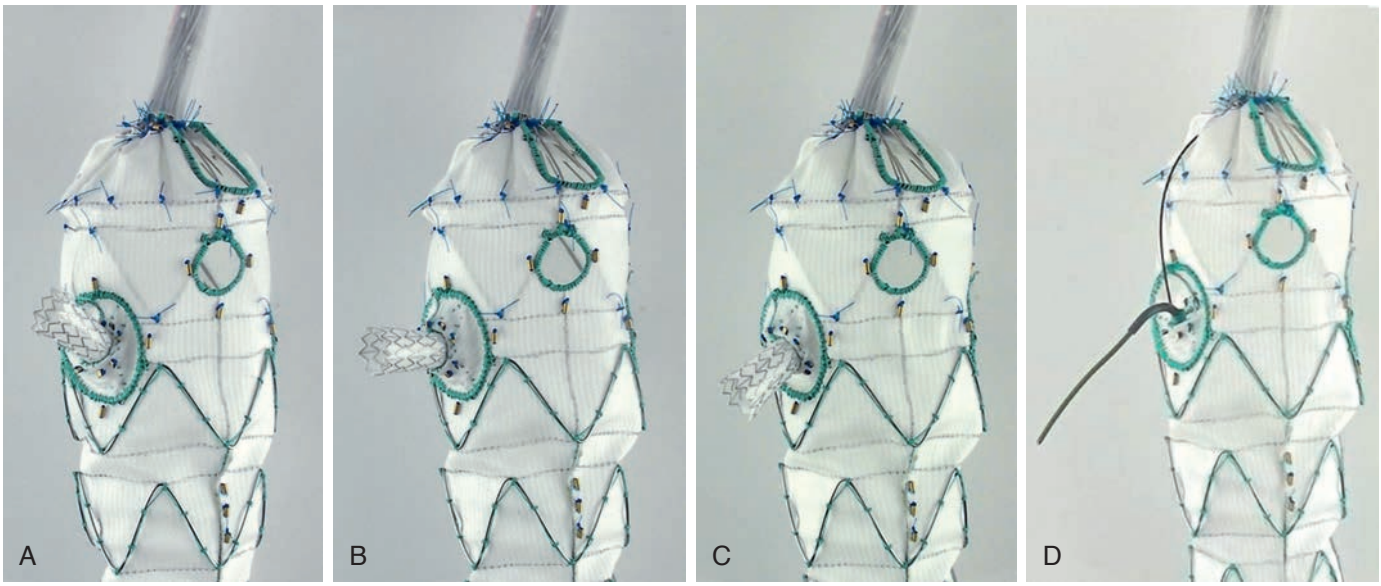

Figure 80.7 The off-the-shelf Zenith Pararenal Endovascular Graft (Cook Medical, Inc., Bloomington, Indiana), currently known as "p-Branch," has a standard configuration consisting of a celiac scallop, a superior mesenteric artery fenestration, and "directional" fenestrations to accommodate most renal arteries with fenestrated branches. (A). This allows stenting of the renal arteries through the renal pivot in a variety of orientations while still attached to a flexible "directional" reinforced fenestration (A-C). Pre-loaded wires and catheters in the renal pivot intended to select the renal arteries (D).

Figure 80.8 The Thoracic Branched ("t-Branch") device (Cook Medical, Inc., Bloomington, Indiana), an off-the-shelf endograft system designed for repaired of thoracoabdominal aortic aneurysms.

treatment of aneurysms involving the visceral segment (Fig. 80.9). The graft has two downgoing internal branches for the celiac artery and SMA into which stent grafts are placed to bridge the gap from the device to these target arteries. There are two separate configurations for the internal renal branches through which stent grafts are placed into the renal arteries. Both renal branches are perfused in an antegrade fashion in one configuration and in a retrograde fashion in the other. Feasibility testing has been performed, and this device is scheduled to enter clinical trial in the United States at the time of writing of this chapter.

Aortic Arch

Encouraging early results using F/BEVAR devices for aneurysms involving the visceral segment has inspired extension of this technology to treat aneurysms of the transverse and descending aortic arch with involvement of the great vessels. Challenges unique to the aortic arch include greater vessel flow, pulsation and rotation within the cardiac cycle and with respiration, greater tortuosity and angulation of the arch and great vessel ostia, longer distance to the target vessels, the proximity of the aortic valve and coronary arteries, and lower cerebral tolerance to transient ischemia and embolism.[27] Given these challenges, experience has dictated that aortic arch pathology appears better suited for treatment with branched endografts rather than fenestrations. While misalignment of fenestrations results in severe neurologic complications, precise alignment of branched grafts is not as critical as long as the branch grafts can be successfully extended into the great vessels.

To date, the majority of the experience in total endovascular repair of aortic arch lesions has been gained outside of the United

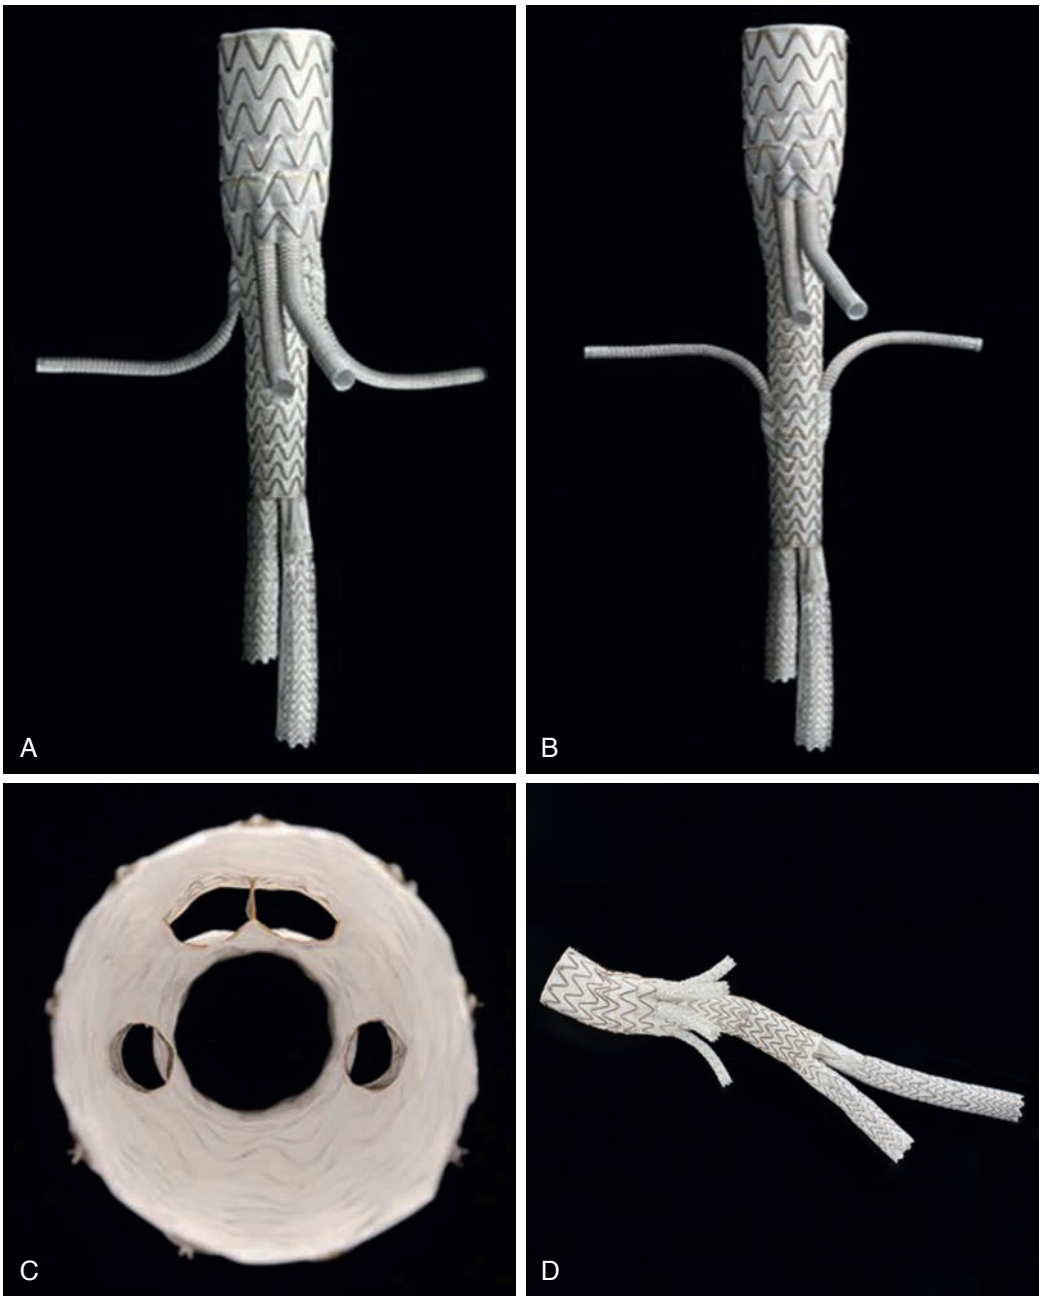

Figure 80.9 The Thoracoabdominal Multibranched Endoprosthesis ("TAMBE" device, Gore Medical, Flagstaff, Arizona), an off-the-shelf endograft system designed for the repair of thoracoabdominal aortic aneurysms. The device has configurations with both antegrade (A) and retrograde (B) orientation of branches for the renal arteries. The visceral arteries are accessed via internal portals in the main body of device (C), through which Viabahn stent-grafts are extended into the target arteries (D).

States. Inoue established the technical feasibility of branched endovascular repair of arch aneurysms with the first published experience in 1999.[28] The high stroke and mortality rate seen in this experience was thought to be due to the use of branches which protruded external to the aortic graft and required extensive manipulation in the arch during cannulation of target vessels.[29] Chuter et al. reported the first use of a modular branched endograft for arch repair in 2003. This design required full arch debranching based on the right common carotid artery followed by delivery of the proximal bifurcated ascending graft via the right common carotid artery. One limb of the ascending graft was extended into the innominate artery while the other served as a gate for mating with the distal tube endograft component which was delivered via the femoral artery.[30] Ultimately, the large sheath size in the carotid artery hindered the broad application of this technique.[29] Fenestrated custom-made endografts have also been used to repair arch aneurysms. The largest cohort study comes from Japan with a precurved endograft with preloaded catheters placed through the fenestrations. This graft came to be known as the Najuta graft, a device with 19

types of three-dimensional (3D) stent skeletons and 8 types of graft fenestrations for arch vessels.[31] From 2010 to 2012, 383 patients were repaired with this device with low morbidity, including a 1.8% stroke rate, and low 30-day mortality (1.6%).

Despite these encouraging early results, the technical challenges associated with arch repair and the desire for immediately available off-the shelf grafts has driven the development of the four arch branch devices which are now the most commonly used worldwide. The use of aortic arch branched grafts for repair of thoracic aneurysms remains in its relative infancy because there are currently no FDA-approved devices for use in the United States. Current grafts are in clinical trials in the United States or Europe or available within physician-sponsored IDE trials (Fig. 80.10).

Cook Arch Branch Device

The current configuration of the Cook custom-made arch device has two internal branches intended for zone 0 deployment. The largest proximal device diameter is 46 mm. A key component of the delivery system is a precurved introducer and sheath. In addition, the outer curvature of the device is attached to the inner cannula with a spiral wire, which aids in orienting the internal branches along the outer curvature of the arch. After graft deployment, there is ongoing arch perfusion through the open branches. After surgical access from above (right carotid artery or right axillary artery; left carotid artery or left axillary artery in the setting of a left carotid subclavian bypass), the internal branches are catheterized and bridging stents deployed from the internal branch into the respective target vessels. Traditional open left subclavian revascularization is generally performed to maintain antegrade perfusion through the left vertebral artery. This graft has the largest worldwide experience, with greater than 200 implants reported.[32]

Relay NBS Plus for Aortic Arch (Bolton Medical, Barcelona, Spain)

This device, based on the Relay NBS platform, is custom-made outside of the United States and is not currently available in

the United States. Proximal diameters range from 32 to 48 mm, and distal diameters range from 22 to 48 mm. Customized tapering of the graft up to 16 mm can be achieved and device lengths vary from 255 to 270 mm, which allows the endograft to span the length of the arch with a single device. A dual sheath design is meant to improve conformability along the inner curve of the arch, and a precurved nitinol hypo tube aids in orientation of the branches along the outer curve. The most current iteration of device includes two 12-mm internal "tunnels," which are oriented such that the anterior tunnel is optimally bridged to the left carotid artery and the posterior tunnel bridged to the innominate artery. The tunnels open into a single large aperture which is meant to direct guide wires into the tunnels from a femoral approach. Dedicated bridging stent grafts are part of the system, with distal diameters ranging from 8 to 20 mm to accommodate the majority of innominate and carotid artery sizes. The results of 40 implantations have been reported.[8,33,34]

Valiant Mona LSA Stent Graft System (Medtronic, Inc., Minneapolis, Minnesota)

The Mona LSA device is a single-branch device designed for zone 2 deployment, although it can also be used in more proximal landing zones assuming any covered arch vessel can be revascularized with open debranching as necessary. This endograft is based on the Valiant thoracic graft platform, with proximal diameters ranging from 30 to 46 mm and distal diameters ranging from 22 to 46 mm. Grafts are 150 mm in length and have a maximum taper of 4 mm over the length of the graft. The branch is a modified fenestration with a short inverted funnel that is intended to engage the origin of the arch vessel. A preloaded catheter is threaded through the fenestration. A guide wire passed through the catheter within the delivery system is snared from access via direct exposure of the arch vessel and the "through-and-through" wire used to orient the fenestration at the origin of the target vessel. The system offers dedicated bridging stent-grafts between 10 and 14 mm in diameter that can be delivered through the arch vessel and flared within the wide mouth of the fenestration. The cuff can pivot, allowing for as much as 20 to 30 degrees of malalignment between the cuff and the subclavian artery. Nine patients were successfully treated in an early feasibility study, and the device is now being evaluated in a feasibility trial at seven sites in the United States.

TAG Thoracic Branch Endoprosthesis (W.L. Gore and Associates)

The Gore device for use in the aortic arch (Gore TBE) is based on the conformable Thoracic Aortic Graft (C-TAG) platform. The device is intended for either zone 0, 1, or 2 deployment, with a caudally oriented internal branch. The device is currently available with proximal diameters ranging from 26 to 45 mm and lengths of 100 or 150 mm. The delivery system has a preloaded catheter threaded through the branch which allows snaring of a guide wire from either upper extremity or left carotid access. A "through-and-through" guide wire is used to orient the device during deployment. A series of bridging stents are available which are delivered and deployed via the femoral artery into the arch vessel. The Gore TBE device has completed a multicenter feasibility trial, and a pivotal trial is currently enrolling patients.

CASE PLANNING AND SIZING

Detailed and accurate planning is absolutely crucial to successfully executing F/BEVAR. Due to the variety of anatomic factors that impact device delivery, deployment, and target artery cannulation, the procedural planning is highly complex and requires a substantial knowledge base. Planning includes not only thorough review of sophisticated imaging and precise measuring, but also sound decision making on the type of device (diameters, lengths, tapering, fabric type, etc.), the type of target artery preservation method (scallop, branch, fenestration), and strategy for cannulation (preloaded systems, ipsilateral or contralateral transfemoral access, access from above, etc.). The physician must also give consideration to the influence that iliac access will have on the ability to deploy the device, manipulate the device superiorly and inferiorly, rotate the device, and the optimal sequence of intraoperative steps for deployment. Although a comprehensive review of all planning details and design decisions is beyond the scope of this chapter, several key considerations are outlined later.

Preoperative Imaging

Aortic imaging with high-resolution computed tomographic angiography (CTA) and 3D reconstruction should be obtained in all patients without strict contraindication to moderate doses of contrast agent. In cases of advanced renal dysfunction, strong consideration should be given to the appropriateness of complex endovascular repair if progression to renal replacement therapy is not acceptable to the patient. The CTA should be reconstructed at slices of 1 mm or less to offer the best possible resolution. If the aortic arch is involved, the CTA should be obtained with electrocardiography gating to provide clear images of the mobile ascending aorta and aortic arch. CTA is the cross-sectional imaging modality of choice because magnetic resonance angiography (MRA) has approximately half the resolution of CTA and does not demonstrate calcification as clearly.[35] In addition, dedicated postprocessing software which can manipulate the Digital Imaging and Communications in Medicine (DICOM) data in three dimensions is crucial to procedural planning. Such software allows for curved planar reformatting and the creation of an aortic centerline of flow; this allows for all measurements to be made perpendicular to the center line of flow and thereby adjusts for angulation and movement of the aorta in three dimensions. Measurements orthogonal to the centerline of flow provides the basis for assessing the location of aortic branches, both in terms of their cranial—caudal position off of the aorta as well as the "clock face" orientation of their origins from the aortic circumference (Fig. 80.11). These measurements are required for both off-the-shelf and custom-made devices. In the case of custom-made devices, F/BEVAR device is designed

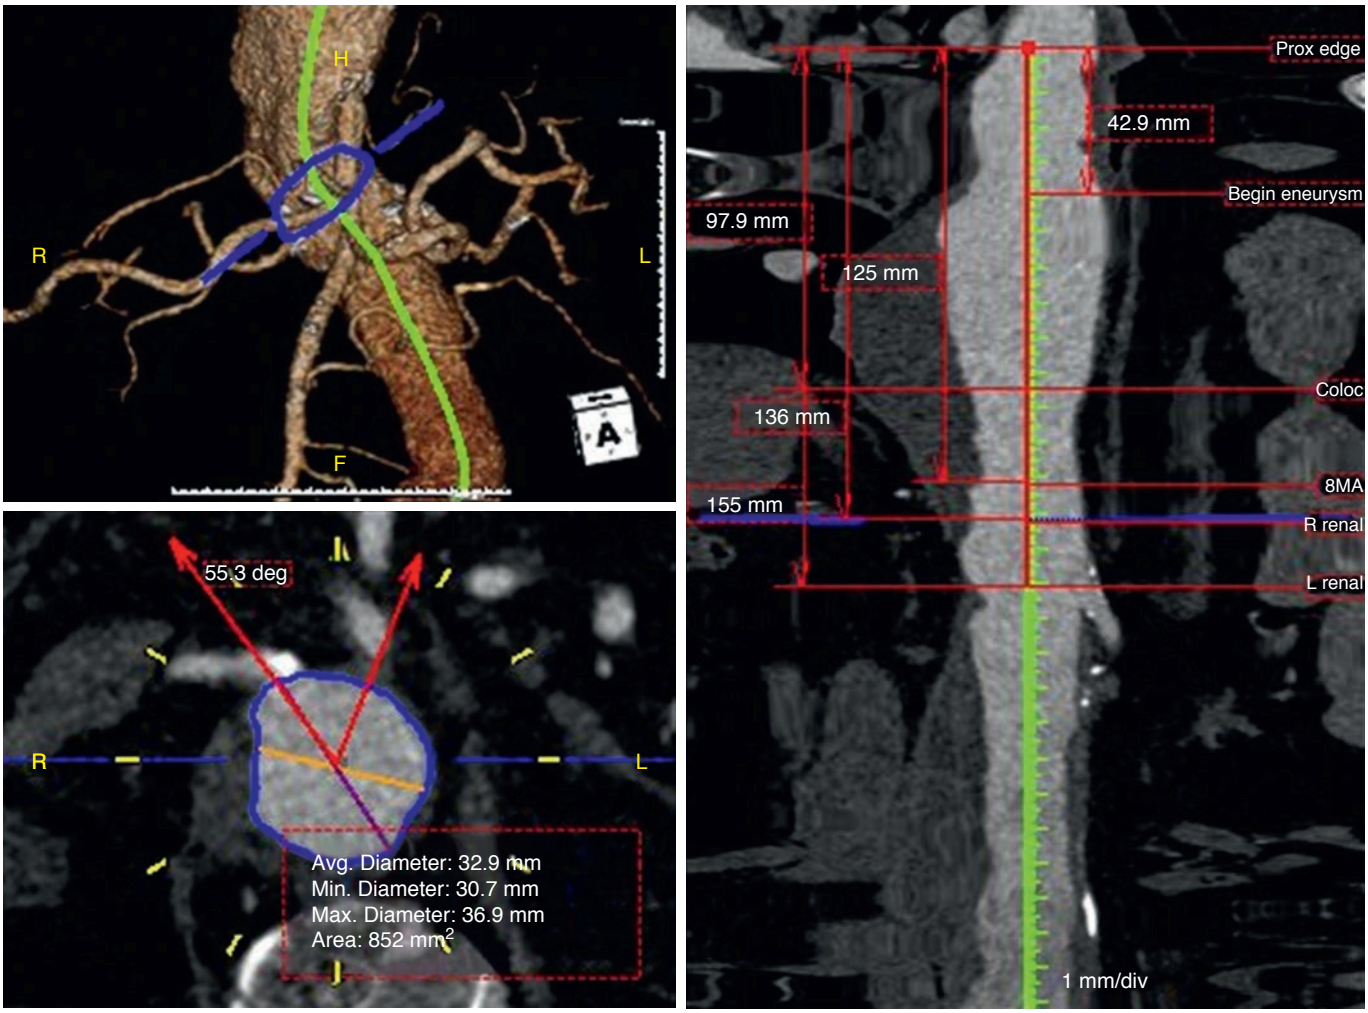

Figure 80.11 The use of dedicated postprocessing software to create centerline of flow and precisely assess location of aortic branches to design and fenestrated and branched endograft.

to match the precise location of aortic branches that will be incorporated into the repair. The person performing the graft implantation should also perform the preoperative measurement and planning because this leads to greater understanding of anatomy which impacts the execution of the procedure, aids in troubleshooting, and provides insight about the short- and long-term risks of the procedure.

Anatomic Considerations for Fenestrated and Branched Repair

Proximal Seal Zone

Choice of the proximal seal zone is one of the most important decisions when planning F/BEVAR. Seal should be achieved in a relatively straight segment of aorta which is cylindrical with parallel walls and without significant mural thrombus or calcification. Degenerated or unhealthy aorta is vulnerable to subsequent aneurysmal degeneration which can destabilize proximal seal and jeopardize the integrity of the repair. One important principle for F/BEVAR is that adequate proximal seal should not be compromised in favor of incorporating fewer aortic branches into the repair. In contrast to infrarenal endografts, where seal lengths as short as 10 to 15 mm may be adequate, seal lengths of 20 to 40 mm are often sought for F/BEVAR. The availability of F/BEVAR devices which can accommodate four visceral vessels often allows for a healthy segment of the thoracic aorta to be chosen as the proximal seal zone. In addition, as with many infrarenal endografts, F/BEVAR endografts often use active fixation (e.g., barbs) in the proximal seal stents.

Aortic Angulation, Calcification, and Mural Thrombus

Significant angulation in the aorta adjacent to the visceral or aortic arch branches can complicate F/BEVAR. Branch location along the aortic centerline and "clock position" along the aortic circumference are more difficult to determine in angulated segments. In addition, angulation often leads to less predictable deployment of the fenestrated or branched portion of the endograft which can lead to misalignment of fenestrations/branches with their target arteries and subsequent challenges, decreasing the success rate of target artery cannulation. In general, for branched paravisceral AAA or TAAA repair, angulation should be limited to less than 45 degrees between the distal thoracic

aorta and the visceral aorta, the suprarenal aorta to infrarenal aorta, and the infrarenal aorta to the iliac artery.

In addition, the degree of aortic calcification and mural thrombus should be evaluated during preoperative planning because they pertain to risk of embolization intraoperatively. F/BEVAR requires stiff wire access across the aortic arch into the ascending aorta to have a stable platform for advancing devices. In addition, compared with standard infrarenal endovascular aneurysm repair, F/BEVAR requires significant rotational movement of the endograft to achieve appropriate branch vessel alignment. Unfavorable vessel characteristics in the arch and proximal descending thoracic aorta greatly increase the risk of stroke. Similarly, vessel calcification, thrombus, and atheroma ("shaggy aorta") in the distal aorta increase the risk of lower extremity embolism.

Branch Vessel Characteristics

The characteristics of the arch branch vessels, celiac artery, SMA, and renal arteries influence the choice of fenestrations or branches and impact the ability to successfully execute F/BEVAR. Branch arteries which are small or highly stenotic at their origin may be difficult to cannulate through a fenestration or branch. In addition, branch arteries which are small and highly tortuous in the proximal segments are more difficult to traverse with wires and catheters. This may prevent advancement of a stable wire/catheter/sheath platform that is necessary to bridge the fenestration or branch to the target artery with a stent graft. All of these anatomic challenges increase the chance that the branch vessel will not be successfully stented. This can lead either to loss of perfusion to the vessel or to an endoleak with perfusion of the aneurysm sac. In addition, branch vessels that are excessively small may have diminished long-term patency.

Access Vessels

F/BEVAR generally requires slightly larger iliac access vessels than standard infrarenal endovascular repair. The "Z-Fen" and "p-Branch" devices are typically loaded in a 22-French delivery system. Although CMDs for F/BEVAR for the thoracoabdominal aorta formerly required 22- to 26-French delivery systems, recent material changes have allowed the devices to be downsized to 18 to 20 French. In addition, the contralateral iliac artery must often accommodate a 20- to 24-French sheath because this sheath size is required to accommodate the multiple 6- to 7-French sheaths used to extend stent grafts into multiple fenestrations. The use of upper extremity access for extension into the visceral arteries and the use of ipsilateral preloaded sheaths can minimize the sheath size required in the contralateral iliac artery. Therefore the iliac arteries must generally be approximately 7 mm in diameter and free of obstructing plaque. In addition, iliac artery tortuosity must be considered during planning because delivering F/BEVAR devices through tortuous anatomy can lead to "stored torque" in the delivery system which can greatly complicate alignment of fenestrations/branches with target vessels. Just as with infrarenal EVAR, in many instances, inadequate access vessels can be overcome with use of aortic or iliac conduits and endoconduits.

Finally, stent-grafting the visceral vessels via downgoing branches must be performed from above using brachial access or axillary access. At a minimum, these arteries must accommodate a 7- to 12-French sheath. When multiple sheaths are required, an 8- to 10-mm axillary conduit can be sewn to the axillary artery, although this is not always necessary. The choice of left or right axillary artery is at the discretion of the physician, with pros and cons to each.

Sequence of Intraoperative Steps and Staging of Repair

Although minimally invasive, complex F/BEVAR is an extensive operation, with several steps necessary in the majority of cases. From the surgeon's perspective, performance of all stages in one procedure is generally technically feasible. However, the duration for which large sheaths may be in the femoral arteries, risking lower extremity ischemia and contributing to spinal cord ischemia, is an important consideration. Various techniques have been described to mitigate this duration of lower extremity ischemia. For example, femoral sheaths can be removed, restoring lower extremity perfusion, prior to cannulating branches from an axillary or brachial approach.[22] In addition, Voerhaven and colleagues have described using purse strings in the femoral arteries to allow for temporary sheath removal to allow for perfusion to the lower extremities.[36] Finally, Resch and colleagues have described connecting an antegrade sheath in the superficial femoral artery to maintain lower extremity perfusion throughout.[37]

Although the length of proximal seal should not be compromised to decrease length of coverage, there is a balance that must be struck between optimal seal length and the risk of spinal cord ischemia. In cases where extensive aortic coverage is required, or prior aortic surgery has increased the risk of spinal cord ischemia, consideration should be given to a staged approach to repair.[38,39] For example, in the case of an extensive TAAA, the thoracic endograft and left carotid-subclavian bypass can be performed first, separated in time by greater than 2 weeks, from the F/BEVAR portion of the procedure incorporating the visceral segment. Other techniques to minimize the risk of spinal cord ischemia intraoperatively are discussed later.

PATIENT SELECTION AND PREOPERATIVE EVALUATION

Patient Longevity

Patients with juxtarenal, pararenal, and TAAA require careful medical evaluation prior to offering F/BEVAR, with careful consideration of overall life expectancy. Currently, in the United States, these repairs are offered within the context of clinical trials, which generally require that patients have been deemed medically unfit for open repair. As with infrarenal AAAs, the anticipated risk of rupture based on aneurysm size must be balanced against the patient's expected longevity and risk of perioperative complications. There are no data

to suggest that availability of this technology and increasing experience with its use should lower the size threshold used for aneurysm repair.

Preoperative Evaluation

Renal Evaluation

There is a high prevalence of renal dysfunction in patients with TAAA, with up to 45% of patients in some series having a glomerular filtration rate less than 60 mL/min per 1.73 m^2.[40,41] Just as with open repair of TAAA, preoperative renal dysfunction has been associated with perioperative morbidity and mortality with endovascular aneurysm repair.[40,42] In addition, evaluation of baseline renal function helps to guide the timing of preoperative and postoperative CTA and determines if intravenous fluid hydration is required before and after CT scans and the operation itself. Furthermore, in cases of baseline renal dysfunction, an operative strategy that minimizes the use of iodinated contrast becomes increasingly important.

Cardiac Evaluation

In spite of the fact that TAAAs appear to be associated with coronary atherosclerosis, there is currently no clear guideline as to the appropriate extent of cardiac evaluation and intervention that should be performed prior to F/BEVAR. In an analysis by Bub et al., the incidence of atrial fibrillation, ventricular arrhythmia, and 30-day cardiac death were 9%, 3%, and 2%, respectively, after complex endovascular aortic repair.[43] In the absence of specific data in this area, most experts would support preoperative cardiac testing according to current guidelines for moderate to high-risk vascular procedures. It is worth noting that for cases in which rapid ventricular pacing or adenosine are to be used for device deployment in the proximal aorta or aortic arch, coronary blood supply must be sufficient to recover from the intentional induction of asystole, and therefore a thorough pre-procedural investigation of coronary blood supply is recommended.[44]

Pulmonary Evaluation

Chronic obstructive pulmonary disease (COPD) is highly associated with TAAAs. Although pulmonary failure is the most common postoperative complication of open TAAA repair, occurring in 10% to 45% of patients, it is reported to occur in only 9% of fenestrated and branched repairs for extensive TAAA.[41,45,46] In one series of 905 patients undergoing endovascular repair of AAA and TAAAs, the incidence of COPD was 32%. There was no difference in perioperative aneurysm-related outcomes or 30-day survival between patients with and without COPD.[47] However, the severity of COPD was highly associated with diminished long-term survival. In a scoring system proposed by Mastracci et al. for high-risk patients undergoing F/BEVAR, the presence of COPD and the need for supplemental home oxygen at baseline were strong negative predictors of long-term survival.[48] There are no clear guidelines for pulmonary function testing before F/BEVAR, although the presence of COPD and its severity should be considered when weighing the overall risk/benefit ratio of any TAAA repair and determining whether open or fenestrated/branched repair is preferable.

Evaluation of Spinal Cord Circulation

Although there is no single method which accurately predicts which patients will suffer spinal cord ischemia after F/BEVAR, special attention should be paid to risk factors that increase the risk of paraplegia. Just as with open TAAA repair, the most significant factor associated with the development of spinal cord ischemia is the extent of aortic coverage with repair.[41,49] However, a prior distal aortic operation or compromised internal iliac artery or vertebral artery flow are also important risk factors for spinal cord ischemia. Collateral networks for spinal cord perfusion are thought to be increasingly important as the extent of endovascular coverage increases.[50] Based on preoperative CTA or MRI/MRA of the spinal cord, intercostal arteries and lumbar arteries should be carefully noted; coverage of these should be limited whenever feasible while still ensuring durable aneurysm exclusion. As mentioned previously, evidence also suggests that coverage of the thoracic aorta should occur in a staged fashion, whenever possible, to improve the recovery of collateral circulation and decrease the risk of spinal cord ischemia.[38,51] In the case of concomitant iliac aneurysms, efforts should be made to preserve flow into both, or at least one, of the internal iliac arteries through the use of iliac artery branch devices or with an external-internal iliac artery bypass.

When repair involves the aortic arch, CTA should be used to assess the entirety of the great vessels. In addition, duplex ultrasonography should be performed to assess the status of the carotid and vertebral arteries, including presence of any occlusive disease and direction of flow.

OPERATIVE TECHNIQUE

Anesthesia

Most authors report the use of general anesthesia due to the duration of the procedures and the necessity to control patient breathing to allow precise imaging and accurate device deployment. Arterial lines are placed routinely for continuous blood pressure monitoring, with consideration to the potential use of right or left brachial or axillary artery for imaging and/or branch artery cannulation. Either large-bore peripheral intravenous lines or central venous catheters are placed to allow appropriate resuscitation if needed. Lumbar spinal drainage catheters are routinely placed in any patient at high risk of development of spinal cord ischemia, including type II and type III TAAAs and those with other risk factors for spinal ischemia. The anesthesiologist must also be prepared to dose anticoagulation and maintain an activated clotting time of at least 300 seconds. This is critical due to the duration of time that large sheaths may be positioned in the femoral arteries or in branch arteries off of the aorta.

Intraoperative Imaging

A "hybrid" operating room with high-quality fixed imaging is invaluable for the performance of F/BEVAR. Although possible to perform F/BEVAR with mobile imaging equipment, it is not recommended. An imaging gantry capable of a full

180-degree rotation around the patient is crucial to obtaining the necessary oblique and lateral views to visualize the origins of aortic branches and their corresponding fenestrations and branches. The need for appropriate equipment to minimize radiation exposure cannot be overemphasized because these procedures often require relatively long fluoroscopy times.[52,53] Fluoroscopy time and radiation dose can be minimized by planning in advance the appropriate imaging gantry angles and bony landmarks which will allow accurate device deployment and fenestration and branch orientation.

Although not an absolute requirement to conduct F/BEVAR, the use of fusion imaging has been reported to reduce contrast volume and radiation dose in comparison to deployment based on standard and/or digital subtraction angiography (see Chapter 27 and Chapter 31).[54–56] With this technique, a preoperative CTA is "fused" with a noncontrast 2D or 3D x-ray obtained immediately before operation based on alignment of bony landmarks. This fusion is registered to the patient's position on the x-ray table so that it is preserved with any movement of the gantry or the table. The end result is a 3D overlay of the aorta, iliac arteries, and branch arteries superimposed on the 2D x-ray image of the patient on the table. This overlay facilitates alignment of the endograft with the patient's anatomy and increases the ease of target vessel cannulation (Fig. 80.12). An alternative to using the overlay of the entire arterial tree is to place markers at the origins of target arteries or other important locations (Fig. 80.13).

It should be noted that aortic anatomy, including the position of branch vessels, can change with the insertion of stiff wires which often straighten tortuous arteries. For this reason, fusion imaging should be supplemented with injections of small amounts of contrast to ensure appropriate identification of branch vessels. Alternatively, preselection of aortic branches to guide endograft deployment is a reliable technique that can be performed with little or no contrast and allows for subtle adjustment of the overlay.

Technical Skills and Resources

Surgeons performing F/BEVAR should have advanced skills in procedure planning and endovascular techniques involving the aorta and branch arteries. To date, in the United States the majority of F/BEVAR repairs have been performed in a limited number of tertiary care centers in the context of industry-sponsored or physician-sponsored IDE studies. With FDA approval of the "Z-Fen" device (Cook Medical) in 2012, fenestrated technology has become more widespread. The requisite experience in endovascular intervention and aortic endografting necessary to optimally execute F/BEVAR has not been specifically defined. Cook Medical has a process by which operators are approved to order "Z-Fen" devices based on case experience and completion of device training. The planning, wire and catheter skills, and the ability to execute a 3D repair using 2D imaging guidance are well above and beyond those required for standard EVAR or TEVAR.

Device Delivery and Deployment

All F/BEVAR procedures begin with access of the femoral arteries by either open or percutaneous technique. When necessary for

Figure 80.12 Use of three-dimensional fusion overlay to identify location of aortic branched to guide fenestrated and branched endograft placement.

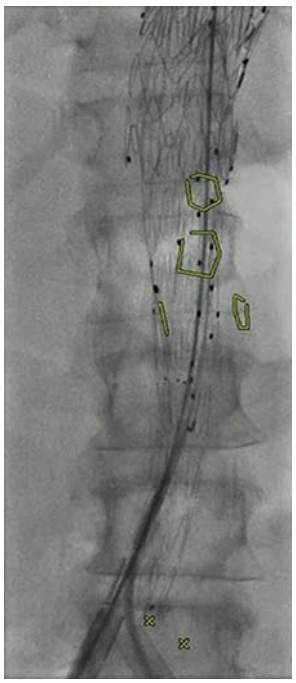

Figure 80.13 Use of markers placed at origin of branch vessels based upon fusion of preoperative computed tomography angiography with a noncontrast two- or three-dimensional x-ray obtained at operation. Markers guide alignment of radiopaque markers at graft fenestrations.

downgoing branches or for fenestrations intended to be cannulated from above, brachial or axillary artery access is performed at case outset before heparinization. As mentioned previously, F/BEVAR devices may be designed with catheters or wires that are "preloaded," facilitating selective catheterization of the fenestration/branch and target artery. There are a number of different options for preloading—wires versus catheters, direction of the wire load relative to the endograft fabric—which are beyond the scope of this chapter.

Nonpreloaded Devices

These devices, such as the Zenith Fenestrated graft, require bilateral femoral access. The contralateral iliac artery is accessed first and a 20- to 24-French sheath is placed over a stiff guide wire into the infrarenal aorta. The hemostatic valve of the sheath can be punctured multiple times to allow for placement of smaller sheath/catheter combinations for cannulation of branch arteries. When fusion imaging is not used as the sole basis for graft orientation, catheters and wires may be placed into the branch vessels to serve as markers for orientation of the device during deployment. The F/BEVAR device is then prepared and oriented extracorporeally prior to insertion. This is a critical step to ensure that the device is deployed with the fenestrations/branches oriented properly.

The device is introduced into the aorta over a stiff wire, such as a double-curved Lunderquist wire, situated in the ascending aorta. The device is then unsheathed slowly, with careful attention paid to the orientation of the fenestrations relative to the target branches (Fig. 80.14). In general, deployment of the device such that fenestrations and branches rest slightly proximal to target artery origins is advantageous for selection and stenting.

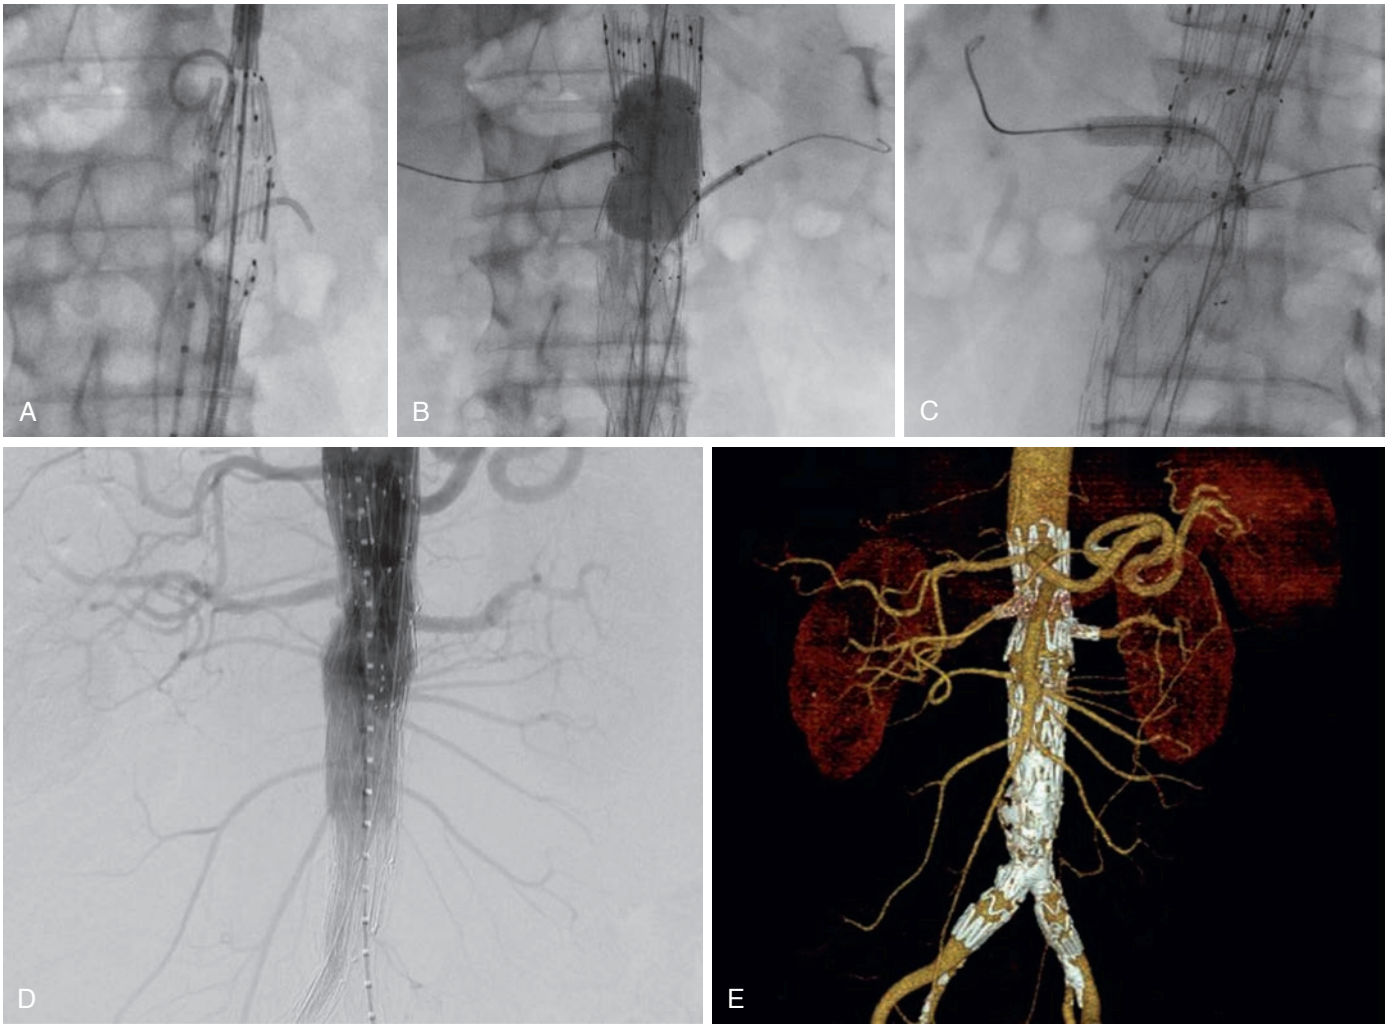

Figure 80.14 Deployment Sequence of the Proximal Portion of a Fenestrated Endograft. Alignment of fenestrated endograft according to location of renal artery origins marked by external selective catheters (A). After sheaths are placed through fenestrations into branch vessels for delivery of covered stents into renal arteries, the graft is molded in proximal seal zone with a noncompliant balloon (B). Deployment of covered stents through both renal fenestrations with appropriate fabric overlap and apposition at the fenestrations (C). Completion angiogram demonstrates aneurysm exclusion with no endoleak and excellent perfusion of superior mesenteric artery and bilateral renal arteries (D). Follow-up computed tomography angiography reveals patency of visceral vessels and aneurysm exclusion (E).

Small adjustments in orientation can be made during and after initial unsheathing, whereas the constraining, diameter-reducing ties remain in place.

Cannulation of target vessels occurs via the contralateral sheath. The distal end of the fenestrated main body device is selected and the wire/catheter is confirmed to be within the endograft. A 6- or 7-French guiding sheath is then delivered into proximity of the target fenestration. Wires and selective catheters are used to select the graft fenestrations followed by the corresponding target arteries; proper catheter selection is key because the catheter alone is typically used to select the fenestration. A selective angiogram confirms proper location. Using exchange catheters, moderately stiff wires such as a Rosen wire are placed into the branch vessels and 6- to 8-French sheaths are then advanced securely into the target vessels (see Fig. 80.14). The stent grafts are then delivered into place, just beyond the tip of the guiding sheath, but not deployed at this stage.

Trigger wires of the fenestrated device, including those which release diameter-constraining ties and the top cap, if present, are then removed. The top cap is then deployed to release the top bare stent (if one is present), and the entire delivery system is removed. Although wire access to the branch vessels is maintained, consideration should be given to whether or not molding of the proximal sealing stents with a compliant balloon is desired to promote apposition of the graft to the aorta (see Fig. 80.14). In contrast to infrarenal endovascular repair, this step may not be necessary, given the longer lengths of seal typically used. Placement of covered stents, usually 6 to 7 mm in diameter, into the target arteries is then performed. It is important to ensure that the image intensifier is oriented perpendicular to each fenestration so that the covered stent is deployed with 3 to 4 mm of fabric overlapping the fenestration into the aortic endograft. The proximal aspect of each covered stent is then flared, or "trumpeted," with a 10-mm balloon to maximize apposition to the endograft fabric (see Fig. 80.14). The distal bifurcated main body graft is then advanced with appropriate overlap into the proximal main body device and unsheathed to the level of the contralateral gate above the aortic bifurcation. Branch vessel access is removed before distal main body deployment. The contralateral iliac limb and then the ipsilateral iliac limb, if necessary, are extended as in standard EVAR.

Preloaded Fenestrations

The deployment sequence is simplified with preloaded fenestrated devices such as the Cook "p-Branch" device, as well as the majority of custom-made CMDs because the fenestration is already selected with the preloaded wire/catheter. With the p-Branch device, after unsheathing the proximal fenestrated portion of the device, the renal arteries are selected through a sheath that is advanced through the delivery system and out the fenestration over a preloaded wire. This obviates the step of needing to get a catheter from inside the endograft to track outside of the fenestration because the sheath is already delivered outside of the fenestration over the preloaded wire. Furthermore, because these target arteries are cannulated through the ipsilateral delivery system, a much smaller diameter sheath can be used in the contralateral femoral artery. After renal artery selection and exchange for a stiffer working wire, the remainder of the main body device is deployed and stenting of the renal arteries proceeds as described previously.

Preloaded Branches

Branched devices that incorporate the SMA and celiac artery into the repair can also be designed with preloaded wires in a diverse host of configurations. One possible configuration includes wires that travel through the delivery system ipsilateral handle, outside of the endograft distally, then enter the branch at its distal aspect, and run within the endograft proximally to exit the endograft at the proximal fabric edge. These wires are snared via upper extremity access (typically necessitating the use of a long 12-French sheath) to achieve through-and-through access from the femoral artery to the brachial or axillary artery. The device is unsheathed in the desired position. If fenestrations are used for the renal arteries, they are cannulated from the femoral arteries as described previously. The visceral segment device is then mated with a bifurcated device in the infrarenal aorta. Perfusion can be restored to the legs at this time with removal of the transfemoral sheaths and attention can be turned to completing the visceral artery branches from access above.

Repeated access of the 12-French brachial or axillary sheath permits delivery of long guiding sheaths over the preloaded wires and out the visceral branches of the graft. Via these sheaths, the visceral arteries are selected and stent grafts are used to bridge the branches to the target arteries (Fig. 80.15).

Aortic Arch Branched Devices

Given the variability of the devices currently in use, a comprehensive and detailed description of device deployment is not possible within the context of this chapter. In most cases, one or more supraaortic trunks is cannulated to access the fenestration(s) and/or branch(es) of the thoracic device (Fig. 80.16). In most cases, open surgical exposure is needed to allow the delivery of appropriate diameter stent grafts which mate with the aortic branch. In general, the arch device is advanced and deployed over a stiff wire that has been placed in the left ventricle. Most experienced practitioners use rapid venous pacing or temporary balloon occlusion of the IVC to decrease the cardiac output during deployment.[27,57] In many instances a preloaded wire is snared to allow through-and-through access from the femoral artery through the supraaortic branch. In addition to facilitating cannulation of the branch, the preloaded wire aids in alignment of the aortic stent-graft during deployment, which is critical to mitigate the challenges associated with the curvature of the arch.

OUTCOMES OF FENESTRATED AND BRANCHED REPAIR

Given the relative infancy of F/BEVAR, the majority of reported outcomes are from small- to moderate-sized single institution

Figure 80.15 Extension of stent grafts into visceral arteries during repair of thoracoabdominal aneurysm with four-vessel branched graft (A). Completion imaging shows flow into all visceral branches and no evidence of endoleak (B).

or multiinstitution series. Level I evidence regarding its efficacy does not exist, and there have been no prospective randomized controlled trials comparing F/BEVAR with open repair. To date, the majority of evidence regarding F/BEVAR has been reported in patients deemed unfit for open repair, making these cohorts not appropriate for comparison to historical cohorts of open repair. Furthermore, the majority of published reports include a heterogeneous mix of patients with varying aneurysm extents and complexities of repair. As experience increases, it will be advantageous to report outcomes according to aneurysm extent to facilitate more granular comparisons with alternative treatment strategies.

Juxtarenal, Pararenal, and Type IV Thoracoabdominal Aortic Aneurysm

Early Outcomes

Excellent technical success and low morbidity and mortality of complex endovascular repair for juxtarenal and pararenal AAA have been reported in prospective clinical trials, institutional reports, and clinical registry data.[58–68] Oderich et al. reported 100% technical success and 1.5% 30-day mortality in 67 patients repaired within the U.S. Zenith Fenestrated AAA Endovascular Graft Trial. There were no renal artery occlusions at 30 days, and no patients had a rise in serum creatinine to a level greater than 2 mg/dL within 30 days. In this cohort, 4.5% of patients developed mesenteric ischemia. Mean hospital length of stay was 3.3 ± 2.1 days.[19] Single institution series have reported slightly higher morbidity and mortality but still encouraging results. In a systematic review and meta-analysis of 14 studies with greater than 10 patients, published between 2005 and 2012, Rao et al. reported a pooled perioperative mortality of 4.1%.[48,59–62,65,66,69–76] Major complications, including cardiac events, pulmonary infections, ischemic colitis, and wound complications, occurred in 15.7% of patients after complex endovascular repair of juxtarenal AAAs. Postoperative renal insufficiency was reported in 11.4% and permanent hemodialysis reported in 1.9% in studies reporting these outcomes.[76]

Midterm Outcomes and Branch Durability

The limited existing data demonstrate promising midterm outcomes, although secondary interventions are not uncommon. Among 67 patients enrolled in the U.S. Zenith Fenestrated AAA Endovascular Graft Trial, there were no aneurysm ruptures or conversions to open repair at a mean follow-up of 37 ± 17 months. Five-year estimated survival was 91% ± 4%, and freedom from major adverse events was 79% ± 6%. In this group of patients, 15 (22%) required secondary interventions, primarily for renal artery stenosis/occlusion. Primary and secondary patency of targeted renal arteries was 81% ± 5% and 97% ± 2% with 91% ± 5% freedom from deterioration of renal function.[19] Among nine institutional series reporting results of complex endovascular repair for juxtarenal aneurysms, the pooled secondary graft related re-intervention rate during follow-up (2–120 months) was 12.7%.[76]

Data regarding long-term mortality remains limited. Rao et al. reported the pooled results from five series reporting long-term follow-up which demonstrated overall estimated Kaplan-Meier survival of 93%, 74%, and 55% at 1, 3, and 5 years, respectively.[48,60,62,69,75,76] Mastracci et al. reported an aortic-related mortality of only 2% at 8 years in patients undergoing fenestrated repair of juxtarenal and type IV TAAA. However, overall survival of these patients was only 20% at 8 years, presumably reflecting the high rate of significant comorbidities in this population.

Thoracoabdominal Aortic Aneurysms

Early Outcomes

Repair of thoracoabdominal aortic aneurysms with F/BEVAR has also been reported with encouraging results since the first significant series was reported by Greenberg and colleagues in 2008. Data from 11 series of F/BEVAR endografts, including 4406 patients, showed a combined perioperative mortality of 3.7% (95% CI 2.02–5.3, SE = 0.008) with individual series estimates ranging from 1.6% to 25%.[21,22,77–84] The risk of

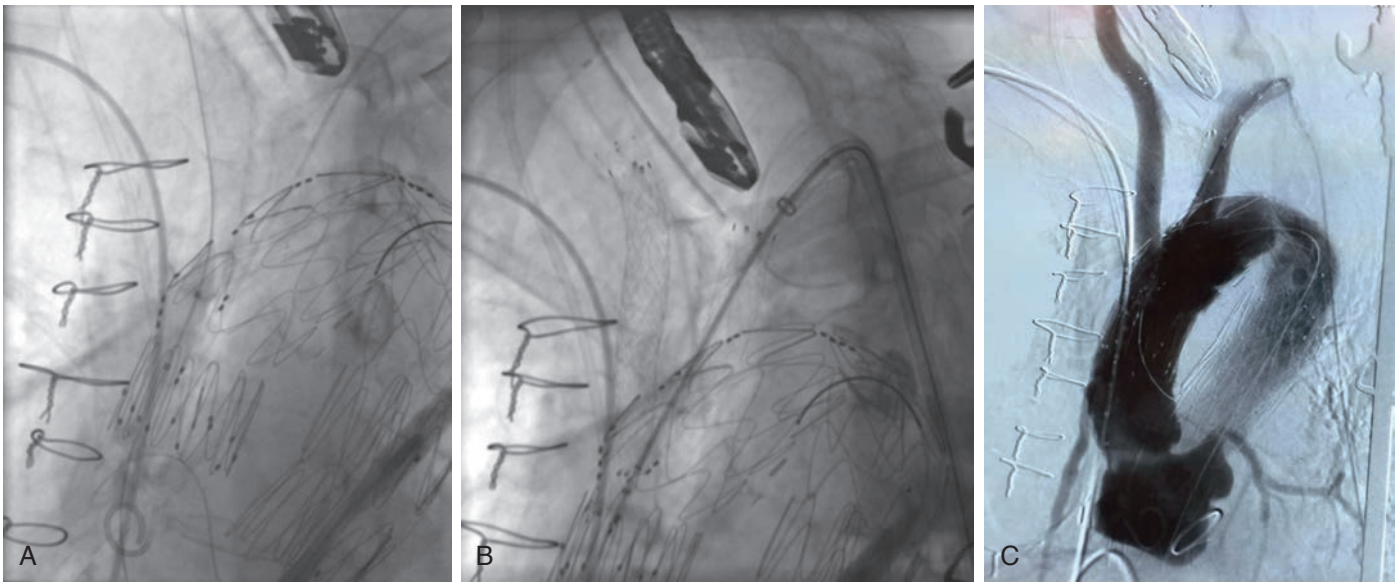

Figure 80.16 Branch Graft Repair of Aortic Arch Aneurysm. The graft is deployed to align internal branches for the supraaortic trunks with external marker wires (A). After cannulation of the branches, stent grafts are extended into supraaortic vessels (B). Completion imaging demonstrated filling of supraaortic branches and aneurysm exclusion (C).

perioperative renal dysfunction and spinal cord injury are 16% (95% CI 8.42–23.7, SE = 0.039) and 2.5% (95% CI 0.5–4.5, SE = 0.10), respectively. In 2016 Eagleton et al. reported on 354 high-risk patients with type II and type III TAAA repaired with F/BEVAR in a physician-sponsored IDEW trial.[41] These authors reported successful stenting in 96% of 1305 implanted fenestrations/branches, with type I or type III endoleak seen in 2.8% of patients on completion aortography. Perioperative mortality was 7% and 3.5% for type II and type III TAAA, respectively. Permanent spinal cord ischemia and renal failure requiring hemodialysis were reported in 4% and 2.8% of patients, respectively.

Midterm Outcomes and Branch Durability

Midterm data after fenestrated/branched endovascular repair of TAAAs are limited, and long-term data are lacking. The limited data suggest that rates of re-intervention are significant but that aneurysm-related mortality remains low.[85] Excellent long-term durability of branches in F/BEVAR has been reported in select centers. Mastracci et al. reported 30-day, 1-year, and 5-year freedom from branch intervention of 98% (95% CI, 96%–99%), 94% (95% CI, 92%–96%), and 84% (95% CI, 78%–90%) after F/BEVAR in 650 patients involving 1679 total branches at a mean follow-up of 3 ± 2.3 years. In this series, only three patients (0.5%) died from branch stent complications.[5] Eagleton et al. reported Kaplan-Meier estimated freedom from secondary intervention of 54% (95% CI, 0.47–0.61) at 36 months after F/BEVAR of type II and type III TAAAs. In 354 patients with a mean follow-up of 22 ± 19 months, secondary procedures were required in 129 (36.3%) patients, including 67 (18.9%) for an endoleak. Only 27 patients required re-intervention to maintain branch vessel patency and primary patency was greater than 92% for renal and mesenteric arteries at 36 months. Aneurysm-related death was rare, with a freedom from aneurysm-related death of 91% (95% CI, 0.80–0.95) at 36 months. However, freedom from all-cause mortality was significantly lower at 57% (95% CI, 0.50–0.63) at 36 months, reflecting the high rate of significant comorbidities in these patients.

Aortic Arch Aneurysms

Outcomes of total endovascular arch repair with branched endografts are limited to small series of selected patients repaired in centers of excellence. The majority of reports include only short-term follow-up, although limited results out to 1 year have been reported. F/BEVAR of arch aneurysms is technically feasible with acceptable short-term morbidity and mortality in patients deemed too high risk for open repair. Haulon et al. reported the world experience with aortic arch repair using an endograft with two inner branches for the supraaortic trunks in 38 patients.[86] The 30-day mortality rate was 13.2% (95% CI, 2.2–24.2), and technical success was obtained in 32 patients (84.2% [95% CI, 72.4–95.9]). Early cerebrovascular complications were diagnosed in six patients (15.8% [95% CI, 4.0–27.6]), including four transient ischemic attacks, one stroke, and one subarachnoid hemorrhage. Four patients required early secondary procedures (10.5% [95% CI, 0.7–20.3]). Over a median follow-up of 12 months (range, 6–12 months), no aneurysm-related deaths were detected. Spear et al. later reported on 27 patients who underwent branched repair with inclusion of the innominate artery and left common carotid artery in all patients.[87] Technical success was 100%, and 30-day mortality was 0%. Early neurologic events included two major strokes (7.4%), one minor stroke (3.7%), and two transient spinal cord ischemia events with full recovery (7.4%). Four patients (14.8%) underwent early (<30 day) re-interventions. Finally, in an analysis of fenestrated and branched endovascular repair of aortic arch

lesions in 29 patients using the Cook custom-made platform, both fenestrated and branched designs were technically feasible with promising results, although there was a trend towards improved results with branched grafts.[57] Reporting of midterm and long-term outcomes is necessary to demonstrate the efficacy and durability of fenestrated and branched arch repair.

SURVEILLANCE RECOMMENDATIONS AFTER FENESTRATED AND BRANCHED REPAIR

The need for secondary interventions to maximize durability of F/BEVAR emphasizes the importance of an aggressive surveillance protocol. Patients should undergo both CTA and duplex ultrasonography of incorporated target vessels prior to leaving the hospital after repair or at a 1-month follow-up visit. Most practitioners use CTA and duplex exam as complementary modalities. CT scans provide a baseline aneurysm sac diameter and also provide important information about the integrity of branched stents. Mastracci et al. have proposed a classification of endoleaks of branched devices to reflect the different modes of failure that have been observed on aggressive and detailed postoperative imaging (Fig. 80.17).[5] Duplex ultrasonography likewise provides important information about stenoses of branch vessels. Ultrasound criteria for renal stent stenoses have been proposed based on comparison with CTA and conventional angiography but have not been widely validated (Table 80.1).[88] Most practitioners repeat surveillance imaging at 6 and 12 months after repair and annually thereafter, although analysis of specific surveillance protocols has not been published in the literature.

The longer procedure times and the need for surveillance imaging as well as secondary interventions have increased concern about the total radiation burden involved in F/BEVAR.[89] Perini and colleagues have demonstrated in a single center study that contrast-enhanced ultrasound (CEUS) is as accurate as CTA in endoleak detection, aneurysm diameter measurement, and evaluation of target vessels after complex endovascular repair of juxtarenal aneurysms.[90] Currently, CEUS is not available in the United States due to lack of FDA-approved contrast agents. In patients who have not received implants composed of stainless steel, contrast-enhanced MRA and noncontrast MR can be used to evaluate for the presence of endoleaks and monitor aneurysm sac size.[91] To our knowledge, data are not yet available regarding the application of these techniques to F/BEVAR grafts after more extensive endovascular TAAA repair and future study is needed. The goal of surveillance is to allow timely and aggressive re-intervention to maintain stability of the repair and target artery patency.

TABLE 80.1 Revised Ultrasound Criteria for the Detection and Grading of Renal Artery Stent Stenosis and Occlusion in Patients With Fenestrated or Branched Endografts

Renal Stent Stenosis	Revised Ultrasound Criteria	Computed Tomography Criteria
<60%	PSV 57-280 cm/s	As visualized from centerline of flow and curved planar reconstructions
60%-90%	PSV > 280 cm/s and/or RAR > 4.5	As visualized from centerline of flow and curved planar reconstructions
Occlusion	No flow seen in renal artery stent *OR* PSV < 1.2 (or RAR cannot be determined because proximal renal artery not visualized)	Lack of contrast enhancement through the lumen of the stent on center line and curved planar reconstruction and marked difference in renal parenchymal opacification in three-dimensional reconstructions

PSV, Peak systolic velocity; *RAR,* renal artery/aorta ratio.

PRACTICE AND REGULATORY ISSUES

The enthusiasm for F/BEVAR of juxtarenal and pararenal AAA, TAAA, and arch aneurysms has grown steadily over the past decade. The lack of commercially available devices to treat these aneurysms has led to the desire to modify currently FDA-approved commercially available abdominal and thoracic aortic endografts to accommodate aortic branch vessels and other anatomic variations. The Society for Vascular Surgery (SVS) issued an advisory statement on the clinical use of PMEGs, emphasizing that serial planned use of PMEGs requires both Institutional Review Board (IRB) approval as well as IDE approval from the FDA.[92] In the United States, approved access to F/BEVAR devices is limited to investigators and hospitals participating in either industry-sponsored or physician-sponsored IDE clinical trials. The SVS statement endorses the physician's discretion to recommend compassionate use of any treatment in an emergency if it is judged to be in the patient's best interests, including off-label use of PMEGs. Compassionate use requires IRB approval and may require FDA or manufacturer approval in some instances.

Despite the steadily growing experience with F/BEVAR endografts, it is necessary to recognize that the overwhelming majority of evidence to date has been provided by surgeons and institutions with interest and resources dedicated to these techniques. It appears that dedicated training in centers of excellence is of great value before undertaking fenestrated and branched repairs.[20] Furthermore, both cumulative case experience and adoption of technological advancements appear to be of critical importance to achieve acceptable results with increasingly complex repairs.[93,94]

Late Therapy 1068

Acute aortic dissection is the most common catastrophic event affecting the aorta, with an incidence exceeding that of ruptured abdominal aortic aneurysm. Without treatment, the majority of patients with aortic dissections will die within 3 months of presentation, and few survive the chronic phase more than 5 years due to aneurysmal degeneration and rupture of the outer wall of the false lumen.[1,2] Despite improvements in both medical and surgical therapeutic options, overall mortality associated with acute dissection remains significant. In a population-based epidemiologic study by Clouse et al., 38% of aortic dissections were diagnosed at autopsy.[3] This substantial mortality rate in undiagnosed patients underscores the importance of early

diagnosis and initiation of appropriate therapy. Indeed, Khan et al. predicted that the mortality of acute dissection (type A and B) left untreated will exceed 22.7% within 6 hours, 50% within 24 hours, and 68% within the first week.[4] Death due to an acute dissection of the ascending thoracic aorta is usually secondary to the central cardio-aortic complications of aortic rupture into the pericardium, acute aortic regurgitation, and coronary ostia compromise,[5,6] while patients with descending thoracic aortic dissections are more likely to die from end organ compromise due to obstruction of visceral or extremity vessels in the acute phase of the disease.[7,8]

Over the last decade, there has been a fundamental shift in the way we approach acute type B aortic dissections. Contributions from multicenter collaborations such as The International Registry of Acute Aortic Dissection (IRAD), the Investigation of Stent Grafts in Aortic Dissection (INSTEAD) trial, and large single institution series have cast doubt on the ability of medical therapy alone to effectively treat acute type B aortic dissections, and it is clear that there is a subset of uncomplicated patients who will benefit from early intervention with a thoracic endovascular aortic repair (TEVAR).[9-11]

In this chapter, we review the classification, pathologic anatomy, clinical presentation, diagnostic, and treatment modalities for acute aortic dissection, with emphasis on the role of the vascular/endovascular surgeon. While a thorough understanding of all components of acute dissection seems requisite for those who propose to treat aortic dissection, the technical principles of graft replacement of the ascending aorta, typically performed by cardiac surgeons, is not detailed. Since open graft replacement for treatment of descending aortic dissection is rarely indicated, it is anticipated that the vascular/endovascular surgeon will become the primary operator in the care of patients with acute dissection of the descending aorta and the complications of peripheral vascular compromise. Finally, treatment of the principal late complication of acute aortic dissection—the development of thoracoabdominal aneurysms—is considered in other chapters (see Chapters 77 and 78).

CLASSIFICATION

Aortic dissections are classified according to the anatomic location of the entry tear and the time between onset of symptoms and patient presentation.

Temporal

A dissection has traditionally been considered acute within the first 2 weeks after the initial onset of symptoms. While such designation appears arbitrary, it is based on autopsy studies showing that 74% of patients who die from aortic dissections do so in the first 14 days.[12] The period from 2 weeks to 90 days after initial presentation is now considered the subacute phase. During this period, the risk of death decreases but the dissection flap remains pliable such that this is the best time to consider performing elective TEVAR coverage of the proximal entry tear.[13] Finally, after 90 days, the dissection is considered chronic as the flap becomes stiff and fibrotic and the aorta begins to positively or negatively remodel. Indeed, such temporal classification combined with the anatomic location of the entry tear (discussed later) should be used to determine intervention.

Anatomic

Anatomically, aortic dissection is classified based on the location of the intimal tear and the extent of aorta involved in the dissection. There are two classification schemes used to describe aortic dissections. The original, proposed by DeBakey in 1965, delineates both the origin of the entry tear and the extent of the descending aortic dissection.[14] The scheme (Fig. 81.1) uses the following classification:

- Type I: Dissection originates in the ascending aorta, extends through the aortic arch, and continues into the descending aorta and/or abdominal aorta for a varying distance.
- Type II: Dissection originates in and is confined to the ascending aorta.
- Type IIIa: Dissection originates in the descending aorta and is limited to same.
- Type IIIb: Dissection involves descending and variable extents of the abdominal aorta.

The Stanford Classification was described by Daily in 1970[15] and simplified the anatomic classification according to the origin of the entry tear alone. A Stanford type A dissection originates in the ascending aorta, and therefore encompasses DeBakey type I and II dissections, while a Stanford type B dissection originates in the descending aorta distal to the origin of the left subclavian artery (DeBakey type IIIa, IIIb, Fig. 81.1).

Because the origin of the entry tear is the key predictor of early outcomes, most patients are now stratified into Stanford type A or B at the time of presentation in order to direct initial therapy. However, neither the Stanford nor the Debakey classification systems address patients whose entry tear originates in the aortic arch between the innominate and left subclavian arteries. The classic Stanford type A dissection is confined to the ascending thoracic aorta, and most cardiac surgeons consider any dissection that originates distal to the innominate artery to be Stanford type B. This is driven by the fact that prompt graft replacement of the ascending aorta is the appropriate treatment for most type A dissections because of the high risk of lethal cardio-aortic complications (principally aortic rupture or myocardial ischemia from extension into the coronary arteries). Alternatively, the classic Stanford type B dissection is confined to the descending thoracic aorta, and vascular surgeons consider any dissection that originates proximal to the left subclavian artery to be type A and the purview of cardiac surgery, because open intervention would require circulatory arrest and placing a stent graft proximal to the left common carotid artery requires surgical debranching or access to investigational branched and fenestrated devices.

EPIDEMIOLOGY

Recent population-based studies have estimated the incidence of acute aortic dissection to range from 2.9 to 3.5 per 100,000 person-years.[3,16] Factors that predispose one to develop aortic

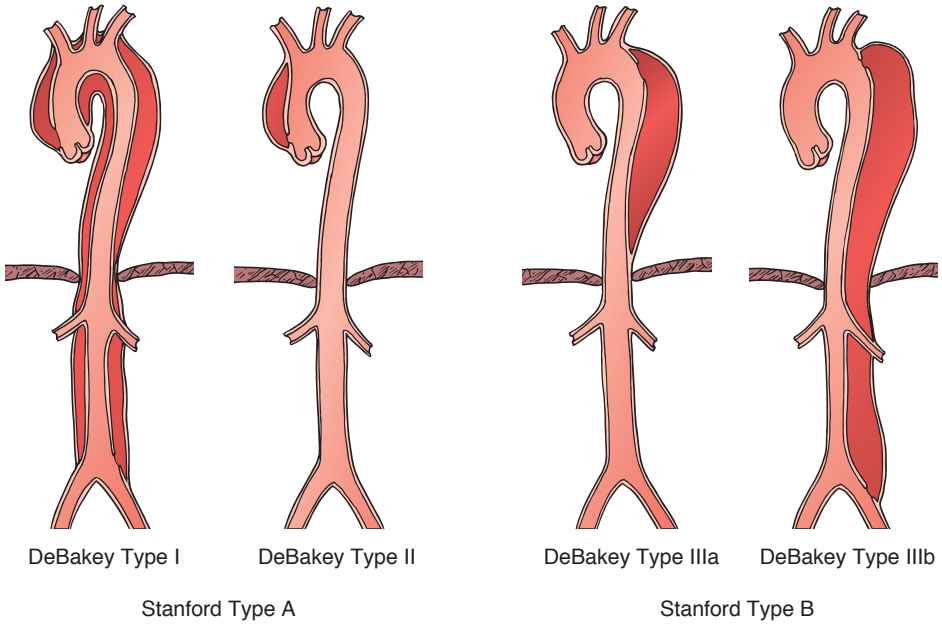

Figure 81.1 Acute aortic dissection can be classified by the original DeBakey system based on location of proximal tear and distal extent of the dissection flap, or the Stanford system that uses location of proximal tear alone.

TABLE 81.1 Demographic and Clinical Features of Combined Mgh and IRAD Experience With Acute Aortic Dissection

Variable	MGH (%)[7]	IRAD (%)[37]	Total (%)
Patients	512	1078	1590
Age (mean)	62 years	62.4 years	
Male	347 (67.8%)	732 (67.9%)	1079 (67.9%)
Type A	278 (54%)	674 (62.6%)	952 (60%)
Hypertension	361 (70.5%)	755 (71.8)	1116 (70.2%)
VC/pulse deficit	159 (31%)	259 (27.7%)	418 (26.3%)

IRAD, International Registry of Acute Aortic Dissection; *VC,* vascular complication.

dissection include age, hypertension, and structural abnormalities of the aortic wall.[4,17] Men are more frequently affected, with a male/female ratio of 4:1 reported by IRAD.[18] In our cumulative experience, type A dissections account for 60% of cases, and this is consistent with the IRAD data, wherein 62.5% of 1417 patients presented with a type A dissection.[11] The incidence of type A dissection peaks between 50 and 60 years, while type B dissections occur more frequently between 60 and 70 years of age.[17] Hypertension is prevalent and was present in 70% of patients in the IRAD database (Table 81.1).[18]

Risk Factors for Dissection

Cardiovascular Conditions

Acute aortic dissections tend to demonstrate chronobiologic patterns of occurrence.[19] The onset of dissection occurs most frequently in the morning hours between 6 a.m. and 12 p.m., and more often in the winter (28%) than the summer (20%), independent of endogenous climate.[19,20] Aortic wall structural abnormalities and the presence of a bicuspid aortic valve with or without its accompanying aortic root dilation are well-established risk factors for ascending aortic dissections. Indeed, the presence of a bicuspid aortic valve has been documented in 7% to 14% of all aortic dissections.[17,21] Other aortic diseases, such as coarctation of the aorta, annuloaortic ectasia, chromosomal abnormalities (Turner syndrome and Noonan syndrome), aortic arch hypoplasia, and hereditary conditions (Marfan syndrome and Ehlers-Danlos syndrome), are also risk factors for the development of acute aortic dissection.[22] Marfan syndrome accounts for 50% of cases of acute aortic dissection in patients less than 40 years of age.[18]

Pregnancy

Pregnancy is associated with a fourfold increased risk of aortic dissection and rupture when compared with nonpregnant women of child bearing age.[23] However, it still remains rare, as the incidence of aortic complications is 5.5 per million pregnant women.[23] Preeclampsia with resultant hypertension is the most common etiology of peripartum aortic dissection, but pregnant women with Marfan syndrome are also at high risk, and the presence of a dilated aortic root (>4 cm) is the best predictor of dissection in the pregnant patient with Marfan syndrome.[24] The most common site of aortic dissection in young (<40 years) patients is the ascending aorta involving the sinuses of Valsalva or the sinotubular junction, while type A dissections in older patients are more likely to originate higher in the ascending aorta.[18]

Cocaine Abuse

Cocaine ingestion, a rare cause of acute aortic dissection in otherwise healthy individuals, has an incidence as high as 37% in an urban setting, but was present in 1.7% of the IRAD population.[18,25-27] The typical patient with a cocaine induced dissection is a young (average age 47 years), male (86%) smoker (92%) with a history of hypertension (82%) and no particular trend toward dissection type (type A 52% vs. type B 48%).[25-27]

One possible mechanism is related to catecholamine release, which causes a triad of profound hypertension, vasoconstriction, and increased cardiac output. This creates a dramatic, acute increase in ventricular contraction (shearing) force (dP/dt) on the aortic wall.[25,28]

PATHOLOGIC ANATOMY OF ACUTE AORTIC DISSECTION

Intimal Tear

The process of aortic dissection is dynamic and can occur anywhere along the course of the aorta, resulting in a wide spectrum of clinical manifestations. The pathognomonic lesion is one of an intimal tear followed by blood surging either antegrade (typically) or retrograde (depending on the hemodynamic gradient between the true and false lumens), and cleaving the intima and media layers of the aortic wall longitudinally for a variable distance.[4,29] The typical tear is transverse, not circumferential, and the intimomedial layer can be cleaved both longitudinally and circumferentially.[4] The adventitia-bound blood-filled space created between the dissected layers of the aortic wall becomes the false lumen. Fenestrations (connections between the true and false lumens) occur within the intimal flap downstream, usually at branch vessel ostia, which are cleaved by the dissection process: these serve as sites of reentry of blood flow into the true lumen (fenestrations), thus maintaining false lumen patency. The presence of an "intimal flap," representing the intimomedial septum between the true and false lumen, is the most characteristic pathology in acute aortic dissection. The origin of the intimal flap/tear is in the ascending aorta in 65%, the descending aorta in 25%, and in the arch and abdominal aorta in 10% of patients.[17] In the descending aorta, the intimal tear typically originates within a few centimeters of the left subclavian artery, because this segment of the aorta is subject to the greatest dP/dt pressure fluctuations.[12,30,31] In the usual pattern of a Stanford type B dissection, the cleavage plane will progress with the distal false lumen on the left posterolateral aspect of the aorta (80% of patients); the celiac, SMA, and right renal arteries typically emanate from the true lumen; and the left renal artery arises from the false lumen.[12] It is to be emphasized, however, that variations in this pattern are frequently encountered.

Cystic Medial Necrosis

One pathologic process that is associated with an increased risk of aortic dissection is medial degeneration of the aortic wall (cystic medial necrosis) that diminishes the structural integrity of the aortic layers.[31,32] The central lesion appears to be deterioration of medial collagen and elastin fibers through elastolysis; this is considered to be a factor in most cases of aortic dissection.[33] In particular, classic cystic medial necrosis appears to be an essential feature of several hereditary conditions, such as Ehlers-Danlos syndrome and Marfan disease.[22] Yet, specific connective tissue diseases account for only 10% to 15% of all acute aortic dissections.[17] Even in "normals," in which dissections occur without any antecedent diagnosis of a specific underlying contributing disease, the degree of medial degeneration still tends to be greater than expected as part of normal aging. The exact cause of this medial degeneration remains unclear, but advanced age and hypertension appear to be the most important factors.[19,33,34]

PATHOGENESIS OF MALPERFUSION SYNDROMES

Malperfusion syndrome occurs when there is end organ ischemia secondary to aortic branch compromise from the dissecting process. This can involve one or more vascular beds simultaneously, with early symptoms often subtle and of varying severity over the hours and days after initial symptom onset. Consistent over several series, aortic branch compromise is present in up to 31% of patients with acute aortic dissection,[8,35-37] with progression to the malperfusion syndrome correlating with early mortality.[7,8,37] Any aortic branch can be affected, and as intuitively suspected, the morbid clinical events will vary as a function of the vascular territory involved. Mesenteric involvement is associated with intestinal infarction, whereas subclavian and/or lower extremity occlusive events are often well-tolerated.

Mechanism

Identifying the mechanisms of branch compromise is a critical step in formulating effective treatment plans. The anatomic and physiologic variables underpinning any compromised vascular bed include (1) the percentage of aortic circumference dissected, (2) the presence of a distal re-entrant focus in the false lumen or true lumen outflow, and (3) the topography of branch ostia to the true versus false lumen.[5] In the minutes after an aortic dissection is initiated, the true lumen (representing the remnant of the original aortic lumen) collapses to a variable degree, and the false lumen expands.[38] The adventitia-bound outer wall of the false lumen must expand to a larger diameter in order to accommodate the same wall tension at a given blood pressure, as governed by the law of LaPlace. In contrast, the true lumen, which contains the majority of the elastic components of the aortic wall, undergoes radial elastic collapse.[38] Therefore the degree to which the true lumen recoils and the false lumen expands (i.e., their respective cross-sectional area) is dependent on the percentage of the total aortic circumference involved with the dissection. In the presence of a deep proximal tear and the absence of distal fenestrations, the mean false lumen pressure increases leading to compression of the true lumen (Fig. 81.2).[39] A compressed true lumen will lead to impaired perfusion of distal structures and should increase the index of suspicion for visceral and renal ischemia.

Two mechanisms for aortic branch vessel compromise have been identified, and each has specific treatment implications in the management of malperfusion syndromes, as originally described by Williams et al.[38] In *dynamic obstruction*, the compressed true lumen is unable to provide adequate volume

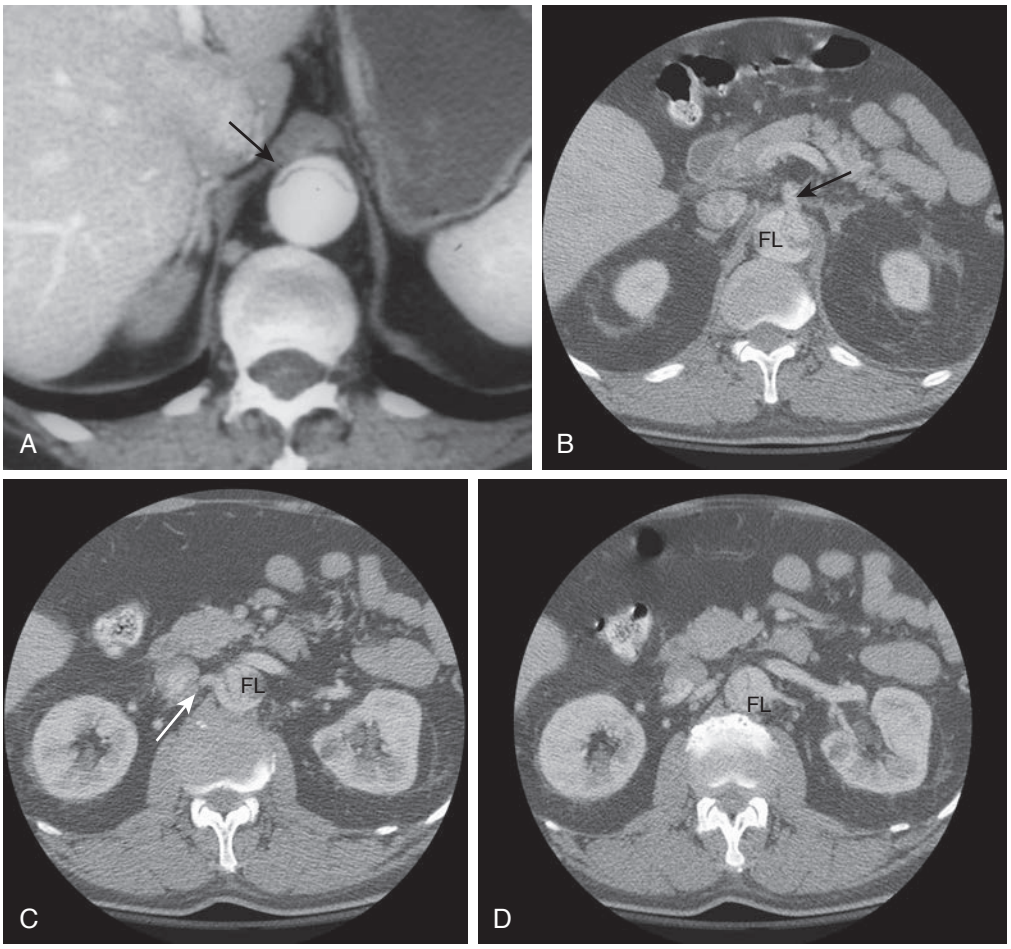

Figure 81.2 Computed Tomography Angiogram Findings of Acute Aortic Dissection. **(A)** Axial image of aortic dissection with compressed true lumen *(black arrow)*. **(B)** Axial image of aortic dissection with SMA arising from the true lumen *(black arrow)*. **(C)** Axial image of aortic dissection with right renal artery *(red arrow)* arising from the compressed true lumen. **(D)** Axial image of aortic dissection with left renal artery originating from the false lumen *(FL)*.

flow, or the dissection flap may prolapse into the vessel ostium, which remains anatomically intact (Fig. 81.3). This is the more common mechanism of branch compromise and is responsible at least in part for some 80% of malperfusion syndromes.[40] The severity of the true lumen collapse and the degree of aortic-level ostial vessel occlusion is determined by the circumference of the dissected aorta, cardiac output, blood pressure, heart rate, and the peripheral resistance of the outflow vessel.[41] Pulse deficits based on dynamic obstruction may wax and wane over time, due to the variability of the aforementioned factors.[5,42] In *static obstruction*, malperfusion is caused by the dissecting process extending into the branch vessel proper, narrowing it to a variable degree.[40] The false lumen is highly thrombogenic as a result of the exposed adventitial and medial layers, and thrombus formation may occur in the blind end of the dissection.[43] If this enters and constricts the ostia of a branch vessel, organ injury can occur by thrombosis or hypoperfusion of the involved vessel. This obstruction is unlikely to resolve with restoration of aortic true lumen flow alone, and some manipulation of the vessel itself (e.g., stent or bypass graft) will typically be required (see Fig. 81.3).

CLINICAL PRESENTATION

Pain

The most common presenting symptom of acute aortic dissection is pain (located in the back, abdomen, or chest), reported in more than 93% of patients, with 85% specifying an abrupt onset.[17,44] While the pain is typically described as anterior in location in type A dissections, for type B dissections, pain is more often experienced in the back (78% vs. 64%, respectively).[17,21] Pain has been localized to the abdomen in up to 21% of patients with type A and 43% of patients with type B dissections.[17] In such patients, a high index of suspicion for mesenteric vascular compromise is warranted. Typically the pain is severe, causing the patient to seek medical attention within minutes to hours of onset, and has been described as "the worst ever" by nearly 90% of patients.[17] The control of pain with antihypertensive therapy is a mainstay of the early management of acute aortic dissection, and the recurrence of pain implies failure of medical therapy, warranting repeat imaging to direct therapy. However, in the absence of clinical or radiographic

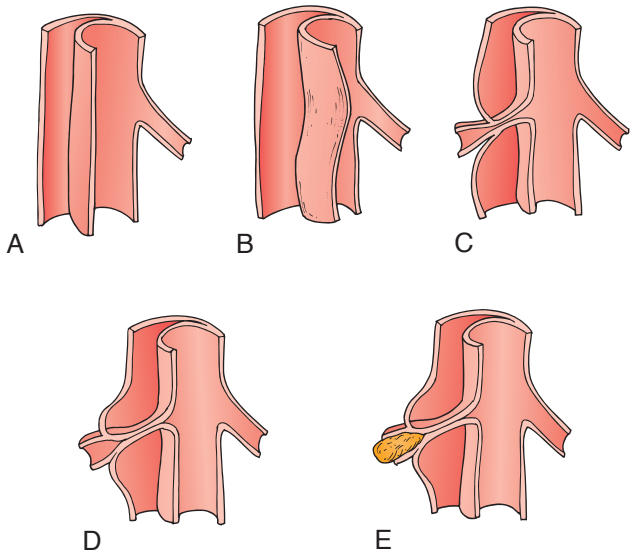

Figure 81.3 Mechanisms of Aortic Branch Obstruction in Acute Dissection. (**A** and **B**) In dynamic obstruction, the septum may prolapse into the vessel ostium during the cardiac cycle, and the compressed true lumen flow is inadequate to perfuse branch vessel ostia which remain anatomically intact. (**C-E**) Near complete circumferential dissection with static obstruction—the cleavage plane of the dissection extends into the ostium and compromises inflow. Thrombosis beyond the compromised ostia may further worsen perfusion.

signs of patho-anatomic changes, medical therapy remains an appropriate management of most patients with early recurrent pain after type B dissection.[45]

Hypertension

On initial physical examination, hypertension is present in 70% of type B dissections, but only in 25% to 35% of type A dissections. The presence of hypotension complicating a type B dissection is rare (<5% of patients), but may be present in 25% of dissections that involve the ascending aorta, potentially as a result of aortic valve disruption or cardiac tamponade.[17] The malperfusion of brachiocephalic vessels by the dissection may falsely depress brachial cuff pressures.[46] Hypertension that is refractory to medical management is common in type B dissections, occurring in 64% patients.[47]

Syncope/Neurologic Symptoms

Syncope may complicate the presentation of acute aortic dissection in 5% to 10% of patients, and its presence often indicates the development of cardiac tamponade or involvement of the brachiocephalic vessels.[48] Patients presenting with syncope have a higher rate of severe complications (tamponade, stroke, death), but in half of the patients, this is not the cause of their loss of consciousness. The mechanisms underlying this fact may be related to other pathophysiologic perturbations, such as vasovagal events or direct stretching of baroreceptors in the aortic wall.[49,50] Spinal cord ischemia from the interruption of intercostal vessels occurs in 2% to 10% of type B dissection.[51] Direct compression of peripheral nerves is rare but can present as paresthesias (lumbar plexopathy), hoarseness (recurrent laryngeal nerve), or Horner syndrome (compression of sympathetic ganglion).[52-54]

Peripheral Vascular Complications

Peripheral vascular complications are common and occur in 30% to 50% patients in whom the aortic arch and/or the thoracoabdominal aorta is involved.[8,35,36] Cambria et al. detailed the distribution of branch vessel compromise and found that brachiocephalic trunk was involved in 14% of patients, the common carotid arteries in 21%, left subclavian in 14%, and ileofemoral arteries in 35%.[8] Patients presenting with pulse deficits more often have neurologic deficits, coma, and hypotension, and a deficit of the carotid artery pulse strongly correlates with fatal stroke.[7] In this population, mortality is clearly linked to the number of pulse deficits at the time of presentation. Indeed, within the first 24 hours, 9.4% of patients with no deficits died, 15.8% of patients with one or two deficits died, and 35.3% of patients with three or more deficits died.[55]

DIAGNOSTIC EVALUATION

In the United States, 4.6 million patients present to the emergency department with acute chest pain annually.[56] The majority of these patients do not have an aortic dissection, and it would be inefficient, unrealistic, and costly to obtain axial imaging on all patients with acute chest pain, as this would yield an 85% false positive rate.[57] However, aortic dissection often affects younger patients (in their 50s) and thus is not readily apparent. Indeed, physicians correctly suspect the entity in only 15% to 43% of presentations, as aortic dissection is often identified as an incidental finding during the evaluation of another pathologic process.[16,58] Historically, retrograde aortography was considered the reference standard in the evaluation of acute aortic dissection. However, the improvement of other techniques, such as contrast computed tomographic angiography (CTA), transesophageal echocardiography (TEE), and magnetic resonance imaging (MRI), has shifted the role of aortography from diagnostic to adjunctive during endovascular management. While the choice of diagnostic modality may be predicated on local availability/practice patterns, certain essentials exist. First, the diagnosis of acute aortic dissection must be confirmed or refuted. Second, the extent of the dissection, the potential involvement of branch vessels, and the presence of immediate life-threatening complications such as tamponade should be provided.

Imaging

Plain Radiography

Plain chest radiography is often the first imaging study obtained during the workup of acute chest pain, but the findings of aortic dissection on chest radiography are nonspecific and never diagnostic. These include widening of the cardiac or aortic silhouette, displacement of aortic calcifications, and effusions.[17,21] Widening of the mediastinum is the most common finding, while displaced aortic calcifications are usually seen with type A dissections.[17] Pleural effusions occur most frequently in patients

with type B dissections and are usually secondary to an inflammatory reaction of the mediastinal pleura.[59] Because these findings are not diagnostic, additional imaging is required.

Computed Tomographic Angiography

CT scanning is readily available, noninvasive, and has a reported sensitivity of 83% to 95% and specificity of 87% to 100% for the diagnosis of acute aortic dissection.[60-62] The chief limitation of imaging is the ascending aorta, where the sensitivity may drop to less than 80%, but this is readily overcome by the addition of TEE.[46] A helical CT dissection protocol will give excellent aortic imaging of the true and false lumens, approximate entry tear sites, and aid in planning intervention. In most cases, the true lumen may be localized by its continuity with an undissected segment of the aorta, and in the descending thoracic aorta, the false lumen is larger than the true lumen in more than 90% of cases.[63]

The orientation and mobility of the dissection flap can be assessed with CTA and if the dissection flap is concave toward the false lumen, a true lumen pressure deficit can be predicted with a 91% sensitivity and 72% specificity.[43] The dissection flap is more often noted to be in a curved orientation (63% of cases) in the acute phase the flap was flat in 75% of cases of chronic dissection.[63] As displayed in Fig. 81.2, a slitlike compressed true lumen is perhaps the key radiographic finding, which should substantially raise the index of suspicion for renal, visceral, or lower extremity malperfusion syndrome.

Echocardiography

The sensitivity and specificity of transthoracic echocardiography (TTE) range from 35% to 80% and 40% to 95%, respectively.[64,65] The chief limitation of TTE imaging is the anatomic blind spot in the distal ascending aorta and arch, secondary to the air-filled trachea and left main stem bronchus, and inability to document dissection extension beyond the diaphragm.[66,67] TEE overcomes the limitations of surface echocardiography and has a sensitivity that is as high as 98%, with a specificity that ranges from 63% to 96%.[68-70] Advantages of TEE include wide availability, ease of use, and bedside capability. Indeed, TEE possesses the ability to detect entry tear sites, false lumen flow/thrombus, involvement of the arch or coronary arteries, degrees of aortic valvular regurgitation, and pericardial effusions. In addition, TEE can be particularly useful in delineating dissection and relevant surgical pathology in the ascending aorta and, therefore, is chiefly applied in this territory.[71] Moreover, in the unstable patient with a suspected acute dissection in the ascending aorta, TEE may be performed in the operating room to expedite diagnosis and definitive therapy.

Magnetic Resonance Imaging

MRI has an overall sensitivity and specificity for diagnosis of aortic dissection in the range of 95% to 100%.[72-74] MRI can detect the site of the entry tear, the extent of the dissection, potential branch vessel involvement, and differential true versus false lumen flow. The overall sensitivity and specificity for diagnosis of branch vessel involvement is 90% and 96%, respectively.[75] The chief limitations of MRI include lack of immediate availability, long examination times, and lack of monitoring for critically ill patients.

TREATMENT OF TYPE B DISSECTION

Optimal treatment of acute type B dissection included timely diagnosis, prompt control of blood pressure, and early recognition of the malperfusion syndrome. In type B dissections, the catastrophic complication of rupture is uncommon, except in those patients who present with advanced false lumen dilation or the equivalent of aneurysm formation at the aortic entry site.[5] A complication-specific approach involving open surgical and endovascular options to treat malperfusion syndromes remains the standard of care and is reviewed as follows. Open graft replacement of the aortic entry tear has been shown to be inferior to medical therapy in patients with uncomplicated type B dissections and is not recommended.[44] However, recent natural history data of medically managed uncomplicated patients suggests that there is a subset of patients who are likely to benefit from elective TEVAR in the subacute period after symptom onset.

Medical Treatment

Medical management in an intensive care unit is the initial therapy for virtually all patients with the tentative diagnosis of aortic dissection. The goal is to reduce the hemodynamic forces that have initiated and propagated the intimal tear and cleavage of the aortic wall. This involves reducing the systolic blood pressure and dP/dT, which should in turn stabilize the extent of the dissection, reduce intimal flap mobility, and relieve the forces predisposing the dissected aorta to rupture or compromise of branch vessels.[76] Intravenous antihypertensive therapy should be started in all patients in whom acute aortic dissection is suspected, with the exception of those with hypotension.[76] For those patients with hypotension in the setting of acute dissection, an expeditious evaluation for tamponade is warranted, but percutaneous pericardiocentesis as a temporizing measure is not advised, as it often accelerates bleeding or shock.[77] In contemporary practice, a combination of a beta-blocker and vasodilator is standard medical therapy. The beta-blocker should be initiated before the direct vasodilator (i.e., sodium nitroprusside); otherwise, reflex sympathetic stimulation from direct vasodilation will cause catecholamine release, and resultant increases in dP/dT, contrary to the desired effect.

Patients should be placed in the intensive care unit during the acute period with continuous blood pressure monitoring via an intraarterial catheter, telemetry monitoring of cardiac rhythms, and hemodynamic surveillance. Once the patient's blood pressure has been controlled to a systolic of 100 to 120 mm Hg (or mean of 60 to 70 mm Hg) and their pain has resolved, they can be transitioned to oral antihypertensives. These patients need to be closely monitored, even after the blood pressure is under control. Durham et al. reported the natural history of patients with uncomplicated type B aortic dissections who were initially medically managed and found that 12% became complicated within the acute follow-up period (<15 days), with

an early mortality of 5%.[9] It is important that patients who are managed medically are followed with serial surveillance imaging with contrast CTA. The first should be obtained prior to discharge from the initial hospitalization, and then at 6-month intervals. Once a dissection has been stable for two scans, follow-up imaging can be obtained on a yearly basis.[78]

The 30-day mortality with medical management of uncomplicated type B dissection is 10% and compares favorably with the near 30% mortality associated with open repair in the acute setting.[79] In addition, multiple studies have shown a 1-year survival of 72% to 90% with medical therapy of type B dissection alone.[80-83] However, the late consequence of medical therapy is aneurysmal degeneration of the false lumen outer wall that can occur in up to 40% of patients despite medical therapy.[14] The natural history study of Durham et al. included 298 patients with medically managed type B dissections and found that 58% of patients failed medical therapy either through the need for aortic intervention (29%) or death (38%) over an average follow-up of 4.3 years.[9] The indication for intervention was aneurysmal degeneration in 66% of the patients and the average time to aneurysm repair was 2.3 years from the initial presentation.[9] Indeed, with long-term serial CT imaging, only 51% of the patients are free from aortic growth at 5 years.[84]

Open Surgical Repair of Descending Aortic Dissection

Threatened or actual rupture at the aortic intimal tear in the proximal descending aorta with no identifiable proximal seal zone remains, in our view, the only indication for acute open graft replacement in distal dissection. Unless an extensive aneurysm is present, resection should be confined to the proximal descending aorta, as mortality and spinal cord ischemia risk increase dramatically with extensive aortic replacement in the setting of an acute dissection.[85] The mortality rate for the open repair of acute type B aortic dissection has ranged from 6% to 69% in several large series.[86-90] The IRAD review of 476 patients with type B dissection showed that 82 (17.2%) were treated surgically with descending aortic replacement (70%), partial arch replacement (21%) or total arch replacement (8%) with an in-hospital mortality of 29%.[89] In addition, a recent series of patients undergoing graft replacement of the descending aorta for acute type B dissections reported spinal cord ischemic complications in 32% of patients.[85]

Endovascular Treatment of Aortic Dissection

Goals of Treatment

Stent-graft coverage of the aortic entry tear provides the means to accomplish the intuitively logical short- and long-term goals of sealing the proximal entry tear and inducing false lumen thrombosis, which has the potential to reduce the risk of late aneurysm degeneration.[91] This approach was initially used only in patients with complicated type B dissections to correct malperfusion syndrome and treat impending rupture, but the promotion of aortic remodeling has promise for all patients with type B dissections.[92-94] When indicated, the goals of TEVAR for acute type B dissection include coverage of the proximal entry tear, expansion of the true lumen with restoration of flow to the visceral vessels, and obliteration of false lumen flow with subsequent complete thrombosis (Fig. 81.4). When these components of therapy are successfully achieved, aortic remodeling should occur with subsequent prevention of future aneurysmal degeneration of the outer wall of the false lumen.

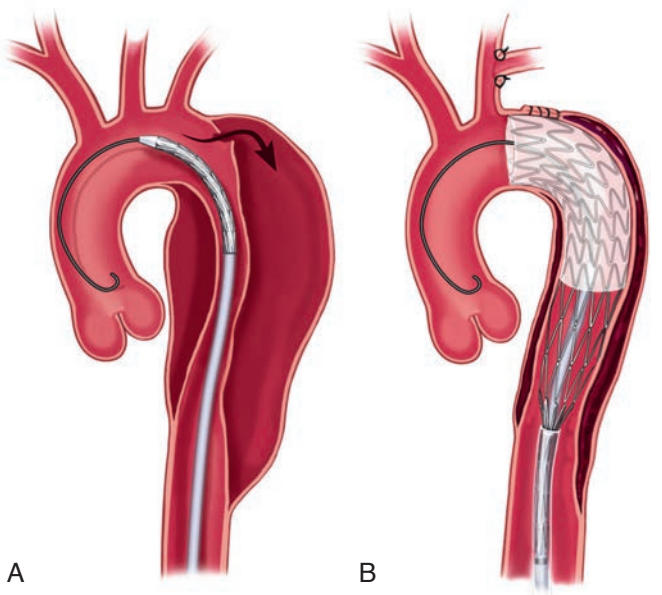

Figure 81.4 Stent graft deployment to cover the proximal entry tear with the goal of inducing false lumen thrombosis and true lumen reexpansion. The latter should also alleviate "downstream" branch compromise caused by dynamic obstruction mechanisms. False lumen thrombosis in the thoracic aorta should, in theory, minimize subsequent aneurysmal expansion of the outer wall of the false lumen. **(A)** Type B aortic dissection with undeployed stent graft advanced to the level of the left common carotid artery. **(B)** Stent graft deployed across the proximal entry tear to induce false lumen thrombosis.

False Lumen Thrombosis

In the natural history of medically managed type B dissections, continued patency of the false lumen is an independent risk factor for aneurysmal degeneration and dissection related adverse events.[84,95] During the first 4 to 7 years after acute aortic dissection managed medically, aneurysmal degeneration of the false lumen in the thoracic aorta may develop in 14% to 40% of patients treated with medical therapy alone.[17,83,96] Indeed, Sueyoshi et al. showed that a patent false lumen will enlarge 3.3 mm/year even in stable, uncomplicated cases,[97] and Tsai et al. showed that partial thrombosis of the false lumen is an independent predictor of postdischarge mortality (patent 13.7%, partial thrombosis 31.6%, complete thrombosis 22.6%).[98] Thus the concept of inducing false lumen thrombosis by sealing the aortic tear with an aortic endograft has the potential to both reduce early and late complications of type B dissection (Fig. 81.5).

Technical Details

There are particular technical points of stent-graft repair of aortic dissection that deserve emphasis (see Chapters 78 and 79). First,

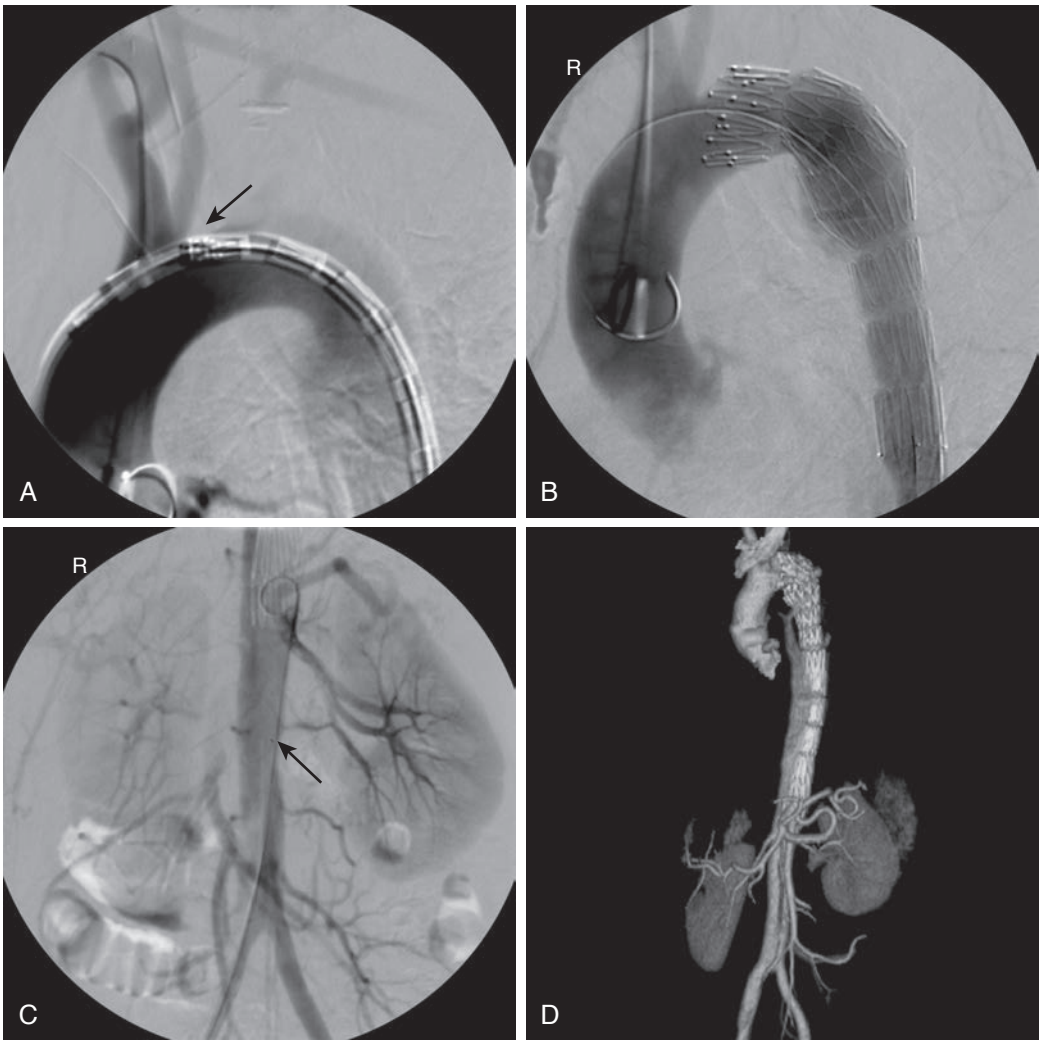

Figure 81.5 Endovascular Repair of Acute Type B Aortic Dissection. (A) Thoracic aortography showing stent graft in descending thoracic aorta. The proximal portion of the graft *(black arrow)* is placed at the level of the left common carotid artery, covering the left subclavian artery in order to obtain proximal seal in normal aorta. **(B)** Thoracic aortography showing stent graft deployed with obliteration of the proximal false lumen. **(C)** Abdominal aortography after proximal stent grafting showing true lumen expansion *(black arrow)* with persistent false lumen flow. **(D)** Three-dimensional aortic reconstruction after endovascular repair showing obliteration of false lumen in the thoracic aorta, persistent flow in the abdominal aorta, expansion of the true lumen, and perfusion to all visceral vessels.

the placement of uncovered stents over the entry tear within the proximal true aortic lumen is ill-advised, and the entry tear should be sealed by a stent graft.[99] If a patient is to be considered a candidate for stent-graft treatment, the location of the entry tear and proper recognition of the proximal zone of fixation is fundamental to the procedural success. Once selected, stent-graft repair of acute aortic dissection should be performed in an operating room with adequate fluoroscopic imaging. True lumen access should be obtained from either a brachial or a femoral approach; typically, since the tear in type B dissection is distal to the left subclavian artery, rapid true lumen access is easily obtained through a right transbrachial approach. Proper true lumen position should then be confirmed using intravascular ultrasound (IVUS), which is also useful for confirming the relationship of branch vessels to the dissection flap (Fig. 81.6). It is ideal to have at least 2 cm of normal aorta proximal to the entry tear for the proximal seal zone in order to prevent retrograde dissection into the ascending aorta. This usually requires coverage of the origin of the left subclavian artery and sealing to the level of the left common carotid artery. We generally limit the length of aorta covered to decrease the risk of paraplegia and use IVUS to assess true lumen expansion and flap mobility after each intervention is performed. Finally, we rarely, if ever, balloon the proximal seal zone in patients with acute dissections.

Outcomes

Short-term results with endovascular therapy for symptomatic acute type B dissection have been promising. Fattori et al. reported on 1129 patients with type B dissections from the IRAD database, of whom 24% were treated with TEVAR. There was 10% in-hospital mortality after TEVAR, which was similar to medical therapy in patients with uncomplicated dissections.[100] There have

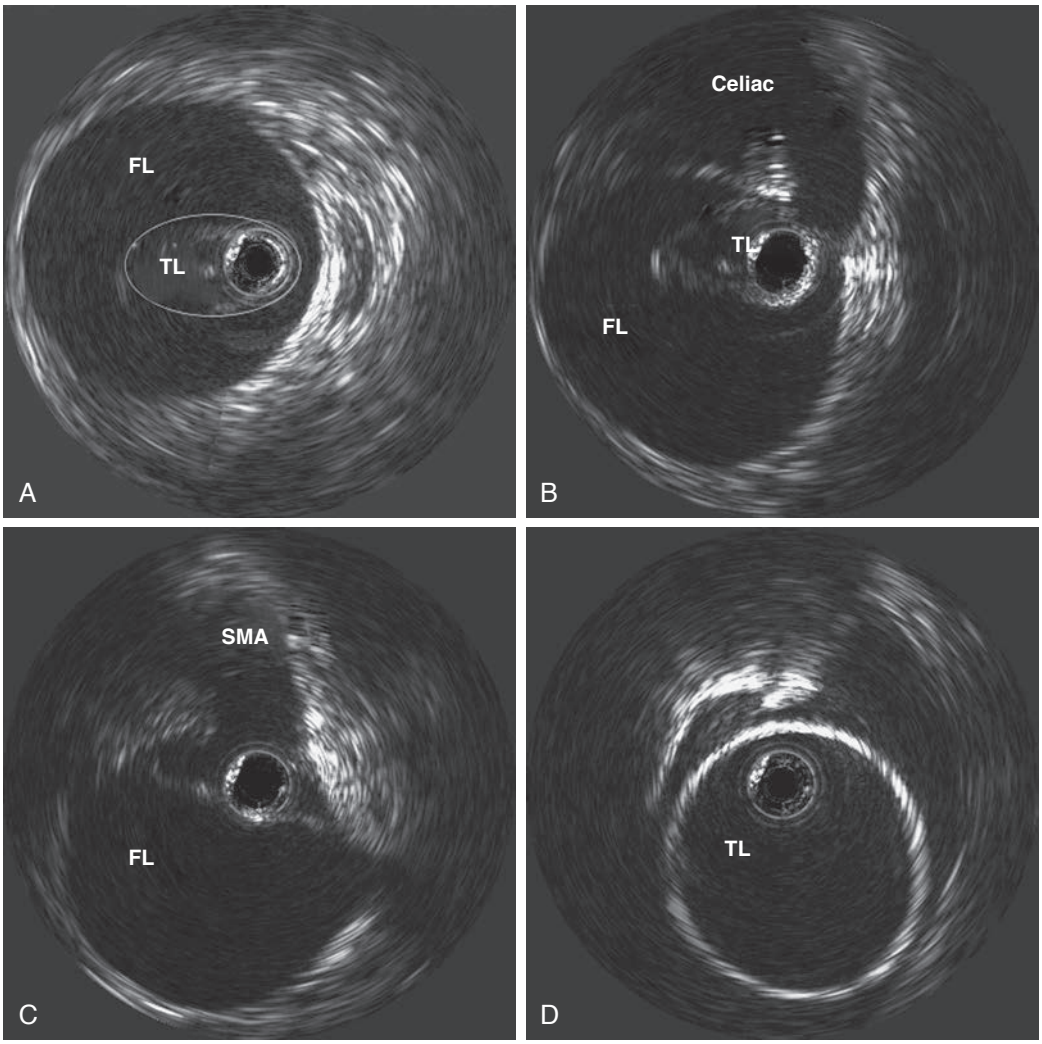

Figure 81.6 Intravascular Ultrasound (IVUS) of Acute Aortic Dissection. **(A)** IVUS of acute type B dissection with "floating" true lumen *(TL)* that is enhanced by the circle. **(B)** IVUS of acute type B dissection at the level of the celiac artery that originates from the compressed TL. **(C)** IVUS of acute type B dissection at the level of the SMA which originates from the compressed TL. **(D)** IVUS of expanded TL after endovascular repair of acute type B dissection. *FL,* False lumen.

been multiple prospective industry-sponsored trials of endovascular stent graft repair of acute type B dissections. The Gore TAG 08-01 study included 50 patients with acute, complicated type B dissections who were treated with TEVAR. The 30-day all-cause mortality in this high-risk population was 8%, with no paraplegia, but the stroke rate was 18%.[93] The Study of Thoracic Aortic Type B Dissection using Endoluminal Repair (STABLE) included 40 patients with type B dissection and reported a 30-day mortality of 5%, with a stroke rate of 7.5% and paraplegia rate of 2.5%.[101] Finally, in an attempt to establish performance goals for future prospective trials, the Society for Vascular Surgery Outcomes Committee reported the results of TEVAR in 85 patients with acute, complicated type B dissections from five centers with single-center Individual Device Exemption (IDE) studies. They established a 30-day mortality of 10.6%, with a stroke rate of 9.4% and paraplegia rate of 9.4%.[101]

The long-term anatomic benefit of TEVAR in patients with acute type B dissection is predicated upon the promotion of false lumen thrombosis and subsequent positive remodeling of the aorta, as evidenced by stabilization of the overall aortic diameter, expansion of the true lumen, and obliteration of the false lumen. Conrad et al. showed positive remodeling at 1 year across the stented segment in 33 patients treated for acute complicated dissection, with 90% of patients maintaining at least partial false lumen thrombosis. This remodeling persisted at 5 years along the stented portion of the aorta in 84% of patients.[94] Lombardi et al. looked at aortic remodeling in 86 patients enrolled in the STABLE trial. With 2 years of follow-up, 74% of patients had a stable or shrinking thoracic aortic segment around the graft.[102]

Treatment of Malperfusion Syndrome

Malperfusion syndromes may complicate the initial presentation of acute aortic dissection in 25% to 40% of patients.[8,103,104] Current indications for aortic fenestration or branch vessel

stenting are dependent upon the anatomic extent of the dissection as determined by CT scanning.[104]

Endovascular Treatment

In the initial endovascular management of the patient with an acute aortic dissection complicated by malperfusion, true and false lumen access must be obtained. IVUS should be performed from the ascending aorta to the iliac vessels in order to define the relationship of the dissection flap to the visceral and renal arteries.[105-107] Angiography can often be limited to hand injections of selected branch arteries to prove that the catheter/wire is beyond the dissection in "normal" artery. Power injection in the true lumen of the dissected aorta may give the false impression of adequate perfusion to branch vessels compromised by dynamic obstruction. All aortic branches should be visualized before intervention, as changes in flap mobility due to relief of obstruction in any single vessel may alter perfusion in other aortic side branches. If compromise of any aortic branch vessel is identified by the dissection, wire access into the distal true lumen of the vessel should be secured. In general, placement of stents in a potentially compromised aortic branch should precede aortic fenestration, as fenestration may unpredictably alter aortic flow and make it extremely difficult to regain endovascular access to compromised vessels.[104]

Percutaneous Fenestration

Fenestration of the intimal flap may be performed by several techniques using the combination of ultrasound and fluoroscopy. Most commonly, fenestration is performed from the smaller (usually true lumen) to the larger false lumen. There is usually a natural fenestration that occurs at the level of the left renal artery or other branch vessel that is being perfused by the false lumen. This fenestration can be identified and selected with the aid of IVUS. If no natural fenestration is identified, a needle, or the back end of a .014 wire, can be used to create a fenestration close to the compromised aortic branch. After the needle and a stiff wire are advanced from the true to the false lumen, a 5 F catheter is advanced into the alternate lumen. Confirmation of the position across the membrane is performed by contrast injection. Subsequently, an angioplasty balloon of at least 12 to 15 mm in diameter and 20 to 40 mm in length is used to create a fenestration tear (Fig. 81.7). A stent can be placed across the fenestration to ensure equal flow on both sides. Patel et al. analyzed 69 patients with malperfusion syndrome treated with endovascular fenestration and found a reasonable 17% 30-day mortality (five from false lumen rupture). The long-term durability was good, with nine patients requiring aortic resection over a 72-month follow-up period.

Open Surgical Treatment

Since dynamic obstruction at the aortic level is the most common mechanism of malperfusion syndromes, surgical fenestration has been the most commonly applied open procedure (Fig. 81.8).[5] The fundamental technique of surgical fenestration is wide resection of the dissected septum to relieve aortic obstruction by equalizing flow between the true and false lumens. It is important to consider whether aortic clamping and the fenestration will be confined to the infrarenal aorta. It may be desirable to extend the septectomy into the visceral segment, permitting direct inspection/repair of the ostia of the mesenteric and renal vessels.[108] Experience has demonstrated that the duration of supraceliac clamping can be limited to the 20-minute range, with repositioning of the clamp to an infrarenal location following closure of the visceral segment aortotomy. Interposition of a short segment polyester graft in the infrarenal aorta facilitates reconstruction of the aortic layers at the distal anastomosis with the double-layer Teflon felt technique. Such an approach permits direct repair of a static obstruction—that is, where the branch vessel itself is dissected. This can be accomplished by circumferential suture of the vessel intima to the aortic wall at the ostia. Since continuous exposure of the visceral segment is desirable in surgical treatment of malperfusion syndrome, we prefer left flank approaches for this procedure (see Chapter 53). Depending on body habitus, an eighth or ninth interspace thoracoabdominal approach is used to allow for complete infradiaphragmatic aortic exposure and transperitoneal inspection of the viscera, with palpation of the superior mesenteric artery pulse caudal to the mesocolon. At a median follow-up of 19

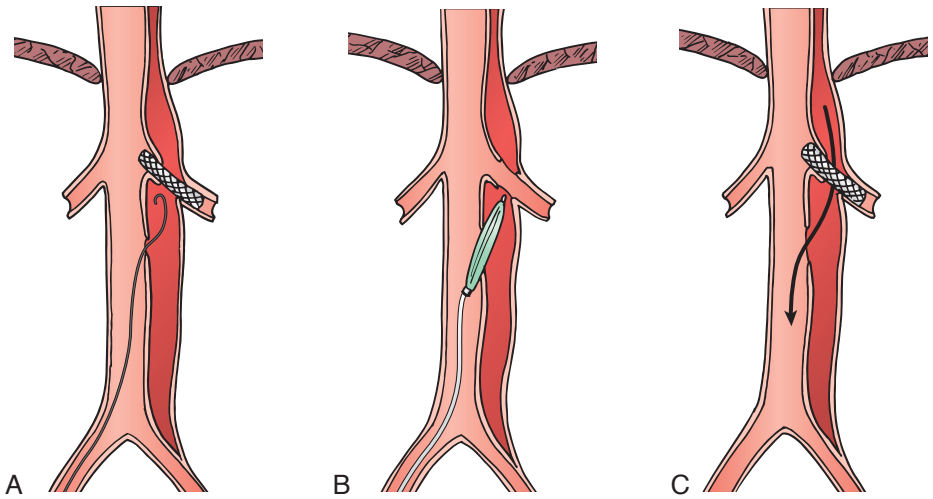

Figure 81.7 Cartoon Depiction of Endovascular Fenestration. **(A)** The left renal artery (coming off the false lumen) made to originate from the true lumen. This requires stenting using either a covered or bare metal stent. **(B)** A balloon is then used to enlarge natural fenestrations in the dissection flap. **(C)** A stent can be used to keep this fenestration open.

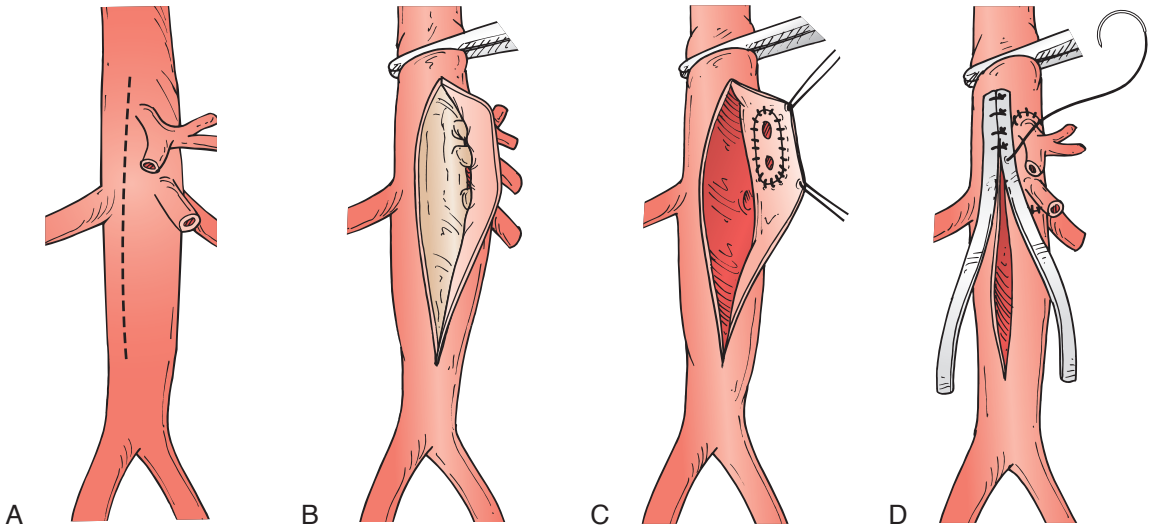

Figure 81.8 Technique of Surgical Abdominal Aortic Fenestration. **(A)** Dissection involving the visceral segment of the aorta. **(B)** If static obstruction of the renal or visceral vessels is suspected based on axial imaging studies, the fenestration can be carried onto the visceral aortic segment. The left kidney has been swept anteriorly, and note the left renal artery is perfused from the false lumen. The septum is incised to expose the origins of the celiac/SMA/right renal artery perfused via the true lumen. **(C)** Direct suture repair of the vessel ostium may be required, herein shown at the left renal origin whose orifice abuts the circumferential terminus of the dissection. **(D)** After septectomy in the visceral segment, the outer aortic wall is closed over Teflon felt and the clamp is moved to the infrarenal aorta, which is most conveniently reconstructed with a tube graft.

months, no significant aortic dilation occurred with such aortic tailoring as a surgical technique.[108]

A report from the Mayo Clinic provides perspective on both the infrequent need for and the durability of surgical fenestration.[109] From their database of 857 patients with a diagnosis of aortic dissection, only 14 (1.6%) patients underwent surgical fenestration during the study period. Recently, the IRAD data reported open fenestration in nine patients with malperfusion, and all survived with successful restoration of visceral flow.[17]

NATURAL HISTORY AND FOLLOW-UP

The primary late complication of aortic dissection is aneurysmal dilation of the outer wall of the false lumen; of patients surviving acute dissection, 25% to 50% will progress to have aneurysmal dilation of the dissected aorta despite medical management.[9,110,111] In most clinical series of thoracoabdominal aneurysms, some 20% of cases are the sequelae of chronic dissection, for which conventional open repair is typically the only treatment option in contemporary practice.[112] Indeed, in our own series of medically managed type B dissections, only 51% of patients were free from aortic growth at 5 years, and almost 30% of patients required intervention for aneurysmal degeneration of the aorta, most of which were open thoracoabdominal aneurysm repairs.[84] A variety of technical and anatomic considerations indicate that stent graft repair of aneurysms of chronic dissection etiology remains a major challenge.[113] Factors that appear to have a significant impact on chronic aneurysm development after dissection include poorly controlled hypertension, and anatomic factors such as a maximal aortic diameter of ≥4 cm in the acute phase, continued patency of the false lumen, a proximal entry tear ≥10 mm, and a partially thrombosed distal false lumen (Fig. 81.9).[114] It is these patients who will likely benefit from elective coverage of the entry tear with a TEVAR during the subacute phase. Finally, some 10% to 20% of those with dissection will subsequently experience late rupture of the aneurysm,[114] and conventional surgical repair of such lesions is considerably more complex than with degenerative aneurysms.

Long-Term Survival

The INSTEAD trial is a prospective, randomized, multicenter trial performed in Europe that compared stent grafting to medical therapy for the treatment of subacute and chronic uncomplicated type B aortic dissection.[81] The study randomized 140 patients to medical versus stent graft therapy. The investigators found no difference in survival between the two cohorts at 2 years, but this served as a break point between the groups, as the 5-year survival was superior in the TEVAR cohort.[10] Recent data from IRAD examined 1129 consecutive patients with acute type B dissection, of whom 24.4% were treated with an early TEVAR. Similar to the INSTEAD trial, there was no difference in early survival between the two cohorts, but at 5 years, it was significantly higher in patients who had undergone TEVAR (84.5% vs. 71%, $P = .018$).[100] Finally, Durham et al. looked at the natural history of 298 patients with acute type B dissection that were initially managed medically, and reported the 6-year survival in patients who eventually required aortic intervention

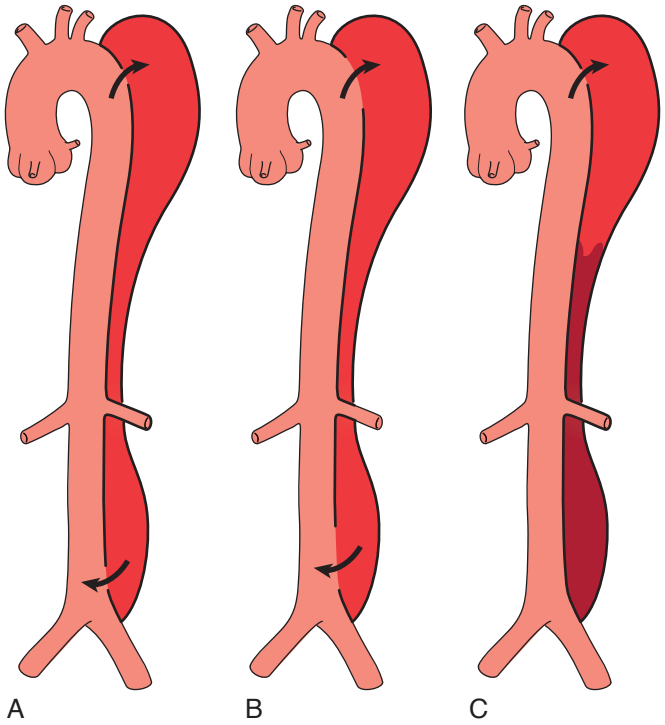

Figure 81.9 Anatomic predictors of aneurysmal degeneration in medically managed type B dissections include **(A)** A descending thoracic aorta that measures greater than 4 cm at the time of presentation. **(B)** Proximal entry tear that measures greater than 10 mm. **(C)** Partially thrombosed false lumen where the outflow fenestrations have thrombosed but proximal flow persists.

was significantly higher than those who were treated with medical therapy alone (76.4% vs. 59.3%, $P = .018$) (Fig. 81.10). Although the exact mechanism for this survival advantage is unknown, there is a clear trend that favors TEVAR over medical therapy over time that begins after 2 years.[9]

Late Therapy

Aneurysms that are the sequelae of chronic dissection tend to be more extensive and occur in younger patients compared with degenerative aneurysms. Treatment with effective beta-blockade is an essential feature of long-term therapy and follow-up. The rationale of such therapy is based on the recognition that patients with aortic dissection have a systemic illness that places their entire aorta at risk for further dissection, aneurysm, or rupture. Guidelines recommend progressive upward titration of beta-blockade to achieve a blood pressure less than 125/80 mm Hg in usual patients and less than 120 in those with Marfan syndrome. In addition, aggressive beta-blockade has been shown to retard the growth of the aortic root in Marfan's syndrome patients and may have a similar effect on the thoracoabdominal aorta.[115] Serial imaging is the cornerstone of long-term follow-up, and axial imaging modalities should encompass the entire aorta. While in the developmental stages at present, branched stent-graft technologies will likely have an important role in the future management of patients with aneurysms of chronic dissection etiology (see Chapter 80).[116]

SUMMARY 1076

INTRODUCTION

The penetrating aortic ulcer (PAU), when present, indicates a severely diseased aorta. Although first described as an incidental component of dissecting aneurysms in 1934, PAU was not clearly defined as an aortic pathology until 1986.[1,2] PAUs are the rarest subset of the acute aortic syndrome (AAS), which comprises aortic dissection (AD), intramural hematoma (IMH), and PAU, affecting between 2% and 3% of the population.[3-5] Most of the principles of PAU management have been established through 20+ years of retrospective case series. Currently, PAUs are better defined, easily identified on imaging, and treatment strategies for symptomatic and concerning lesions have been shown to improve outcomes.

PATHOPHYSIOLOGY

A PAU is a focal ulcerative lesion that develops in the region of an atheromatous plaque that penetrates the internal elastic lamina of the vascular wall. Sheenan was the first to describe PAU, but it was not described as a distinct lesion distinguished from other aortic pathologies until Stanson's report in 1986.[1,6] Often, PAUs occur in an area of significant atheroma, but not all PAU are associated with atherosclerosis. Only 53% of PAU identified on imaging were associated with atherosclerotic lesions.[7] Regardless of the etiology of the PAU, the pathology commonly resolves with treatment such as after endovascular stenting, with most PAUs found to regress on follow-up imaging. Unfortunately, getting tissue to determine a true histologic diagnosis of PAU is infrequent, since so many of these lesions are treated with conservative medical management or endovascular therapy.

The diagnosis of a PAU in most cases is made based on radiologic appearance. Imaging shows a localized, contrast material-filled, craterlike, outpouching of the endoluminal border with discontinuity of the internal elastic lamina into the aortic wall. Distinct from AD, there is an absence of an intimal flap or double-barreled true and false lumen.

Macrophages are frequently present in the vascular media of a PAU, and similar inflammatory markers are expressed in both PAU and IMH, including matrix metalloproteinases. Both etiologies of AAS have apoptosis and medial layer, specifically *vaso vasorum,* degeneration.[8] Up to 80% of PAU may have an associated IMH within the medial layer of the aortic wall.[9] If an IMH is associated with the PAU, the hematoma is often focal without much extension. PAU with IMH, as compared to isolated PAU, may have behave differently and eventually may progress to an AD.[10] PAU with IMH is also more difficult to treat in endovascular fashion.[11,12]

Traumatic injuries to the aortic wall are not contributory to the development of PAU. PAU do not necessarily occur more commonly in patients with genetic mutations associated with AD, such as Marfan syndrome, cystic media necrosis, or seronegative spondyloarthropathies. Ulcers can be circumferential or longitudinal lesions. Unlike AD, PAUs do not necessarily occur at points of maximal hydraulic stress, such as the right lateral wall of the ascending aorta or at the ligamentum arteriosum of the descending aorta.[13]

PAUs, despite a similar appearance, are separate entities from pseudoaneurysms, saccular, and mycotic aneurysms. However,

Abstract

Penetrating aortic ulcers (PAUs) are important lesions of which vascular surgeons should be aware. With the aging population and improvements in vascular imaging, their observed frequency will likely increase. The presence of a bland PAU in an asymptomatic patient is not necessarily predictive of an evolving vascular pathology. However, those patients presenting with symptoms associated with a PAU or other associated aortic pathologies in addition to a PAU are at increased risk for poor outcomes, even after intervention. The onset of endovascular stent-grafting has provided patients with PAU, who would have not been eligible for open repair, an opportunity for therapeutic intervention.

pseudoaneurysm

PAUs can degenerate into pseudoaneurysms and saccular aneurysms with adventitial expansion beyond the original borders of the aortic wall. Saccular aneurysm degeneration with associated PAU occurred in nearly a quarter of abdominal and thoracic PAUs.[14] Mycotic aneurysms can also have an ulcerated appearance on imaging; however, there is an associated systemic response (fevers, leukocytosis, tachypnea, or tachycardia). Characteristic radiographic findings of a mycotic aneurysm include the appearance of surrounding phlegm with stranding on imaging representing infected fluid or tissue. Patients presenting with such symptoms or radiographic findings should have blood cultures drawn, broad spectrum antibiotics started, and definitive surgical repair if appropriate.[15]

INCIDENCE

Of those patients diagnosed with AAS, only 2% to 8% have PAU with the majority of these lesions found in the descending thoracic aorta.[13,16] ADs are much more common compared with PAUs. In 120 patients undergoing transesophageal echocardiograms to assess suspected AAS, only 2.5% of the population was found to have PAU, whereas 37.5% of patients had an AD identified.[17] In 684 consecutive aortograms performed for suspected AD, the occurrence of PAU was noted to be similar at 2.3%.[6] However, others have reported a higher incidence. In a retrospective review of 198 patients with the initial diagnosis of AD, Coady et al. noted the incidence of PAU to be 7.6%.[13]

PAU can be identified in the presence of other AAS pathologies or they can be solitary. They can be symptomatic or incidentally identified on imaging. The percentage of patients with a symptomatic PAU as opposed to those with an asymptomatic PAU incidentally discovered is unknown, making their true incidence difficult to determine. As more frequent high-resolution, cross-sectional imaging is performed, their incidence is likely to increase.

PAUs are most frequently found in elderly male patients compared to other AAS etiologies, and the majority of patients with PAUs are in their 7th and 8th decade of life.[11,13,18-22] Patients with PAUs are considerably older than those with other aortic pathologies, with the exception of aortic aneurysms, and are generally a decade older than patients with ADs.[9,23] The mean age at PAU diagnosis is 71.9 ± 6.1 years, which is considerably older than the mean age of patients with an AD (63 years).[24,25] Gender dispersion is two-thirds male and one-third female, which is similar to AD.[24,25] Female patients with PAU in some reviews were noted to have worse outcomes compared with their male counterparts.[23] However, survival after treatment with TEVAR for females with PAU was no different from males at 1 and 5 years.[26]

As with IMH and AD, patients with PAUs almost universally have a concurrent medical history of hypertension with case series quoting a hypertension incidence of 92%. Unlike IMH and AD, patients with PAU generally are infirm with multiple serious comorbidities. Other common comorbidities include smoking history, coronary artery disease, and chronic obstructive pulmonary disease.[20-22,24,27-29] Multiple studies suggest the smoking incidence in patients with PAU is between 60% and 80%.[9,19-21,23,27,30] Other vascular pathologies are frequently identified in PAU patients. For example, approximately 50% will have a concomitant aneurysm that may or may not be near the identified PAU. Aneurysms identified are most frequently located in the abdominal aorta.[31-33] Peripheral arterial disease is also notable with a third of abdominal aortic PAU patients so diagnosed.[31]

PAU can occur anywhere along the aorta, iliac, and femoral arteries, but the most common location is in the descending thoracic aorta. PAUs in the ascending aorta and aortic arch are infrequent.[9,13,34] In a retrospective review assessing a single center experience treating PAU over 11 years, PAU distribution was as follows: 17% aortic arch, 68% descending thoracic aorta, and 14% thoracoabdominal aorta (Fig. 82.1).[35] PAU found

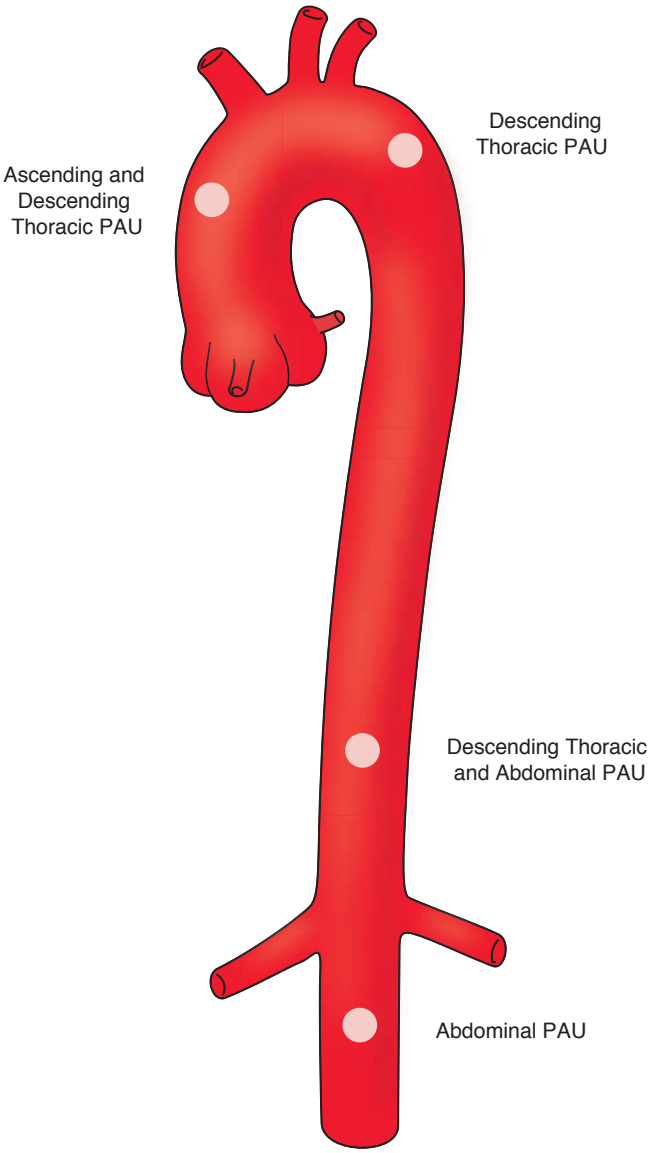

Figure 82.1 Distribution of Penetrating Aortic Ulcer *(PAU)* Along the Aorta and Associated Common Symptoms. Ascending and descending thoracic PAU: 47% chest pain, 40% midscapular pain. Coady et al.[13]; **Descending thoracic PAU:** 100% pain, 38% back pain, 14% chest pain, 9.5% abdominal pain, 14% combined chest and abdominal pain. Brinster et al.[20]; **Descending thoracic and abdominal PAU:** 22% chest pain, 45% back pain, 22% combined chest and back pain, 11% abdominal pain. Dalainas et al.[21]; **Abdominal PAU**: 46% lumbar pain, 11% lower limb ischemia 4% shock. Batt et al.[27]

along the infrarenal aorta and distally are more atypical with less than 4% of patients being affected.[18,27] The frequency of abdominal PAUs is 0.48% and the frequency of iliac and femoral PAU is 0.3% for all patients undergoing computed tomography angiography (CTA) of the abdomen and pelvis,[28,31] and multiple PAUs are identified in 17% to 22% of patients.[19]

CLINICAL PRESENTATION

Symptoms associated with PAUs can be quite variable, and they can present similar to acute coronary syndrome with chest pain and shortness of breath. If the ascending aorta is involved, the affected patient can have anterior chest, neck, and jaw pain. PAU can also present with symptoms similar to AD with sudden onset of tearing or ripping back pain. Upper back, mid-scapular, and abdominal pain is frequently present if the arch or descending aorta is involved, and presentation can be as subtle as isolated dyspnea or mild abdominal pain or as dramatic as hemodynamic instability with frank bleeding from the oropharynx. A few reports of patients with hemoptysis and hematemesis from ruptured PAU with associated bronchial tree or esophageal fistula are described.[36-38]

PAUs can be completely asymptomatic, and the true incidence of these silent PAUs is dependent upon imaging performed for other indications. Thoracic PAUs most commonly present with chest, back, or abdominal pain; and most are symptomatic. In a recent meta-analysis of multiple studies treating thoracic PAUs, as a whole, only 9% of patients were asymptomatic at initial presentation.[24] Generally, more than 75% present with acutely worsening pain for less than 2 weeks.[7,20] PAUs in the abdominal aorta can also have an insidious presentation with a history of chronic lower back or intermittent abdominal pain. Not infrequently, patients with abdominal PAU are completely asymptomatic. All 53 patients identified with PAU along the abdominal aorta were asymptomatic in a recent retrospective review.[31]

Ruptures associated with PAUs are also variable. While a rupture is not necessarily predictable, it is almost uniformly and immediately lethal if not treated expeditiously, and rupture associated with PAU is more common than rupture associated with AD. In symptomatic patients with PAU, 9% to 44% were found to have an aortic rupture.[6,9,11,16,18-23,30] Patel et al. noted that 41% of the patients evaluated with a PAU of the descending thoracic aorta presented emergently with rupture. Similarly, Stanson et al. recognized the rate of rupture associated with a PAU to be around 44%.[6] Unlike descending thoracic PAUs, abdominal PAUs are thought to be responsible for only 1% to 5% of all aortic ruptures.[18]

When assessing for AAS in the symptomatic patient, there are often physical findings that distinguish patients with a PAU from those with AD. The differences generally occur in the cardiovascular exam and neurologic assessment. Patients with PAU seldom have aortic valve regurgitation, which is frequently observed in patients with type A AD, and peripheral pulses are typically equivalent in bilateral upper and lower extremities in patients with PAU, whereas pulses may not be equivalent in patients with AD, especially in those with lower extremity malperfusion. Moreover, patients with AD may also present with neurologic deficits, mesenteric malperfusion, and renal failure, which are not typically found in patients even with symptomatic PAU.

Generally, patients with PAUs have large aortic diameters at the time of diagnosis. Geisbusch et al. found the aortic diameter in 48 patients with PAU to be a mean of 5.0 ± 1.7 cm (range 2.7-10.5),[19] and multiple groups have noted an association between PAU and abdominal aortic aneurysms (AAA). Both patients with thoracic and abdominal PAU are likely to have AAA (Fig. 82.2).[13,31] Coady et al. found concomitant AAA in 6 of 15 patients (40%) with PAU. Stanson et al. and Kazerooni et al. found 38% and 75% of patients with a PAU to have an associated aortic aneurysm.[6,39] The incidence of AAA associated with PAU is higher as compared to the AAA associated with

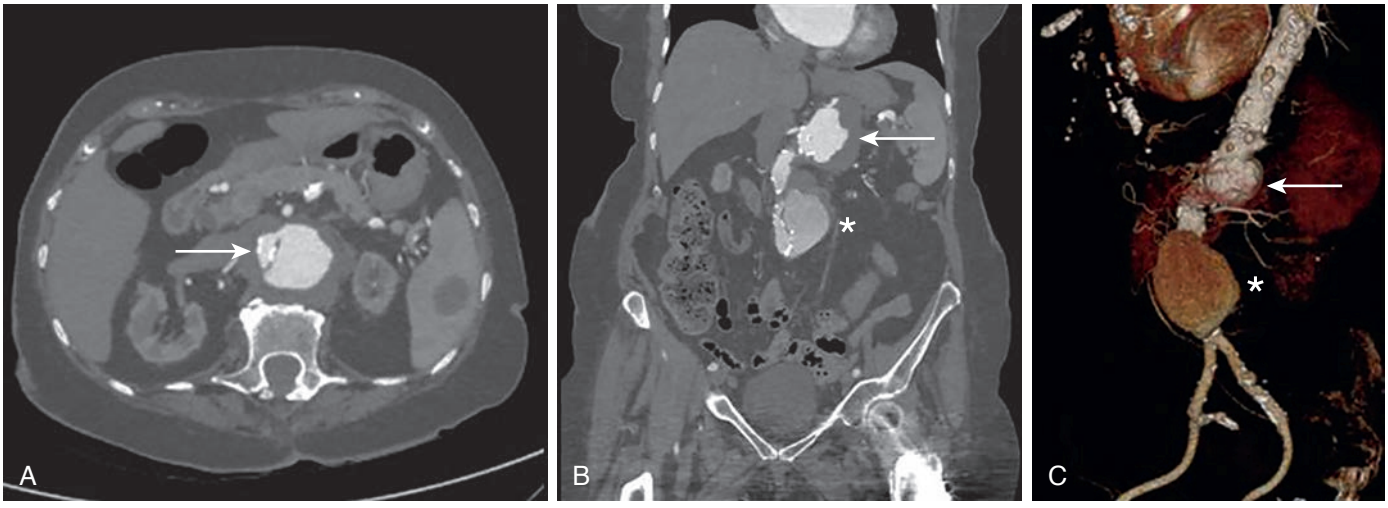

Figure 82.2 Penetrating Aortic Ulcer (PAU) of the Descending Thoracic Aorta and Infrarenal Abdominal Aortic Aneurysm. (A) Sagittal images of the PAU *(arrow)*, (B) coronal images of PAU *(arrow)* and infrarenal aortic aneurysm *(asterisk)*, (C) three-dimensional construction showing left lateral projection with the PAU *(arrow)* protruding and infrarenal aortic aneurysm *(*)* below.

type A and B dissections (9% and 31%, respectively).[13] These findings suggest the pathophysiologic process of PAU formation is similar or related to AAA formation.

Symptomatic PAU frequently will often have pulmonary complications, and respiratory complications can be aggravated especially if other vascular pathologies (IMH, AD and rupture) are present. Pleural effusions are found in conjunction with 10% to 44% of PAU.[9,20,30,39] An enlarging hemothorax is also a notable finding associated with 9.5% of PAU. These respiratory findings suggest an acute presentation of a PAU and impending rupture necessitating urgent treatment, whether or not the patient presents with pain.[20]

PAUs may also present with embolization of atheromatous particles resulting in ischemia or even distal infarction.[18] If no cardiac origin is determined to be the source for the lower extremity embolism, a search for an aortic etiology, particularly a PAU, should be pursued with CTA of the chest, abdomen, and pelvis. Abdominal PAUs, in contrast to thoracic PAUs, are more likely to cause embolization and distal ischemia.[6,31,40,41]

OTHER AORTIC PATHOLOGIES ASSOCIATED WITH PENETRATING AORTIC ULCER

IMH are not universally associated with PAU, but the two aortic pathologies are frequently found together. The frequency of IMH with PAU is reported to be 22% to 94%.[7,9,11,13,21,39,42] The surrounding aortic wall near a PAU is typically thickened with intimal calcification and is often inwardly displaced. Chronic atherosclerosis in the affected area leads to fibrosis in the vascular media preventing hematoma propagation. The mean longitudinal extension of an IMH found with a PAU is limited and was noted to be approximately 2.8 cm.[21] Cho et al. found that more than 85% of IMH diagnosed with PAU spontaneously thrombosed after 1 year.[9] Patel et al. suggest that patients with a PAU and an associated IMH require urgent or emergent intervention due to an increased risk of rupture.[11] In this study, of the 11 patients with concurrent IMH and PAU, seven patients (64%) developed AD or a new intimal tear during hospitalization.

Mortality associated with IMH and PAU was considerably higher compared to isolated IMH. Thirty-six percent of the patients with an IMH and PAU died during the follow up period, while only 8% of patients with a solitary IMH died.[42] This study implies that IMH found in the presence of a coexisting PAU might be associated with worse outcomes, as PAUs found in conjunction with IMH might be the cause of newly developed dissections with intimal tear and aortic rupture. In patients with an isolated PAU compared to those patients with IMH and PAU, there was no difference in age, prevalence of comorbidities, presentation with rupture, and extent of repair performed.[11] Importantly, no difference in overall patient survival between those presenting with an IMH and PAU compared to PAU alone was noted.[11] However, IMH presence with PAU was associated with a higher risk of endovascular treatment failure treatment compared to isolated PAU. Treatment failure was defined as the additional need for open repair, endovascular re-intervention, aortic rupture, or aortic-related death.[11] The optimal treatment time is still debated for patients presenting with both PAU and IMH, and allowing for IMH resolution prior to endovascular intervention especially might be of value.[11]

PAU presenting with an AD is not uncommon. The frequency of PAU with thoracic AD is reported between 11% and 20%.[7,43] Often a thicker calcified, static flap is affiliated with the tear.[44] Like IMH found in association with PAU, the AD with PAU are typically shorter in length as compared to a classic AD. When studied in conjunction with AD, patients with PAU are more likely to suffer aortic rupture than patients with AD alone (AD + PAU, 40% versus type A AD alone 7.0% and type B AD alone 3.6%).[13] The survival trend of AD in association with a PAU is worse as compared to solitary AD because of increased rupture potential.[13]

DIAGNOSTIC IMAGING

CTA imaging has now become the standard imaging of PAU. CTA can accurately visualize PAU-associated vascular pathology, including aortic wall enhancement, thrombosed IMH external to the calcified intima, contrast extravasation through the ulceration, the absence of a double lumen, a thrombosed pseudoaneurysm, and transmural rupture.[43]

In addition to evaluating for other adjacent aortic pathologies, PAUs are assessed for ulcer dimensions. These include the maximum width of the entry defect from the lumen, the maximum depth from the lumen to the aortic wall, and the maximum length of the intramural component of the ulcer itself (Fig. 82.3). Cho et al. reviewed CTA imaging of 105 patients with PAUs. Three quarters of the patients were symptomatic upon presentation. All three PAU dimensions measured, width, depth, and length, were found to be significantly greater in the symptomatic patients as compared to asymptomatic patients.[9]

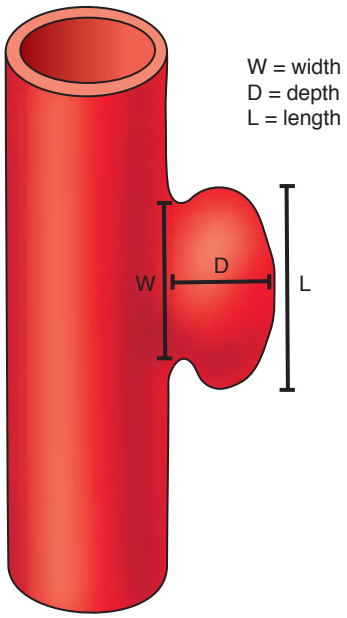

Figure 82.3 Penetrating Aortic Ulcer Dimensions Measured.

The greatest disadvantage of CTA is the requirement for iodinated contrast and radiation exposure. Another limitation of CTA imaging is that if intimal calcification associated with the PAU is not present, intraluminal thrombus and IMH can be difficult to distinguish.[44] Imaging techniques used to identify PAU generally demonstrate an outpouching of the aortic wall with the presence of jagged edges surrounded by extensive aortic atheroma. The starting point for a PAU is distinct, whereas the starting point for an AD can be difficult to determine.

Alone, magnetic resonance angiography (MRA) might not be as sensitive for detecting PAU. MRA is of little value in the identification of aortic wall calcification, and Yucel et al. reported that MRA identified six of seven PAU as compared to aortography.[44] However, MRA is useful as adjunctive imaging and may even be superior to aortography at identifying complicating features. MRA shows the PAU as a craterlike ulceration in the absence of an intimal flap or false lumen, and the aortic wall appears thickened with high intensity signals on T1 and T2 weighted images when the PAU was complicated by an acute IMH. An obvious advantage of MRA is that no iodinated contrast is required and that images may be acquired using time of flight sequences. Unfortunately, the high cost of MRA, the long time needed for evaluation, the difficulty monitoring unstable patients, and the limitation for patients with metal implants still limits its use.

Other imaging modalities useful for evaluating PAU include transesophageal echocardiography (TEE). With TEE, PAUs appear as crater-like ulcers with ragged edges in the presence of extensive atheroma without an intimal flap or false lumen. When an IMH is present in conjunction with a PAU, the IMH will appear echolucent with mottled thickening of the aortic wall and inward displacement of intimal calcification. When a PAU is identified, the benefit of TEE is the ability to simultaneously evaluate cardiac function and identify regional wall motion abnormalities. The results are operator dependent relying on the ability to obtain accurate images and the interpreter's read of the imaging acquired.

TREATMENT

The goal of intervention for symptomatic PAU, as well as those with concerning features, should be to prevent aortic rupture and progression to AD. Incidentally discovered PAU, depending on location and appearance, might not require intervention and might be best followed with repeat imaging and conservative measures including treatment of hypertension and hyperlipidemia if present. Tittle et al. found progression of aortic diameter to be 0.2 cm/year in the presence of a PAU and suggested annual imaging surveillance.[29] Harris et al. found that approximately one-third of patients with PAU progressed to form a saccular or fusiform aneurysm.[44]

Conservative management is preferred in patients presenting with an isolated PAU without associated symptoms or if symptoms are well controlled with antihypertensive medications. Patients with PAU should have strict blood pressure control with beta blockade or vasodilators. Cho et al. presented a retrospective series of 105 patients with conservatively treated PAU over a 1- to 7-year period. Medical management in this study was associated with a significantly lower early mortality rate compared to open surgical repair and were 4% and 21%, respectively.[9] Conservative treatment with antihypertensive therapy in this study showed one-third of patients required intervention for progression of PAU to aneurysms, dissection, or perforation over a 25-year period.[9]

Some research has yielded better results associated with the conservative management of PAU. Hussain et al. found few if any patients treated with conservative management progressed to aneurysm formation or rupture. In this study, patients with thoracic PAU were followed for 30 months, and none required surgical intervention. Within 6 months of diagnosis, all patients were symptom-free, and imaging showed that 80% of patients had a resolution of their PAU with no signs of progression to aneurysm or rupture.[43]

Treatment should be pursued for all symptomatic PAU to prevent possible rupture and should incorporate both blood pressure control and operative intervention. Other PAU treatment indications include recurrent or refractory pain and signs of impending or contained rupture. Rapidly growing aortic ulcers, periaortic hematoma, hemothorax, and pleural effusions are all signs of impending PAU rupture. PAUs presenting with symptoms are more malignant, and urgent operative intervention is warranted.[16] The median time between admission and endovascular repair for patients who failed conservative management for their PAU was 2 days (range 1-4 days).[21] In addition, Geisbusch et al. advocated PAU repair, specifically with endovascular intervention in their study, within 48 hours of symptom onset.[28]

Radiologic characteristics of PAU more likely to rupture in asymptomatic patients have also been identified. Patients with aortic diameters greater than 60 mm adjacent to the PAU, PAU diameter greater than 20 mm, and PAU depth greater than 20 mm should be referred for repair.[14,16,45,46] Prognosis for the PAU is correlated with size, with most believing that PAU with larger diameters and depths require earlier intervention. It is important to note however that PAU adjacent to normal diameter aorta have been known to rupture. Continued observation with repeat imaging for asymptomatic PAU that develop concerning features and patient education regarding the symptoms that might be attributed to impending rupture are important.

PAU should be repaired if there are signs of progression (accelerated growth) or impending vascular compromise. These signs include an expanding IMH, an evolving AD, distal embolization, or hemodynamic instability. Failure of medical management to control pain or blood pressure is another indication for surgical repair.

The use of fludeoxyglucose-positron emission tomography/CT is being investigated for the assessment of aortic lesion inflammation. Associated inflammation is thought to be a marker for aortic wall instability.[47] These findings in combination with PAU imaging characteristics might prove valuable in determining which PAU should be intervened upon and appropriate timing. Interestingly, D-dimer levels in patients with PAU are not as elevated as compared to other AAS etiologies (AD and IMH), suggesting that PAU might not always have associated

inflammation.[48] Janosi et al. did find that both biomarkers, d-dimer and troponin, were significantly elevated in symptomatic PAU patients as compared to asymptomatic PAU patients ($P = .016$ and $P = .04$, respectively).[35]

OPERATIVE REPAIR

Some of the larger studies describing their results treating patients with PAU are listed in Table 82.1. Historically, PAUs were treated with open aortic repair. In 1959, Shumacker and King were the first to perform successful open operative repair of a ruptured PAU in the descending thoracic aorta.[49] Open surgical repair for all aortic pathologies, including PAU, has improved greatly in recent years (see Chapter 77). Studies from specialized aortic surgery centers have demonstrated 30-day mortality rates for all open aortic surgery as low as 6%.[45] However, the subset of patients affected by PAU is an elderly group of patients with multiple comorbidities. Therefore, operative mortality for PAU

patients undergoing open repair has ranged between 5% and 21%.[9,50-52] One of the few advantages of open surgical repair is that it allows for a histologic diagnosis.

Disadvantages of open surgical repair include operative duration under general anesthesia, a large incision, clamping and unclamping the aorta, possible cardiopulmonary bypass, and an extended hospital stay with potential frequent post-procedural complications.

ENDOVASCULAR REPAIR

Endovascular management of PAU has largely become the operative treatment of choice. Nonetheless, no randomized study has been performed confirming the superiority of open or endovascular repair for PAU. In addition, no difference in late survival has been noted between patients with thoracic PAU undergoing open repair as compared to endovascular repair suggesting noninferiority.[12]

While the anatomic features of the PAU will ultimately dictate the appropriate intervention, generally, patients affected by PAU are not ideal candidates for open repair because of advanced age, poor functional status, and multiple comorbidities. PAUs, because of their focal, segmental nature, are an ideal lesion to be treated with stent-grafting. Multiple groups have shown that endovascular repair of PAU associated with symptoms or concerning features such as associated pseudoaneurysm, and rupture is a feasible option for treatment. Endovascular repair, specifically thoracic endovascular aortic repair (TEVAR), for descending thoracic PAU has proven safe and efficacious (Table 82.2).[11] TEVAR for PAU has been demonstrated to be at least as effective as traditional open surgical repair or a hybrid procedure. Multiple groups have reported their results with TEVAR for PAUs, and in a meta-analysis of these studies with over 300 PAU treated with TEVAR, the overall reported technical success was 98.3%.[24] Clinical success of endovascular stenting ranges from 76% to 100%.[11,18-20,22-24,30]

There are many appealing features of endovascular repair as compared to open repair for the treatment of PAU. The less invasive nature with small incisions or percutaneous approach is desirable as compared to a large thoracotomy or abdominal incision. Mean operative time with endovascular stent-graft placement is decreased compared to open repair.[18,20,53] In addition, hospital length of stay is less with endovascular stent placement for PAU with multiple studies reporting a mean hospital stay after endovascular repair ranging from 4 to 8 days.[18,20,53]

Limitations of endovascular repair include adjacent aneurysm, PAU in proximity to the branch or mesenteric vessels, steep aortic angulation, heavy burden of atherosclerotic disease in the associated area, inadequate working length (insufficient landing zones), and other proximal aortic pathology. Sufficient landing zones remain important for successful PAU exclusion and as close to 20 mm proximal and distal to the PAU of healthy aorta is the goal for endovascular exclusion.

Most studies suggest that only a 5% to 10% maximum oversizing should be performed.[11,21] Aggressive attempts to dilate the landing zones for stent grafts are usually not indicated in the presence of PAU.[54] Balloon dilation should only be done in areas of stent-graft overlap, and dilation around the region of PAU should not done to avoid device erosion into the aortic wall.[54] Hybrid approaches, including preoperative aortic debranching, carotid to subclavian bypass, mesenteric debranching/bypass, or snorkeling techniques, have been reported prior to PAU endovascular repair. Interestingly, Patel et al. reported aortic arch repair to be protective on multivariate analysis with regard to late aortic outcomes associated with TEVAR repair of thoracic PAU. While the study lacked sufficient numbers of patients treated to yield statistical significance, the researchers hypothesized that the aorta associated with proximal and mid-descending thoracic PAU without prior arch repair is subject to propagating retrograde dissection, aneurysm formation, and rupture. Their suggestion was for more extensive coverage with multiple centimeters above and beyond the PAU to be treated.[11]

Postprocedural imaging usually with CTA should demonstrate lesion regression or thrombosis. Clinical symptoms associated with PAU should resolve in most cases after endovascular treatment. In a retrospective review of 14 symptomatic patients

PUA, Penetrating aortic ulcer.

undergoing TEVAR for thoracic PAU, all patients treated had their preoperative pain relieved after endovascular stent-graft placement.[20]

The mortality associated with the procedure is still considerable despite the less invasive nature of the procedure, and the mortalities were most likely due to the comorbidity of the patient population treated. Thirty-day mortality overall was 4.8% and has ranged between 0% and 26%.[11,18-20,22,23,30,53] Some groups have reported higher in-hospital mortalities, although their treated populations included patients with PAU complicated with AD and other aneurysmal disease.[19] Not surprisingly, PAU patients who were asymptomatic at presentation had a lower in-hospital mortality rate than symptomatic patients (0% vs. 23%, respectively).[19] By univariate analysis, Patel et al. found older age correlated with early mortality.[11]

Mid- and long-term follow-up statistics are limited for PAU patients treated with TEVAR, and the data does show that long-term survival is limited by patient comorbidity and not by PAU disease progression after stent-graft placement. D'Annoville et al. found after a mean follow-up of 17.7 months (range 1-52 months), all-cause mortality was 22.9% (71 of 310).[24] In a separate study assessing long term results, median survival was 89.8 months and 7-year actuarial survival was 84.4% ± 10.2% with operative status, elective versus urgent or emergent at the time of presentation, being an independent risk factor for late all-cause mortality (OR 14.7, $P = .007$).[11]

Other factors found to correlate with late mortality in patients following endovascular treatment of PAU included history of congestive heart failure, perioperative stroke, or need for dialysis.[12] In a meta-analysis of PAU treated with TEVAR, overall aortic-related mortality after treatment was 4.1% (13 of 310) with individual studies reporting a range of aortic-related mortality rates between 1.3% and 15.3%.[11,23,24,55-61]

COMPLICATIONS ASSOCIATED WITH REPAIR

The same complications associated with any aortic surgery can occur after both open and endovascular PAU repair. Some of the most common perioperative complications include myocardial infarction, cerebrovascular accidents, pulmonary complications, renal failure, sepsis, and multi-organ failure. Most of the data available to evaluate complication frequency is obtained from the multiple case series reporting TEVAR for thoracic PAU repair. While the aforementioned complications are not common, they can be devastating. D'Annoville et al. quoted an early (<30 days post) morbidity incidence of 36.4% (113 of 310)[24] and noted that the incidences of postoperative sepsis, multiorgan failure, renal failure, and pulmonary complication in patients undergoing TEVAR repair of PAU were 1.2% (2 of 157), 2.3% (6 of 261), 4% (9 of 221), and 4.7% (9 of 189), respectively.[24] Out of 21 studies reporting post-operative coronary complications, only one patient reviewed suffered a myocardial infarction. Twenty-seven studies reported a post-operative stroke rate of 2.4% (7 of 287).[24]

Spinal ischemia with associated paraplegia among thoracic PAU patients undergoing TEVAR occurred in 2.9% of cases, but reversed in eight of nine patients with cerebrospinal fluid drainage.[24] Only 25% of patients with thoracic PAU treated with TEVAR underwent preventative cerebrospinal drainage. Given the focal nature of most PAU and the urgency for treatment, cerebrospinal drainage is not uniformly recommended.

Complications after TEVAR repair for PAU specific to the stent-graft include endoleaks, access complications, peripheral embolization, stent migration, stent fragmentation, infection, and PAU progression. The most common complication specifically related to TEVAR repair of thoracic PAU is access complications with a reported rate of 16% (26 of 161).[24] Endoleaks can be observed at the time of treatment or noted with follow up imaging. Proximity to aortic arch branches, mesenteric, and renal vessels increases their probability of endoleaks. The number of stent-graft pieces used to cover the PAU also increases their likelihood. Early endoleaks were observed in 19% of patients with thoracoabdominal PAU included in the study by Geisbusch et al. However, this study included PAU found in conjunction with multiple other aortic pathologies including AD, associated aneurysms, and aortic fistulas.[19] Others describe a less frequent rate of endoleaks. D'Annoville et al. identified endoleaks in 8% of cases (25 of 310).[24] In this large meta-analysis, type I ($n = 9$), II ($n = 10$), and III or IV ($n = 6$) endoleaks were observed. During follow-up, new endoleak and ulcer recurrence were observed in 5.4% and 4.5%, respectively, requiring a new aortic endovascular procedure in 50% ($n = 10$).[24] Dalainas et al. demonstrated a 5.5% rate of endoleak after endovascular repair of both thoracic and infrarenal PAU. The only endoleak experienced in this study was associated with covering a pseudoaneurysm found in association with a PAU at the time of presentation.[21]

Several predictors of treatment failure have been identified. As with rupture risk, Demers et al. identified increased aortic diameter adjacent to the PAU as a risk factor for treatment failure.[23] PAU in the presence of other aortic pathology is also a risk for treatment failure. PAUs have also been described complicating aneurysm repair. Some groups have elected to treat PAU with coil embolization in addition to stent-graft repair with the intention of eliminating the risk of type I endoleak, but only a handful of case reports describe such treatment. Patients presenting with PAU and associated IMH were more likely to have treatment failure defined as the need for open or endovascular aortic re-intervention, aortic rupture, or aortic-related death.[11,12] Finally, late mortality correlated with urgent or emergent endovascular repair.[11]

SUMMARY

Despite being rare compared to the other AAS pathologies, PAUs are important aortic lesions. With the aging population and improvements in vascular imaging, their observed frequency will likely increase; and the presence of a bland PAU in an asymptomatic patient is not necessarily predictive of an evolving vascular pathology. However, those presenting with symptoms and other associated aortic pathologies in addition to a PAU

are at increased risk for poor outcomes, even after intervention. The onset of endovascular stent-grafting has provided patients with PAU, whom would have not been eligible for open repair, which is an opportunity for therapeutic intervention. Endovascular repair has also become the preferred treatment for PAU.

CONCLUSION 1093
TIBIAL ARTERY AND PEDAL ARTERY ANEURYSMS 1093

Aneurysms occurring in the arteries of the lower extremity are second in frequency only to aneurysms of the infrarenal aorta and iliac arteries. Historically, lower extremity aneurysms were typically mycotic, syphilitic, or traumatic in origin. However, most aneurysms in the femoral, popliteal, and tibial arteries are currently either degenerative aneurysms or posttraumatic pseudoaneurysms related to catheterization or instrumentation. True aneurysms occur far more commonly in men than in women, at a ratio of 30:1.[1,2] Furthermore, true aneurysms of the femoral or popliteal arteries are often associated with aortic aneurysms and aneurysms in the contralateral lower extremity. The association with aortic aneurysms ranges from 50% to 90% for femoral aneurysms,[2-6] from approximately 30% to 50% for popliteal aneurysms, and as high as 70% for bilateral popliteal aneurysms.[1,2,7,8] Bilaterality is also common, occurring in approximately 25% to 50% of femoral aneurysms and 50% to 70% of popliteal aneurysms.[2-4,7,9] Conversely, up to 14% of men with aortic aneurysms have been found to have femoral or popliteal aneurysms, but this combination is a rare finding in women.[6] Additional imaging, such as duplex ultrasound (DUS), may therefore be indicated to evaluate for concomitant aneurysmal disease when an aortic or lower extremity aneurysm is diagnosed.

Aneurysms in the lower extremity are of clinical significance because of their potential to cause limb-threatening ischemia. More rarely, such aneurysms can rupture, particularly false aneurysms of the common femoral artery. Treatment is preferable when they are asymptomatic—hence the importance of detection and a thorough knowledge of the association with other aneurysms. Symptomatic true aneurysms have a much higher incidence of limb loss because of the prevalence of embolization of thrombus from within the aneurysm sac to more distal arteries. Clinicians must always consider embolization from an aneurysm when evaluating lower extremity ischemia and when planning

interventions. There have been significant changes in the treatment of lower extremity aneurysms, along with additional treatment options, including various endovascular therapies.

FEMORAL ARTERY ANEURYSMS

Femoral artery aneurysms occur primarily in the common femoral artery and less commonly in the profunda femoris and superficial femoral arteries. The common femoral artery (CFA) can be the site of true aneurysms and of pseudoaneurysms related to prior instrumentation or previous revascularization procedures. True aneurysms are less common and are often associated with popliteal artery and aortic aneurysms.[10] In any artery, an aneurysm is defined as a focal, fusiform dilation of the artery to 1.5 times the normal diameter of the adjacent segment of artery.[11] The normal size of a CFA in men is approximately 1.0 and 0.8 cm in women.[12] Repair has been considered clinically indicated for aneurysms more than 2.5 cm in diameter, but data from 2014 has 3.5 cm as an indicated diameter for repair.[13,14]

Pseudoaneurysm of the CFA usually appears as a saccular outpouching of the vessel and has a narrow neck representing a defect in the vessel wall due to instrumentation. The pseudoaneurysm is actually a rim of fibrous tissue containing thrombus and arterial flow in continuity with a defect in the CFA. Iatrogenic pseudoaneurysms are addressed separately from true aneurysms.

True Aneurysms

Epidemiology

In a large study of true aneurysms of the femoral arteries, 57% were in the CFA, 26% in the superficial femoral artery (SFA), and 17% in the profunda femoral artery (PFA); 26% were bilateral and 48% were associated with additional aneurysms.[10] They are found predominantly in older men (70 years or older) and are associated with smoking and hypertension.[3] The majority are degenerative, but they have also been reported with atriomegaly and other conditions such as Behçet disease, Parkes Weber syndrome, and Wegener granulomatosis.[15-20]

In addition, a recent study on true aneurysms in the femoral arteries by Lawrence et al., in which eight institutions pooled data in the Vascular Low Frequency Disease Consortium, showed similar results, with a higher percentage (81%) in the CFA, and lower percentage (14%, 5%) in the SFA and PFA, respectively,.[13]

Clinical Presentation and Diagnosis

Isolated true femoral aneurysms are asymptomatic in 30% to 40% of patients, and are often found on physical examination or DUS scan. Another 30% to 40% cause localized pain and tenderness or compressive symptoms, resulting in neuropathic pain or leg edema. The most common presentation in up to 65% of cases is lower extremity ischemia, including claudication or critical ischemia resulting from embolization.[2,3,10] Rupture is a rare occurrence—occurring in approximately 4% of cases.[21]

Duplex ultrasound is the modality of choice for diagnosis and assessment of femoral artery aneurysms. It is cost-effective and accurate. Computed tomography angiography (CTA) and magnetic resonance angiography (MRA) can also be used and may be of additional value in the planning of endovascular repair and when specific measurements are needed to identify normal artery proximal and distal to the identified aneurysm. CTA and MRA can also be useful to look for additional aneurysms such as aortic, iliac artery, contralateral femoral artery, and popliteal artery aneurysms (PAAs).

Indications for Treatment

All symptomatic femoral aneurysms should be treated to prevent embolization, thrombosis, worsening of local compressive symptoms, and rupture. Although the natural history of asymptomatic femoral artery aneurysms is unclear, it had previously been suggested that the repair of asymptomatic femoral aneurysms more than 2.5 cm diameter is indicated in "good-risk" patients.[14] This suggestion is based on one of the largest reported series of 172 femoral aneurysms in 100 patients; 40 were asymptomatic, and 105 small (<2.5 cm) aneurysms were managed nonoperatively.[2] In the more recent study by Lawrence et al., it was noted that acute complications such as ischemia or rupture did not occur in patients with asymptomatic femoral artery aneurysms less than or equal to 3.5 cm. The size threshold for elective repair may be reduced in the presence of intraluminal thrombus.[3] Smaller asymptomatic aneurysms can be managed with observation by duplex scan and do not require intervention unless they expand or become symptomatic.[13]

Surgical Treatment

Treatment of CFA true aneurysms usually consists of open repair, in which the aneurysm is excluded with an interposition graft. To prevent injury to surrounding structures that may be adherent to it, the aneurysm sac is usually not resected. The preferred graft material is synthetic—either polytetrafluoroethylene (PTFE) or Dacron.[3,10,14] The prosthetic grafts are better size matches and have equivalent or better patency rates than vein grafts in this positon.[3] Preoperative assessment of the aorta and the iliac, superficial femoral, and popliteal arteries should be performed to detect additional aneurysmal disease. In both elective procedures and emergency procedures for rupture, open repair can be achieved with minimal morbidity and excellent long-term patency.[3,10,14] Proximal control can usually be achieved with a clamp on the distal external iliac artery or proximal CFA via a longitudinal groin incision. In cases of large aneurysms, proximal control can be achieved with balloon occlusion placed via the contralateral femoral approach. If this is not possible, a suprainguinal retroperitoneal exposure of the external iliac artery may rarely be required to obtain proximal control of a large, proximal CFA aneurysm.

An aneurysm confined to the CFA can be treated with a short interposition graft (Fig. 83.1). An aneurysm extending into the PFA or SFA requires more complex reconstruction with an interposition graft from the proximal CFA to the PFA

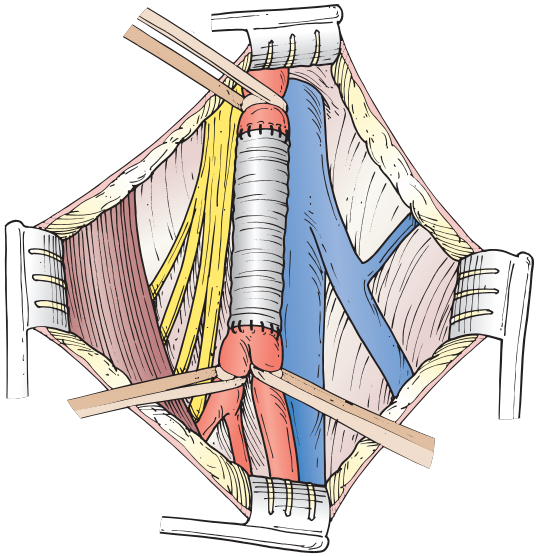

Figure 83.1 Surgical repair of an aneurysm confined to the common femoral artery can be accomplished with a simple interposition graft. (From Ouriel K, Rutherford RB, eds. *Atlas of Vascular Surgery: Operative Procedure.* Philadelphia: WB Saunders; 1998.)

or SFA, and a jump graft to the other femoral branch (Fig. 83.2). It is important to preserve flow to the PFA to prevent future severe ischemia.[14]

Endovascular Treatment

Endovascular treatment of CFA aneurysms has largely been limited to emergency situations or performed as part of a hybrid approach with an open surgical procedure. Bakoyiannis et al.[22] described such a procedure using a stent-graft to exclude a distal external iliac artery aneurysm and a traditional Dacron graft for the femoral portion of a large aneurysm extending from the distal external iliac artery into the common femoral artery. Percutaneous endovascular treatment of a ruptured femoral artery aneurysm has also been described.[21] Contralateral femoral access is often required in these cases for delivery of the stent-graft. However, caution should be used in the consideration of placement of a stent-graft in the CFA, particularly when it crosses the inguinal ligament, because of possible stent fracture or dislodgement in this location.

Endovascular techniques can be used as adjuncts to open procedures. For example, proximal control can be obtained via a balloon placed under fluoroscopic guidance through the opened aneurysm sac in standard surgery,[23] or percutaneously via the contralateral CFA when necessary.

Pseudoaneurysms

Pseudoaneurysms in the CFA occur most commonly from iatrogenic causes such as instrumentation for cardiac or peripheral catheterization and after open reconstructions.[14,24] Iatrogenic false aneurysms can be treated with open surgery or ultrasound-guided therapy, or with observation alone if they are small in diameter. Pseudoaneurysms may also occur as a result of infection

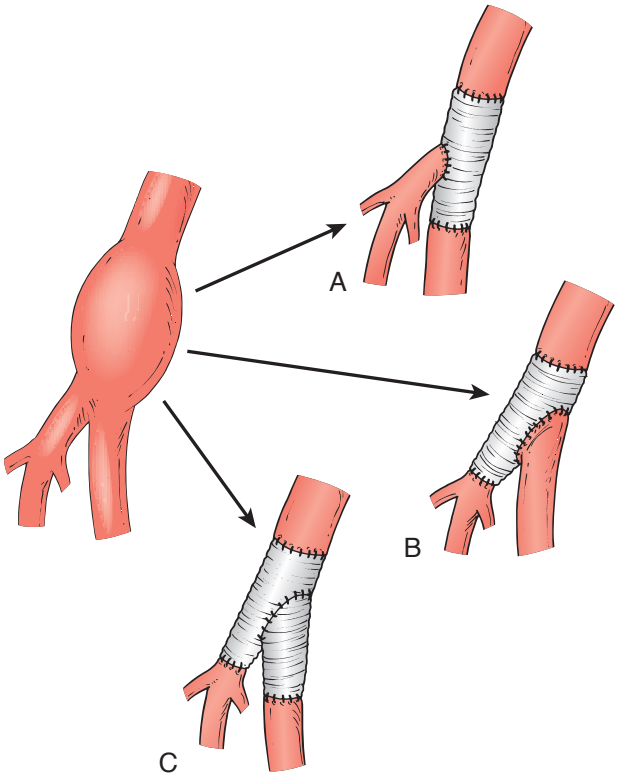

Figure 83.2 Surgical reconstruction of a femoral artery aneurysm extending beyond the common femoral artery bifurcation can be performed with different configurations, depending on local anatomy. The interposition graft can be placed between the common femoral and either the superficial femoral artery (A) or the profunda femoris artery (B) with reimplantation of the other branch into the side of the graft. (C) If the origin of the artery to be implanted is diseased or not long enough, a short interposition graft can be used. (From O'Hara P. Treatment of femoral and popliteal artery aneurysms. In: Zelenock GB, Huber TS, Messina LM, et al., eds. *Mastery of Vascular and Endovascular Surgery.* Philadelphia: Lippincott Williams & Wilkins; 2006.)

that causes focal erosion of the arterial wall, usually from external sources such as contaminated needles used during intravascular substance abuse. The management of infected pseudoaneurysms is difficult and requires ligation either alone or with extraanatomic bypass.[25] Infected aneurysms are discussed in detail in Chapter 47. Management of anastomotic pseudoaneurysms is discussed in Chapter 48.

Clinical Findings and Natural History

The most common clinical manifestation of a femoral pseudoaneurysm is a painful pulsating mass in the groin, usually with an associated hematoma. Femoral bruits are heard frequently, and if an arteriovenous fistula is present, the bruit has a characteristic continuous to-and-fro quality. Patients may also complain of femoral neuropathic pain, paresis of hip flexion, or edema from compression of adjacent structures. Progressive enlargement can result in overlying skin ischemia and necrosis. In our experience, distal embolization or limb ischemia is rare. Rupture can lead to cardiovascular collapse and death from hemorrhagic shock and is a surgical emergency.[26] Significant bleeding can occur without overt clinical findings if the initial

puncture is in the external iliac artery or through the inguinal ligament, and results in occult bleeding into the retroperitoneal space.

Aneurysm size and the presence of anticoagulation determine which pseudoaneurysms require treatment. Most aneurysms less than 2 or 3 cm in diameter undergo spontaneous thrombosis and may be safely observed with periodic DUS examinations. Continued anticoagulation therapy greatly decreases the likelihood of spontaneous closure of such a pseudoaneurysm.[27,28] In one prospective series, 18 pseudoaneurysms were identified after 1838 femoral catheterizations over an 8-month period (0.98% incidence). Aneurysms that were less than 1.8 cm in diameter and causing no symptoms were observed. Surgical repair was carried out if the aneurysms enlarged by 100% or did not close within 2 months. Of the 16 that were managed expectantly, half underwent spontaneous thrombosis and the other half required repair. Although the difference did not reach statistical significance, the likelihood of spontaneous closure was lower for aneurysms more than 1.8 cm in diameter, and no aneurysm closed spontaneously in the presence of continued anticoagulation, regardless of size.[29]

Diagnosis

Duplex ultrasound is the preferred imaging method. The sensitivity and specificity of DUS for femoral false aneurysms are 94% and 97%, respectively.[30] Duplex ultrasound also provides important information on diameter, morphology, and anatomy of the neck and location of the femoral artery defect. On B-mode imaging, an aneurysm appears as a characteristic echolucent mass adjacent to the femoral artery and a channel, usually narrow, with arterial flow into the mass (Fig. 83.3).

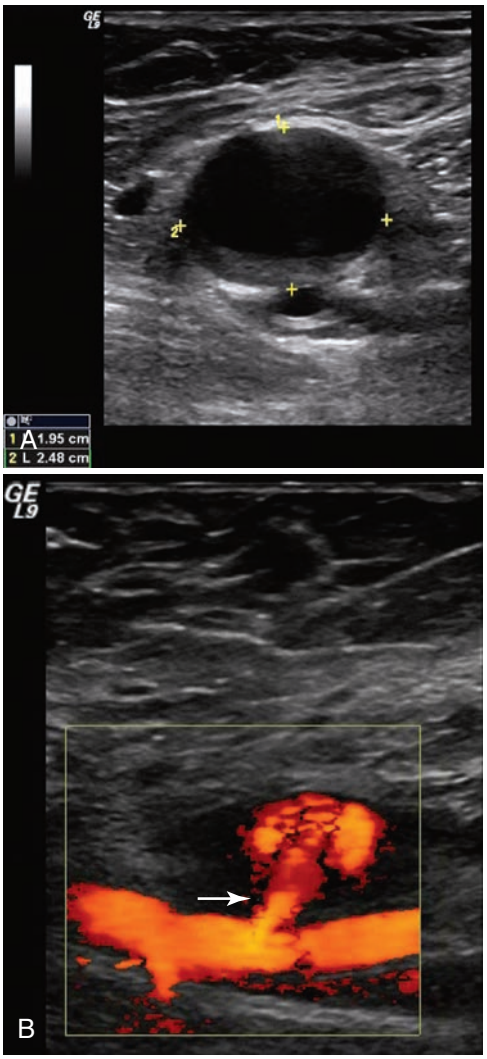

Figure 83.3 (A) Duplex ultrasound of a femoral false aneurysm in B mode demonstrating a large echolucent mass anterior to the femoral artery. The *cursor* marks the dimensions of the aneurysm cavity. (B) Color-flow imaging demonstrating blood entering the aneurysm sac via a relatively long channel or "neck" *(arrow)*, arising from the femoral artery.

Treatment

Ultrasound-Guided Compression

Compression of false aneurysms to induce thrombosis was proposed as a less invasive alternative to surgery in 1991.[31] Duplex ultrasound is used to locate the aneurysm, and suitable pressure is applied with the transducer to stop flow within the aneurysm cavity while maintaining flow in the adjacent femoral artery. Excessive pressure can result in femoral artery thrombosis.[32] Compression is maintained for 10 to 20 minutes, after which time flow is reassessed. If flow persists, the procedure is repeated one or more times until flow within the aneurysm cavity is noted to have stopped. The patient is kept on bed rest for 6 hours, being reevaluated with DUS at 24 and 48 hours after the procedure to rule out recurrence. If the procedure is performed in the outpatient setting, the patient may be discharged home after the initial 6 hours.

Success rates for ultrasound-guided compression (UGC) range from 66% to 86%, with required compression times averaging 30 to 44 minutes.[31-33] Recurrence has been reported in 4% of cases.[32] The presence of anticoagulation greatly reduces the likelihood of success to less than 40%.[32-34] UGC is contraindicated in patients with ischemic skin changes or infection, and when the puncture site originates above the inguinal ligament. Moreover, UGC is not usually possible in patients with severe pain and very large hematomas. Imaging and compression are technically more difficult in obese patients, thus decreasing the likelihood of success. Aneurysm rupture, femoral vein thrombosis, limb ischemia from femoral arterial thrombosis, and hypotension from vasovagal events are all potential complications that have occurred in 2% to 4% of cases.[32,33,35]

From a practical standpoint, UGC has the disadvantage of being time-consuming and placing demands on the vascular laboratory, time, equipment, and personnel. Operator and patient fatigue and management of the often significant pain that patients experience during compression are common problems.[36] The use of mechanical compression devices can obviate some of these issues, but requires a cooperative and immobile patient and repeated reevaluation during compression.[37] Such devices offer little advantage and have not generally been widely accepted.

Ultrasound-Guided Thrombin Injection

Angiographically directed thrombin injection via percutaneous access into the aneurysm cavity to induce immediate thrombosis was first described by Cope et al.[38] more than 20 years ago. Kang et al.[39] modified the technique by performing direct percutaneous aneurysm puncture under duplex ultrasound guidance. Thrombin directly converts fibrinogen to fibrin, thereby leading to immediate clot formation and "short-circuiting" the upstream mechanism of the coagulation cascade, where heparin and warfarin interact. Consequently, thrombin injection is effective even in patients receiving anticoagulation. Bovine and human thrombin are commercially available in powder form that is reconstituted in normal saline immediately before use.

Ultrasound-guided thrombin injection (UGTI) is quick, simple, and relatively painless. Duplex ultrasound is used to identify the aneurysm cavity. After infiltration with local anesthetic, the cavity is punctured with either a 22-gauge catheter or a 25-gauge hypodermic needle. Spinal needles can be used for deeper aneurysms. Identification of the needle or catheter within the aneurysm sac is a critical step (Fig. 83.4) and can be facilitated with the use of a commercially available echodense needle.[40-42] The needle is filled with thrombin, which when inserted causes a small clot to form at the needle tip that is readily visualized on ultrasound.[39] Once proper positioning of the needle is confirmed, thrombin (1000 IU/mL) is injected slowly through a 3-mL syringe for a period of about 10 to 15 seconds, until flow within the cavity ceases. In our experience and that of others, a dose of approximately 1000 units of thrombin is required to induce thrombosis. It is important to inject slowly and to stop immediately once thrombosis has occurred to minimize the chance of thrombin entering the circulation. A second injection is sometimes required.[39] Patients are given bed rest for 1 hour. Duplex ultrasound is repeated 24 hours later to confirm permanent thrombosis of the aneurysm. UGTI has a success rate of 96% to 100%.[40,43-45] Second injections of thrombin are necessary in up to 7% of cases to achieve complete thrombosis.[45]

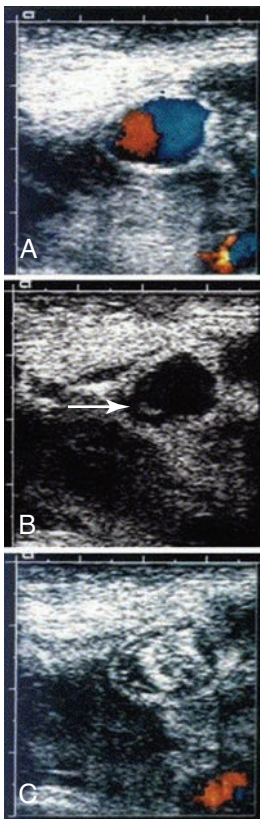

Figure 83.4 Duplex Ultrasound of a Femoral Pseudoaneurysm. (A) Color-flow image demonstrating typical swirling flow in the pseudoaneurysm cavity. (B) Image taken 18 seconds later with color flow turned off shows the tip of a 22-gauge needle in the left lower portion of the pseudoaneurysm *(arrow).* After placement of the needle, color flow is turned back on and thrombin is injected. (C) Color-flow image demonstrating that the pseudoaneurysm cavity is completely filled with echogenic thrombus. (From Kang SS, Labropoulos N, Mansour MA, Baker WH. Percutaneous ultrasound guided thrombin injection: a new method for treating postcatheterization femoral pseudoaneurysms. *J Vasc Surg.* 1998; 27:1032-1038.)

Most writers prefer to use UGTI to treat pseudoaneurysms and to use UGC only in patients in whom thrombin products are contraindicated. Contraindications to bovine thrombin include known allergy, infection, and pregnancy. A relative contraindication to UGTI is a short, wide channel or "neck" of flow into the pseudoaneurysm. In these cases there can be a higher incidence of embolization of thrombus into the CFA with thrombin injection. An update of a Cochrane review compared multiple no-surgical treatments, including ultrasound-guided compression, blind compression, and ultrasound-guided thrombin injections. Compression was effective in achieving pseudoaneurysm thrombosis. Ultrasound-guided application did not confer an additional benefit. Percutaneous thrombin injection was more effective than a single session of ultrasound-guided compression within individual randomized controlled trials.[46]

Open Surgical Repair

Open surgical repair is usually reserved for ruptured pseudoaneurysms, failures of or contraindications to UGC or UGTI, overlying skin ischemia, or pseudoaneurysms associated with an arteriovenous fistula. Direct repair with polypropylene sutures or patch angioplasty is an effective method of repair (Fig. 83.5). However, complications are not infrequent, with wound complications in up to 4% to 8% of cases and an associated mortality rate of 2.9% related to the underlying cardiac disease for which the catheterizations are often performed.[46,47] In high-risk cases, open repair can be performed with local anesthesia and the use of balloon occlusion for proximal control of the external iliac artery. If there is extensive damage to the femoral arterial wall, patch angioplasty with autologous or synthetic tissue may be required. Autologous tissue is preferred, because pseudoaneurysms may be associated with latent infections.

Superficial Femoral Artery Aneurysms

Isolated aneurysms of the SFA are rare and considerably less common than those of the common femoral artery. They more commonly manifest as proximal extensions of popliteal artery aneurysms. An extensive review of all language literature by Leon et al.[48] identified 61 reported cases of isolated SFA

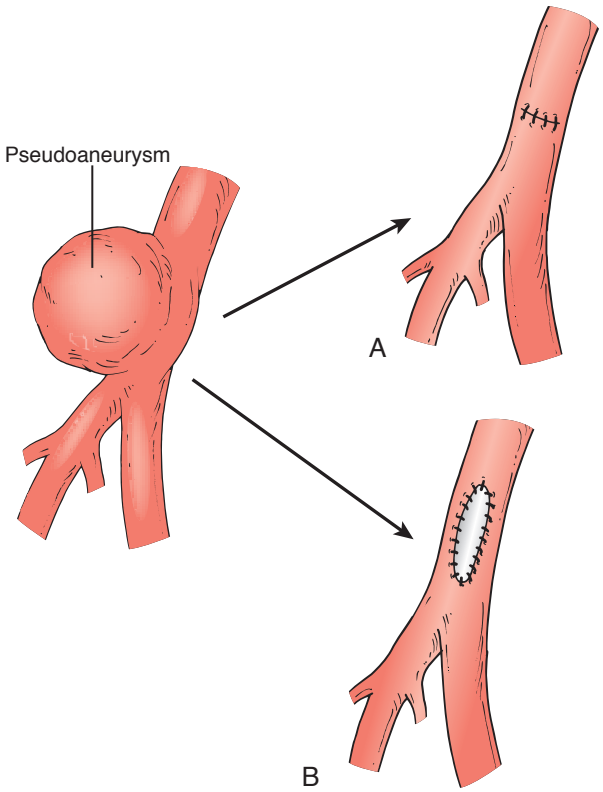

Figure 83.5 Surgical Repair of a Femoral Artery False Aneurysm. After proximal and distal control is obtained, the sac is opened and the arterial defect exposed. Repair can be accomplished in most cases by direct suture repair (A), although patch angioplasty may occasionally be required (B). (From O'Hara P. Treatment of femoral and popliteal artery aneurysms. In: Zelenock GB, Huber TS, Messina LM, et al., eds. *Mastery of Vascular and Endovascular Surgery.* Philadelphia: Lippincott Williams & Wilkins; 2006.)

aneurysms. They occurred most commonly in elderly men (87%), with an average age of 75.7 years. Most were located in the middle third of the artery and were large at presentation, with a mean diameter of 8.4 cm at diagnosis. Such a large size is likely related to the deep anatomic location of the distal SFA, which precludes early detection. The most common mode of manifestation was a pulsatile tender thigh mass (59%) associated with localized pain. Rupture was more common manifestation (42%) than distal ischemia (13%), and repair most commonly consisted of interposition graft or exclusion with bypass. Limb salvage rate is reported at greater than 90%. Endovascular repair was reported in three cases in this review.[48]

Because of the rare nature of this entity, the natural history is not well known, and no specific aneurysm diameter has been identified at which the incidence of complications increases. SFA aneurysms of 2.5 cm or more in diameter, particularly those that are known to have grown over time, are usually repaired. Duplex ultrasound scan is an accurate imaging modality for following smaller asymptomatic aneurysms.

Prior to surgical treatment, arteriography is performed to evaluate the inflow and outflow vessels. Either saphenous vein or prosthetic graft can be used. Prosthetic grafts work well in the groin or thigh and can usually be matched to the diameter of the artery. Vein grafts are preferred for any reconstruction crossing the knee joint, which may be necessary with distal occlusive disease or if the aneurysm is being treated in conjunction with a PAA. Exposure is obtained in either the groin or midthigh or at both sites, depending on the extent of the aneurysm. The surgical approach is nearly identical to that for popliteal aneurysm repair. Focal aneurysms are treated by opening of the sac, evacuation of thrombus, and creation of an end-to-end interposition graft. For more extensive aneurysms, proximal and distal ligation can be performed, followed by placement of a bypass graft. Although long-term follow-up is not available, Rigdon et al.[49] reported a limb salvage rate of 94% with no deaths, whereas Jarrett et al.[50] reported successful bypass in 11 cases with no mortality. Two patients underwent primary amputation for unsalvageable ischemia at initial evaluation.

Perini et al. retrospectively reviewed surgical outcomes in multiple centers over a 10-year period for patients treated for isolated superficial femoral artery aneurysms and noted 5-year survival, limb salvage, and graft patency rates of 62%, 88%, and 85%, respectively. Mean follow-up was 41 months.[51]

Although endovascular repair has been reported in only a few instances of isolated SFA aneurysms, it is likely that percutaneous repair will become more prevalent as the profile of devices is reduced and they are easier to deploy. However, long-term data on the effectiveness of this treatment method are not available at this time.

Profunda Femoral Artery Aneurysms

Degenerative aneurysms of the PFA are extremely rare, representing less than 3% of all femoral artery aneurysms (Fig. 83.6). Most cases are unilateral, although bilateral aneurysms have also been reported.[52] Synchronous aneurysms are common and occur in up to 70% of cases, with popliteal aneurysms being the most common.[53,54] They can manifest as either rupture or limb-threatening ischemia from distal embolization of thrombus, particularly if there is concomitant SFA occlusive disease. Like SFA aneurysms, PFA aneurysms are often of large size at presentation because of their deep anatomic location.[55] Repair is always recommended because of the high rate of complications and unknown natural history of asymptomatic PFA aneurysms.

Surgical repair is carried out through a vertical groin incision. In most cases, aneurysmectomy within an interposition graft of either saphenous vein or prosthetic material is preferred. In the construction of interposition grafts, large branches of the profunda femoral artery should be preserved whenever possible. Dissection is usually started at the CFA bifurcation and extends inferiorly and slightly laterally over the course of the deep femoral artery. The SFA is retracted medially, and as the dissection extends more distally, the sartorius and rectus femoris muscles are reflected laterally. Larger crossing branches of the deep femoral vein are encountered and must be carefully divided and suture-ligated. Branches of the femoral nerve are also encountered and must be preserved and protected from injury by self-retaining retractors or cautery. Gentle dissection is necessary to avoid troublesome venous injury. Proximal control is usually obtained at the level of the CFA, although in instances of rupture with massive hematoma in the groin, control of the distal external iliac artery may be necessary. Distal arterial control can be

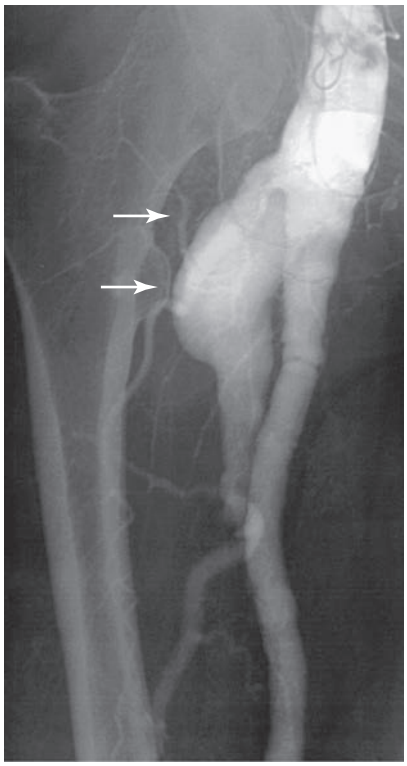

Figure 83.6 Arteriogram of a large symptomatic aneurysm of the profunda femoris artery *(arrows)*. The aneurysm originates at the origin of the profunda femoris artery, and there is ectasia in the common femoral and superficial femoral arteries.

accomplished with silicon rubber vessel loops or balloon catheter occlusion.

Although graft replacement is generally preferred, simple ligation may be a reasonable treatment for aneurysms confined to the distal branches of the deep femoral artery.[56] Proximal PFA ligation may also be reasonable in patients with rupture, especially when the SFA is patent; however, such ligation may put the patient at risk for future limb ischemia and amputation.[54] In highly selected cases of aneurysms involving distal branches of the PFA, embolization may be a reasonable nonsurgical alternative.[57,58]

Endovascular management of PFA aneurysms has been reported. Stent-grafts have been used to treat three cases of PFA pseudoaneurysms after instrumentation or penetrating trauma, with good short-term results.[59] This approach may be effective in stable patients without major compressive symptoms. Coil embolization has also been shown to be successful treatment, particularly if the aneurysm involves distal branches of the main PFA.[58] Embolization of the main PFA has been reported via a contralateral approach and may be a useful alternative if the SFA is patent.[60]

PERSISTENT SCIATIC ARTERY ANEURYSM

Persistent sciatic artery (PSA) is a rare vascular anomaly present in 0.01% to 0.05% of the population. Embryonic blood flow in the lower extremities is provided by the sciatic artery originating from the umbilical artery. As the external iliac artery system develops by gestational month 3, the sciatic artery regresses and becomes a small part of the inferior gluteal artery. When it fails to regress, the remnant is called a *persistent sciatic artery*.

It is prone to aneurysmal degeneration, potentially leading to distal ischemia, sciatic neuropathy, and rupture. When present, most PSAs involve the dominant limb arteries of the lower extremity, with aneurysm formation occurring in up to 40% of cases. The femoral artery is often hypoplastic. The patient with PSA aneurysm may present with an enlarged buttock mass, with local compressive symptoms and distal ischemia. An interposition graft is the preferred method of repair.[61] Because of potential damage to the adjacent sciatic nerve, exposure and surgical dissection of the aneurysm are not recommended.

Endovascular stent placement has been reported as an effective method of repair for PSA aneurysm, provided that there are no significant associated compressive symptoms.[62] Embolization of a ruptured PSA aneurysm with Amplatzer plugs (St. Jude Medical Inc., St. Paul, Minnesota) in a hemodynamically unstable patient has also been reported. This maneuver successfully controlled the hemorrhage but was complicated by footdrop, likely secondary to sciatic nerve ischemia and a buttock abscess.[63]

POPLITEAL ARTERY ANEURYSMS

The popliteal artery, a continuation of the superficial femoral artery in the thigh, extends from the adductor canal to the origin of the anterior tibial artery below the knee. The definition of what constitutes a popliteal artery aneurysm varies in the contemporary literature. The normal diameter of the popliteal artery varies with the size and gender of the patient, ranging from approximately 0.5 to 1.1 cm.[11,64] Anatomic studies have now shown that the popliteal artery itself differs in diameter from proximal to distal, with the proximal portion more closely approximating the diameter of the SFA and the distal popliteal artery tending to be smaller.[65] Most PAAs appear to occur in the proximal part or midportion of the artery. According to 1991 suggested standards, an aneurysm may be considered to be present if the total enlargement is 1.5 times the diameter of a normal adjacent segment of artery.[11] Other writers consider a diameter of 1.5 cm or greater in the "average" patient to be an aneurysm, although in clinical practice most surgeons use 2 cm as the threshold diameter.

Epidemiology

PAAs are rather rare in the general population, although they are the most common peripheral artery aneurysms, accounting for at least 70% of them.[66] PAAs are found almost exclusively in men. One study of hospitalized patients identified the incidence of femoral or popliteal artery aneurysms to be 7.4 per 100,000 men and only 1.0 per 100,000 women.[66] Another study that screened more than 1000 men between the ages of 65 and 80 years in the United Kingdom revealed a prevalence

of only about 1%.[67] About 50% of patients have bilateral PAAs, and 30% to 50% of patients may have an associated abdominal aortic aneurysm (AAA).[7,68] On the contrary, less than 15% of all patients with AAAs have coexisting PAAs.[6] In patients treated for isolated popliteal aneurysms, the likelihood of development of another aneurysm at a remote site over a 10-year period is estimated to be as high as 50%, thus mandating careful scrutiny of all patients upon initial encounter and lifelong surveillance after treatment.[69]

Pathogenesis

With the exclusion of trauma and rare congenital disorders, the majority of PAAs are considered to be true aneurysms, involving all layers of the arterial wall. Many writers in the past regarded PAAs as atherosclerotic, but most PAAs are degenerative. Jacob et al.[70] identified disruption and fragmentation of the elastic lamellae in the walls of PAA specimens in comparison with normal popliteal arteries. In addition, they identified decreased numbers of vascular smooth muscle cells in the walls and an increased expression of molecules linked to apoptosis. A significantly greater number of $CD68^+$ macrophages and $CD3^+$ T cells in the media of the PAA wall specimens were detected than in normal arteries. The researchers attribute the aneurysm formation to a loss of the mechanical integrity of the popliteal artery wall and the altered balance between the production and degradation of the vascular wall constituents.[70]

The anatomic location of the popliteal artery at a high flexion point and the encountered repetitive stresses of the artery in this location may be additional causative factors for PAAs.

Natural History

The mean growth rate for PAAs is 1.5 mm/year for PAAs smaller than 20 mm, 3 mm/year for PAAs 20 to 30 mm, and 3.7 mm/year for those larger than 30 mm.[71] Hypertension is the most common risk factor associated with increased PAA growth. In contrast to AAAs, PAAs rarely rupture, with a reported incidence of only 2.5%. In patients in whom rupture occurs, there is a very high rate of limb loss.[72] When PAAs are symptomatic, they more typically manifest as acute or chronic ischemia due to distal embolization or thrombosis. Although it may be difficult to determine the actual percentage of patients with PAAs who become symptomatic over time, several series of observed patients report a high incidence of thromboembolic complications. Szilagyi et al.[73] reported that over a 5-year period, only 32% of observed (nonoperated) patients with PAA remained without lower extremity complications. Dawson et al.[69] reviewed 71 PAAs, 25 of which were initially treated nonsurgically. Complications developed in 12 of the 21 asymptomatic popliteal aneurysms (57%) and in two of the four symptomatic aneurysms (50%). The probability of development of complications increased with time to 74% within 5 years. Lowell et al.[74] identified the presence of aneurysmal thrombus and poor distal runoff as risk factors for ischemic complications among asymptomatic PAAs.

Clinical Findings

Although a PAA may be found incidentally, more than half of patients with the lesions typically have symptoms at initial presentation.[75-78] Lower extremity ischemia is the most common presenting symptom. The ischemia is usually secondary to embolization or thrombosis, and patient symptoms can range from being essentially none or minimal claudication to acute limb-threatening ischemia. Patients may present with chronic ischemic symptoms similar to those of atherosclerotic occlusive disease when chronic emboli occlude the outflow vessels and collaterals develop prior to thrombosis of a PAA. It is not uncommon for patients to have occlusion of multiple tibial vessels secondary to chronic emboli. The patient with chronic symptoms and a nonpulsatile popliteal mass should be evaluated for a thrombosed PAA.

Less frequently, patients present with compressive symptoms, which may include vein (leg swelling, deep venous thrombosis) or nerve compression as a result of the mass effect associated with large aneurysms. Rupture is an unusual complication that occurs at a rate of 0% to 7% in published series,[1] with an average of about 2%. Patients with rupture most commonly are seen initially with severe swelling and pain in the popliteal space and distal limb edema. Approximately 14% have an associated popliteal vein thrombosis. Hemorrhagic shock is rare, probably because of containment of the hematoma by the small confines of the popliteal space.

Diagnosis

Ideally the diagnosis of PAA should be made before the onset of limb-threatening complications. The outcomes of surgical treatment are best in asymptomatic patients and progressively worse in those with either chronic ischemic symptoms or advanced acute limb ischemia.[7] The diagnosis of PAA is suspected any time a prominent or widened popliteal artery pulse is felt on physical examination, which is especially true if it can be easily felt with one hand. A PAA is more likely to be found in men with known AAA, femoral artery aneurysm, or contralateral PAA. Therefore special attention should be given to detecting possible PAAs in these patients. Likewise, a prominent popliteal pulse with gangrene of the ipsilateral foot in a nondiabetic man should trigger the diagnosis of possible PAA. A nonpulsating popliteal mass in a patient with ischemic symptoms should lead one to suspect a possible thrombosed PAA. Physical examination has, however, been proven unreliable, with both false-positive and false-negative results.[79]

Imaging

The main imaging modalities used for the diagnosis of PAA are DUS, CTA, and MRA. Occasionally a PAA can be seen on a plain radiograph as a radiopaque, calcified, enlarged aneurysm perimeter. Digital subtraction angiography (DSA) may identify a PAA, but its results can be misleading because of nonvisualization of mural thrombus or an overlooked thrombosed PAA. Although not a good first diagnostic test,

DSA can be very useful for planning of revascularization once the diagnosis is confirmed. Duplex ultrasound has the advantage that neither ionizing radiation nor contrast agents are required. It can be accurate in detecting PAA, thrombus burden, and patency of outflow vessels.[80,81] Duplex ultrasound is also useful in detecting PAAs when DSA reveals an occluded popliteal artery and PAA is suspected.

CTA is a very useful and accurate imaging modality for the diagnosis and evaluation of PAAs. Disadvantages include the use of ionizing radiation and intravenous contrast agent, which limits its use in patients with renal insufficiency and severe contrast allergy. CTA can accurately demonstrate the size, thrombus burden, and inflow and outflow vessels. It can also be extremely helpful in the planning of either open or endovascular repair of a PAA.

In addition to not utilizing radiation, MRA is a very accurate imaging modality for PAA. Its use is limited to patients without pacemakers and somewhat limited to those with advanced renal failure. MRA can give good information on the inflow and outflow vessels, as well as the thrombus burden, as long as the cross-sectional images are evaluated.

DSA is used in conjunction with the aforementioned radiologic examinations to determine inflow and outflow vessel patency and for operative planning. It is the "gold standard" for determining the status of the outflow vessels. In most institutions, CTA and MRA, particularly with three-dimensional reconstructions, may provide very accurate information about the runoff vessels. However, if there is any question about the outflow or distal perfusion, DSA should be obtained prior to any intervention.

Indications for Treatment

Although it is generally accepted that all symptomatic PAAs and those 2.0 cm or more in diameter should be considered for treatment in medically suitable candidates, some controversy exists. Treating asymptomatic patients with PAAs 2.0 cm or larger may be justified, given the associated 30% to 40% risk for development of acute ischemic complications and the subsequent high risk of limb loss.[1,73,82,83] Some writers suggest that all popliteal aneurysms should be repaired once found, regardless of size, because of the high complication and limb loss rates.[83-85] Ascher et al.[83] suggested, in a review of 34 popliteal aneurysms, that a higher incidence of embolic and thrombotic complications may be associated with smaller PAAs, although only two in their series were less than 2 cm in diameter. Those who advocate repairing all PAAs, regardless of size and before limb-threatening symptoms develop, quote high limb salvage and patency rates and low operative mortality for smaller, asymptomatic aneurysms.[8,74,78] Critical limb ischemia prior to intervention is associated with an up to three or four times higher perioperative mortality and considerably higher rates of limb loss.[75-77]

Other writers advocate that some asymptomatic PAAs can be safely observed.[86-89] Galland et al.[88] evaluated 95 popliteal PAAs. Of those that were asymptomatic, less than 3 cm, and without distortion, none became thrombosed. The presence of thrombus in a PAA, however, appears to increase the incidence of the development of symptoms and may raise expansion rates.[74,90]

The decision to treat a patient with a PAA must be individualized, with careful weighing of the risks and benefits of treating and observing. Treatment should generally be offered to the medically fit patient who has a symptomatic PAA or whose PAA is asymptomatic but is at least 2.0 to 2.5 cm in diameter and contains thrombus. In older patients with multiple comorbidities, observation of even a larger aneurysm may be warranted. Extensive thrombus or asymptomatic occlusion of tibial vessels may be indications for intervention. Chronically thrombosed PAAs associated with lifestyle-limiting claudication or limb-threatening ischemia may also need revascularization.

Elective Treatment

Once the decision has been made to treat the patient with a PAA, the preoperative evaluation involves ensuring that the patient's medical status is optimized and determining the operative approach. If indicated, beta blockers should be considered and statins should be added, ideally at least 1 month prior to the procedure.[91] The patient should be taking aspirin or some other antiplatelet agent.

Planning for surgery and deciding to proceed with an endovascular, open, or hybrid approach depends on the patient's anatomy, age, and comorbidities. The patient's arterial system should be imaged from the abdominal aorta down to the pedal vessels. If the preoperative imaging is not of sufficient quality, an angiogram should be performed. Options for elective repair of PAAs include an endovascular approach (purely percutaneous or hybrid with exposure of the femoral artery) utilizing an intraluminal stent-graft and an open approach utilizing an arterial bypass. It should be stated here that although endovascular repair of PAAs is being widely performed and reported on, no devices have been approved yet by the US Food and Drug Administration (FDA) for this particular procedure. Endovascular repair of PAAs is therefore considered an off-label use of a stent-graft.

Endovascular and Hybrid Treatment

Endovascular treatment has the benefit of not requiring general or regional anesthesia, and therefore the theoretical advantage of decreasing cardiac risk. The procedure can be performed either via either a percutaneous puncture or a small cutdown to expose either the SFA or CFA. If a cutdown is to be performed, SFA exposure is preferred because it is an easy dissection, the artery is usually fairly large in patients with PAAs, and direct access avoids the extra step of directing a wire into the vessel from the CFA. Anatomic selection criteria for endovascular repair of PAAs include a normal proximal and distal segment (landing zones) of at least 2 cm (without a large discrepancy in size between proximal and distal landing zones), lack of extensive vessel tortuosity, and an aneurysm that is not extremely large (which would make a stent-graft prone to kinking and displacement). Patients who frequently flex their knees to more

than 90 degrees, such as carpenters or people who garden, are usually excluded from endovascular repair of a PAA owing to the risk of stent deformation and thrombosis. In addition, if antiplatelet therapy is contraindicated, an endovascular approach is not recommended.

All patients are given a loading dose of clopidogrel and then maintenance doses, an approach that has been shown to be a predictor of success after endovascular PAA repair.[92] If there is no contraindication to the drug's prolonged use, clopidogrel is prescribed indefinitely. A minimum of 4 to 6 weeks of dual antiplatelet therapy is recommended in all cases. Unless there is a known hypercoagulable state, anticoagulation with warfarin is not routinely used. Patients with single-vessel outflow have been shown to have a statistically significantly higher stent-graft thrombosis rate than patients with two- or three-vessel outflow.[93] However, at present there are no data demonstrating improved patency in this subset of patients with the addition of warfarin therapy.

Procedure

For an endovascular approach, the Viabahn endoprosthesis (W.L Gore & Associates, Newark, Delaware) has been useful. It is made of polytetrafluoroethylene (PTFE) with a nitinol exoskeleton. The Viabahn is approved by the US Food and Drug Administration for treating arterial occlusive disease. The device is usually oversized to about 10% to 15% more than the internal diameter of the popliteal vessel above and below the aneurysm. Oversizing the graft much more than 15% is not recommended. Graft infolding and operative occlusion related to oversizing, requiring conversion to an open femoral-to-popliteal bypass, have been reported.[94] The vessel measurements can be based on preoperative imaging and checked with the intraoperative angiogram. Because the profile of the device has decreased, up to an 8-mm graft can be delivered via a 7-Fr sheath using an 0.018-inch guide wire. Therefore, in most cases, percutaneous common femoral artery access via an ipsilateral prograde or contralateral retrograde approach (over the iliac bifurcation) can be used. If a larger sheath is required (9- to 13-mm device requires a 9- to 12-Fr sheath and 0.035-inch guide-wire system) or if direct vessel exposure is desired, the superficial femoral artery can be easily exposed with the use of local anesthesia.

Once vascular access is obtained and the appropriate sheath is placed, an angiogram is performed. The proximal and distal landing zones as well as the runoff vessels are confirmed. The patient is systemically heparinized to an activated clotting time (ACT) exceeding 250 seconds. The PAA can then be carefully crossed, and the correct devices can be chosen on the basis of preoperative imaging and the intraoperative angiogram. A maximum of 1 mm of size differential between grafts is suggested if more than one stent-graft is required because of a discrepancy in proximal and distal landing zones. It is preferable to avoid landing the distal end of the graft at the bend of the popliteal artery, which is usually a few centimeters above the actual knee joint and can be located by performing an angiogram with the knee bent (Fig. 83.7).

Figure 83.7 Arteriogram With Knee Bent. *Arrow* points to the actual bend in the artery a few centimeters above the knee joint.

Some advocate routinely extending the stent-graft to the P3 segment of the popliteal artery to avoid having the distal end of the graft in a mobile segment of the popliteal artery.

The stent-grafts are deployed from small to large if more than one is needed, preferably starting most distally. Usually at least 2 or 3 cm of normal artery on either side of the aneurysm are preferable for landing zones. If more than one graft is required, minimum 2- to 3-cm overlap between stent-grafts is preferred. Each stent-graft is always molded with a balloon about the size of the graft. The balloon is inflated inside the stent-graft, and not in native artery, to avoid arterial dissection. A completion angiogram is performed, and runoff is assessed. An angiogram is performed again with the knee bent (Fig. 83.8). If the stent-graft ends on the bend of the popliteal artery, it is usually extended. The access site is either repaired open or through an access closure device, or direct manual pressure is held on the puncture site for 20 to 30 minutes after the activated clotting time is normalized (Box 83.1).

Open Treatment

The primary objective of the treatment of PAAs is to exclude them from the circulation while maintaining distal perfusion. In 1785 John Hunter ligated the popliteal artery of a coachman with a large popliteal aneurysm in the canal that now bears his name. Hunter correctly postulated that collateral circulation would maintain the viability of the limb.[95] In the modern era, arterial bypass with ligation or interposition grafting has replaced simple ligation and remains the gold standard for treatment.

As with any lower extremity arterial reconstruction, proper treatment requires careful planning and starts with a comprehensive arteriogram of the entire extremity from the groin to

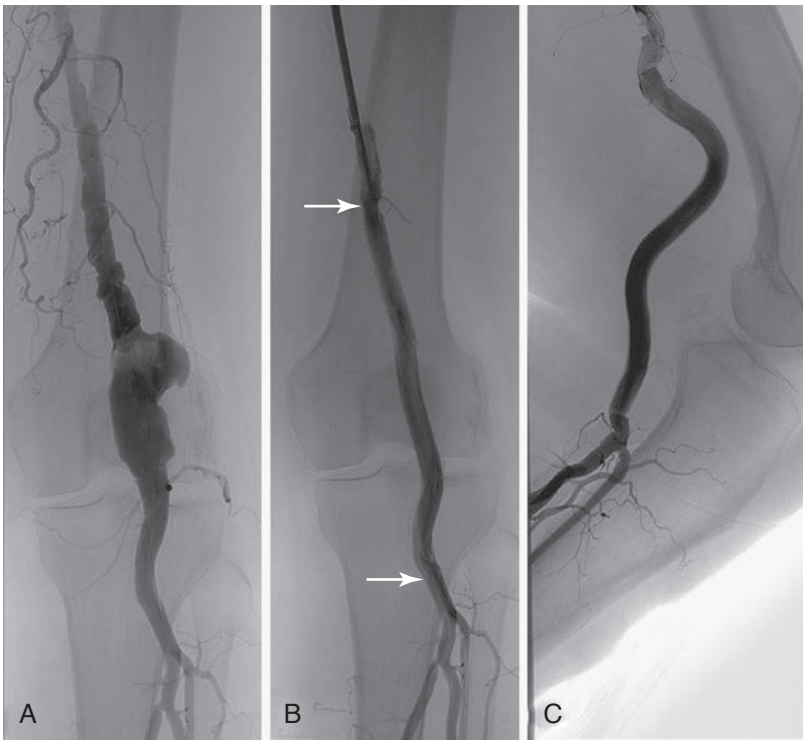

Figure 83.8 Endovascular Repair of a Popliteal Artery Aneurysm. (A) Initial arteriogram demonstrating that the aneurysm involves most of the above-knee popliteal artery. The below-knee popliteal artery is normal and will be the distal attachment site for the stent-graft, which necessitates crossing the knee joint with the device. (B) Completion arteriogram through the introducer sheath showing the stent-graft in place across the knee joint *(arrows).* (C) A lateral projection with the knee flexed 90 degrees demonstrates that the point of maximal flexion is actually proximal to the joint and does not result in kinking of the graft. Minimal bending and some posterior deflection of the graft are evident at the level of the articular surface of the joint (see text).

BOX 83.1 Steps in Deployment of an Endograft for a Popliteal Aneurysm

1. Pretreat with clopidogrel.
2. Perform femoral puncture with a delivery of an appropriately sized delivery sheath either via a contralateral approach over the bifurcation or via an ipsilateral approach into the superficial femoral artery. Ipsilateral superficial femoral artery cutdown may also be performed with direct puncture of the ipsilateral superficial femoral artery.
3. Heparinize to an activated clotting time of more than 250 seconds.
4. Cross the aneurysm into the distal popliteal artery or tibial vessels with a 0.035- or 0.018-inch wire, depending on the instructions for use of the device. Create a road map angiogram.
5. Deploy the graft from the distal to the proximal landing zone and overlap with additional grafts as needed. Post-dilate the entirety of the graft to "iron out" any kinks or stenoses.
6. Perform a completion angiogram to evaluate for endoleak and preservation of runoff without embolization. In addition, an angiogram with the knee in extreme flexion should be performed to identify potential areas of kinking. A fluoroscopic image should be saved as a baseline for assessing the structural integrity of the graft.
7. Prescribe clopidogrel to be taken postoperatively indefinitely.

the toes. Alternatively, this information can be obtained with MRA or spiral CTA, as previously described. Duplex ultrasound is used for screening and diagnosis and has a limited role in terms of anatomic imaging for bypass, although it is very useful for vein mapping in preparation for bypass. The information obtained from contrast-enhanced angiography or MRA is used to determine the location of the proximal and distal anastomotic sites. MRA and CTA can also provide information about the size, shape, and extent of the aneurysm, which is helpful in determining whether to use a medial or posterior approach. Small or fusiform aneurysms are best approached medially and treated with conventional bypass and aneurysm ligation. For a large, saccular aneurysm, particularly one with symptoms attributable to compression of adjacent structures, direct exposure from the posterior approach with interposition grafting from within the sac is preferable, unless the aneurysm extends too far proximally. The posterior approach is also advantageous for decompressing an aneurysm that has continued to enlarge after bypass and ligation because of backfilling from geniculate branches.

Medial Approach

For the medial approach, the patient is positioned supine and the saphenous vein is exposed as the first step, starting in the groin, midthigh, or ankle, depending on the procedure. Once the vein has been mobilized and harvested, the same incision can be used to expose the popliteal artery above and below the knee joint in a fashion identical to that used for femoropopliteal bypass. Similarly the same incision can be used to expose the posterior tibial and peroneal arteries. For the anterior tibial and pedal arteries, or if a lateral approach is planned for the distal peroneal artery, separate incisions are required. Arterial exposure of the above-knee or below-knee popliteal artery can be difficult with large aneurysms or in the presence of atriomegaly. Compression of the popliteal veins can lead to venous engorgement and venous hypertension. Extensive kinking, tortuosity, and lateral displacement, especially of the distal popliteal artery, can occasionally make exposure challenging. In cases of atriomegaly, even the inflow and outflow arteries may be unusually large,

making their separation from the adjacent structures more difficult. Vessels are isolated with conventional silicone rubber vessel loops. In most cases a tunnel is then created from the above-knee to the below-knee popliteal space between the heads of the gastrocnemius muscle. This maneuver may be difficult in patients with large popliteal aneurysms filling most of the popliteal space. Decompression of the aneurysm sac and endoaneurysmorrhaphy may be required before tunneling can be performed safely. The patient is administered intravenous heparin at a dose of 80 to 100 units/kg or at a dose to prolong the activated clotting time to 250 to 300 seconds.

Arterial bypass is performed in standard fashion with either an end-to-side or an end-to-end anastomosis. There is frequently a size discrepancy between the vein graft and the popliteal arteries, especially above the knee, thus making the end-to-side technique preferable. Either reversed or nonreversed vein grafts can be used, depending on surgeon preference and experience. In bypasses extending from the CFA to a distal tibial vessel, in situ bypass is an alternative. For occluded aneurysms, the procedure is conducted like any other lower extremity arterial bypass. If the aneurysm is patent, ligation must be performed in conjunction with the bypass procedure. The inflow and outflow arteries to the aneurysm sac should be ligated as close to the aneurysm as possible. In focal aneurysms confined to the proximal and mid popliteal artery, the aneurysm is ligated just distal to the proximal anastomosis and just proximal to the distal arterial anastomosis. If an in situ bypass to a more distal target is performed, separate exposure of the two points of ligation is required. The aneurysm should always be ligated both proximally and distally as close to the sac as possible to promote aneurysm thrombosis and decrease the likelihood of continued expansion from collateral filling. Jones et al.[96] demonstrated that proximal ligature alone or ligature of the inflow and outflow arteries performed remotely from the aneurysm sac increases the likelihood of continued aneurysm expansion.[96] Completion arteriography, angioscopy, or DUS is performed before closure.

The medial approach is the preferred technique for most popliteal aneurysm repairs and the only logical option for bypass grafts that must extend to the distal tibial or pedal vessels. The medial approach has the advantages of being familiar to all vascular surgeons and providing easy access to the entire great saphenous vein. Virtually all of the procedure is performed at some distance from the aneurysm, thus reducing the likelihood of operative injury to structures adherent to the surface of the popliteal aneurysm. The principal disadvantage of the medial approach is that it is generally used in conjunction with aneurysm ligation but without decompression. Numerous studies have shown that even with proximal and distal ligation, as many as 30% of aneurysms do not ultimately undergo thrombosis and may continue to enlarge if collateral blood flow into the aneurysm sac persists, in a situation analogous to that of a type II endoleak with endovascular aneurysm repair.[96-98] Continued expansion can result in pain, compression symptoms, and even rupture.[99] To avoid this problem, most writers are proponents of opening all but the smallest popliteal aneurysms in order to suture-ligate back-bleeding side branches. This can usually be done from the above-knee or below-knee popliteal space. A thigh tourniquet can decrease bleeding from collaterals once the aneurysm sac is opened.[7] In some cases it may be necessary to divide the tendon of the medial head of the gastrocnemius muscle to facilitate access to the popliteal aneurysm. After decompression the tendon can be reattached with a heavy-gauge monofilament suture. In our experience, this procedure rarely leads to disability.

Posterior Approach

The posterior approach is preferred for large aneurysms that are confined to the popliteal space and are causing symptoms from compression, or for those that have caused distortion and displacement of the normal anatomy as a result of tortuosity, elongation, and kinking. This is also an appropriate approach for a smaller aneurysm, but it is not applicable for aneurysms that extend proximally beyond the popliteal space.

The patient is placed prone. An S-shaped incision is made with the superior end starting on the medial side of the thigh to expose the proximal popliteal artery and great saphenous vein. The incision extends laterally across the flexion crease of the knee and ends on the lateral aspects of the proximal part of the calf, directly over the proximal small saphenous vein (Fig. 83.9). If the small saphenous vein is of adequate size for bypass, the incision can be continued for harvest of the vein. Alternatively, the great saphenous vein can be harvested relatively easily from the thigh with the patient prone. Preoperative vein mapping should always be performed before popliteal aneurysm repair to ensure that the vein is adequate in caliber or quality and to avoid unnecessary extension of the incision if it is not.

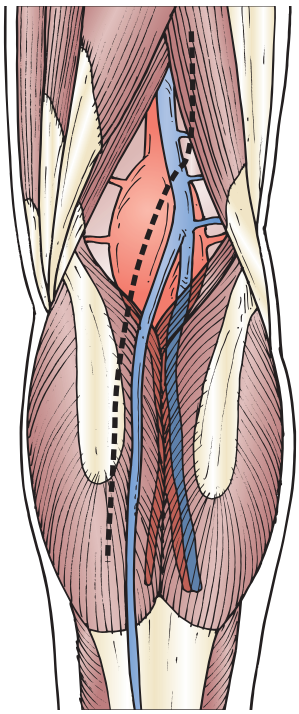

Figure 83.9 Placement of a "lazy S" incision for the posterior approach to a popliteal artery aneurysm. (From Ouriel K, Rutherford RB, eds. *Atlas of Vascular Surgery: Operative Procedure,* Philadelphia: WB Saunders; 1998.)

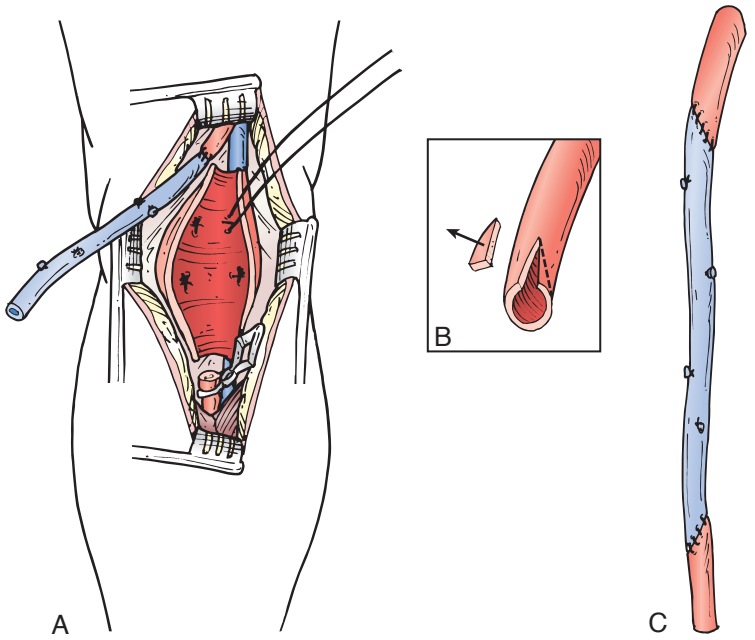

Figure 83.10 Posterior Approach. The aneurysm is opened, thrombus is removed, and the geniculate vessels are ligated, a procedure analogous to aortic aneurysm repair **(A).** A spatulated interposition bypass graft is then used to reconstruct the popliteal artery **(B,C).**

The proximal popliteal artery is identified by palpation distal to the adductor canal and exposed by separation of the semimembranosus and semitendinosus muscles located medially from the long head of the biceps femoris located laterally. Circumferential control is obtained with silicone rubber vessel loops. Dissection is continued distally on the anterior surface of the aneurysm sac to avoid injury to the tibial and peroneal nerves, which may be encountered coursing lateral and slightly posterior to the aneurysm. The distal popliteal artery is identified and circumferentially controlled. If exposure of the tibioperoneal trunk or proximal tibial vessels is required, access from this approach is possible, although the medial approach is preferable if tibial bypass is required.

After the administration of intravenous heparin, proximal and distal control is obtained and the aneurysm sac is opened. Thrombus is removed, and back-bleeding geniculate collaterals are oversewn from within, analogous to the approach used for aortic aneurysms. Circulation can be restored by either bypass or an interposition graft. If an interposition vein graft is planned, the graft can be beveled to facilitate end-to-end anastomosis to the transected popliteal artery (Fig. 83.10). Alternatively, a standard end-to-side bypass can be performed and is preferable when there is a significant size discrepancy between the popliteal artery and the bypass graft, which commonly occurs when vein conduit is used. For interposition prosthetic grafts, an end-to-end anastomosis can be created from within the aneurysm sac by application of the graft inclusion technique used for abdominal aortic aneurysm repair. This approach has the advantage of requiring less dissection of the popliteal artery. Some surgeons prefer the routine use of prosthetic conduits for the posterior approach because the diameter of the graft can be more closely matched to the diameter of the popliteal artery and the complications associated with vein harvest are avoided. Excellent short-term results with prosthetic popliteal bypass have been reported in some series, especially when outflow is good.[100]

Urgent/Emergent Repair

Approximately 30% of patients with popliteal aneurysms have acute ischemic symptoms at initial evaluation.[101] In patients who present with acute occlusion or symptomatic embolization, there is a high rate of limb loss.[75-77] In an acutely symptomatic PAA patient without motor or sensory deficits, preoperative imaging can be very useful. The patient should be admitted to the hospital and systemically heparinized. Either CTA or MRA can be used to evaluate the perfusion of the affected extremity and the outflow vessels. If the diagnosis of PAA is already made, angiography can be used in place of either of these tests; it can give additional information about the status of the runoff vessels. DSA is still considered the gold standard for evaluation of the outflow vessels. A treatment strategy can be formulated on the basis of the symptoms and the preoperative imaging. If there are no motor or sensory deficits, treatment can be delayed to allow for imaging and preoperative planning. The patient with neurosensory deficits should be taken directly to the operating room, ideally a hybrid operating room/angiosuite.

Open Approach

In a patient with a viable limb and no symptoms of sensory or motor dysfunction, intravenous heparin can be administrated to stabilize him or her. Arteriography and surgery are performed during the same admission. If the aneurysm is fully occluded and a patent distal outflow vessel is identified on arteriography, a vein bypass to the patent outflow vessel is performed as described previously. If no outflow vessel is identified and the patient's limb is not immediately threatened, intraarterial thrombolysis is started with the objective of restoring flow to potential outflow target vessels (see Endovascular Treatment—Thrombolysis).

In cases in which the patient's limb is immediately in jeopardy because of sensory and motor dysfunction, and there is no time

for thrombolysis, surgery should be performed immediately. If no outflow vessel was identified on the arteriogram, thromboembolectomy of the distal popliteal or tibial vessels (or both) should be attempted. Embolectomy or thrombectomy of the popliteal artery is relatively straightforward and best approached from the below-knee popliteal artery. For embolectomy of individual tibial arteries, blind passage of embolectomy catheters from the popliteal artery usually fails and is ill-advised. The region of the trifurcation of the popliteal artery should be exposed to gain access to all three arteries. A No. 2 Fogarty balloon embolectomy catheter can then be passed into each of the three tibial vessels. This must be done with utmost care to avoid potential intimal injury, perforation, and rupture. Alternatively, tibial vessels can be exposed at the ankle, and retrograde passage of Fogarty catheters attempted.[102] Bypass grafts can then be extended to this level via the same arteriotomy, or a vein patch angioplasty of the distal arteriotomy can be performed with bypass to the more proximal portion of the artery. Intraarterial thrombolysis in conjunction with bypass and embolectomy to further clear residual thrombus from the outflow vessels has been described in some cases.[103,104] After bypass, patients may exhibit signs of reperfusion injury, including rhabdomyolysis, and may require fasciotomy.

Endovascular Treatment—Thrombolysis

When studied with angiography, 25% to 45% of acutely ischemic patients have thrombosis of the aneurysm with either no visible runoff vessel or with severely compromised runoff thought to be unsuitable for bypass because of embolization. In these challenging cases, pre-bypass catheter-directed intra-arterial thrombolysis has been shown to be effective in improving the likelihood of limb. Considerable judgment is required to determine whether a patient is a suitable candidate for thrombolysis, and the need to delay surgery for 12 to 24 hours for the performance of thrombolysis must be taken into account. Moreover, the potential risk of serious or life-threatening bleeding complications must be considered, and it may vary from patient to patient. Ultimately the decision to perform thrombolysis must be individualized according to patient factors and clinical circumstances.

Traditional lysis is usually performed via a 6-Fr sheath placed in the contralateral CFA, over the bifurcation, and into the affected leg. One of the best predictors of success after lytic therapy is easy traversal of the thrombus. A 5-Fr lytic catheter can be placed in the thrombosed popliteal artery, and a lytic wire advanced through the lytic catheter into one of the tibial outflow vessels. Direct intraarterial lytic therapy can be begun with tissue plasminogen activator (t-PA) or other thrombolytic agent at equivalent doses. The patient is placed in a monitored setting (intensive care or postanesthesia care unit) during the infusion for careful monitoring. The infusion rate is typically 2 mg/h of t-PA or less, administered via the catheter and wire combined. Five hundred units of heparin are given via the 6F sheath to prevent thrombosis around the catheter. The t-PA is diluted to 25 mg in 500 mL to ensure sufficient volume via the catheters (20 mL/h = 1 mg/h). Partial thromboplastic time (PTT) and fibrinogen are checked every 3 to 4 hours. The PTT should be less than therapeutic to prevent bleeding complications (PTT < 50 seconds). As long as the fibrinogen level is above 200 mg/dL, lytic therapy is continued. If it drops below 200 mg/dL, the dose is halved and the drip is withheld until the fibrinogen drops below 150 mg/dL.

Angiography is performed again within 6 to 18 hours or earlier if required. On the basis of the angiographic findings and clinical scenario, either a bypass can be performed if a target vessel opens, lytic therapy can be continued, or the patient can undergo an attempt at urgent thrombectomy/bypass if the leg is acutely threatened. Alternatively, if the thrombus lyses and anatomy permits (as described earlier), and there is more than one outflow vessel, an endovascular stent-graft can be placed as previously described. As already mentioned, patients with PAAs and single-vessel outflows who are treated with endovascular stent-grafts have inferior patency rates.[93] A rheolytic percutaneous thrombectomy catheter may also be used to spray t-PA (10 mg t-PA in 100 mL) directly using the power-pulse spray technique into thrombus, and the catheter can then help to debulk the thrombus prior to initiation of a lytic drip as described.

Results

Several series have demonstrated the value of preoperative thrombolysis started at the time of diagnostic arteriography for improving outflow before bypass in 29% to 45% of patients with acute ischemia.[7,101,105-107] Marty et al.[108] found that thrombolysis restored one- or two-vessel runoff in 77% of cases and predicted short- and long-term limb salvage, whereas failure of thrombolysis resulted in the need for amputation. In the series by Aulivola et al.,[101] 13 patients had acute ischemia. In the emergency group, the cumulative primary and secondary patency rates were 85% and 100% at 1 and 5 years, respectively. In the four patients who underwent thrombolysis, none required amputation. Tibial or pedal arteries were the outflow artery in 57% of the bypasses performed in the emergency group. In another series from the Mayo Clinic, of the 74 patients with an acute manifestation, 38 underwent thrombolysis, 24 preoperatively and 14 during surgery.[7] Thirty-day results were 94% primary patency and 91% limb salvage for patients who underwent lysis, and 87% primary patency and 92% limb salvage for those who did not. Preoperative thrombolysis appeared to reduce the amputation rate from 96% to 69% in the group of patients presenting with severe critical limb ischemia.

The largest report on thrombolysis for popliteal aneurysms comes from the Swedish Vascular Registry, which included treatment of 717 limbs for popliteal artery aneurysms over a 15-year period.[103,109] Acute ischemia was present in 235 limbs, 100 of which (43%) were treated by preoperative thrombolysis, whereas 135 other limbs went directly to surgery. In the immediate surgery group, 32 limbs underwent intraoperative thrombolysis. On the basis of review of preoperative and postoperative arteriograms, thrombolysis significantly improved runoff in 87% of limbs and remained unchanged in 13%, all of which ultimately required amputation.

Intraarterial thrombolysis can uncover outflow target arteries suitable for bypass, thereby improving the chance of limb salvage.

However, the decision to use thrombolysis in cases of critical ischemia is never straightforward and must be individualized to the specific clinical situation. If surgeons do not possess the requisite endovascular skills and expertise to perform it themselves, they must have the immediate support of a committed interventionalist. The importance of adhering to the principles of treatment of acute limb ischemia must be remembered; most important is that any patient in whom the use of thrombolysis is being considered must be able to withstand another 12 to 18 hours of ischemia. It should never be used in marginally viable or nonviable limbs or in patients with specific contraindications to its use.

Hybrid Approach

It is not uncommon for a combination of the aforementioned endovascular and open techniques to be used for emergency cases, which should ideally be performed in a hybrid operating room with optimal angiographic equipment and operative capability. Open thrombectomy can be performed via the below-knee popliteal artery if intraoperative lysis is not successful or the patient's symptoms would not allow for the time that it takes for the lytic therapy to work. Likewise, if open thrombectomy is not successful, intraoperative lytic therapy and pharmacomechanical thrombectomy can be attempted.

If distal tibial thrombus remains after open thrombectomy and the below-knee popliteal artery is patent, a below-knee bypass can be performed. A 4-Fr sheath is placed percutaneously and then into the bypass graft. A lytic wire can be advanced into the tibial outflow vessel for further lytic therapy.

A 1 mg of t-PA diluted in 10 cc therapy may be injected as a pulse spray in the vessel and then continued at a low dose. Alternatively the t-PA is just started without a pulse spray dose, keeping the dose fairly low (0.5 to 1 mg/h) to avoid bleeding from surgical sites.

The t-PA dose is kept fairly low in this circumstance because bleeding can be encountered from the surgical sites. The patient is taken back to the operating room for a second angiogram and removal of the catheter/repair of the graft.

Results: Open Versus Endovascular Repair

The results of both open repair and endovascular repair of PAAs are somewhat dependent on the severity of the patient's symptoms upon presentation, with the most symptomatic having the worst outcomes.[75-77]

Pulli et al.[106] give support to this assumption in their review of 159 PAAs in 137 patients treated surgically. Asymptomatic limbs had significantly better results than symptomatic ones in terms of limb salvage (93% vs. 80%) and primary patency (87% vs. 52%). Patients who presented with critical limb ischemia had a low 5-year limb salvage rate—only 59%. Likewise, Huang et al.[7] reported on 289 patients with PAAs treated with open repair with a mean follow-up of 4.2 years. They divided the patients into three groups: group 1 consisted of 144 (40%) patients with asymptomatic limbs, group 2 of 140 patients (39%) with chronic symptoms, and group 3 of 74 patients (21%) with acute ischemia. Early mortality was 1% (3/358), all in group 3 (4% [3/74]). All six early amputations (8%) were also in group 3. In addition, six out of seven patients with perioperative myocardial infarctions were in group 3 (8%). Overall, 5-year primary and secondary patency rates were 76% and 87%, respectively. The overall 5-year limb salvage rate was 97% (85% in group 3).

Endovascular repair of PAAs overall has been shown to be relatively safe with patency rates approaching those of open repair in patients who have appropriate anatomy. We earlier reported on the endovascular treatment of PAA on 26 limbs in 21 patients.[93] Primary and secondary patency rates were both 91% at 1 year and 86% and 91%, respectively at 2 years. Single-vessel runoff was the only significant predictor of graft failure. Mohan et al.[110] reviewed 35 PAAs treated with stent-grafts. They found 3-year primary and secondary patency rates to be 75% and 83%, respectively. In a review of 73 PAAs treated with stent-grafts, a follow-up report by Tielliu et al.[111] after their original study found 5-year primary and secondary patency rates of 70% and 76%, respectively. When analyzing the later cases, they found that with more experience and the addition of clopidogrel, the 5-year primary patency increased to 80%. Jung et al.[112] performed a retrospective review of 15 PAAs treated with stent-grafts that had long-term follow-up (mean, 54 months). Primary and secondary patency rates were 85% and 100%, respectively. Two patients experienced endoleaks, which were successfully treated with additional stent-grafts. Both amputation-free survival and overall survival were 86% by Kaplan-Meier analysis.

Antonello et al.[113] reported one of the first prospective randomized trials comparing open and endovascular PAA repair. This trial, however, included only 30 patients, 15 in each group. These investigators did not find a statistically significant difference in patency or limb salvage rates, with a follow-up period of up to 4 years. As would be expected, they did find a statistically significant decrease in operative time and length of stay in the hospital for the endovascular group. Lovegrove et al.,[114] in a meta-analysis comparing open with endovascular repair of PAAs, reported similar results with no significant difference in long-term patency rates; however, patients who underwent endovascular repair were more likely to have graft thrombosis and reintervention at 30 days than those who had open repair. They also reported significantly shorter lengths of hospital stay and shorter operative times with endovascular repair.

A retrospective review by Curi et al.[115] of 56 PAA repairs, in which open and endovascular treatments were compared, demonstrated no significant difference in primary patency, secondary patency, or survival rates between the two treatment groups (Fig. 83.11). All urgent cases, however, were treated with open repair, and endoleaks developed in 20% of the patients undergoing endovascular repair.

Lastly, a 2015 consecutive cohort of patients undergoing either open or endovascular repair of PAAs was retrospectively reviewed by Leake et al.[116] They reviewed 186 PAAs (110 open and 76 endovascular). Open repair was associated with a longer hospital stay (5.8d vs. 1.6d; $P < .001$) and increased 30-day complication rate (22% vs. 6%; $P < .001$). While open repair is associated with a better 3-year primary patency rate (88.3%

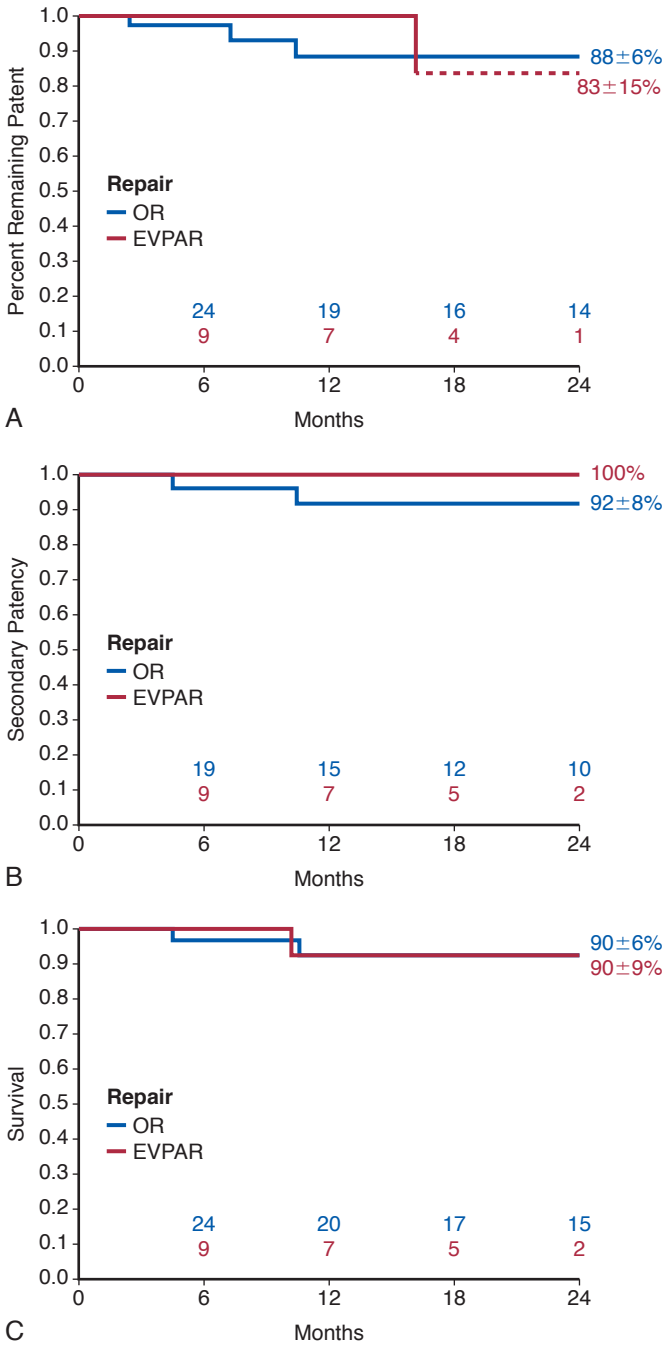

Figure 83.11 Rates of primary patency (A) and secondary patency (B) and survival (C) after open repair *(OR)* versus endovascular repair *(EVPAR)* of popliteal artery aneurysms and Kaplan-Meier analysis of patient survival after undergoing open repair versus endovascular repair of popliteal artery aneurysms. (From Curi MA, Geraghty PJ, Merino OA, et al. Mid-term outcomes of endovascular popliteal artery aneurysm repair. *J Vasc Surg.* 2007;45:505-510.)

vs. 69.8%; P = .03), there was no difference in secondary patency or amputation rates.[116]

CONCLUSION

Although PAA is a relatively uncommon disease, its presence has the potential to put the limb at risk. Once suspected, it should be fully evaluated. PAAs that are larger than 2 to 2.5 cm

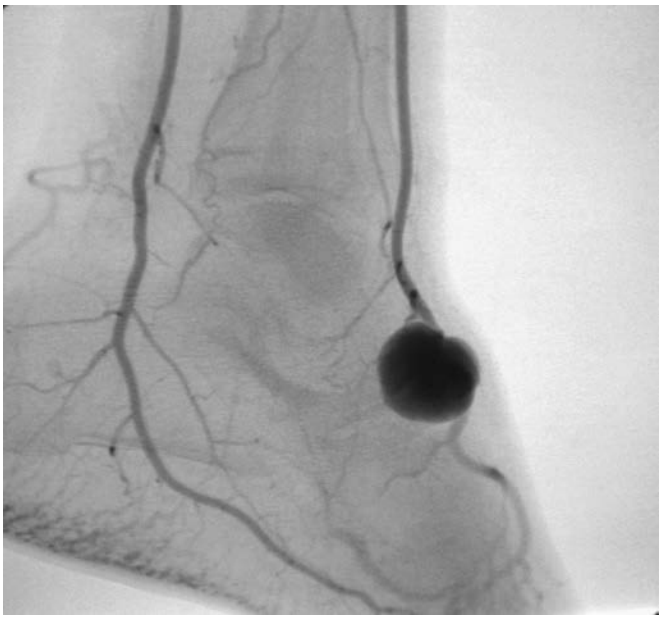

Figure 83.12 Aneurysm of the dorsalis pedis artery without prior trauma manifested as a pulsatile mass on the dorsum of the foot. It was treated with excision and ligation. Arterial flow to the foot was maintained by the patent posterior tibial artery and intact pedal arch.

and symptomatic in any way should be considered for repair in medically fit patients. Although endovascular repair of PAAs has been shown to decrease length of hospital stay and operative morbidity, data are somewhat varied as to its durability in comparison with open repair. In addition, endovascular devices for PAA repair are yet to be approved by the US Food and Drug Administration. On the basis of current literature, endovascular repair in general should be reserved for patients who have good anatomy (as described earlier), who do not frequently bend their knees more than 90 degrees, and who can take clopidogrel for a minimum of 4 to 6 weeks. The decision to perform open or endovascular repair should be individualized and should involve a clear discussion between the treating physician and the patient.

TIBIAL ARTERY AND PEDAL ARTERY ANEURYSMS

True aneurysms of the tibial and pedal arteries are rare, and their description in the literature has been limited primarily to case reports.[117-119] They most commonly occur in the setting of penetrating trauma, fractures, or iatrogenic injury during orthopedic surgery or peripheral interventions.[120] In addition, they can occur as a result of thromboembolectomy of the tibial vessels with balloon catheters.[121] Symptomatic aneurysms should be repaired with autologous vein bypass grafts if there is distal ischemia.[117,119] If other tibial arteries are patent, treatment with simple ligation will suffice (Fig. 83.12). Coil embolization has been reported as an effective treatment of tibial artery aneurysms, and observation with spontaneous thrombosis of small pseudoaneurysms has also been described.[122,123]

Corriere MA, Guzman RJ. True and false aneurysms of the femoral artery. *Semin Vasc Surg*. 2005;18:216–223.

An excellent review article of the current management of both atherosclerotic and femoral artery false aneurysms.

Dawson I, Sie RB, van Bockel JH. Atherosclerotic popliteal aneurysm. *Br J Surg*. 1997;84:293–299.

Large review of the behavior and treatment of popliteal aneurysms encompassing more than 2400 patients over a 15-year period.

Diwan A, Sarkar R, Stanley JC, Zelenock GB, Wakefield TW. Incidence of femoral and popliteal artery aneurysms in patients with abdominal aortic aneurysms. *J Vasc Surg*. 2000;31:863–869.

A prospective analysis that identifies the high incidence of lower extremity aneurysms in patients with aortic aneurysms.

Harbuzariu C, Duncan AA, Bower TC, Kalra M, Gloviczki P. Profunda femoris artery aneurysms: association with aneurysmal disease and limb ischemia. *J Vasc Surg*. 2008;47:31–34, discussion 34–35.

Largest single-center series of an unusual and infrequently seen aneurysm.

Huang Y, Gloviczki P, Noel AA, et al. Early complications and long-term outcome after open surgical treatment of popliteal artery aneurysms: is exclusion with saphenous vein bypass still the gold standard? *J Vasc Surg*. 2007;45:706–713, discussion 713–715.

Updated single-center series with important details on the results of emergency and elective treatment, the behavior of vein and prosthetic grafts, and thrombolytic therapy.

Jung E, Jim J, Rubin BG, et al. Long-term outcome of endovascular popliteal artery aneurysm repair. *Ann Vasc Surg*. 2010;24:871–875.

Single-institution study with first long-term follow-up (54 months) of patients undergoing endovascular repair of popliteal artery aneurysms.

Lovegrove RE, Javid M, Magee TR, Galland RB. Endovascular and open approaches to non-thrombosed popliteal aneurysm repair: a meta-analysis. *Eur J Vasc Endovasc Surg*. 2008;36:96–100.

A meta-analysis of three studies (141 patients) comparing open with endovascular popliteal aneurysm repair.

Piffaretti G, Mariscalco G, Tozzi M, Rivolta N, Annoni M, Castelli P. Twenty-year experience of femoral artery aneurysms. *J Vasc Surg*. 2011;53:1230–1236.

Long-term experience with 35 true femoral artery aneurysms treated with open repair and observation.

Schneider C, Malisius R, Kuchler R, et al. A prospective study on ultrasound-guided percutaneous thrombin injection for treatment of iatrogenic post-catheterisation femoral pseudoaneurysms. *Int J Cardiol*. 2009;131:356–361.

Prospective study on 274 patients undergoing thrombin injection with 97% success rate, suggesting that US-guided percutaneous thrombin injection as first-line therapy for postcatheterization femoral pseudoaneurysms.

Tisi PV, Callam MJ. Treatment for femoral pseudoaneurysms. *Cochrane Database Syst Rev*. 2009;(2):CD004981.

Updated review with meta-analysis of four randomized controlled trials comparing US-guided compression, blind manual compression, and US-guided percutaneous thrombin injection for the treatment of femoral pseudoaneurysms.

Upper extremity aneurysms are uncommon relative to other peripheral arterial aneurysms.[1] Arch vessel aneurysms, the most frequent type of upper extremity aneurysm, can lead to life-threatening exsanguination as a result of rupture, as well as numerous other complications, including stroke, local nerve compression (leading to hoarseness or brachial plexus palsy), and dysphagia from esophageal compression in cases of an aberrant right subclavian artery (ARSA) aneurysm, localized pain, or limb ischemia. More distally located upper extremity aneurysms are manifested almost exclusively by thromboembolic complications of the hand and digits.

The earliest reported attempts at surgical correction of arch vessel aneurysms were common carotid aneurysm ligations by Astley Cooper in 1805 and 1808,[2] followed by ligation of the innominate artery by Valentine Mott in 1818 for the treatment of a subclavian artery aneurysm.[2,3] Mott's patient expired within 1 month as a result of hemorrhage from the necrotic aneurysm. The first successful treatment of a subclavian artery

Abstract

Arch vessel aneurysms are the most frequent type of upper extremity aneurysms that may result in rupture or other complications, including stroke, local nerve compression, dysphagia from esophageal compression or limb ischemia. More distally located upper extremity aneurysms are manifested almost exclusively by distal thromboembolic complications. True subclavian aneurysms are usually degenerative and are the most common type of arch vessel aneurysm.

Aneurysmal degeneration of the aberrant right subclavian artery usually affect adults older than age 50 years. The majority of these require intervention, owing either to symptoms or to the risk of rupture. Degenerative aneurysmal changes may occur in up to 60% of patients in the proximal portion of the aberrant subclavian artery, a condition known as Kommerell's diverticulum.

Axillary artery aneurysms are rare and usually caused by blunt or penetrating trauma. Aneurysms of the brachial artery are primarily false aneurysms secondary to repetitive trauma, or iatrogenic complications. More recently, brachial artery aneurysms associated to the creation of arteriovenous access for hemodialysis have increasingly been reported.

Although open repair has been the main treatment modality of upper extremity aneurysms, endovascular therapies are increasingly been used alone or as hybrid repairs. Early results demonstrate safety and effectiveness of these therapies as well as decreased periprocedural morbidity and mortality. Long-term outcomes and the need for surveillance and secondary interventions remain to be established and warrant further investigations.

aneurysm was achieved in 1864 by Smyth in New Orleans, who ligated the right common carotid and innominate artery.[4] The aneurysm recurred and ruptured 10 years later. Halsted was the first to combine ligation successfully with resection of a subclavian artery aneurysm in 1892 at the Johns Hopkins Hospital.[5] In 1913 Matas reported 225 cases of aneurysms treated by endoaneurysmorrhaphy, and seven of these were subclavian aneurysms.[6]

ARCH VESSEL ANEURYSMS

Epidemiology and Etiology

Innominate, common carotid, and subclavian artery aneurysms usually arise from degenerative disease. In a series of 74 patients with arch vessel aneurysms, Cury et al. reported that 63% were degenerative in nature with the vast majority in men older than 60 years.[7] Less commonly, these aneurysms can also result from trauma, fibromuscular dysplasia, syphilis, cystic medial necrosis, vasculitis, invasion of the vessel wall by contiguous tuberculous lymphadenitis, and idiopathic congenital causes. Although only 1% of all peripheral arterial aneurysms involve the subclavian and innominate arteries, 30% to 50% of patients with nonspecific, degenerative arch vessel aneurysms have aortoiliac or other peripheral aneurysms.[8,9] Patients presenting with these aneurysms should therefore be evaluated thoroughly for concurrent aneurysms.

Aneurysms of the distal subclavian artery, frequently with extension into the first portion of the axillary artery, are usually associated with a thoracic outlet obstruction, cervical rib, and other bony abnormalities that result in arterial compression and poststenotic dilation. This specific type of aneurysm is discussed in Chapter 122.

Subclavian Artery Aneurysms

True subclavian aneurysms, typically seen in older adult patients, are usually degenerative and are the most common type of arch vessel aneurysm, accounting for 50% of the cases in the two largest series reported.[7,10] Pairolero et al.[8] reported the treatment of 31 patients with subclavian artery aneurysms treated over a 20-year period. True degenerative aneurysms were repaired in 12 patients, traumatic pseudoaneurysm in 10, and aneurysms secondary to thoracic outlet obstruction in 6. McCollum et al.[9] also reported their 25-year experience with subclavian artery aneurysm repairs, which included 15 patients, more than half of whom had true degenerative aneurysms. More recently, Naz et al.[11] reported their series of 10 patients of whom five were traumatic in origin, four were related to thoracic outlet syndrome, and only one was degenerative. Pseudoaneurysms frequently occur as a result of blunt and penetrating trauma. Iatrogenic injury from inadvertent cannulation of the subclavian artery with pseudoaneurysm formation is uncommon but increasing in frequency due to subclavian vein catheterization for various indications.[12,13] Although many small-caliber (<7 F) misplaced catheters can be removed and simple compression applied, removal of larger catheters, such as those used for hemodialysis, can lead to significant hemorrhage or pseudoaneurysm formation because of an inability to compress the puncture site beneath the clavicle. Recent reports have described the successful use of endovascular techniques to repair arterial injuries occurring during central venous access using endografts or percutaneous closure devices.[12,14-17]

Innominate Artery Aneurysms

True aneurysms of the innominate artery are rare, representing 2% to 5% of cases of arch vessel aneurysms. Bower et al.[10] reported their 40-year experience, which included only four patients with true aneurysms of the innominate artery among 73 patients treated surgically for brachiocephalic aneurysms. Similarly, in the series reported by Cury et al.,[7] 2 out of 74 surgically treated supraaortic aneurysms were of the innominate artery. As is the case with subclavian artery aneurysms, iatrogenic pseudoaneurysms after inadvertent arterial puncture during central venous access have recently been reported.[18] The largest series of innominate aneurysm repair is by Kieffer et al.,[19] in which they found six degenerative aneurysms among 27 patients with innominate artery aneurysms. Other etiologies included mycotic, dissecting, and connective tissue disorders, extension of arch aneurysms, and traumatic and iatrogenic pseudoaneurysms. Because of the devastating consequences of untreated innominate artery aneurysms, Bower et al.[10] have recommended operative treatment of all symptomatic and asymptomatic affected patients fit for surgical repair to avoid the natural history that inevitably leads to rupture or thromboembolism.

Common Carotid Artery Aneurysms

True aneurysms of the common carotid arteries are very rare. In fact, pseudoaneurysms of the carotid arteries are considerably more frequent and usually result from complications of carotid reconstructions, blunt or penetrating trauma, carotid dissections, or infection.[20,21] The vast majority of the true aneurysms of the carotid arteries are degenerative[22]; other less frequent causes include fibromuscular dysplasia, Marfan syndrome, Behçet disease, and Takayasu arteritis.[20,23] Bilateral common carotid artery aneurysms are extremely unusual, generally associated with Takayasu arteritis or Cogan syndrome.[24,25] Carotid bifurcation and internal carotid artery aneurysms are discussed in Chapter 94.

Clinical Presentation

Symptoms

Given the prevalence of imaging in modern medical practice, most arch vessel aneurysms are discovered incidentally and only 25% demonstrate symptoms at the time of diagnosis.[8] Presenting symptoms include (1) chest, neck, and shoulder pain from acute expansion or rupture; (2) upper extremity acute and chronic ischemic symptoms from thromboembolism; (3) upper extremity pain and neurologic dysfunction from brachial plexus compression; (4) hoarseness from compression of the right recurrent laryngeal nerve; (5) respiratory insufficiency from tracheal compression; (6) transient ischemic attacks and stroke

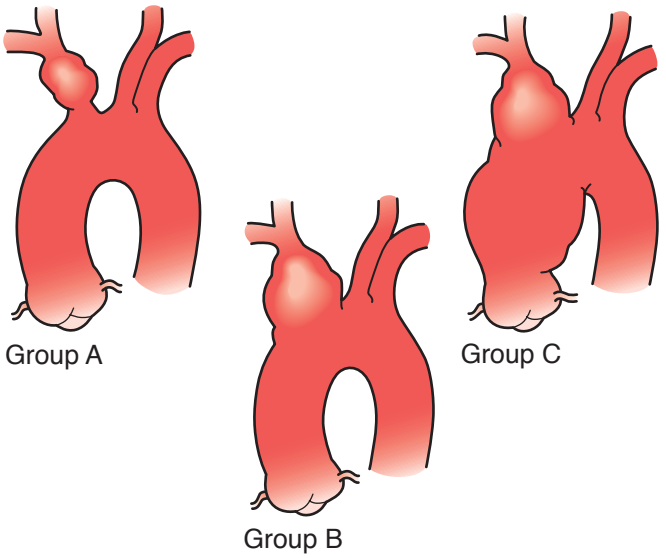

Figure 84.2 Classification of aneurysms of the innominate artery according to extent of involvement. (A) *Group A*, no involvement of origin of the innominate artery. (B) *Group B*, involvement of origin of the innominate artery but not of aorta. (C) *Group C*, involvement of innominate artery and aorta. (From Kieffer E, Chiche L, Koskas F, et al. Aneurysms of the innominate artery: surgical treatment of 27 patients, *J Vasc Surg*. 2001;2:222.)

from thromboembolism in the vertebral and carotid circulations; (7) dysphagia from esophageal compression in cases of aberrant right subclavian artery; and (8) hemoptysis from erosion into the apex of the lung. Tracheobronchial or esophageal fistulization from contiguous arch vessel aneurysms can also occur. In the case of iatrogenic pseudoaneurysms, clinical presentation includes a pulsatile mass, airway or nerve compression, chest pain, upper limb ischemia, or hemodynamic instability.[26]

Signs

Patients without symptoms may be diagnosed through imaging studies for unrelated conditions (Fig. 84.1). In cases of subclavian artery aneurysms, patients may note the presence of a supraclavicular pulsatile mass. However, most asymptomatic pulsatile masses in this area represent tortuous and elongated common carotid and subclavian arteries and not necessarily aneurysmal degeneration. Other physical signs may include (1) a supraclavicular bruit, (2) absent or diminished pulses in the upper extremity, (3) normal pulses with signs of microembolization ("blue finger" syndrome), (4) sensory and motor signs of brachial plexus compression, (5) vocal cord paralysis, and (6) Horner syndrome resulting from compression of the stellate ganglion and other contributions to the cervical sympathetic chain at the base of the neck.[27]

Imaging

Plain films of the chest may reveal a superior mediastinal mass that may suggest the presence of a neoplasm. Ultrasonography, MR, or CT imaging establishes the diagnosis. Conventional arch and upper extremity angiography, or MR or CT angiography (CTA) are important to delineate the extent of the aneurysm, to assess the sites of vascular occlusion in cases complicated by thromboembolism, to note the competency of the contralateral vertebral circulation if the ipsilateral vertebral artery originates from an aneurysmal vessel, and to assess anatomic suitability for endovascular repair. These points are essential in planning appropriate management (i.e., surgical reconstruction or endovascular repair).

Open Surgical Repair

Contemporary surgical repair of arch vessel aneurysms involves resection or endoaneurysmorrhaphy and reestablishment of arterial continuity with an end-to-end anastomosis (for very small aneurysms) or, more commonly, an interposition arterial prosthetic graft. Although proximal and distal ligation of arch vessel aneurysms occasionally has been successful in the past, ligation without direct or extraanatomic reconstruction generally should not be performed because ischemic symptoms develop in 25% of cases so treated.[8]

Innominate Artery Aneurysms

An anatomic classification of the extent of the aneurysm has been proposed by Kieffer et al.[19] to guide the surgical repair of aneurysms of the innominate artery (Fig. 84.2). Type A is confined to the innominate artery distal to its origin. Type B is the most common and involves the innominate artery and its origin, whereas type C involves both the innominate artery and the ascending aorta. The innominate and proximal right subclavian arteries are usually exposed through a median sternotomy extended into the right neck. Proximal control of the innominate is obtained at the aortic arch. The right subclavian and right common carotid arteries are exposed and dissected for distal control. The aneurysm is resected, and reconstruction with a prosthetic graft is usually performed. For type A and B

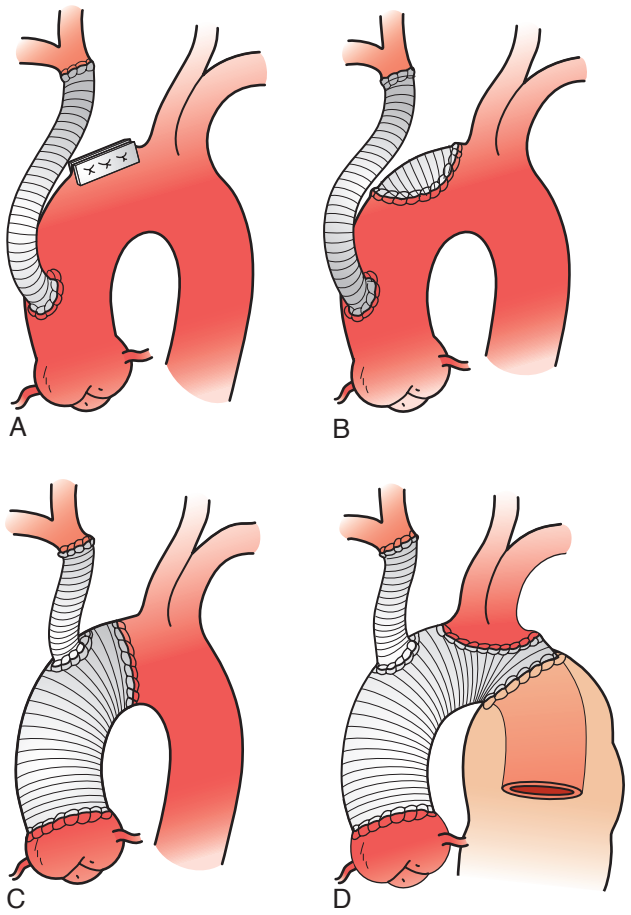

Figure 84.3 Techniques used for treatment of aneurysms of the innominate artery. (A) Lateral suture of aorta. (B) Patch angioplasty of aorta. (C) Replacement of ascending aorta. (D) Replacement of ascending aorta and transverse aortic arch in association with distal elephant trunk prosthesis. (From Kieffer E, Chiche L, Koskas F, et al. Aneurysms of the innominate artery: surgical treatment of 27 patients, *J Vasc Surg*. 2001;2:222.)

aneurysms, the proximal graft anastomosis is usually performed to the native ascending aorta proximal to the innominate origin. The graft is then anastomosed to the uninvolved distal innominate artery (Fig. 84.3). The origin of the innominate artery is oversewn with a running suture, or patch angioplasty of the aorta may occasionally be required. For lesions extending into the origins of the right subclavian or common carotid artery, a bifurcated graft can be used, or a branch graft to the subclavian artery can be sewn onto the graft going into the common carotid artery. The bifurcated configuration may sometimes be prone to compression or kinking when the sternum is closed, so caution should be taken to perform the proximal anastomosis in the lateral aspect of the ascending aorta. In cases of a bovine arch, additional graft reconstruction of the left common carotid artery may be necessary. Type C innominate artery aneurysms usually require aortic arch and innominate artery prosthetic graft replacement using cardiopulmonary bypass and hypothermic circulatory arrest.

Subclavian Artery Aneurysms

Subclavian artery aneurysms can be divided into proximal, typically degenerative, or distal, usually related to thoracic outlet syndrome. For proximal right subclavian aneurysms, median sternotomy with extension into the supraclavicular fossa is usually necessary to gain adequate exposure for proximal control. Supraclavicular and infraclavicular incisions may be used to mobilize the proximal and distal subclavian artery. Resection of the clavicle also offers excellent exposure of the subclavian artery. Partial medial clavicular resection is rarely necessary, although it may be helpful for proximal subclavian artery exposure when median sternotomy is not feasible. The supraclavicular incision is extended medially, and the fascia and periosteum are incised. The origins of the sternocleidomastoid and pectoralis major muscles are reflected subperiosteally, the first superiorly and the second inferiorly. The medial third of the clavicle is disarticulated and subperiosteally resected with care to avoid injury to the subclavian vein. In cases of proximal left subclavian aneurysms a left thoracotomy combined with supraclavicular exposure may be necessary.

Extraanatomic reconstruction combined with proximal and distal aneurysm ligation has also been described in unusual circumstances.[28] For aneurysms involving the midsubclavian artery and the distal subclavian artery, a supraclavicular incision often gives adequate exposure and may be complemented by an infraclavicular incision for distal control. Alternatively, proximal and distal control may be obtained endovascularly using balloon occlusion catheters placed angiographically. Division or resection of the midportion of the clavicle may be necessary to gain additional exposure; if so, the clavicle may be reconstructed at the completion of the operation. If the aneurysm involves the origin of the vertebral artery, reconstruction by reimplantation or other means is appropriate, particularly if this is the dominant vertebral artery or for cases in which the contralateral vertebral artery is hypoplastic or diseased.

Results

Aneurysm resection with graft replacement is durable and yields excellent long-term results. In one of the largest reported series, normal upper extremity circulation was maintained and there were no procedure-related complications during a mean follow-up of 9.2 years.[8] Although open repair frequently results in durable and excellent long-term outcomes, considerable associated morbidity and mortality has been reported. In-hospital mortality could be as high as 11% according to a report of open repair of innominate artery aneurysms, in which 18% of patients required prolonged ventilation.[19] Because many patients with true aneurysms are unfit for open repair because of their advanced age and multiple comorbidities, careful patient selection is mandatory to improve outcomes. Relative contraindications to open repair also include severely compromised pulmonary function, prior sternotomy or left thoracotomy, and hemodynamic instability secondary to multiple trauma.

Endovascular Repair

Endovascular repair is an attractive option for patients unfit for open repair because it is associated with lower morbidity and mortality. Many reports of endovascular repair of arch vessel aneurysms, particularly those involving the innominate

and the subclavian artery, have been published in recent years.[26,29-34] This has led to treatment of better-risk patients with appropriate anatomy, to avoid the morbidity of open surgery. Aneurysms secondary to connective tissue disorders may also be more suitable for endovascular repair to avoid direct resection and anastomoses to diseased vessels, although long-term outcomes are not known.[35]

Anatomic Considerations

The proximal portion and midportion of the subclavian artery are most amenable to endovascular treatment. However, several anatomic limitations exist. It is unusual for true subclavian or innominate aneurysms to have adequate proximal and distal landing zones. Also, coverage of branch vessels, such as the right carotid, vertebral arteries, and left internal mammary when it has been used for coronary bypass, may not be feasible. Endografts crossing the first rib may be subject to extrinsic compression. The distal subclavian artery is located between the clavicle and the first rib, and endografts in this location are subject to compression, deformation, and fracture.[35-38] Another potential complication of endograft placement in the right subclavian artery is stroke from embolic debris dislodged into the right common carotid artery.[35] The vertebral artery origin is vulnerable on both sides and may be covered during stent-graft deployment. This usually is well tolerated when the contralateral vertebral artery is patent and of adequate size. However, posterior circulation stroke may occur when the contralateral vertebral artery is highly stenotic, hypoplastic, or occluded. In this circumstance, the ipsilateral vertebral artery should be revascularized by end-to-side anastomosis to the common carotid artery or other means. Whenever the origin of the vertebral artery is involved by the aneurysm, coil embolization of the ipsilateral vertebral artery is desirable to prevent future branch vessel endoleaks.

Technique

Endovascular repair of subclavian or innominate artery aneurysms is usually performed through a transbrachial or transfemoral approach. A transaxillary approach has occasionally been necessary.[39] Both balloon-mounted and self-expandable endografts have been used off label for endovascular repair of arch vessel aneurysms.[40] The most frequently used endografts include the Wallgraft (Boston Scientific, Natick, Massachusetts), Viabahn (W.L. Gore & Assoc, Flagstaff, Arizona), or Fluency (C.R. Bard, Inc, Murray Hill, New Jersey).[41] Most contemporary endografts usually require 7 to 9 F delivery sheaths, depending on endograft diameter. However, larger endografts, such as those required for endovascular repair of innominate artery aneurysms, require still larger introducer sheaths, usually 11 or 12 F. The more flexible Viabahn endograft may be more suitable in cases of considerable arterial tortuosity. Lower-profile devices, such as the balloon-mounted iCast endograft (Atrium Medical, Hudson, New Hampshire), which is currently available up to 10 mm in diameter, can be delivered through a 7-F sheath. Of note, the largest iCast endograft can potentially be dilated up to 14 mm in diameter. Because of discrepancy in proximal and distal landing zone diameters, a combination of endografts of different sizes may be necessary. Furthermore, given the rigidity of balloon-mounted endografts, these may be used for accurate proximal deployment at the level of the ostium of the vessel and combined with more flexible distal self-expanding endografts. A novel approach is the use of multilayer stents to cause aneurysm thrombosis while maintaining flow through branch vessels.[42] Although technically feasible, mid- and long-term results of these techniques have yet to be reported to accept them as valid alternatives for the treatment of aneurysms.

Hybrid Operations

In this minimally invasive approach, embolization with coils or a vascular plug of a proximal subclavian artery aneurysm (not involving the origin) is combined with subclavian artery transposition or carotid-subclavian bypass, avoiding placement of an endograft.[43] Complete exclusion of the subclavian aneurysm is facilitated by ligation of the subclavian artery proximal to the distal anastomosis of the carotid-subclavian bypass. These procedures can be staged or combined in an operating room equipped with high-resolution imaging equipment. As with endograft placement, care must be taken to preserve the vertebral artery, if the contralateral vertebral artery is inadequate, and the left internal mammary when it has been or is anticipated that will be used for coronary bypass.

Off-label use of iliac limb endografts has been reported for the exclusion of right subclavian as well as innominate artery aneurysms combined with carotid-subclavian or carotid-axillary bypass (Fig. 84.4).[44-46] This technique introduces the endograft into the innominate artery in a retrograde fashion using the carotid-subclavian bypass limb as a conduit before anastomosis to the subclavian artery. Cerebral embolization is a risk and may be minimized by occluding antegrade carotid flow during endoprosthesis introduction and deployment.[44]

With the introduction of endografts specific for endovascular treatment of thoracic aortic aneurysms, hybrid procedures have become feasible for more proximal aneurysm of the great vessels extending into the aortic arch. In these procedures, exclusion of the orifice of aneurysmal arch vessels is combined with thoracic endovascular aortic aneurysm repair and extraanatomic arch vessel revascularization (i.e., carotid-carotid, subclavian transposition, and carotid-subclavian bypass).[34,47]

Results

Because of the low incidence of arch vessel aneurysms, only small case series and case reports are available to assess outcomes of endovascular treatment of these aneurysms. For nonatherosclerotic aneurysms such as those due to connective tissue disorders,[40,48] Takayasu arteritis,[45] or infections such as HIV,[46] only case reports are available and reveal acceptable outcomes. However, there is an inherent bias in case reports because successful outcomes are primarily published. Thus the long-term durability of endovascular therapy, particularly endografts, in arch vessels is unknown. Short-term patency for subclavian stent-grafts ranges from 83% to 100% over a mean follow-up of 7 to 29 months.[33,36,37,49] Endograft compression, deformation, and fracture and stenosis from intimal hyperplasia have been reported and may limit the applicability of endovascular repair

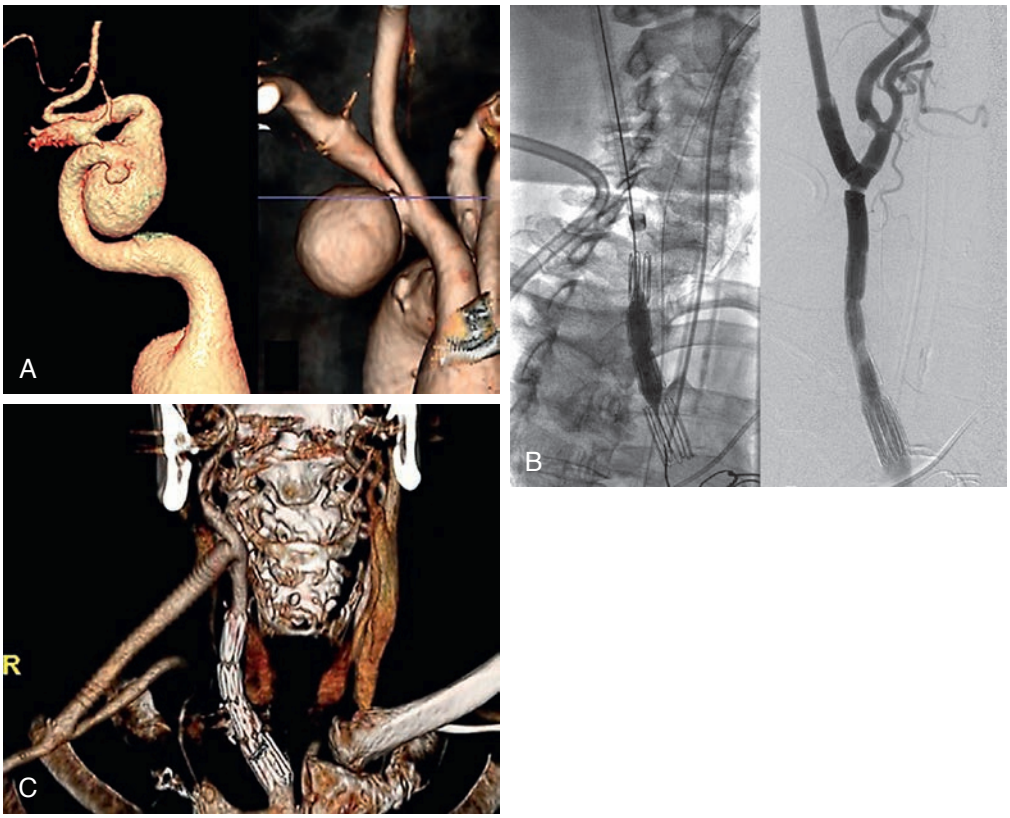

Figure 84.4 (A) Three-dimensional computed tomography (CT) volume rendering of right subclavian artery aneurysm. (B) Deployment of iliac extender limb via a right carotid conduit placed for bypass to the right axillary artery after exclusion of right subclavian artery aneurysm. (C) Follow-up CT angiography of the excluded aneurysm and patent carotid-axillary bypass. (From Bruen KJ, Feezor RJ, Lee WA. Hybrid management of proximal right subclavian artery aneurysms, *J Vasc Surg*. 2011;53:528.)

in this location.[49-51] Bruen et al.[44] reported a case series of four patients with right subclavian aneurysms treated with carotid-axillary bypass and retrograde placement of iliac limb endografts across the innominate bifurcation into the common carotid artery. Mean follow-up time was 232 days (range, 50-564) with 100% patency of the endograft limbs and bypass grafts. No endoleaks were found on follow-up scans. Two of the four patients suffered a minor stroke. Cury et al.[7] reported on the experience at the Cleveland Clinic in treating supraaortic vessel aneurysms that included 11 patients treated endovascularly. Eight of these aneurysms were of the subclavian artery. In this series, one death occurred in the endovascular group, with no endoleaks and no sac enlargement in the follow-up period. Patency rates were not reported. In the series of Andersen et al.,[34] outcomes of 13 hybrid or completely endovascular repairs of intrathoracic subclavian artery aneurysms were reported. All patients underwent repair with thoracic aortic stent-graft placement with (10/13) or without (3/13) revascularization. One death (7.7%) occurred within 30 days after urgent zone 0 hybrid arch repair for an aberrant subclavian artery-esophageal fistula. One incidence of stroke was reported. In a recent series of 26 extracranial carotid aneurysms, three were treated with covered stents.[52] At a mean follow-up of 33 months (range, 23-47 months), all carotid stent-grafts remain patent. In a systematic review of 113 studies including 224 patients undergoing endovascular repair of extracranial carotid artery aneurysms, Li et al.[53] reported a procedure success of 93%, with in-hospital mortality of 4%. Periprocedural stroke rate was 1.8%, with a postprocedural endoleak rate of 8%. At a mean follow-up of 15 months, stent-graft patency was 93%. Late surgical conversion and re-intervention rates were 2.4% and 4.7%, respectively. In a series of four patients reported by Zehm et al.[54] who underwent endovascular repair of subclavian artery aneurysms, all stent-grafts remained patent at a mean follow-up of 38 months. Re-interventions were required in two patients, including coil embolization and additional stent-grafting. Although these case series are small, they provide encouraging results for continued advancement of endovascular therapy for these complex lesions.

ANEURYSM OF ABERRANT SUBCLAVIAN ARTERY AND KOMMERELL DIVERTICULUM

Anatomy

Aberrant Subclavian Artery

An aberrant right subclavian artery arising from the proximal portion of the descending thoracic aorta is the most common congenital anomaly of the aortic arch, occurring in 0.5% to 1% of the population.[55] It was first described in 1735 at autopsy

Figure 84.5 Anterior (A) and posterior (B) three-dimensional computed tomography angiography views of the aortic arch reveal that the anomalous right subclavian artery *(arrowheads)* originates both distal and posterior/inferior on the arch relative to the left subclavian origin.

by Hunauld. In 1794 Bayford described "dysphagia lusoria," a difficulty in swallowing caused by impingement of the aberrant vessel on the esophagus. The anomalous right subclavian artery originates distal to the left subclavian origin, typically posterior and inferior on the arch, and in 80% of cases crosses the midline between the esophagus and the spine (Fig. 84.5). Less commonly, it crosses the midline between the esophagus and trachea or anterior to the trachea. In individuals with a right-sided aortic arch, an aberrant left subclavian artery may originate distal to the origin of the right subclavian, and this may also become aneurysmal. During embryologic development, the left fourth arch becomes part of the aortic arch and the right fourth arch becomes the root of the right subclavian artery. An aberrant right subclavian artery occurs when the right fourth aortic arch and right dorsal aorta involute cranial to the seventh intersegmental artery. Most patients with this anomaly are asymptomatic, and the aberrant subclavian artery is of no clinical consequence. A nonrecurrent right laryngeal nerve is associated with this anomaly.

Aberrant Subclavian Artery Aneurysm

Aneurysmal degeneration of the aberrant right subclavian artery is encountered most frequently in adults of either sex older than 50 years. The majority of these require intervention, owing either to symptoms or to the risk of rupture. Clear size criteria have not been established due to the rarity of this finding, although Cina et al. have proposed repair of aneurysms larger than 3 cm in size in good-risk patients.[56] Mean size of the aneurysm is greater than 4 cm, according to a multicenter registry.[57]

Kommerell Diverticulum

Degenerative aneurysmal changes may occur in up to 60% of patients in the proximal portion of the aberrant subclavian artery.[58] This condition has been termed Kommerell diverticulum after Kommerell, who in 1936 described a diverticulum of the aorta at the origin of the anomalous subclavian artery.[55] McCallen and Schaff[59] first called attention to the clinical significance of aneurysmal change in an anomalous right subclavian artery in a report of 1956. The largest experience to date with this condition was reported by Kieffer et al.,[60] who surgically treated 33 adults with aberrant subclavian arteries, 17 of whom had a Kommerell diverticulum or aneurysmal change of the thoracic aorta at the origin of the aberrant subclavian artery.

Clinical Presentation

Aberrant Right Subclavian Artery

A classification system based on clinical presentation and anatomy has been proposed for aberrant subclavian arteries (Fig. 84.6).[60] Nonaneurysmal aberrant right subclavian artery may result in dysphagia and symptomatic arterial occlusive disease (groups 1 and 2). According to Kieffer et al.,[60] 11 of 33 patients without aneurysmal degeneration presented with dysphagia, whereas five developed upper right limb ischemia because of either arterial occlusive disease or embolism originating from the nonaneurysmal aberrant right subclavian artery. More recently, Stone et al.[61] reported 24 patients diagnosed with an aberrant right subclavian artery over a period of 6 years in the Mayo Clinic health system. Sixteen (66%) were asymptomatic at the time of presentation, and eight presented with various symptoms of dysphagia, upper extremity ischemia, or findings of aneurysmal degeneration. Intervention was performed in 10 patients. Fourteen patients were observed with no complications or aneurysmal degeneration over a mean follow-up period of 38 months.

Aberrant Subclavian Artery Aneurysm

Although patients with aneurysms of an aberrant right subclavian artery are sometimes diagnosed incidentally, they usually present with dysphagia from esophageal compression, dyspnea and coughing from tracheal compression, chest pain from expansion or rupture, or symptoms of right upper extremity ischemia secondary to thromboembolism. Patients may also present emergently with aneurysm rupture or dissection. According to a multicenter registry,[57] 14% of patients presented with rupture. Cina et al.[56] reported that 53% of patients in their series presented with either rupture or dissection. Aneurysm rupture in these cases seems to be unrelated to the size of the aneurysm. Many reported cases were in asymptomatic patients whose

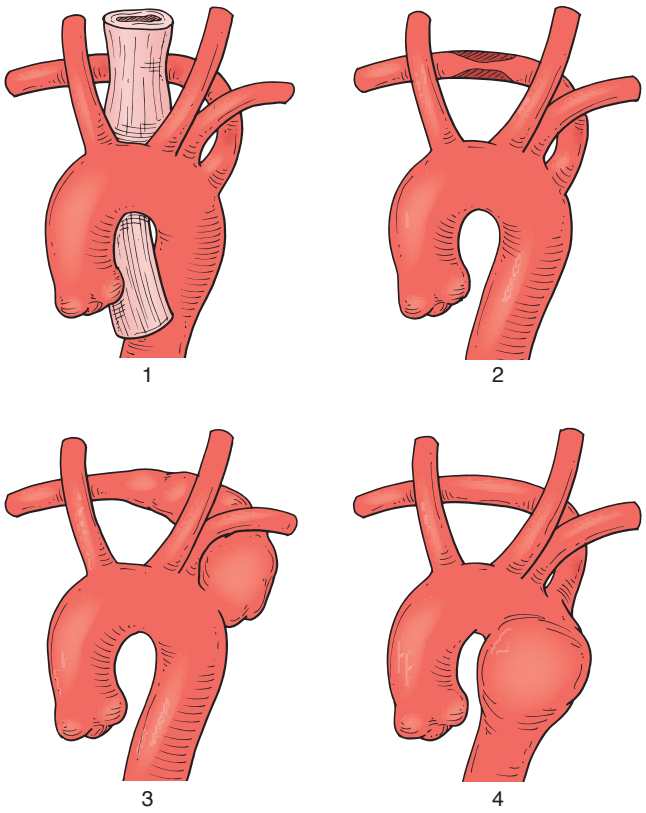

Figure 84.6 Classification system for aberrant subclavian artery as proposed by Kiefer et al.[60] *Group 1*, Nonaneurysmal aberrant right subclavian artery (ARSA) causing compressive symptoms. *Group 2*, Occlusive disease of a nonaneurysmal ARSA. *Group 3*, Aneurysmal dilation of the ARSA without aortic involvement. *Group 4*, Aneurysmal ARSA with aortic involvement. (From Kieffer E, Bahnini A, Koskas F. Aberrant subclavian artery: surgical treatment in thirty-three adult patients. *J Vasc Surg*. 1994;19:100–9.)

aneurysm was found on chest radiography and interpreted as a superior mediastinal mass. Chest CT can detect this condition noninvasively, but CT or digital subtraction angiography is necessary to plan surgical treatment or endovascular repair (Fig. 84.7). Approximately one-fifth of reported patients with this anomaly have an associated abdominal aortic aneurysm.[55]

Treatment

Conservative management is appropriate for asymptomatic patients without a Kommerell diverticulum.[61] No specific surveillance or follow-up protocol exists for these patients, but the presence of symptoms or aneurysmal degeneration should prompt treatment.

Surgical Treatment

Aberrant Right Subclavian Artery

Open repair is usually performed through a supraclavicular incision. The aberrant right subclavian artery is divided after dissecting it to the left of the esophagus via a right supraclavicular incision. The distal end of the subclavian is then transposed and anastomosed end-to-side to the right common carotid artery.

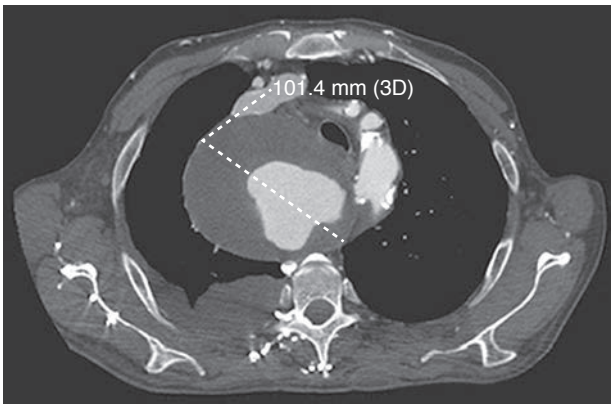

Figure 84.7 Contrast enhanced axial computed tomography scan at the level of the aortic arch. A large aneurysm of the aberrant right subclavian artery is demonstrated passing posterior to the trachea and esophagus. (From Ilijevski N, Nenezic D, Popov P, et al. Images in vascular medicine: giant aneurysm of the aberrant right subclavian artery, *Vasc Med*. 2011;16:157–158.)

Ligation to the left of the esophagus relieves local pressure symptoms. This approach is satisfactory when the more proximal aberrant subclavian is not aneurysmal.[62,63]

Aberrant Subclavian Artery Aneurysm

Because of the propensity of these aneurysms to cause symptoms—and because of the possibility of lethal rupture—resection or exclusion of the aneurysmal artery with vascular reconstruction of the subclavian artery is recommended. Multiple procedures and reconstructions for open repair of these aneurysms have been described. The best approach depends on the anatomic characteristics of the lesion, patient fitness, and acuity of presentation. In the elective setting, open repair consists of staged extraanatomic bypass to reconstruct the aberrant subclavian artery, followed by thoracotomy to oversew the origin of the Kommerell diverticulum. Simple side-biting clamp exclusion may be possible, although interposition graft resection of the aorta itself may be necessary in up to 30% of patients with aortic involvement.[60] Considerations for the procedure are similar to those for open repair of a degenerative proximal left subclavian aneurysm. This repair may be accomplished via a right or left posterolateral thoracotomy (depending on the position of the aortic arch) or a median sternotomy.[55,60,64,65] The subclavian artery is reconstructed by interposition arterial grafting in which the proximal anastomosis may be performed to the ascending aorta. Alternatively, a left posterolateral thoracotomy for proximal resection of the aneurysm coupled with a right supraclavicular incision for reconstruction of the subclavian artery by end-to-side anastomosis to the right common carotid artery has been described.[66] A staged approach with right carotid-subclavian bypass or transposition (end-subclavian to side-carotid) preceding left thoracotomy and aneurysm resection with oversewing of the origin from the aortic arch is attractive because the risk of cerebral and right upper extremity embolization is minimized. Extraanatomic reconstruction of the right subclavian artery also has been described. Because it is necessary to resect the aneurysmal vessel near its origin from the aorta, the modified extrathoracic approach alone, described

for treatment of dysphagia lusoria with nonaneurysmal aberrant subclavian vessels, would not be effective.

Endovascular-Hybrid Treatment

Open repair may be associated with high rates of neurologic complications and mortality, particularly in patients unfit for open major vascular reconstructions. Because the thoracotomy and aortic clamping are the most morbid portions of open repair, which has a reported mortality up to 30%,[60] the combination of aortic endografting and extraanatomic bypass is a particularly appealing combination for treatment of this condition. In addition, open repair may be contraindicated after previous thoracotomy. As the preferred treatment has evolved to an endovascular approach, significant improvement has occurred in perioperative outcomes, with no affection of late outcomes according to a recent review.[67]

Hybrid Approach

Endovascular occlusion of a symptomatic aberrant right subclavian artery, with or without aneurysm, using thoracic aortic endografts combined with distal ligation is an alternative to open repair. Hybrid repair is currently the most frequent treatment method according to a recent multicenter registry.[57] Because exposure to the proximal aberrant right subclavian artery is limited through a cervical approach—and to avoid leaving a stump that may evolve into an aneurysm, a hybrid approach to the proximal end of the artery may be used as an alternative. For this purpose an occlusion device may be placed in antegrade or retrograde fashion at the origin of the aberrant right subclavian artery (Fig. 84.8).[68] The antegrade approach may be preferable to have better control of the deployment and to avoid embolization of the occluder into the aortic arch, which may occur when a retrograde approach is used.

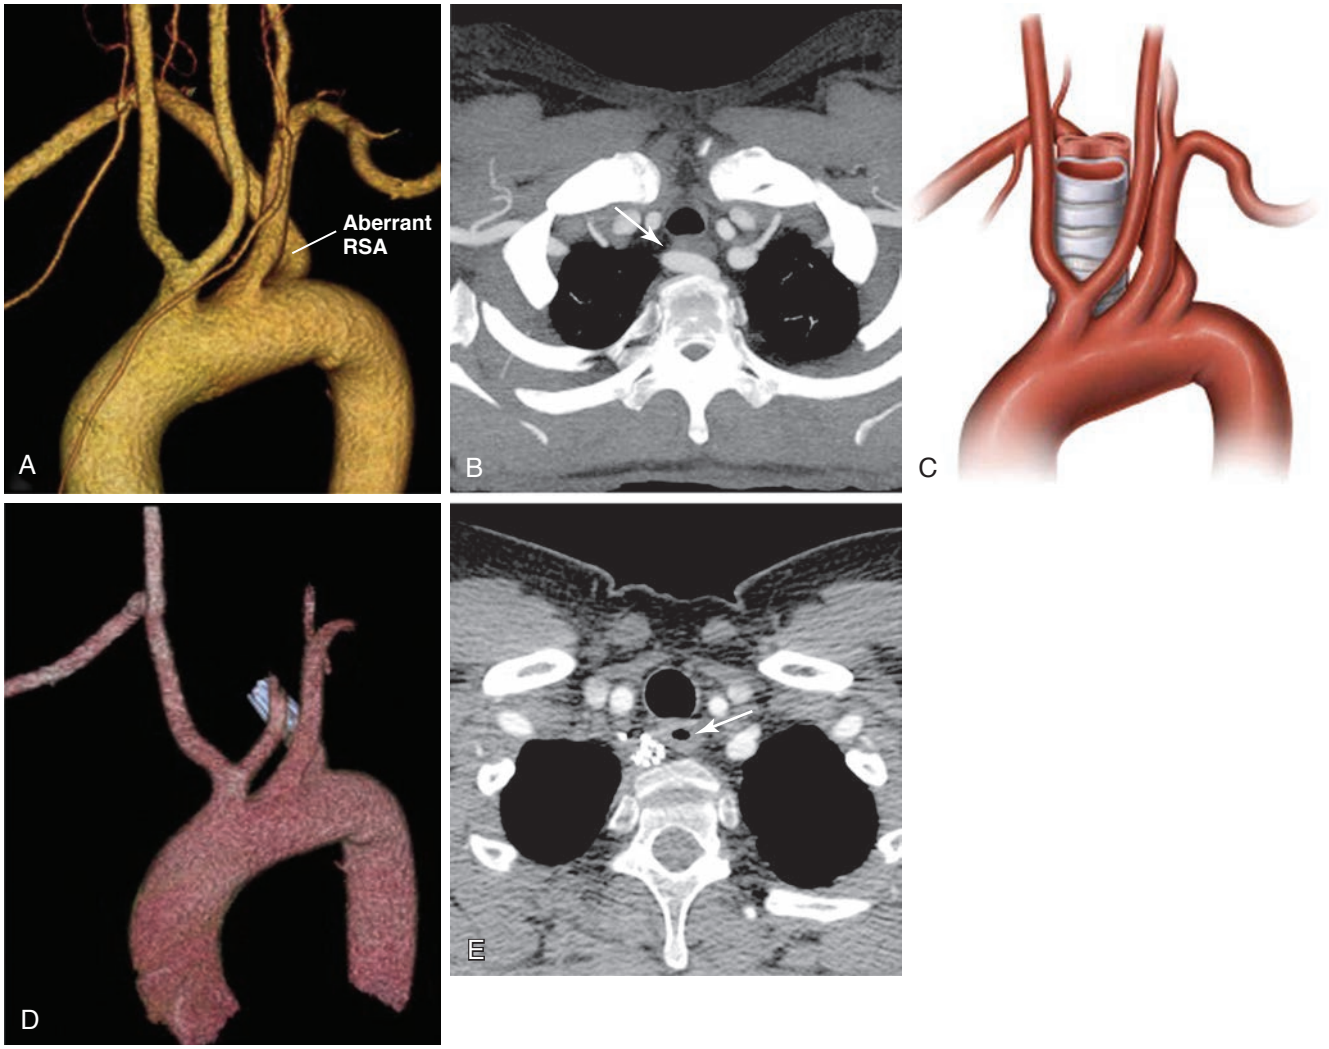

Figure 84.8 (A) Three-dimensional computed tomography angiography (CTA) shows the aberrant right subclavian artery arising from the distal arch and running posterior. (B) A CT scan axial image shows aberrant right subclavian artery compressing the esophagus through a posterior course. (C) Illustration of the aberrant origin and course of the right subclavian artery. (D) Postoperative CTA shows the right carotid-subclavian bypass and occlusive device within the aberrant subclavian artery. (E) Postoperative CT scan axial image at same level as in the preoperative CT shows decompression of the esophagus. (From Shennib H, Diethrich EB. Novel approaches for the treatment of the aberrant right subclavian artery and its aneurysms, *J Vasc Surg*. 2008;47:1066.)

A thoracic endograft can effectively exclude antegrade flow into an ARSA aneurysm (Fig. 84.9).[69-71] However, with current devices, endovascular repair alone is insufficient for treatment of most lesions. Thoracic aortic endografting usually needs to be combined with revascularization of one or both subclavian arteries (Fig. 84.10). In the majority of cases the orifices of the aberrant right and left subclavian arteries are situated at the same level or in close proximity. To effectively occlude the origin of the aberrant vessel with a thoracic endograft, its placement usually requires exclusion of both subclavian arteries.[70] Although single subclavian artery coverage may be feasible during thoracic aortic endografting, bilateral occlusion is not recommended because subclavian steal syndrome or upper limb ischemia may occur, as well as spinal ischemia or stroke.[72] To reduce these complications, bilateral subclavian transposition or carotid-subclavian bypass procedures may need to be performed before endovascular treatment.[73] In some cases the left common carotid artery can also arise from the aortic arch in very close proximity to the origins of the left subclavian and aberrant right subclavian artery. Transposition and revascularization of two or three arch vessels to provide an adequate neck for thoracic endografting may be necessary.[69]

The combination of endovascular and subclavian revascularization procedures significantly reduces morbidity and mortality of the repair of these aneurysms and, if effective and durable, could become standard treatment. Midterm results reveal a 36-month survival of 90% with two late endoleaks (one type I and one type II) among 24 patients with ARSA aneurysms.[57] However, long-term outcomes of such therapy are not established and, more important, it remains unclear whether covering the aortic origin of the aneurysm using an aortic endograft can effectively relieve compressive symptoms of the diverticulum and prevent rupture.

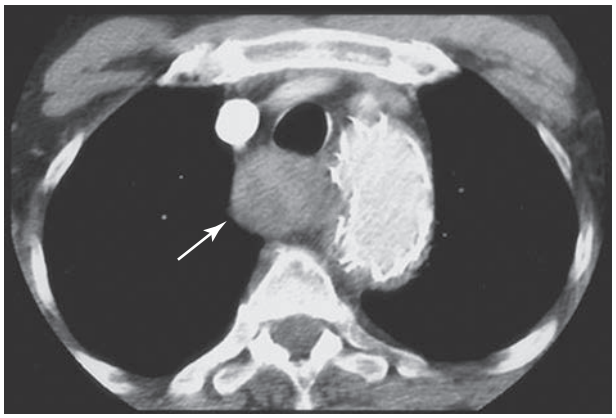

Figure 84.9 Contrast-enhanced computed tomography performed 6 weeks following endovascular repair, demonstrating thrombosed right subclavian artery aneurysm *(arrow)*. (From Munneke GJ, Loosemore TM, Belli AM, et al. Aneurysm of an aberrant right subclavian artery successfully excluded by a thoracic aortic stent graft with supra-aortic bypass of three arch vessels, *Cardiovasc Intervent Radiol.* 2005;5:653.)

Endovascular Approach

Total endovascular repair of aberrant subclavian artery aneurysms may be feasible using chimney or branched stent-grafts. A chimney graft repair was reported in one case in which open debranching was not considered feasible because of prior cardiac transplantation and comorbidities. A type III endoleak occurred postoperatively from the gutters left between the stent-grafts, which is a limitation afflicting these type of repairs.[74] Other endovascular techniques for the treatment of ARSA aneurysm have been described. Davidian et al.[31] reported a case in which the aneurysm exclusion was performed by intraluminal placement of an endograft confined to the aberrant vessel. A similar approach has been used to seal the entry site of an aortic dissection originating from an aberrant right subclavian artery.[71] In this case the dissection involved the aortic arch and the distal aorta. A Wallgraft endograft was deployed in the aberrant right subclavian artery to seal the main intimal tear. Alternatively, Hoppe et al.[75] chose to occlude an aberrant subclavian artery

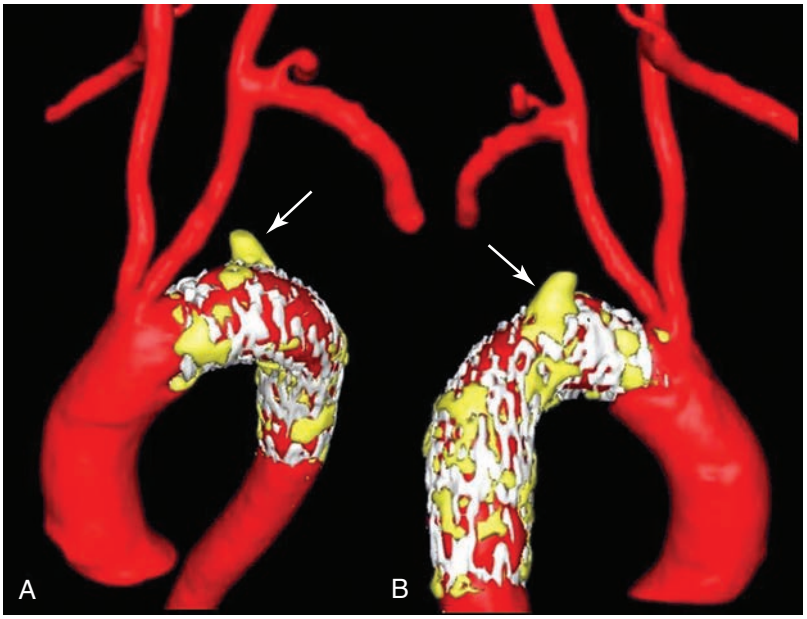

Figure 84.10 Anterior (A) and posterior (B) three-dimensional computed tomography angiography views after thoracic aortic endografting combined with revascularization of one or both subclavian arteries and exclusion of the proximal left subclavian artery *(arrows)*.

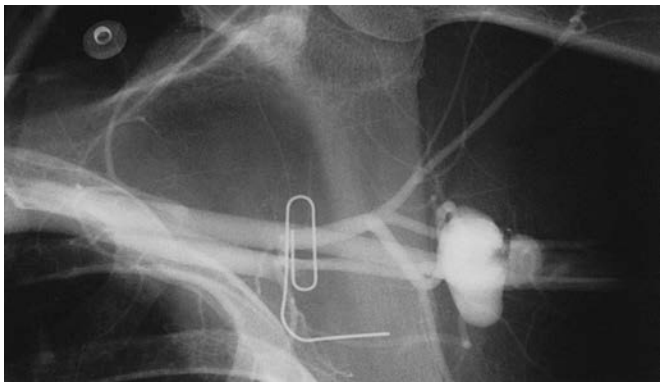

Figure 84.11 Pseudoaneurysm of the axillary artery as a result of a stab injury.

aneurysm with two Amplatzer septal occluders (AGA Medical, Golden Valley, Minnesota) at the proximal and distal ends of the aneurysm, preserving antegrade flow in the left common carotid, subclavian, and vertebral arteries while excluding the aneurysm. The eventual need for revascularization of the right upper extremity could be assessed after the procedure.

AXILLARY ARTERY ANEURYSMS

Etiology and Pathology

Axillary artery aneurysms are rare and usually caused by blunt or penetrating trauma (Fig. 84.11).[76] Congenital axillary aneurysms have infrequently been reported.[77,78] Most posttraumatic axillary artery aneurysms occur typically in young men involved in athletic activities that are associated with repetitious, forceful extension of the upper extremity.[79,80] The mechanism of injury is probably related to the repeated abduction and external rotation of the upper extremity with downward displacement of the humeral head. The repeated compression of the axillary artery can lead to intimal damage, thrombosis, and aneurysm formation. Posttraumatic axillary artery aneurysms have been primarily reported in baseball pitchers, but such aneurysms should be suspected in any athlete with signs and symptoms suggestive of digital ischemia.

Pseudoaneurysms

Pseudoaneurysms of the axillary artery usually occur with penetrating trauma, but they also may occur with blunt trauma in the form of humeral fractures and anterior dislocation of the shoulder.[81,82] These aneurysms often present late as chronic false aneurysms because diagnosis is delayed. Given the excellent collateral circulation in this area, distal perfusion may be adequate despite extensive axillary artery injury. However, these aneurysms can lead to serious and permanent neurologic disability because of hemorrhage into the axillary sheath and compression of the brachial plexus.

Arteriography should be considered in all cases of significant penetrating trauma to the shoulder or arm, blunt trauma with abnormal pulse examination, and blunt trauma with normal pulse examination, but brachial plexus palsy, because the likelihood of concomitant vascular injury is high in these cases. Duplex ultrasonography also may allow accurate diagnosis. Digital, CT, or MR angiography should be performed in patients with blunt trauma to the shoulder or axilla with a normal neurovascular examination initially but with signs of brachial plexus neuropathy on follow-up. The presence of an expanding chronic pseudoaneurysm should be suspected in such cases.

Crutch-induced blunt trauma producing aneurysmal dilation of the axillary artery usually occurs in older patients. These were first described by Rob and Standeven[83] in 1956. Pathologic examination of these aneurysms reveals markedly thickened walls and wrinkled, roughened intima. Instead of the typical changes of degenerative aneurysms, severe fragmentation of medial elastic fibers and marked periadventitial fibrosis are present, suggesting chronic trauma.[84] Thrombus, usually loosely adherent to the damaged intima, may become dislodged by further trauma from crutches and is the source of acute, chronic, or repetitive emboli. In many cases the aneurysm thromboses completely when symptoms begin. The most common presenting complaints relate to upper extremity ischemia, and these aneurysms should be suspected when a patient who has been using crutches for a prolonged period presents with an absent brachial pulse.

Treatment

Open Surgery

Surgical treatment of axillary artery aneurysms is straightforward and involves resection of the aneurysm and interposition vein grafting. The brachial plexus and surrounding vascular structures should be protected during dissection of the aneurysm. Prosthetic reconstruction of the axillary artery may be performed when adequate vein conduits are not available. Autogenous vein grafts in upper extremity reconstructions are preferred because of improved patency rates with these conduits.[85] Occasionally, an adjacent segment of the axillary or brachial vein has been used to reconstruct the artery. However, this vein is extremely thin walled and may itself become aneurysmal with time (Fig. 84.12). For this reason a segment of saphenous vein is the conduit of choice. Perioperative morbidity is usually minimal. Long-term results are excellent, with 100% graft patency in one report with a mean follow-up period of 3.2 years.[86] Presenting symptoms usually resolve, except for paralysis.

Endovascular Treatment

Endovascular repair of axillary artery aneurysms and pseudoaneurysms has been reported (Fig. 84.13).[87,88] In most cases, endograft placement is sufficient to obtain complete exclusion of the aneurysm cavity. Occasionally, embolization with microcoils of avulsed branch vessel to isolate the sac and prevent retrograde endoleak may be required.[89] However, case series of endovascular treatment are small, with limited follow-up. DuBose et al.[41] conducted a review of the literature, describing a total of 160 patients undergoing management of axillosubclavian arterial injuries by endovascular techniques. Pseudoaneurysm formation was present in 77 of these cases. Technical success was 97%; however, significant variability occurred in the reported follow-up period, ranging from hospital discharge to 70 months.

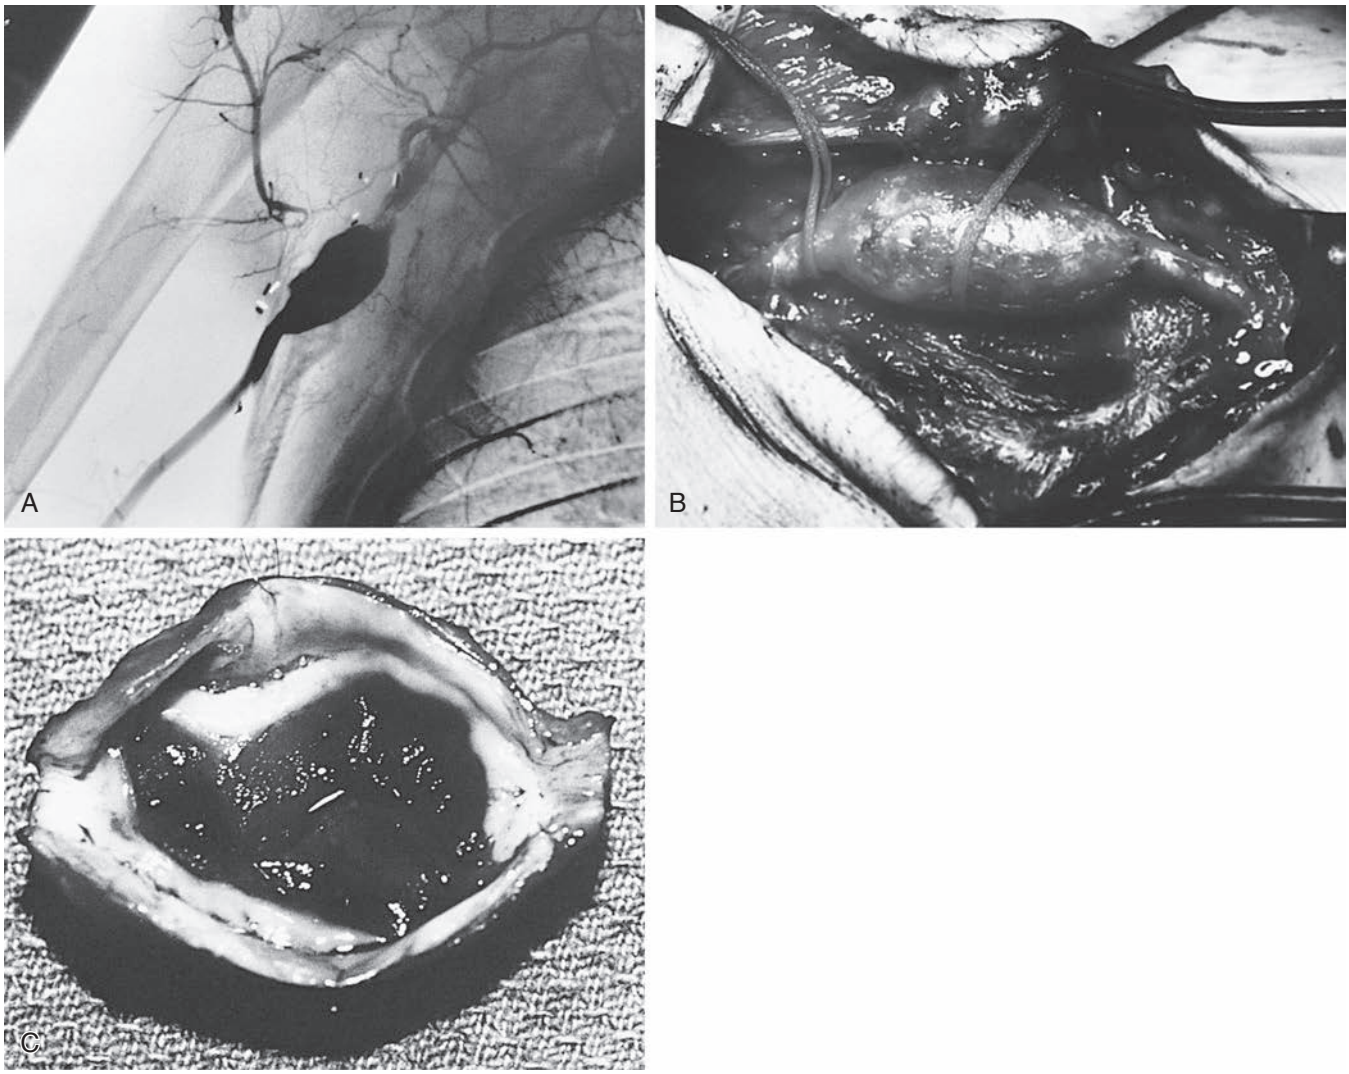

Figure 84.12 (A) Aneurysmal dilation of an interposition brachial vein graft used to reconstruct the axillary artery at the time of penetrating trauma 4 years previously. (B) Operative dissection of the aneurysmal interposition brachial vein graft. (C) Mural thrombus lining the aneurysmal interposition brachial vein graft.

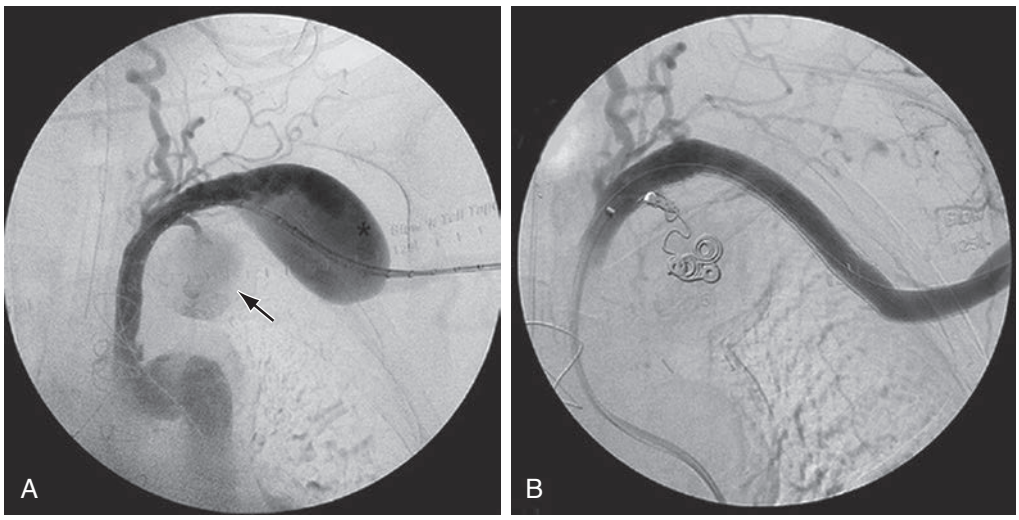

Figure 84.13 (A) Arteriography demonstrating a 6-cm axillary artery and internal mammary artery aneurysm *(arrow)* in a patient with Marfan syndrome. (B) Successful treatment with coil embolization of the LIMA and placement of msultiple stent-grafts for exclusion of the axillary aneurysm. (From Rose JF, Lucas LC, Bui TD, et al. Endovascular treatment of ruptured axillary and large internal mammary artery aneurysms in a patient with Marfan syndrome, *J Vasc Surg*. 2011;53:478.)

Overall patency during the follow-up period was reported at 84.4%. These reports provide encouraging results for endovascular treatment of these life-threatening injuries, and endovascular repair of axillary aneurysms and pseudoaneurysms should be considered an alternative to surgical treatment in patients with major comorbidities and high surgical risk.

BRACHIAL ARTERY ANEURYSMS

Etiology

Aneurysms of the brachial artery are primarily false aneurysms secondary to repetitive trauma, or iatrogenic complications. More recently, brachial artery aneurysms associated to the creation of arteriovenous access for hemodialysis have increasingly been reported. Occupational and recreational activities have also been implicated. However, in many instances, no specific cause can be identified, and these aneurysms are classified as idiopathic.[90] Matas was the first to recognize a traumatic aneurysm of the brachial artery; the patient was a young laborer, and the aneurysm was repaired with Matas's classical endoaneurysmorrhaphy technique.[87] Repetitive blunt trauma can lead to aneurysm formation by compression of the arterial wall and contusion of the arterial media. Penetrating trauma can also cause partial arterial wall laceration and pseudoaneurysm formation. Intravenous drug abuse is currently a frequent cause of infected pseudoaneurysms in the antecubital fossa.[91] Similarly, frequent arterial catheterization contributes to increased incidence of false-aneurysm formation.[92] Arteriovenous access creation can lead to aneurysmal degeneration of donor arteries as well.[93] Other uncommon causes of true aneurysms of the brachial artery include congenital connective tissue abnormalities, such as those found in association with type IV Ehlers-Danlos syndrome,[94] Kawasaki syndrome,[95] Buerger disease,[96] Kaposi sarcoma,[97] cystic adventitial disease,[98] and dissection.

Clinical Evaluation

Most patients with brachial artery aneurysms present with symptoms of median nerve compression or local pain given the close proximity of the two structures. Other symptoms include hand and digital ischemia as a result of thrombosis of the aneurysm and/or distal embolization. Diagnosis of brachial artery aneurysm can be made on physical examination. The presence of an obvious pulsatile mass is also frequently recognized by patients. Duplex ultrasonography can establish the diagnosis. However, upper extremity arteriography is usually necessary to delineate the extent of the aneurysm, to assess the sites of vascular occlusion in cases complicated by thromboembolism, and to determine whether anatomic variants are present that might affect reconstruction. Simple iatrogenic brachial artery false aneurysms can usually be repaired without the need for angiography.

Treatment

Although brachial artery aneurysms have been safely followed nonoperatively, it is impossible to predict which aneurysms are more likely to become symptomatic and lead to complications. Because of the high incidence of symptoms and complications and the minimal morbidity associated with operative treatment, aneurysm repair should be offered to all patients.

Open Surgical Treatment

Open surgical repair, the preferred method of treatment, can be performed under local, regional, or general anesthesia. It usually consists of resection with either patch or interposition vein grafting, resection and primary anastomoses, or, in the case of iatrogenic false aneurysms, simple suture repair. Chemla et al.[93] reported on the outcomes of 13 brachial artery aneurysm repairs, which were associated with arteriovenous fistula creation. Seven patients underwent simple resection with end-to-end anastomosis, and six required interposition grafting with autologous vein conduits. Patency at a mean follow-up of 16 months was 100%.

Endovascular Treatment

Although few reports have described the use of endografts for repair of traumatic brachial artery injuries, only two case reports have described their use in the treatment of brachial artery aneurysms. In one case a mycotic brachial pseudoaneurysm developed secondary to a methicillin-resistant *Staphylococcus aureus* (MRSA) wound infection that occurred after an emergency brachial artery bypass grafting using greater saphenous vein.[99] This pseudoaneurysm was successfully treated with an endograft and antibiotics. In a second case a brachial artery aneurysm was treated with an endograft in a patient who had sustained a gunshot wound to the left arm.[100] This patient had a complex open humerus fracture and brachial plexus injury, initially treated with wound débridement, skin grafting, external fixation, and physical therapy. Two months after the initial injury, the patient developed acute left arm pain and a pulsatile mass in the upper arm. Arteriography demonstrated near total transaction of the proximal left brachial artery. The origin of the pseudoaneurysm was successfully excluded with an endograft.

Iatrogenic Injury

Presentation

Brachial artery pseudoaneurysms secondary to access injuries during peripheral angiography, cardiac catheterization, or endovascular interventions are common indications for upper extremity arterial repairs.[101] However, brachial artery thrombosis is more frequent; it occurs in 1% to 7% of cases.[102,103] Although percutaneous brachial access for peripheral and cardiac angiography or interventions has largely replaced brachial artery cutdown, the frequency of brachial artery pseudoaneurysm formation continues to be low (0.3% in one large series)[102] and not different from pseudoaneurysm rates for the femoral artery approach.[101] Distal (near antecubital) access of the brachial artery is recommended because the artery is less mobile and easier to puncture here than more proximally; furthermore, improved compression against the distal humerus is possible here. The presence of a pseudoaneurysm may be suggested by a mass at the puncture site, evidence of distal occlusion or

embolization, or neurologic complications related to compression. Diagnosis can usually be made with duplex ultrasonography.

Treatment

Nonoperative treatment of brachial artery pseudoaneurysms can be considered when they are small and asymptomatic and likely to thrombose spontaneously. However, in most instances, symptomatic iatrogenic brachial artery pseudoaneurysms should be surgically repaired under local or regional anesthesia because it is difficult to predict which ones will continue to expand and require more difficult later repair. Direct suture repair with evacuation of the hematoma is usually sufficient. Although reported, thrombin injection of pseudoaneurysms of the brachial artery may be considered less favorable because the superficial location of the vessel is usually associated with pseudoaneurysms with relatively short necks.[104,105] If thrombin injection is deemed appropriate, small-gauge needles and lesser amounts of thrombin than those typically used in the femoral artery may be injected in the brachial artery pseudoaneurysm using duplex ultrasound guidance.

Splanchnic artery aneurysms represent a rare pathology that mandates awareness due to their potentially lethal clinical course. These lesions were described more than 200 years ago, and initial case reports consisted mostly of emergent interventions for rupture.[1] Diagnosis in these cases was often made postmortem. The first reported successful operative repair was performed by Kehr in 1903; it consisted of ligation of a proper hepatic artery aneurysm (HAA).[1] This was followed many years later in 1951 by Paul, who described ligation and revascularization of a traumatic HAA,[1] and in 1953 by Debakey and Cooley, who described their repair of a mycotic superior mesenteric artery (SMA) aneurysm.[2] Since that time, evidence has been steadily accumulating in the vascular literature, and the natural history of these aneurysms is becoming better understood. Additionally, the advent of

Abstract

Splanchnic artery aneurysms are defined as aneurysms involving the celiac, superior mesenteric, and inferior mesenteric arteries as well as their associated branches. These aneurysms are incompletely understood given the rare nature of the disease, however remain an important topic for which vascular specialists need to be familiar. This chapter provides an overview of the diagnosis and general treatment principles regarding splanchnic artery aneurysms followed by more in depth review of specific splanchnic artery aneurysms.

modern technologic advances—including improved imaging modalities along with complex endovascular techniques—has revolutionized the management of these often lethal entities. This chapter reviews the previous experience as documented in the literature and attempts to establish management guidelines for the various types of splanchnic artery aneurysms.

INCIDENCE AND ETIOLOGY

Traditionally an aneurysm is defined as a dilation or enlargement of an artery more than 1.5 to 2 times its normal diameter.[3] Splanchnic (or visceral) artery aneurysms include those affecting the celiac artery, SMA, inferior mesenteric artery, and their branches. Aortic and renal artery aneurysms are excluded in this categorization despite the fact that they encompass approximately 95% of all intra-abdominal aneurysms.[4] Nearly one-third of patients with a splanchnic artery aneurysm will have an associated aortic, renal, iliac, lower extremity, or cerebral artery aneurysm, signifying the importance of screening these individuals. The overall incidence in the adult population is estimated to range from 0.1% to 2%,[5-9] which, based on autopsy review, increases to 10% in the elder population.[10] Splenic artery aneurysms (SAAs) encompass the majority (60%); followed by HAAs, 20%; superior mesenteric artery aneurysms (SMAAs) 6%; celiac artery aneurysms (CAAs), 4%; gastric artery aneurysms (GAAs), 4%; jejunal, ileal, and colic artery aneurysms (4%); pancreaticoduodenal artery aneurysms (PDAAs), 2%; gastroduodenal artery aneurysms (GDAAs), 1.5%; and inferior mesenteric artery aneurysms (IMAAs), less than 1%.[11-13]

The etiology of splanchnic artery aneurysms differs from that of true aneurysms and pseudoaneurysms. Causes of true splanchnic aneurysm formation include atherosclerosis, medial degeneration, collagen vascular diseases, and fibromuscular dysplasia.[14] Other factors—such as multiparity, portal hypertension, and posttransplant status—have been implicated in true SAA formation,[15-17] and celiac artery occlusive disease has been implicated in true GDAA and PDAA formation.[18] Splanchnic pseudoaneurysms result from infectious or inflammatory conditions, vasculitis, surgery/iatrogenic intervention, and trauma.[12,14,19-23] Furthermore, evidence suggests that pseudoaneurysms display relatively rapid growth soon after the initial insult, such that treatment strategies should focus on early intervention regardless of size.[24]

However, aneurysmal morphology can impact treatment options and the application of endovascular therapies.

Special Considerations for Associated Conditions

Rare medical conditions such as von Recklinghausen disease, Ehlers-Danlos syndrome, periarteritis nodosa, and Behçet disease have been implicated in the development of splanchnic aneurysms. Reported case series have demonstrated the association of multiple splanchnic aneurysms with systemic arteritis, endocarditis with septic emboli, connective tissue disorders, and even excessive use of acetaminophen.[25]

GENERAL TREATMENT PRINCIPLES

Advances in endovascular therapies have caused a paradigm shift in the management of splanchnic artery aneurysms. These aneurysms can be managed by a variety of methods including open surgery, laparoscopic surgery, endovascular techniques, or any combination of these modalities.[26-28] A prior review including 27 published case series of splanchnic artery aneurysms concluded that there is no consensus dictating indications for treatment or specific treatment options.[29] Expert opinion indicates that this is guided by patient and aneurysmal characteristics. Patient age, gender, and comorbidities in conjunction with aneurysmal size, anatomic location, and collateral circulation should dictate optimal management strategies.

Elective Repair

The elective treatment of splanchnic artery aneurysms allows for complete evaluation and imaging with ultrasound, CT, MRI, or a combination of these.[30] Diagnostic angiography is usually combined with percutaneous intervention. A thorough evaluation of the patient should address any history of trauma, pancreatitis, or any other infectious/inflammatory process to ascertain etiology and risk of rupture. Past surgical intervention or hepatobiliary instrumentation, current pregnancy status, history of pregnancies, and risk factors associated with atherosclerosis are also pertinent. Patients undergoing SAA embolization or ligation may be at risk for splenic loss and should receive pneumococcal, meningococcal, and *Haemophilus influenzae* type b vaccinations.[31] A recent literature review noted the benefits of endovascular treatment options in the elective setting, particularly in poor surgical candidates and patients with a hostile abdomen.[32]

Emergent Repair

Ruptured splanchnic artery aneurysms represent a true surgical emergency, and patients should be expeditiously transferred to the operating room for exploratory laparotomy in the setting of hemodynamic collapse. Often, the preoperative diagnosis is ruptured abdominal aortic aneurysm and exploration leads to the actual ruptured artery. Ligation of the splanchnic aneurysm can be performed with or without vascular reconstruction. Patients presenting with ruptured SAAs are most often treated with concomitant splenectomy. Given the extensive collateralization of the viscera, vascular reconstruction is rarely needed in the emergent treatment of proximal HAAs, PDAs, and GAAs.[33,34] When mesenteric arterial aneurysms are ligated, small bowel affected by ischemia may require resection. Arterial reconstruction may be necessary for ruptured SMAAs and CAAs. Endovascular management of ruptured splanchnic artery aneurysms has been reported as a feasible option but should be used selectively.[35,36]

Observation

Most large case series involving the management of splanchnic artery aneurysms have included an observational cohort, with encouraging results.[15,23,24,34,37-40] The majority of observational

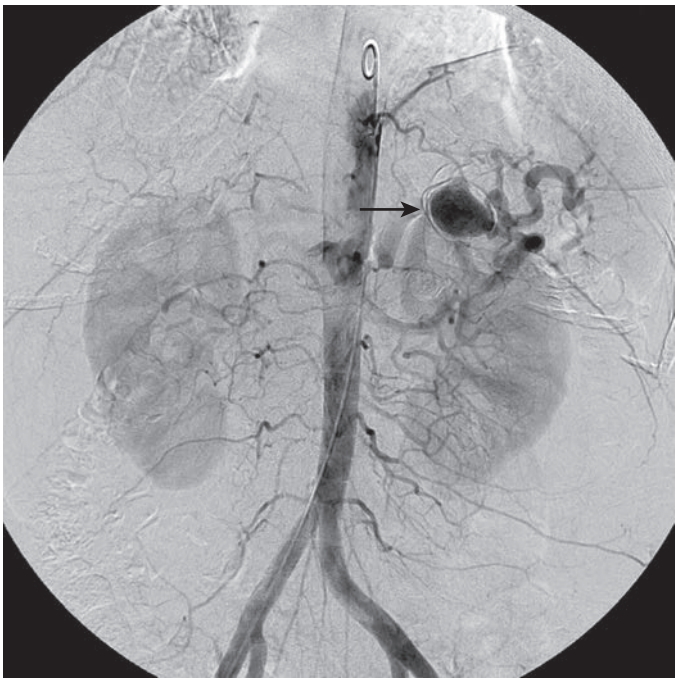

Figure 85.1 A 2.7-cm splenic artery aneurysm *(arrow)* is visualized during an abdominal angiogram. A calcified shell covers the aneurysm sac, with flow maintained to the end organ.

cases involve the splenic artery. General guidelines state that SAAs less than 2 cm in size that are asymptomatic and show little to no growth can be safely observed and monitored with serial imaging. Women who are either pregnant or of childbearing age should have any SAA treated regardless of size.[41] There is no firm evidence to show that aneurysmal calcification protects against growth or rupture, but calcified SAAs (Fig. 85.1) may be associated with smaller size at initial diagnosis.[38] Most series advocate for all pseudoaneurysms to be treated irrespective of size or location owing to their rapid growth rate and propensity to rupture.[22,42] There is also evidence to support intervention in all SMAAs, GDAAs, and PDAAs because of their high rupture rate and the associated mortality.[18,43]

SURGICAL AND ENDOVASCULAR TECHNIQUES

Open Repair

Treatment of splanchnic artery aneurysms with open surgery has been established as a safe and durable standard. An open surgical approach allows for direct visualization of end organs and concomitant diseases processes, including pancreatic pseudocysts or abscesses; thus this approach is useful in determining the need for arterial reconstruction. Expeditious ligation of both the proximal and distal branches is generally performed without reconstruction in the case of frank rupture and hemodynamic collapse and during elective cases if adequate collateralization to end organs is present.[44] The spleen has a rich blood supply from the short gastric arteries and pancreaticoduodenal arcade, which usually allow the splenic artery to be sacrificed without major consequence. The celiac axis and common hepatic artery can also be ligated if there is sufficient collateralization from the gastroduodenal and pancreaticoduodenal arteries and the portal vein is patent. Vein grafts should be used preferentially in cases of suspected infection or bowel ischemia.

Arterial ligation is the procedure of choice in the setting of free rupture.

Endovascular Therapy

The immediate benefits associated with endovascular intervention include a shorter hospital stay, the use of local/conscious sedation, lower cost, and faster recovery. Patients with comorbidities prohibitive to open surgical management, including intra-abdominal malignancy and previous surgery, can also benefit from minimally invasive techniques.[45] Drawbacks to endovascular repair include the risk of access-related injury, contrast toxicity, end-organ embolization, a relatively higher rate of failure compared with open surgery, and the need for prolonged postembolization imaging surveillance. Treatment by means of endovascular intervention can be achieved through several different modalities often in combination, including deployment of coils and glue, injection of particles or Gelfoam, placement of covered stents or flow-diverting stents (FDSs), and injection of thrombin or ethyl alcohol.[7,14,24,37,46-51] Results of the endovascular treatment of 48 consecutive patients—(60% men, mean age 58) with 20 splanchnic artery aneurysms and 28 splanchnic artery pseudoaneurysms—have been reported.[24] The endovascular treatment of visceral artery aneurysms was technically successful in 98% of 48 these procedures, comprising 20 splenic arteries, 12 hepatic arteries, 1 SMA, 3 celiac axis arteries, 2 pancreaticoduodenal arteries, 2 left gastric arteries, 7 gastroduodenal arteries, and 1 middle colic artery. Coil embolization was used for aneurysm exclusion in 96% of the cases, and *N*-butyl-2-cyanoacrylate (glue) was used selectively in 19%. The 30-day mortality was 8.3%, with all perioperative deaths occurring in patients who required urgent or emergent intervention in the setting of hemodynamic instability. Complete exclusion of flow within the aneurysmal sac occurred in the 97% interventions with follow-up imaging, with postembolization syndrome (PES) developing in three patients (6%) after splenic artery embolization. Another report detailed the endovascular treatment results of 185 splanchnic artery aneurysms encountered over 10 years in three distinct geographies.[48] Thirty-four percent of the aneurysms were located in the splenic artery, followed by 30% in the hepatic artery. Initial intervention was successful 98% of the time. Coiling was used alone in 75% of the cases and in combination with at least one other technique in 11% of cases. Thirty-day aneurysm-related mortality was low at 3.4%, and all involved death due to bleeding.

Embolization

Ablation of splanchnic artery aneurysms through endovascular intervention can be accomplished with nitinol coils, cyanoacrylate glue, thrombin, and even ethyl alcohol.[51-55] A unique characteristic of cryanoacrylate glue is that the rate of glue

polymerization can be altered for precision targeting using ethiodized oil dilution in different ratios. A 3-Fr microcatheter is useful for intervention in the distal aspect of an arterial aneurysm before selective embolization material is deployed.[24] Both true aneurysms and pseudoaneurysms of the splanchnic circulation can be managed with embolization. Endovascular exclusion to both inflow and outflow can be achieved by placement of coils first distally, in the sac, and then proximally to the sac (Fig. 85.2). For aneurysms supplied by terminal branches, the sac can be directly injected or coiled.[56]

Covered Stents

In selected cases, a covered self-expanding stent may be placed to maintain flow within a vessel (Fig. 85.3). This technique is often limited by relatively large, rigid delivery devices that are not ideal for navigating secondary and tertiary visceral branches.

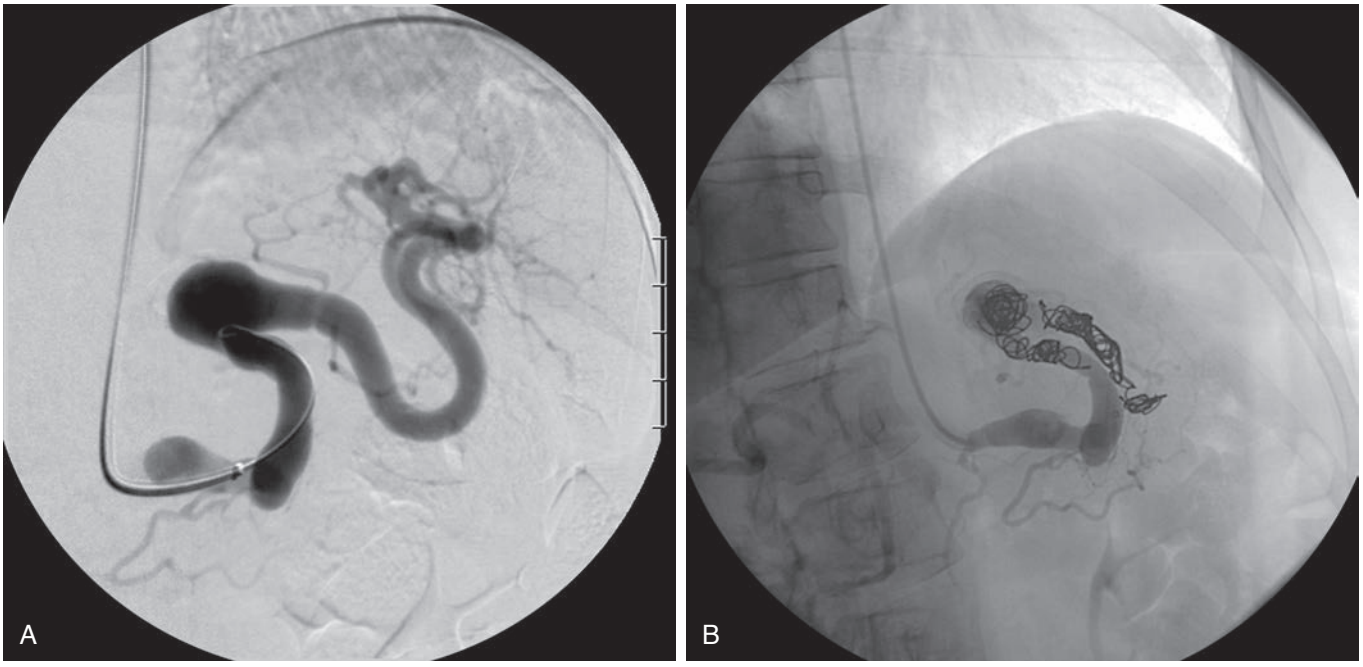

Figure 85.2 **A,** Angiogram of a 2-cm splenic artery aneurysm prior to intervention. **B,** Post intervention angiogram. Aneurysm ablated with nitinol coils. Occlusion of both inflow and outflow to the sac is achieved.

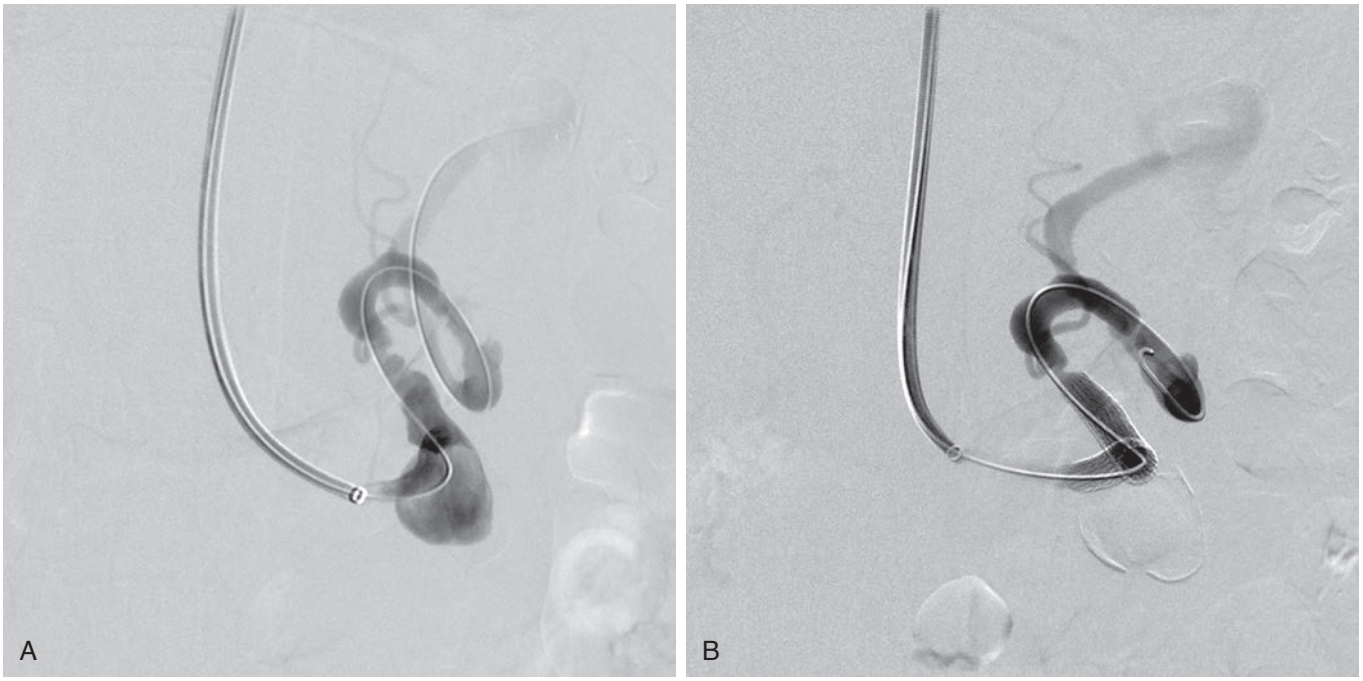

Figure 85.3 **A,** Angiogram of a 2-cm splenic artery aneurysm prior to intervention. **B,** Post intervention angiogram. Aneurysm excluded with covered stent. Post deployment imaging demonstrates intact flow to end organ.

Covered stents also risk occluding flow into side branches of the target vessel.[57-61]

Follow-up imaging is not limited by artifact from radiopaque coils or glue, and this notable advantage of covered stent placement over embolization has allowed for accurate documentation and surveillance of aneurysm sac growth or shrinkage.[62]

Flow-Diverting Stents

FDSs, sometimes referred to as multilayer stents, are specially designed to reduce flow velocity in the aneurysmal sac while promoting thrombosis and maintaining flow within the main artery and any branch vessels. The FDSs were originally developed for the endovascular treatment of intracranial aneurysms. By 2010, this technology had been used to treat over 2500 intracranial aneurysms.[63] Initial case reports demonstrated success in multiple peripheral and splanchnic vascular vessels.[64-69] A prospective, multicenter study of FDS use in 19 splanchnic artery aneurysms recently reported encouraging results of freedom from rupture, patency of the stents and vessel branches, aneurysmal thrombosis, sac shrinkage, and low morbidity and mortality.[70] Widespread use of these modalities should be tempered, however, until more experience regarding efficacy becomes available.

SPECIFIC SPLANCHNIC ANEURYSMS

Splenic Artery Aneurysms

Epidemiology

SAAs have been established as the most common of the splanchnic artery aneurysms, accounting for nearly 60% of reported splanchnic aneurysms. Like any splanchnic artery aneurysm, their clinical significance is related to the potential for rupture. The most accurate calculated incidence in the general population is most often cited as 0.78%, which is based on a review of incidentally noted SAAs seen on nonselective angiography.[71] One general autopsy study cited the overall incidence to be 0.01%,[72] with incidence increasing to 10.4% in an elder population autopsy series.[10] In contrast to other arterial aneurysms, SAAs disproportionately affect females at a ratio of 4 : 1 over males.[44,73] Although incidence increases markedly in the elder population, they occur at a younger age compared with other splanchnic aneurysms.[71,73]

Most SAAs are close to 2 cm in diameter when initially noted. Reports of SAAs associated with symptoms and/or with rupture average closer to 3 cm at presentation.[15,38,74] The majority of these aneurysms have saccular morphology and are located more commonly in the mid- or distal splenic artery and its bifurcations.[73,75] The rare phenomenon of a "giant" SAA greater than 10 cm in diameter has been encountered in the literature and seems to be found more often in men.[76]

Etiology

The underlying pathologic processes in the development of most SAAs are related to atherosclerosis, arterial fibrodysplasia, and arteritis.[23,71] Associated risk factors include female gender, multiparity, and portal hypertension.[17,73] Several reports have established an association between multiparity and SAA development,[15,74] but the precise interactions of hormonal influence, fibromuscular dysplasia, and wall stress are not yet fully understood.[35,77] Some series have noted that nearly 50% of females with more than six pregnancies had been diagnosed with an SAA.[75,78] Yet another noted that 80% of females with SAAs had averaged 4.5 pregnancies.[74] Still, the utility of screening women for SAAs who are either pregnant or of childbearing age has been proven to be unwarranted in one recent study.[79]

The association between SAAs and portal hypertension has been documented, especially in patients undergoing orthotopic liver transplantation.[11] Evaluations of patients with known portal hypertension or cirrhosis have shown a likely incidence of SAA incidence ranging from 10% to 20%,[80] with one study reporting an incidence as high as 50%.[16] Notable etiologies of splenic artery pseudoaneurysm formation include blunt trauma, infection, and pancreatitis.[22] Pseudoaneurysm formation associated with pancreatitis has been attributed to digestion of the splenic artery by pancreatic enzymes.[81] Hemosuccus pancreaticus is a rare cause of upper chronic and intermittent gastrointestinal hemorrhage, usually due to the rupture of a visceral aneurysm into the main pancreatic duct. Splenic artery pseudoaneurysm formation associated with chronic pancreatitis represents the leading cause of hemosuccus pancreaticus and presents as a challenging clinical scenario.[82]

Clinical Presentation

Prior to the introduction of modern imaging techniques and their abundant use in everyday practice, it was estimated that more than 10% of SAAs were ruptured at the time of diagnosis.[73,78] Most current case series report that SAAs are incidental findings noted on imaging performed for unrelated symptoms. Incidental diagnosis can often be presumptive, based on circular calcified shadows or "signet rings" seen in the left upper quadrant of an abdominal roentgenogram.[83] In cases not associated with pregnancy, SAAs have a relatively low rupture rate of less than 2%.[84] Most patients with otherwise asymptomatic SAAs will have benign physical examinations. Hemodynamic collapse secondary to rupture is most often accompanied by acute left-sided abdominal pain. The patient will typically present in extremis as a result of free intraperitoneal rupture and shock.[72] On occasion the initial rupture may be contained in the lesser sac. This "double rupture" phenomenon, which occurs after initial tamponade of splenic artery hemorrhage into the lesser sac, can occur in up to 25% of ruptured SAA cases and can sometimes precede free rupture into the retroperitoneum by as long as 4 days.[21,83,85,86] Mortality reports associated with ruptured SAAs range from 10% to 25%.[15,83,75] Pregnancy is a significant contributing risk factor and may be associated with as many as half of all ruptures.[73,87] Significant maternal and fetal mortality has been documented to be close to 75% for pregnant women and about 95% for the fetus.[88,89] Rupture occurs almost exclusively in the third trimester; to date there have been only three reported cases of first-trimester rupture in the literature.[90] Although the prevalence of SAAs in pregnancy is thought to be low, at only 0.1% in one series,[79] their clinical importance is highlighted by the thought that over

50% of these aneurysms rupture during pregnancy[73,87] Portal hypertension is an additional significant risk factor for rupture, as it was associated with nearly 20% of all SAA ruptures.[74] A recent review of the English and French literature found only 613 reported cases of splenic rupture without risk factors or previously diagnosed disease.[91] The most common associated diseases with these patients were infectious in nature, followed by hematologic and nonhematologic neoplasms.

Treatment

All patients who present with a ruptured SAA should undergo immediate and definitive treatment. Additionally, any patient who has symptoms attributed to a nonruptured SAA should undergo intervention. Women who are pregnant or are of childbearing age should undergo treatment as well. Most advocate for the treatment of any splenic artery pseudoaneurysm regardless of size or symptoms owing to their propensity to rupture. In the absence of these scenarios, the threshold for intervention is based mainly on size of the aneurysm and/or rate of growth. Consensus in the literature has generally established the indications for treatment to include those aneurysms greater than 2 cm in diameter.

A large review reported from the Mayo Clinic involved 217 patients with SAAs. Of these patients, 168 underwent nonoperative management for a mean period of 75 months.[15] The mean size in the nonoperative group was 2.1 cm, with a range from 0.8 to 5 cm in diameter. About half of these aneurysms were monitored with serial imaging, of which only 10% were noted to have growth averaging 0.06 cm per year. No rupture or other complications related to the SAAs occurred and only 3 of the original 168 required intervention due to aneurysmal growth. Similar results were reported by Lakin et al. in reviewing the Cleveland Clinic experience of 128 SAAs managed over a 15-year period.[38] The observational cohort of 66 SAAs had a mean diameter of 1.7 cm at presentation with a range from 0.8 to 4.2 cm. Serial imaging was available for 94% of the aneurysms, and these patients received an average of 2.5 CT scans over 4.6 follow-up years. The average growth rate was a nominal 0.2 mm per year over 3.1 follow-up years. There were again no ruptures or other complications attributed to the aneurysms in the observed group. More recently, Corey et al. reported the experience from Massachusetts General Hospital, which included 95 patients with SAAs, 59 of which underwent nonoperative management.[18] These investigators found that only 10.5% of aneurysms less than 2.5 cm in diameter grew over an average surveillance period of 31 months.

Open Surgical Repair

Options include complete resection with splenectomy, proximal and distal ligation of the aneurysm, or ligation with arterial reconstruction. To visualize the splenic artery, dissection proceeds with mobilization of the splenocolic ligament. The splenic flexure is then mobilized away from the retroperitoneum and abdominal wall. Splenectomy is not uniformly needed, since the short gastric vessels will adequately perfuse the organ after splenic artery ligation. Splenectomy is preferred for lesions adjacent to the splenic hilum or those involving the intrasplenic branches within the parenchyma.

The long-term results of open surgical repair for SAAs show a high survival and low complication rate, confirming the durability of the surgical approach. Marone reported a series of 34 SAAs treated with elective open surgical repair in which survival at 1 and 5 years was 100% and 92%, respectively.[40] In the Mayo Clinic series, 49 patients underwent surgical intervention; 39 of these procedures were elective. Operative mortality was 20% in the ruptured group and 5.1% in the elective group. Complications were low for the nonruptured group, with no reported recurrence over a mean follow-up of 70 months. More recently, a meta-analysis by Hogendoorn et al. reported the results of 1321 patients with true SAAs; 511 of these patients were managed with open techniques, 385 with endovascular techniques, and 425 nonoperatively.[92] This study found that open surgical management was associated with fewer long-term complications and reinterventions as compared with endovascular management. Endovascular management brought improved short-term results in this study—namely, lower perioperative mortality—but the open management group contained more instances of ruptured SAAs, which could account for this difference. In the setting of splenectomy, it is important to remember to administer splenectomy vaccinations to reduce the risk of overwhelming postsplenectomy infection.

Endovascular Therapy

Endovascular techniques have emerged as an effective option in the management of SAAs. Treatment usually includes coil embolization, the use of cyanoacrylate glue, stenting, or a combination of both. The Cleveland Clinic series reported the outcomes of 49 SAAs treated with endovascular intervention.[38] Coil embolization was performed in 45 cases, of which 11 had glue used adjunctively. There was a 96% technical success rate in the initial procedure, with secondary intervention ultimately achieving desired results when needed. Complications included a femoral access site hematoma requiring operative drainage and two brachial artery access site injuries. Splenic abscess was noted in three patients, which required reintervention.

PES occurred in an additional five patients. PES is a known complication of SAA embolization, and infarcts are common events; however, they generally resolve without sequelae.[93] Other selected series have reported similar success rates in the endovascular management of SAAs, ranging from 90% to 100%.[24,49,94,95] Covered stent repair is thought to be ideal for exclusion of the aneurysm and preservation of the splenic artery and in theory will not lead to PES.[96] The use of covered stents in treating SAAs remains limited to proximal lesions, and their use has not been as widespread as endovascular ablation. One of the main limitations is getting adequate wire support to advance the covered stent through the tortuous splenic artery, especially in the case of distal aneurysms. Multilayered stents have also been used sporadically.

Hepatic Artery Aneurysms

Epidemiology

HAAs were first described by Wilson in 1809, with the first successful ligation being reported in 1903.[97] The hepatic artery is the

second most common location of splanchnic aneurysm formation and is believed to represent approximately 20% of these lesions. The true incidence is not known, but it is estimated to be less than 0.4% in the general population.[98] Approximately 75% to 80% of these aneurysms are located along the extrahepatic vasculature, with the remainder involving the intraparenchymal and/or extraparenchymal liver space (20%); in rare cases (<5%) they may be located exclusively within the liver. Along the extrahepatic vasculature, 63% are found in the common hepatic artery, 28% in the right hepatic artery, 5% in the left hepatic artery, and 4% in both the left and right hepatic arteries (Fig. 85.4).[39,99] The male-to-female ratio is 3 to 2, with reported rates of rupture ranging from 20% to 80%.[39] Unlike SAAs, these lesions have no known association with pregnancy in either incidence or rupture rate. The age of presentation is closer to a mean of 60 years old if trauma etiologies are excluded.[8] Notably, HAA incidence appears to be on the rise with increasing use of hepatobiliary instrumentation and manipulation.[100-102] In some recent series, HAAs were actually the most frequently reported aneurysms encountered.[12,103] Half of these were pseudoaneurysms located within the parenchyma of the liver, which underscores the increasing incidence of an iatrogenic etiology for hepatic pseudoaneurysms. Mycotic etiology, once seen frequently in patients with a history of endocarditis, has decreased with the widespread availability of antibiotics.

Etiology

As with SAAs, atherosclerosis is the leading cause of HAA formation, accounting for approximately 30% of cases.[98] In a Mayo Clinic series of 36 true HAAs, the most commonly associated comorbidity was hypertension, occurring in 72% of patients.[39] Arterial dysplasia, medial degeneration, trauma, polyarteritis nodosa, and biliary diseases have also been implicated in the formation of HAAs. Percutaneous and endoscopic procedures will undoubtedly contribute an ever-increasing source of HAA formation.[99] Concomitant aneurysms of other splanchnic vasculature are seen with HAAs in nearly one-third of cases; in one series, 20% also had a SAA. Nonsplanchnic aneurysms are also seen in nearly 40% of patients with HAAs.[8,39] A recent review of the Mayo Clinic experience found that, among patients who ultimately underwent intervention for a HAA, 63% had synchronous aneurysms, which most commonly involved the aorta.[104]

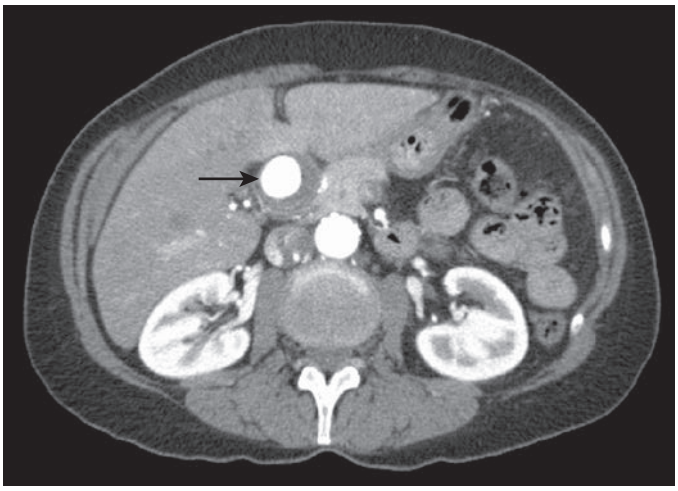

Figure 85.4 This abdominal computed tomography scan of a 61-year-old female shows an incidentally noted 2.5-cm proper hepatic artery aneurysm *(arrow)*. The patient underwent excision and repair with a reversed greater saphenous vein bypass graft from the common hepatic artery to both the right and left hepatic arteries.

Clinical Presentation

The majority of HAAs are identified incidentally on cross-sectional imaging or abdominal ultrasound.[105] Abdominal discomfort and back pain are vague symptoms that may be caused by rapidly expanding aneurysms. In the setting of true HAAs, rupture risk approaches 25% for larger aneurysms.[78] Rupture into the peritoneal cavity or hepatobiliary tract can be seen with equal frequency. Quincke's triad of hemobilia, jaundice, and right-upper-quadrant pain can be seen when rupture into the bile ducts occurs.[106] HAA with erosion into the stomach is a rare but serious cause of upper and lower gastrointestinal bleeding.[107]

Mortality rates associated with rupture are high, ranging from 20% to 70%.[21,39,108,109] Risk factors associated with rupture remain poorly defined, and there are currently no studies correlating HAA size with the likelihood of rupture.[110] In the Mayo Clinic case series, 22 patients with HAAs averaging 2.3 cm in diameter were managed nonoperatively for a mean of 68 months.[39] No aneurysm-related complications were reported. Aneurysmal growth was identified in 27% of patients, with the greatest being 0.8 cm over 34 months.

It is important to distinguish between true and false HAAs as this may prove to be one of the most important prognostic factors when planning management. The Cleveland Clinic experience found that pseudoaneurysms of the hepatic artery were more likely to be symptomatic versus true aneurysms and more often required urgent intervention.[24] Consistent with trends over the past two decades, nearly all (11/12) of the HAAs in this series were pseudoaneurysms. Most of the splanchnic pseudoaneurysms in the series presented with gastrointestinal bleeding or hemobilia, such that 92% of these patients required urgent intervention. Based on their experience, the authors concluded that all splanchnic artery pseudoaneurysms should be treated regardless of size due to their higher risk for rupture.

Treatment

General guidelines for intervention include the treatment of any symptomatic aneurysm, pseudoaneurysm, and aneurysms greater than 2 cm in diameter in appropriate surgical candidates. Patients presenting with multiple HAAs should also be treated regardless of size. HAAs presenting in patients with PAN or other inflammatory conditions are also considered at increased risk for rupture and should be repaired regardless of size.[111] True aneurysms of the hepatic artery have been safely observed, particularly in the case of smaller aneurysms. Similar to the Mayo Clinic experience, Corey et al. reported their surveillance of 18 patients with HAAs (average diameter 17.8 ± 6.9 mm) and found no instance of increased aneurysmal growth with a mean follow up of 28 months.[18]

HAAs are accessible via a right subcostal or midline laparotomy incision. The proper hepatic artery can be visualized in the gastrohepatic omentum. The use of intraoperative ultrasound may assist in identifying the aneurysm.

Open Surgical Repair

Techniques include aneurysmorrhaphy with or without patch angioplasty, ligation with or without bypass using autologous vein or graft, and, if needed, hepatic resection.[39,104] Common HAAs can be treated with simple ligation or endovascular embolization if the GDA is patent, since it provides sufficient collateral flow in most patients. HAAs distal to the GDA can be treated by arterial reconstruction or other methods to restore blood flow to the end organ if the revascularization is straightforward. Aneurysms located within the parenchyma may be treated with resection, ligation, or embolization.[102] If the hepatic artery is ligated, an increase in the oxygen content of the portal vein blood as it passes through splanchnic arteriovenous shunting occurs.[112] Therefore hepatic artery ligation should never be performed in the presence of cirrhosis or any other condition where liver function is compromised. If the proper or right hepatic artery is ligated, the gallbladder is at risk for necrosis and cholecystectomy should be performed simultaneously.[113] Embolization techniques are ideally suited for lesions located within the hepatic parenchyma. These lesions are not only relatively difficult to access with open surgery but also often require parenchymal resection or hepatic lobectomy. However, patients undergoing embolization should be watched carefully for hepatic parenchymal necrosis, which may require operative intervention or drainage.

Special consideration must be made for the association of hepatic artery pseudoaneurysm formation after liver transplantation. Although the incidence is relatively low, ranging from 0.3% to 2% after liver transplantation, this represents a severalfold increase relative to the general population.[114] Liver transplant patients who develop hepatic artery pseudoaneurysms usually present with intra-abdominal or gastrointestinal bleeding within 2 months of transplantation. In many cases, there is evidence of intra-abdominal infection, and bile-containing drainage often precedes the rupture of these pseudoaneurysms.

Endovascular Repair

Treatment results of HAAs have shown endovascular intervention to be a safe and effective method of repair in limited series.[100] Endovascular coil embolization was the predominant therapeutic strategy. Tulsyan et al. reported on 11 hepatic artery pseudoaneurysms and 1 true hepatic aneurysm.[24] Two patients required a second intervention; they were both successfully managed with an additional ablation procedure. No liver infarctions, hepatic insufficiency, or intestinal ischemia attributable to aneurysm ablation occurred in the cohort. Sachdev and colleagues reported similar success in their series of 11 HAAs treated with endovascular intervention.[95] An endovascular approach predominated in the treatment of hepatic artery pseudoaneurysms, whereas true aneurysms involving the extrahepatic circulation were more likely to be treated by an open surgical approach.

Superior Mesenteric Artery Aneurysms

Epidemiology

Aneurysms of the SMA represent approximately 6% of all splanchnic artery aneurysms. Traditionally they were thought to affect men and women equally, with most patients presenting over the age of 50.[84] Recent studies, however, have shown a more male predisposition and, particularly in the setting of mycotic SMAAs, a wide range in age among those affected.[18,115] Incidence based on autopsy studies is reportedly 1 in 12,000 to 1 in 19,000.[116] They occur almost exclusively along the first 5 cm of the artery (Fig. 85.5). In addition to hemorrhagic shock in the case of rupture, SMAAs place a majority of the intestine at risk for ischemic complications. Because of these potentially devastating consequences, timely diagnosis and treatment of SMAAs is essential for the optimization of outcomes.[117]

Etiology

Unlike other aneurysms found in the viscera, the most common etiology of SMAAs continues to be infection.[118,119] Mycotic etiologies account for 60% of all SMAAs, and many patients have a history of bacterial endocarditis and the use of intravenous drugs. The SMA may be more vulnerable to mycotic aneurysm formation owing to the size and orientation of its base in relation to the aorta; however, this predisposition is not completely understood. Other conditions related to true SMAA formation include atherosclerosis, connective tissue disease, PAN, and pancreatitis with trauma implicated in the development of SMA pseudoaneurysms.[43,117,120]

Clinical Presentation

Nonruptured SMAAs are more likely to cause symptoms compared with other splanchnic artery aneurysms, and history of vague colicky pain, intestinal angina, weight loss, or other symptoms may be elicited in 70% to 90% of such patients. Like HAAs, SMAAs are associated with a significant rate of

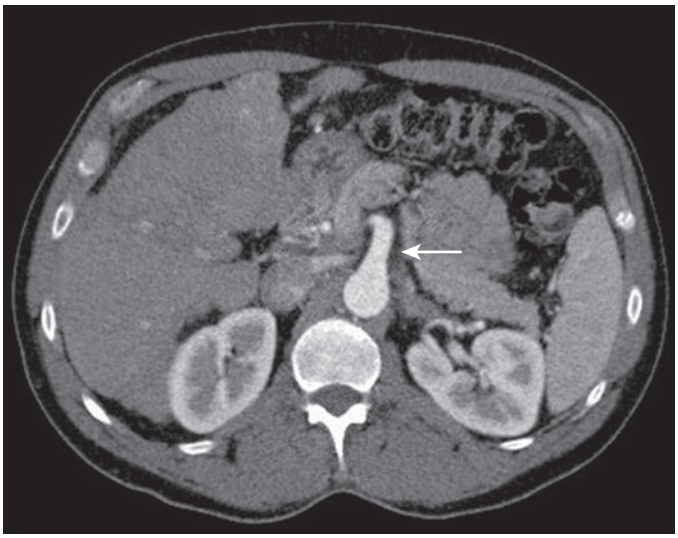

Figure 85.5 A 49-year-old male with a history of hepatitis B received a preoperative computed tomography scan of a 1.7-cm superior mesenteric artery aneurysm *(arrow)*. The aneurysm was treated with a reversed greater saphenous vein bypass.

rupture. One series of 52 patients with SMAAs cited the most frequent symptoms to be abdominal pain, nausea, vomiting, and gastrointestinal bleeding.[12,117] A recent meta-analysis by Kordzadeh and colleagues reviewed the contemporary literature involving mycotic SMAAs. They reviewed 38 cases from 1944 to 2015 and found the most common presenting symptoms to include abdominal pain (65%), pyrexia (60%), malaise (26%), weight loss (23%), and nausea/vomiting (20%). Additionally, the most common pathogens were *Streptococcus* (47%) and *Staphylococcus* (28%). Ruptures rates for all SMAAs ranged from 38% to 50%, with an associated mortality of 30% to 90%.[43,117,121] The high mortality rates are likely attributed to the result of free rupture into the peritoneal cavity, with accompanying intestinal ischemia.

Spontaneous isolated dissection of the SMA is a clinically rare disease that can be associated with aneurysmal dilation. Clinical findings range from incidental discovery on CT scans to frank bowel ischemia or aneurysm rupture.[122]

Treatment

Previously, due to the high risk for rupture and its associated mortality, repair of any SMAA was advocated regardless of size or symptomatology.[117] More recently, evidence has suggested that observation of small (<2.5 cm) aneurysms may be a safe alternative, especially in patients at poor surgical risk.[18,43] All pseudoaneurysms and those with a mycotic etiology should be repaired, as these show a greater potential for rupture and subsequent mortality. SMAAs can be treated surgically with aneurysmectomy, arterial reconstruction, and rarely simple ligation. It is important to take into account that SMAAs have a predilection for a mycotic or inflammatory etiology rather than being caused by fibrodysplasia or atherosclerosis. The predisposition for mycotic or inflammatory etiologies may serve as a contraindication for polytetrafluoroethylene (PTFE) or Dacron bypass grafts.

Open surgical treatment is performed via a midline or retroperitoneal approach. The SMAA can be identified by ultrasound or palpation. Dissection is continued proximally and distally until there is normal-caliber vessel. The proximal dissection may extend underneath the renal vein, and if necessary the adrenal vein can be ligated. It is essential to confirm the presence or absence of a replaced or aberrant right hepatic artery branch, which is one of the most commonly encountered variants in the splanchnic circulation. SMAA surgical repair carries a relatively high mortality of close to 15%.[117]

Endovascular therapies provide an additional therapeutic option to high-risk candidates in whom open surgery may not be feasible. Reports of endovascular management of SMAAs describe the use of coil embolization and stent grafts.[7,24,43,95,123] Endovascular therapy is particularly useful in patients with a hostile abdomen and medical comorbidities.[46]

Celiac Artery Aneurysms

Epidemiology

Celiac aneurysms represent approximately 4% of all splanchnic aneurysms, with little over 100 cases reported in the literature.[11,124] True prevalence based on autopsy review is about 1 in 8000.[125] They are found concomitantly with other splanchnic artery aneurysms 40% of the time and with abdominal aortic aneurysms in 20% of cases.[5,126] Atherosclerosis is associated with the majority of these aneurysms, with an infectious etiology implicated in 20% of cases. The majority are discovered in male patients in their fifth or sixth decade of life.[18,44,127]

Etiology

A literature review of 108 CAAs revealed an interesting trend in CAA pathogenesis.[128] Among 60 CAAs encountered before 1950, a total of 40% were infectious (usually syphilis), 7% were traumatic, and 52% were of undetermined cause. Most of these were also symptomatic. The majority presented with rupture, and 95% were diagnosed at postmortem examination. Atherosclerosis and/or medial degeneration of the arterial wall are the most common causes of contemporary CAAs. Additionally, median arcuate ligament syndrome has been implicated in the formation of CAAs.[129] Most aneurysms in the contemporary group were either asymptomatic or accompanied by vague abdominal pain. Additionally, only 13% of these aneurysms presented with rupture. CAAs have also been reported to develop as a result of iatrogenic intervention or spontaneous isolated dissection of the celiac artery.[130] Patients with spontaneous dissections are predominantly male and younger than 50 years. Mortality can be high if dissection extends to the hepatic artery and warrants immediate operative or endovascular treatment. Conservative treatment can be justified in patients with isolated celiac dissection without bowel ischemia or hemorrhage.[131] There is also a reported association with anomalous origins of the right and left hepatic arteries, a common celiacomesenteric trunk, and other anomalous mesenteric vasculature.[132-134]

Clinical Presentation

CAAs remain noteworthy due to the high mortality rates associated with rupture. Historically, mortality after rupture approached 100%.[135] Modern series report rupture rates ranging from 10% to 20%, with a mortality of 50%.[75,127,128] There are no established aneurysm characteristics or patient comorbidities that may predict rupture risk. Size at presentation, aneurysm etiology, and aneurysm calcification do not appear to influence the propensity to rupture.[127] Patients may present with a history of vague colicky abdominal pain or intestinal angina.[136] Acute abdominal pain and hemorrhagic shock are frequently encountered in cases of rupture. Patients experiencing biliary obstruction may also present with gastrointestinal bleeding and jaundice. The "double rupture" phenomenon seen in SAAs is reported in nearly 25% of ruptured CAAs.[33]

Treatment

Given the reported mortality rates associated with rupture of 50% and higher,[12,75] previous consensus suggested treating any CAA encountered regardless of size unless patient comorbidities prevented intervention. Corey et al. recently described their experience with 78 patients with CAAs, of whom 71 were managed with surveillance. Only 3 (5%) of those patients' aneurysms were noted to grow in size during an average

44-month surveillance time and none ruptured. A size criterion of greater than 2.5 cm for repair was advocated as a result of these findings.[18] Additionally, the Mayo Clinic reported the outcomes of 18 CAAs.[127] The patients observed in this series ($n = 8$) were considered to pose too high a risk for intervention and were followed with serial imaging. The only reported rupture occurred in a patient with a 2.5-cm CAA 5 years after initial presentation, with no other complication or aneurysmal growth reported in the remaining observed patients. The authors concluded that observation of CAAs can be a reasonable option if comorbidities preclude operative repair. However, the use of endovascular intervention for treating CAAs has been shown to be effective and may be an appropriate option for patients otherwise considered at high risk for surgery.[137]

Before the incorporation of endovascular intervention into modern practice, open surgical repair was the only option for the treatment of CAAs. Surgical options include ligation with or without reconstruction, aneurysmectomy, and aneurysmorrhaphy.[44,128,138] The need for arterial reconstruction depends largely on aneurysmal location and the adequacy of mesenteric collateralization. Ligation alone has been reported to be performed in one-third of cases, but this option is avoided in patients with liver disease.[12,128] A transabdominal approach is used to access the celiac axis. A prosthetic conduit or saphenous vein graft may be used in cases where simple ligation cannot be performed alone.[127] Intestinal viability should be assessed, and patients will need to be monitored for evidence of bowel, liver, or splenic ischemia in the postoperative course. A review of the modern literature demonstrated that operative therapy was successfully undertaken in 91% of 43 patients during the contemporary era, including eight in the author's series.[128] Endovascular intervention has been used with increasing success, incorporating coil or glue embolization, percutaneous thrombin or ethanol injection, and stent grafting.[63,136,137,139-142]

OTHER RARE SPLANCHNIC ANEURYSMS

Gastric/Gastroepiploic Aneurysms

Etiology

GAAs and gastroepiploic artery aneurysms (GEAAs) together represent less than 4% of all splanchnic artery aneurysms. The etiology of GAAs and GEAAs has been attributed to atherosclerosis in 30% of cases, trauma in 25%, and infection in 15%, but their true natural history is poorly defined.[143] Comorbid conditions include peptic ulcer disease, vasculitis, and pancreatitis.[34,75] There is a reported male predominance, with initial presentation in the sixth or seventh decade of life.[144] The majority of these aneurysms are located along the left or right gastric artery, whereas aneurysms along the greater curvature of the stomach are encountered much less frequently, at a reported ratio of 1 : 10.[145]

Clinical Presentation

Over 90% of reported GEAAs are ruptured on initial presentation, resulting in hemorrhage into the peritoneum. They usually present with mild epigastric pain, hemoperitoneum, and hemorrhagic shock requiring some form of intervention.

Treatment

Mortality rates for patients presenting with ruptured GAAs and GEAAs are near 70%.[75] Any GEAA or GAA discovered before rupture should be repaired. Emergent or ruptured cases are usually managed with open laparotomy. Open surgical repair includes either aneurysmectomy or exclusion. Simultaneous revascularization to maintain arterial inflow is generally not required. If proximal embolization is performed alone, the aneurysm may recruit a new vascular supply in a retrograde manner, hence the importance of simultaneous distal and proximal embolization.[146]

Pancreaticoduodenal and Gastroduodenal Artery Aneurysms

Etiology

PDAAs, GDAAs, and any aneurysms of their branches are extremely rare entities representing 2% and 1.5% of all splanchnic artery aneurysms, respectively. Since Ferguson's original description of a superior pancreaticoduodenal aneurysm in 1895, there has yet to be a definitive study evaluating the natural history of these lesions or a description of a preferred method of treatment.[147] Roughly 100 cases of PDAAs (Fig. 85.6) are described in the literature, most as single case reports.[148] Consistent with other splanchnic artery aneurysms, distinguishing between true and pseudoaneurysms is clinically significant due to varying etiologies and prognoses. GDA and PDA pseudoaneurysms are almost always associated with pancreatic pathology, celiac occlusion or stenosis, or abdominal trauma, including iatrogenic injury from percutaneous and laparoscopic interventions.[149,150] The male-to-female predominance is 4 to 1, with the average age of presentation in the sixth decade of life. This disproportionate

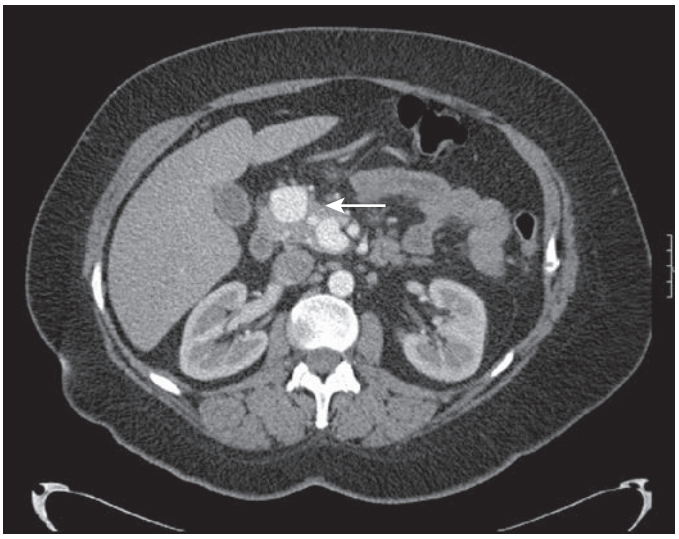

Figure 85.6 A 45-year-old female presented with abdominal pain and pancreatitis. A computed tomography scan revealed two aneurysms in the pancreatic head *(arrow)* that originated from branches of the superior mesenteric and celiac arteries.

ratio in relatively younger men may reflect alcoholic pancreatitis leading to pseudoaneurysm formation in the PDA or GDA.[151]

Clinical Presentation

Although the majority of patients have clinical findings, symptoms arising from PDAAs and GDAAs are most often vague and include epigastric abdominal pain, which may radiate to the back (Fig. 85.7). Other symptoms may include gastrointestinal bleeding, hypotension, emesis, diarrhea, and jaundice.[147] The gastrointestinal or biliary tract is the site of rupture in 65% of cases, whereas rupture into the retroperitoneal space occurs in 35% of cases.[152,153] In one series, 75% of PDAAs presented as rupture, with 50% mortality.[50] Another recent series reported 62% of PDAAs initially diagnosed at the time of rupture, with a 21% mortality rate.[148]

Treatment

There is no correlation between size and rupture risk of PDAAs and GDAAs. Diagnosis of these rare aneurysms mandate timely intervention given the high rate of rupture and mortality.[12] General consensus favors treatment of these lesions regardless of size.[148] Patients presenting with rupture have reported mortality rates of 30% to 40% even with intervention.[154] Ligation of the aneurysm and a partial pancreatectomy or pancreaticoduodenectomy may have to be performed.[148,155]

Endovascular techniques offer an excellent option in treating lesions that would otherwise be surgically challenging to access. Successful treatment requires ablation or exclusion of the aneurysmal sac from the circulation. Coil embolization techniques are generally preferred for these aneurysms, and limited case reports have reported promising success rates.[14,24,45] A large series reported a 78% success rate with coil embolization of 32 cases.[156] Reported complications included rupture and reperfusion of the sac. Percutaneous transabdominal thrombin injection of these aneurysms has also been described.[157]

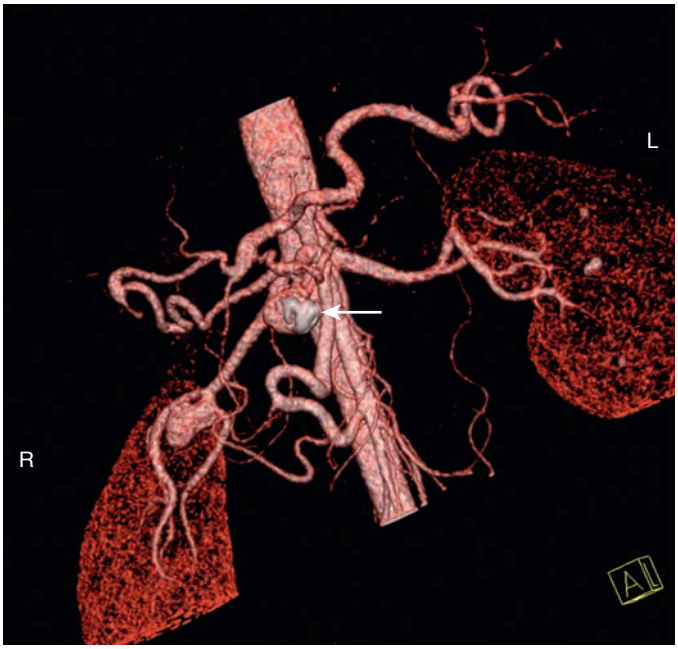

Figure 85.7 A computed tomography scan to evaluate a 44-year-old male with a history of nephrolithiasis revealed an aneurysm involving his right renal artery as well as a 2-cm aneurysm involving his gastroduodenal artery.

Inferior Mesenteric, Jejunal, Ileal, and Colic Artery Aneurysms

Etiology

Aneurysms of the inferior mesenteric and colic arteries are extremely rare, usually anecdotally reported in the literature, and have no clear treatment modalities beyond lifesaving intervention in the setting of free rupture. Most reported lesions are small (<1 cm) compared with other splanchnic aneurysms.[44,121,158] Literature review and large case series estimate that inferior mesenteric branch aneurysms comprise less than 2% of all reported splanchnic artery aneurysms.[12,44,159] The etiologies of these aneurysms remain poorly defined, with inflammation and infection associated with one-third of the cases. A large series from the Mayo Clinic reported eight patients with these mesenteric branch aneurysms, adding that most of these had a significant smoking history and used alcohol.[15] Two of the three females reported a history of multiple pregnancies, but no true relationship with multiparity and these aneurysms has been established. A recent literature review showed a male-to-female predominance of nearly 5 to 1.[160] There is also an association with inferior mesenteric branch aneurysm formation and stenosis or occlusion of the SMA and celiac trunk.[161]

Clinical Presentation

Mesenteric branch artery aneurysms are usually symptomatic and often ruptured at the time of presentation, and emergent operations are performed for lifesaving intervention. When rupture occurs, the mortality has been reported to be close to 20%.[12] Abdominal pain and hypovolemic shock are seen in approximately 85% of cases. In one series, 50% of patients presented with symptoms, whereas the other aneurysms were found incidentally.[15] Diagnosis can be made with cross-sectional imaging. As with other ruptured splanchnic aneurysms, diagnosis is often made at the time of laparotomy.

Treatment

Inferior mesenteric, jejunal, ileal, and colic artery aneurysms can rupture freely into the peritoneal cavity or into adjacent intestinal segments, causing gastrointestinal hemorrhage. Most reported cases of rupture involve an aneurysm less than 1 cm in size; therefore, any such lesion encountered should be treated.[15,44,121] Preoperative arteriography can aid in identification of the lesion and operative planning.[160,162] Open surgical treatment usually involves aneurysmectomy, particularly in the setting of IMAAs or ligation. Cases of endovascular treatment have been limited due to the scarcity of these lesions. Treatment results have generally been favorable, with few reported technical failures.[15,163] Successful treatment with endovascular intervention has been reported in the setting of rupture.[164]

Visceral Venous Aneurysms

Aneurysms of the visceral veins are an extremely rare and seldom encountered in the clinical setting. A recent meta-analysis of the English and French literature identified 93 reports wherein 176 patients with 198 visceral venous aneurysms were described.[165] Aneurysms are usually located at the main portal vein, the junction of the superior mesenteric and splenic veins, or the hepatic hilus.[166,167] Thrombosis, adjacent organ compression, and rupture are rare complications. The majority of these lesions can be followed with serial imaging. Open aneurysmorrhaphy or aneurysmectomy is indicated for symptomatic cases, thrombosis, adjacent organ compression, or rupture. Cases involving aneurysms of the splenic vein often require concomitant splenectomy and distal pancreatectomy. The role for endovascular intervention remains undefined.

BACKGROUND

Until fairly recently, stroke was largely believed to be a result solely of intracranial pathology. Indeed, in the seventh edition of his textbook published in 1909 and entitled *The Principles and Practice of Medicine*, William Osler attributed stroke mainly to intracranial hemorrhage or vasospasm and made no mention of carotid or vertebral artery occlusive disease.[1] Yet the relationship between extracranial carotid disease and stroke had been surmised previously as early as 1875, when Gowers reported on a patient with carotid occlusion, left visual loss, and right hemiplegia.[2] Subsequently, in 1905, Chiari studied 400

Abstract

Stroke is among the major causes of mortality and disability worldwide. The relationship of extracranial cerebrovascular disease to ischemic stroke has been clearly demonstrated. In particular, atherosclerotic occlusive disease of the carotid artery is considered to be one of the key treatable causes of ischemic stroke, and thus the role of the vascular surgeon in stroke prevention is critical. In this chapter, we provide an overview of the risk factors, epidemiology and natural history of both stroke and carotid artery occlusive disease, with an emphasis on those factors which influence the decision to treat carotid artery stenosis with either medical therapy or surgical or endovascular intervention.

transient ischemic attack

consecutive autopsies and discovered thrombus superimposed on carotid artery atherosclerotic plaque in seven patients, four of whom had suffered embolic strokes.[3] This important observation likely represented the first pathophysiologic description linking carotid plaque atheroembolism to ischemic stroke. Perhaps the greatest breakthrough in the study of the mechanism of cerebrovascular disease was Fisher's publication of clinicoanatomic correlations on occlusion of the carotid arteries in 1951 and 1954.[4,5] He describes the atherosclerotic plaque as the culprit lesion in carotid artery disease and importantly notes that the distal internal carotid artery (ICA) is usually free of disease, raising the possibility of surgical bypass to a healthy target vessel. Fisher's prediction of surgical treatment for carotid atherosclerosis was soon realized. In 1954, Eastcott, Pickering, and Rob reported on the first successful carotid surgery for occlusive disease, in which the carotid bifurcation was resected and in-line flow restored via a common carotid-to-ICA anastomosis.[6] The first successful carotid endarterectomy (CEA) was performed by DeBakey in 1953 and reported along with a 19-year symptom-free follow-up in 1975.[7,8]

The precise role of this operation in the treatment of cerebrovascular disease remained controversial until the early 1990s, when several randomized clinical trials clearly demonstrated not only its safety and effectiveness but also its superiority to contemporaneous medical treatment in both symptomatic as well as certain asymptomatic patients.[9-13]

STROKE—BACKGROUND/INTRODUCTION

Stroke, or cerebral infarction, is the acute development of a focal neurologic deficit caused by disruption of the blood supply to an area of the brain. Strokes can be ischemic, due to occlusion of a blood vessel or other causes of malperfusion, or hemorrhagic, due to rupture of a blood vessel. Hemorrhagic strokes include both intracerebral hemorrhage, which is bleeding within the brain parenchyma, and subarachnoid hemorrhage, which is bleeding in the subarachnoid space.[14] The majority of strokes in the United States, approximately 87%, are in fact ischemic in etiology.[14] Extracranial cerebrovascular disease consisting of atherosclerotic occlusive disease of the carotid artery is considered to be one of the key preventable cause of ischemic stroke, along with atrial fibrillation and hypertension.

Stroke

Stroke is defined as an acute neurologic dysfunction of vascular etiology with corresponding signs and symptoms lasting more than 24 hours and resulting from infarction of focal areas of the brain. Ischemic stroke related to the carotid artery can present with sudden contralateral sensorimotor loss, speech deficit, and ipsilateral monocular blindness. In a transient ischemic attack (TIA), the ischemic parenchyma recovers and returns function to baseline. The full clinical impact of a stroke is often not apparent for up to 2 weeks, as the ischemic penumbra either recovers or succumbs to infarction. Although supportive care and rehabilitation following stroke allow for some or significant recovery in many patients, many deficits are long-lasting if not permanent as the cerebral parenchyma is irrevocably lost.

Cost of Caring for Stroke Patients

The estimated total direct and indirect cost of stroke in the United States in 2013 was $33.9 billion.[15,16] The direct costs of $18.8 billion included hospital outpatient or office provider visits, hospital inpatient stays, emergency department visits, medicines, and home healthcare.[15,17] Between 2012 and 2030 total direct medical stroke-related costs are projected to triple, from $71.6 billion to $184.1 billion, with the majority of the increase arising from patients between the ages of 65 to 79 years.[18] The total cost of stroke from 2005 to 2050 is projected to be approximately $1.52 trillion for non-Hispanic white patients, $313 billion for Hispanic patients, and $379 billion for black patients.[15,19]

Treatment of Acute Stroke

The acute treatment of ischemic stroke is generally and historically supportive and medical. The role of urgent surgical (CEA) or endovascular treatment of acute ischemic stroke related to carotid artery occlusive disease is controversial and its indications uncertain. In several recent studies, improved functional outcome in stroke patients who received endovascular intervention in conjunction with thrombolysis within a defined period of symptom onset was noted.[20-22] Although urgent thrombolytic therapy in combination with adjunctive endovascular therapy within several hours after an ischemic stroke is an attractive and important option, its widespread application may be limited from a practical and logistical point of view. Therefore the principal strategy against cerebrovascular disease and its role in causing ischemic stroke remains primary stroke prevention.

STROKE—PREVALENCE/INCIDENCE

Stroke Prevalence

Stroke is among the major causes of mortality and disability worldwide; it is estimated that in 2013 the prevalence of stroke was 25.7 million, with 10.3 million people experiencing a first stroke.[23] Stroke causes 5.5 million deaths and over 44 million disabilities every year.[24] In the United States alone, a stroke occurs approximately every 40 seconds; this translates into about 2160 strokes each day. Each year, approximately 800,000 Americans suffer a stroke.[14] The overall stroke prevalence or proportion of the population affected by stroke relative to the population as a whole in the United States during the years 2005 to 2008 was approximately 3.0%. The prevalence of additional but clinically silent cerebral infarction is estimated to range from 6% to 28%.[15,25-27] Projections show that by 2030, an additional 3.4 million people will have had a stroke, a 20.5% increase in prevalence from 2012.[16,18]

The prevalence of stroke varies with the population studied and is related to age, ethnicity, sex, and risk-factor profile (Figs. 86.1 and 86.2).[15] The prevalence of ischemic stroke increases with age in both men and women. In the United States, the prevalence of stroke varies by race and ethnicity; it is 6% among American Indian/Alaska Native populations, 4.0% among blacks, 2.6% among Hispanics, 2.3% among whites, and 1.6% among Asians.[28]

Stroke Incidence

Each year in the United States approximately 800,000 people experience a new or recurrent stroke[15]; approximately 185,000 of these are recurrent strokes.[15] Although women have a lower age-adjusted stroke incidence than men, women have a higher lifetime risk of stroke than men because of their longer life expectancy.[15,29,30] African Americans have a risk of first-ever stroke twice that of whites (Fig. 86.3).[15,29] Data from the Framingham Heart Study indicate that the age-adjusted incidence of clinical stroke per 1000 person-years in 1950 to 1977, 1978 to 1989, and 1990 to 2004 was 7.6, 6.2, and 5.3 in men and 6.2, 5.8, and 5.1 in women, respectively.[29] Analysis of data from the Framingham Study additionally suggests that stroke incidence is declining over time in this largely white cohort.[31] Unfortunately a similar decline was not noted in African Americans.

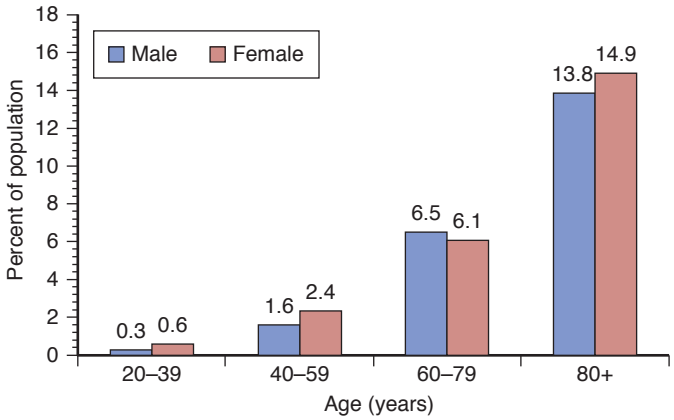

Figure 86.1 Prevalence of stroke by age and sex (National Health and Nutrition Examination Survey: 2011-2014). (From Benjamin EJ, et al. Heart disease and stroke statistics-2017 update: a report from the American Heart Association. *Circulation*. 2017;135:e146-e603. *Used with permission.*)

DECLINING PREVALENCE/INCIDENCE OF STROKE

Possible Decreasing Prevalence and Incidence of Stroke

In December 2010, the Centers for Disease Control and Prevention announced that stroke had become the fourth leading cause of death in the United States, down from the third place ranking it had held for decades.[32,33] Currently stroke is felt to be the fifth leading cause of death when considered separately from other cardiovascular diseases.[16] Several additional population-based studies have tracked stroke incidence during recent decades.[34] Rothwell et al. reported a decrease in stroke incidence of nearly 40% between the 1980s and the year 2002 in the United Kingdom.[35] In an additional report from the American Heart Association, the lifetime risk of stroke in a 65-year-old male decreased from 19.5% 50 years ago to 14.5% in 2013.[36,37] In the United States, the Framingham cohort and the Greater Cincinnati/Northern Kentucky Stroke Study (GCNKSS) also found that the incidence of stroke has been

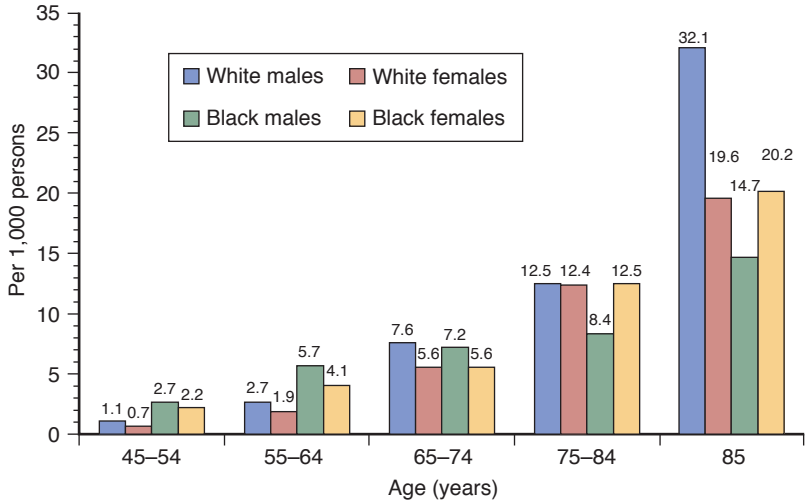

Figure 86.2 Annual incidence of first cerebral infarction by age, sex, and race (Greater Cincinnati/Northern Kentucky Stroke Study: 1999). Rates for black men and women 45 to 54 years of age and for black men 75 years of age and above are considered unreliable. *GCNKSS*, Greater Cincinnati/Northern Kentucky Stroke Study. (From Unpublished data from the Greater Cincinnati/Northern Kentucky Stroke Study; From Benjamin EJ, et al. Heart disease and stroke statistics; 2017 update: a report from the American Heart Association. *Circulation*. 2017;135:e146-e603. *Used with permission.*)

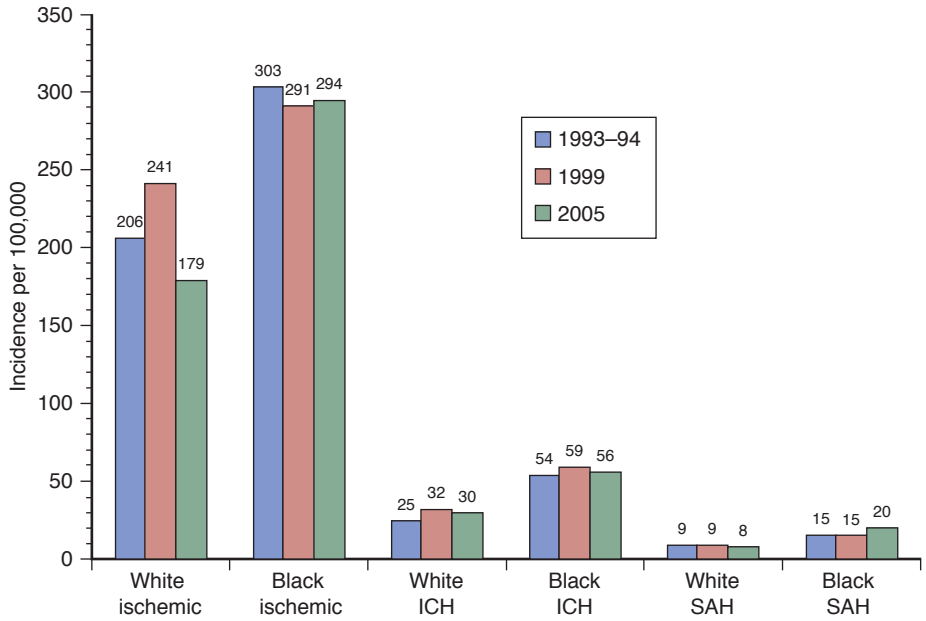

Figure 86.3 Annual age-adjusted incidence of first-ever stroke by race. *ICH*, Intracerebral haemorrhage; *SAH*, subarachnoid haemorrhage. (From Benjamin EJ, et al. Figure 86.4 Ischemic stroke incidence rates and trends over time by sex. Incidence rates and 95% confidence intervals. Incidence rates were adjusted by age and race. (From Madsen TE, et al. Sex-specific stroke incidence over time in the Greater Cincinnati/Northern Kentucky Stroke Study. *Neurology*. 2017;89:990-996. *Used with permission.*)

declining over the past 50 years (Fig. 86.4).[29,34] In contrast to the prior reports, the Minnesota Stroke Study noted that the incidence of stroke appeared to be stable in both men and women between the years 1990 and 2000.[38]

In 2012, Koton et al. reported on trends in stroke incidence and mortality in the United States from 1987 to 2011.[39] This report from the Atherosclerosis Risk in Communities Study (ARIC) was a prospective cohort study of 14,357 participants. Stroke was ultimately diagnosed in 1051 of 14,357 participants (7%). Stroke incidence was strongly related to older age, male sex, black race, hypertension, diabetes, coronary heart disease, and current smoking. It was negatively associated with the use of cholesterol-lowering medications. Stroke incidence decreased over time in both white and black subjects. The decrease in age-adjusted incidence was evident in participants aged 65 years and older but not in younger subjects. The decrease in incidence was similar by sex. Additionally, mortality after stroke was noted to decrease over time. The authors conclude that there was a demonstrable decrease in stroke incidence and mortality rates in the United States during this time period. The decrease varied across age groups but was similar across sex and race.[39]

A review article by Zhang et al. in 2012 noted that the prevalence of stroke reported in the United States by the Centers for Disease Control (CDC) Behavioral Risk Factor Surveillance System in the years 2005 and 2008 was equivalent at 2.6%.[40] After a comprehensive review of multiple population-based studies, it was not possible to prove or disprove whether the prevalence of stroke may be decreasing. However, it was felt that there was abundant evidence that the *mortality* attributable to acute stroke is decreasing, likely related to improvements in acute stroke treatment.[40] It was furthermore noted that an increase in the burden of stroke due to the aging populations of both the United States and European countries was still to be expected.

Finally, more recent data from GCNKSS reported in 2017 showed that decreases in stroke incidence over time have been driven primarily by a decrease in ischemic stroke in men as opposed to women. In contrast to their reports from prior study periods, stroke incidence rates were noted to be similar by sex in 2010.[41]

Effect of Improved Medical Therapy on the Reduced Incidence of Stroke

The possible effect of improved modern medical therapy on the decreased incidence of stroke has received great attention

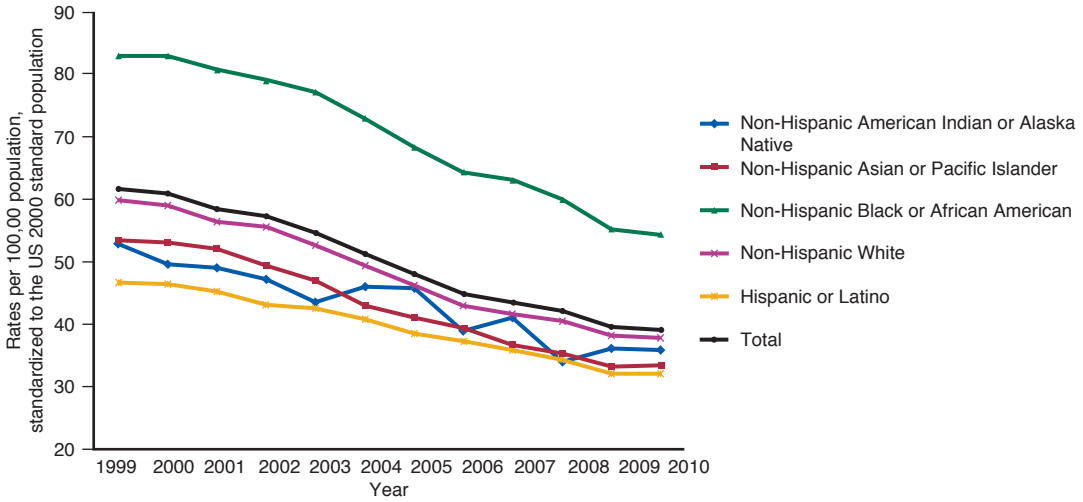

Figure 86.5 Age-adjusted death rates for cerebrovascular disease by race and by year. United States 1999–2010. (From Lackland D, et al. Factors influencing the decline in stroke mortality: a statement from the American Heart Association/American Stroke Association. *Stroke*. 2014;45:315-353.)

in the recent literature and has resulted in challenges to the role of CEA for asymptomatic patients. Previous randomized trials have demonstrated a clear benefit of surgical therapy with CEA over contemporaneous medical therapy regarding stroke prevention in both asymptomatic and previously symptomatic patients with severe extracranial ICA stenosis.[11,13,42] Some recent analyses have additionally reported that the annual risk of stroke even in patients with known asymptomatic ICA stenosis is lower than that reported in the CEA trials, presumably due to improved medical therapy.[43,44] Nevertheless it remains clear that asymptomatic ICA stenosis continues to cause a significant number of strokes.[45] Data from the GCNKSS have resulted in conservative estimates that about 41,000 strokes may be attributed to previously asymptomatic extracranial ICA stenosis annually in the United States.[45] The increased usage of cholesterol-lowering medications is often cited as the likely reason behind the decreased incidence of stroke.

The epidemiologic association between elevated cholesterol levels and stroke is inconsistent and somewhat controversial.[46] Despite this, treatment with statins has generally shown stroke reduction, as also reflected in the report of a meta-analysis of more than 90,000 patients.[47] It should be noted that many of the studies included in this meta-analysis involved secondary as opposed to primary stroke prevention. Nevertheless the relative reduction in stroke risk was found to be 21%. Statins have also been demonstrated to be associated with a reduction in stroke incidence in a variety of specific patient populations, including those with known coronary artery disease,[48] hypercholesterolemia,[48] normocholesterolemia,[48] elderly patients,[48] and diabetics.[49] Statins have also been demonstrated to consistently reduce carotid intima-media thickness (CIMT).[50] A recent meta-analysis including over 113,000 patients has shown that the use of statin therapy at stroke onset is associated with improved late outcome, including both rates of functional independence and survival.[51] Although data regarding the utility of statin medications for the primary prevention of stroke is less conclusive than for secondary prevention, current guidelines do in fact recommend statins for the prevention of first stroke in high-risk patients, including those with LDL levels greater than 4.1 and for males older than age 45 and females older than age 55 with the following risk factors: a positive family history, smoking, hypertension, or left ventricular hypertrophy.[46] However, it is unclear what exact role and effect statins have in patients with known severe carotid occlusive disease with regard to stroke prevention (see Chapter 13).

In a recent report authored by Writing Group Members on behalf of the American Heart Association's Stroke Council, a clear decline in stroke mortality is noted (Fig. 86.5).[52] The authors feel that this reduction is mainly due to the treatment of hypertension as opposed antilipid therapy. The authors note that epidemiologic studies have shown that elevated blood pressure is the most important determinant of the risk of stroke.[52] They also believe that improved treatment of hypertension is likely the most important factor that has contributed to the decline in stroke mortality (see Chapter 14).

ISCHEMIC STROKE—EPIDEMIOLOGY

Risk Factors for Stroke

Stroke prevention strategies should ideally be focused on high-risk populations. The risk factors for ischemic stroke include many of the risk factors for generalized atherosclerosis, as listed further on and shown in Fig. 86.6.[14,15,53] In addition to these risk factors for ischemic stroke, prior TIA and carotid artery atherosclerosis represent obvious major clinical risk factors for future ischemic stroke. The following factors have been clearly shown to be related to the risk of stroke in the general population:

Sex: The estimate 10-year stroke risk in adults 55 years of age and older differs by sex and the increasing presence of multiple risk factors.[16] Ischemic stroke is in general more prevalent in men than in women.[54] However, women tend to account for a higher percentage of stroke mortalities; this is likely because of their greater longevity.[14]

	A	B	C	D	E	F
Systolic BP	95–105	130–148	130–148	130–148	130–148	130–148
Diabetes	No	No	No	Yes	Yes	Yes
Cigarettes	No	No	No	Yes	Yes	Yes
Prior A Fib	No	No	No	No	Yes	Yes
Prior CVD	No	No	No	No	No	Yes

(From Benjamin EJ, et al. Heart disease and stroke statistics; 2017 update: a report from the American Heart Association. *Circulation*. 2017;135:e146-e603. *Used with permission.*)

Age: Increasing age is a major risk factor for ischemic stroke. For each decade after 55 years of age, the risk of stroke approximately doubles.[55]

Race: Blacks and Hispanics have a risk of first-ever stroke that is approximately twice that of whites.[56] Blacks may have a lower prevalence of carotid artery disease than whites, and it is hypothesized that the increased stroke rate among black patients is more likely related to hypertension and intracranial disease.[57]

Hypertension: Hypertension is a significant risk factor for both ischemic stroke and intracranial hemorrhage.[16] Appropriate treatment of blood pressure in hypertensive patients is associated with a significant reduction in the risk of ischemic stroke; patients with a blood pressure less than 120/80 have half the lifetime risk of stroke than subjects with hypertension.[15,58] So-called intensive blood pressure control as opposed to standard treatment has also resulted in a significantly lower risk of stroke.[59] Strict blood pressure control can also reduce the risk of recurrent stroke.[60]

Family history: A parental history of stroke, TIA, or myocardial infarction is associated with a 1.4- to 3.3-fold increased risk for stroke.[61]

Atrial fibrillation: Patients with atrial fibrillation have a three- to fivefold increased risk of cardioembolic ischemic stroke.[62]

Cigarette smoking: Current cigarette smokers have a two to four times increased risk of stroke as compared with nonsmokers or those who have quit for more than 10 years.[15,63,64] Discontinuation of smoking reduces future stroke risk in multiple demographic patient categories.[65]

Hypercholesterolemia: Trials specific to ischemic stroke have demonstrated that there may be a 25% increased risk of ischemic stroke with each 38.7 mg/dL increase in total cholesterol levels.[66] However, not all trials have consistently demonstrated a correlation between hypercholesterolemia and ischemic stroke.[14] An association between total cholesterol levels and ischemic stroke has been found in some studies but has not been confirmed in others.[16]

Physical activity: Increased leisure-time physical activity is protective against stroke across race, sex, and age, and related to the level of intensity and the duration of activity.[67] In the REGARDS study, participants who reported physical activity less than four times a week had a 20% increase in stroke risk as compared with those who exercised more than four times a week. However, it is possible that this is related to the fact that physical activity also improves traditional risk factors such as diabetes and obesity.[16,68]

Diabetes: Diabetes is a risk factor for ischemic stroke at all ages, but the most significant risk increase appears to occur among patients less than 65 years of age.[16] Diabetes mellitus nearly doubles the risk of stroke among persons with diabetes as compared with others who have normal glucose levels.[69] The effect of diabetes on stroke risk appears to be more significant in women than in men.[70] Intensive glucose control did not appear to result in reduced stroke risk as compared with conventional glucose control (see Chapter 12).[71]

Diet: A protective relationship between fruit and vegetable consumption and decreased ischemic stroke risk has been reported.[72] A Mediterranean-style diet higher in the consumption of nuts and olive oil has been shown to be associated with a reduced risk of stroke.[73]

Obesity: Obesity is a specific risk factor for ischemic stroke in both men and women.[74,75] There is an additional association between abdominal obesity and ischemic stroke in men.[76]

Alcohol: There is a reported increased risk of ischemic stroke with "irregular" drinking, including heavy and binge drinking.[77] However, moderate drinking may be associated with a decreased risk of ischemic stroke.[78]

Renal insufficiency: Mild to moderate renal insufficiency is an independent predictor of ischemic stroke in both asymptomatic patients and patients with peripheral arterial disease.[79-81]

The INTERSTROKE Study, in 2010, reported a case-control study of 2337 ischemic stroke cases in 22 countries worldwide. Patients with an acute first stroke were compared with controls with no history of stroke and were matched for both age and sex.[53] The authors found that five factors accounted for more than 80% of the global risk of all ischemic strokes: hypertension, current smoking, abdominal obesity, poor diet, and physical inactivity.[53] Hypertension was the most important risk factor for all stroke subtypes.[53,82]

ISCHEMIC STROKE—NATURAL HISTORY

Because carotid artery interventions are performed to prevent future stroke, it is essential to understand the natural history

of carotid disease, stroke, and TIA in order to properly assess the risks and benefits of potential intervention.

Outcome of Stroke

Following an ischemic stroke, the risk for recurrent ischemic stroke is 2% at 7 days, 4% at 30 days, 12% at 1 year, and 29% at 5 years.[83] The risk of death after an initial ischemic stroke is 7% at 7 days, 14% at 30 days, 27% at 1 year, and 53% at 5 years (Fig. 86.7).[83] Somebody in the United States dies every 4 minutes from a stroke,[15,84] and strokes accounts for 1 out of every 18 deaths.[15,84] When considered separately from other cardiovascular diseases, stroke currently ranks fifth among all causes of death, behind heart disease, cancer, and chronic lower respiratory disease.[15,84] As previously discussed, stroke mortality rates appear to be decreasing; from 1998 to 2008 the actual number of stroke deaths declined by 19.4%.[15,85]

Stroke is the leading cause of serious long-term disability in the United States.[15,86] Among ischemic stroke survivors who were 65 years of age or older, the following disabilities were observed at 6 months after a stroke: 50% had hemiparesis, 30% were unable to walk without assistance, 26% were dependent in activities of daily living, 19% had aphasia, 35% had depressive symptoms, and 26% were institutionalized.[15,87] A contemporary perspective on the impact of stroke is available from the Carotid Revascularization Endarterectomy Versus Stenting Trial (CREST) data[88]; even though few of the strokes related to either CEA or carotid artery angioplasty and stenting carotid artery stenosis (CAS) were major in extent, the estimated 4-year mortality after stroke was 21.1%, compared with 11.6% for those without stroke, including those who had undergone carotid revascularization. The adjusted risk of death at 4 years was higher after periprocedural stroke (hazard ratio, 2.78).

Stroke may also be associated with long-term cognitive decline.[89] Although it is obvious that acute stroke may be responsible for acute changes in cognition, it has also been demonstrated that acute stroke is additionally associated with accelerated and persistent cognitive decline over 6 years.

Recurrent Stroke Following an Initial Event

Patients who have had an initial stroke are additionally at greatly increased risk for subsequent events. Based upon a population cohort study of more than 10,000 patients discharged from hospitalization with a diagnosis of stroke, the rates of recurrent stroke were 1.8% at 1 month, 5% at 6 months, 8% at 1 year, and 18.1% at 4 years.[90] This information is particularly relevant in considering the timing of carotid intervention in appropriate patients following an initial nondisabling stroke so as to most successfully prevent a subsequent cerebrovascular event. Recurrent stroke is associated with a greater number of baseline risk factors and with large artery occlusive disease as opposed to other causes of stroke (Fig. 86.8).[91,92]

In the North American Symptomatic Carotid Endarterectomy Trial (NASCET), medically randomized patients with symptomatic carotid artery disease (stroke or TIA) and high-grade carotid stenosis had an ipsilateral stroke rate of 26% over 2 years.[13] Major or fatal ipsilateral stroke occurred in 13.1% of patients. In the 32-day period following randomization of medically treated symptomatic patients, 3.3% experienced stroke or death.

Stroke Mortality

Stroke accounts for approximately 1 of every 20 deaths in the United States.[16] Data from the ARIC study revealed that all-cause mortality rate after a stroke was 10.5% at 30 days, 21.2% at 1 year, 39.8% at 5 years, and 58.4% at 24 years.[39] A CDC report found that among Medicare beneficiaries, the 30-day mortality following a stroke varied by age and ranged from

9% in patients 65 to 74 years of age to 23% in those over 85 years of age.[93]

TRANSIENT ISCHEMIC ATTACK—BACKGROUND/INTRODUCTION

A TIA, often referred to as a "ministroke," is a neurologic event that presents with stroke-like symptoms less than 24 hours in duration. In fact, the vast majority of these symptoms last for only a few minutes. A TIA should be considered a warning sign for future stroke, as approximately 30% of patients who have had a TIA go on to suffer a stroke within 5 years.[94] Unlike a stroke, where flow is permanently interrupted, resulting in infarction, TIA symptoms are short-lived and resolve upon restoration of flow to the brain, returning the patient to neurologic baseline. Yet it is important to note that a TIA is a clinical diagnosis; although neurologic baseline is restored within 24 hours, cell death may have occurred nonetheless. Indeed, brain computed tomography performed on 284 patients presenting with clinical TIA and without previous clinical stroke revealed demonstrable infarction in 24% of patients.[95]

Symptoms of TIA or stroke resulting from carotid disease are related to the cerebral vascular territory affected. The carotid artery supplies the anterior circulation; thus carotid disease can result in symptoms associated with injury to brain parenchyma of the anterior cerebral artery or middle cerebral artery distribution. Motor symptoms can range from mild hemiparesis to complete hemiparalysis contralateral to the affected hemisphere. Likewise, sensory deficits may consist of mild numbness or complete paresthesia of the contralateral extremities. Language loss (dysarthria, dysphasia, or aphasia) can occur when the dominant hemisphere is affected. Amaurosis fugax (transient monocular blindness or field cuts), resulting from emboli to the retinal artery via the ophthalmic artery, is considered to be the classic symptom of TIA related to carotid artery lesions. Unlike thromboemboli of cardiac origin, carotid emboli tend to present with TIAs rather than stroke. Moreover, TIAs of carotid artery origin tend to occur in the same vascular territory, whereas TIAs of cardioembolic origin are more haphazard in location and symptomatology.[96,97]

TRANSIENT ISCHEMIC ATTACK—PREVALENCE

Like the epidemiology of stroke, the incidence of TIA increases with age and varies by sex and race/ethnicity.[16] Approximately 15% of all strokes are heralded by a TIA.[98] Patients who have had a TIA have a significant risk of subsequent stroke in the short term: among a cohort of patients seen in an emergency room with a TIA, 11% experienced a subsequent stroke within

90 days, and 5% experienced a subsequent stroke within 2 days.[99] This finding and other supportive data are relevant to the recommendations for the timing of carotid intervention in appropriate patients following an initial TIA so as to prevent a subsequent episode of frank or completed clinical infarction. The estimated incidence of self-reported or physician-diagnosed TIA in the United States is approximately 2.3%, but the true incidence is likely higher.[15,99] Additionally, the true prevalence of TIAs may actually be higher than reported because many patients who may experience subtle neurologic symptoms do not report them to a healthcare provider.[16]

TRANSIENT ISCHEMIC ATTACK—NATURAL HISTORY

The most important consideration in patients who have experienced a TIA is their future relevant stroke risk. The presence and diagnosis of a TIA, if found in the setting of ipsilateral and appropriate severity of carotid artery disease, offers the practitioner the opportunity to intervene to prevent subsequent stroke.

Independent predictors of subsequent stroke following a TIA included age greater than 60 years, diabetes mellitus, the presence of focal symptoms, and TIAs that lasted longer than 10 minutes.[15,99] Individuals who experience a TIA and survive the initial high-risk period have a 10-year stroke risk of about 19%.[15,100] Two meta-analyses of TIA patients reported that the short-term risk of stroke following TIA was a similar: 3% to 10% at 2 days, and 9% to 17% at 90 days.[98,101] Approximately one-third of episodes characterized as a TIA according to the clinical definition would probably be considered cerebral infarctions on the basis of diffusion-weighted magnetic resonance imaging (MRI) findings.[15,102,103] Because of the substantial risk of ischemic stroke following a TIA, patients with transient focal hemispheric symptoms should be expediently evaluated for the presence of significant carotid artery disease.

Patients with TIA are also at risk for disability as well as long-term morbidity and mortality.[104] In 2017, Edwards et al. reported that among more than 25,000 patients who were initially stable after a TIA or stroke, both clinical groups were at significant risk for recurrent stroke. Although patients who initially had a stroke were the higher-risk group, even 31.5% of TIA patients specifically experienced an adverse event within 5 years.

EXTRACRANIAL CAROTID ARTERY ATHEROSCLEROSIS—BACKGROUND

Pathophysiology

Most acute coronary syndromes are caused by thrombus formation in moderately stenotic coronary arteries at the site of a ruptured or eroded fibrous cap.[105,106] Atherosclerotic plaque in the carotid artery causes a substantial proportion of ischemic strokes, but the mechanisms are less well understood than those of acute coronary thrombosis.[105] Carotid artery plaque can cause TIA or stroke by two mechanisms: embolization and hypoperfusion. Due to the abundant collateral circulation in the brain, global cerebral hypoperfusion is rare; it occurs only in patients with severe multivessel occlusive disease in both the carotid and vertebral artery territories. Atheroembolization of debris originating from carotid artery plaque and traveling to the brain is felt to be the predominant cause of both TIA and ischemic stroke related to carotid artery disease. Evidence for the role of embolization comes from the early reports of Hollenhorst, who found embolic debris in the retinal vessels of patients with transient monocular blindness.[107] The severity of carotid artery stenosis is strongly associated with stroke risk in symptomatic patients.[10,105,108] Currently it is the most important predictor of benefit from carotid artery intervention.[109] However, other factors predictive of stroke clearly exist, including an ulcerated appearance present on carotid arteriography or duplex ultrasonography, which is also a strong independent risk factor for acute stroke.[105,110,111]

The degree of carotid artery stenosis is a critical factor involved in identifying patients at increased risk of future ischemic stroke; in fact, however, most asymptomatic patients with moderate degrees of carotid artery stenosis are at relatively low risk for future stroke. On the other hand, only 15% of ischemic strokes are preceded by a warning TIA. Therefore waiting for stenosis to become symptomatic fails to prevent most strokes caused by carotid artery disease.[112] Hence there is a critical need to improve the selection of asymptomatic patients for carotid intervention so as to improve the potential effectiveness of treatment in stroke prevention.[113] With this goal in mind, there has been a great deal of focus on identifying other characteristics of both the patient and the carotid plaque itself that would be distinguishable on imaging studies and allow the clinician to identify patients at increased risk for ischemic stroke who would most benefit from vascular intervention. The term "vulnerable" plaque is often used to denote unstable plaques, or plaques prone to complications, including embolization and subsequent stroke.

The Vulnerable Plaque and Patients at Increased Risk for Ischemic Stroke

A strong attempt has been made to identify patients with carotid disease at increased risk for stroke by combining both morphologic plaque features and clinical patient characteristics. The Asymptomatic Carotid Stenosis and Risk of Stroke (ACSRS) Study Group attempted to determine the cerebrovascular risk stratification potential of baseline degree of stenosis, clinical features, and ultrasonic plaque characteristics in patients with asymptomatic carotid artery stenosis.[79] This was a prospective cohort study involving 1121 patients with 50% to 99% asymptomatic ICA stenosis who were followed for 6 to 96 months. The authors found that the following characteristics were associated with increased risk for ipsilateral cerebral or retinal ischemic events: severity of stenosis, age, systolic blood pressure, increased creatinine, smoking history of more than 10 pack-years, history of contralateral TIA or stroke, low

TABLE 86.1 Estimated Percent Risk of Ipsilateral Ischemic Cerebral Stroke Within 5 Years Based Upon Degree of Stenosis, History of Symptoms, and Plaque Characteristics

Degree of Stenosis	History of Contralateral TIA or Stroke	DWAs Present	Plaque Area (mm^2)	GSM		
				>30	15–30	<15

gray-scale median, increased plaque area, and the absence of discrete white areas without acoustic shadowing. Combinations of these characteristics could stratify patients into different levels of risk for stroke (Table 86.1). Of 923 patients with 70% or greater stenosis, the predicted cumulative 5-year stroke risk was less than 5% in 495, 5% to 9.9% in 202, 10% to 19.9% in 142, and 20% or more in 84. The authors concluded that cerebrovascular risk stratification related to carotid artery disease is possible using a combination of clinical and ultrasonic plaque features. In a more recent update from the ACSRS group,[114] the authors expounded on their previous work and noted that the size of a juxtaluminal black hypoechoic area in ultrasound images of asymptomatic carotid artery plaques is linearly related to the risk of future stroke and is an additional factor that can be utilized to predict the risk of future ipsilateral ischemic stroke (see Chapter 87).

Transcranial Doppler Detection of Microembolization

Since thromboembolization is generally regarded as the mechanism of ischemic stroke in patients with carotid bifurcation atherosclerosis, the detection of subclinical embolization may help to identify patients at high risk of future stroke.[113] Transcranial Doppler (TCD) testing involves the detection of microembolism in the MCA using TCD insonation; the detection of high-intensity transient signals ("HITS") is felt to represent microemboli to the brain. HITS are detectable only in the presence of an embolic source, are undetectable days after CEA, and are absent in controls without carotid stenosis, suggesting a relationship between carotid atherosclerotic plaque and microembolization.[113] HITS frequency rises with increasing stenosis, and an increased rate of HITS is associated with plaque ulceration; this emphasizes the likely association between HITS and plaque instability.[113] Thus the concept of HITS represents an attractive option for stratifying patients with carotid artery disease who may be at increased risk for future stroke.

The Asymptomatic Carotid Emboli Study (ACES) attempted to investigate whether detection of embolic signals by use of TCD could predict stroke risk in patients with asymptomatic carotid stenosis.[112] This was a prospective observational study including patients with carotid stenosis of at least 70% who were followed for at least 2 years. The primary endpoint was ipsilateral stroke or TIA. The study included 267 patients; embolic signals were present in 77 patients at baseline. The hazard ratio for stroke or TIA was 2.54 as compared with patients without embolic signals at baseline. The hazard ratio for ipsilateral stroke alone was 5.57. The absolute annual risk of ipsilateral stroke or TIA was 7.13% in patients with embolic signals and 3.04% in those without; for stroke alone the annual risk was 3.62% in patients with signals and 0.7% in those without.[112] The authors concluded that detection of asymptomatic embolization on TCD can be used to identify patients with asymptomatic carotid stenosis who are at higher risk of stroke and TIA and who might benefit from carotid intervention. Similarly, Spence et al. studied 319 patients with carotid artery stenosis of 60% or more who had been asymptomatic for at least 18 months.[115] Of these, 32 patients or 10% had emboli

signals at baseline examination. Patients with embolic signals were more likely to have a stroke within 1 year (15.6% vs. 1%).

Unfortunately TCD may not represent a practical screening tool on a widespread scale in view of its having a time consuming nature, there is no reliable automated emboli detection system, and a small proportion (10%) of subjects lack a cranial acoustic window needed for TCD.[113]

Types of Strokes and Relationship of Stroke to Carotid Artery Atherosclerosis

There are five general categories of ischemic stroke, according to the Trial of ORG 10172 in Acute Stroke Treatment (TOAST) classification: cardioembolic strokes, large vessel disease strokes, strokes due to small vessel disease, strokes related to unusual causes, and strokes of undetermined etiology.[116] The TOAST classification is based on clinical and radiologic findings as well as additional investigations such as duplex ultrasonography, electrocardiography (ECG) analysis, echocardiography, and blood tests. Clinical studies on stroke subtype fail to identify a definitive cause of stroke in at least 25% to 39% of patients.[117] Traditionally it has been estimated that large vessel disease caused stroke in 50% of cases.[117] Recent studies, however, have shown that small vessel disease is more frequent and large vessel disease less frequent than previously estimated.[118]

In the Rochester Epidemiology Project, 442 patients with a first ischemic stroke from 1985 through 1989 were evaluated. Four major categories were identified: large vessel cervical or intracranial (16.7%), cardioembolic (29.9%), lacunar (16.3%), and strokes of uncertain cause (37.1%). Therefore the large vessel cervical etiology comprised approximately 16% of all ischemic strokes and 27% of strokes with determined causes. Interestingly, patients with large vessel strokes had the highest rates of recurrent stroke at 30 days (18.5%).[119]

In an additional study, patients with first-ever or recurrent ischemic stroke in the greater Cincinnati area were identified during the year 2005.[45] This report comprised 2204 ischemic strokes, including 365 (16.6%) of the large vessel subtype. Carotid artery stenosis was associated with 8% of all ischemic strokes, while ICA occlusion was associated with an additional 3.5%. The annual rate of first-ever and recurrent stroke attributed to the extracranial carotid artery was 13.4 per 100,000 persons. Based on this analysis, it was conservatively estimated that about 41,000 strokes per year in the United States may be attributed to extracranial ICA stenosis alone (without considering additional strokes related to complete carotid artery occlusion).[45]

Most prior studies on this topic have examined patients who have sustained strokes, and tried to ascertain the etiology of the cerebrovascular event. An additional study took an alternative approach by following a group of patients with known unilateral asymptomatic carotid artery stenosis and analyzed the types of strokes that occurred in such patients.[120] The risk of stroke at 5 years in 1820 patients increased with the severity of stenosis; it reached 3.2% annually among the 216 patients with 60% to 99% stenosis. Among this cohort, however, the 5-year risk of a stroke in the territory of a large artery was 9.9%, that of lacunar stroke was 6%, and that of cardioembolic stroke was 2.1%. Risk factors for large artery stroke included silent brain infarction, a history of diabetes, and a higher degree of stenosis. The study concluded therefore that 45% of strokes in patients with asymptomatic stenosis of 60% to 99% are attributable to either lacunar strokes or cardioembolism and are not a direct result of large artery disease.

Racial differences have been noted in stroke subtypes.[121] Of ischemic stroke patients, large vessel strokes were felt to account for 10% in black patients and 12% in white patients. However, stroke cause was felt to be undetermined in approximately 50% of both racial groups. Only 60% of patients in both racial groups underwent a carotid duplex examination, and only 3% to 5% underwent a cerebral angiogram.

Based on these and other studies and in consideration of the fact that most studies on this topic fail to determine with certainty the etiology of ischemic stroke in a high percentage of cases, most experts in this field feel that at least 20% of ischemic strokes are likely related to extracranial carotid artery atherosclerosis.

EXTRACRANIAL CAROTID ARTERY ATHEROSCLEROSIS—EPIDEMIOLOGY

Prevalence of Carotid Artery Disease

As with atherosclerosis in other vascular territories, cerebrovascular disease, particularly in the extracranial carotid artery, is relatively prevalent in the general population In the Tromso Study involving nearly 7000 adults aged 25 to 84 years, ICA stenosis was detected in 3.8% of men and 2.7% of women. The prevalence increased with age, total cholesterol, systolic blood pressure, and cigarette use.[122] In another population-based study of older healthy patients aged 60 to 79 years, the prevalence of ICA stenosis found by duplex examination was 10.5% in men and 5.5% in women.[123] Despite the increased risk of carotid artery disease in known patient populations, the actual role of screening in asymptomatic patients remains controversial.

In a screening program of asymptomatic patients in the United States for treatable causes of ischemic stroke, 610 patients were evaluated. Unilateral or bilateral ICA stenosis of 50% or greater was detected in 66 patients (10.8%). The finding of occult ICA stenosis was more frequent than that of new hypertension (2.6%) or new atrial fibrillation (0.5%); therefore, ICA stenosis was the most frequently detected treatable cause of ischemic stroke. Patients with known hypertension were significantly more likely to have CA stenosis (12.7% vs. 7.8%) than were patients with heart disease (18.2% vs. 8%). Patients with both risk factors were significantly more likely to have CA stenosis than were patients without either risk factor (22.1% vs. 8.5%; $P < .0001$).[124]

A meta-analysis of nearly 24,000 subjects accumulated from large population studies reported in 2010 noted the overall prevalence of moderate-range carotid stenosis varied from 0.2% in men under 50 years of age to 7.5% in men over 80 years of age. The prevalence was lower in women. The following variables were predictive of both moderate and severe carotid stenosis

in the populations: age, sex, a history of vascular disease, systolic and diastolic blood pressure, total cholesterol/high density lipoprotein (HDL) ratio, diabetes, and current smoking.[125]

In recent analyses of another database comprising nearly 3.5 million patients in the United States who underwent voluntary screening for vascular disease, 3.9% were found to have ICA stenosis.[57,126-129] Independent risk factors for ICA stenosis included advanced age, smoking, peripheral arterial disease, hypertension, coronary artery disease, diabetes, hypercholesterolemia, and abdominal aortic aneurysm. Exercise and the consumption of fruit, vegetables, and nuts were noted to have a modest protective effect.[130] Women had a 3.4% prevalence of ICA stenosis of 50% or more, whereas males had a 4.2% prevalence.[57] Prevalence increased dramatically with age (Fig. 86.9). It was also noted that the prevalence of ICA stenosis varied significantly by race: Native American subjects had the highest prevalence of ICA stenosis across all age ranges and in both sexes, while Caucasian subjects had the second highest prevalence of ICA stenosis across most age ranges and in both sexes (Figs. 86.10 and 86.11). African American males and Asian females appeared to have the lowest prevalence. In all races, increasing age was the most significant risk factor for carotid stenosis. Additional risk factors included smoking history, diabetes, hypertension, and hypercholesterolemia.[57] It has been previously noted that African American patients may have a lower relative risk of severe carotid artery disease and that the increased stroke rate in this population is likely due to small vessel disease and hypertension.[57]

The prevalence of carotid artery stenosis was noted to be significantly increased in subjects with lower extremity peripheral arterial disease, and in diabetics (Fig. 86.12). Increasing severity of peripheral arterial disease as quantified by the ABI was significantly associated with an increasing prevalence of carotid artery stenosis.[127] In this large population-based study, higher levels of physical activity were independently associated with lower odds of carotid artery stenosis.[129] Age remains a critical factor; after adjustment for sex, race, body mass index (BMI), family history, smoking, diabetes, hypertension, hypercholesterolemia, and physical activity, the odds of carotid artery stenosis increased with every decade of life (odds ratio, 1.8).[128]

A report from Berger et al. analyzed modifiable risk factors and their relationship with carotid artery stenosis.[126] Risk factors included hypertension, hypercholesterolemia, smoking, diabetes, and sedentary lifestyle. The multivariate adjusted prevalence of carotid artery stenosis with 0 to 5 risk factors was, respectively, 1.41%, 2.36%, 3.72%, 5.73%, 8.48%, and 11.58% (Fig. 86.13). Results were similar in men and women. For every additional modifiable risk factor that was present, the multivariate-adjusted

odds of having carotid disease increased significantly (odds ratio, 1.57) (Figs. 86.13 and 86.14).

In comparing medical to endovascular or surgical treatment of carotid artery disease, it is essential to understand how the treatment of risk factors might affect the natural history of the condition. In patients with ICA stenosis, the treatment of risk factors—including hypertension, diabetes, lipid disorders, as well as lifestyle modifications, particularly smoking cessation—is of utmost importance.[131,132] Medical therapy of ICA stenosis includes treatment of hypertension with target BP of less than

140/90 and statins with a goal of decreasing LDL to less than 100, triglyceride less than 150, and increasing HDL to more than 40. Statins lower stroke risk by approximately 30%, and likely work by improving plaque stabilization.[133] Antiplatelet therapy in the form of aspirin or clopidogrel is also recommended for all patients with asymptomatic ICA stenosis.[134] Some studies have reported that the combination of aspirin and clopidogrel may be more effective than aspirin alone, but larger trials have not confirmed the benefit of adding clopidogrel (see Chapter 89).[135]

EXTRACRANIAL CAROTID ARTERY ATHEROSCLEROSIS—NATURAL HISTORY

Whether carotid artery disease remains a significant cause of ischemic stroke, and whether optimal medical therapy can decrease this risk to the same degree as proven carotid revascularization procedures is currently a matter of significant controversy. Although mortality rates from stroke have declined globally in the past two decades, the absolute numbers of people affected has risen and the costs of caring for stroke survivors are increasing.[23,136]

When a patient has already experienced an initial TIA or nondisabling stroke in the carotid territory, there is little disagreement that prompt intervention on an appropriate carotid lesion is warranted to decrease the otherwise extremely high risk of a subsequent infarction. These recommendations are based on the relatively undisputed known high risk of subsequent stroke in these patient categories, as discussed previously. The debate is ongoing in the case of asymptomatic carotid atherosclerosis in patients who have never experienced cerebrovascular symptoms. Challenges to the role of CEA in the treatment of asymptomatic carotid stenosis supported by level I data generally fall into two categories: (1) the view that modern optimal medical therapy may allow better stroke protection, obviating the need for CEA (or CAS), and (2) the argument that the degree of stenosis alone is a poor surrogate for vulnerable plaque and does not allow the accurate prediction of patients at high risk for stroke.[137]

Carotid intervention should only be undertaken in asymptomatic patients who are at a high lifetime risk of stroke. In addition to age, sex, the degree of stenosis, medical comorbidities, and life expectancy, relevant factors include the severity of the stenosis,[136,138] progression of stenosis,[136,139] evidence of infarction on brain imaging,[140] and plaque imaging characteristics.[79]

A consistent rate of stroke risk of approximately 2% per year in patients with high-grade asymptomatic stenosis was reported in ACAS, NASCET, and ACST. Although the ACAS study results have been criticized as obsolete in the current era of improved medical management of atherosclerosis, in the later years of ACST 80% of patients in fact were on statins.[11,13,42,120] Additionally, the Reduction of Atherothrombosis for Continued Health Registry (REACH) states that carotid stenosis of 70% or more was associated with a significantly increased stroke risk despite the fact that more than two-thirds of subjects were on statin medications.[141]

Progression of carotid stenosis has been shown to be a significant predictor of stroke risk in multiple natural history studies.[142-144] In a follow-up study from the ACSRS group, 1121 patients with asymptomatic carotid stenosis of 50% to 99% were analyzed with a mean follow-up period of 4 years (Figs. 86.15 and 86.16).[145] Progression occurred in 19.8% of patients. Independent predictors of progression included male sex, high creatinine, not taking lipid-lowering medications, low grade of stenosis, and increased plaque area. A total of 130 first ipsilateral cerebral of retinal events occurred, including 59 strokes. Forty strokes (67.8%) occurred in patients whose stenosis was not changed and 19 strokes (32.2%) occurred in those with progression. For patients with baseline 70% to 99% stenosis

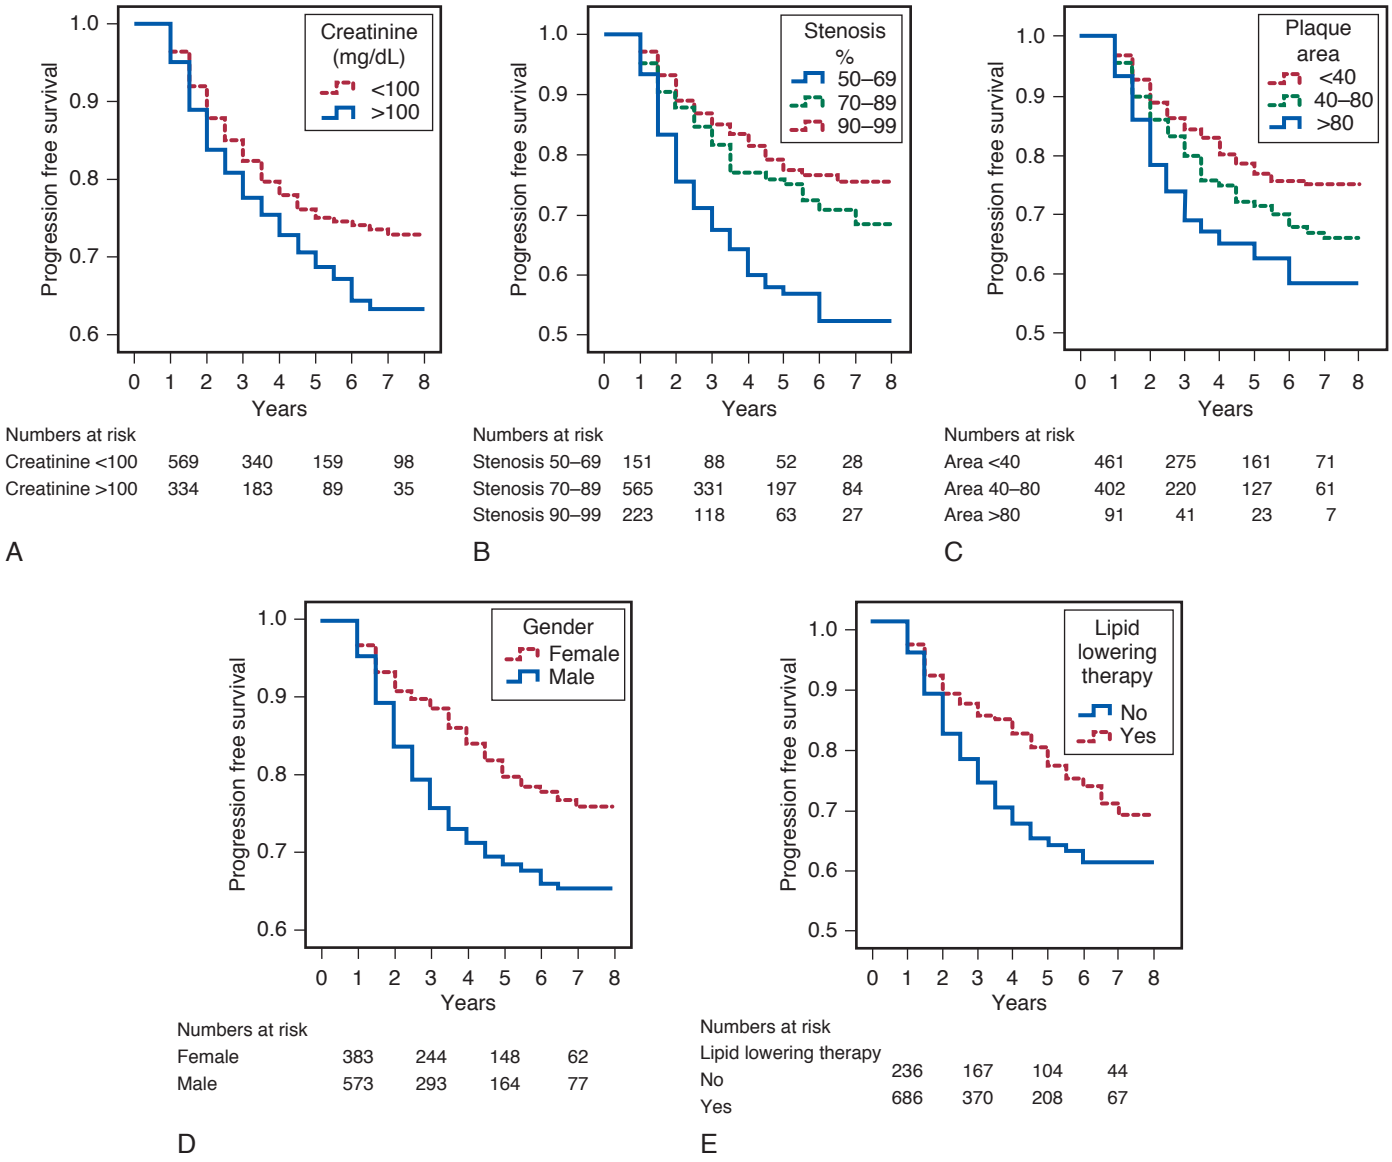

Figure 86.15 Predictors of progression of asymptomatic carotid stenosis; progression-free survival. Effect of significant factors, including (A) creatinine, (B) ipsilateral stenosis, (C) plaque area, (D) gender, and (E) lipid-lowering therapy. (From Kakkos SK, et al. Predictors and clinical significance of progression or regression of asymptomatic carotid stenosis. *J Vasc Surg.* 2014;59:956-967 e1. *Used with permission.*)

and in the absence of progression ($n = 349$), the 8-year cumulative ipsilateral ischemic stroke rate was 12%. In the presence of progression, it was 21% ($n = 77$).

Another report comprised 126 arteries with severe stenosis in patients who were treated medically.[137] Of this cohort, including 86% taking a statin medication with a mean follow-up period of 63 months, ipsilateral neurologic symptoms developed related to 25% of the arteries (Fig. 86.17). Of these events, 14 (45%) were strokes and 17 (55%) were TIAs or retinal events. Of this cohort of patients who initially were not considered for carotid artery intervention or were refused, 33% ultimately underwent carotid revascularization during the follow-up period.

Conrad et al. reported a study including 900 arteries in 794 patients with moderate stenosis.[36] Optimal medical therapy included aspirin and a statin with documented LDL levels less than 100 mg/dL. Mean follow-up was 3.6 years. The 5-year freedom from progression to severe stenosis was 61.2% ± 2.6%, with no benefit seen from optimal medical therapy (Fig. 86.18, Table 86.2). Plaque progression occurred in 262 arteries, and 36 (13.7%) of these developed symptoms. Average time to plaque progression was 32 months. Of this cohort, 90 patients (11.3%) developed ipsilateral neurologic symptoms during follow-up; 58% of these were strokes. Average time to symptom onset was 36 months. A total of 36 (40%) symptomatic patients also showed plaque progression, but the remaining 60% developed symptoms with a stable moderate stenosis. Five-year freedom from symptoms was 88.4%, with no benefit seen with OMT. Overall the authors concluded that current medial therapy was unable to halt the progression from moderate to severe stenosis or the development of symptoms in 45% of the cohort.

Patients with significant carotid atherosclerosis are also at increased risk for cardiovascular disease and death. In the Tromso study, a cohort of 248 individuals with greater than 35% carotid stenosis was shown to have a 3.5 times higher risk of death from any cause as compared with patients with no carotid disease, even when other risk factors were controlled for. Most deaths were from cardiovascular causes.[146] In another large systematic review of 12 studies involving more than 4000 patients with greater than 50% stenosis, there was an average cardiac mortality of 2.9% per year.[147]

Most recently Zhang et al. studied the relationship between asymptomatic carotid artery stenosis and the development of cardiovascular disease (Fig. 86.19), including 1376 subjects over 55 years of age.[148] After adjustment for demographics and risk factors, the odds ratios for the risk of cardiovascular disease for those with minimal carotid disease, nonstenotic carotid plaque, and stenotic plaque was 0.8, 2.0, and 3.1, respectively, as compared with patients without significant carotid artery

TABLE 86.2 Multivariate Models of Outcomes

Predictor	HR	CI	*P* Value
Predictors of Death			
Age[a]	1.1	1.04–1.09	<.0001
Contralateral occlusion	1.9	1.1–3.3	.017

stenosis During a mean follow-up 62 months, 136 new strokes occurred in this cohort.

ADDITIONAL TOPICS

Vertebrobasilar Insufficiency

Vertebral artery origin stenosis may cause as many as 20% of posterior circulation ischemic strokes.[149] Additionally, symptoms may be caused by occlusion or stenosis of the subclavian artery proximal to the origin of the vertebral artery, causing the classic "subclavian steal" syndrome (see Chapters 98 and 99). Vertebrobasilar ischemia can result from embolic, thrombotic, or low-flow hemodynamic mechanisms.[150] The indications for surgical or endovascular treatment of vertebral artery disease are not as clearly defined as are those for carotid artery occlusive disease.

Vertebrobasilar insufficiency (VBI) results in ischemia to the posterior circulation of the brain, vascular territories supplied by the paired vertebral and common basilar artery (brain stem, cerebellum, thalamus, and occipital cortex). Posterior circulation TIAs and strokes represent approximately 20% of all TIAs and strokes.[149] Vertebral artery insufficiency can result from occlusive disease that interrupts flow to the posterior circulation or from hemodynamic mechanisms resulting in hypoperfusion. The most common causes of VBI include large artery atherosclerosis, emboli, penetrating small artery disease, and arterial dissection.[151]

The subclavian steal phenomenon is perhaps the best example of VBI resulting from hypoperfusion. Proximal subclavian artery stenosis or occlusion and associated retrograde ipsilateral vertebral flow can result in a collection of symptoms including arm pain with exertion as well as posterior cerebral neurologic symptoms, most commonly dizziness or vertigo. Sensorimotor deficits are extremely rare in subclavian steal syndrome and usually indicate the presence of concomitant carotid occlusive disease.

Atherosclerotic lesions usually occur at the vertebral artery origins and present with transient ischemia due to hypoperfusion of the brain stem and cerebellum, resulting in dizziness, difficulty focusing visually, and loss of balance. Thromboembolic events can also result in vertebrobasilar ischemia. Large emboli often involve the intracranial vertebral arteries, resulting in cerebellar infarction, or the distal basilar artery, affecting the upper cerebellum, brain stem, and territories of the posterior cerebral arteries. Cerebellar infarction usually presents with vertigo, vomiting, blurred vision, and difficulty walking.

Global Cerebral Ischemia

Global ischemia or systemic hypoperfusion represents only a small fraction of all ischemic strokes from carotid occlusive disease. Patients presenting with global ischemia often present unconscious to an emergency room or with symptoms resembling near syncope.[152] Neurologic symptoms can be varied and are usually attributable to decreased perfusion of watershed territories in the cerebral circulation. Decreased visual acuity, cognitive difficulties, bilateral upper extremity weakness, and symptoms of VBI are possible.[153] This can be a result of prolonged cardiogenic shock, dysrhythmias, or cardiac arrest, and treatment should initially focus on correcting cardiac failure and improving perfusion pressure to the brain.

Symptoms may be asymmetric in cases where hypoperfusion is isolated to a territory distal to a severe extracranial stenosis if inadequate collateral flow exists. Such patients may benefit most from treatment of proximal flow-limiting lesions and have been shown to fare better than those with more global hypoperfusion.[154]

Lacunar Infarcts

Lacunar infarcts are typically defined as small subcortical infarcts that result from presumed occlusion of a single penetrating artery of the brain.[155] These arteries are thought to be so small that they cannot be readily imaged in vivo, so these lesions are presumed to be ischemic in etiology. Typical risk factors for lacunar infarcts include increasing age, male gender, hypertension, diabetes, and smoking.[155] Lacunar infarcts represent roughly 20% of all ischemic strokes[156] and consist of small (1- to 2-cm) subcortical defects often located in the internal capsule or basal ganglia, areas supplied by the lenticulostriate vessels (small proximal branches of the intracranial carotid). The typical presentation can include pure motor hemiparesis, pure sensory syndrome, sensorimotor syndrome, ataxic hemiparesis, and dysarthria–clumsy hand syndrome.[157,158] Therefore from a clinical perspective lacunar infarcts can easily mimic carotid artery–related

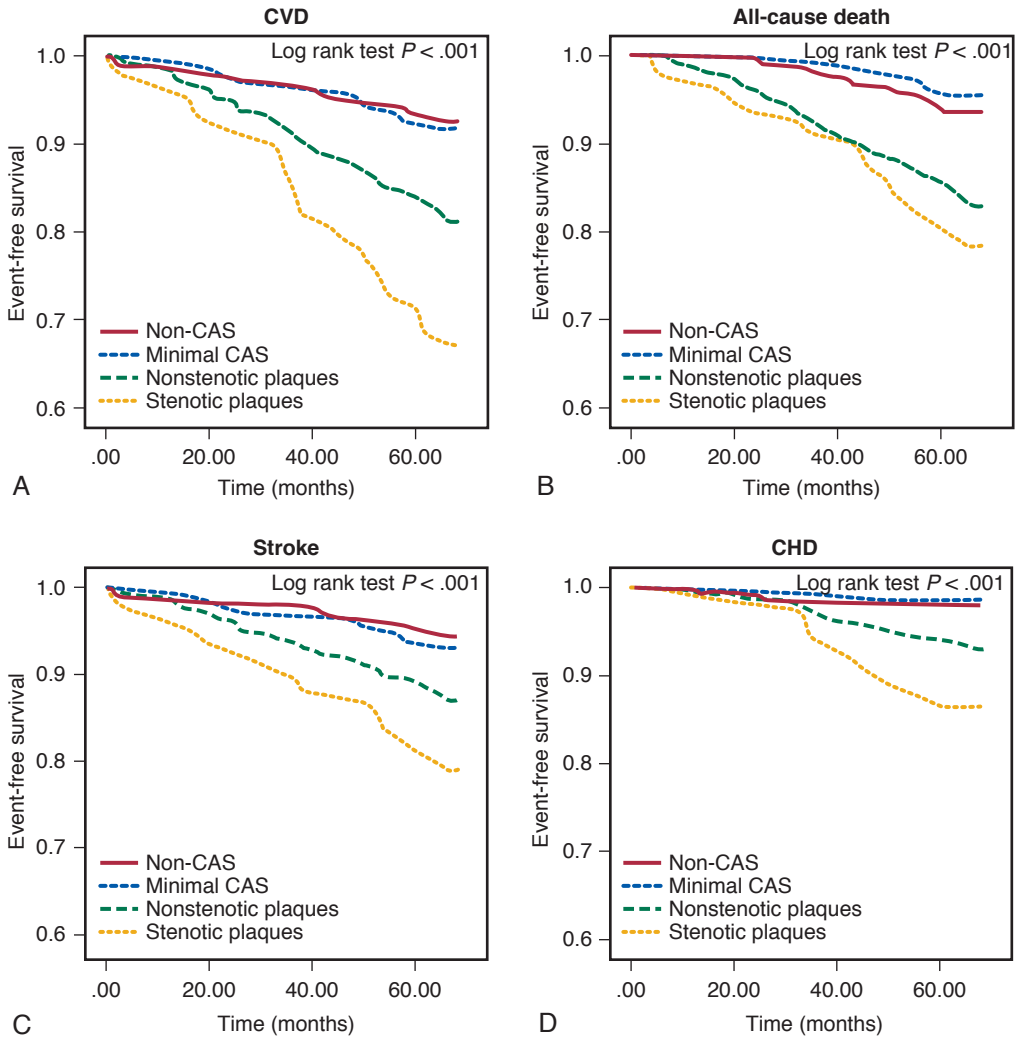

Figure 86.19 Kaplan-Meier curves for cardiovascular disease (all-cause death, stroke, and coronary heart disease) in participants according to the degree of carotid atherosclerosis. (A) *CVD*, cardiovascular disease. (B) All-cause death. (C) Stroke. (D) *CHD*, coronary heart disease. *CAS*, Carotid artery stenosis. (From Zhang Y, et al. Carotid artery plaques, carotid intima-media thickness, and risk of cardiovascular events and all-cause death in older adults: A 5-year prospective, community-based study. *Angiology*. 2018;69:120-129. *Used with permission.*)

ischemic events. Lacunar infarcts may be present in as many as 23% of persons over 65 years of age and remain asymptomatic or silent in up to 89% of patients.[159]

The association between atherosclerotic extracranial lesions and lacunar infarcts is controversial. Most believe that such infarcts are a result of small-vessel disease deep in the brain resulting from long-standing hypertension and/or diabetes unrelated to carotid occlusive disease.[160] This is consistent with the variable pattern of distribution for lacunar infarcts. They can occur alone or in groups and are often present in both hemispheres. Recent studies, however, show that ICA stenosis (>70%) was found more commonly on the side of lacunar infarction and may be associated with large vessel disease in up to one-third of patients.[161,162] This would lend support to the theory that embolization from carotid atherosclerosis to the lenticulostriate vessels may contribute to lacunar infarction in some cases.

Cognitive Decline

Although stroke is a well-established cause of dementia, the relationship between carotid stenosis itself and cognitive impairment is less clear. A systematic review of the literature found 18 studies examining cognitive function in patients with carotid stenosis who had not yet undergone surgery. Of these, 14 studies found deficits in patients with both symptomatic and asymptomatic lesions and 4 showed no cognitive impairment.[163] Cognitive function is rarely considered in evaluating or treating carotid stenosis. Moreover, patients with carotid occlusive disease share many of the known conventional risk factors for dementia (hypertension, diabetes, dyslipidemia, and smoking). Thus carotid stenosis may be a direct cause of cognitive impairment or serve simply as a marker of intracerebral or generalized atherosclerosis.[164,165] Asymptomatic carotid stenosis may logically result in cognitive impairment by causing cerebral infarction. However,

it is less clear if the asymptomatic carotid lesion represents an independent risk factor for cognitive decline. Silent brain infarcts may prove to be a link between carotid stenosis and cognitive impairment. Lacunar infarcts, known to be associated with vascular dementia, may also be more prevalent in patients with ipsilateral carotid stenosis, as discussed earlier.[166]

Atheroembolization and hypoperfusion represent two proposed mechanisms by which carotid stenosis could result in cognitive decline.[167] Thus asymptomatic carotid stenosis may in theory contribute to cognitive impairment via microembolization even in the absence of radiographic evidence of brain injury (i.e., lacunar infarcts or silent stroke). Cerebral hypoperfusion has also been implicated in the onset of clinical dementia.[168] Although critical carotid stenosis may contribute to global ischemia to varying degrees, there is a paucity of data correlating degree of carotid stenosis with cognitive decline.[169]

MECHANISM OF STROKE IN CAROTID ATHEROSCLEROSIS

Autopsy studies in the early 1950s confirmed the association between atherosclerotic plaques in the carotid artery bifurcation and stroke. The vast majority of strokes from carotid artery plaques are from focal ischemic brain injury. Flow restriction from luminal encroachment can occur in extremely tight stenoses in the presence of inadequate cross-collateralization across brain hemispheres, and some strokes in patients with carotid stenosis are indeed attributable to hypoperfusion.[1] Most strokes, however, do not occur in watershed areas of the brain. Further support for plaque disruption with embolic infarction as the mechanism is that microemboli are detectable in the middle cerebral artery of several patients with symptomatic carotid stenosis.[2] Carotid plaque disruption with embolic cerebral infarction, rather than hemodynamic compromise from luminal narrowing, is therefore the primary contributor in the pathogenesis of stroke in patients with carotid atherosclerotic stenosis.[3]

STABLE VERSUS UNSTABLE CAROTID PLAQUES

In the Asymptomatic Carotid Atherosclerosis Study (ACAS), a majority (89%) of patients in the medical treatment alone arm remained stroke-free over 5 years.[4] The Asymptomatic Carotid Surgery Trial (ACST) also confirmed that plaques in most patients with high grade carotid artery stenosis did not develop a stroke.[5] In these and other studies, a small proportion of asymptomatic patients did, however, harbor plaques that progressed to disruption and caused cerebral infarction and stroke. This suggests that carotid atherosclerotic plaques exist as two distinct types: a majority are those that remain quiescent, and a smaller proportion are "unstable" and vulnerable to disruption, leading to atheroembolization and brain infarction. The percent diameter reduction in the carotid artery lumen is the most readily measured feature of the disease and currently used as a marker for identifying plaques that may be vulnerable to disruption. Increasing degrees of stenosis, however, have not

Abstract

It is likely that several mechanisms contribute to carotid plaque disruption with consequent cerebral infarction. Morphologic changes occurring within the plaque in combination with biomechanical forces acting on the plaque influence vulnerability to disruption. Conversely, plaques may also stabilize, leading to a phenotype-reversal to a normal-risk plaque, depending on their surrounding milieu. Duplex ultrasonography and magnetic resonance imaging can quantify morphologic features (lipid-rich necrotic cores and intraplaque hemorrhage) implicated in plaque vulnerability. Computational fluid dynamics and speckle tracking allow for mapping of biomechanical forces on the plaque (wall shear stress, plaque wall stress and plaque strain).

(Adapted from Lal BK, Hobson 2nd RW, Pappas PJ, et al. Pixel distribution analysis of B-mode ultrasound scan images predicts histologic features of atherosclerotic carotid plaques. *J Vasc Surg*. 2002;35(6):1210-1217.)

been consistently associated with a correspondingly increased risk for stroke in asymptomatic patients.[6] Neither ACAS nor ACST showed a correlation between degree of stenosis and stroke-risk. The degree of stenosis is therefore not an adequately sensitive or specific marker for determining plaque instability and stroke-risk.

HISTOMORPHOLOGY OF THE UNSTABLE CAROTID PLAQUE

Carotid bifurcation plaques are representative of atherosclerosis at other locations in the vascular tree. Our understanding of plaque histology comes largely from studies of the coronary arteries and the aorta, substantiated subsequently with studies of the carotid arteries. Histologic evaluation of explanted human arteries indicates that atherosclerotic lesions originate as "early" forms (types I, II, and III). Plaques start as fatty streaks, found as early as at 6 months of life. Over time, they coalesce into lipid cores.[7] A fibroatheroma develops next as fibrous tissue accumulates over the core and forms a fibrous cap.[8] Some plaques then continue to progress to "later" or more advanced forms (types IV, V, and VI), with a growing lipid rich necrotic core (LRNC), developing intraplaque hemorrhage (IPH) and demonstrating thinning of their fibrous cap.[9] The Oxford plaque study reviewed histology on 526 carotid plaques explanted post-carotid endarterectomy and found that these histomorphologic features were associated with plaques that had recently caused neurologic symptoms (transient ischemic attacks and stroke).[10] Our group[11,12] and others have identified these features in plaques from patients presenting with neurologic symptoms (large LRNCs,[13] located close to the flow lumen,[14] IPH,[15] fibrous cap disruption, and luminal surface ulceration[16]; Fig. 87.1). A review of 31 histologic studies with 4447 explanted carotid plaques indicated a strong association between IPH and ischemic neurologic symptoms.[17] Conversely, smooth homogeneous fibrous plaques tend to be clinically stable and less prone to atheroembolization.[9]

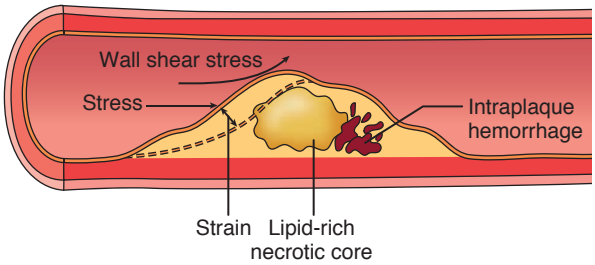

Figure 87.2 Morphologic and biomechanical correlates of carotid plaque vulnerability. See the text for a description of individual terms.

BIOMECHANICS OF THE UNSTABLE CAROTID PLAQUE

Not all plaques with unstable histologic features cause symptoms. Approximately 50% of asymptomatic patients with carotid stenosis have identifiable IPH or fibrous cap rupture,[18] yet only approximately 2% of asymptomatic patients develop a neurologic event at 1 year.[4,5] Therefore morphology alone has limited ability to identify unstable carotid plaques and predict future strokes (Fig. 87.2).[19] Furthermore, the histomorphology of plaques is not static, and plaques may transition from one morphologic type to another, in response to biological influences such as inflammation and oxidative stress. These biological processes are in turn potentially influenced by mechanically induced signaling. Mechanical forces can alter several aspects of vascular biology. Short-term elevations in arterial wall shear stress (WSS), the result of frictional force on the luminal surface exerted by flowing blood, can activate endothelial cell signaling and induce nitric oxide and prostacyclin production with consequent vasodilation. Long-term elevations in blood flow–related forces

such as WSS impact endothelial function, wall permeability, plaque formation, vessel wall remodeling, plaque progression, and changes in plaque composition to a more vulnerable phenotype.[20] For instance, endothelial cells may modify the balance between extracellular matrix synthesis versus degradation in the fibrous cap by metalloproteinases secreted by infiltrating macrophages in response to WSS.[21] Acting over time, these changes can create conditions suitable for disruption.

In addition, blood pressure–induced forces (e.g., plaque wall stress, PWS) can exceed the plaque's material strength, leading to disruption.[13,22] PWS was higher in disrupted coronary artery plaques from 12 randomly selected patients who died from acute myocardial infarction (MI), compared with plaques from 12 patients who died of noncoronary causes.[23] ApoE−/− mice and rabbits with inheritable hyperlipidemia develop some "unstable plaque" histologic features that do not rupture on their own. When these models are subjected to additional hemodynamic or mechanical stresses, disruption can be induced.[24,25]

Repetitive deformation of plaques from cardiac cycle-induced motion can result in excessive plaque strain and tissue fatigue that may also contribute to disruption.[26] Due to its high temporal resolution, duplex ultrasonography (DUS) is well suited for imaging plaque motion, deformation, and resulting plaque strain during the cardiac cycle. Ultrasonography has identified asymmetric discordant motion with high strain patterns in carotid plaques from symptomatic patients compared to asymptomatic plaques.[27]

NONINVASIVE IDENTIFICATION OF THE UNSTABLE CAROTID PLAQUE

Carotid plaque disruption likely results from a combination of biological and histomorphologic changes within the plaque occurring in the context of biomechanical forces acting on it. Noninvasive plaque characterization can assist in several aspects of the management of carotid occlusive disease. It could help stratify asymptomatic patients for treatment; serial assessments could track response to potentially "plaque stabilizing" pharmacotherapy, and it may guide appropriate stent designs (e.g., open vs. closed cell). The challenge is to develop imaging techniques that can reveal this level of structural detail. Several noninvasive imaging approaches can assist in identifying histomorphologic (e.g., large LRNC, IPH) and biomechanical (WSS, plaque strain) markers for patients at risk for plaque disruption.

Ultrasonography is cost-effective and safe for serial testing. The morphologic appearance of carotid plaques was first quantified in two-dimensional B-mode images. The first generation of three-dimensional ultrasound transducers that reduce operator-dependence and variability are now clinically available. Ultrasonography provides additional physiologic information enabling measurement of disruptive forces acting on the plaque. Magnetic resonance imaging (MRI) is a sensitive and specific method for determining plaque histomorphology, biomechanical forces, and metabolic activity. Computed tomography angiography (CTA) is at present not as accurate in delineating plaque composition. It is, however, useful for identifying the luminal surface.[28]

TWO-DIMENSIONAL B-MODE IMAGING

B-mode (brightness mode or 2D mode) imaging displays anatomic wall features that range from primarily hyper- or hypoechoic, to heterogeneous in echogenicity. Since different tissues reflect ultrasound to varying degrees, the first histologic interpretation of the B-mode appearance of carotid plaques was a subjective visual classification (Gray-Weale): pure hypoechoic (type I), hypoechoic with small hyperechoic areas (type II), hyperechoic with small hypoechoic areas (type III), and hyperechoic (type IV).[29] Type I and type II plaques occurred commonly in patients with neurologic symptoms.

The Gray-Weale classification is subject to observer variability, both during image acquisition and during image-interpretation. Nicolaides and his group subsequently introduced standardization in image acquisition and normalization of image brightness. The plaque was then outlined, and the median brightness of all the pixels in a single longitudinal image of the plaque was measured and expressed as a Grayscale Median value (GSM).[30] In 1121 patients with 50% or greater carotid stenosis followed for 6 to 96 months, the longitudinal plaque area (hazard ratio [HR] 1.92, confidence interval [CI] 1.50 to 2.46) and a GSM ≤40 (HR 0.09, CI 0.04 to 0.17) were predictors for future stroke.[31]

Histologic studies show that the necrotic core of a symptomatic plaque is located closer to the luminal surface than in asymptomatic plaques.[32] On B-mode imaging this necrotic core appears hypoechoic and has been named the Juxtaluminal Black Area (JBA). In the Asymptomatic Carotid Stenosis and Risk of Stroke trial (1121 patients), a JBA of 8 to 10 mm^2 represented an annual risk of stroke of 3.2%, while JBAs greater than 10 mm^2 were associated with a stroke rate of 5.0%.[33]

ULTRASONOGRAPHIC VIRTUAL HISTOLOGY

Different tissues reflect ultrasound differentially, resulting in B-mode images with variable brightness or pixel intensities. Using this principle, we identified the echogenicity of key histologic components of atherosclerotic plaques (calcium, fibromuscular tissue, LRNC, and IPH). These pixel intensity ranges were mapped in normalized longitudinal images of carotid plaques (pixel distribution analysis, PDA) to measure the virtual histology (DUS-VH) of individual tissues and the architectural features (lipid core size and location) of the plaques.[11] Eighteen symptomatic plaques demonstrated larger quantities of IPH ($P < .001$) and LRNC ($P = .002$), and LRNCs located closer to the flow lumen ($P = .01$), while 27 asymptomatic plaques demonstrated larger amounts of calcium ($P < .001$).[12] The PDA approach provides quantification of carotid plaque histomorphology using simple and readily available B-mode ultrasound technology.

THREE-DIMENSIONAL ULTRASONOGRAPHY

Plaques progress along the vessel 2.4 times faster than they thicken.[34] Therefore methods that capture both longitudinal and circumferential growth (area and volume) are more sensitive than methods limited to thickness measurements (diameter-reducing stenosis). The 5-year risk of stroke, MI, and vascular death was 19% for plaques with a longitudinal-sectional area of 1.2 to 6.7 cm^2 compared with 6% for areas of 0 to 0.1 cm^2. Similarly, progression of total carotid plaque volume predicted cardiovascular events (stroke, vascular death, TIA, or MI) in 349 patients with carotid stenosis.[35] Three-dimensional (3D) ultrasonography involves collating a series of 2D cross-sectional slices in a computer and reconstructing them into a 3D volume. It reduces the operator variability inherent in traditional 2D imaging. It requires a special 3D transducer with a motorized linear array transducer that moves within a housing to capture a series of 2D image-frames. The operator's hand and patient's head must be steadied to prevent movement artifacts. It takes less than a second to acquire a complete volume, which minimizes artifact from cardiac and respiratory movements.

We have developed a standardized postprocessing protocol for 3D plaque quantification.[36] The lumen-intima boundary defining the plaque surface, and the outer wall boundary defining the outer surface of the plaque, are segmented in each image. The region between these two boundaries is the vessel wall containing plaque. The stacked 2D images are collated to develop volume-rendered reconstructions that reproducibly quantify total plaque volume (Fig. 87.3). While 2D imaging detected changes of 19% or more in the carotid plaque area between two scans on a patient (minimum detectable change), 3D imaging could detect changes as small as 12.9% in plaque volume when two different technologists performed the test, and 4.5% or more for the same technologist.[36] Our semiautomatic postprocessing algorithm is comparable to manual segmentation in accuracy and takes 10 to 15 minutes to complete (Fig. 87.4). It reliably detects plaque volume changes as low as 4% to 6% with 95% confidence.[37] These developments are bringing 3D quantification of carotid plaques closer to the clinical environment. Another advantage of 3D imaging is an improved ability to evaluate the plaque surface. In 313 patients with asymptomatic carotid plaques, an ulcer volume ≥5 mm^3 was associated with a higher combined rate of stroke, TIA, MI, death, and revascularization ($P = .017$).[38] In another study, patients with three or more ulcers detected by 3D ultrasonography were more likely to have a stroke or death during 3 years of follow-up (18% vs. 2%).[39]

CONTRAST ENHANCED ULTRASONOGRAPHY

Contrast enhanced ultrasonography (CEUS) has traditionally been used in cardiac echocardiography, and its use is now being explored in carotid ultrasonography.[40] It uses standard B-mode imaging after administration of an intravenous ultrasonographic contrast agent. This improves the delineation of structures where the contrast can reach. The contrast consists of 1 to 10 micron microbubbles of an inert gas usually stabilized by a phospholipid shell. These microbubbles stay in the vascular system for a few minutes and then are eliminated by the respiratory tract. Ultrasound contrast is not nephrotoxic and does not require radiation, and complications are uncommon.

In CEUS of the carotid artery, the plaque and intima-media complex appear hypoechoic, while the carotid lumen and adventitia appear enhanced. It improves visualization of luminal irregularities, thereby improving the detection of ulcerated plaques.[41,42] One potentially important characteristic of unstable carotid plaques is increased neovascularization, identified on CEUS as increased enhancement within the plaque.[43] Histologic analysis confirms that plaques with enhancement have more neovascularization. Such plaques have increased microembolic signals and neovascularization could be a marker of carotid plaque instability and increased risk for future stroke.[44] After the administration of ultrasound contrast, some carotid plaques remain enhanced for up to 30 minutes postinjection. Contrast microbubbles are ingested by monocytes and become adherent to inflamed endothelium, thereby retaining the contrast for a longer time period.[45] Increased presence of inflammatory cells may predispose the plaque to early rupture;[46] therefore, late phase enhancement may be a marker for plaque instability. Late phase enhancement offers an opportunity to develop novel contrast agents that will generate "molecular images" of the carotid plaque. Microbubbles tagged with monocytes or antibodies would then concentrate in areas of inflammation or other target proteins within or on the carotid plaque such as receptors to P-selectin and VCAM-1 to target inflammation, or VEGF-1 to target neo-vascularization.[47]

PLAQUE STRAIN MEASUREMENT

The motion of carotid plaques and its associated arterial wall can be complex and may play a role in plaque rupture.[48] Carotid plaques with increased mobility or with asymmetric discordant motion may have an increased risk for disruption. Ultrasound elastography or strain imaging visualizes and quantifies the deformation that tissues undergo in response to a force. Elastography has been utilized to differentiate normal from abnormal tissue in the thyroid, liver, breasts, prostate, and lymph nodes.[49] Measurement of carotid plaque deformation has been challenging due to the small target size and its mobility during the cardiac and respiratory cycles. Recently introduced optical tracking techniques allow quantification of the direction, extent, and rate of movement of individual pixels within a plaque image through the cardiac cycle.[50]

Displacement of plaques can occur along the length of the artery due to blood flow or radially due to pulsatile expansion of the artery. Therefore data must be acquired in two planes. Studies using radiofrequency ultrasound protocols have found that increased strain patterns correlated with high-risk histomorphologic features.[51] We have developed a B-mode protocol for strain measurement that is suitable for clinical vascular

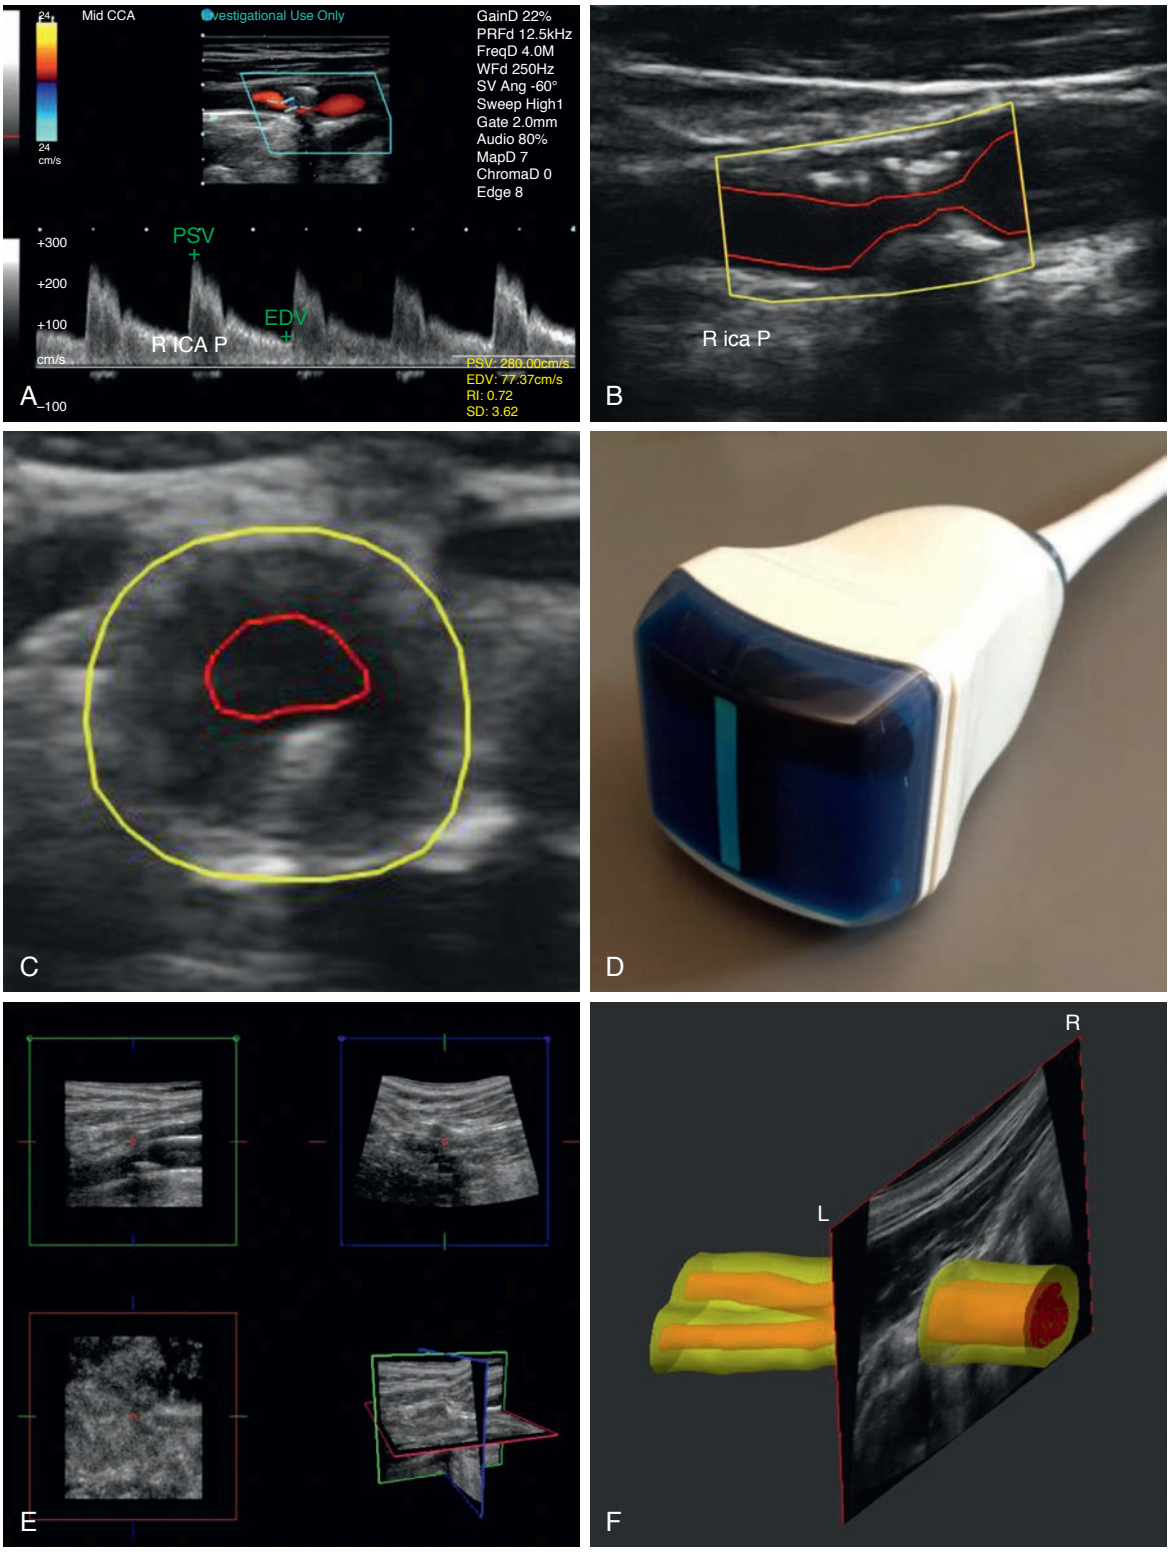

Figure 87.3 Duplex Ultrasound Imaging for Plaque Morphometry. (A) Standard Doppler measurements to localize the plaque and measure peak systolic and end-diastolic velocities to estimate the percentage of stenosis. Semiautomatic quantification of carotid plaque volume with three-dimensional ultrasound imaging. *J Vasc Surg*. 2017;65(5):1407-1417.)

laboratories. Thirty-six percent of plaques in 25 asymptomatic patients demonstrated high strain and high heterogeneity in displacement patterns (Fig. 87.5). These plaques were hypoechoic (mean GSM 19), indicating that softer plaques had higher and more variable strain rates.[52] Whether these findings translate into high stroke risk will need to be evaluated in larger longitudinal studies; one of which (CREST-Imaging) is being conducted within the context of the CREST-2 trial.[53]

INTRAVASCULAR ULTRASOUND

Information about morphologic characteristics of a carotid plaque may be important at the time of carotid intervention. For example, endovascular instrumentation of a soft plaque could provoke embolization, or a stiff calcified plaque could prevent stent expansion during carotid artery stenting (CAS). Periprocedural stroke is more frequent with CAS; therefore, every attempt should be made to reduce embolization during stenting.

Intravascular ultrasound (IVUS) is used in the coronary arteries to obtain useful information on plaques. As with DUS-VH, IVUS uses the intensity and frequency of reflected ultrasound to provide a map of the constituent histologic components of the plaque. Carotid plaque IVUS-VH correlates with histology (accuracy of 72.4% for calcified fibroatheroma and of 99.4% for thin-cap fibroatheroma).[54] In this study, plaque fragments were identified more frequently in filter devices during CAS for plaques with larger LRNCs. In another study, IVUS-identified calcification in the carotid artery predicted microembolization during CAS.[55] IVUS has not been used routinely in the carotid arteries, and its role is not well established. It is an invasive procedure, and its utility must be weighed against the risks of inducing a stroke from passing the ultrasound catheter across the lesion.

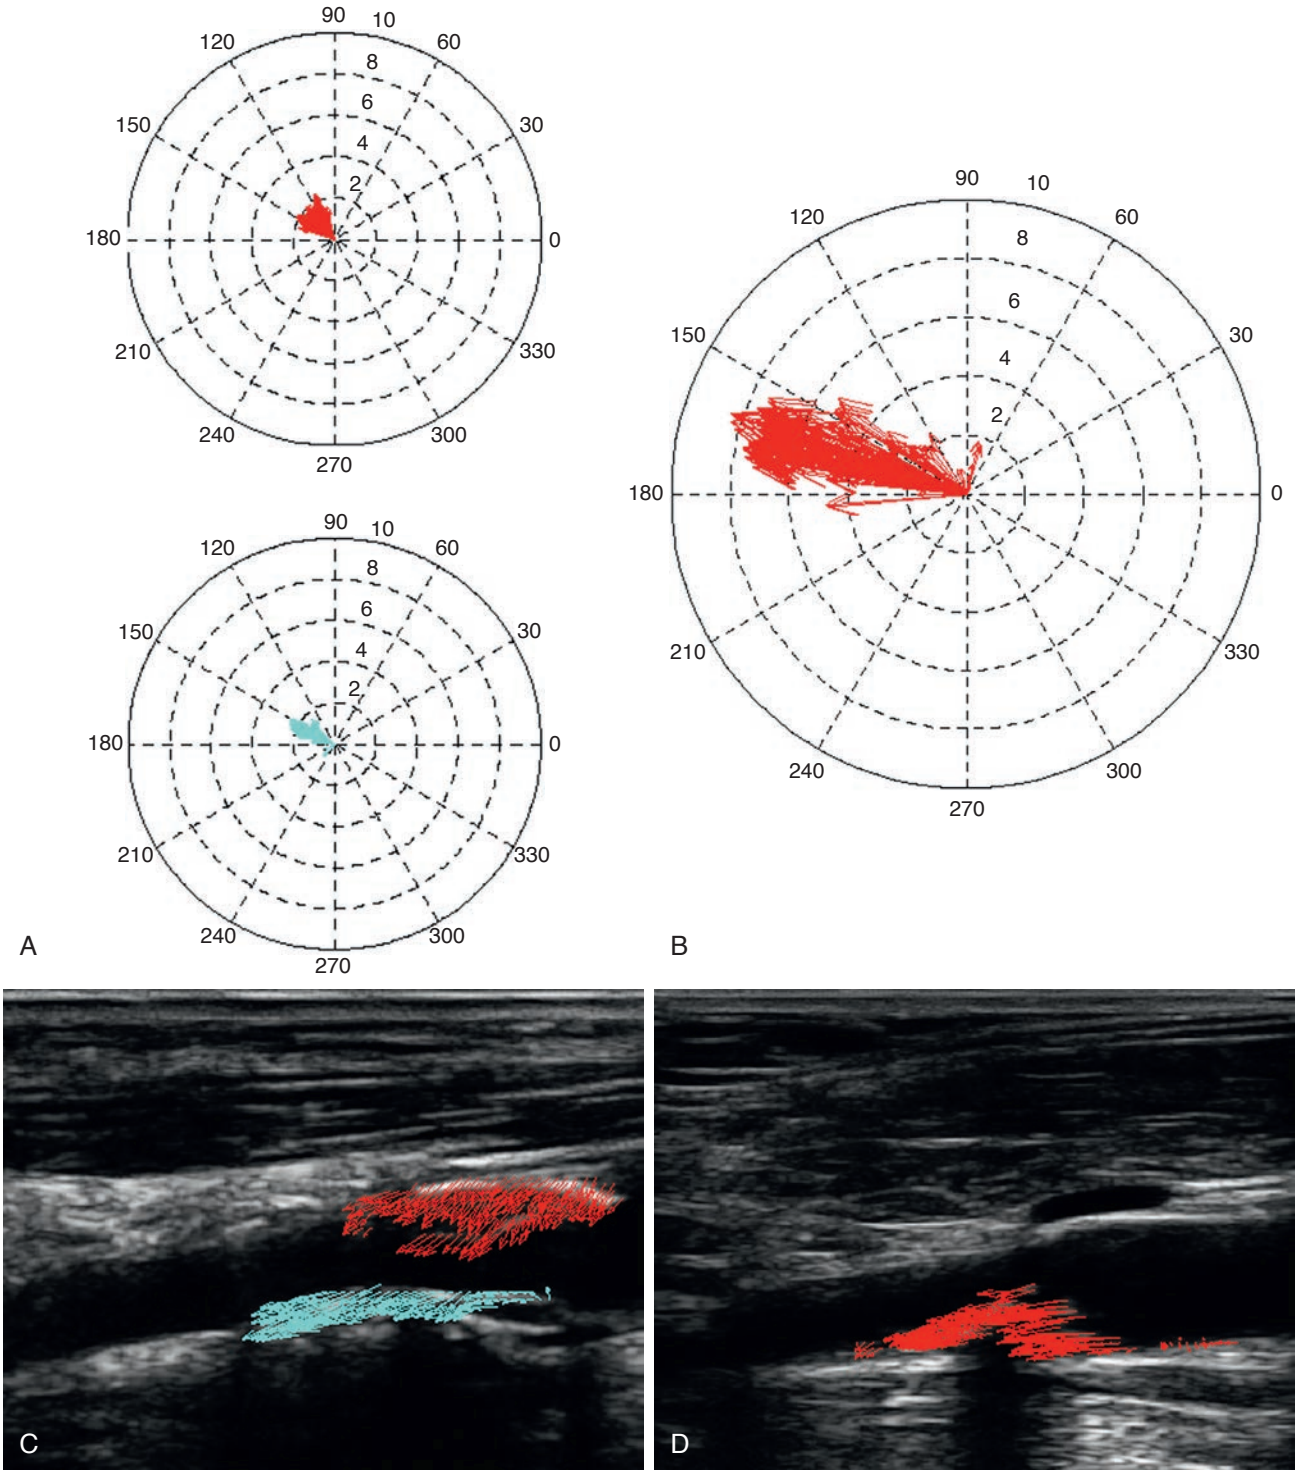

Figure 87.5 Speckle tracking-based displacement fields from B-mode cine-loops of two carotid plaques. (A and B) Compass plots representing displacement fields for the plaque regions in two different patients. The length of the arrows represents the magnitude of plaque displacement, and the angle of arrows represents the angular orientation of displacement. (C and D) Quiver plots showing the displacement vectors superimposed on B-mode images of the plaque regions. (Adapted from Khan AA, Sikdar S, Hatsukami T, et al. Noninvasive characterization of carotid plaque strain. *J Vasc Surg.* 2017;65(6):1653-1663.)

MAGNETIC RESONANCE IMAGING FOR HISTOMORPHOLOGY

In vivo carotid plaque MR imaging has been extensively validated against histology.[56-58] MRI identifies large LRNC, IPH, and luminal surface ulceration accurately and with good reproducibility.[59,60] Traditionally, long duration scanning protocols using customized carotid coils and large magnets were required to produce high-resolution images with sufficient tissue detail.[61] Such protocols were not readily translatable to the clinical environment. However, advances in 3D-MRI protocols have reduced scan times and now permit differentiation of disrupted versus intact carotid plaques or detection of IPH and LRNC on clinical scanners using standard commercial coils.[62] Clinical contrast-enhanced MR angiography and vessel wall imaging improves quantification of the LRNC and delineation of the luminal surface to identify ulceration.[63] Gupta et al. compared studies utilizing multisequence carotid coil-dependent protocols versus those using a single sequence with standard commercially available neck coils.[64] Using either technique, IPH correlated with risk for TIA or stroke (HR 4.40 and 5.04 for multisequence versus standard imaging protocols).

Histologic studies indicate that enlarging LRNCs, presence of IPH, and fibrous cap thinning or ulceration are precursors of plaque disruption, and could serve as imaging markers of stroke risk. Studies utilizing MRI have detected a higher prevalence of these features in patients with symptomatic carotid plaques.[64,65] The presence of IPH on MRI has also been associated with the risk for future neurologic events.[64,65] Conversely the absence of IPH portends a benign clinical course.[66] Plaques with a large lipid core are at a high risk for disruption.[67] In addition, MRI-detected luminal surface ulceration has also been associated with increased stroke risk.[68] Small prospective studies[69] and meta-analyses[64,65] demonstrate an elevated risk of developing neurologic symptoms in the presence of IPH (HR 3.66 to 5.86), large LRNC (HR 2.41 to 5.74), and thin or ruptured fibrous cap (HR 4.54 to 6.30). While these are compelling findings, they need to be substantiated in large prospective longitudinal studies with objective adjudication of stroke endpoints. One such study (CREST-Imaging) is being conducted within the CREST-2 cohort of patients.[53]

COMBINED MAGNETIC RESONANCE IMAGING AND ULTRASONOGRAPHY FOR BIOMECHANICS

Direct in vivo measurement of WSS in patient carotid bifurcations is difficult to obtain. However, provided that the luminal geometry from MRI and the entrance and exit flow waveforms from DUS are obtained, patient-specific computational fluid dynamics (CFD) models can be constructed.[70] These models yield the velocity, pressure, and WSS fields at all points along the vessel wall. Using this approach, patients with 60% or greater carotid stenosis had a higher mean WSS (>100 dynes/cm^2) compared with those with normal or minimal stenosis (mean <60 dynes/cm^2).[70] Ten patients with carotid plaques underwent MRI-based WSS measurement across the cardiac cycle.[71] WSS was higher in subjects with IPH or with large LRNC compared with those without. Similarly, MRI of 12 carotid arteries underwent fluid structure interaction modeling to compute PWS. Ulcerated plaques had higher plaque wall stress (PWS, 247 vs. 108 kPa, $P < .0016$) and WSS (39 vs. 14 dynes/cm^2, $P < .001$) compared with nonulcerated plaques.[22] In another study, PWS was 11% higher ($P = .0003$) and WSS was 30% higher ($P = .0002$) in plaque regions with IPH compared with IPH-free regions.[72] This indicates possible links between biomechanical forces on the plaque (high WSS and PWS), and plaque histomorphology features associated with adverse neurologic outcomes (ulceration and IPH). The heterogeneity in populations studied and analytic techniques utilized, the small sample sizes, and paucity of serial assessments for these studies precludes firm conclusions on the relationship.

SUMMARY

The estimation of degree of stenosis based on Doppler velocity measurements is the most well established role of ultrasonography in the diagnostic workup of carotid artery atherosclerotic disease. There is, however, a clinical imperative to obtain additional information on the plaque. Characteristics of the plaque such as volume, LRNC size, and location, surface ulceration, IPH, as well as hemodynamic effects around the plaque have been associated with an increased risk of stroke. 2D B-mode imaging with GSM analysis, ultrasonographic VH using PDA, and additional analyses of the image texture provide improved information about plaque composition and architecture. Recently introduced 3D imaging technology offers an excellent opportunity to reduce observer-dependence and to sample the entire plaque for volumetric and surface assessments. CEUS has improved the definition of the plaque luminal surface and of neovascularization. It has the potential to allow targeted visualization of plaque inflammation with molecular imaging. While IVUS has found limited adoption in the carotid artery, it may have the potential to assist in planning endovascular procedures. MRI provides consistent and reliable identification and quantification of IPH, LRNC, and thin fibrous caps. Clinical scanners are improving rapidly and afford excellent resolution. Ultrasonography and MRI also offer an opportunity to quantify biomechanical forces acting on the plaque. Adequately powered prospective longitudinal studies are underway to definitively establish the role of noninvasive risk stratification of carotid plaques in clinical practice.

DUPLEX ULTRASOUND

Indications

Carotid Artery Disease

In 2006,[1] a UK Health Technology Assessment (HTA) meta-analysis of the accuracy of noninvasive imaging (but not multidetector computed tomography [CT] angiography [MDCTA]) concluded that while contrast enhanced magnetic resonance angiography (CEMRA) was the most accurate (Table 88.1), its "clinical effectiveness" was limited by accessibility, availability, and delays. HTA concluded that duplex ultrasound (DU) remained the "first line" imaging modality for identifying patients with 70% to 99% internal carotid artery (ICA) stenoses because of (1) low cost, (2) the higher number of strokes likely to be prevented in the long-term (because patients are scheduled more rapidly for surgery), (3) robustness in sensitivity analyses, and (4) its ability to match the needs of current surgery (i.e., patients were selected for surgery through attendance at "single visit clinics" incorporating DU imaging with a low probability of the surgeon encountering unexpected findings at operation that might otherwise compromise patient safety).[1]

The HTA[2] did, however, highlight concerns about DU accuracy for diagnosing 50% to 69% stenoses (see Table 88.1). Because the benefit conferred by carotid endarterectomy (CEA) in patients with 50% to 69% stenoses falls significantly with delays to surgery, HTA recommended that if 4 weeks or more had elapsed after the index event, corroborative imaging (CEMRA/MDCTA) should be performed to confirm stenosis severity. If, however, DU was performed within 4 weeks of the index event, the HTA felt it reasonable to proceed to CEA based on DU alone, as the number of strokes prevented through rapidly performed surgery exceeded the potential risk to patients with less than 50% stenoses undergoing inappropriate surgery.

Consensus ultrasound criteria for diagnosing carotid stenosis severity[3] are summarized in Table 88.2. These have been validated by AbuRahma et al.,[4] who concluded that the criteria could accurately diagnose a greater than 70% stenosis. However, the accuracy for diagnosing a 50% to 69% stenosis would be improved by changing the peak systolic velocity (PSV) range from 125 to 230 cm/s to 140 to less than 230 cm/s.[4]

TABLE 88.1 Results of a Meta-Analysis of the Accuracy of Noninvasive Imaging for All Stenosis Groups and Imaging Modalities

Stenosis Group	Imaging	Sensitivity (95% CI)	Specificity (95% CI)
70%-99% (0.77-0.89)	US	0.89 (0.85-0.92)	0.84
(0.91-0.97)	CTA	0.77 (0.68-0.84)	0.95
(0.76-0.90)	MRA	0.88 (0.82-0.92)	0.84
(0.89-0.96)	CEMRA	0.94 (0.88-0.97)	0.93
50%-69% (0.87-0.94)	US	0.36 (0.25-0.49)	0.91
(0.63-0.89)	CTA	0.67 (0.30-0.90)	0.79
(0.78-0.97)	MRA	0.37 (0.26-0.49)	0.91
(0.93-0.99)	CEMRA	0.77 (0.59-0.89)	0.97
0%-49%, 100% (0.62-0.95)	US	0.83 (0.73-0.90)	0.84
(0.74-0.98)	CTA	0.81 (0.70-0.88)	0.91
(0.76-0.95)	MRA	0.81 (0.70-0.88)	0.88
(0.90-0.99)	CEMRA	0.96 (0.90-0.99)	0.96

Vertebrobasilar Disease

Extracranial DU offers limited information about flow dynamics in the vertebral arteries (VAs), and nothing about the basilar system. It is not always possible to image VA origins and only those sections running between the transverse processes can be imaged distally. Accordingly, if a patient presents with suspected

TABLE 88.2 Consensus Panel Gray-Scale and Doppler Ultrasound Criteria for Diagnosis of Internal Carotid Artery Stenosis

Degree of Stenosis (%)	PRIMARY PARAMETERS		ADDITIONAL PARAMETERS	
	ICA PSV (cm/s)	Plaque Estimate (%)[a]	ICA/CCA PSV (ratio)	ICA EDV (cm/s)
Normal	<125	None	<2.0	<40
<50	<125	<50	<2.0	<40
50-69	125-230	≥50	2.0-4.0	40-100
>70 but less than near occlusion	>230	≥50	>4.0	>100
Near occlusion	High, low or undetectable	Visible	Variable	Variable
Total occlusion	Undetectable	Visible, no detectable lumen	Not applicable	Not applicable

[a]Plaque estimate (diameter reduction) with gray-scale and color Doppler US.
CCA, Common carotid artery; *EDV*, end-diastolic velocity; *ICA*, internal carotid artery; *PSV*, peak systolic velocity.

vertebrobasilar symptoms, DU assessment can exclude co-existent carotid disease, but diagnostic imaging with MRA/MDCTA remains mandatory. DU is, however, useful for demonstrating complete/partial VA flow reversal, suggesting proximal subclavian or innominate artery disease.

Role in Screening

While the Society for Vascular Surgery advocates carotid screening in patients aged greater than 55 years with cardiovascular risk factors, the 2014 US Preventive Services Task Force continues to recommend against this.[5] For those committed to screening, DU is the first-line modality. Portable DU machines are available, but there is little data regarding accuracy. Users of portable machines are, therefore, advised to undertake a corroborative DU study in an accredited vascular laboratory (or use MDCTA/CEMRA) should a greater than 50% stenosis be suspected. DU remains the preferred screening modality prior to coronary artery bypass graft (CABG) surgery. Screening all CABG patients is not cost-effective (2% yield for 80%-99% stenoses),[6] but the yield increases in selected patients (left mainstem disease, carotid bruit, previous stroke/TIA). Any patient being considered for CABG using internal mammary artery (IMA) and who has weak/absent radial pulses should undergo DU assessment of the subclavian, innominate, and VAs. Where inflow disease or VA flow reversal is suspected, further imaging (MDCTA/CEMRA) is essential, and the cardiac surgeon should be warned that unless corrected, use of the ipsilateral IMA (as a conduit) could cause postoperative coronary steal syndrome (Fig. 88.1).

Role in Trauma

Duplex offers a screening/surveillance role in patients with zone II carotid injuries (between cricoid cartilage and angle of mandible), especially intimal irregularities or small false aneurysms treated conservatively. DU is, however, less reliable in zone I injuries (clavicle to cricoid cartilage) or zone III injuries (angle of mandible to skull base).

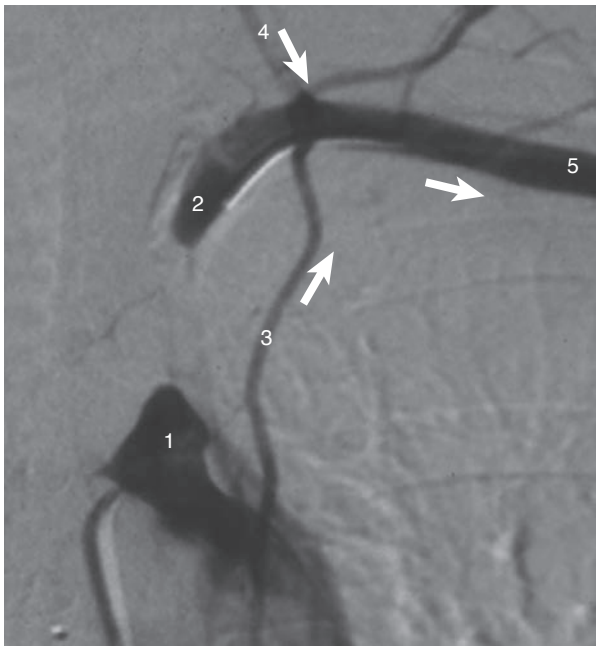

Figure 88.1 Intraarterial digital subtraction arteriography in a patient with coronary steal syndrome that had previously undergone coronary artery bypass graft using the left internal mammary artery as a conduit. There is occlusion of the proximal left subclavian artery (1), which refills distally (2, 5) via reversed flow in the left vertebral (4) and internal mammary artery (3). It was treated successfully by angioplasty.

Evaluation of Carotid Body/Glomus Vagale Tumors (See Chapter 95)

Because of their vascularity, DU is ideal for diagnosing carotid body (CBT) or glomus vagale tumors (GVTs). Given the availability of DU, it is unwise to biopsy a "lymph node" in the jugulodigastric region without first undertaking a DU. Once suspected, MDCTA/MRA should be performed to exclude

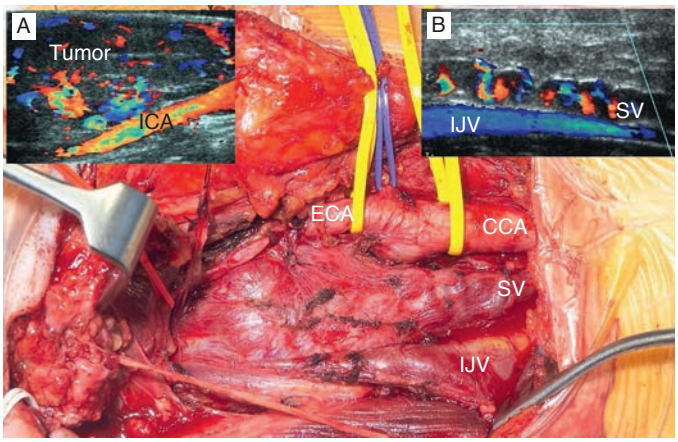

Figure 88.2 Glomus vagale tumor (GVT, *main picture*). This does not splay the bifurcation but displaces the distal internal carotid artery (ICA) (*duplex image*, A). Occasionally, preoperative ultrasound features can suggest that this is a GVT and not a carotid body tumor. Note the serpiginous feeding vessels extending down the vagus nerve (SV: main picture and duplex ultrasound scan [B]). These are separate from the common carotid artery (CCA) and internal jugular vein (IJV). *ECA*, External carotid artery.

bilateral lesions (5%) and to image the upper and lateral extent of the lesion. Large, distally placed lesions require a totally different operative strategy, which must be anticipated preoperatively (temporomandibular subluxation cannot be performed once the operation is underway). Duplex can also warn the surgeon that a GVT might be present (Fig. 88.2), enabling the patient to be counseled about vagus nerve division (hoarseness, swallowing difficulties). CBTs cause splaying of the carotid bifurcation. GVTs do not splay the bifurcation, but they do tend to cause displacement of the distal ICA (see Fig. 88.2). In addition, GVTs tend to have vascular serpiginous feeding vessels tracking down the proximal vagus nerve. These usually lie separately from the bifurcation, internal jugular vein, and common carotid artery (CCA).

Role in the Planning of Carotid Endarterectomy and Carotid Artery Stenting

Up to 95% of CEAs are undertaken on the basis of DU, and there is no evidence that reliance on DU compromises safety or operability,[1] provided certain caveats are met: First, the vascular laboratory should be accredited and have validated criteria for measuring stenosis severity. Second, European vascular units must be absolutely clear which measurement method is being used (NASCET/ECST) (see Chapter 21). Evidence suggests that there may be confusion.[7] Third is awareness of DU findings that suggest tandem inflow/outflow problems or subocclusion. In each situation, corroborative imaging is mandated (MDCTA, CEMRA).

In practice, one of the most frequent pathologic lesions to be missed with DU is the coiled distal ICA (see Chapter 96). In most situations, coils do not cause problems to the surgeon, but they can be a cause of shunt failure (hemodynamic stroke) should the distal shunt tip occlude against the distal loop and not be recognized. DU is useful in diagnosing unusual causes of cerebral symptoms, such as ICA "stump syndrome" (Fig. 88.3). In this rare condition, a "vault" at the origin of an occluded ICA stump (identifiable on DU) acts as a reservoir for fresh thrombus formation that can embolize up the external carotid artery (ECA) and into the brain via retrograde flow through the supra- and infraorbital vessels.

By contrast, carotid artery stenting (CAS) cannot be planned using DU alone. Table 88.3 details anatomic and morphologic features that are associated with difficulties in performing CAS or which influence choice of cerebral protection device (CPD) or stent. For example, choice of CPD will depend upon ECA patency, integrity of the circle of Willis (COW), and whether there is a straight, nontortuous distal ICA. Stent selection will depend upon vessel tortuosity and plaque friability. DU can demonstrate (1) the presence of an appropriate ipsilateral stenosis, (2) ECA patency, (3) extent of contralateral disease, (4) tortuosity at the bifurcation, (5) it can advise on plaque morphology, and (6) warn that there may be coexistent inflow and outflow problems. However, DU cannot provide information regarding (1) type of aortic arch, (2) extent of calcification at the great vessel origins, (3) proximal CCA tortuosity, (4) whether there is an adequate distal landing zone for a filter CPD, or (4) COW status. If the COW is not intact, CAS practitioners tend not to deploy the flow reversal type of CPD. This type of information can only be provided by MDCTA or CEMRA. However, reliance on additional imaging will introduce delays in planning the management of symptomatic patients. If delays are likely, patients may be better treated by CEA.

Evaluating Plaque Morphology

In the Asymptomatic Carotid Surgery Trial (ACST), the subjective Gray-Weale classification (Table 88.4) was unable to predict outcome in medically treated asymptomatic patients,[8] but the Asymptomatic Carotid Stenosis and Risk of Stroke (ACSRS) study showed that provided computerized "image normalization" was undertaken, 94% of strokes destined to occur in a cohort of 1008 asymptomatic patients with 50% to 99% stenoses had Type 1 to 3 plaques (see Table 88.4).[9-12]

The ability to identify "higher-risk for stroke" patients with asymptomatic carotid disease is important, as it is believed that up to 95% of interventions in asymptomatic patients are ultimately unnecessary.[13] The weakness of DU plaque morphology studies (in the past) has been a lack of objectivity, but this has been addressed by developing a number of computerized plaque analyses including the Gray-Scale Median (GSM) and measurement of overall plaque area and juxta-luminal black area (JBA).[11,12] High-resolution B-mode images are combined with a quantitative computer assisted measurement of plaque echogenicity. The GSM is a numerical measure representing average echogenicity of the plaque (low values are observed in predominantly echolucent plaques, while high values are seen in more sclerotic lesions). ACSRS[11,12] observed that asymptomatic patients with a 60% to 99% stenosis and an overall plaque area less than 40 mm^1 had a 1.0% annual risk of stroke, increasing to 1.4% (40-80 $mm)^1$ and 4.6% for plaque area greater than 80 mm.[1] Asymptomatic patients with a JBA less than 4 mm^1 had a 0.4% annual risk of ipsilateral stroke, increasing to 1.4%

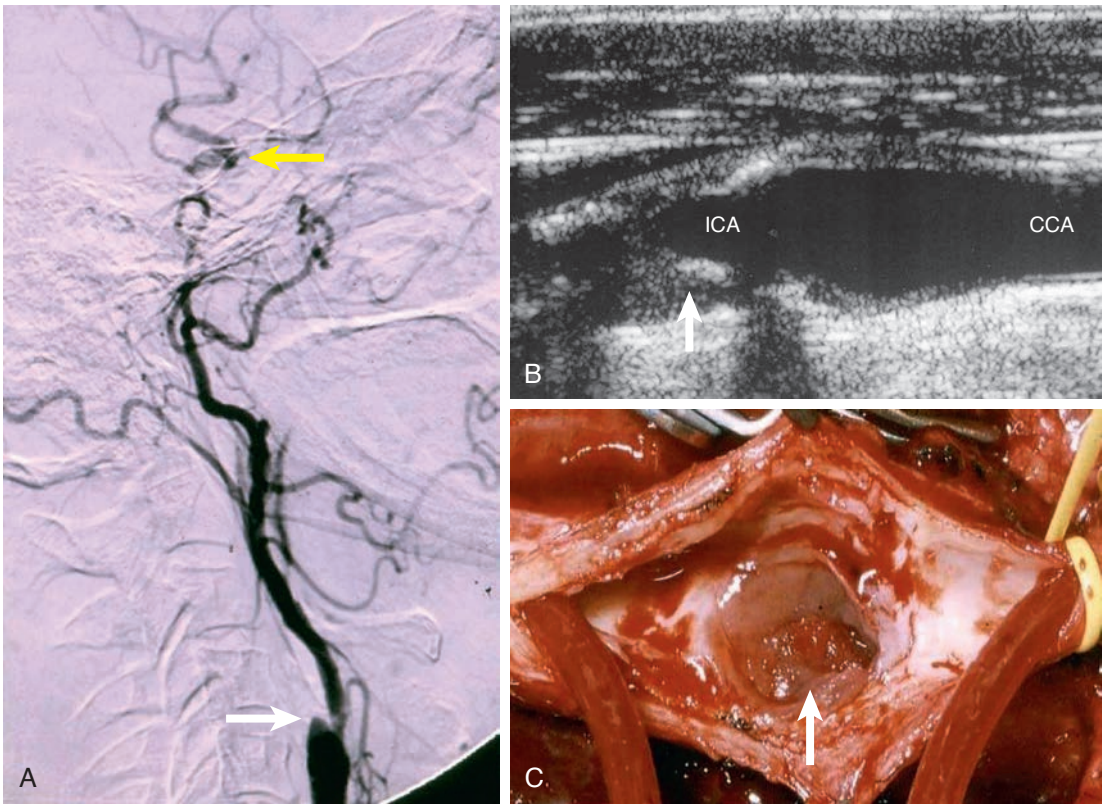

Figure 88.3 Internal carotid artery (ICA) stump syndrome. (A) Selective intraarterial digital subtraction arteriography with delayed imaging confirms the presence of an occluded ICA with a small stump *(white arrow)*. The external carotid artery (ECA) is an important source of collateral flow because there is refilling of the distal ipsilateral carotid syphon *(yellow arrow)*. (B) B-mode ultrasound image of the ICA stump in this patient *(arrow)*. (C) Operative image with a shunt inserted between the common carotid artery (CCA) and the ECA. Note the extensive fresh thrombus within the ICA stump *(arrow)*.

(4-8 mm),[1] 3.2% (8-10 mm),[1] and 5.0% for JBAs greater than 10 mm.[1] In addition, the presence of ≥3 carotid plaque ulcers on high-resolution three-dimensional (3D) DU in asymptomatic patients was associated with a significantly higher annual risk of late ipsilateral stroke (6%) compared to 0.6% in patients with 0 to 2 micro-ulcers.[14]

In recently symptomatic patients, Salem reported that the presence of a large lipid core on DU and a GSM less than 25 were predictive of a significantly increased risk of recurrent neurologic events in the 48- to 72-hour time period before undergoing expedited CEA.[15] The same group performed a logistic regression analysis of computerized plaque DU features in 126 patients prior to undergoing CEA (with blinded histologic assessment) and showed that the combination of a plaque area greater than 95 mm^1 and a JBA greater than 6 mm^1 was 90% predictive of there being an unstable carotid plaque following ex-vivo histologic examination.[16]

Perioperative Roles

DU should be repeated prior to CEA if greater than 4 weeks have elapsed since the initial DU. This ensures the ICA has not occluded (i.e., CEA is unnecessary), it is also the final opportunity to warn of distal disease extension (last chance to consider temporomandibular subluxation or alternative exposure techniques), and it fulfills an important internal validation role. Intraoperative DU enables completion assessment following flow restoration through (1) residual filling defects (luminal thrombus), (2) undue turbulence, and (3) evidence of intimal flaps/residual stenoses (see Chapter 91). Evidence from the Imaging in Carotid Angioplasty and Risk of Stroke (ICAROS) study suggested that a GSM ≤25 was associated with a 7.1% stroke rate after CAS compared with 1.5% in patients whose plaque had a GSM greater than 25.[17]

Postoperative Roles

Because of its versatility, DU is invaluable in guiding the management of postoperative neurologic deficits. These often occur when other imaging modalities are unavailable and DU can be brought to the patient's bedside. Air in the deep tissues can interfere with insonation early after surgery, but it is usually possible to exclude thrombosis. Diagnosing the exact cause of the deficit can be difficult, and the role of DU is enhanced if combined with transcranial Doppler ultrasound (TCD).

The role of serial DU surveillance after CEA/CAS remains controversial. As with screening, this is rarely undertaken in the United Kingdom and Scandinavia, but this is common practice in North America, Australasia, and mainland Europe. On a practical note, those who offer DU surveillance after CAS

		Type 5	Calcified cap (>15% of cap) with acoustic shadow

must be aware that stents change the physical properties of the carotid artery so that different diagnostic criteria are required.[18]

DU is also useful in warning about the possibility of late prosthetic patch infection (Fig. 88.4). DU is the first line investigation in patients returning with pulsatile neck swellings, discharging sinus tracts, or neck pain, and the recognition of patch "corrugation" may precede clinical diagnosis of patch infection by up to a year (i.e., recognition of this phenomenon can alert the surgeon to the possibility of patch infection and start antibiotics early).[19] Duplex DU can also identify "leaks" into false aneurysms (see Fig. 88.4).

Contraindications

There are no contraindications to DU, but it should only be undertaken by an operator who has been adequately trained.

Accuracy and Limitations

The most important determinant is the experience and skill of the operator. Second is awareness of the wide array of stenosis thresholds being used in individual centers (>50%, >60%, >70%) and the spectrum of PSV and velocity ratios being used

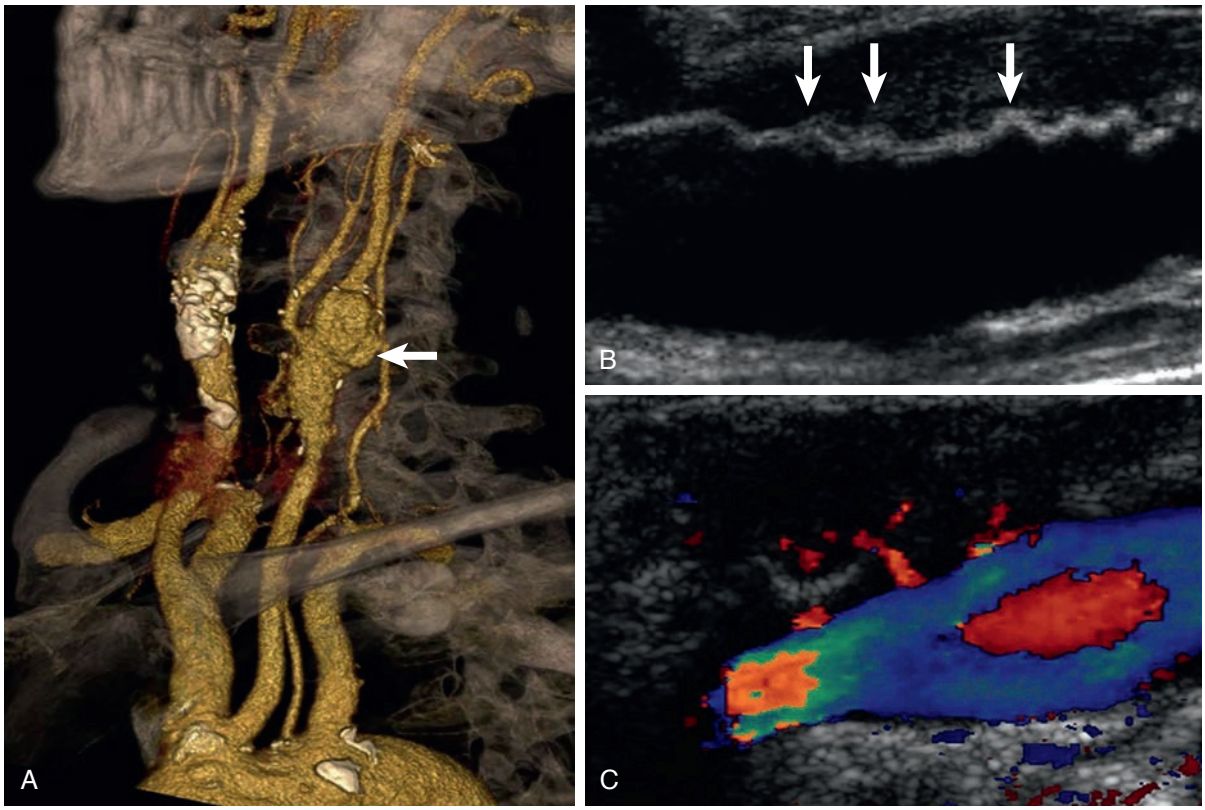

Figure 88.4 Prosthetic patch infection 15 years after CEA. Multidetector computed tomography angiography (A) shows a false aneurysm *(arrow)* at the left carotid bifurcation. (B) Corrugation of the polyester patch on B-mode ultrasound imaging *(arrows)*. (C) Color duplex ultrasound showing jets of blood into a false aneurysm secondary to patch infection (not the same patient as in A or B).

to diagnose stenosis subgroups. This uncertainty has been reduced by publication of North American DU consensus criteria.[3] Third most important is knowing whether the operator is using ECST or NASCET measurement criteria. UK experience suggests that many vascular laboratories remain unsure.[7] Interestingly, the North American consensus document provides no advice for grading the large carotid bulb that contains large amounts of atherothrombotic material. This could score 0% using the NASCET measurement method (i.e., no need for CEA) but 70% stenosis using the ECST method (i.e., CEA justified). This anomaly has been addressed in the UK carotid stenosis guidelines.[20] Fourth are those situations where caution should be exercised when interpreting DU findings. These include (1) the inability to image above the plaque, (2) dampened waveforms in the proximal CCA suggesting inflow stenosis, (3) high resistance flow in the distal ICA suggesting a distal tandem lesion, (4) in the presence of a contralateral occlusion or very severe stenosis, since PSV velocities may be increased in the contralateral ICA (due to hyperemic collateralization), leading to overestimating the degree of ipsilateral stenosis based on PSV measurement, (5) excessive calcification (which prevents accurate velocity measurement due to acoustic shadowing), and (6) suspicion of subocclusion.

The diagnosis and management of subocclusion has aroused considerable controversy. Previously considered to be a marker of increased stroke risk, the Carotid Endarterectomy Trialists Collaboration observed that chronic subocclusion (a severe ICA stenosis that does not open into a normal-caliber lumen) is not a high-risk predictor for stroke and that CEA does not confer long-term benefit.[21] An important exception to this rule, however, is when DU is performed in the first 7 to 14 days after onset of symptoms. Here it is not uncommon for the DU technician to report a very narrow lumen extending up into the neck, with no apparent opening out into a normal-caliber lumen. Previously, this would have been diagnosed as a "subocclusion," but the critical difference is that there are high peak systolic and end-diastolic velocities across the stenosis. In chronic subocclusions, there are very low peak systolic velocities (<20 cm/s) with no diastolic flow. In the hyperacute situation, corroborative CTA/MRA imaging is mandatory and will usually confirm that the stenosis opens out into a normal lumen (i.e., revascularization is appropriate). In short, no one should be "labeled" as having a subocclusion in the hyperacute period after onset of symptoms without corroborative imaging.

MAGNETIC RESONANCE IMAGING/MAGNETIC RESONANCE ANGIOGRAPHY

Indications

MR angiography has been available since 1996, but only following the introduction of CEMRA has it become a legitimate

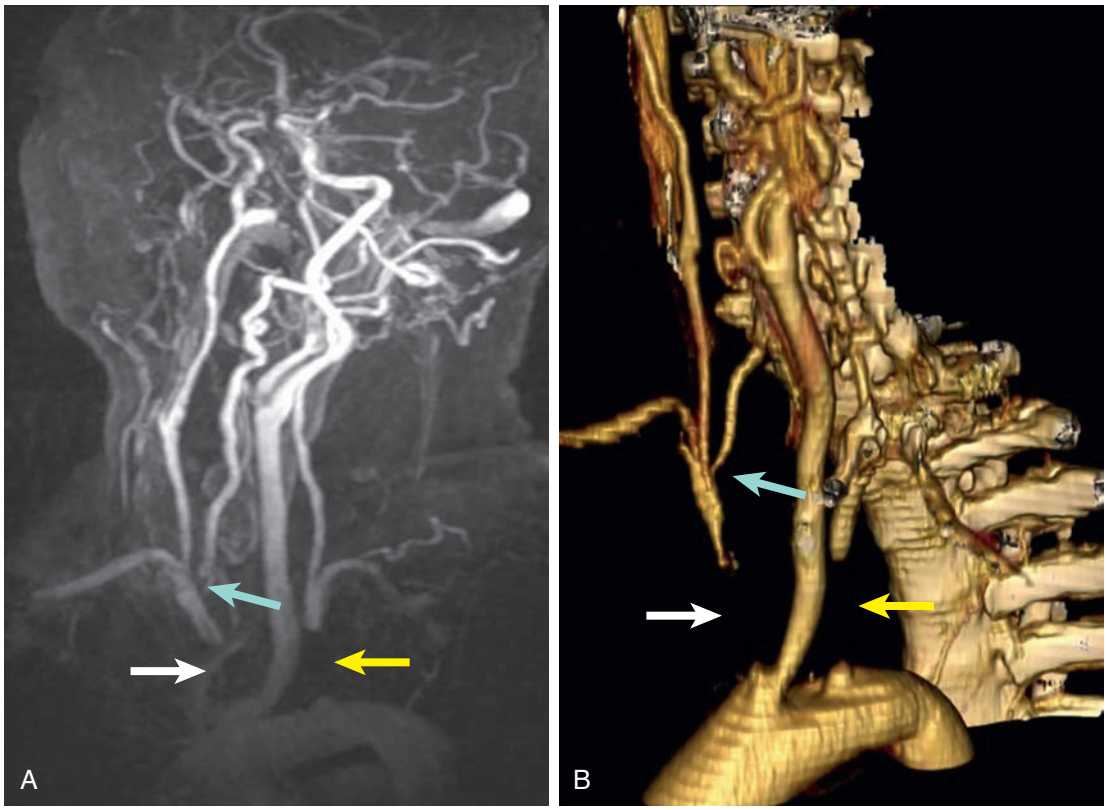

Figure 88.5 Sixty-year-old female with a vertebrobasilar stroke and recurring unsteadiness of gait imaged by contrast-enhanced magnetic resonance angiography (CEMRA; A) and multidetector computed tomographic angiography (MDCTA; B). There is complete occlusion of the innominate artery *(white arrow)* and left subclavian artery *(yellow arrow)*. The right vertebral artery has a stenosis at its origin *(blue arrow)*. CEMRA and MDCTA have shown identical features, but MDCTA is easier to interpret because of venous contamination in the CEMRA image.

rival to angiography for the title of "gold standard" (see Chapter 28). Its main advantage is the avoidance of exposure to radiation. Because of the way magnetic resonance imaging (MRI) images are acquired, bony structures are not present on the resultant image, thus avoiding the need for complicated postprocessing. However, adjacent soft tissue structures are not well visualized unless unsubtracted or additional MRI imaging is performed, and calcium within a plaque is not well defined.

Carotid Disease

MRA has assumed an increasingly important role in the evaluation of patients with carotid artery disease. Table 88.1 summarizes sensitivity analyses from the HTA systematic review for time of flight (TOF) MRA and CEMRA. Sensitivity and specificity for diagnosing a 70% to 99% stenosis with TOF MRA is identical to that for DU and similarly poor for diagnosing 50% to 69% stenoses. Two-dimensional TOF MRA provides strong vascular signals, even when flow is low (useful for differentiating occlusion from "subocclusion"), while 3D TOF MRA offers better spatial resolution for measuring stenosis severity and enabling assessment of flow directionality in steal phenomena. However, to minimize acquisition times and artifacts (flow related, motion and boundary), the field of view must be restricted. Accordingly, while it is possible to image both carotid bifurcations simultaneously, two further acquisitions are required to image the aortic arch/great vessels and the COW using TOF. This limits overall versatility and accessibility and means that TOF-MRA for the most part offers little in addition to DU.

CEMRA uses the paramagnetic agent Gadolinium and (compared to TOF-MRA) images are obtained more rapidly. CEMRA incurs fewer flow related artifacts and provides a much greater field of view that enables high-resolution imaging from the aortic arch (Fig. 88.5) up to the COW while retaining the ability to evaluate flow directionality. The HTA meta-analysis (see Table 88.1) concluded that CEMRA was the best (noninvasive) imaging modality (although MDCTA was not evaluated), and it has superseded TOF-MRA.[2] Another advantage of CEMRA is that it can be combined with MR brain imaging, although this requires an additional period of data acquisition. The recent use of blood-pool contrast agents facilitates high-resolution image acquisition by allowing equilibrium phase imaging, thereby increasing the temporal window.

There is evidence that the presence of infarction on CT/MR can identify patients at increased risk of suffering an early recurrent stroke in the early time period after presenting with a TIA or minor stroke (Table 88.5). The ABCD^2 score is a clinically based scoring system that predicts the 48-hour and 7-day risk of stroke based on A: age, B: blood pressure, C: clinical presentation, D: duration of symptoms, and D: diabetes.[22]

The maximum score is 7, and the risk of recurrent stroke increases as the score increases (see Table 88.5). The table shows that the presence of acute infarction on CT/MR in a patient with a recent TIA or minor stroke should warn the surgeon of an increased risk of early recurrent stroke, prompting expedited CEA. Interestingly; where no infarction was present on CT/MRI; a high ABCD[2] score no longer predicts an increased risk of recurrent stroke.[23]

TABLE 88.5 Early Risk of Stroke After Presenting With a TIA Stratified for the ABCD2 Score and Presence/Absence of an Infarction on Computed Tomography/Magnetic Resonance Imaging

	Stroke Risk at 48 Hours	Stroke Risk at 7 Days
ABCD2 score 0-3[22]	1.0%	1.2%
ABCD2 score 4-5[22]	4.1%	5.9%
ABCD2 score 6-7[22]	8.1%	11.7%
Infarction on CT/MRI + ABCD2 score 0-3[23]		2.3%
Infarction on CT/MRI + ABCD2 score 4-5[23]		8.9%
Infarction on CT/MRI + ABCD2 score 6-7[23]		15.0%
No infarction on CT/MRI + ABCD2 score 0-3[23]		0.2%
No infarction on CT/MRI + ABCD2 score 4-5[23]		1.4%
No infarction on CT/MRI + ABCD2 score 6-7[23]		3.3%

CT, Computed tomography; *MRI*, magnetic resonance imaging.

Role in Vertebrobasilar Disease

One of the advantages of TOF-MRA and CEMRA is that they can provide information regarding flow directionality. This is useful in evaluating steal phenomena (subclavian, coronary). Both, however, are limited by artifact at the VA origins due to vessel tortuosity, respiratory motion, and cardiac pulsation. In practice, MDCTA is probably the preferred (noninvasive) investigation for evaluating patients with suspected vertebrobasilar symptoms.

Role in Screening

MRA has no role as a screening modality. It is simply not cost-effective.

Role in the Evaluation of Trauma

MRI/MRA studies are seldom undertaken in trauma patients. This is because of scanner location (relative to the emergency department or operating room), prolonged acquisition times, and poor access to an unstable patient for monitoring.

Role in the Evaluation of Carotid Body/Glomus Tumors

MR and CEMRA provide basic information, which is useful for planning surgical management and for excluding contralateral lesions (Fig. 88.6). MDCTA is probably the best imaging modality in this situation, largely because of the high-resolution axial images that detail the full extent of the lesion and its relationship to adjacent bony structures. However, while MR is limited by the fact that there are no "bony landmarks" retained

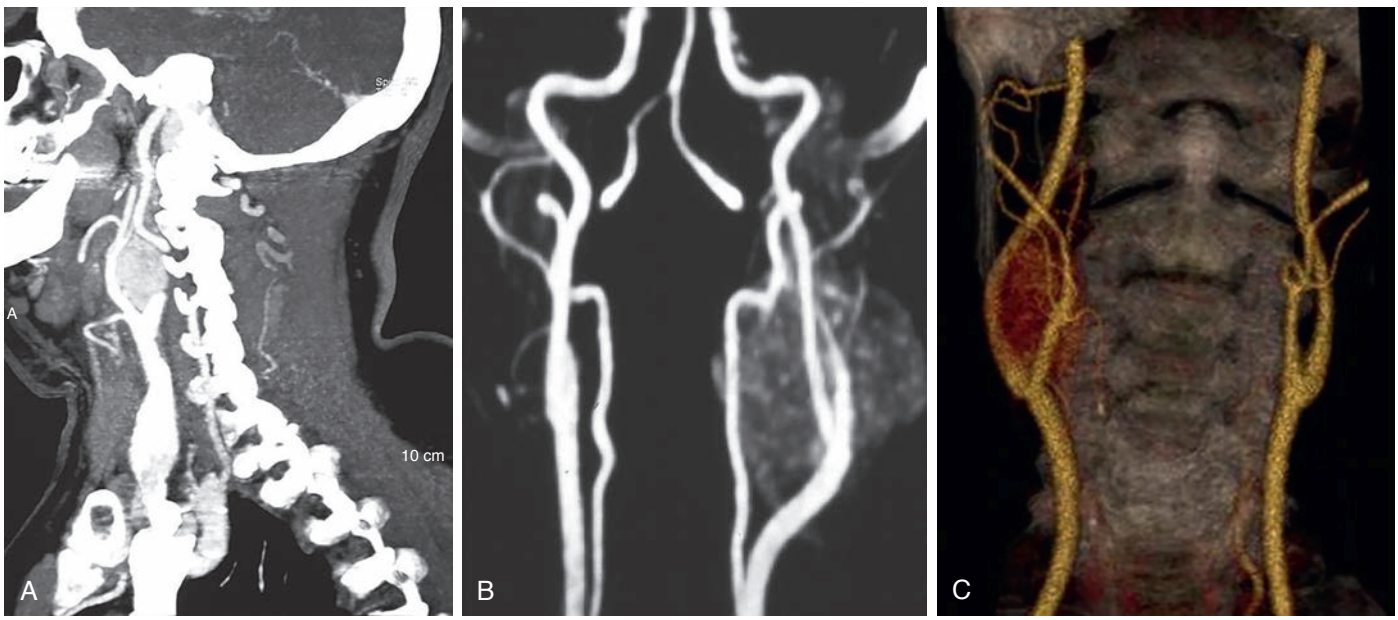

Figure 88.6 Carotid body tumor. (A) Multidetector computed tomographic angiography (MDCTA) maximum intensity projection (MIP) image. (B) Contrast-enhanced magnetic resonance angiography MIP image. (C) MDCTA volume rendition image.

on the image, it does provide excellent soft tissue contrast resolution that may be helpful when evaluating intracranial extension of lesions.

Role in the Planning of Carotid Endarterectomy and Carotid Artery Stenting

Surgeons who regularly perform CEA based on DU alone will be unlikely to find any additional role for CEMRA and little or no use for TOF-MRA. If DU studies are nondiagnostic, MDCTA is probably preferable to CEMRA. However, CAS requires much more imaging information during the planning process than CEA (see Table 88.2; Chapter 92) Accordingly, the choice between CEMRA, MDCTA, and DSA for planning CAS will reflect resources, clinician preferences, and local expertise. CEMRA is preferable to conventional spiral CT, while MDCTA is accepted to be superior because of its versatility and ability to combine anatomical imaging with the identification of calcification, vessel tortuosity, and vascular anomalies in addition to being able to perform functional brain imaging during one period of data acquisition.

CEMRA can identify vessel anomalies, but if arteries are occluded, they can sometimes be missed because of the way images are acquired. The main limitation of CEMRA is its inability to display calcification. Documenting extent of calcification in the arch and origins of the great vessels is not a major problem for CEA, but with increasing age, the arch and great vessels become more tortuous and calcified. This makes CAS more challenging (especially for less experienced practitioners)[24] and are associated with increased procedural risks. A further problem with CEMRA is the tendency for multiple vessels to be included in the final image (some venous). This can lead to difficulties in overall image interpretation without reference to the source dataset or without time consuming postprocessing to "tidy up" the final images (see Fig. 88.5).

Role in Evaluating Plaque Morphology

There is growing interest in the role of MR for evaluating subtle changes in carotid plaque morphology that might help identify a subgroup of patients who may be at higher (or lower) risk of suffering a stroke if left untreated (see Chapter 87). MR is probably the best modality for visualizing the fibrous cap and lipid core,[25] while inflammatory molecules within the plaque can be imaged using MR Spectroscopy (still very much a research tool). Newer contrast agents that facilitate prolonged imaging now permit higher resolution without compromising the signal to noise ratio. This allows greater accuracy in the depiction of ulcers or subtle plaque surface irregularities.[26]

Considerable interest has focused on the ability of MR to diagnose intraplaque hemorrhage (IPH), which is thought by many to be one of the most important predictors of increased stroke risk. In a series of themed projects, Altaf showed that an MR diagnosis of IPH in recently symptomatic patients was associated with (1) increased spontaneous embolization, (2) increased embolization during initial dissection during CEA, (3) an increased prevalence of white matter hyperintense lesions (leukariosis), and (4) a much higher risk of ipsilateral recurrent stroke/TIA in symptomatic patients with 70% to 99% stenoses awaiting CEA and in recently symptomatic patients with 30% to 69% stenoses managed medically.[27-30] It has also been shown that 78% of acutely symptomatic patients with AHA type VI plaques (intraplaque hemorrhage, fibrous cap rupture, mural thrombus) diagnosed using MRI had an average of seven new ischemic lesions on diffusion weighted imaging.[31]

In terms of predicting late stroke, Hosseini et al. pooled data from three prospective data sets involving 179 patients with recently symptomatic 50% to 99% ICA stenoses who underwent high resolution MRI imaging within 6 weeks of symptom onset.[32] Two-thirds had evidence of MRI diagnosed IPH at baseline. During follow-up (1 day to 9 years), 62/179 patients (35%) suffered recurrent TIA/stroke and 57 (92%) had IPH on the baseline MRI scan. The cumulative 5-year risk of "any recurrent neurologic event" was 85% in patients with an MRI diagnosis of IPH compared with 13% in non-IPH patients.[32]

One of the key imaging goals is to identify "high risk for stroke" asymptomatic patients. A few studies have now evaluated MR plaque features in asymptomatic patients, although most are restricted to patients with less severe carotid stenoses (50%-79%). Takaya observed that asymptomatic patients with MR evidence of a thinned or ruptured fibrous cap, large lipid core, or intraplaque hemorrhage faced a higher risk of late ipsilateral stroke than those without these features.[33] Similarly, Singh showed that 6/36 asymptomatic patients (17%) with MR evidence of intraplaque hemorrhage suffered an ipsilateral stroke during follow-up compared with 0/62 that did not exhibit this MR feature.[34]

Perioperative Roles

There is no role for MR in the perioperative setting.

Postoperative Roles

MR/MRA does not have a role in the investigation of patients suffering a neurologic deficit after CEA/CAS. The exception might be the rare patient suffering a suspected hyperperfusion syndrome stroke where CT imaging suggests that there is an evolving ischemic infarct (usually in the posterior circulation). Perfusion MR imaging will usually demonstrate that this area of "infarcted" brain tissue is normally perfused and that the area of low attenuation on CT represents vasogenic as opposed to cytotoxic edema.[35] New hyperintense white matter lesions (attributed to microembolization) have been well documented in the early period after CEA (and particularly after CAS).[36] To date, there is no evidence that these lesions predispose toward declining cognitive function in the long term, but they have been shown to be a marker for an increased risk of recurrent stroke or TIA in the long term.[37] Finally, CEMRA has no role in surveillance after CEA/CAS. This is partly because it will never be cost-effective and because of difficulties imaging near the metallic stents used in CAS.

Contraindications

Contraindications include (1) selected metallic implants (pacemakers, defibrillators, stents, joint replacements), (2)

claustrophobia, and (3) obesity. Caution should be exercised in patients with chronic renal impairment, as they are more likely to develop nephrogenic systemic fibrosis following Gadolinium exposure.[38]

Accuracy and Limitations in Clinical Practice

Diagnostic accuracy is related to technology and expertise, and 2D and 3D-TOF MRA are limited by a tendency to overestimate stenosis severity and need multiple data acquisitions to image the inflow and outflow vessels accurately and artifact (motion, flow related). These are less of an issue with CEMRA, although the same contraindications apply. The inability to image calcification makes it less attractive for working up patients for CAS, while lower spatial resolution can lead to difficulties in identifying subtle tandem lesions. Anomalous vessels that have occluded may not be apparent on CEMRA. In practice, however, the main limitation of MRI is lack of availability and the need for specific sequences and hardware to enable dedicated plaque imaging.

POSITRON EMISSION TOMOGRAPHY-COMPUTED TOMOGRAPHY (See Chapter 29)

Indications

Carotid Artery Disease

Positron emission tomography-computed tomography (PET-CT) has no role in the work-up of patients for CEA/CAS. However, because it can measure cerebral blood flow and oxygen extraction fraction, PET is the "gold standard" for evaluating the hemodynamic effect of extracranial disease, particularly autoregulatory failure and impaired cerebral vascular reserve (CVR).[39] However, in patients with a recently symptomatic extracranial ICA occlusion and evidence of impaired CVR on PET, patients randomized to extracranial-intracranial bypass had no reduction in ipsilateral stroke rates at 2 years compared to patients randomized to medical therapy.[40]

In contrast, a recent meta-analysis suggests that the presence of impaired CVR in asymptomatic patients may serve as a predictor of increased late stroke risk if treated medically (OR 3.9 [95% CI 2.0-7.5]).[41] However, while this could become a novel role for PET in the future, it is likely that more accessible and less technologically complicated imaging strategies will assume this function.

Role in Evaluating Plaque Morphology

PET scanners offer good spatial resolution (2 mm), and many are combined with a CT scan to allow tomographic radionuclide imaging (with anatomic correlation). F^{18} Fluorodeoxyglucose (FDG), like glucose, is transported into cells where its metabolites accumulate at a rate proportional to glycolysis. The accelerated metabolism associated with inflammatory cells raises the possibility that a number of cellular processes can be targeted within the carotid plaque (inflammation, macrophages, apoptosis, angiogenesis, protease enzyme function). The ability to link metabolic activity with biomarkers and plaque imaging could have important implications in the future (patient selection, monitoring drug therapy), especially in diagnosing an unstable plaque in high-risk patients. Marnane et al. undertook FDG-PET studies in recently symptomatic patients and observed that an FDG standardized uptake value of 2.14 had a 98% specificity and a 31% sensitivity for predicting late recurrent stroke, with 83% of all patients suffering a recurrent stroke having an FDG standardized uptake value greater than this threshold.[42]

Other Roles

PET-CT has no role in the evaluation of vertebrobasilar disease, screening, the evaluation of trauma, perioperative management, or in the evaluation of carotid body/glomus tumors.

Accuracy and Limitations in Clinical Practice

While becoming more commonplace in Oncology Units, CT-PET for carotid disease is currently limited by inaccessibility, high cost, and lack of relevance to clinical practice.

COMPUTED TOMOGRAPHY ANGIOGRAPHY

Indications

Carotid Artery Disease

CTA is less likely to overestimate stenosis severity, compared with MRA. Since the HTA meta-analysis in 2006, 64, 256 and 320 section MDCTA have now been developed and are widely available. MDCTA has revolutionized the role of CTA because it is (1) extremely fast (5 seconds to perform scan from aortic arch to COW) (Fig. 88.7), (2) it is cheaper than CEMRA, (3) it offers submillimeter spatial resolution (0.3 mm spatial resolution compared with 0.8 mm for CEMRA and 0.2 mm for DSA), (4) it has sophisticated imaging workstations that enable the production of high-quality 2D and 3D reformatted images from the aortic arch to COW, which are easy to interpret (see Fig. 88.5), (5) it offers faster processing times, (6) it can visualize soft tissue, bone, and vessel at the same time, (7) it can rapidly demonstrate vascular anomalies, even if occluded (Fig. 88.8), and (8) it is able to provide data regarding the extent of vessel calcification, especially in the aortic arch (Fig. 88.9). Because of these characteristics, it is now possible to define extra- and intracranial vascular anatomy in combination with brain imaging during one period of data acquisition. By utilizing rapid advances in software and hardware, combined with bolus tracking, imaging can be achieved with a lower radiation dose and with reduced contrast.

Vertebrobasilar Disease

Imaging the VAs has always presented a challenge (see Fig. 88.7). The VA has a tortuous course, a thick bony covering, adjacent veins, and a large variation in normal vessel caliber,

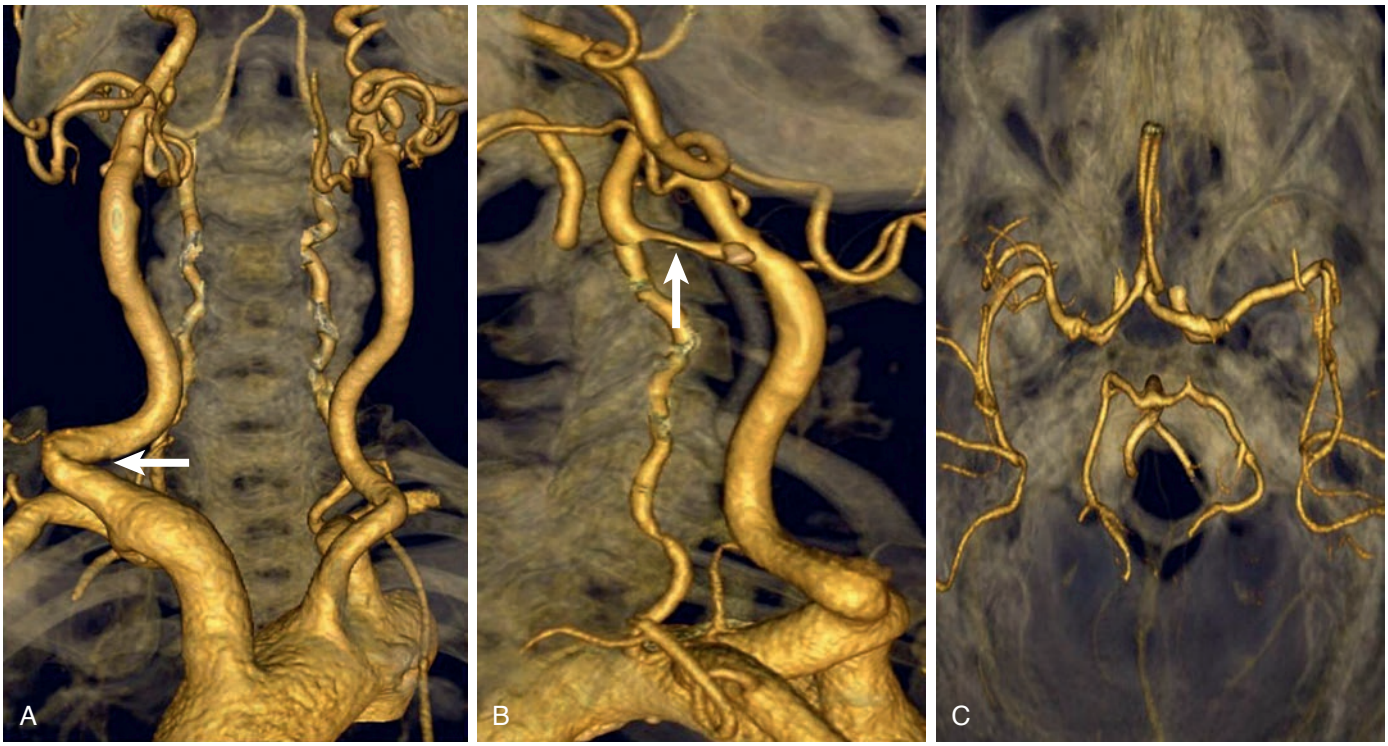

Figure 88.7 Multidetector computed tomographic angiography of the aortic arch and great vessels (A), carotid and vertebral arteries (B), and circle of Willis (C). This scan took 10 seconds to acquire. Note the acutely angled right common carotid artery (CCA; A, *arrow*), which would pose a significant challenge to safe passage of a wire and sheath for carotid artery stenting. The left CCA is less angulated and would not pose such a problem. A severe, relatively smooth stenosis is seen in the internal carotid artery (B, *arrow*).

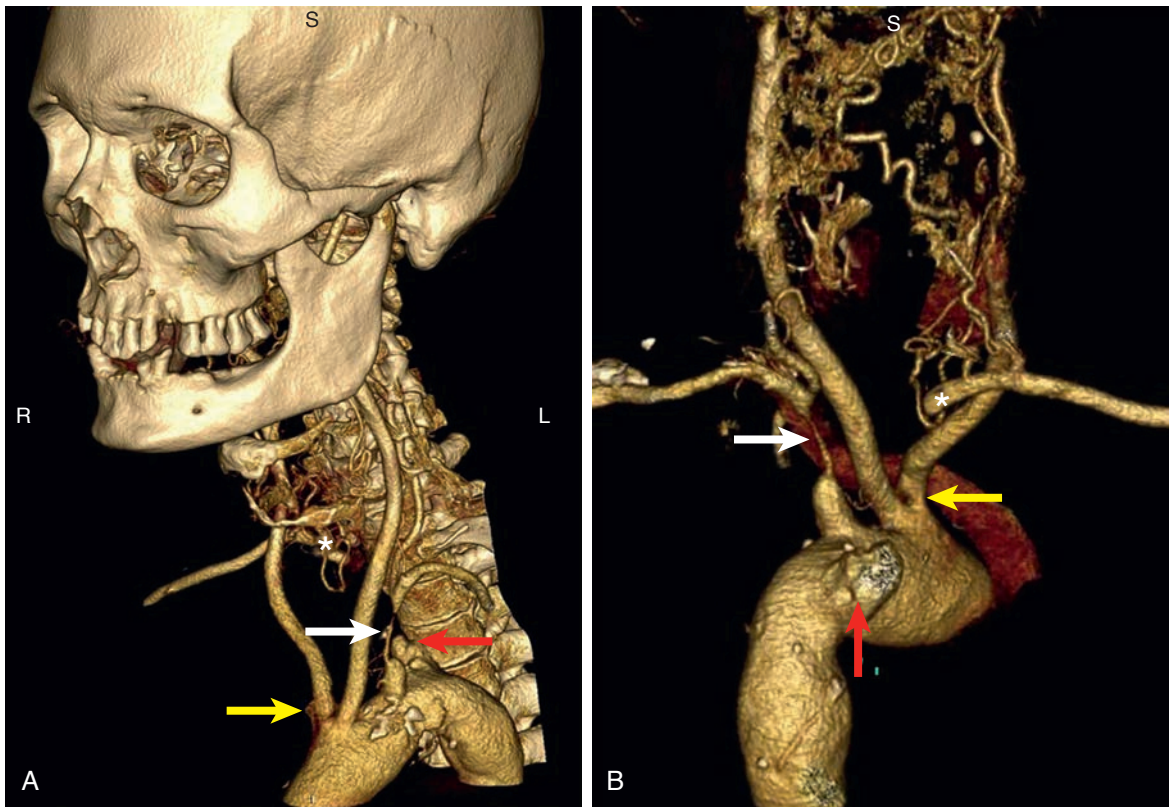

Figure 88.8 Multidetector computed tomographic angiography showing an unexpected anomaly of the great vessels of the aortic arch. (A) Arch viewed from its anterior aspect. (B) Arch viewed from its posterior aspect. Both common carotid arteries arise from a joint origin *(yellow arrow)*, and there is a long, severe stenosis of the proximal left subclavian artery *(white arrow)*. The right subclavian artery arises from an aberrant position and is occluded just beyond its origin *(red arrow)* with refilling distally *(asterisk)*. The *red arrow* marks the "diverticulum of Kommerl."

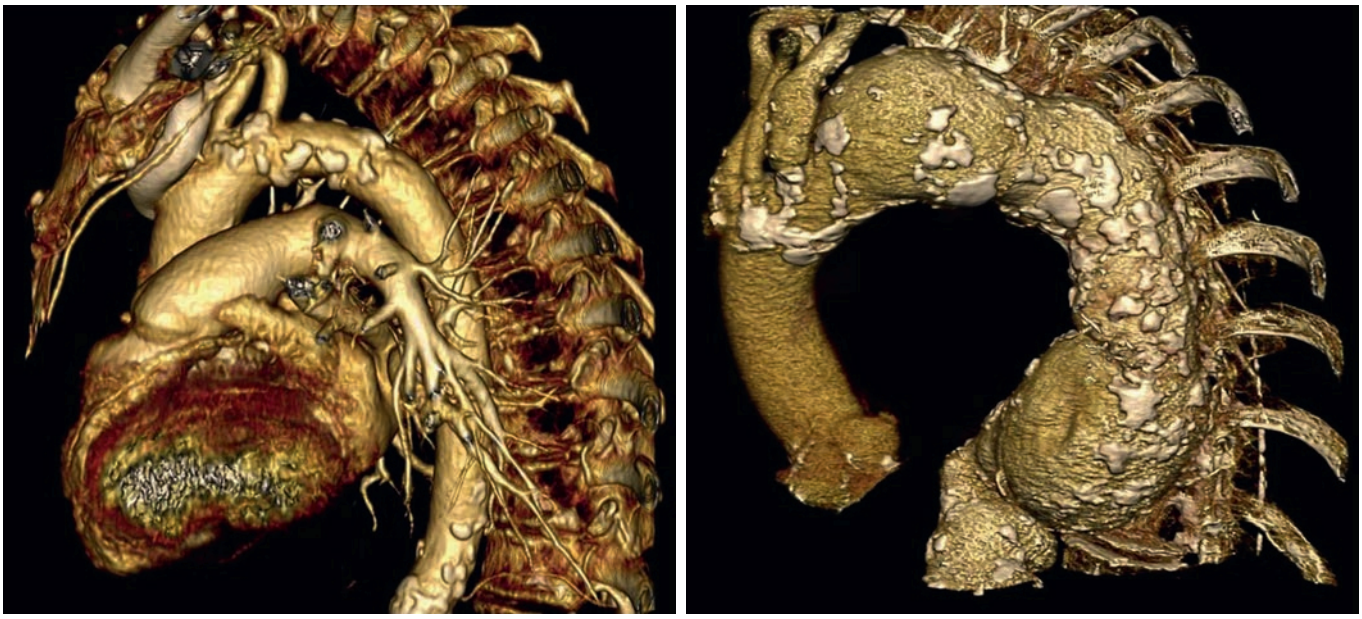

Figure 88.9 Volume rendition multidetector computed tomographic angiography showing calcification in the thoracic aorta, aortic arch, and origins of the great vessels.

and it is not unusual to find that one is hypoplastic. MDCTA provides better images of the extra- and intracranial vertebrobasilar system than CEMRA. An important advantage of MDCTA is that it retains bony landmarks (see Fig. 88.7) and vessel coverings (which can then be "virtually dissected off" as required). Automated subtraction enables easier evaluation of the VAs (and the internal carotid arteries) as they pass through bony structures. In this technique, a low dose scan is obtained immediately prior to the contrast angiogram. The two scans are coregistered and bone and calcified structures from the low dose mask image are automatically subtracted from the post-contrast images, leaving the vessels and soft tissues behind.[43] Vessel tortuosity is easily demonstrated, and there is no problem with artifact at the VA origins. MDCTA cannot, however, provide information regarding flow directionality.

Role in Screening

There is no role for CTA as a screening tool, as it is not cost-effective and it would be unethical to expose patients to the radiation involved.

Role in the Evaluation of Trauma

MDCTA has an important role, because it can rapidly provide anatomical vascular images from the arch to COW, together with bony, soft tissue, and functional brain imaging during a single scan, even in a ventilated patient. CT angiography and venography of neck structures are easily incorporated into trauma whole body CT scan protocols for comprehensive vascular assessment.

Role in the Evaluation of Carotid Body/Glomus Tumors

Due to its better spatial resolution and easy interpretation, MDCTA is the optimal imaging modality for evaluating tumor circulation (see Fig. 88.6), tumor extent, whether it is bilateral, and the relationship between tumor and adjacent soft-tissue structures. This information is usually more than enough to plan a safe surgical resection and can be relied upon to warn when a high or difficult dissection might be encountered (i.e., enabling the surgeon to plan for temporomandibular subluxation as required).

Role in the Planning of Carotid Endarterectomy and Carotid Artery Stenting

Most CEAs can be performed without CTA. However, if there is evidence of inflow/outflow disease or excessive calcification on DU, MDCTA can reliably provide the additional information to plan management. MDCTA is currently the optimal non-invasive imaging modality for planning CAS (see Table 88.2). This is partly because of the production of easily interpretable 3D images from aortic arch to COW (see Fig. 88.7) and because of the ease of demonstrating vessel tortuosity (see Fig. 88.7), abnormalities of the COW (see Fig. 88.7), patterns of calcification in the aortic arch (see Fig. 88.9), and status of the great vessel origins (see Fig. 88.5). Unlike CEMRA, MDCTA is unaffected by occluded anomalous vessels arising from the arch (see Fig. 88.8). Procedural risks after CAS increase with age, and this is probably related to progressive calcification/tortuosity of the arch and great vessels. This can lead to difficulties in accessing the carotid arteries with guidewires and sheaths (see Fig. 88.9). While many of the adverse features detailed in Table 88.2 may not "deter" the experienced interventionist, they should help the less experienced operator (on his/her learning curve) to identify unsuitable or suboptimal cases for CAS.

In a preceding section (see Table 88.4), the presence of infarction on CT/MR was predictive of an increased risk of stroke in the first few days after onset of TIA or minor stroke symptoms,[23] irrespective of the ABCD^2 score. This should alert the surgeon

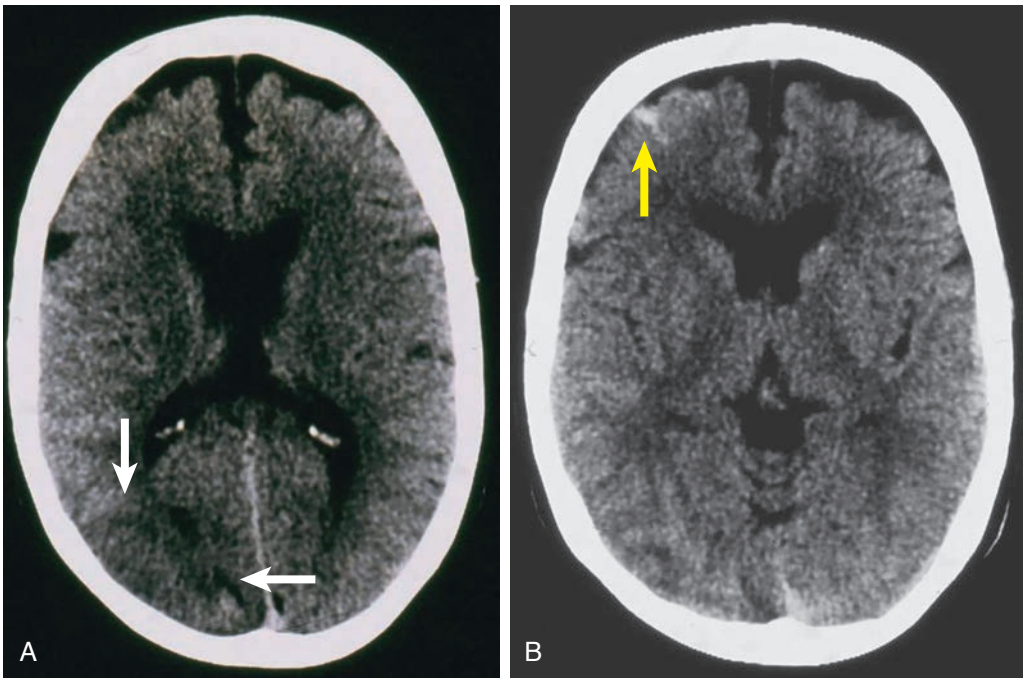

Figure 88.10 Computed tomography (CT) scan in a patient who underwent right carotid endarterectomy and was seen 5 days later with seizures, hypertension, and left-sided weakness. The CT scan revealed an area of white matter edema in the right posterior circulation (A, *arrows*) and a focal petechial hemorrhage in the right frontal region (B, *arrow*). White matter edema in the posterior circulation is not an uncommon finding in this syndrome and is often mistaken for an evolving infarct. (Reproduced with permission from Naylor AR, Evans J, Thompson MM, et al. Seizures after carotid endarterectomy: hyperperfusion, dysautoregulation or hypertensive encephalopathy? *Eur J Vasc Endovasc Surg.* 2003;26(39).)

of the need to consider expedited CEA. In addition, ACSRS has reported that the presence of "silent" infarction on CT (in asymptomatic patients with 50%-99% stenoses) was associated with an increased annual risk of stroke on medical therapy (3.6%) compared to 1.0% in patients with no infarction.[44]

Role in Evaluating Plaque Morphology

The available evidence suggests that MR is better than CT at visualizing thrombus, the fibrous cap, and its rupture (largely because MRI is better than CT at differentiating soft tissues structures), but MDCTA may be better at identifying plaque ulcers.[45] Intraplaque hemorrhage (provided it is >1 mm in diameter) can be visualized indirectly on MDCTA, but it is not as reliable as MR. In addition, MDCTA can measure carotid artery wall thickness (CAWT) with a thicker (>1 mm) CAWT being associated with an increased risk of stroke.[46]

Perioperative Roles

There is no role for CTA in the intraoperative management of patients with cerebral vascular disease.

Postoperative Roles

MDCTA has an important role in the evaluation of patients suffering a neurologic deficit after CEA/CAS. In the first 12 hours, the likelihood of intracranial hemorrhage (ICH) is remote. Accordingly, the patient should be considered for reexploration, and this should not be delayed to perform a CT scan (in most circumstances). However, because MDCTA can be performed rapidly, it may be useful in selected cases of early postoperative neurologic deficit, especially if a completion DU or DSA was normal and intracranial embolism is suspected. After 12 hours, there is an increased likelihood that the stroke was due to ICH or the hyperperfusion syndrome. In this situation, it is important to avoid an unnecessary (and potentially dangerous) return to the operating room. An emergency CT scan will exclude ICH but may demonstrate features associated with the hyperperfusion syndrome (Fig. 88.10). In the latter situation, middle cerebral artery velocities are generally elevated (usually in association with hypertension), and it is not unusual for the CT scan to display areas of low-attenuation (usually in the posterior fossa) that are often misinterpreted as evolving infarction.[35] DWMRI studies have shown that the white matter edema seen in the hyperperfusion syndrome on CT is vasogenic (if it was an evolving infarct, it would be cytotoxic), while perfusion studies show no loss of blood supply.[46] Why the hyperperfusion syndrome causes vasogenic edema predominantly in the posterior circulation has never been adequately explained.

Once ICH and hyperperfusion syndrome have been excluded, the possibility remains that the neurologic deficit was thromboembolic (see section on Transcranial Doppler/Duplex). Duplex imaging of the carotid bifurcation can be difficult to interpret in the early postoperative period (air in deeper tissues, edema, overlying hemostatic gauze), and it may not be possible to exclude an intraluminal filling defect. In this situation, MDCTA will quickly provide high quality images of the extracranial circulation, which will not unduly delay the patient from

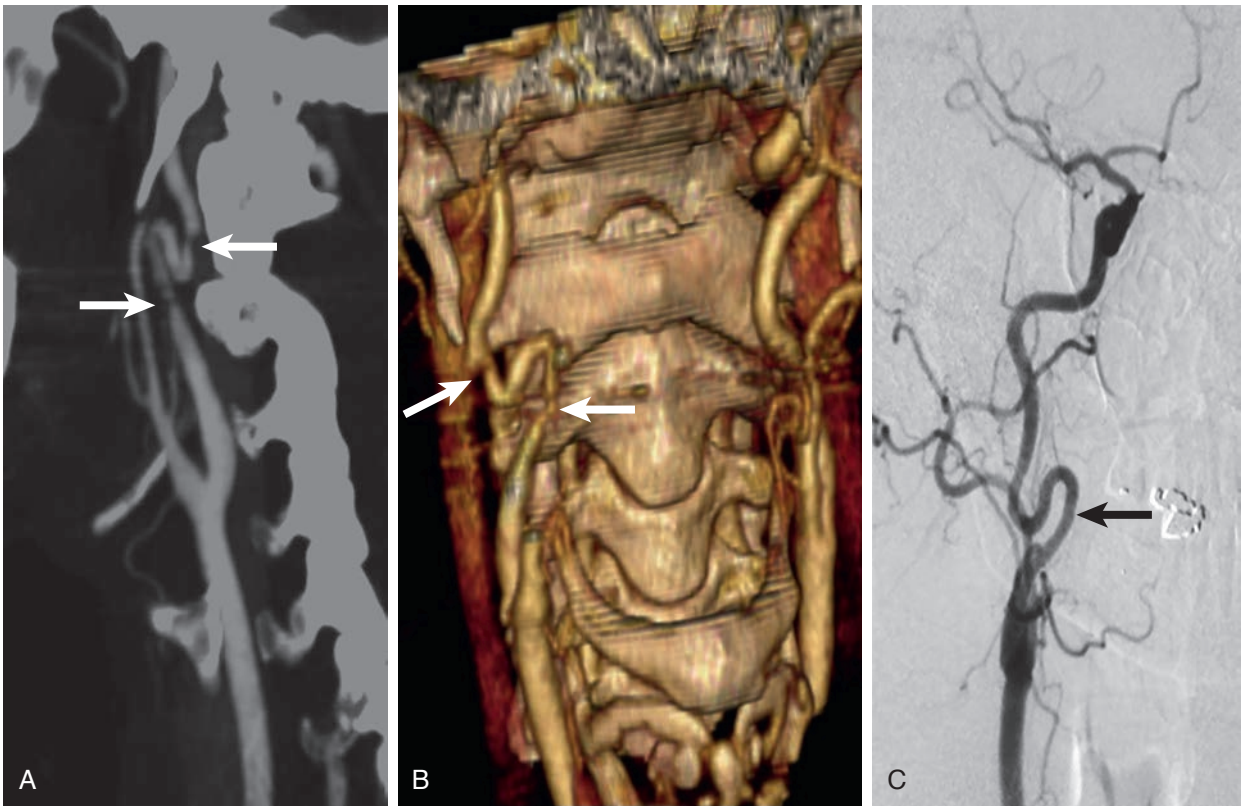

Figure 88.11 Image processing in patients with distal internal carotid artery (ICA) loops can lead to the creation of artifacts that can be interpreted as clinically important stenoses. (A) Multidetector computed tomographic angiography (MDCTA) maximum intensity projection; note the normal bifurcation and a distal looped ICA with apparent inflow and outflow stenoses (*arrows*). (B) Three-dimensional MDCTA in the same patient suggesting that the stenoses were real (*arrows*). (C) Selective intraarterial digital subtraction arteriography showing the looped ICA *(arrow)* but no stenoses. The "stenoses" identified on A and B were caused during image processing.

returning to surgery if necessary. Finally, MDCTA does not have a routine role in serial surveillance after CEA and CAS. This is better achieved using DU.

Contraindications

A history of allergy or reaction to iodinated contrast agents may be a contraindication to CTA, although in milder cases, parenteral steroid therapy may allow safe test completion. Caution must be exercised in patients with impaired renal function who require intravenous hydration beforehand.

Limitations in Practice

MDCTA has superseded previous CT technologies and is becoming the "new" gold standard. Notwithstanding, MDCTA is limited by the need for intravenous contrast, a risk of contrast-related nephropathy (hence the occasional need for hydration), not being able to provide information on flow directionality, and the exposure to radiation. Newer CT scanners, however, have automatic exposure control systems that continuously modulate the x-ray tube (based on patient size and tissue density) enabling potential reductions in radiation dose. Finally, there are occasional situations where MDCTA (and CEMRA) cannot reliably provide accurate and diagnostic imaging information in selected complex patients, especially those with tandem syphon disease or stenoses within coiled segments of the ICA (Fig. 88.11). In these cases, high quality selective carotid DSA imaging remains the "gold standard" (see later).

DIGITAL SUBTRACTION ANGIOGRAPHY

Indications

Conventional catheter angiography was previously the "gold standard" prior to surgery (see Chapter 25). Used in four out of five randomized trials comparing CEA with best medical therapy, its easily interpreted images found favor among surgeons and neurologists. However, the performance of angiography is not without potential risks. In the Asymptomatic Carotid Atherosclerosis Study (ACAS),[47] angiographic related stroke accounted for 50% of the procedural risk after CEA. In a review of complications following 23,416 carotid angiograms,[48] groin hematomas occurred after 4% of procedures, while 2.6% of patients suffered a transient or permanent neurologic deficit. The prevalence of anaphylaxis was 0.03%, while death complicated

0.06% of all carotid angiograms. The risk of suffering a neurologic deficit after catheter angiography was significantly higher in patients with carotid atherosclerosis (hazard ratio 2.5 [95% CI 1.9-3.3]) and in patients with frequent TIAs (hazard ratio 1.7 [95% CI 1.3-2.1]). The prevalence of TIA following angiography in 7614 patients with atherosclerotic carotid disease was 3.2%, while minor strokes occurred in 0.6% and permanent strokes occurred in 0.2%. Angiography-related neurologic deficits have significantly declined with time (reflecting better case selection and improved technology and techniques) from 3.8% in 1988 to 0.6% in 2003.

Carotid Artery Disease

There is no role for routine catheter angiography in modern cerebrovascular practice. However, there are still situations where intraarterial digital subtraction angiography (IADSA) can provide valuable diagnostic information (see Fig. 88.11). Improvements in CEMRA and (especially) MDCTA mean that it is rarely necessary to undertake IADSA to look at the origins of the great vessels (see Figs. 88.5 and 88.8). Similarly, MDCTA can reliably image patients with heavily calcified plaques in the arch or great vessel origins (see Fig. 88.9). However, CEMRA and MDCTA can provide misleading information in patients with severe distal ICA disease (Fig. 88.12) and in patients where there is marked coiling of the ICA in the upper reaches of the neck (see Fig. 88.11). In the former, slow flow through a tiny lumen can be missed. In the latter, unless extreme care is taken with image processing (i.e., ensuring that the axial measurements are in a true perpendicular cross-sectional plane), it is possible that an artifact introduced during image processing can lead to the surgeon or interventionist being persuaded that significant carotid disease exists. Advances in automated bone removal techniques, as described above, or using dual source CT scans, may be useful in such circumstances.[43]

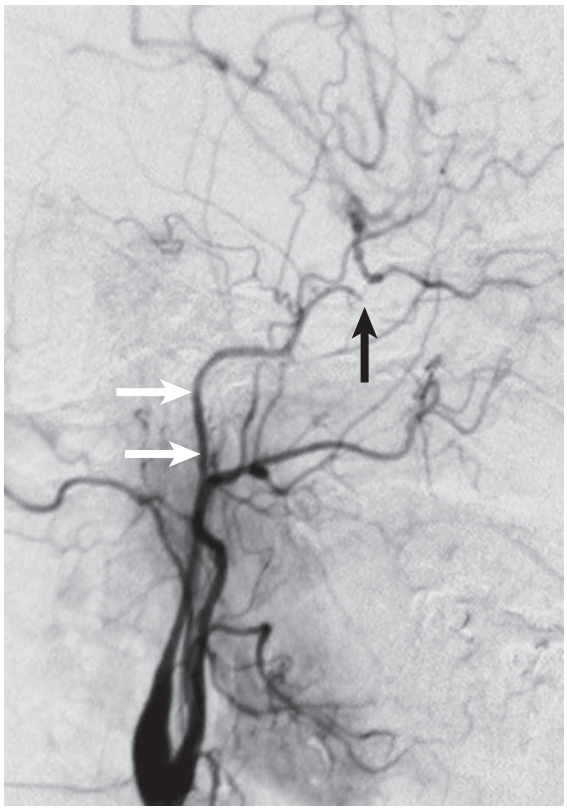

Figure 88.12 Selective intraarterial digital subtraction arteriography (IADSA) in a 38-year-old woman with stroke (middle cerebral territory infarct on computed tomography scan). Duplex ultrasound showed slow, high-resistance flow in the carotid artery but a normal bifurcation. Contrast-enhanced magnetic resonance angiography suggested a subocclusion but could not image the distal internal carotid artery (ICA). This delayed IADSA image shows a normal-caliber carotid bifurcation with a narrow-caliber ICA in its midsection (*white arrows* where flow was extremely slow). In the very distal ICA *(black arrow)*, vessel diameter dwindles toward complete occlusion. The images are probably consistent with acute dissection and compression of the true lumen by thrombus in the false lumen.

Vertebrobasilar Disease

There is no role for IADSA in the routine investigation of patients with suspected vertebrobasilar disease.

Role in Screening

There is no role for IADSA as a screening tool in vertebrobasilar disease.

Role in Trauma

Angiography was previously the first-line imaging modality in patients with a suspected extracranial arterial injury. This role has, however, been superseded by MDCTA, which can perform a diagnostic study from arch to COW in 5 seconds. However, IADSA remains an important secondary option in situations where image quality is compromised or difficult to interpret. Furthermore, angiography retains the unique distinction of allowing one to proceed with endovascular interventions (coil/balloon occlusion, insertion of a covered stent).

Role in the Evaluation of Carotid Body/Glomus Vagale Tumors

There is no role for IADSA in the routine evaluation of patients being considered for resection of CBTs and GVTs. It provides no information on the overall extent or operability of the lesion. However, preoperative embolization of ECA feeding vessels is considered by some to reduce perioperative bleeding (Fig. 88.13), while insertion of a covered stent into the ECA can significantly reduce bleeding in patients with very large tumors.[49]

Role in the Planning of Carotid Endarterectomy/Carotid Artery Stenting

Most centers now perform the majority of CEAs without preoperative IADSA and without compromising patient safety, and the surgeon rarely encounters operative scenarios that cannot be addressed.[1] In reality, the safe performance of CEA does not depend on preoperative imaging of inflow or distal vessels (unless the DU scan suggests an abnormal flow pattern) and there is no evidence that imaging the intracranial circulation alters outcome.

In contrast, some CAS practitioners have been reluctant to dispense with diagnostic IADSA (usually an arch angiogram) as part of the routine work-up of their patients. Advocates of this strategy must, however, remember that the need for a diagnostic angiogram (in place or in addition to CEMRA/MDCTA) will inevitably delay treatment and so potentially

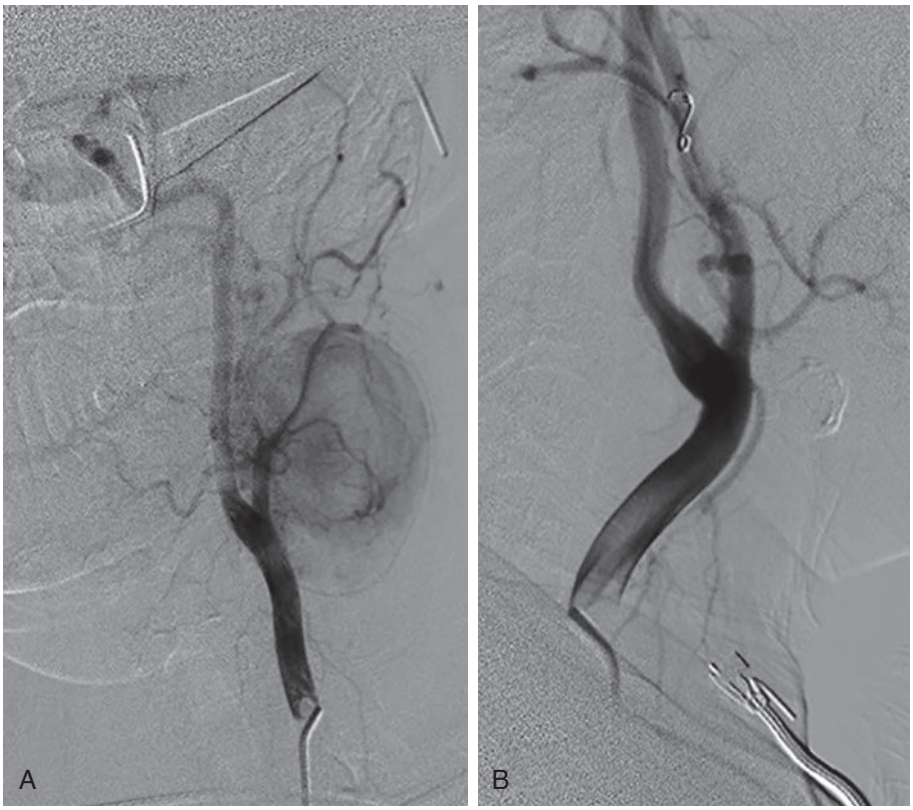

Figure 88.13 (A) Preoperative intraarterial digital subtraction arteriography of carotid vessels in a patient with a large carotid body tumor. Most of the tumor circulation is derived from external carotid artery (ECA) branches. (B) All major feeding ECA branches have been coiled. The patient went direct from the Angio suite to the operating theater for an uneventful tumor resection.

reduce the overall effectiveness of CAS in recently symptomatic patients while also exposing the patient to two catheterization procedures. The advent of CEMRA and (especially) MDCTA with the drive towards expedited treatment in symptomatic patients has probably rendered this practice obsolete. In practical terms, this could mean that a patient may be worked very rare occasions up for CAS solely based on CEMRA/MDCTA only to have the procedure abandoned following the diagnostic IADSA that immediately precedes the planned CAS procedure. In reality, this is unlikely to happen due to excellent preinterventional imaging and planning.

Role in Evaluating Plaque Morphology

DSA has no role in evaluating plaque morphology other than demonstrating that surface irregularity and angiography are not particularly good at identifying intraluminal thrombus.[50] Although NASCET and ECST showed that plaque irregularity (using angiography) was associated with an increased risk of stroke in medically treated patients, as well as an increased risk of major cardiac events during follow-up,[50] there is no evidence to justify IADSA for plaque morphology evaluation.

Perioperative Roles

Intraoperative completion angiography can identify technical errors (intimal flaps, luminal thrombus, residual stenoses) following flow restoration, but it has been superseded by color DU imaging (facilitated by dedicated "L"-shaped probes) or angioscopy. Completion angiography can be cumbersome; it requires the presence of a C-arm and radiology technician in the operating room and (for most patients) represents an unnecessary exposure to radiation.

On table angiography does, however, retain a useful diagnostic role in the rare patient who suffers a stroke due to carotid thrombosis or acute distal dissection in the early postoperative period after CEA/CAS. After CEA, the key to ensuring the best outcome is early reexploration (preferably within 1 hour). At reexploration, it is not uncommon to find a "pulse" in the ICA (suggesting to the unwary surgeon that the vessel is still patent). In this situation, it is important to avoid manipulation of the bifurcation, as this can precipitate major embolization. Despite the apparent "pulsation," it is not unusual for an angiogram to demonstrate complete occlusion. Angiography can also identify the very rare case of acute distal dissection that may follow shunt trauma. In the latter situation, the diagnostic angiogram can be followed by insertion of a stent/covered stent into the true lumen, while embolic occlusion of intracranial vessels can be treated by intraarterial, low dose thrombolysis, or catheter-directed embolus retrieval.

Thromboembolic stroke in the first few hours after CAS raises the possibility of in-stent thrombosis (Fig. 88.14). For a detailed discussion of CAS and prevention/ management of complications, please see Chapter 92.

Postoperative Roles

There is no role for IADSA in the serial surveillance of patients after CEA or CAS.

Contraindications

Previous allergic reaction to iodinated contrast media is a contraindication.

Figure 88.14 Selective intraarterial digital subtraction arteriography in a patient who had undergone uneventful carotid stenting of an extensive symptomatic plaque at the origin of the internal carotid artery. He was readmitted on day 5 with extensive hemiplegia. This image shows extensive in-stent thrombosis.

Accuracy and Limitations in Clinical Practice

IADSA now has a "supporting role" because of radiation exposure, delays to performing studies, and the risk of neurologic deficits. IADSA is also associated with a small risk of access complications (bleeding, dissection, thromboembolism) and contrast-induced nephropathy.

TRANSCRANIAL DOPPLER

Indications

Carotid Artery Disease

TCD can provide a simpler evaluation of the hemodynamic effect of a stenosis (compared to PET) by measuring the proportional increase in middle cerebral artery (MCA) velocity in response to intravenous administration of Acetazolamide (a cerebral vasodilator). TCD is, however, the only modality capable of diagnosing spontaneous in-vivo embolization. This is because the embolus reflects more back-scattered signal than red cells, and despite initial skepticism, there are now validated criteria for diagnosing embolization and for excluding artifacts.[51] Embolization is more commonly encountered in the MCA ipsilateral to a symptomatic carotid stenosis, and this is indicative of an unstable plaque. Recognition of this phenomenon should prompt the surgeon to undertake an expedited CEA, and although it seems intuitive that these patients might be suboptimal candidates for CAS, this has never been properly evaluated.

TCD diagnosed spontaneous embolization may, however, assume an increasingly important role in identifying a "high risk for stroke" cohort of patients with asymptomatic carotid disease. A meta-analysis of six observational studies (1144 patients with an asymptomatic 70%-99% stenosis) observed that the presence of a single embolic signal during one hour of TCD monitoring was associated with a near eightfold increase in stroke during follow-up (odds ratio 7.6 [95% CI 2.3-24.7]).[52] Interestingly, patients with Geroulakos type I/II plaques (see Table 88.3) and evidence of spontaneous embolization at baseline had an annual stroke rate of 8.9%, versus 0.8% in the remaining patients.[53]

Spontaneous embolization rates are significantly higher in recently symptomatic patients, especially in the hyperacute period, reflecting underlying plaque instability. In a study involving 123 recently symptomatic patients, 43% who underwent CEA within seven days of symptom onset had evidence of spontaneous embolization (preoperatively), decreasing to 22% in patients who underwent CEA 8 to 14 days after onset of symptoms and 16% in patients whose CEA was performed greater than 14 days after onset of symptoms. Interestingly, 23% of symptomatic patients with spontaneous embolization on their admission TCD went on to suffer recurrent neurologic events prior to surgery.[54] In terms of predicting 90 day rates of recurrent stroke, the presence of spontaneous embolization on TCD at baseline in symptomatic patients was associated with a threefold excess risk (OR 3.35 [95% CI 1.7-6.7]).[55]

Vertebrobasilar Disease

One practical role for TCD (in the vertebrobasilar circulation) involves patients who report isolated dizziness or vertigo following head movements. In the past, many were labeled as having suffered "vertebrobasilar TIAs" due to compression of the VAs within the transverse processes of the upper cervical vertebrae during neck movement. Subsequent research has shown this to be rarely the case. In a series of 46 "symptomatic" patients undergoing extracranial DU and intracranial TCD with the head rotated into provocative positions, not one patient exhibited flow reversal or flow reduction,[56] suggesting that most historical cases were probably misdiagnosed. In reality, most have inner ear pathologies.

Role in the Evaluation of Trauma

TCD has no proven role in the management of trauma other than being used to monitor the effect of intraoperative carotid ligation/endovascular balloon occlusion in an unconscious patient should reconstruction prove impossible or to determine whether any vessel injury is associated with distal embolization. During CEA, provided mean MCAV is greater than 15 cm/s, most will tolerate carotid ligation (balloon occlusion) without suffering a stroke.[57] Whether this velocity threshold also applies to head trauma patients has never been evaluated.

Intraoperative Monitoring

The main reason that monitoring and quality control assessment has failed to gain wider acceptance is a simple failure to ask the appropriate questions.[58] TCD warns of embolization

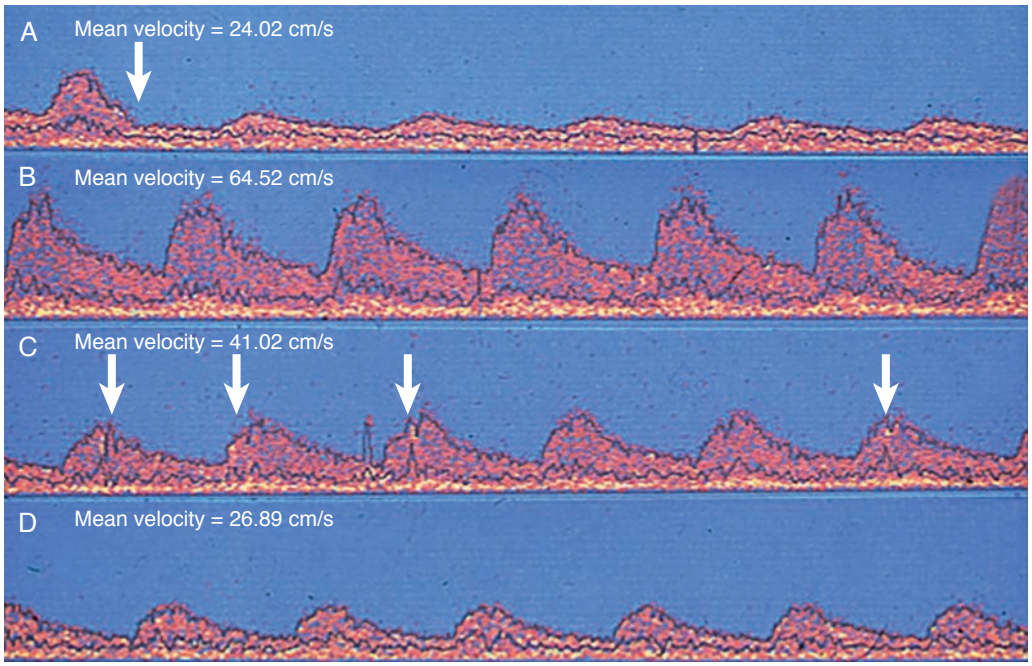

Figure 88.15 Transcranial diagnosis of a patient suffering an on-table carotid thrombosis. (A) Last cardiac cycle *(arrow)* before the carotid clamp is applied. After clamping, middle cerebral artery (MCA) velocity falls to 24.02 cm/s. (B) MCA waveform after restoration of flow (i.e., after endarterectomy). MCA velocity is now 64.52 cm/s. (C) Increasing embolization is detected within 12 minutes of restoration of flow *(arrows)* which is associated with a gradual decline in MCA velocity. (D) Within 23 minutes of restoration of flow, the internal carotid artery is occluded, as demonstrated by the fact that MCA velocity (26.89 cm/s) is now virtually identical to that noted during carotid clamping (A).

(enabling the surgeon to modify technique), but it cannot prevent stroke due to embolization of luminal thrombus following restoration of flow.

Accordingly, TCD has only four roles during CEA:[58](1) determining if there is spontaneous embolization during operative carotid exposure (i.e., warning the surgeon of an unstable plaque), (2) determining if the shunt is working (3% malfunction following insertion),[59] (3) determining if MCAV is greater than 15 cm/s (if not flow can be increased by pharmacological elevation of blood pressure), and (4) determining if this patient is one of the very rare ones destined to thrombose their ICA before the operation is completed (Fig. 88.15). At present, the role of TCD monitoring during CAS has not been clarified, but the potential to answer some of the questions posed above during CEA could also be relevant for CAS.

Role in Evaluating Postoperative Strokes

TCD has a useful (but unexploited) role in determining the cause of intra- and postoperative stroke. Intraoperative stroke mostly follows inadvertent technical error. Hemodynamic failure accounts for only 20% of intraoperative events, with the remainder being thromboembolic.[58] In a large, prospective audit, intraoperative stroke was virtually abolished using TCD and completion angioscopy.[58] Although intimal flaps were occasionally diagnosed on angioscopy, 5% of patients had retained luminal thrombus (despite venting and irrigation) that was derived from transected vasa vasorum.[58]

For those without the availability of angioscopy or other quality control methods, the patient wakening with a new neurologic deficit poses a considerable management dilemma. However, if TCD-derived MCA velocity is now the same as observed during carotid clamping, it is highly likely that the carotid artery has thrombosed (see Fig. 88.15). If MCA velocity is unchanged but with ongoing embolization, it is likely that there is an evolving thrombus within the endarterectomy zone. Both scenarios warrant immediate reoperation.

The etiology of postoperative stroke is multifactorial. After 24 hours have elapsed, most follow ICH or the hyperperfusion syndrome. Unfortunately, no TCD protocol has been developed to reliably anticipate and prevent either of these. In the first 24 hours after CEA, postoperative carotid thrombosis (POCT) remains the most frequent etiology of stroke.[58] Previously considered unpredictable, there is now growing evidence that it is probably related to patient mediated factors (e.g., increased platelet sensitivity to ADP) and may be preventable.

In the past, the Leicester Unit performed TCD monitoring for three hours after CEA.[57] The aim was to identify the 5% cohort of patients with high-rates of early postoperative embolization (who faced a 50% risk of progression onto thrombotic stroke) in whom to target incremental dose Dextran therapy.[58] However, a randomized trial subsequently showed that the addition of a single 75 mg dose of Clopidogrel the night before surgery (in addition to routine aspirin therapy) virtually abolished postoperative embolization. Routine postoperative TCD

monitoring ceased in 2009, all patients now receive dual antiplatelet therapy and none have suffered a postoperative thrombotic stroke.[58]

INTRODUCTION

Despite extensive clinical experience, including several prospective randomized trials comparing carotid endarterectomy (CEA) to "best" medical therapy (BMT), providing a large body of level 1 evidence, there is still controversy regarding the indications for carotid intervention for the prevention of stroke.

Clinical Implications of Carotid Stenosis and Goals of Therapy

Patients with evidence of extracranial carotid stenosis have an increased overall risk of cardiovascular events, including stroke. Therefore the identification of extracranial carotid stenosis should prompt a program of BMT, including control of hypertension, antiplatelet and statin therapy, as well as smoking cessation.[1] Approximately 20% of ischemic strokes are due to extracranial carotid stenosis, whereas only about 15% of strokes are preceded by a warning transient ischemic attack. An estimated 13 million Americans have evidence of silent cerebral infarction.[2] Therefore the identification of carotid stenosis in a patient provides an important opportunity to intervene with the goal of stroke prevention.

The most important initial step in clinical evaluation is the identification and accurate quantification of carotid bifurcation disease, expressed as the percent diameter stenosis. In a neurologically symptomatic patient, the presence of "significant" carotid bifurcation disease is a target for intervention, whereas its absence should prompt a search for another source of symptoms. In a neurologically asymptomatic patient, the presence of "significant" carotid bifurcation disease, as defined further on, should prompt the institution of BMT, patient education on the signs and symptoms of stroke, and consideration of carotid intervention. The most common and cost-effective method to identify carotid bifurcation stenosis is duplex ultrasound. This should be performed in all patients in whom extracranial cerebrovascular disease is suspected (see Chapter 21).

TREATMENT OPTIONS WHEN CAROTID BIFURCATION STENOSIS IS IDENTIFIED

When a patient is identified as manifesting neurologic symptoms or harboring moderate to severe carotid bifurcation stenosis, BMT should be instituted. Whether or not to add intervention to BMT will depend on balancing three factors:

1. The estimated risk of stroke in a particular circumstance (combination of clinical scenario and plaque phenotype)
2. Assessment of patient-specific benefit (functional capacity, life expectancy)
3. Intervention-specific risk (both procedure- and operator-related)

TABLE 89.1 Effect of Risk Reduction and Best Medical Therapy on Stroke and Cardiovascular Events

Treatment	Goal	Comments
Antiplatelet therapy	Either single or dual drug acceptable	Reduces both stroke rate and overall MACEs
Antihypertensive therapy	Decrease BP by 10 mm Hg systolic 5 mm Hg diastolic or to 140/90 mm Hg with 130/90 mm Hg for recent lacunar in hypertensive patients	Reduces stroke recurrence Treat all patients regardless of baseline BP, after first 24 h
Diabetes mellitus	Aim for $HgbA_{1c}$ <7	Reduce overall stroke rate, no benefit in tight control
Smoking cessation	Total abstinence	Reduces stroke and MACEs
Statin therapy	Reduce LDL by 50% or <70 mg/dL	Treat hyperlipidemia and normolipemic patients with H/O stroke, may be beneficial before CEA/CAS
Alcohol	Avoid excessive consumption	

BP, Blood pressure; *CAS*, carotid artery stenting; *CEA*, carotid endarterectomy; *$HgbA_{1c}$*, glycosylated hemoglobin; *H/O*, history of; *LDL*, low-density lipoprotein; *MACEs*, major adverse cardiovascular events.

BEST MEDICAL THERAPY

Risk-Factor Reduction and Medical Management

A variety of clinical conditions have been associated with increased stroke risk: hypertension, diabetes, hyperlipidemia, smoking, and alcoholism. Efforts to control these conditions have been shown to reduce stroke risk in large population studies. In addition, treatment with antiplatelet agents and the use of statins have been shown to reduce long-term stroke risk and also overall cardiovascular morbidity and mortality. The current data on BMT have recently been recapitulated in a set of guidelines from the American Heart Association (Table 89.1).[3]

Blood Pressure Control

Control of blood pressure has been shown to reduce the overall risk of stroke and recurrent stroke in a number of studies.[4,5] This beneficial effect is seen in both hypertensive patients and those whose baseline blood pressure falls within the accepted guidelines. The one exception to this occurs in the first 24 hours after an acute stroke, where aggressive reduction of blood pressure should be avoided in order to optimize cerebral perfusion pressure. Efforts to reduce blood pressure after the first 24 hours should be made in all patients after stroke.[3] There is no definitive

benefit of one class of antihypertensive agents over another for stroke reduction.

Diabetes Mellitus

Diabetes is an independent predictor of recurrent stroke, with an incidence of 9%.[6,7] The potential advantage of "tight" glucose control (HgbA1c <7) in stroke reduction has been addressed in two large trials: ACCORD[8] and ADVANCE.[9] In the ACCORD trial, 251 patients were randomized between "tight" glucose control (HgbA1c ≤6) and routine control (HgbA1C <7). No benefit in stroke reduction or overall reduction in the rates of adverse cardiovascular events was seen with tight control, and there was an increased mortality rate in the tight control group (HR 1.22, CI 1.01-1.46). The ADVANCE trial randomized 11,140 patients between targets for HgBA1C of ≤6.5 and ≤7 and demonstrated no difference in stroke, overall cardiovascular events, or overall mortality (unlike ACCORD). These trials conclude that there was no benefit from increasing glucose control for diabetics for stroke prevention to levels below the recommended levels of Hgb A1c <7%.[10]

Lipid Management

Elevated cholesterol has been shown to be related to increased risk of stroke.[11-13] Statins exert both a lipid-lowering and anti-inflammatory effect and have been shown to reduce the risk of subsequent neurologic events in neurologically symptomatic patients as well in patients following carotid intervention.[14-16] Meta-analyses of major trials using statins in patients with hyperlipidemia revealed a strong correlation between reduction of low-density lipoprotein C (LDL-C) and a reduced risk of stroke.[17,18] However, the patients in most of these trials also had a history of cardiovascular disease. The Stroke Prevention by Aggressive Reduction in Cholesterol Levels (SPARCL) trial[14] tested the efficacy of atorvastatin (80 mg) on reducing the risk of subsequent stroke and the overall cardiovascular event rate in patients with a history of stroke or transient ischemic attack (TIA) but no evidence of cardiac disease and moderate elevations of LDL-C (100-190). At 5 years there was an absolute risk reduction for subsequent stroke in the atorvastatin group from 13.1% to 11.2% (RR = 0.84, $P = .03$) and an absolute reduction in overall cardiovascular risk of 3.5% (RR = 0.8, $P = .002$). There was an increased risk of hemorrhagic stroke in the atorvastatin group, primarily in patients who presented initially with hemorrhagic stroke. The most significant reduction of events was seen in patients with the more significant reductions in LDL-C. Patients whose LDL-C was reduced by more than 50% had a RR of 0.63 (CI 0.49-0.81) for developing subsequent stroke, whereas those whose LDL-C was below 70 had a RR of 0.72 (CI 0.59-0.89) compared with control patients.

There are no compelling data on the use of statins in stroke patients with a normal lipid profile and no evidence of cardiovascular risk factors. It is worth noting that none of these large population-based studies stratified patients based on the type of stroke or the status of their carotid arteries. Thus the data from these studies cannot be directly extrapolated to the asymptomatic patient with known carotid bifurcation stenosis.

Behavioral Modification

Smoking and excessive alcohol consumption have both been associated with increased stroke risk. Every effort to encourage smoking cessation should be made, including the use of pharmacotherapy.[19,20] Alcohol seems to have a bimodal effect, with mild alcohol consumption (<2 drinks per day) associated with a reduced risk of stroke, but excessive alcohol consumption (>2 drinks per day) should be discouraged.[3] There are no data to support encouraging the consumption of alcohol for stroke prevention. There are also no data documenting a relationship between obesity and stroke risk.

Metabolic Syndrome

This syndrome is defined by the coexistence of three of the following five factors: increased waist circumference (>102 cm for males, >88 cm for females), triglycerides greater than 150 mg/dL, high-density lipoprotein C (HDL-C) below 50 for males and below 40 for females, fasting blood glucose above 100 mg/dL, and blood pressure (BP) above 135 systolic and above 85 diastolic.[21] Patients with metabolic syndrome are known to have increased insulin resistance and are at increased risk for adverse cardiovascular events. Although there is an association between metabolic syndrome and increased stroke risk, it has not been shown to be additive to the individual risk factors that make up the syndrome.

Antiplatelet Therapy

Several studies have demonstrated the benefit of aspirin in secondary stroke prevention and over a wide range of aspirin doses (50-1500 mg).[22] The gastrointestinal side effects of aspirin increase with increasing dosage. Therefore a low dose of aspirin, such as 81 to 325 mg/d, is generally recommended. There is some evidence that enteric-coated aspirin is more frequently associated with aspirin resistance[22]; therefore low-dose non–enteric coated aspirin may be preferred. Dipyridamole has been combined with aspirin for stroke reduction in patients with a history of stroke or TIA. The European Stroke Prevention Study (ESPS-1) showed a benefit from 325 mg aspirin daily plus 75 mg dipyridamole thrice daily over placebo ($P < .001$). ESPS-2[23] compared low-dose aspirin (25 mg twice daily), extended-release dipyridamole (200 mg/d), and a combination of the two drugs to placebo. Both aspirin ($P = .013$) and dipyridamole ($P = .039$) reduced the risk of subsequent neurologic events compared with placebo, and the combination therapy was superior to either drug alone for the reduction of stroke ($P = .006$). However, headache and gastrointestinal symptoms were more common with combination therapy, an observation also made in the PROFESS study,[24] which showed no benefit from the combination of aspirin and dipyridamole over clopidogrel alone.

Ticlopidine (250 mg twice daily) has been shown to be effective in preventing recurrent cardiovascular events including stroke in patients with a history of prior stroke[25] and is similar to aspirin in its effectiveness,[25,26] with a slightly lower bleeding profile. The side effects of neutropenia and rarely thrombotic thrombocytopenic purpura associated with ticlopidine have

limited its clinical use. Clopidogrel has emerged as an alternative antiplatelet agent; as noted earlier, it has been shown to be as effective as the combination of aspirin and dipyridamole for stroke prevention.[24] Clopidogrel was compared with aspirin in the Clopidogrel versus Aspirin in Patients at Risk of Ischaemic Events (CAPRIE) trial,[27] which included 19,000 patients and demonstrated an overall cardiovascular event rate of 5.32% in the clopidogrel group versus 5.83% in the aspirin group ($P = .043$). Whether this is clinically significant enough to justify the increased cost of clopidogrel is a matter of clinical judgment. The MATCH trial[28] randomized patients with recent stroke or TIA to clopidogrel or clopidogrel plus aspirin. There was no incremental benefit of adding aspirin to clopidogrel therapy, but there was a 1.3% absolute increase in bleeding risk with dual therapy. The CHARISMA trial[29] compared aspirin alone with aspirin plus clopidogrel and found no difference between monotherapy with aspirin and dual therapy (HR 0.93, $P = .22$). The role of DAPT in patients who do not have a recently placed intravascular stent remains unsettled.[30,31] DAPT has been shown to reduce stroke rate (HR 0.61) but also to increase the rate of reexploration for bleeding (HR 1.71) in patients who undergo CEA, although the absolute risks remain low for both conditions.[30,31] In summary, antiplatelet therapy in patients with stroke or other manifestations of cardiovascular disease is beneficial in reducing both stroke risk and overall cardiovascular morbidity. The benefit of combining antiplatelet agents is modest at best. Resistance to aspirin or other antiplatelet agents clearly exists in some patients, and failure of therapy should prompt a change in agents or tests for drug resistance.[32] Newer drugs such as prasurgel may have a role, especially in patients with drug resistance.[33]

In clinical practice most patients are placed on aspirin (81 or 325 mg daily) alone, clopidogrel (75 mg daily), or a combination of these drugs. Currently routine testing of efficacy is not recommended and drug resistance is investigated only when symptoms recur on standard therapy. Either monotherapy or dual antiplatelet therapy is acceptable for patients prior to CEA, whereas DAPT (ASA aspirin and clopidogrel) is indicated prior to carotid angioplasty and stenting (CAS).

ESTIMATING THE STROKE RISK IN A PARTICULAR CLINICAL SCENARIO

Patient Characteristics

Prior Neurologic Symptoms

The most important indicator of future stroke risk is the presence of recent (within 6 months) ipsilateral neurologic symptoms. The stroke risk in the medical arms of the two major symptomatic carotid trials[34-36] was much higher than that seen in the medical arms of the two major asymptomatic trials (Table 89.2).[37,38] Furthermore, the North American Symptomatic Carotid Endarterectomy Trial Collaborators (NASCET) and European Carotid Surgery Trial (ECST) both demonstrated that stroke risk is highest within the first month after an initial neurologic event and then declines to approach that of an "asymptomatic" lesion by about 6 months.[39] The observed reduction in stroke risk as the initial event becomes more remote likely reflects "stabilization" or healing of the plaque over time either spontaneously or in response to medical therapy.

In symptomatic patients with high-grade (70%-99%) stenosis, the relationship of the stenosis to future stroke risk is so strong that a causal relationship can be assumed. However, in symptomatic patients with more moderate degrees of stenosis (50%-69%) the benefit of carotid intervention is not as great, implying that the relationship between the bifurcation lesion and stroke is not as clear. In these patients, therefore, other

TABLE 89.2 Results of Randomized Trials of Carotid Endarterectomy Versus Best Medical Therapy (NASCET, ECST, ACAS, ACST)

Study	Population Studied	Number of Patients	Stroke Rate BMT	Stroke Rate BMT+CEA	Study Conclusions
NASCET	Symptomatic patients with carotid stenosis ≥70%	649	26% (2 yr) 28% (5 yr)	9% (2 yr) 13% (5 yr)	CEA is beneficial for symptomatic patients with ≥70% carotid stenosis (P <.001)
NASCET	Symptomatic patients with carotid stenosis ≥50% to 69%	858	15% (2 yr) 22.2% (5 yr)	9% (2 yr) 15.7% (5 yr)	CEA is beneficial for symptomatic patients with ≥50% carotid stenosis ($P = .045$)
ECST	Symptomatic patients with carotid stenosis 80%-99% ECST (=60%-99% by NASCET)	1279	20.6% (3 yr)	6.8% (3 yr)	CEA is beneficial for symptomatic patients with 60% carotid stenosis (NASCET) (P <.0001)
ACAS	Asymptomatic patients with carotid stenosis ≥60%	1662	11% (5 yr)	5.1% (5 yr)	CEA is beneficial for asymptomatic patients with ≥60% cartoids stenosis ($P = .004$)
ACST	Asymptomatic patients with carotid stenosis ≥60%	3120	11.8% (5 yr)	6.4% (5 yr)	CEA is beneficial for asymptomatic patients with ≥60% cartoids stenosis (P ≥.0001)

ACAS, Asymptomatic carotid atherosclerosis study; *ACST,* asymptomatic carotid surgery trial; *BMT,* best medical therapy; *ECST,* European Carotid Surgery Trial; *NASCET,* North American Symptomatic Carotid Endarterectomy Trial Collaborators.

Halliday A, Harrison M, Hayter E, et al. 10-year stroke prevention after successful carotid endarterectomy for asymptomatic stenosis (ACST-1): a multicentre randomised trial. *Lancet*. 2010; 376(9746):1074-1084.

potential sources of neurologic symptoms should be excluded before carotid intervention is undertaken. This includes a search for a cardiac source, interrogation of the intrathoracic and intracranial circulation, and brain imaging to evaluate both the presence of ipsilateral infarction (supporting carotid bifurcation intervention) and the existence of intracranial lesions (interdicting carotid bifurcation intervention).

Although ipsilateral neurologic symptoms are the strongest predictor of stroke risk, a history of stroke of any kind is also associated with increased risk of subsequent stroke. In the Asymptomatic Carotid Stenosis and the Risk of Stroke (ACSRS) study, any prior stroke or a prior contralateral TIA was an independent predictor of stroke risk in a patient with asymptomatic carotid stenosis.[40] Imparato observed that an individual patient tends to have the same type of plaque in both carotid arteries.[41] This implies that patients with prior symptomatic carotid plaque are more likely to have "vulnerable plaque" in the contralateral artery. It is clear that a totally asymptomatic patient and a patient with any prior neurologic events are not at equal risk of stroke.

Contralateral Carotid Occlusion

The presence of contralateral carotid occlusion (CCO) may be associated with increased stroke risk in patients with significant carotid stenosis. Although a post hoc analysis of patients in the ACAS study with contralateral carotid occlusion[42] demonstrated a decreased risk of stroke (3.5% at 5 years) in 168 patients from the medical arm of the trial, the explanation for this is unclear and this association has not been substantiated by other studies, including the Asymptomatic Carotid Surgery Trial (ACST).[38] AbuRahma et al.[43] followed 82 patients with greater than 60% stenosis and CCO and documented a combined neurologic event rate of 60%, including a stroke rate of 33% at a mean of 5 years follow-up, with events distributed between ipsilateral and contralateral arteries. In patients with contralateral carotid occlusion, the degree of intracranial collateral circulation is related to late stroke risk. The adequacy of collateral cerebral circulation can be measured by imaging collateral intracranial circulation or functional assessment of collateral flow by measuring cerebrovascular vasomotor reactivity. Several studies employing this technique have shown that patients with CCO and impaired collateral circulation are at an increased risk of late stroke, whereas CCO patients with relatively normal intracranial hemodynamics have a lower risk of late stroke.[44,45]

Evidence of Clinically Silent Emboli

Clinically silent cerebral infarction can be manifest in one of two ways: (1) evidence of prior ipsilateral cerebral infarction on computed tomography (CT) or magnetic resonance imaging (MRI) imaging of the brain or (2) detection of embolic material in the ipsilateral middle cerebral artery using transcranial Doppler (TCD) techniques.

Routine CT scans taken prior to operation in asymptomatic patients demonstrated an incidence of silent cortical infarction in up to 20% of cases.[46] Subsequent studies have correlated the presence of such infarcts with an increased risk of subsequent ipsilateral hemispheric symptoms.[47,48] A systematic review of 19 studies of TIA patients demonstrated that evidence of acute ischemic lesions on diffusion-weighted MRI was associated with an early increased risk of ischemic stroke.[49] A prospective cohort study of asymptomatic individuals has correlated the presence of microembolic "hits" detected by transcranial Doppler (TCD) with increased risk of subsequent clinical stroke.[50] A review of 58 articles investigating the impact of TCD microemboli on subsequent neurologic events was recently reported by Jayasooriya et al.[51] The duration of TCD monitoring ranged from 30 minutes to 8 hours, with the most common intervals being 30 or 60 minutes. Several of the studies used multiple monitoring sessions. The prevalence of microemboli was higher in patients with neurologic symptoms. Between 4% and 30% of neurologically asymptomatic patients had microemboli with a frequency of 0.35 to 4 embolic signal events per hour. There was an increased rate of subsequent stroke or TIA in patients with silent microemboli detected by TCD as compared with patients in whom no microemboli were identified (28% vs. 2% $P = .001$). The authors concluded that there is level 1 evidence for using TCD indications of microembolization as a risk stratification tool and that it might be used with other techniques such as sophisticated carotid plaque imaging to identify increased stroke risk associated with asymptomatic carotid stenosis. This technique is both patient- and operator-dependent.

Plaque Characteristics

Degree of Stenosis

In the major symptomatic trials as well as in natural history studies, the degree of stenosis was directly related to stroke risk. In NASCET, each decile of stenosis was correlated with an increase in stroke risk, and lesions from 70% to 99% were much more likely to progress to stroke on medical therapy than were lesions of 50% to 69% diameter stenosis, while lesions of less than 50% stenosis were unlikely to result in subsequent neurologic symptoms.[34,35] This finding of increasing stroke risk with an increasing diameter of stenosis was also demonstrated in the ECST trial.[36] In asymptomatic patients, no linear correlation between diameter of stenosis and increased stroke risk was seen in the medical arms of the ACAS trial[37] or in ACST.[38] There are a number of potential explanations for this seeming inconsistency. First, the use of duplex ultrasound to determine stenosis in the asymptomatic trials may not have permitted as accurate a distinction between degrees of stenosis as was possible in ECST and NASCET trials, which quantified stenosis angiographically. Second, the low number of events in the asymptomatic trials may have resulted in inadequate sample size to demonstrate a difference between patients with 60% to 79% stenosis and those with 80% to 99% stenosis. In the ACST study, the mean diameter reduction of the group with greater than 60% stenosis was 69%, suggesting that the lesions in the trial were not evenly distributed across deciles of stenosis but rather were weighted toward the in the 60% and 79% category.[38] It is likely that there were not enough "severe" (80% or greater) stenosis in the large asymptomatic

trials to estimate gradation in risk between deciles of stenosis. Natural history studies of asymptomatic plaques with stenosis ranging from minimal to severe confirm the increased risk of stroke associated with plaques with more severe stenosis.[52-54] In the larger and more detailed study of asymptomatic plaques (ASCRS) including 1121 asymptomatic plaques subjected to observation and BMT, Nicolaides et al. found a linear correlation between degree of stenosis as measured by the ECST method and stroke risk.[55] It is of interest to note that analysis of asymptomatic contralateral stenosis in the NASCET study did find a correlation between degree of stenosis and stroke risk.[48] The risk of "large artery" stroke ipsilateral to an asymptomatic 60% to 99% stenosis was 9.9% in addition to a 6.0% risk of lacunar stroke (many such cases are now thought to result from artery-to-artery emboli). The overall 5-year risk of stroke was higher in the 75%-94% stenosis category (18.5%) than it was in the 60%-74% (14.8%) or the 95%-99% (14.7%) groups. Although these patients are not identical to neurologically asymptomatic patients, such findings do confirm a relationship of angiographically determined stenosis and an increased risk of late stroke.

Since the diameter of most carotid arteries falls within range of a few millimeters, diameter of stenosis is in fact a surrogate measure of plaque size or volume. Plaque size has been correlated with plaque composition, larger plaques being less likely to be fibrotic and more likely to contain lipid, intraplaque hemorrhage with a necrotic core and inflammatory cells.[56] It is likely that diameter of stenosis is a surrogate measure for plaque size. Although stenosis is an important feature used to assess stroke risk, on a hierarchal basis it is not as important as the presence or absence of symptoms.

Plaque Progression

Plaque progression is associated with increased risk of subsequent stroke. The natural history studies noted earlier demonstrate that patients with plaques that progressed from less to more than 50% stenosis while under observation were at increased risk of stroke, and this was even more marked when the progression was to greater than 80% stenosis. Bertges et al., studying 1701 asymptomatic carotid arteries over a 9-year period, demonstrated that plaque progression increased the odds risk of subsequent stroke or TIA by 1.68 ($P < .001$).[57] More recently, Sabeti followed 1065 asymptomatic patients with carotid plaque for a mean of 3.2 years. They documented a correlation between carotid plaque progression and major adverse cardiovascular events (MACE) (OR 2.01, $P < .001$), stroke (OR 2.0, $P > .035$), and cardiovascular death (OR 1.75, $P = .039$).[58] It is likely that plaque progression is a manifestation of dynamic plaque events such as inflammation, intraplaque hemorrhage and/or rupture of the fibrous cap and consequent exposure of necrotic plaque elements to the flow lumen.

Plaque Character

Features associated with "vulnerable plaque" include plaque heterogeneity with increased echolucency, evidence of surface irregularity as manifest by ulcerations on angiography, a thin or disrupted fibrous cap with adjacent echolucent plaque area, and increased inflammatory infiltrate as seen on MRI or positron emission tomography (PET) scan (see Chapter 29). Moore et al. first described the relationship between surface irregularity (ulceration) and stroke risk more than four decades ago.[59] Asymptomatic lesions that were ulcerated had an annual stroke risk of up to 12%. Fisher et al., studying plaques from both the NASCET and ACS trials, found that ulceration was more common in symptomatic patients, as was the presence of thrombus.[60] The Oxford plaque study confirmed an association between ulceration and histologic plaque rupture, large lipid core, macrophage infiltration, and general evidence of inflammation.[61] More recent studies of plaque from patients with remote symptoms suggest that they have a higher incidence of unstable plaque characteristics than do patients who have never been symptomatic.[62]

The Nicolaides group has also used normalized duplex ultrasound to correlate plaque echolucency with the frequency of ipsilateral neurologic symptoms.[63-65] Plaque echogenicity has also been correlated with the amount of embolic material recovered after carotid stenting.[66] The ACSRS study[40] followed 1121 neurologically asymptomatic patients with known carotid plaque on ultrasound between 50% and 99% stenosis. Using a combination of clinical and anatomic risk factors, the investigators were able to identify patients at very low (<5%), low (5%-9.9%), moderate (10%-19.9%), and high (>20%) 5-year risk of stroke. The factors they found that were associated with an increased risk of stroke for patients with asymptomatic carotid stenosis included percent of stenosis, smoking history, renal insufficiency, prior contralateral events, plaque area, and plaque character (gray scale median and presence of "discrete white areas within the plaque"). At present, however, the most reliable imaging predictor of stroke risk remains the accurate measurement of diameter stenosis. Factors associated with increased stroke risk are enumerated in Table 89.3.

TABLE 89.3 Clinical Factors Associated With Increased Stroke Risk

Plaque Characteristics	Patient Characteristics
Diameter stenosis[a]	Neurologic symptoms
Plaque ulceration	H/O contralateral stroke[a]
Plaque progression	Contralateral carotid occlusion[a]
Echolucent plaque[a]	Renal insufficiency[a]
Plaque area[a]	Smoking[a]
Disrupted fibrous cap	Clinically silent emboli by TCD or MRI/CT
"Discrete white areas" within plaque[a]	
Active inflammation by MRI	

[a]See Nicolaides (Ref #40) for risk model.

Factors Influencing the Decision to Recommend Intervention

Life Expectancy

The patient's longevity plays an important role in considering intervention, particularly in the case of asymptomatic patients. In NASCET, ECST, and ACAS, only patients who had a life expectancy of 5 years were eligible for enrollment.[34-37] In the symptomatic studies,[34,35] patients in the medical arm with most recurrent events occurred within the first 1 to 3 months of the initial symptom. In the asymptomatic studies, the risk of stroke in the medical arms was considerably less: 11% in ACAS and 11. 8% ACST at 5 years.[37,38] These observations suggest that symptomatic patients with high-grade stenosis can be reasonably considered for intervention even when their life expectancy is only 2 to 3 years. However, asymptomatic patients should be expected to survive at least 3 to 5 years to derive significant benefit in stroke reduction from CEA. Of interest, long-term results from Carotid Revascularization Endarterectomy Versus Stenting Trial (CREST) indicate that patients in that trial had an estimated life expectancy approximating that of the population at large, indicating that patients in this trial were well selected for intervention.[67]

Age

There is a complex interaction of age with the decision to recommend intervention. NASCET, ECST, and ACAS excluded patients over the age of 80, whereas ACST permitted randomization up to age 91. However, the number of patients above age 80 in ACST was low, and reliable subgroup analysis of the effect of advanced age on outcomes was not possible.[38] There are data demonstrating that age itself is not associated with an increased risk of adverse events after CEA,[68-70] although age does seem to influence the outcomes after CAS.[70,71] Whereas the effect of age on the combined endpoints in CREST was reached at approximately age 70, the age at which stroke rates (as opposed to the composite endpoint) increased with CAS was 64 years.[71] Multiple other reports indicate that older patients are at significantly higher risk of stroke and to a lesser degree of death after CAS (see Chapter 92).[68,71-75]

Gender

Most of the major randomized trials have found a greater benefit from CEA in males as compared with females.[34-37,39] Female gender was associated with an overall increase in MACE (HR 1.98) in the ICSS trial.[76] Women generally have smaller carotid arteries than men and more often require patching after endarterectomy. There were no standard criteria for patching after CEA in any of the major carotid trials, and routine patching after CEA was not standard of care during the time those trials were performed. It is impossible, therefore, to know the effect inconsistent patching may have had on the postoperative results in the female cohort of these studies. NASCET[35,39] and ECST[36] both reported this gender-based difference, although CEA was still beneficial in women with 70% to 99% stenosis. ACAS did not find a benefit for CEA in women,[37] although the number of women enrolled in the trial was small. The ACST trial,[38] with almost double the enrollment of ACAS, found benefit from CEA in both men and women. Several recent population-based studies suggest that CAS may be associated with more complications than CEA in women.[77,78]

Functional Status

Functional status is an important element in decision making. The patient should have a baseline level of function sufficient that a further neurologic event would result in serious deterioration in functional or cognitive ability. Patients with dense hemispheric neurologic deficits are unlikely to benefit from further intervention. Similarly, intervention for patients who have evidence of mild to moderate dementia or limitation in functional ability should be undertaken only after very detailed and careful discussions with the patient, family, and another physician familiar with the patient. There is an argument that intervention in patients with mild to moderate disability can be justified in an attempt to maintain function, but these decisions are often complex, and an unbiased assessment of the patient's functional status and future course is imperative to avoid unnecessary intervention. Poor functional status—as reflected particularly in cardiac, renal, and pulmonary impairment—has been correlated with increased perioperative risk and a higher risk of adverse events during follow-up, thus limiting the effectiveness of operation for asymptomatic stenosis in this patient group.[79]

Cardiac Status

Recent studies have shown that CEA is associated with an increased risk of overall cardiac events, including subclinical infarction, compared with carotid stenting.[80-82] There is evidence that perioperative cardiac events are associated with late mortality.[83] Therefore it is important to evaluate the cardiac status of patients prior to recommending intervention. Predictors of adverse cardiac events include evidence of uncompensated congestive heart failure and of untreated significant coronary disease. In symptomatic patients with 70% to 99% stenosis cardiac risk may be established by clinical risk assessment alone. Stress testing is reserved for those with a history of active angina, new onset of EKG changes or new onset of congestive heart failure. In the asymptomatic patient, where benefits of surgery are less robust, a full cardiac workup, including evaluation for subclinical coronary ischemia, should be strongly considered. A recent analysis of data from CREST[84] indicates that the use of regional anesthesia for CEA was associated with a decreased risk of myocardial infarction (MI) compared with general anesthesia (1.8% vs. 3.4%). This rate was not significantly different from that reported in the CAS subgroup. Although this is a post hoc analysis, one might consider regional anesthesia for CEA in patients with a significant cardiac history. Attention to these details will optimize the results of intervention, whereas failure to consider them sufficiently may result in suboptimal outcomes as a result of intervening in "high risk" asymptomatic individuals, as was done in the SAPPHIRE trial.[81]

Pulmonary Disease

In general, pulmonary disease does not play a major role in morbidity after carotid intervention. Any active pulmonary disease should be stabilized before intervention is undertaken

and the effect of pulmonary disease on longevity should be considered.

Renal Insufficiency

Moderate to severe renal insufficiency reduces life expectancy and is associated with increased complication rates after both CEA and CAS.[85-89] Chronic kidney disease has also been associated with features of increased plaque instability on histologic examination as well as an increased incidence of cerebrovascular events prior to surgery.[90] Renal insufficiency was an independent risk factor for subsequent stroke in the ASCRS study.[40] Patients with chronic renal insufficiency have been excluded from the randomized trials; therefore, the natural history of asymptomatic carotid stenosis in this group of patients is unknown. As a consequence, although it is clear that intervention in these patients is associated with increased risk, no clear recommendations regarding the impact of renal insufficiency on decision for type of intervention can be made.

Contralateral Carotid Occlusion

NASCET identified increased perioperative stroke risk after CEA in patients with contralateral carotid occlusion from 5.8% to 14%.[48] However, a number of single-center studies have not confirmed this increased risk,[91-94] and a meta-analysis of the literature suggests a statistically significant but small (overall risk 2.4%-3.7%) increase in perioperative stroke rate in the face of a contralateral carotid occlusion following CEA.[95] Recently results of both CEA and CAS in patients with contralateral carotid occlusion were compared in patients entered into the Society for Vascular Surgery (SVS) Carotid Registry database.[96] This comparison demonstrated a small but statistically significant increased risk of stroke after CEA (3.15% vs. 1.06%) in the presence of carotid occlusion. The stroke risk in the CAS group was not affected by the presence of contralateral occlusion (2.1% vs. 2.3%). It is relevant that in the data from the SVS Carotid Registry, which included both symptomatic and asymptomatic patients, the overall stroke rate in all patients with a contralateral occlusion still fell within the AHA guidelines and did not statistically favor CAS or CEA (CEA 3.15%, CAS 2.13%, $P = .2$). As noted earlier, data on stroke risk in patients with contralateral occlusion treated with BMT alone are conflicting.

PATIENT-SPECIFIC FACTORS THAT INFLUENCE THE CHOICE OF THERAPY

Early application of CAS was focused on patients at "high risk" for CEA. With increasing clinical experience with CAS, it has become clear that there are also clinical scenarios where CAS is "high risk" (Table 89.4). Fortunately risk factors for CAS and CEA are, for the most part, different and these techniques can be considered complementary. Clearly, when a patient exhibits risk factors for both CAS and CEA, the need for intervention should be carefully considered, and BMT alone may be the best option.

TABLE 89.4 Factors Associated With Increased Stroke Risk From Carotid Endarterectomy and Carotid Artery Stent

Carotid Endarterectomy	Carotid Artery Stent
Poorly compensated cardiac ischemia/heart failure	Symptomatic lesion
Lesion above C2 or below clavicle	Age >70
Scarring from prior surgery or XRT	Vessel/arch tortuosity
Recurrent carotid stenosis	Adverse lesion characteristics: Length >15 mm Echolucent, irregular Tandem lesions Preocclusive lesion Circumferential calcification
Stoma in neck	

Presence of Neurologic Symptoms

The preponderance of data has shown that results with CAS are inferior to CEA in neurologically symptomatic patients.[97-100] This position is reflected in all of the societal guidelines published to date (see further on). A publication combining the results of the three large European trials comparing CEA and CAS in symptomatic patients suggest that the benefit of CEA over CAS (stroke rate 2.8% vs. 9.4% HR 3.4) is especially high in the first week after symptom onset.[101] This is particularly relevant, since most guidelines currently recommend early carotid intervention after stroke (see later text).

Hostile Neck

This is defined by neck anatomy with poor tissue planes or increased risk of postoperative infection. A history of prior radiation, stoma, or prior surgery alone does not in itself define a hostile neck; rather, it is the degree of local change in the tissues surrounding the carotid artery that is relevant. There are series reporting excellent results with CEA for recurrent carotid stenosis[102] and after cervical radiation.[103] However, it is generally accepted that cranial nerve injury is increased when CEA is performed for restenotic lesions, and this is likely also true with radiated fields. Increased wound complications following radiation and/or in the presence of a tracheotomy are well known. In general these conditions represent a relatively increased risk for CEA.

Lesions Outside the Area of the Cervical Carotid Artery

Lesions that are below the clavicle or above the level of the second cervical vertebra also present challenges for open surgical repair. These lesions are infrequently encountered in practice. High lesions, requiring mandibular subluxation or other maneuvers to increase surgical exposure, may result in an increased incidence of cranial nerve injury after CEA.[104] Although

tandem lesions involving the proximal common carotid artery and carotid bifurcation have been treated by CEA combined with retrograde stenting with good results,[105] they cannot be assumed to be equivalent to those of CEA alone. A recent analysis of the CREST data indicates that tandem lesions are associated with an increased risk of stroke after CAS.[106] Intervention in these lesions should be carefully considered, particularly in the asymptomatic patient.

Vessel Tortuosity

Tortuosity of the aortic arch, aortic arch atheroma, and tortuosity of the proximal carotid vessels all increase the difficulty of establishing a stable platform for CAS and increase the risk of embolization with CAS.[75,107] Some surgeons have tried to address this by transcervical CAS.[108] In a recent trial of transcervical stenting, Kwolek et al.[109] reported a stroke rate of 1.4% and a MACE rate of 3.5% in a cohort of 208 patients (20% symptomatic) from 18 centers. The relative role of transcervical CAS in relation to CEA and transcervical CAS remains to be defined. Tortuosity of the distal internal carotid artery may also present challenges for CAS,[75] so that proximal protection with flow reversal should be considered.[109,110]

Lesion Character

There are data suggesting that lipid-rich, echolucent lesions (i.e., "vulnerable plaque") are more likely to result in emboli after CAS than after CEA (see Chapter 88). In addition, lesions that are greater than 15 mm in length, preocclusive and highly calcified, or contain fresh thrombus have all been associated with worse outcomes after CAS.[75,106,111]

EVIDENCE-BASED SELECTION OF THERAPY

Best Medical Therapy Alone Versus Carotid Endarterectomy Plus Best Medical Therapy

Major trials have demonstrated a clear benefit of CEA for stroke risk reduction in symptomatic patients with stenosis of 50% to 99% as well as a less robust but still significant benefit in asymptomatic patients with a 60% or greater bifurcation stenosis (see Table 89.2).[34-38] Even a modest reduction in stroke risk can be "cost effective" given the cumulative cost of stroke.[112]

Maximizing the efficacy of CEA for asymptomatic stenosis requires both focusing intervention on patients with "stroke prone" lesions and limiting the complication rates. The ACST trial demonstrated that this net benefit of CEA in stroke prevention can be maintained over 10 years of follow-up even in those patients on maximal medical therapy at the time of intervention, indicating that BMT and CEA are complementary (Fig. 89.1).[113]

Improvements in medical therapy for conditions associated with an increased risk for stroke and the concurrent reduction in stroke risk has prompted a reexamination of CEA versus BMT alone in patients with asymptomatic carotid stenosis.[114-118]

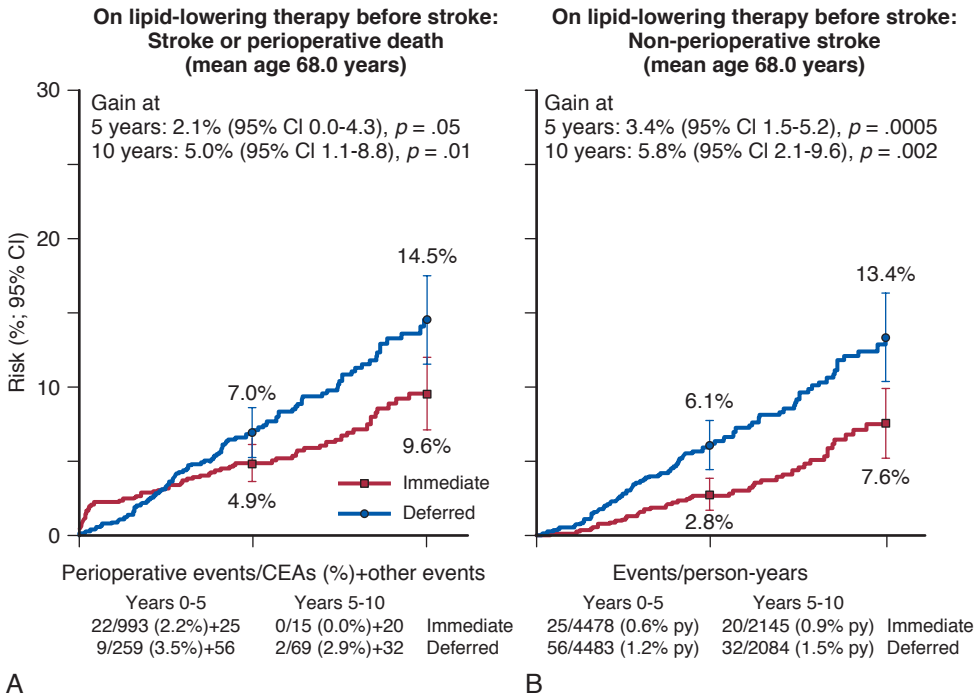

Figure 89.1 Plot of asymptomatic carotid surgery trial long-term results comparing immediate (CEA + BMT) with deferred (BMT alone) treatment strategies in patients who were on lipid-lowering and antiplatelet therapy at the time of randomization. (A) Stroke or perioperative death, (B) late stroke. *BMT*, Best medical therapy; *CEA*, carotid endarterectomy.

Proponents of BMT as sole therapy point to the small annual absolute risk reduction conferred by CEA in the asymptomatic randomized trials, which is similar to risk reduction seen in trials of BMT such as SPARCL.[14] However, it is important to note that trials of medical therapy in stroke prevention included large numbers of patients with a variety of mechanisms for stroke and no information as to the status of their carotid arteries. Since only 20% of all strokes are thought to be related to carotid stenosis, the results in these large medical trials of stroke prevention cannot be extrapolated to patients with known carotid bifurcation stenosis.

In an effort to address the efficacy of medical therapy in patients with known carotid stenosis, Abbott performed meta-analyses of 11 trials, including 3724 patients from 1985 to 2007 in which there were data available on the outcome of medical therapy alone in patients with greater than 50% carotid stenosis.[115] She concluded that the risk of stroke in patients with carotid stenosis had declined significantly over the time-interval studies and that it was now equal to or lower than the stroke risk of the surgical cohort in ACAS. This argument has achieved significant acceptance in the medical community, although the analysis is flawed in several respects. First, trials chosen for analysis were heterogeneous and included both completely asymptomatic patients (ACAS), asymptomatic contralateral stenosis in symptomatic patients (NASCET and ECST), and other small single-center studies. The degrees of stenosis varied from 50% to 100%, and the techniques to measure stenosis differed among studies. Some studies included patients with asymptomatic carotid occlusion, which is known to have a benign natural history. Second, these studies were given equal weight in the analysis to extrapolate a contemporary stroke risk regardless of their sample size. The two largest studies in this analysis, ACAS and ASCRS (comprising two-thirds of the total cohort) both concluded that there was a correlation between diameter of stenosis and stroke risk in patients treated with BMT alone. Third, the "contemporary" stroke risk estimated from these chronologically and methodologically heterogeneous data was compared with the results from ACAS, published 2 decades earlier. Finally, the most contemporary and largest trial comparing CEA plus BMT to BMT alone, ACST,[38] was inexplicably excluded from the analysis. Taken together, these concerns seriously undermine the validity of the conclusions drawn from these comparisons.

Considering only patients with stenosis greater than 70% for CEA, the impact of BMT alone is attenuated. The Oxford vascular study[114] identified a low stroke risk (0.7% annual event rate) in patients with stenosis of 50% to 70% but a 3% annual stroke rate in the 32 patients with greater than 70% stenosis, somewhat higher than seen in ACAS. In the SMART study,[117] of 2684 neurologically asymptomatic patients with arterial disease or diabetes, asymptomatic carotid stenosis of 50% or greater was seen in 221 patients (8%), 147 of whom had a stenosis of 70% to 99%. There was a relationship between degree of stenosis (50%-69% vs. 70%-99%) and the risk of ischemic stroke during the 3-year follow-up, although the numbers were too small to attain significance. The REACH registry documented a twofold increased risk of stroke in patients with asymptomatic carotid stenosis greater than 70% even though a preponderance of patients in the registry were treated with statins.[118] Sabeti et al. have documented plaque progression in nearly 10% of patients despite the fact that some 80% were on statin medications.[122] Finally, level 1 data comparing BMT with BMT plus CEA come from a subgroup analysis of the patients in the ACST trial[111] who received both antiplatelet agents and statins during follow-up documented a statistically significant benefit of CEA in addition to BMT in patients treated with statins and antiplatelet agents, all of whom had stenosis greater than 60% by NASCET criterion (see Fig. 89.1).

The case for BMT alone was bolstered by the results of the SAMMPRIS trial, comparing BMT with intracranial angioplasty for patients with symptomatic intracranial carotid stenosis.[120] The efficacy of BMT alone was much greater than expected and negated any benefit of endovascular intervention. Whether these rates can be implemented on a large scale and at what cost remains a subject for debate.[121]

At present the data do not support BMT as stand-alone therapy in patients with significant carotid stenosis who are good candidates for intervention and have a reasonable life expectancy. The long-term data from both CREST[67] and ACST[113] indicate that intervention performed with low perioperative complication rates can bring lasting protection against stroke with a low rate of restenosis. Further, these data indicate that patients who undergo carotid intervention are likely to live for many years after their procedure. The question of BMT as stand-alone therapy is currently being addressed in the CREST 2 trial[122]; however, data will not be forthcoming for a number of years.

Interventional Strategies: Carotid Angioplasty and Stenting Versus Carotid Endarterectomy

CAS and CEA have been compared in multiple prospective trials. Since 2011, multiple meta-analyses of these clinical trials, each including between 8 and 16 trials predominantly involving patients with neurologic symptoms, have reached similar conclusions (Table 89.5). In summary, the results are quite consistent, indicating a roughly 1.5- to twofold increase in periprocedural stroke and/or death for CAS as compared with CEA, most striking in symptomatic patients. There is a consistent reduction, approximately 55%, in the incidence of MI associated with CAS. In all reviews there was a benefit of CAS in terms of cranial nerve deficits. Differences in mortality, while slightly in favor of CEA, were not statistically different between CAS and CEA. When age-related analyses were performed, the significant differences between CAS and CEA in stroke and death were seen primarily in patients over the age of 70.[74,123-126] It is clear that contemporary data supports CEA over CAS in "normal risk" patients who are fit for surgery because of the consistently lower stroke risk associated with CEA.

The largest trial to date comparing CEA and CAS patients was the CREST study,[80] including 2500 normal-risk patients, 1182 with asymptomatic stenosis, to either CAS or CEA. Interventionalists in CREST were required to demonstrate competence and meet threshold outcomes before they were

TABLE 89.5 Summary of Published Meta-analyses Comparing Carotid Endarterectomy and Carotid Artery Stent

[a]This analysis used CAS as the standard comparator, while others used CEA.

CAS, Carotid artery stent; *CEA*, carotid endarterectomy; *MI*, myocardial infarction; *OR*, odds ratio.

allowed to participate in the trials.[131] Dual antiplatelet therapy and embolic protection were required for all CAS patients. Therefore the CREST results represent the optimal results currently achievable for either CAS or CEA.[132] The CREST investigators found no significant difference in the composite MACE rate between CEA and CAS (6.8% CEA, 7.2% CAS). However, stroke occurred significantly less often in the CEA group, MI significantly less often in the CAS group, and death was slightly but not significantly less frequent, in patients who underwent CEA. Perioperative occurrence of stroke and MI were both associated with a reduction in long-term survival.[83,133] The reduction in survival was associated with the occurrence of either endpoint and was independent of which intervention was undertaken (i.e., CAS or CEA). A quality-of-life analysis of the CREST cohort did demonstrate that the occurrence of stroke had a greater impact on perceived quality of life than did MI, although this increased impact was lost at late follow-up.[134] Advancing age increased the risk of CAS and the benefit of CEA, with an inflection point at 64 years.[71] When analyzed by symptom status, reduction in stroke and/or death was significant in symptomatic patients (6.0% CAS vs. 3.2% CEA, OR 1.89, $P = .02$). Stroke and death rates were also reduced after CEA in asymptomatic patients (1.4% vs. 2.5% after CAS, OR 1.88), but this did not reach statistical significance.[100] Ten-year follow-up has been reported in 1607 of the 24,502 patients in CREST.[67] The primary composite endpoint was 11.8% in CAS and 9.9% in CEA, with total ipsilateral stroke rates of 6.9% in CAS and 5.6% in CEA. The late stroke and/or death rate favored CEA (HR 1.37, $P = .04$), driven primarily by the difference in perioperative events. The major long-term stroke rates were equivalent after both procedures (2.5%-2.7%), as were rates of restenosis (12.4% CAS and 9.7% CEA, $P =$ NS). There was no effect of initial symptom status on restenosis or late stroke risk. Of particular note was the average survival in patients aged 65 at the time of enrollment, estimated to be 18 years in men and 20 years in women. For patients aged 75 at the time of enrollment, estimated life expectancy was 10.8 years in men and 12.4 years in women.[67]

Recently the role of CAS in asymptomatic normal-risk patients was evaluated in the ACT1 trial.[135] As in CREST, the operators were vetted for experience with a lead-in phase, and a single closed cell stent along with distal embolic protection was used. The study was designed to recruit 1658 patients but stopped after 1453 because of slow enrollment. Based on these numbers, there was a 75% chance of establishing noninferiority (defined as an overall adverse event rate of 3% or less). There was no difference between CEA and CAS for MACE (3.8 ± 0.5% CAS, 3.4 ± 0.98% CEA), or perioperative stroke/death (2.9% CAS, 1.7% CEA, $P = .33$). There was also good durability, with freedom from ipsilateral stroke in both groups greater than 97% at 3 years and any stroke 94% at 5 years.

It is clear that the results of CAS, as demonstrated in CREST and ACT1, have improved over the last decade as a result of increasing technical experience, the development of new technologies, and better patient selection as well as avoiding clinical scenarios associated with increased risk. Proper patient selection is critical to achieving optimal results, especially in asymptomatic patients (see Table 89.4). Recent data document

as much as a fourfold variations in outcomes after CAS.[136] It has become apparent that outcomes are related to both operator experience and volume to a much greater extent than are those with CEA.[137] Optimal CAS results will require that the procedure be performed in centers of excellence with sufficient volumes and documented excellent outcomes.

SOCIETAL GUIDELINES REGARDING CAROTID REVASCULARIZATION AND STROKE PREVENTION

Several professional organizations have published evidence-based guidelines to help define the role of carotid intervention in stroke prevention.[138-141] All guidelines share the following recommendations:

1. Symptomatic patients with angiographic stenosis less than 50% and asymptomatic patients with stenosis less than 60% should not undergo intervention and should be treated by BMT.
2. The particulars of medical therapy include control of comorbid conditions, risk reduction with antiplatelet therapy, and with statins and beta blockers as indicated.
3. CEA is preferred over CAS in symptomatic patients with stenosis greater than 50% unless there are contraindications to CEA, such as uncompensated cardiac disease or local scarring, which increase the risk of cranial nerve complications. The greater the degree of stenosis, the stronger the indication for intervention.
4. In symptomatic patients with stenosis greater than 50% who are at high risk for CEA, CAS is preferred over BMT. The greater the degree of stenosis, the stronger the indication for intervention.
5. In patients with stroke or TIA, intervention should be performed within 2 weeks unless there are contraindications.
6. In good-risk patients with asymptomatic stenosis greater than 60%, CEA may be recommended in addition to BMT for the reduction of stroke risk as long as the combined stroke and death rate is less than 3%.
7. In asymptomatic patients at high risk for intervention, neither CAS nor CEA has proven superior to BMT.
8. Intervention is not indicated for patients with chronic total occlusion of the internal carotid artery or with severe disability that precludes the preservation of useful function.

The role played by CAS in stroke prevention is somewhat different in the various guidelines. The American College of Cardiology/American Heart Association (ACC/AHA)[138] and European Society for Cardiology[140] support a role for CAS *as an alternative* to CEA in symptomatic patients of normal risk and in asymptomatic patients provided that one can demonstrate sufficient institutional volume and document outcomes within AHA standards. In contrast, the SVS guidelines[139] and those of the Australasian College of Physicians[141] support CAS only symptomatic patients at high risk for CEA due to specific cardiac or anatomic characteristics and do not recommend CAS in asymptomatic patients. Their conclusions place greater emphasis on the reduction of stroke risk rather than MACE; accept the validity of the symptomatic stroke trials, particularly ICSS; and take the position that overall lowest stroke and death rates should be used to recommend a specific therapy.

The biggest difference in approach is to the asymptomatic patient. AHA guidelines suggest that "Prophylactic CAS might be considered in highly selected patients with asymptomatic carotid stenosis (minimum 60% by angiography, 70% by validated Doppler ultrasound), while at the same time acknowledging that "its effectiveness compared to medical therapy alone in this situation is not well established."[138] The SVS guidelines, though supporting CEA in asymptomatic patients at normal risk, do not support CAS in asymptomatic patients except in centers that can demonstrate periprocedural stroke and death rates less than 3%.[139] In situations where this threshold cannot be met or life expectancy is less than 3 years, the SVS position favors medical management of the neurologically asymptomatic lesion due to the relatively benign natural history of asymptomatic carotid stenosis (Table 89.6).

TABLE 89.6 Summary of Societal Guidelines

	Symptomatic	Asymptomatic
AHA[138]	CEA for 50%-99% stenosis, CAS is recommended when CEA complication rates are high and CAS can be performed with complication rates of 4%-6%	CEA for 60%-99%, *CAS in selected pts, but its effectiveness is not well established.*
SVS[139]	CEA preferred in pts 50%-99%, CAS in hostile neck and severe uncorrectable cardiac conditions	CEA in good-risk pts with 60%-99% stenosis and 3- to 5-year life expectancy with complication rates >3%. Insufficient data to support CAS outside of trials, may be used by selected interventionalists with established complication rates <3%. High-risk pts should have BMT alone.
ESC[140]	CEA for 70%-99% stenosis, CAS for high surgical risk	CEA for 60%-99% stenosis with complications <3% and 5-year survival, CAS *as an alternative* in high-volume centers with complications <3%.
Australasian[141]	CEA for 50%-99%, CAS for pts at high surgical risk	CEA for 60%-99%, no evidence to support CAS, consider BMT as primary treatment.

BMT, Best medical therapy; *CAS*, carotid artery stent; *CEA*, carotid endarterectomy; ESC, European Society of Cardiology; *SVS*, Society for Vascular Surgery.

SELECTING THE APPROPRIATE THERAPY FOR THE APPROPRIATE PATIENT

Patients With Carotid Bifurcation Stenosis of Less Than 50%

Data from all symptomatic trials indicate that BMT alone is indicated for neurologically symptomatic patients with stenosis less than 50% (NASCET criterion). In neurologically asymptomatic patients with carotid stenosis less than 50% and no other manifestations of cardiovascular disease there is no clear support for BMT, as the data supporting pharmacotherapy for primary prevention are not robust. Patients found to have evidence of asymptomatic carotid plaque greater than 50% should be evaluated for evidence of cardiovascular risk factors such as hypertension, dyslipidemia, diabetes, and smoking and these risk factors should be appropriately modified. Antiplatelet therapy with aspirin is likely beneficial in this patient group and poses no significant risk. There is some evidence to support statin therapy even in patients with a normal lipid profile.

Asymptomatic Patients With Carotid Bifurcation Stenosis of 70% to 99%

Although both ACAS and ACST demonstrated the efficacy of CEA at a threshold of 60% diameter stenosis, most surgeons prefer to reserve intervention for asymptomatic plaques with stenosis in the range of 70% to 99%. Adverse plaque characteristics (echolucency, ulceration, evidence of silent emboli) strengthen the indication for intervention. Even with severe stenosis and "high risk" asymptomatic plaque, the rate of subsequent neurologic events is low and careful patient selection and preparation is essential. Asymptomatic patients should be operated on if perioperative morbidity is minimal and they have at least a 3- to 5-year life expectancy. Patients should be thoroughly evaluated for cardiac comorbidity, including occult coronary ischemia, since this may affect not only their perioperative complication rate but also their long-term survival. Patients with multiple comorbidities and poor functional status have an increased rate of MACE at 1 year and are less likely to benefit from prophylactic endarterectomy.[142]

To date the available data support CEA as the intervention of choice in most circumstances. The results of CREST and ACT1 have not been achieved outside the limits of a controlled clinical trial; they represent "proof of concept" rather than justification for general application of the procedure in asymptomatic patients. CAS or CEA should be considered only in the asymptomatic lesion if there are no factors that increase periprocedural risk (see Table 89.4). Based on the increased complication rate of CAS seen in older patients, CAS cannot be recommended at this time for asymptomatic patients over the age of 80 (and perhaps over the age of 70) outside of a clinical trial. The goal for intervention in an asymptomatic patient should be a complication rate as close to zero as possible.

Symptomatic Patients With Carotid Bifurcation Stenosis 50% to 99%

Patients with symptoms of anterior or middle cerebral artery embolic stroke and an ipsilateral carotid bifurcation stenosis of greater than 50% should be considered for carotid intervention.[34-36] The more severe the stenosis, the greater the justification for intervention. Patients who have moderate (50%-69%) stenosis without adverse plaque features (described earlier) should be carefully evaluated to be sure that there is no other source of emboli such as the heart or great vessels or evidence of a culprit lesion in the intracranial circulation.

Data from randomized trials, including CREST,[80,98] indicate that CEA is preferred to CAS in symptomatic patients whose cardiac condition is stable or can be stabilized on the basis of reduced stroke risk. For symptomatic patients with a high likelihood of a major adverse event after CEA due to physiologic or anatomic factors, CAS by an experienced operator is preferred. In symptomatic patients with moderate stenosis who are at high risk for both CAS and CEA, consideration of plaque stabilization with maximal medical management is appropriate as first-line therapy, with intervention reserved for breakthrough symptoms.

Contralateral Carotid Occlusion

Patients with contralateral carotid occlusion are at increased risk from intervention after CEA. This increased risk is relatively mild and actually controversial.[91-96] However, the benefits of operation in a symptomatic patient should not contravene intervention. The natural history of an asymptomatic patient with contralateral occlusion is a matter of dispute. In the medical arm of the ACAS trial these patients exhibited a relatively benign postoperative course, with a 3.2% 5-year stroke rate—an observation not validated in any other study.[42] In the ACST[38] trial, patients with contralateral occlusion faced a similar long-term stroke risk as other asymptomatic patients and derived benefit from CEA. It appears that the modestly increased risk of intervention in the face of contralateral occlusion would support intervention in an otherwise good-risk patient. Based on the data from the SVS database,[96] it is likely that both CEA and CAS done by an experienced interventionalist would be equally effective in the face of contralateral occlusion.

Timing of Intervention After Acute Stroke

At the time of the NASCET and ECST trials, clinical practice was to defer CEA for 4 to 6 weeks after a stroke to allow for stabilization of the ischemic penumbra and prevent postoperative hemorrhagic transformation of a bland infarction. Data from the medical treatment arms of both these studies demonstrated that the highest risk of recurrent neurologic events was in the first 2 to 6 weeks after the incident event. These findings prompted reexamination of the 4- to 6-week delay of surgery. Several studies[143-149] have demonstrated that early endarterectomy after an acute neurologic event, including crescendo TIA and evolving stroke, could be performed with increased but acceptable

risk in patients with mild to moderate neurologic deficits and limited infarction on CT scan. Appropriate patients should have mild to moderate neurologic deficits as reflected in the NIH stroke scale, no evidence of cerebral hemorrhage, and less than 30% of the hemisphere involved in the stroke. Patients with more profound deficits are less likely to be improved by early intervention and more likely to suffer hemorrhagic transformation.

Despite this compelling evidence and recommendations from several guidelines,[138,139] compliance with recommendation for early intervention is poor in clinical practice.[150,151] Barriers to such early intervention include delays in the diagnosis and treatment of patients with TIA, delayed diagnosis of carotid stenosis in patients with stroke, and surgeon reluctance to operate on such patients in an urgent fashion. Early referral of patients to a stroke unit, with admission and in-hospital referral for surgery, has been proposed as a method to increase compliance with these guidelines.[148]

Unstable Neurologic Syndromes

Patients who present with unstable neurologic syndromes such as crescendo TIA or stroke in evolution (waxing and waning neurologic events) have either highly unstable plaque or compromised intracranial collateral circulation. A meta-analysis of the literature in from 1980 to 2008[152] confirmed an overall increased risk of postoperative stroke or death for both crescendo TIA (OR 5.6, $P < .0001$) and stroke in evolution (OR 5.5, $P > .001$) compared with neurologically stable patients who presented with stroke or TIA. Comparisons with the results of early medical management are unfortunately not readily available. A review of the literature suggests that properly selected patients can be stabilized and prepared for early endarterectomy with an expectation of good results.[152-154] Such patients should be managed by an experienced multidisciplinary team, including stroke neurologists and surgeons skilled in CEA, so as to optimize patients' preparation and selection. The role of CAS in the management of these patients is not established at present.

Recurrent Carotid Stenosis

Recurrent carotid stenosis occurs after both CAS and CEA with a similar incidence of between 8% and 12%.[67,155,156] Early recurrent stenosis after both CEA and CAS is generally a proliferative lesion (intimal hyperplasia) and the data suggest a relatively benign course. A number of reports indicate that patients who demonstrate recurrent stenosis after either CEA or CAS are more prone to restenosis after a secondary intervention.[155,156] These observations, along with the benign history of the lesion, should prompt careful consideration before either CAS or CEA is undertaken for an asymptomatic stenosis that recurs within 24 months of the initial intervention. In contrast, a stenosis that recurs late (>36 months) after CAS or CEA is more often the result of recurrent atherosclerotic disease and for this reason is more likely to be associated with new neurologic symptoms. The case for intervention in a symptomatic patient or one with a documented late recurrence is more robust. When intervention is contemplated for recurrent stenosis after CEA, CAS has been generally recommended over CEA. This is based on the increased risk of cranial nerve dysfunction seen with reoperation in a scarred neck. However, recurrent stenosis is not an absolute contraindication to CEA, and several series[102,103,157-159] reported good results with CEA for recurrent stenosis in carefully selected patients (see Chapter 92).

The decision to intervene in recurrent stenosis depends on many factors, including the symptomatic status of the patient, the nature and location of the collateral circulation, and the status of the neck and the degree to which it is viewed as "hostile" due to scarring, stoma, obesity, or expectations of difficulty with proximal or distal exposure. The fact that asymptomatic recurrent disease is usually benign and the propensity for second and third recurrences in these patients are important factors that should temper the enthusiasm for treating asymptomatic recurrent disease, especially if the remaining extracranial vessels are relatively normal.

Radiation-Induced Stenosis

Reports of small series[160,161] of patients demonstrate good results with either open surgery or CAS, with reduced rates of cranial nerve injury and wound infection after CAS and better durability of open carotid surgery, which may include interposition vein grafts (see Chapter 92). A meta-analysis of the literature including 533 patients revealed no difference between CAS and CEA in terms of stroke risk 3.9% versus 3.5% with a higher risk of cranial nerve injury with CEA and a higher risk of restenosis with CAS.[162] Because many of these lesions are asymptomatic and patients may have a limited life expectancy due to an underlying disease that requires radiation, a thoughtfully conservative approach should be taken, particularly in asymptomatic individuals.[163]

Although the majority of carotid artery disease encountered by the vascular specialist is primarily atherosclerotic, there are a number of nonatherosclerotic carotid artery pathologies with clinical implications as well. This chapter focuses on carotid stenosis after radiotherapy and recurrent carotid artery stenosis. Both disorders have pathologic features, natural histories, and clinical management considerations that are distinct from those of primary atherosclerotic disease.

More than 40,000 people in the United States were diagnosed with cancers of the oral cavity and pharynx in 2012, and nearly 75% of these patients are treated with radiation therapy. There were an estimated 9000 new cases of Hodgkin and 70,000 new cases of non-Hodgkin lymphoma diagnosed in the same year, with 30% and 18% of these patients, respectively, receiving radiation therapy.[1] Although breast cancer is the most common cancer diagnosis in women, only a small proportion of new cases (<1%) require radiation to the supraclavicular fossa. In all, an estimated 50,000 people underwent radiation therapy of the neck in 2012 in the United States. With a 25% incidence of carotid stenosis after radiotherapy and 6% incidence of restenosis after carotid endarterectomy (CEA), approximately 12,500 cases of radiation stenosis and 8500 cases of carotid restenosis can be expected annually in the United States alone.

CAROTID STENOSIS AFTER RADIOTHERAPY

Radiation damage to the carotid artery is associated with both asymptomatic and symptomatic stenosis. The mechanism involves

Abstract

Although the majority of carotid artery disease encountered by the vascular specialist is primary atherosclerotic, there are a number of nonatherosclerotic carotid artery pathologies with clinical implications as well. This chapter focuses on carotid stenosis after radiotherapy and recurrent carotid artery stenosis. The epidemiology, clinical decision making, treatment options, technical considerations, and outcome of the described approaches are discussed here.

carotid artery stent

direct damage to the artery and the acceleration of atherosclerosis. CEA and carotid artery stent (CAS) are well-studied treatments for postradiotherapy carotid stenosis. The clinical decision making, technical considerations, and outcomes of these modalities are discussed here.

Epidemiology

A number of case control studies have demonstrated an increased prevalence of carotid artery stenosis of 16% to 55% among patients who have undergone neck irradiation.[2] The association is observed even when studies are controlled for age and comorbidities,[3] and the effect is seen even in the very young. A study of 30 pediatric cancer survivors who underwent carotid duplex imaging on average 15 years after completion of radiation therapy compared to 30 age-, ethnicity-, and gender-matched controls found that those treated with neck irradiation were much more likely than controls to have plaque deposits in their carotid arteries (18% and 2%, respectively).[4] Neck irradiation has also been shown to be associated with an increased risk of cerebrovascular events, as high as 2.6% compared with 0.29% in matched controls (OR 9.0).[5] The stroke risk varies by pathology, with the relative risk of stroke highest for patients treated with radiation for head and neck cancers. For survivors of Hodgkin lymphoma, one-fifth of ischemic cerebrovascular events are attributable to significant carotid stenosis.[6] Irradiation of the supraclavicular fossa for breast cancer may be an exception. Although a small but statistically significant association between supraclavicular radiation for breast cancer and cerebrovascular events has been demonstrated in some studies,[7,8] other studies found no such association, including a large study of 5752 women from the Surveillance, Epidemiology, and End Results (SEER) Medicare database.[9]

A number of factors may be associated with the risk of developing carotid stenosis after neck irradiation, including older age, a history of smoking, heart disease, and treatment of malignancy without surgical resection; but the data are inconsistent regarding the effects of these factors.[10,11] The risk of developing carotid artery stenosis and associated cerebrovascular events has consistently been shown to increase with the passage of time after radiotherapy. A prospective cohort study of patients who received unilateral irradiation for head and neck cancers determined that carotid stenosis increased as the time after radiotherapy increased, but the difference in rate of stenosis compared with the contralateral side reached significant only 10 years or more after radiotherapy.[12] In a study of 367 patients with a history of irradiation for head and neck malignancy,[13] the relative risk for stroke was 10.1 after more than 10 years of follow-up, and the 15-year cumulative risk of stroke was 12%.

Pathogenesis

Radiation arteritis, though histologically similar to primary atherosclerosis, results from a distinct mechanism of arterial injury. The endothelial cell of both the artery proper and the vasa vasorum is the most radiosensitive mesenchymal cell within the radiotherapy field.[14] In the acute phase, radiation causes swelling, vacuolization, and vesicle formation within capillary endothelial cells. The acute changes are followed by platelet aggregation and fibrin deposition, which obstructs the capillary lumen and results in obliteration of the vasa vasorum. Focal necrosis and fibrosis of the media along with periadventitial fibrosis develop late as a result of this damage to the vasa vasorum, resulting in extrinsic compression and narrowing of the vessel lumen.[15,16] Nitric oxide and prostacyclin-mediated endothelium-dependent relaxation have been shown to be impaired in cervical arteries at 4 to 6 weeks after radiation, which may also contribute to the development of carotid artery stenosis.[17] Radiation-induced release of endothelium-derived growth factors is thought to be involved in the pathogenesis of both early vascular damage and late fibrosis.[18] Inflammation in irradiated arteries of the head and neck can be demonstrated even years after radiation treatment, with one study showing sustained activation of the transcription factor nuclear factor-kappa B, which results in alterations in the expression of adhesion molecules and cytokine production in the cervical arteries of irradiated patients an average of 7 years after radiation.[19]

Atherosclerosis is also accelerated by radiation, but the relationship between radiotherapy and atherosclerotic risk factors has not been elucidated. Macrophage foam cell formation is induced by radiation through activation of CD36 scavenger receptors[20]; in a mouse model, the atherosclerotic plaque of irradiated carotid arteries was macrophage-rich compared with that of nonirradiated mice, where the plaque demonstrated only minimal macrophage infiltration.[21] Histologic examination of carotid plaques after endarterectomy, however, suggests that radiation-induced carotid stenotic lesions are more stable than primary atherosclerotic plaques, with less infiltration of macrophages and a smaller lipid core (Fig. 90.1).[22]

Carotid artery intima-media thickness (CIMT), as measured by duplex ultrasound, has been shown to be directly associated with risk of stroke.[23] A significant increase in CIMT after neck irradiation has been demonstrated in multiple case-control studies.[24-29] Increased CIMT compared with controls is demonstrated in the early phase, within the first year after radiotherapy,[30] and persists as long as 50 years after treatment,[31] increasing in a linear manner with duration after radiotherapy when adjusted for age and gender.[32] Increases in CIMT are found with increasing doses of radiation.[33] There appears to be a threshold radiation dose for carotid artery injury,[34] with significantly increased CIMT demonstrated only at doses higher than 35 Gy.

Clinical Findings

History and Physical Examination

A detailed history should be taken to distinguish symptomatic from asymptomatic carotid stenosis. Symptomatic patients may present with amaurosis fugax, transient ischemic attack, or stroke. The physical exam should include inspection of the head and neck with attention to the location of scars from prior neck reconstruction, presence of patent or healed tracheostomy

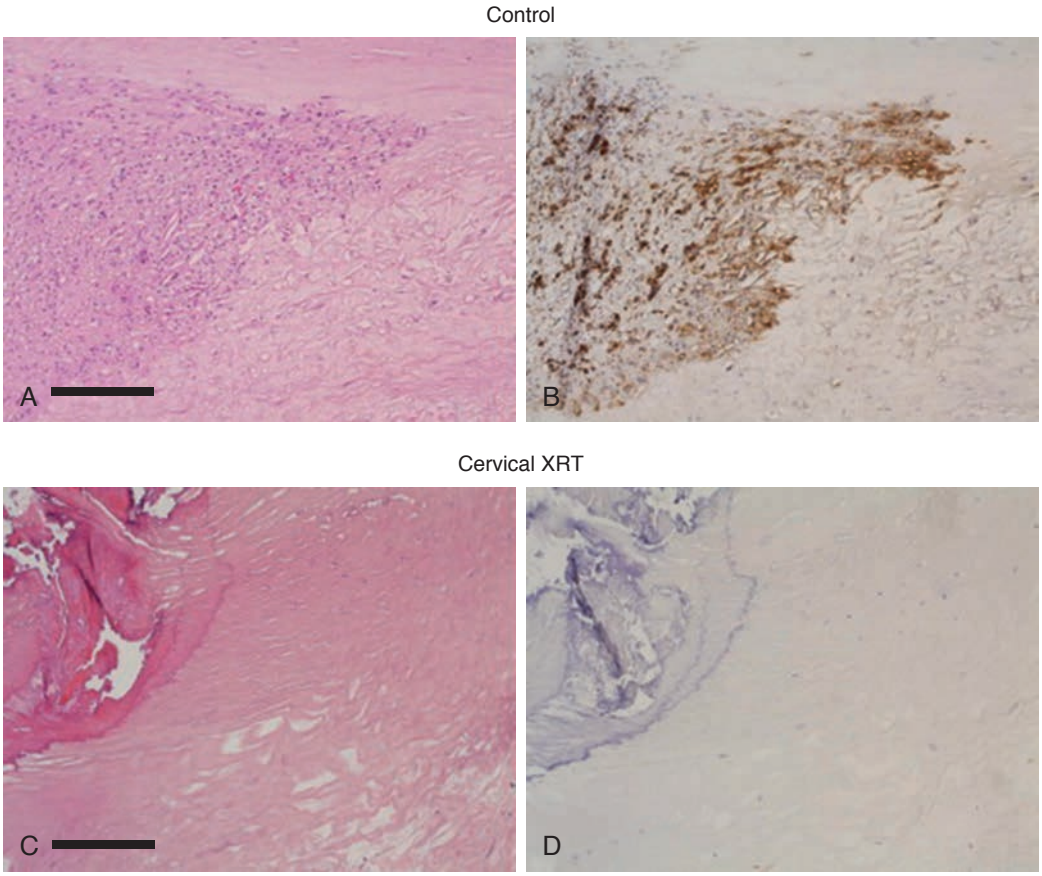

Figure 90.1 Carotid plaque histology of radiated and nonradiated patients' carotid endarterectomy specimens. sites, auscultation for carotid bruits, as well as a thorough pulse exam and neurologic exam.

Diagnostic Evaluation

Carotid duplex surveillance (CDS) may be indicated for patients after radiotherapy, but since radiation-induced stenosis rarely develops until 5 to 10 years after treatment, no consensus exists regarding when screening should begin.[35] CDS should be performed for all symptomatic patients. Any patient with a positive CDS should be further studied with MRA, CTA, or catheter-based contrast angiography; this is necessary to fully evaluate the lesion and for preoperative planning. Carotid stenosis following radiation presents in more diffuse and atypical locations than primary atherosclerotic carotid artery disease.[36] One study of patients with greater than 70% carotid artery disease by duplex compared the location of stenosis in 30 patients who had a history of neck radiation with that of 100 patients with typical atherosclerotic disease, and found that those who had undergone prior neck irradiation were significantly more likely to have severe disease in the common carotid artery and the distal internal carotid artery.[37] The unusual location of stenosis in irradiated patients was similarly found by Tallarita,[38] who characterized the location of stenosis in 60 patients undergoing intervention for postradiotherapy carotid stenosis. The common carotid artery was the site of stenosis in 16% of vessels and the distal internal carotid artery was involved diffusely in 38%. On angiography the radiation-induced lesion appears significantly longer than the primary atherosclerotic lesion, with the maximal area of stenosis in the irradiated carotid at the end of the stenotic lesion rather than the center of the lesion, as seen in atherosclerotic disease.[39]

Treatment

General Considerations

The decision to treat with medical, surgical, or endovascular intervention should be individualized. Multispecialty consensus guidelines for the selection of patients for carotid revascularization include recommendations for revascularization of symptomatic patients with greater than 50% stenosis by angiography and asymptomatic patients with greater than 70% stenosis if the periprocedural risk is low. Prior radiation therapy is identified

TABLE 90.1 Anatomic and Physiologic Factors Affecting Perioperative Morbidity With Carotid Intervention

Favors Carotid Endarterectomy	Favors Carotid Artery Stenting	Favors Medical Management
Age >70 years	Prior neck irradiation	Life expectancy <3 years
Severe aortic arch calcification	Prior radical neck dissection or laryngectomy	Asymptomatic patient with one of the following:
Type III arch	Patent tracheostomy	CHF with EF <30%
Carotid artery tortuosity	Prior carotid endarterectomy	Severe uncorrectable CAD
Circumferential heavy plaque calcification	History of cranial nerve injury	Oxygen-dependent COPD
Ulcerated/soft plaque on duplex	Proximal common carotid artery stenosis below clavicle	
Near-occlusive lesion	Distal internal carotid artery stenosis above C2	
Extensive (>15 mm) plaque	Symptomatic carotid stenosis with one of the following:	
	CHF with EF <30%	
	Severe uncorrectable CAD	
	Oxygen-dependent COPD	

CAD, Coronary artery disease; *CHF*, congestive heart failure; *COPD*, chronic obstructive pulmonary disease; *EF*, ejection fraction.

as a high surgical risk category for which CAS may be preferred over surgical revascularization.[40] In asymptomatic patients, the more stable morphology of postradiation stenosis makes it appropriate to manage these patients medically and monitor the degree of stenosis for longer than recommended for the primary atherosclerotic plaque. Intervention should be delayed until at least 80% stenosis is demonstrated in the asymptomatic patient and should be planned only if periprocedural risk is low. Medical comorbidities, level of disability, life expectancy, physical exam, arch anatomy, and technical expertise of the practitioner should be considered (Table 90.1).

Carotid Stenting (See Chapter 92)

Carotid stenting is preferred for most symptomatic patients since it eliminates the risk of cranial nerve injury associated with dissection in the irradiated field. For patients with calcified type III arches (arch vessels arise proximal to the lesser curvature of the aortic arch) and near-occlusive or ulcerated plaque morphology, the risk of stroke from carotid stenting may outweigh the added risk of cranial nerve injury in the postradiotherapy CEA.

Carotid Endarterectomy (See Chapter 91)

CEA may also be preferred in young patients with minimal comorbidities even if they are anatomically appropriate candidates for CAS due to the higher rate of restenosis after carotid stent placement. In older patients or those with multiple comorbidities, CEA after radiotherapy should be reserved for those patients with anatomic factors that preclude stent placement.

Medical Management

No specific studies of the effect of atherosclerotic risk-factor modification on stroke risk in the postradiotherapy plaque have been performed; therefore, no specific recommendations for medical management of radiation-induced carotid injury exist. Antihypertensive treatment, smoking cessation interventions, statin medication (goal LDL 100 mg/dL), and glucose control (through diet, exercise, and glucose-lowering medications) are components of best medical management of carotid atherosclerosis and should be utilized for risk-factor modification in the postradiotherapy patient as well.[40]

Open Surgical Approach

Given the difficulty of dissection and thus potential prolonged operating time, general anesthesia is preferred. The groin should be prepped for possible greater saphenous vein harvest in any patient with a tracheostomy or previous extensive neck dissection. A longitudinal neck incision may be beneficial rather than a transverse incision, particularly when a prior ipsilateral neck dissection incision is present or when the lesion is diffuse or extends into the distal internal carotid, so that the incision may be lengthened to provide additional exposure (Fig. 90.2). The surgeon should anticipate a more tedious dissection, as normal tissue planes may be obliterated from prior neck dissection and/or radiation injury. Identification and preservation of the hypoglossal, vagus, and superior laryngeal nerves are essential. Careful attention to avoid injury to the marginal mandibular and glossopharyngeal nerves is of increased concern during high dissections of the internal carotid artery. Given the atypical lesions found in postradiation therapy patients, conventional is preferred to eversion endarterectomy, and may be more challenging than removing primary atherosclerotic plaque due to radiation-induced fibrosis that obliterates the endarterectomy plane. In most cases reconstruction (Fig. 90.3) is performed with patch angioplasty. An interposition graft with saphenous vein or prosthetic conduit may be necessary if the endarterectomy results in a vessel wall so attenuated that segmental resection is required or if the severity of radiation arteritis makes endarterectomy impossible.[41] In the setting of a patent tracheostomy, an autogenous vein patch or conduit is preferred to decrease subsequent risk of infection. Subclavian-to-carotid bypass grafting is an alternative approach if there is extensive involvement of

the common carotid artery.[42] If there has been previous extensive dissection leaving little soft tissue for coverage, a myocutaneous flap should be used to provide adequate closure (Fig. 90.4).[43] An elliptical skin and soft tissue flap is created in the ipsilateral inframammary region and the attachments of the pectoralis major are divided from the anterior chest wall, sternum, and clavicle so that the muscle can be rotated 180 degrees on its thoracoacromial pedicle. The myocutaneous flap is then advanced through the subcutaneous tunnel into the incision in the neck.[38]

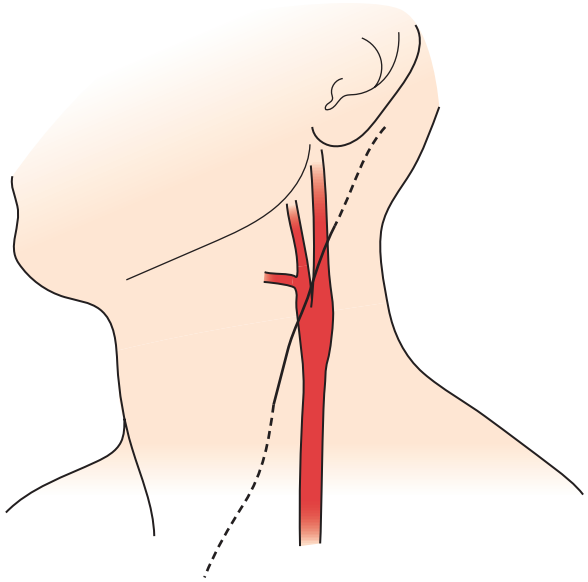

Figure 90.2 Typical carotid endarterectomy incision overlying carotid bulb *(solid line)*. Proximal and distal extension of incision for exposure of extensive plaque *(dashed line)*.

Endovascular Approach

The procedural steps are identical to those of primary atherosclerotic disease. The extensive nature of disease involvement may present a larger surface area for embolization. Evaluation of the embolic material captured in embolic protection filters demonstrates that filters from postradiotherapy patients have more numerous large particles per filter and larger mean particle size.[44] Long-segment angioplasty and the placement of additional stents may be necessary to attain procedural success but may also predispose to intimal hyperplasia and early recurrence.[45] A completion carotid and cerebral angiography should be performed after retrieval of the embolic protection device. Patients should be monitored postoperatively with neurologic assessment for 24 to 48 hours.

Results

The outcomes after surgical revascularization and stent placement for carotid stenosis in postradiotherapy patients have been reported in a number of small studies over the last few decades.[38,41-60] These results are summarized in Table 90.2. A recent meta-analysis of these studies demonstrates that for patients undergoing surgical revascularization or stent placement, there was no significant difference in 30-day mortality or combined stroke and death rate. For symptomatic patients, the 30-day mortality rate was 2.6% and the combined stroke or death rate was 2.7% in the surgical group compared with carotid stenting, which was associated with a 5.1% mortality rate and 5.1% stroke and death rate at 30 days. For asymptomatic patients, the 30-day mortality rate was 0% and combined stroke and death rate was 1.1% after surgical revascularization and 1.4% and 2.3% after stent placement, respectively. The rate of permanent nerve palsy in the surgical revascularization group was low (0.6%). Restenosis of postradiotherapy carotid stenosis was more common after carotid stent placement (18%) than after surgical revascularization (10%).[61] Although 30-day outcomes of carotid stent placement for postradiotherapy stenosis are similar to those for atherosclerotic disease,[59] long-term patency rates of carotid stent placement in the irradiated neck are significantly lower than those for primary atherosclerotic disease.[53,62] A history of head and neck cancer as the indication for stent placement has been found to be an independent risk factor for in-stent restenosis after carotid angioplasty and stenting.[52]

Follow-Up

After CEA or CAS in the postradiotherapy patient, postoperative monitoring for the first 24 to 48 hours should include an initial inpatient neurologic exam. Following CEA, patients should be maintained on antiplatelet medication indefinitely. After CAS, dual-antiplatelet therapy should be continued for 6 weeks after the procedure followed by aspirin daily for life. Follow-up after CEA or CAS with physical examination and duplex is performed every 6 months during the first year and annually thereafter.

RECURRENT CAROTID STENOSIS

Epidemiology

Rates of restenosis range from 3% to 12% for CEA and 2% to 31% for CAS in these studies over 2 to 5 years, and they favor CEA (Table 90.3).[63-68] For patients with high-grade carotid restenosis (≥70% by duplex) the 5-year cumulative risk of cerebrovascular events including transient ischemic attack and stroke is 23%, with most events occurring within the first year.[65] A number of predictors of restenosis have been identified, including patient age, female gender, history of head and neck cancer, diabetes, history of smoking, dyslipidemia, residual stenosis after stent placement, and larger number of stents deployed.[52,65,67-69] Restenosis is five times more common after CEA with primary closure than if a patch is used (see Chapter 91).[70,71] No differences have been found for rates of in-stent restenosis after CAS between different carotid stents or embolic protection devices.[72]

Pathogenesis

Early restenosis after CEA or CAS can be attributed to intimal hyperplasia, whereas late stenosis represents recurrence of atherosclerotic disease. Histologic examination of restenotic plaques has demonstrated that early restenotic plaques (<5 years postendarterectomy) contain less calcification, more luminal thrombus, and a smaller lipid core compared with primary atherosclerotic plaques. The late recurrent stenotic plaques (>5 years) demonstrate marked macrophage infiltration, calcification, and a larger lipid core, making these lesions histologically indistinguishable from primary atherosclerosis.[73] The extent of inflammatory response has been associated with early restenosis after stent placement, with a postinterventional rise in leukocyte count and C-reactive protein associated with early restenosis (see Chapter 92).[74,75]

Clinical Findings

History and Physical

Pertinent history—including symptoms of cerebrovascular events, atherosclerotic risk factors, and medical comorbidities that pertain to surgical risk, including a history of cranial nerve injuries—should be elicited. The physical examination should include evaluation of the head and neck as well as vascular and neurologic examinations.

Diagnostic Evaluation

Duplex ultrasound should be performed every 6 months for patients with stenosis of 50% or more on postoperative duplex. The intimal hyperplasia observed in early restenosis appears homogeneous and echolucent on duplex, whereas the late atherosclerotic recurrences demonstrate heterogeneity with marked luminal irregularity.[76] Duplex criteria developed for grading primary atherosclerosis can be used for measuring restenosis, with similar sensitivity and specificity. However, a number of studies have suggested that velocity criteria developed for the native carotid artery may overestimate the degree of in-stent restenosis after CAS,[77-79] but no consensus criteria exist for the interpretation of carotid duplex for stents. Proposed criteria are listed in Table 90.4.

Carotid restenosis often involves the distal extent of the endarterectomy[80] or the proximal or distal extent of the stent. Therefore a CTA, MRA, or conventional angiogram should be obtained prior to intervention to determine the extent of the lesion. This will also help with decision making between an open or endovascular approach as well as preoperative planning for either approach.

Treatment

General Considerations

A history of previous CEA has been identified as posing a high surgical risk for which CAS is preferred over surgical

revascularization. Patients with recurrent carotid stenosis greater than 50% who have cerebrovascular symptoms attributable to the stenosis should be revascularized unless life expectancy is low or the patient has high level of disability at baseline. The threshold for treatment for asymptomatic recurrent stenosis should be higher than for primary atherosclerosis in early lesions due to the characteristics of these plaques, continuing surveillance until the stenosis is greater than 80%,[76] but the decision should be individualized (see Table 90.1).

Carotid Stenting

The main benefit of CAS for treating both asymptomatic and symptomatic patients with recurrent stenosis following CEA or CAS is the ability to avoid a difficult redo dissection that puts the patient at risk for cranial nerve injury. Because these lesions originate from intimal hyperplasia, plaque embolization and perioperative stroke risk are lower than in the case of primary stenting. However, CAS may not be possible in patients with difficult type III arch anatomy, extensive calcifications, ulcerated plaque morphology, or damaged stents.

Redo Carotid Endarterectomy

In young patients with minimal comorbidities, even if, anatomically, they are candidates for carotid stenting, redo CEA may be preferred owing to the higher rate of restenosis after carotid stent placement (see Chapter 92). In older patients with more comorbidities, redo CEA should be reserved for those with anatomic factors precluding stent placement. Conversion to a CEA after CAS is rarely done; in general this is reserved for carotid stenting in patients who have damaged stents requiring removal.

Medical Management

As in primary atherosclerotic disease, antihypertensive treatment, smoking cessation intervention, statin medication, and glucose control should be utilized for risk-factor modification.

Reoperative Surgical Revascularization

General anesthesia is preferred for redo CEA given the possibility of extensive dissection and prolonged operating time. If possible the previous neck incision should be used. The exposure for redo CEA is often more challenging due to the disruption of normal tissue planes with postoperative scarring, which can make identification of anatomic structures, particularly cranial nerves, quite difficult. The vagus and hypoglossal nerves in particular may become adherent to the planes of previous dissection.[81] Retraction injury is most common, but transections must also be avoided. The most common site of recurrence is the endarterectomy site; however, stenosis may be observed at the proximal or distal extent of the previous arteriotomy or at the prior clamp site of the proximal common carotid artery. Intimal hyperplasia in early recurrent stenosis may make separation of the layers of arterial wall impossible, necessitating patch angioplasty without endarterectomy. Venous or prosthetic bypass is indicated for extensive disease in as many as one-third of patients.[82] The raw surface area of the reoperative field makes hemostasis of the wound bed more challenging. The risks of cranial nerve injury, hematoma formation, and wound complications are notably higher than expected for initial CEA.

Endovascular Management of Post-Endarterectomy Stenosis

CAS has been increasingly performed for carotid restenosis since the Centers for Medicare and Medicaid Services approved reimbursement for the procedure in patients with symptomatic restenosis after CEA.[83] The anatomic considerations and procedural steps are the same as in CAS for primary atherosclerotic disease. Anatomic variations such as severe calcifications, pathologic elongations of the carotid arteries, tortuosity or ectasia of the thoracic aorta, and acute angulation or anomalous origin of the left common carotid artery—which create difficult angles for tracking and sheath stabilization prior to stent deployment—may increase the risk of embolic events during CAS.[84] The risk of bradycardia during carotid angioplasty and stent placement is lower for patients who have previously undergone CEA.

Stenting Versus Endarterectomy for Restenosis After Carotid Endarterectomy

Two recent meta-analyses compare repeat CEA to stenting for recurrent carotid stenosis after CEA. The first, by Fokkema et al.,[85] included 13 studies and 1132 patients (CEA $N = 479$, CAS $N = 653$). The baseline characteristics of the two groups differed in that the redo CEA group was significantly younger, more likely to be symptomatic, and more likely to be current or past smokers, whereas the CAS group was significantly more likely to have hypertension and/or renal failure and to be taking antiplatelet therapy. After adjusting for confounders, there were no significant differences in the outcomes of stroke, death, or combined perioperative stroke or death between CEA and CAS (2.7% versus 2.3%, respectively). There were no differences in these outcomes between symptomatic and asymptomatic patients. Cranial nerve injury, bleeding, and wound infections were uncommon in the redo CEA group: 5.5%, 2.7%, and 0.2%, respectively. Technical failures and access-site complications were rare in the CAS group at 1.3% and 1.9%. Restenosis rates were available for 712 patients with a median follow-up of 13 months. The restenosis rate (≥70% stenosis) for redo CEA was 7.7% and for CAS 4%, which was not a statistically significant difference.

The second meta-analysis, by Tu,[86] included 4399 patients from 50 studies (CEA $N = 2292$, CAS $N = 2107$). There were no significant differences in the baseline characteristics or comorbidities between the patients who underwent CEA or CAS for recurrent stenosis after CEA, but the duration of follow-up was significantly longer for the redo CEA group (50 months) compared with that for the CAS group (24 months). There were no significant differences in rates of perioperative stroke between redo CEA and CAS or between treatment modalities within subgroups of symptomatic or asymptomatic patients. Cranial nerve injury was observed in 6% of the redo-CEA group, with more than 80% of the deficits resolved within 3 months. Significant differences were identified in rates of restenosis between redo CEA and CAS at 1 year (1.7% vs. 8.3%), 2 years (2.6% vs. 9.8%), and 5 years (4.4% vs. 13.5%).

Surgical Revascularization for In-Stent Restenosis

CEA with stent removal for in-stent restenosis may be necessary in cases of stent kinking, fracture, or erosion through the vessel wall. Control of the internal carotid artery distal to the stent can be challenging, and inflammation of the periarterial tissue makes identification and protection of nerves more difficult than with a standard CEA.[87,88]

Techniques of surgical exposure are discussed in Chapters 55 and 91. The length of the longitudinal arteriotomy will depend on the length of the implanted stent. The stent should be removed in toto, carefully, to avoid penetration through the thinned arterial wall.[89] The intimal endarterectomy should be continued until the proximal and distal resection planes are free from atherosclerotic debris. The distal internal carotid artery should be carefully inspected where the stent is removed since the artery may be very fragile in this area. Reconstruction may be performed with a venous or prosthetic patch. If the extent of the inflammatory response causes the stent to become adherent to the arterial wall, reconstructive options include internal to external carotid artery transposition, common to internal carotid artery bypass or subclavian to internal carotid artery bypass.[90] Results from 15 patients in a multicenter prospective registry indicate that surgical revascularization for in-stent carotid stenosis is safe and durable, with 1 perioperative stroke (7%), no mortalities, and no recurrent stenosis at 21-month follow-up.[91]

Endovascular Management of In-Stent Restenosis

Endovascular treatment strategies for carotid in-stent restenosis include percutaneous balloon angioplasty alone, cutting balloon angioplasty, and balloon angioplasty with stent placement.[72,92-94] Technical success can be achieved in most cases using these techniques.[72,92-94] Placement of an additional stent to resolve a distal in-stent stenosis may result in a kink or bend in the distal internal carotid artery and elicit a significant hyperplastic response.[95]

Follow-Up

Patients must be followed closely after reintervention since the rate of recurrent restenosis based on available published data is around 14%,[96] with some studies describing rates as high as 50%.[97] Recommendations are physical examination and duplex every 6 months during the first year and annually thereafter.

Abstract

Carotid endarterectomy, introduced in the 1950s, has been the most frequently performed open vascular surgical procedure for many years. Several randomized prospective clinical trials have demonstrated the safety and efficacy of this procedure in the prevention of ischemic stroke in symptomatic and properly selected asymptomatic patients with significant carotid stenoses. The excellent perioperative results of this procedure reported in multicenter randomized clinical trials are being matched by the results reported in individual institutional series and in large population-based studies. Numerous studies have confirmed the long-term efficacy of carotid endarterectomy based in terms of stroke prevention and anatomic durability. This chapter outlines evidence to support the role of carotid endarterectomy as the gold standard procedure to treat patients with clinically significant carotid artery disease, the technical details of its performance, and its risks and long-term benefits.

First performed in the 1950s, carotid endarterectomy (CEA) experienced remarkable growth in the 1970s and 1980s after several studies demonstrated that carotid stenosis was an important risk factor for disabling stroke and death,[1-6] and a randomized multicenter trial published in 1969 showed that carotid surgery reduced the incidence of stroke from symptomatic carotid lesions.[7] However, other studies reported high complication rates, thus compromising the potential benefit of CEA.[8] However, randomized controlled trials (RCTs) performed in the 1990s definitively established the safety and efficacy of CEA and its superiority over the best medical management of patients with symptomatic and asymptomatic carotid disease.[9-12]

EPIDEMIOLOGY

Incidence

At least 750,000 strokes occur annually in the United States: approximately 15% are fatal, 15% to 20% are severely disabling, and another 15% to 20% of stroke patients who recover will experience a subsequent disabling stroke. At least 80% of these strokes are ischemic and atherosclerotic disease of the cervical carotid artery is responsible for 20% to 40% of ischemic strokes.[13]

Etiology

Strokes secondary to carotid artery stenosis are a consequence of atheroembolization, thromboembolism, or are secondary to a low flow state through the carotid artery.

INDICATIONS FOR CAROTID ENDARTERECTOMY

Based on the most recent evidence-based guidelines published by the Society for Vascular Surgery, CEA is recommended for most symptomatic patients with a 50% to 99% ICA stenosis. Further, CEA should be considered for patients with a 60% to 99% asymptomatic ICA stenosis if perioperative stroke and death rate is less than 3% and if the patient has at least a 3- to 5-year life expectancy. In the symptomatic patient with a 50% to 99% ICA stenosis, and either medical or anatomic contraindications to CEA, carotid artery stenting (CAS) should be considered (see Chapter 92). Medical therapy, rather than CEA or CAS, should be selected in symptomatic patients with a less than 50% (although there is some recent evidence suggesting that CEA may be indicated for rare symptomatic patients with <50% ICA stenoses [see below]) and for asymptomatic patients with a greater than 60% stenosis and surgical contraindications.[14]

PREOPERATIVE IMAGING

Duplex ultrasound in an accredited laboratory is the most appropriate first test to evaluate the patient with suspected carotid artery disease, with either CTA or MRA reserved for patients with suspected disease proximal or distal to the neck, when there are indeterminate duplex findings, or other confounding issues.[15-21] There is some evidence that CTA underestimates, and MRA overestimates, the degree of stenosis.[19] It is the practice in some centers to proceed to endarterectomy based on duplex findings alone.[14] Since the benefit of CEA is highly dependent on the degree of stenosis, others maintain that verification of duplex findings is essential before proceeding to operation.[22] Clearly, if the patient is found to have an intermediate stenosis and is asymptomatic, one should perform at least another noninvasive test to confirm this finding before recommending CEA. If there is discordance between these studies, one should either obtain a third noninvasive test or proceed to angiography.

PERIOPERATIVE MEDICAL MANAGEMENT

Risk stratification is important in determining the most appropriate preoperative cardiac work-up and perioperative management of the patient undergoing CEA (see Chapter 32). The American Heart Association's (AHA) perioperative guidelines classify CEA as an intermediate risk procedure.[23] The perioperative medical management of the patient undergoing CEA should include blood pressure control, and beta blocker, statin, and antiplatelet therapy.

Beta-Blockers

Based upon early small clinical trials, it was felt that all patients with vascular disease would benefit from perioperative beta-blockade. This recommendation has evolved based on several large trials, especially the pivotal POISE trial.[24] Perioperative

beta blockade, with a goal of achieving a maximum heart rate of 60 to 80 beats per minute, is recommended in the recent Society for Vascular Surgery carotid guidelines.[14]

Antiplatelet Therapy

Meta-analyses of antiplatelet therapy trials published by the UK Antithrombotic Trialist Group in 1994 and 2002 concluded that antiplatelet therapy significantly reduces the incidence of stroke in high-risk patients, with a resultant 25% reduction in strokes overall.[25,26] The majority of these studies included aspirin or aspirin plus another antiplatelet agent. Recent studies of clopidogrel provide evidence that perioperative embolization is decreased without an increase in bleeding complications or transfusion requirements after CEA. Other antiplatelet agents, such as ticlopidine and glycoprotein IIb/IIIa antagonists have not been specifically studied during CEA and generally have a higher risk profile than ASA or clopidogrel. Based on this evidence, it is possible to recommend either ASA or clopidogrel, or both, for use before and after CEA. Based upon the preponderance of evidence, the authors do not withhold aspirin and will continue clopidogrel if there is a clinical indication in the CEA patient.[14]

Heparin

Although the International Stroke Trial did not find any benefit of routine heparin administration for acute stroke because of increased numbers of hemorrhagic stroke and fatal extracranial bleeding,[27] a report from the Oregon Health Sciences University found that urgent crescendo TIAs could be controlled with intravenous heparin, thereby allowing CEA to be delayed in these patients.[28] Unfractionated heparin (UFH) is routinely used intraoperatively to prevent carotid thrombosis despite a lack of level I evidence to support this practice. The combination of aspirin and intraoperative heparin administration appears to be especially effective in preventing thrombosis.[29]

Protamine Administration

Numerous publications have examined whether reversing heparin with protamine during CEA is safe. In the GALA trial (General Anesthesia versus Local Anesthesia for carotid surgery), protamine was not found to be associated with stroke.[30] The preponderance of recent evidence suggests that protamine administration does not increase perioperative stroke risk, although the authors prefer not to use it routinely unless there is truly unusual bleeding.

Dextran

Dextran is a polysaccharide that inhibits platelet aggregation.[31] It has been used to control embolic episodes both preoperatively and postoperatively. British investigators in 1997 showed that a 6-hour dextran infusion effectively controlled postoperative embolic events as measured by transcranial Doppler (TCD), with a 0% stroke and mortality rate in a series of 100 patients.[32] We favor dextran infusion for 24 hours after CEA to control platelet aggregation on the endarterectomy site and potential microembolization.

Statins

The potential benefits of statins in patients with carotid artery disease are several-fold. A reduction in cholesterol levels with statins may be associated with plaque regression (see Chapter 29).[33-41] The Asymptomatic Carotid Artery Progression Study (ASAPS) demonstrated that lovastatin was associated with reduced carotid artery intima-media thickness and also a lower rate of combined cardiovascular events, although not the stroke rate.[42,43]

Numerous trials conducted over the past decade have demonstrated statin medications to be highly effective in primary and secondary stroke prevention.[44-48] Furthermore, it appears that the stroke prevention benefits of statins are related to the pleiotropic effects of statin medications rather than their cholesterol-lowering effects. In addition, several studies have demonstrated that statins are associated with a reduced rate of perioperative cardiac morbidity and overall mortality in patients undergoing major vascular surgical procedures.[49-52]

In a series of 1566 patients undergoing CEA at our Institution, statins were associated with a reduced 30-day incidence of stroke (1.2% vs. 4.5%, $P = .002$), TIA (1.5% vs. 3.6%, $P = .01$), and mortality (0.3% vs. 2.1%, $P = .002$).[53] A large administrative database analysis from Canada documented a significantly lower rate of perioperative stroke and death in symptomatic patients who were taking statin medications at the time of CEA.[54] Furthermore, LaMuraglia and coworkers reported that lipid-lowering agents were associated with significant protection against recurrent carotid stenosis or late anatomic failure after CEA.[55] The evidence seems clear that all patients undergoing CEA should be taking statin medications at the time of surgery and long-term.

OPERATIVE TECHNIQUE

Anesthesia

CEA may be performed under GA regional anesthesia (RA) with deep or superficial cervical block, and even under pure LA, with comparable lengths of stay. The majority of studies comparing the two techniques have reported improved perioperative cardiac stability with RA, but this does not necessarily result in a reduced incidence of myocardial infarction (MI).[56,57]

Disadvantages of RA include patient discomfort or anxiety, risk of seizure or allergic reaction, anxiety for the operating surgeon, and compromise of technique in a teaching setting. The main benefit of LA is that it facilitates efficient selective shunting if that is the surgeon's preference (see below).

Patient Positioning

A roll is placed behind the scapulae used in conjunction with a padded ring under the head to achieve some hyperextension of the neck without being overextended. If LA or RA is used,

a Mayo stand is placed over the patient's head to suspend the surgical drapes away from the patient's face to prevent sensations of claustrophobia. The patient is placed in the flexed position with the table rotated to expose the side of the neck to be operated on.

Skin Incision

One of two skin incisions may be used (Fig. 91.1). The standard incision is a longitudinal incision parallel to the medial border of the sternocleidomastoid muscle. The upper portion of the incision is angled posterior to the earlobe if cephalic exposure above the angle of the jaw is required. An alternative method is to place the incision in an appropriately located skin crease, usually 1 to 2 cm inferior to the angle of the jaw. If the incision is made too low, more cephalic exposure can be obtained by extending the skin crease incision posteriorly. If the incision is made too high, more caudal exposure can be obtained by extending the incision more anteriorly.

Carotid Exposure (see Chapter 55)

Manipulation of the carotid artery should be minimized because intraoperative embolization can result from careless handling. The external jugular vein lies deep to the platysma and is more commonly encountered with an oblique skin crease incision. The other structure located at this level is the greater auricular nerve; injury to this nerve leads to numbness of the earlobe. The carotid sheath is entered and the facial vein is identified crossing medially in the base of the wound and divided; sometimes it has an early bifurcation or trifurcation, and multiple branches need to be ligated. The jugular vein is then retracted laterally. The vagus nerve is identified at this point in the carotid sheath, usually located posteriorly between the jugular vein and carotid artery, although in a minority of patients it may lie anteriorly. The CCA is controlled circumferentially with an umbilical tape and a Rummel tourniquet. The ansa cervicalis nerve should be identified; it usually lies medial to the distal CCA and identifying this nerve facilitates safe dissection of the carotid bifurcation and avoids injury to the hypoglossal nerve, which crosses medially from a superior to an inferior location. The dissection should be continued along the posterior edge of this nerve. If one dissects along the anterior border of the ansa, it is possible to inadvertently transect the hypoglossal nerve in the crotch of the junction of these two nerves before the hypoglossal nerve is identified (Fig. 91.2).

The superior thyroid artery originating from the medial border of the carotid bifurcation or proximal ECA is controlled with a tie or plastic vessel loop. The ECA is controlled with a vessel loop. Finally, the ICA is exposed coming off the lateral side of the bifurcation and should be controlled distal to the plaque. In this location the artery has a typical bluish appearance because of translucency of the vessel. During dissection of the carotid bifurcation and its branches, one should avoid dissecting in the crotch of the carotid bifurcation to avoid injuring the carotid body to minimize hemodynamic instability and troublesome bleeding. If hemodynamic instability results, the carotid body can be gently injected with 1% lidocaine.

Before clamping, the patient is administered 70 to 100 U/kg of heparin, which is allowed to circulate for 3 minutes. The ICA is clamped first to prevent the embolization that can result when the CCA or ECA is clamped. Care should be taken to make sure that the ICA is clamped on a normal portion of the artery distal to the plaque.

If LA or intraoperative electroencephalography is used for selective shunting, a test clamp on the distal ICA should be applied for at least 3 minutes to check for changes in the neurologic examination or electroencephalographic (EEG) pattern. If such changes occur, the artery should be unclamped to allow reperfusion before reclamping and opening the carotid bifurcation; opening the bifurcation and placing a shunt may take 2 to 3 minutes and should not be performed while the brain is already ischemic. However, unclamping the ICA introduces the potential for embolization from disrupted plaque.

Figure 91.1 Longitudinal and transverse skin incisions for carotid endarterectomy.

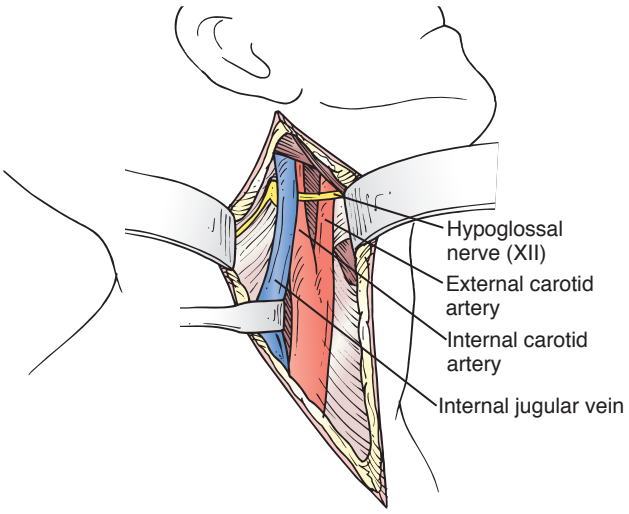

Figure 91.2 Operative field. Note the internal jugular vein mobilized posteriorly after ligation of the anterior facial branch and the hypoglossal nerve crossing the vessels superior to the bifurcation.

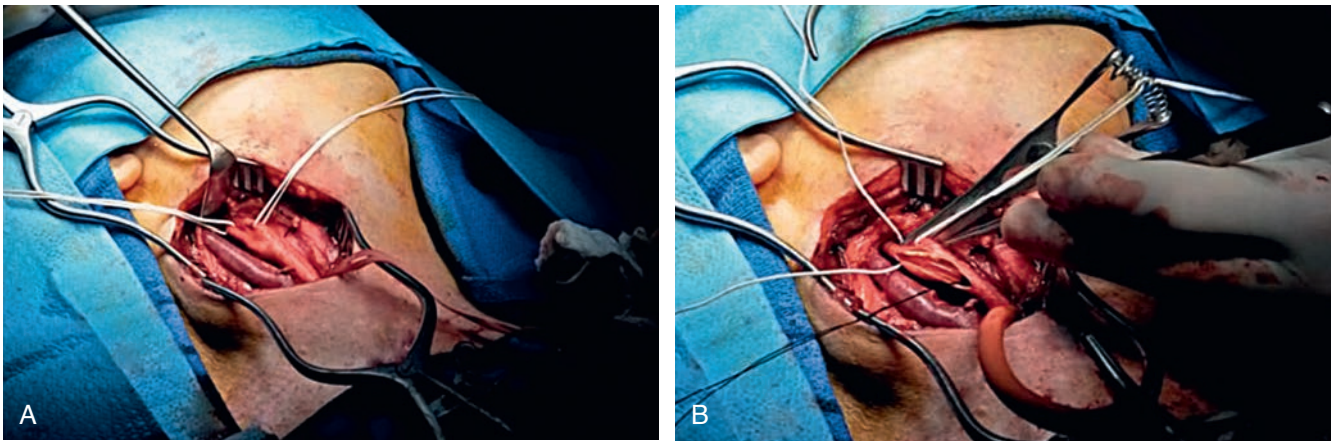

Figure 91.3 (A) Initial operative exposure with the Rumel tourniquet around the common carotid artery and the internal and external carotid arteries isolated with vessel loops. (B) The arteriotomy has been made and the shunt, with a silk suture attached, lies within the vessel.

If carotid stump pressure is to be measured, clamps are placed on the CCA and the ECA, and a needle connected to a pressure line is placed into the distal CCA below the carotid bifurcation. Both clamping the CCA and placing the needle into the artery introduce the potential for embolization.

Conventional Endarterectomy

The conventional technique for CEA consists of a vertical arteriotomy and closure usually by patch angioplasty. One should avoid making the incision too close to the flow divider at the ECA origin because this can distort the anatomy and make the closure more difficult (Fig. 91.3).

The endarterectomy is begun in the CCA in the plane between the media and the adventitia. The proximal endpoint in the distal CCA is established and the plaque is trimmed in that location in a beveled manner. The endarterectomy is continued into the orifice of the ECA, first with a Freer elevator and then with a fine clamp that is passed up into the ECA in the plane of the endarterectomy and spread to further mobilize the plaque away from the adventitia in the 6-, 9-, and 12-o'clock positions; it is usually hard to pass the clamp in this plane at the 3-o'clock position next to the flow divider. The vessel loop on the ECA is released transiently while the plaque is everted from within the ECA. The endpoint of the plaque is inspected; an ideal endpoint is gradually tapering and feathered (Fig. 91.4). In our practice, all loose bits of intima and media in the orifice of the ECA are removed to perform complete endarterectomy of the ECA, although others believe that endarterectomy of the ECA may be neglected without compromising results.[58]

A technically perfect endpoint in the ICA is critical. Occasionally special maneuvers may be required to expose the distal ICA to extent the arteriotomy to achieve an acceptable endpoint, as seen in Fig. 91.4. Tacking sutures at the distal endpoint should be avoided unless absolutely necessary; such suturing is problematic and associated with an increased perioperative stroke rate.[59] The endarterectomy is best ended by pulling the plaque transversely away from the artery with lateral traction. One should avoid pulling out or down on the plaque, which is more likely to result in a step-off that can be difficult to correct.

Figure 91.4 Carotid endarterectomy specimen. Note the smooth endpoints of the distal plaque from the external and internal (longer portion) arteries.

We believe that repairing the arteriotomy with a patch angioplasty represents the standard of care in contemporary practice (Fig. 91.5). A variety of patch materials are available, including autologous vein, polytetrafluoroethylene (PTFE), woven polyester (Dacron), and bovine pericardium, and no material appears to be clearly superior to another.

When the suture line is nearly completed, the CCA and ICA clamps are briefly sequentially released to flush air or debris (or both) out of the arteries. The carotid bifurcation is flushed vigorously with heparinized saline and inspected again for debris or intimal flaps before the arteriotomy is finally closed. Once again the clamp on the ICA is briefly released to fill the bifurcation with blood. It is then replaced while the clamps on the CCA and ECA are released so that any remaining air or debris will be flushed up the territory of the ECA rather than the ICA. At this point the ICA clamp is removed.

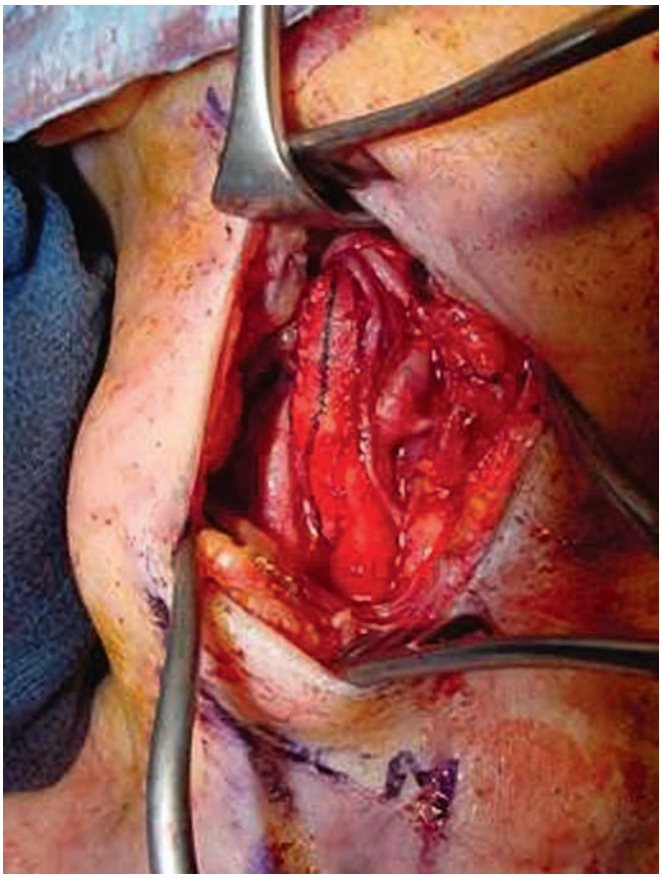

Figure 91.5 Patch closure of the arteriotomy for carotid endarterectomy. Dacron was used in this case. Note the ansa cervicalis coursing along the vessel, the vagus nerve posteriorly, and the hypoglossal nerve at the apex of the incision.

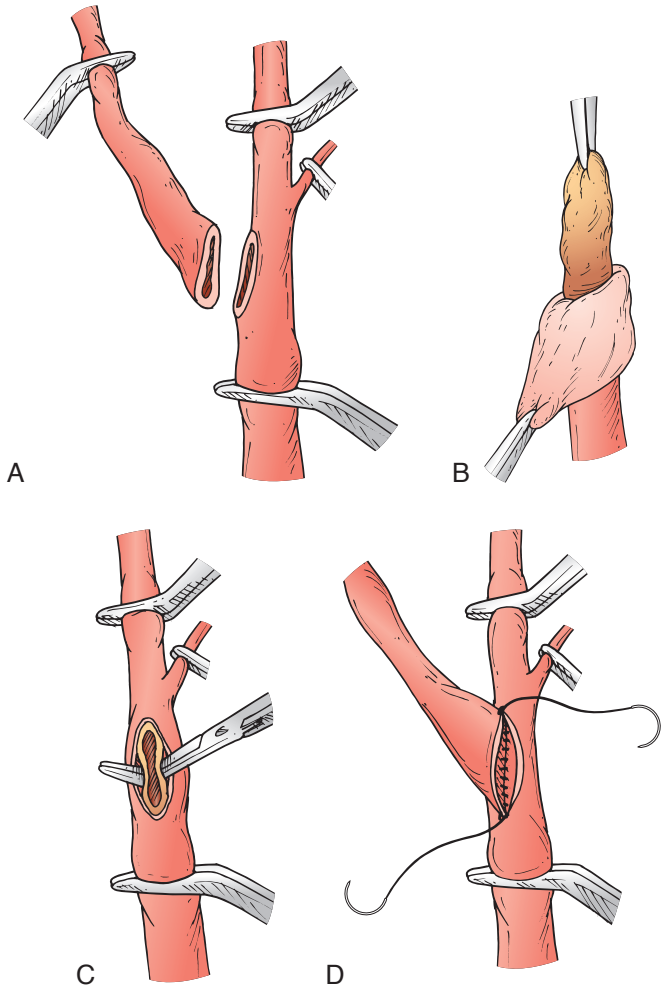

Figure 91.6 Eversion endarterectomy. (A) Internal carotid artery transected from the bifurcation. (B) Adventitia teased back off the internal carotid artery plaque. (C) Plaque endarterectomized from the common carotid and origin of the external carotid artery. (D) Reanastomosis of the internal carotid artery to the bifurcation. (Modified from Saratzis N, Saratzis A, Milaras S, et al. Eversion carotid endarterectomy illustrated: tips and tricks of the procedure. *Surg Rounds.* 2006;29(8):382-389. http://www.hcplive.com/general/publications/surgical-rounds/2006/2006-08)

Any bleeding from the suture line is addressed at this time. One should avoid re-clamping unless absolutely necessary to control bleeding at this stage and avoid the risk for formation of thrombus or a fibrin-platelet aggregate on the patch or endarterectomized vessel.

Eversion Endarterectomy

DeBakey originally described eversion endarterectomy with partial transection of the anterior portion of the carotid bifurcation.[2] Etheredge revised DeBakey's technique with complete transection of the bifurcation,[60] which allowed the origins of both the ICA and ECA to be everted for a longer distance. The endarterectomy is performed by mobilizing the entire circumference of the carotid adventitia off the plaque (described as a "circumcision" by Etheredge) and then everting the adventitia and mobilizing it upward while gentle caudad traction is applied to the plaque. This maneuver is performed distally into the orifices of the ICA and ECA and then proximally into the CCA. Once the endarterectomy is complete, the divided bifurcation is reunited with a simple end-to-end anastomosis.

Kieney and coworkers introduced a modification of eversion endarterectomy in 1985 in which the origin of the ICA is excised obliquely off the carotid bifurcation, and is inverted on its own, and endarterectomy of the CCA and ECA is performed through an arteriotomy in the side of the carotid bifurcation.[61] The ICA is reanastomosed to the carotid bifurcation primarily (Fig. 91.6).

Advantages of the eversion technique are that the anastomosis can be performed rapidly and it is not prone to restenosis, and therefore patching is not required. Disadvantages of this technique are that more extensive dissection is sometimes necessary to mobilize the vessels during the eversion; the procedure does not lend itself readily to shunting (although shunting is not precluded by this technique), and it can be difficult to visualize the endpoint in the ICA after the plaque has been removed. Therefore, in our opinion, a completion study should be performed with this technique, which is particularly effective for dealing with a redundant, coiled, or kinked ICA as the ICA can be pulled down and straightened and the redundant portion excised. The remaining portion of

the ICA is spatulated and reattached to the arteriotomy on the carotid bifurcation.

Comparison of Conventional and Eversion Carotid Endarterectomy

In EVEREST (EVERsion CEA vs. Standard Trial study), a randomized, prospective multicenter study including more than 1400 patients randomized to eversion or standard CEA, there were no statistically significant differences in outcomes between the two techniques, although a slightly higher incidence of perioperative complications was noted with eversion CEA and a slightly higher incidence of restenosis with standard CEA. While other studies have shown better outcomes with eversion CEA,[62,63] a large meta-analysis comparing eversion to conventional CEA found no significant differences in the rate of perioperative stroke or death (1.7% vs. 2.6%, odds ratio [OR] 0.44; 95% confidence interval [CI], 0.10-1.82), but did note that eversion endarterectomy was associated with a lower rate of restenosis during follow-up (2.5% vs. 5.2%, OR 0.48; 95% CI, 0.32-0.72).[64]

EXPOSURE FOR HIGH LESIONS

The carotid bifurcation can be located anywhere between the second and seventh cervical vertebrae, and a bifurcation located high in the neck poses technical challenges that can increase perioperative risk for stroke and cranial nerve injury. Ideally, one will recognize a high bifurcation on the preoperative imaging study. This is a potential advantage of CTA, in which bony anatomy is always included in the images. A conscious effort must be made to locate the bony anatomy with DSA if unsubtracted images are not provided with the study, but the anatomy can still be defined from subtracted images. Bony landmarks are never provided with carotid duplex imaging, but an astute vascular technologist will note a high bifurcation and should record it in the report.

Nasotracheal Intubation

The initial approach is to utilize nasotracheal intubation. With the patient's mouth closed, the vertical ramus of the mandible is displaced anteriorly 1 to 2 cm relative to its position when the mouth is open with an oral endotracheal tube. The additional few millimeters of exposure afforded by this maneuver will often be the difference in achieving a suitable endarterectomy endpoint in the distal ICA.

Division of the Digastric Muscle

The next step to enhance distal exposure is to divide the posterior belly of the digastric muscle. The hypoglossal nerve should be carefully identified and protected before the muscle is divided. Two other nerves that can be injured high in the neck are the spinal accessory nerve, which enters the tendinous portion of the sternocleidomastoid muscle usually in the upper third of the muscle, and the glossopharyngeal nerve, which lies deep to the digastric muscle.

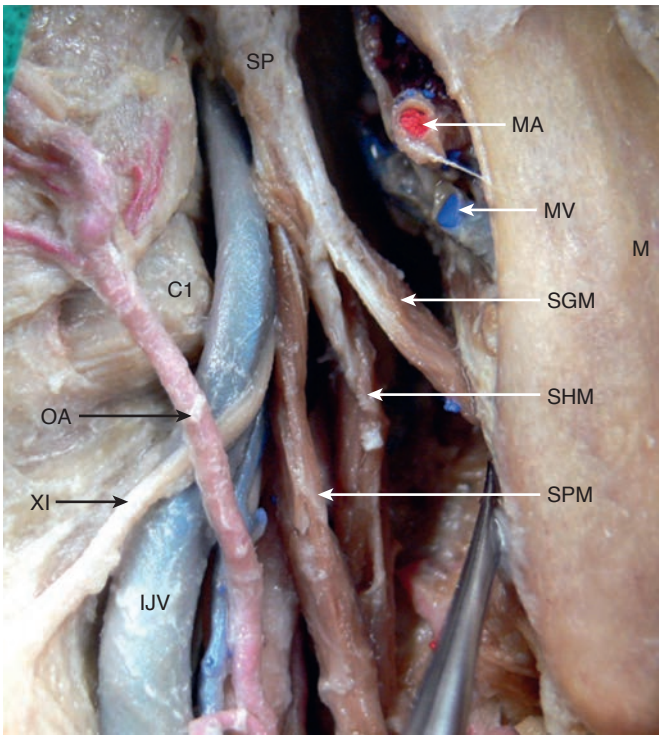

Figure 91.7 Anatomic relationships of the styloid process. *C1*, Transverse process of C1; *IJV*, internal jugular vein; *M*, mandible; *MA*, maxillary artery; *MV*, maxillary vein; *OA*, occipital artery; *SGM*, styloglossus muscle; *SHM*, stylohyoid muscle; *SP*, styloid process; *SPM*, stylopharyngeus muscle; *XI*, spinal accessory nerve. (Modified from Izci Y, Moftakhar R, Pyle M, et al. Retromandibular fossa approach to the high cervical internal carotid artery: an anatomic study. *Neurosurgery.* 2008; 62[5 Suppl 2]:ONS363-ONS369.)

Resection of the Styloid Process

The final maneuver that can be extremely effective in gaining cephalic exposure is resection of the styloid process (Fig. 91.7). After the posterior belly of the digastric muscle is divided, the insertions of the styloid apparatus: styloglossus, stylopharyngeus, and stylohyoid muscles on the styloid process are excised with a scalpel. The stylohyoid muscle can be found posterosuperior to the ECA and inserts into the posterior portion of the styloid process.[65] In addition, the occipital artery runs along the inferior border of the posterior belly of the digastric muscle. Identification and division of the occipital artery can prevent bleeding secondary to trauma caused by retraction (see Fig. 91.7). The styloid process is carefully resected with a rongeur.[66] This can extend the exposure of the ICA by an additional 4 to 5 mm. However, damage to the underlying facial nerve is a potential complication of styloidectomy.[67]

Anterior Subluxation of the Mandible

Two other options can be used to improve exposure of a high bifurcation, and both require preoperative planning and coordination with an oral or plastic surgeon (Fig. 91.8). These patients should all be nasotrachealy intubated. Anterior subluxation of the mandible was described for use in high carotid exposures in 1984. The authors describe their technique for subluxation

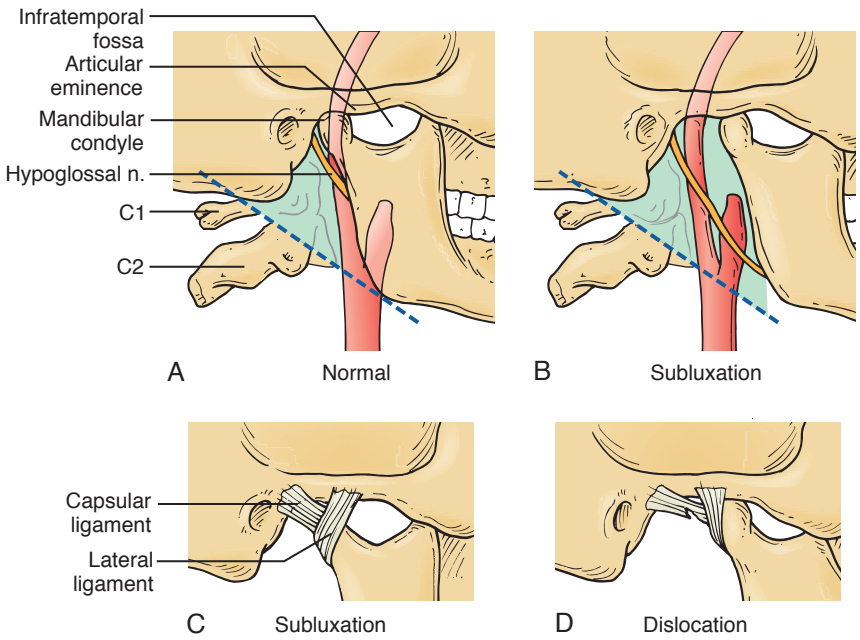

Figure 91.8 Mandibular subluxation/dislocation. (A) Normal bony anatomy with high carotid bifurcation. (B) The mandibular condyle is pulled forward onto the articular eminence, providing additional exposure when the subluxed mandible is fixed in place at this position. (C) Illustrates the desired position of the temporomandibular ligaments during subluxation. (D) Illustrates the potential undesired position of the temporomandibular ligaments from dislocation, which may cause a tear in the capsular ligament. (Modified from Simonian GT, Pappas PJ, Padberg FT, et al. Mandibular subluxation for distal internal carotid exposure: technical considerations. *J Vasc Surg.* 1999; 30:1116-1120. [ref. xvii].)

as an evolution from full mouth arch bars with circumdentate wiring to unilateral subluxation by circummandibular/transnasal wiring.[68] For patients with healthy dentition, anterior subluxation of the mandible can be accomplished by placing circumdental wires around the mandibular cuspid and bicuspid teeth on the side ipsilateral to the vascular lesion. Corresponding wires should be placed around the corresponding contralateral maxillary teeth. The mandible is then subluxed anteriorly and the wires are twisted together to hold the fixation. Patients with poor dentition can have arch bars placed prior to wiring to facilitate the placement of the wires.[69] An even more aggressive approach involves the use of a complete vertical osteotomy through the vertical ramus of the mandible and separation of the mandible to expose the ICA.

CEREBRAL PROTECTION AND MONITORING

Shunting

CEA may be performed with the routine nonuse of shunts,[70-72] routine shunting,[73-76] or selective shunting. Under GA, selective shunting may be determined by intraoperative measurement of carotid "stump pressure," intraoperative monitoring of the EEG or somatosensory evoked potentials (SSEP), measurement of MCA flow by TCD, and monitoring with cerebral oximetry. An alternative method is to perform CEA under RA, with shunt insertion if symptoms develop after the carotid artery is clamped. These adjuncts are designed to detect intraoperative cerebral ischemia, whereas TCD has the added advantage of detecting intraoperative emboli. Two commonly used shunts are the Pruitt-Inahara and Javid shunts. In a randomized trial the Pruitt shunt was less likely to maintain physiologic flow in the MCA, whereas the Javid shunt was associated with a higher incidence of cerebral embolism at declamping.[77]

Placing a shunt has the capacity only to prevent ischemic stroke, but it could actually increase the risk for embolic stroke if performed poorly. Intraoperative cerebral ischemia is a relatively uncommon cause of intraoperative stroke.[78-80] This would support the argument of the routine nonshunters who believe that cerebral ischemia is a rare cause of stroke and that shunting may do more harm than good (by causing embolic complications) so that even selective shunting is never justified. However, it is clear that cerebral ischemia can lead to perioperative stroke[81-83] and can be completely relieved by placement of a shunt. This should translate into the prevention of stroke in these patients if embolic complications related to shunt placement are minimized. In fact, there is evidence that the benefits of shunting outweigh the risks in these patients.[84-86]

A recent meta-analysis by AbuRahma, et al., including papers published from 1990 to 2010, found that the mean perioperative stroke rate for CEA with routine shunting was 1.4% and for routine nonshunting was 2%. For selective shunting, the stroke rate varied depending upon the method used for intraoperative monitoring. It ranged from 1.1% for cervical block anesthesia, 1.6% for EEG and carotid stump pressure, to 4.8% using TCD. The authors concluded that both routine and selective shunting are acceptable and should be employed at the surgeon's discretion.[87]

Stump Pressure

Measurement of carotid stump pressure was the first method used to predict intraoperative ischemia.[88] In patients with measured stump pressures lower than 50 mm Hg, Hays and colleagues noted a 50% neurologic event rate in those who were not shunted versus a 10% rate in those who were in a

series of 297 patients.[89] Kelly and coworkers measured stump pressure with concurrent EEG monitoring in 289 patients[90] and performed shunting only in those with evidence of ischemia by EEG criteria. They found that 6% of patients with stump pressure higher than 50 mm Hg had ischemia by EEG criteria. Stump pressure correlated well with EEG findings in patients with completed strokes but had a false-negative rate of 77% in patients with vertebral artery disease. In another report using EEG as a "gold standard," Harada and associates found that a stump pressure lower than 50 mm Hg had a positive predictive value of only 36%.[91] In this series, 11% of patients with ischemia by EEG criteria would not have received shunts and 64% of patients with a stump pressure lower than 50 would have received them unnecessarily by stump pressure criteria. Similarly, Brewster and coworkers found that 11 of 17 patients with ischemic EEG findings would not have been shunted by stump pressure criteria, and 7 of 63 would have unnecessary shunts.[92] Finocchi and colleagues used TCD to verify stump pressure and found that stump pressure did not correlate well with ischemia by TCD criteria in patients with postoperative deficits.[93] Clearly, even in the setting of what appears to be a satisfactorily high stump pressure, there may still be regions of the brain that are relatively hypoperfused.

Electroencephalographic and Somatosensory Evoked Potential Monitoring

Intraoperative EEG monitoring is the most widely used method of intraoperative cerebral monitoring.[94-97] Evidence suggests that electroencephalography is overly sensitive—positive in 10% to 40% of patients with unilateral carotid disease and positive in as many as 69% with bilateral carotid disease,[98,99] thereby overestimating the number of people who require shunts. Blume and coworkers observed postoperative strokes in only 9% of patients with abnormal EEG findings in whom shunts were not placed.[100] Furthermore, several series have documented neurologic events that occurred in the absence of EEG abnormality when shunting was not used.[95,101] Tempelhoff and associates found that 5 of 6 patients with postoperative deficits in a series of 103 patients showed EEG changes only late in the operation, when shunting was no longer feasible.[101]

Similarly, while there are multiple published studies on the use of SSEP suggesting that it is a useful adjunct to detect ischemia,[102-106] a meta-analysis of 15 studies, Wober and colleagues found that SSEP monitoring is not a reliable means of detecting ischemia and predicting neurologic outcome.[107]

Transcranial Doppler

TCD was introduced by Schneider and coworkers in 1988.[108] Visser and coauthors reported that with normal TCD findings one could safely avoid shunting in one third of patients, but that abnormal findings on TCD predicted ischemia by EEG criteria only 60% of the time.[109] TCD has the unique advantage of detecting microemboli intraoperatively, which may alert the surgeon to avoid further vessel manipulation and microembolization.[110,111] However, Belardi and associates also reported that TCD (as well as stump pressure) was not accurate in predicting cerebral ischemia.[112]

Awake Carotid Endarterectomy With Regional or Local Anesthesia

In view of these findings, performing CEA under RA is the most reliable method of predicting the need for selective shunting. Shunt rates of 5% to 15% are consistently lower than with other modalities.[112-119] In two recent prospective trials in which both stump pressure and EEG measurements were recorded before performing endarterectomy under RA, but in which the need to shunt was ultimately determined by neurologic changes, both EEG findings and stump pressure were found to inaccurately predict the need for shunting.[120,121] In a study by Calligaro and Dougherty published in 2005, a cost analysis found that RA saved more than $3000 per case by avoiding EEG measurements.[120]

Three studies have shown decreased length of stay with RA,[116,122,123] but in two of them the length of stay in the GA group was not reflective of modern practice, approximately 5 days.[116,123] There is no evidence in the literature that demonstrates the cost effectiveness of selective shunting versus routine shunting, and insufficient data to conclude that CEA performed under RA is associated with a lower rate of MI or neurologic complications.[117-124]

Routine Shunting

One risk of selective shunting is that neurologic events may be attributable to the shunt itself secondary to embolism or ischemia and may not occur with routine shunting. Specifically, selective shunting, regardless of the adjunct used, always involves a test clamp. In the case of stump pressure measurement, instrumenting the carotid artery with a needle introduces the added risk of embolism. When a test clamp is positive, there are two options. One is to unclamp the vessels and reperfuse the brain while preparations are made to shunt. This maneuver exposes the patient to the risk of embolization. The other option is to proceed with the endarterectomy and placement of a shunt. In this instance, the brain is ischemic when the test clamp becomes positive and is exposed to an additional period of ischemia while the shunt is being placed, whereas during routine shunting, shunt placement can usually be accomplished in 1 to 2 minutes after clamping before the brain becomes ischemic.[56,57,89,101,125]

The routine use of carotid shunts allows CEA to be performed in a consistent manner, which eliminates surgeon and patient anxiety, without the added cost or complexity of monitoring equipment. Studies consistently show that carotid shunting relieves the intracerebral ischemia caused by clamping, whether measured by neurologic status, EEG changes, MCA flow on TCD, or cerebral blood flow, and there is no convincing evidence that placement of a shunt increases embolic complications or causes arterial injury leading to more subacute or chronic complications. However, there is evidence that placing a shunt in the setting of severe ischemia decreases the stroke rate[126] and may limit ischemia-reperfusion injury. Further, Parrson and

associates have shown that carotid shunting diminishes the inflammatory response of ischemic brain injury, as demonstrated by the production of various inflammatory mediators.[125] This may be an important mechanism in the occurrence of delayed postoperative strokes, which can account for up to 70% of perioperative strokes.[79]

Several large series including nearly 7000 patients have documented a perioperative stroke rate of 1.0% to 1.6% with routine shunting.[73-76,127] In our practice, routine shunting is the preferred technique. Despite acceptable results in some individuals' hands, routine nonuse of shunts cannot be advocated in view of the abounding evidence that intraoperative ischemia can be a source of stroke that is preventable with shunts. Selective shunting based on stump pressure, TCD, or neurophysiologic monitoring does not accomplish the goal of improving results through decreased shunt use and only adds to the cost and complexity of the procedure. The only form of selective shunting that is truly reliable is that based on neurologic examination during RA.

ARTERIOTOMY CLOSURE

Considerable experience indicates that patch closure yields superior clinical and anatomic outcomes compared to primary arteriotomy closure.

Patch Material

Saphenous Vein Patches

Saphenous vein patching has been used extensively with good results. Complications specific to saphenous vein patching include wound complications at the harvest site, potential compromise of a valuable conduit for later bypass procedures, and the potentially devastating complication of patch rupture, which has been reported to occur in 0.5% to 4% of cases.[128-133] Because most of these were ankle veins, several investigators recommended harvesting the great saphenous vein (GSV) from above the knee. Lord and coworkers also noted that aneurysmal expansion of saphenous vein patches can occur in up to 17% patients.[134]

Archie and Green investigated the relationship of GSV diameter and rupture pressure and found that GSVs with diameters less than 3.5 mm were more prone to rupture.[135] Their group also noted that women were three times more likely to have a GSV measuring less than 3.5 mm. Applying this knowledge to their practice, Archie found that by using a GSV with a distended vein diameter of greater than 3.5 mm and maintaining a carotid bulb diameter of less than 13 mm, patch rupture was completely avoided in a series of 534 patients over an 8-year period.[136]

Synthetic Patches

Synthetic materials that are commonly used include PTFE, woven polyester (Dacron), and bovine pericardium.

Comparative Analyses

Pooled data from meta-analyses and large databases demonstrated no definitive clinical benefit of vein versus prosthetic patching. In a New York state database including 1972 CEAs performed at six regional hospitals, perioperative stroke was significantly more common with primary closure than with eversion or patching (5.6% vs. 2.2%, no difference between eversion and patching), as well as higher perioperative stroke rates and death with primary closure versus eversion or patching (6% vs. 2.5%). There were no differences in any outcomes between eversion and patching.[137] In a review of more than 10,000 CEAs performed in several states, the use of a patch—in particular a prosthetic patch—was a statistically significant indicator for improved outcomes.[138] Based on these findings, the U.S. Centers for Medicare and Medicaid Services adopted patching of conventional CEA as a physician quality measure for 2009.

After these studies were published, Al-Rawi and coworkers reported an RCT that included 328 patients in which primary closure was performed by a single surgeon using microvascular techniques. There were no statistically significant differences in outcomes, but a trend toward a higher combined stroke and death rate was noted in the patched group.[139] Therefore, primary closure with microvascular technique may be the only instance in which it might be justified, although the preponderance of evidence supports patch closure after conventional CEA.

In a randomized trial of 160 CEAs with either external jugular vein and PTFE patches, there was no difference in stroke-free survival at 12, 30, and 60 months, and no difference in recurrent stenosis rates, but there was a trend toward improved results with a vein patch.[140] In an RCT comparing bovine pericardium with Dacron in 95 CEAs performed in 92 patients, there was significantly less suture line bleeding with bovine pericardium than with Dacron (4% vs. 30%) and no difference in neurologic outcomes.[141] Another study compared saphenous vein and internal jugular vein with knitted Dacron in 275 CEAs and found no significant differences in perioperative morbidity, mortality, or early restenosis between any of these groups.[142] Another report studied internal jugular vein, GSV from the thigh, and knitted Dacron, and documented a higher death rate in the jugular vein group (8% vs. 0% with GSV and 1.1% with knitted Dacron), as well as a higher stroke rate that was not statistically significant (4% vs. 1.3% and 1.1%, respectively).[143] In another study of primary closure versus patching with GSV, jugular vein, and PTFE,[144] perioperative neurologic event rates were significantly higher with primary closure than with all patch methods. Event rates were slightly higher with jugular vein patches, and recurrent stenosis was also higher in this group than in the GSV or Dacron patch group and similar to primary closure. In a follow-up study 2 years later, primary closure had a higher incidence of restenosis and need for reoperation, especially in women who had smaller carotid arteries.[145] Finally, in a small RCT comparing Dacron with PTFE, a higher stroke rate with Dacron was largely due to perioperative thrombosis.[146] As a result of this trial the manufacturer of the Dacron patch re-engineered it, and this group found no difference in outcomes between the two patches.

Selective Patching

It has been suggested that carotid patching may not be necessary in all patients, and the technique does have some drawbacks,

such as longer operative time, greater potential for bleeding from longer suture lines, and increased cost. To avoid these pitfalls while preventing the increased morbidity associated with primary closure, some surgeons use a policy of selective patching. Golledge and associates studied selective patching based on intraoperative measurement of the outer diameter of the ICA and found that selective patching was safe in arteries measuring at least 6 mm.[147] Other work has clearly identified other risk factors for recurrent carotid stenosis and indications for selective patching, including female gender, elevated cholesterol level, and possibly cigarette smoking and hypertension[105] (see section on "Recurrent Carotid Stenosis," below).

COMPLETION STUDIES

A preventable cause of perioperative stroke is thromboembolism or carotid artery thrombosis resulting from technical imperfection. To minimize this risk, intraoperative completion studies have been used, including continuous wave Doppler, duplex ultrasound, and intraoperative angiography. Using continuous wave Doppler, an experienced operator can document vessel patency and a stenosis by the associated high-pitched audible signal. However, it is insensitive to small intimal flaps or more subtle stenoses, and its accuracy is operator dependent. Duplex ultrasound is a much more sensitive tool that provides detailed anatomic imaging, as well real-time physiologic information. However, this modality is also operator dependent. The authors have found completion duplex ultrasound to be particularly helpful in identifying plaque disruption secondary to clamp or Rommel tourniquet trauma in the proximal CCA as well as distal intimal flaps (Fig. 91.9). Intraoperative angiography has been considered the gold standard of completion studies. However, the quality of the information obtained from an angiogram may vary significantly depending on the technique used.

Results of Completion Studies

Several studies have demonstrated the utility of completion studies to identify technical defects, with subsequent improvement of results.[148,149] On the other hand, not all technical imperfections, such as minor intimal flaps and especially ECA lesions, will cause strokes. In addition, attempts to revise significant lesions can convey additional morbidity from repeat manipulation of the vessels and a further risk for ischemia, embolism, thrombosis, or bleeding. In the EVEREST trial, the only significant risk factor for a major defect was plaque extension greater than 2 cm into the ICA (OR 1.5; $P = .03$). One of the unanswered questions about completion studies is the extent of abnormality (either flap length or stenosis severity) that warrants intervention. Clearly, other workers have found no significant benefit in completion imaging.[150,151] However, if there is any doubt about the condition of the endpoint, a completion study should be obtained.

During eversion endarterectomy one may have only a fleeting glimpse of the endarterectomy endpoint before the artery retracts when the plaque separates from the artery, or none at all. Therefore, completion studies are more likely to be useful in this procedure.

PERIOPERATIVE STROKE MANAGEMENT

In a comprehensive study of the etiology of perioperative stroke associated with CEA, more than 20 mechanisms were delineated.[81] These mechanisms can be grouped in decreasing order of frequency as perioperative arterial thrombosis and embolization, cerebral ischemia during carotid clamping, and intracerebral hemorrhage. Perioperative carotid arterial thrombosis most often results from technical imperfection in performance of the operation, such as disruption of the intima during placement of the intraluminal shunt, residual intimal flaps or atheromatous disease, or residual luminal thrombus. Completion imaging studies, as described in the previous section, will help identify technical imperfections and can reduce the incidence of neurologic complications (see Fig. 91.9). Maximizing the chance for neurologic recovery is most dependent on early recognition of the deficit and immediate institution of proper therapy. Establishing the correct diagnosis is dependent on the time of

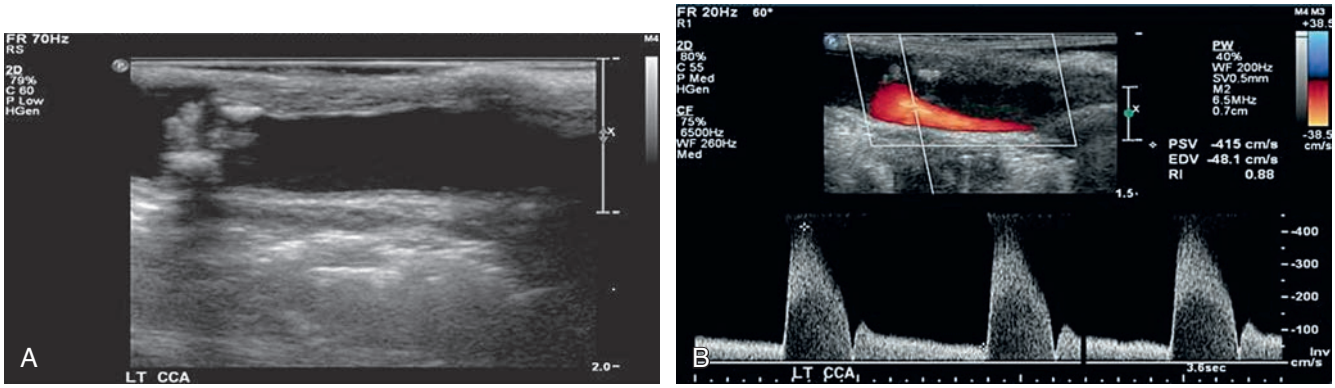

Figure 91.9 (A) Intraoperative completion carotid B mode image revealing significant plaque disruption in the proximal common carotid artery. (B) Note the markedly elevated flow velocities at the site of plaque disruption. The vessel was re-clamped and this site was endarterectomized.

onset of symptoms and is supported by selected noninvasive vascular laboratory or radiologic studies.

Intraoperative

A patient undergoing CEA under GA should be awakened in the operating room immediately after wound closure, and a neurologic examination performed. If a new focal central neurologic deficit is identified, the incision should be immediately opened, and the ICA is checked for flow with Doppler. If flow appears to be present, the surgeon should perform duplex ultrasonography or arteriography to identify a potential correctable etiology. Angiography should include intracranial imaging if no cause is found at the endarterectomy site because a distal embolus is potentially treatable by thrombolysis or extractable via microcatheter techniques. However, if the ICA does not have flow, or if a local defect is suspected, the endarterectomy must be re-explored. If there is acute thrombosis of the endarterectomy site, a meticulous search for a technical defect, such as a distal intimal ledge, should be carried out after careful thromboembolectomy. It is best not to clamp the distal ICA initially in the case of thrombosis and to extract the clot in the bulb and visible ICA so that backpressure may extrude any more distal ICA thrombus with the CCA clamped. If there is no back flow, a balloon catheter can be used, but care must be taken to prevent distention in the distal ICA to avoid causing a carotid artery–cavernous sinus fistula.[152] If there is a local flap, platelet accumulation, or other problem within the endarterectomy, it should be corrected. In the setting of re-exploration, great care must be taken if a shunt is reinserted to be sure that the distal endpoint is not injured and a flap created with insertion of the shunt.

At re-exploration, if the vessel is found to be patent without a local defect, the most likely cause is either ischemia during carotid clamping or, much more likely, intraoperative embolization. Despite careful technique, in a small minority of patients, excessive platelet deposition may occur acutely on the endarterectomy site and predispose to distal embolization or even acute thrombosis of the vessel. In this case, we favor resection of the endarterectomy segment and replacement with an interposition graft and preferentially a ringed 6 mm PTFE graft. Conversely, if the vessel appears normal at re-exploration, thus suggesting that the patient experienced either embolization during vessel dissection before clamping or ischemia during clamping, treatment is medical (namely, close attention to hemodynamic monitoring, oxygenation, and blood pressure stability postoperatively) or thrombolysis/microcatheter embolus extraction in institutions with such capability.

Postoperative

If the patient awakens neurologically intact in the operating room and then a new deficit develops in the recovery room or later postoperatively, the differential diagnosis is more complex. Initially, the patient should undergo Duplex ultrasound if it can be performed rapidly. If this testing indicates occlusion of the vessel or abnormal flow velocities suggestive of an intimal flap or other anatomic deficit, the patient should be immediately be taken to the operating room for re-exploration. Timing is crucial because most neurologic deficits are significantly reversible if flow is restored within 1 to 2 hours after vessel thrombosis. If the noninvasive studies are negative and thus suggest a patent vessel, head computed tomography (CT) should be performed immediately to rule out a cerebral hemorrhage. If negative, carotid angiography should be performed to identify any technical defect requiring revision at the operative site, or a possible intracerebral embolus.

The availability of intracerebral catheter-directed thrombolysis has provided another tool for neurologic salvage in a patient who experiences an embolic event associated with CEA. In addition, catheter-based thrombectomy of ICA and MCA emboli has been accomplished successfully in the setting of acute ischemic stroke and as "neurorescue" for carotid thrombosis complicating CAS.[153-160]

SURGICAL RESULTS

Considerable clinical experience reported over the last three decades indicates that CEA can be performed with low rates of perioperative complications, and that it substantially reduces the risk for subsequent stroke in patients with significant symptomatic as well as asymptomatic extracranial carotid atherosclerotic lesions.[161-166]

Randomized Trials

Symptomatic Disease

The National Institutes of Health (NIH)-funded North American Symptomatic Carotid Endarterectomy Trial (NASCET) included investigations of both high-grade (70%-99%) and moderate-grade (50%-69%) stenosis (Table 91.1). The 30-day mortality, disabling stroke, and nondisabling stroke rates were 1.1%, 0.9%, and 4.5%, respectively.[9,167] In the NASCET high-grade stenosis investigation, 659 patents with symptomatic ICA stenoses (70%-99%) were randomized to optimal medical management versus CEA and optimal medical management. At the 2-year follow-up, there was a highly significant reduction in ipsilateral stroke incidence (9% vs. 26%) in patients who underwent CEA.[9] This benefit became apparent within 3 months of randomization and has persisted through 8 years of follow-up.

In the moderate-stenosis limb of the investigation including 865 patients with 50% to 69% ICA stenoses, at 5 years of follow-up the ipsilateral stroke rate was 22.2% in medical patients and 16.7% in surgical patients ($P = .045$), and this benefit has persisted through 8 years of follow-up.[167]

Two recent randomized clinical trials comparing CEA to CAS have provided further evidence of the safety and efficacy of CEA. In the Carotid Revascularization Endarterectomy versus Stent Trial (CREST), the 30-day stroke and death rate was 3.2% among symptomatic patients.[168] In the International Carotid Surgery Trial, the 30-day stroke, death, and MI rate was 5.2%.[169]

Asymptomatic Disease

Management of asymptomatic carotid disease has recently become somewhat controversial because the long-term risk for stroke is not as high in asymptomatic when compared to symptomatic patients, and because the natural history of asymptomatic carotid disease may be improving due to improvements in medical therapy. In the NIH-funded Asymptomatic Carotid Atherosclerosis Study (ACAS), 1600 patients with greater than 60% asymptomatic stenosis were randomized to optimal medical management versus CEA and optimal medical management (Table 91.1). The 30-day stroke per death rate was 2.3% in the surgical cohort by intent-to-treat analysis. However, there were seven strokes and two deaths preoperatively, so the actual perioperative stroke rate was 1.3% and the mortality rate was 0.1%. At the 5-year follow-up, stroke and death rates were 5.1% in the CEA group and 11% in the medical management group ($P = .004$).[11]

The Asymptomatic Carotid Surgery Trial (ACST) was carried out in Europe, and was similar in design to ACAS, and randomized 3200 patients with greater than 60% asymptomatic ICA stenoses to best medical therapy versus CEA and best medical therapy. The 5-year stroke and death rates were 6.4% for CEA and 11.8% for medically managed patients ($P < .0001$; see Table 91.1).[11,170] In CREST, the 30-day stroke and death rate was 1.2% among asymptomatic patients who underwent CEA.[168]

Institutional Experience

Since publication of the NASCET, ACAS, and ACST results, the safety and efficacy of CEA have been confirmed in multiple individual institutional reports. For example, in a series 2236 CEAs performed between 1989 and 1999 at the Massachusetts General Hospital, the perioperative stroke and death rate was only 1.4%.[171] In a report of 1566 CEAs performed at the authors' institution from 1994 through 2004, the 30-day stroke and death rates were 2.5% and 0.8%, respectively.[53]

Population-Based Experience

In recent years several population-based analyses have demonstrated results of CEA in community practice comparable to the outcomes in tertiary referral centers and randomized trials (Table 91.2).[172-183]

COMPLICATIONS

Cardiac

MI is responsible for 25% to 50% of all perioperative deaths after CEA.[184-186] Furthermore, more late deaths are due to MI than to stroke or other causes.[184,185,187] At least 40% to 50% of patients who undergo CEA have symptomatic CAD.[25,26,188-191] In a prospective angiographic study, severe surgically correctable CAD was identified in 20% of patients about to undergo treatment of carotid disease.[192] However, operative mortality has declined significantly over the past 2 decades in large measure due to a significant reduction in the incidence of major cardiac complications reflecting improvements in screening, as well as perioperative medical management of this patient population (see Chapter 32).

Cranial Nerve Injury

Incidence

Cranial nerve dysfunction is the most common neurologic complication of CEA. The incidence of postoperative dysfunction of cranial nerves ranges from 5% to 20% in several series, and a variety of nerves may be affected (Table 91.3).[193-202] In the CREST trial, the incidence of cranial nerve injury was 4.7%.[168]

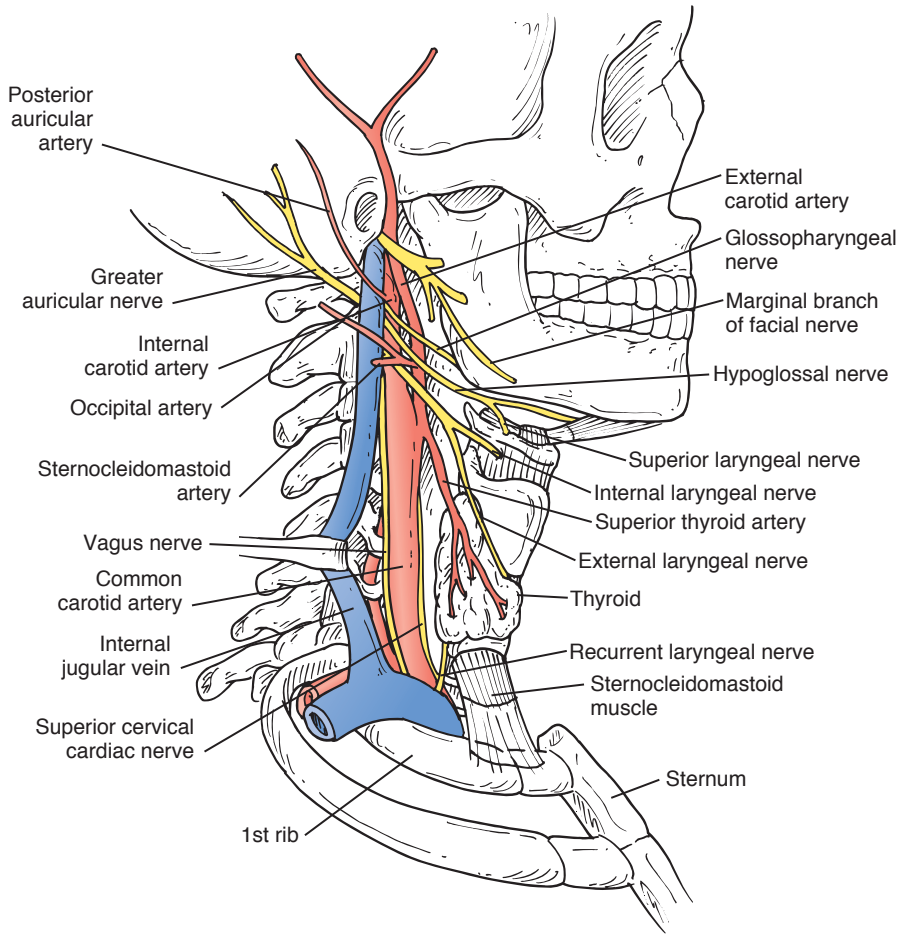

Figure 91.10 Relationship of the cranial nerves and their major branches to the common, internal, and external carotids in the neck. (Modified from Eisele DW, Smith RV, eds. *Complications in Head and Neck Surgery*, Philadelphia: Elsevier; 2009.)

TABLE 91.3 Incidence of Cranial Nerve Dysfunction Following Carotid Endarterectomy

Nerve	Reported Incidence (%)
Hypoglossal	4.4-17.5
Recurrent laryngeal	1.5-15
Superior laryngeal	1.8-4.5
Marginal mandibular	1.1-3.1
Glossopharyngeal	0.2-1.5
Spinal accessory	<1.0

Retrospective reviews may significantly underestimate the true incidence of cranial nerve dysfunction after CEA. In a prospective study of patients undergoing 450 CEA procedures and who also underwent postoperative otolaryngology examination, 72 cranial nerve injuries were identified in 60 (13%) patients. Approximately one third of the patients with documented deficits were asymptomatic and would have been missed by cursory clinical examination.[202] In the vast majority of cases, the clinical deficit is transient, with complete resolution noted within weeks to months after the procedure. In one prospective study, all injuries resolved within 5 months.[198] In another prospective study, almost all nerve deficits resolved within 12 months after CEA, although it was noted that two patients with recurrent laryngeal nerve dysfunction regained normal function at 20 and 50 months after CEA, respectively.[196] In the CREST trial, there was no significant adverse impact of cranial nerve injury on the patients' quality of life 1 year later.[168] In the ECST randomized prospective trial, it was noted that the risk for permanent nerve injury was 0.5%.[198] In another report, the incidence of permanent cranial nerve injury was only 1.1%.[196]

Anatomic and Clinical Considerations

Iatrogenic injury to the cranial nerves results from the close anatomic proximity of these structures to the carotid bifurcation (Fig. 91.10). Most deficits are due to direct blunt injury during dissection, stretch trauma from excessive retraction, electrocoagulation damage, inexact placement of ligatures, or pressure injury secondary to postoperative hematoma formation. Cranial nerve injury is much more likely during reoperative surgery because of excessive scar formation.[194] In one recent detailed analysis, the incidence of cranial nerve dysfunction correlated with the duration of surgery; there was a significantly higher incidence of nerve injury when the duration of CEA exceeded 2 hours.[198]

Hypoglossal Nerve

Hypoglossal nerve dysfunction, manifested by ipsilateral tongue weakness and deviation to the affected side with protrusion

and difficulty masticating, is the most frequent cranial nerve deficit documented in most reports (see Table 91.2). The structure descends from the hypoglossal canal (anterior condylar foramen) medial to the ICA and then courses lateral to the ECA, usually several centimeters distal to the carotid bifurcation, although in rare cases it may cross at the carotid bifurcation.[202] In this situation, if a patient has an unusually high carotid bifurcation or if atheromatous plaque extends well past the origin of the ICA, cephalad mobilization of the nerve is usually required for adequate operative exposure. In most cases mobilization can be accomplished safely without morbidity by division of the ansa hypoglossi. In other cases, division of tethering branches of the ECA or internal jugular vein is required, which increases the likelihood of transient injury. Although unilateral hypoglossal nerve injury is rarely serious, bilateral deficits have been associated with serious articulation and swallowing difficulty and upper airway obstruction requiring tracheotomy.[203] Therefore, it is important to assess the functional integrity of this nerve after CEA in a patient who is scheduled for early contralateral CEA.[197]

Vagus Nerve

The vagus nerve is easily identified within the carotid sheath posterior to the CCA, although in the occasional patient it may lie anterior to the carotid and be mistaken for the ansa hypoglossi. Therefore, before division of the latter structure, the vagus nerve should be clearly identified. The recurrent laryngeal branch usually originates from the vagus within the mediastinum, loops around the subclavian artery on the right or the aortic arch on the left side, and passes cephalad in the tracheoesophageal groove behind the strap muscles. In most cases, this nerve is not in close proximity to the operative field and is not likely to be directly injured. Typically, recurrent laryngeal nerve dysfunction results from vagus nerve trauma. In rare cases, the recurrent laryngeal nerve arises from the vagus at the level of the carotid bifurcation, the so-called nonrecurrent recurrent laryngeal nerve, and enters the larynx posterior to the CCA. Vagus or recurrent laryngeal nerve injury results in paralysis of the ipsilateral vocal cord in the paramedian position and is manifested as hoarseness and loss of an effective cough mechanism. In occasional patients, the vagus and hypoglossal nerves will be in apposition in the upper portion of the operative field, and no effort should be made to separate these structures to minimize the risk for injury. Patients who have previously undergone contralateral carotid, thyroid, or parathyroid surgery should have a careful examination of their vocal cords before CEA if there is any suggestion of recurrent laryngeal nerve injury because bilateral vocal cord paralysis may cause postoperative airway obstruction.

Superior Laryngeal Nerve

The superior laryngeal nerve originates from the vagus near the jugular foramen and passes obliquely to the larynx posterior to the ECA and ICA where it divides into internal and external branches. It is not usually visualized during routine dissection for CEA, and it may be injured by injudicious clamping of the ICA or ECA. Injury to the external branch of the superior laryngeal nerve primarily results in loss of tensioning of the ipsilateral vocal cord and may be manifested clinically by early fatigability of the voice and difficulty with voice modulation at the high registers. Conversely, injury to the internal branch may result in decreased sensation at the laryngeal inlet and mild swallowing difficulty.[196]

Facial Nerve: Marginal Mandibular Branch

Injury to the marginal mandibular branch of the facial nerve causes drooping of the ipsilateral lower lip. Although this may be cosmetically bothersome to the patient, it is of little functional significance. This nerve courses from the anterior border of the parotid gland between the platysma and deep cervical fascia across the masseter muscle and ramus of the mandible. It may be drawn into the operative field as the patient's head is turned to the opposite side and the chin is extended for exposure of the carotid bifurcation. Injury is usually due to excessive stretch from self-retaining retractors in a transverse cervical incision. When a longitudinal incision is used for CEA, angling the superior aspect of the incision posteriorly toward the mastoid process below the angle of the mandible will minimize the risk of injury to the nerve.[204]

Glossopharyngeal and Spinal Accessory Nerves

Injury to the glossopharyngeal and spinal accessory nerves is exceedingly uncommon during CEA because of their anatomic location at the upper extent of the operative field. However, in rare cases in which excessive mobilization or division of the digastric muscle is required for distal ICA exposure, either nerve may be encountered and traumatized. The glossopharyngeal nerve provides sensory and motor innervation to the larynx. Symptoms of glossopharyngeal nerve injury range from mild dysphasia to recurrent aspiration.[196,199]

The spinal accessory nerve exits the jugular foramen, runs posterior to the stylohyoid muscle, and enters the most cephalic extent of the sternocleidomastoid muscle. Injury is manifested as shoulder droop and pain, scapular winging, and difficulty abducting the shoulder because of weakness of the trapezius muscle.[196,200]

Cutaneous Sensory Nerves

Two important cutaneous sensory nerves that are not infrequently injured during the performance of CEA are the greater auricular and transverse cervical nerves. In one prospective study, the incidence of greater auricular and transverse cervical nerve injury was 60% and 69%, respectively, 1 week after CEA.[205] The greater auricular nerve courses along the most superior and the transverse cervical nerve along the most inferior area of the typical CEA longitudinal incision. Injury to the greater auricular nerve is manifested as numbness of the angle of the mandible and the lower part of the ear, and injury to the transverse cervical nerve is manifested as anesthesia of the anterior neck skin.

Hemodynamic Instability

Incidence and Etiology

If hypotension occurs after CEA, it usually does so within the first 2 hours after CEA, is generally associated with bradycardia,

and most likely results from disordered baroreceptor function.[206-208] Considerable evidence suggests that endarterectomy of fixed atheromatous plaque at the bifurcation, with its chronic dampening effect on pulse pressure, creates a heightened sensitivity of the baroreceptor mechanism that results in reduced central nervous system sympathetic activity with resultant hypotension or bradycardia, or both.[206,207,209,210] This reflex hypotension persists until the carotid sinus mechanism has been reset.[211]

Although perioperative hypertension is closely correlated with preoperative hypertension, its mechanism remains poorly understood. Baroreceptor dysfunction as a result of denervation of the carotid bulb is commonly assumed to be responsible, although there is considerable evidence to refute this hypothesis[208,212] and other mechanisms may be responsible, such as elevated cerebral norepinephrine or renin production.[213,214] In at least 80% of patients, this hypertensive response normalized within the first 24 hours, and in approximately 60% of patients it did so within the first 16 hours after surgery.[163]

Treatment

The episodic and generally unpredictable nature of post-CEA hypotension or hypertension is one of the more cogent reasons for observing the patient in a monitored unit after CEA, at least initially, with an indwelling radial artery catheter for systemic blood pressure monitoring. Hypotension should initially be treated by infusion of colloid solutions while a careful evaluation is conducted for any other causes of hypotension. Once normovolemia has been achieved, if hypotension persists, we favor supporting blood pressure with an intravenous infusion of phenylephrine (Neo-Synephrine), with the dosage adjusted to maintain systolic blood pressure within at least 20 mm Hg of the preoperative level. In almost all cases, the patient may be weaned from this vasoconstricting agent during the first postoperative day.

Conversely, postoperative hypertension is most effectively treated with intravenous sodium nitroprusside. Its effect is immediate, and it is quickly dissipated by stopping the infusion. The agent should be titrated to maintain systolic pressure within 20 mm Hg of the preoperative level. If myocardial ischemia is associated with these hypertensive episodes, intravenous nitroglycerin should also be administered. Most patients are able to resume their preoperative oral antihypertensive agents on the evening of surgery or within the next 12 hours, and this often obviates the need for further and more prolonged intravenous therapy.

Cerebral Hyperperfusion Syndrome

Cerebral hyperperfusion syndrome usually occurs several days after CEA and is often associated with severe hypertension. The reported incidence of cerebral hyperperfusion syndrome ranges from 0.4% to 7.7%.[215,216] This complication is now also being recognized after CAS procedures as well.[217,218] Symptoms include a migraine like headache progressing to seizures and, in its most severe manifestation, intracerebral hemorrhagic stroke. Though an infrequent complication of CEA and CAS, it is associated with a very high mortality rate that approaches 75% to 100% in some series.[219,220]

The cause of hyperperfusion syndrome appears to be increased regional cerebral blood flow secondary to disordered intracerebral autoregulation after relief of a high-grade carotid stenosis in the setting of severe contralateral carotid disease.[217] Systemic hypertension appears to be an important risk factor. Therefore, strict attention to postoperative blood pressure control is paramount, especially in a patient who undergoes CEA for a high-grade stenosis contralateral to complete ICA occlusion or severe stenosis. There may be some association with the use of anticoagulants and antiplatelet agents, but this evidence is speculative at best. If cerebral hemorrhage occurs, neurosurgical consultation is required to determine the necessity for craniotomy. One report noted that hyperperfusion syndrome can be predicted by a significant drop in pressure across the carotid stenosis and that it is related to temporary loss of cerebral autoregulation as evidenced by a transient increase in mean arterial velocity of the ipsilateral MCA after CEA.[221-223] Another study found that CEA performed less than 3 months after contralateral CEA was associated with a higher risk for hyperperfusion syndrome.[224]

Other Complications

Infections

CEA is rarely associated with infectious complications. Difficulty in primary healing is occasionally seen when this operation is performed in a previously irradiated field, but it is almost nonexistent in the absence of this complicating factor.[194] The reported incidence of wound infection, generally cellulitis, ranges from 0.09% to 0.15%.[225,226] Although the true incidence of patch infection has not been established, it appears to be extremely rare. In several studies, no cases of patch infection were documented.[226-228] However, in a recent systematic literature review, 14 publications were cited with a total of 77 cases of graft infection, including 0.25% to 0.5% for Dacron patches.[229] In another comprehensive review of the literature, 57 carotid pseudoaneurysms were identified, and 40 were associated with carotid patches. However, only four (10%) were infectious in etiology.[228]

Bleeding

Postoperative hemorrhage has a reported incidence of 0.7% to 3.0%.[189,209,230-232] Most cases result from diffuse capillary oozing secondary to the administration of heparin during the procedure and the concomitant administration of antiplatelet drugs. Though not systematically studied, at least anecdotally this degree of oozing appears to be greater in patients who are taking the antiplatelet agent clopidogrel at the time of surgery. Nevertheless, if there are indications for the administration of this agent, such as a recent coronary stent procedure or symptomatic carotid disease, we would not stop clopidogrel before surgery. In general, unless bleeding appears excessive at surgery, we do not favor reversal of the heparin effect with protamine sulfate at completion of the procedure, but this practice varies widely (see later).

If the neck incision has been closed over a suction drain, the acute onset of drainage of bright red blood postoperatively is suggestive of suture line disruption and is an indication for

urgent re-exploration. Similarly, the development of a hematoma in the neck, often caused by inadequate function of the drain, may compress the trachea and is an indication for re-exploration of the wound. More gradual development of a neck hematoma usually results from inadequate ligature of facial veins or other muscle arterioles or venules.[194]

Recurrent Carotid Stenosis

Recurrent carotid stenosis has been estimated to occur in 5% to 22% of patients, although only approximately 3% of these lesions were symptomatic.[55,233-236] In a meta-analysis of 55 reports, the overall incidence of recurrent carotid stenosis after CEA was 6% to 14%, which reflected an annual incidence of restenosis or occlusion of 1.5% to 4.5%.[237] In another analysis of the MEDLINE database, the rate of restenosis was 10% within the first year, 3% in the second, and 2% in the third year after CEA, thus suggesting that the rate of restenosis is clearly not a linear process biologically.[238] In CREST, at 2 years the rate of significant restenosis or occlusion was 6.3%.[239]

Recurrent stenoses develop more frequently in women, in patients who continue to smoke, and in hypercholesterolemic, diabetic, and hypertensive individuals.[234] It has also been suggested that intraoperative injury secondary to arterial clamping, insertion of an intraluminal shunt, or placement of tacking sutures within the vessel may also predispose to early myointimal hyperplastic lesions.[233] As noted earlier, there is compelling evidence that closure of the arteriotomy with a patch will reduce the incidence of recurrent stenosis.

Long-term follow-up of 950 CEAs performed at the Massachusetts General Hospital demonstrated that reintervention was required in 3.8% of patients with a cumulative follow-up of 4.5 years. There was no difference in restenosis rates between patients who underwent patch closure and eversion endarterectomy.[240] In another series that included 1150 patients, 98.8% were free of occlusion or restenosis greater than 70% at a mean follow-up of 74 months after CEA.[241] In the EVEREST trial, life-table estimates of the cumulative risk for restenosis at 4 years was not significantly different between eversion CEA and conventional CEA with patch closure.[242] Therefore, while there may be anatomic indications for performing an eversion CEA—or it may be surgeon preference—the consensus is that this technique is not associated with a significantly lower rate of restenosis.

Early recurrent stenosis usually develops within 2 years of CEA and typically results from intimal hyperplasia, an inflammatory response that produces a firm, rubbery plaque rich in fibroblasts and smooth muscle cells surrounded by dense accumulation of collagen and acid mucopolysaccharide, and it typically develops within the endarterectomy bed (see Chapter 5). Regression of these lesions is not uncommon and is observed in as many as one third or more of cases.[243,244] Therefore, one should have a very high threshold for reintervention for an early restenosis. Later restenoses typically have features of atheromatous plaque and are more widely distributed along the carotid artery. There are no prospective, randomized trials to support repeat CEA, but most available evidence supports treatment of symptomatic and very high grade asymptomatic recurrent stenoses.[233,245]

Repeat Carotid Endarterectomy

Scarring typically makes the carotid dissection more technically difficult, so a higher incidence of cranial nerve injury and hematoma has been reported.[246] In addition, the more extensive disease within the carotid artery may necessitate carotid artery replacement with an interposition graft. This is technically more difficult, may preclude shunting, and could be associated with longer periods of cerebral ischemia, possibly leading to higher perioperative stroke rates.[246] However, repeat endarterectomy is often possible, even after eversion endarterectomy.[247] Furthermore, with careful planning and technique, excellent results can be achieved in this situation as well, and reoperative CEA has been shown to be a very durable procedure. In one series, for example, at 48 months follow-up, 100% of patients were free of recurrent stenosis after repeat CEA.[248]

Carotid Artery Stenting Versus Repeat Carotid Endarterectomy

The increased technical difficulty and higher complication rate anticipated with repeat CEA has led some to advocate CAS as an alternative to CEA for recurrent stenosis. However, AbuRahma and coauthors reported lower perioperative stroke rates with repeat CEA than with CAS for recurrent stenosis[248] Repeat CEA on the other hand was associated with a much great incidence of cranial nerve injury (14% vs. 0%, $P < .0001$).[182]

SPECIAL CONSIDERATIONS

Combined Carotid Artery and Cardiac Disease

Significant carotid disease occurs in approximately 3% to 14% of patients undergoing cardiac surgery.[249] Between 1970 and 2000, Naylor and colleagues found that the risk for stroke after coronary artery bypass grafting (CABG) was 2% overall—less than 2% in patients without carotid disease, 3% in asymptomatic patients with unilateral 50% to 99% stenosis, 5% in those with bilateral 50% to 99% stenosis, and 7% to 11% in patients with carotid occlusion. However, the authors noted that 50% of CABG patients who experienced a stroke did not have significant carotid disease and that 60% of territorial infarctions on CT scan/autopsy could not be attributed to carotid disease alone. They estimated that CEA could prevent only about 40% to 50% of perioperative strokes in this patient population.[250] Nevertheless, carotid bifurcation disease is easily diagnosed and therefore at least one preventable cause of perioperative stroke in the cardiac surgical patient population.

Simultaneous Carotid Endarterectomy and Coronary Artery Bypass Grafting

One strategy pursued to reduce the risk of perioperative stroke is to perform simultaneous CEA and CABG. A prospective,

randomized trial performed at the Cleveland Clinic demonstrated a significantly lower stroke rate in patients undergoing combined CEA/CABG (2.8%) versus staged CABG followed by CEA (14%), although mortality was not significantly different. The stroke rate was much higher if CEA was performed early after CABG than at later intervals.[213]

Conversely, other studies have documented increased morbidity or no benefit from combined CEA/CABG.[251-253] Naylor and colleagues reviewed 97 published studies and found no significant difference in outcomes for staged and synchronous procedures.[253] Mortality was highest in patients undergoing synchronous CEA/CABG (4.6%; 95% CI, 4.1-5.2). Reverse staged procedures (CABG followed by CEA) were associated with the highest risk for ipsilateral stroke (5.8%) and any stroke (6.3%). Perioperative MI was lowest after the reverse staged procedure (0.9%) and highest in patients undergoing staged CEA-CABG (6.5%). The risk for death with or without any stroke was highest in patients undergoing synchronous CEA-CABG (8.7%) and lowest after staged CEA/CABG (6.1%). The risk of death/stroke or MI was 11.5% after synchronous procedures versus 10.2% after staged CEA and then CABG. In a related paper they found that the risk for death/stroke appeared to significantly diminish in studies published after 1993.[254] Patients with severe bilateral carotid disease or symptomatic stenoses were significantly more likely to suffer death or stroke (or both).[255] The communitywide outcomes of combined CEA/CABG in the Medicare population are inferior to those reported in many single-institution reviews.[256]

More recently, off-pump coronary artery bypass (OPCAB) has been introduced as an alternative method for coronary bypass, and outstanding results have been published on combined CEA/OPCAB, with combined stroke and mortality rates of 0% to 1.2%.[257,258]

In our institution, we prefer to stage CEA followed in 1 or 2 days with CABG in patients with significant carotid disease. These are typically patients with symptomatic significant ICA stenoses, or those with bilateral severe asymptomatic ICA stenoses. A combined CEA/CABG is reserved for patients with significant carotid artery disease and severe three-vessel or left main coronary disease and/or critical aortic stenosis.

Carotid Artery Stenting Before Coronary Artery Bypass Grafting

To date, the results of CAS followed by CBG have been conflicting, with some series demonstrating this strategy to be safer than combined CEA/CABG but other reports do not confirm this.[259-262]

Advanced Age

While the prevalence of stroke increases exponentially with advancing age, patients 80 years and older were excluded from NASCET and ACAS; therefore, it has been assumed that advanced age represents a high-risk factor for CEA and that such patients might thus be optimally treated by CAS. However, compelling evidence accumulated over the past 2 decades has confirmed the safety of CEA in elderly individuals. In a recent meta-analysis that included more than 20 institutional series and over 3000 elderly patients with a minimum age of 75 or 80 who underwent CEA, the perioperative stroke rate was 2.2% and the mortality rate was 1.5%.[263] In a population-based analysis of CEA in the state of Maryland from 1990 through 1995, we reported that the outcome in octogenarians was the same as in younger patient cohorts (perioperative stroke and death rate of 2.6%).[264] Considerable experience reported to date has confirmed the safety of CEA among the elderly and also excellent long-term survival and clinical results.[169,265-267]

Gender

There are conflicting reports with respect to the impact of gender on the outcome of CEA. In ACAS, for example, women received less benefit in terms of stroke prevention than did men, as they experienced more strokes in both the perioperative period and long-term follow-up.[11] However, other studies have shown no difference in outcomes between men and women.[268-270]

Race

There are conflicting results on the impact of race on CEA outcomes. In a national Medicare database analysis, between 1994 and 1999 African American patients experienced crude mortality rates higher than white patients in seven of the eight procedures, including CEA. The study suggests multiple reasons for this finding, including more frequent emergency operations and residence in low-income areas. Additionally, African Americans were more likely to receive care in lower volume hospitals and hospitals with overall higher mortality.[271] Likewise, a 2002 meta-analysis demonstrated a 40% greater likelihood of short-term death after CEA for African Americans than for whites undergoing CEA.[272] In our review of the Maryland state database, African American patients undergoing CEA had an increased incidence of in-hospital stroke, longer hospital stays, and higher hospital charges. This research noted that African American patients were more likely to undergo CEA in low-volume hospitals and were less likely to be treated by higher volume surgeons.[273]

Conversely, Horner and colleagues' review of the National Surgical Quality Improvement Project (NSQIP) data revealed similarly low stroke and death rates between African American and white patients in the VA system. In patients with TIA, though, Hispanic males experienced significantly worse outcomes in terms of stroke and death when compared with white patients.[274] An institutional review from Henry Ford Hospital revealed similar stroke and death rates between African American and white patients, as well as acceptable protection from ipsilateral stroke without racial variation. However, African American patients in this study did have a higher incidence of all strokes in the long term than did white cohorts.[275] In a study of the NIS from 2005 to 2008 including 347,450 CEAs, Hispanics were found to have the greatest risk of operative mortality ($P < .001$) and African Americans were found to have the highest stroke rate ($P = .02$). However, on multivariable analysis, Hispanic ethnicity remained an independent risk factor

for mortality after CEA whereas the increased risk of perioperative stroke in black patients was no longer significant.[183]

Symptomatic Disease With Less Than 50% Carotid Stenosis

There is no Level I evidence to support CEA for patients with less than 50% ICA stenoses. However, a growing body of evidence suggests that plaque morphology is an important predictor of subsequent neurologic events. For example, intraplaque hemorrhage has been shown to be associated with a high rate of recurrent ischemic events.[276,277] In one series of 25 patients with symptomatic low-grade carotid artery stenosis with intraplaque hemorrhage, there were 30 recurrent ischemic events (46% per patient per year).[276] At our institution, we have utilized contrast-enhanced duplex and contrast-enhanced MRA to identify plaque instability, including hemorrhage and ulceration, among symptomatic patients with less than 50% ICA stenoses, and have performed CEA with complete long-term symptomatic resolution (Fig. 91.11).[278] In addition, recent reports have identified carotid webs as another risk factor for ischemic stroke among patients with hemodynamically insignificant ICA stenoses. A carotid web is a thin membrane of tissue that typically extends from the posterior wall of the ICA into the lumen, which can be a nidus for thrombus formation and cerebral emboli, and is best seen on CTA imaging.[279-281]

External Carotid Endarterectomy

In the setting of ICA occlusion, atherosclerotic disease of the ipsilateral ECA can result in embolic stroke through the collateral pathways that exist between the external carotid and intracranial circulation.[282] There have been several small series of patients treated successfully for symptomatic ECA stenoses with ECA endarterectomy.[283-290] One large series the perioperative stroke rate varied from 0% to 10%[289,291] but was as high as 33% to 38% in patients with contralateral disease and previous stroke, or if ECA endarterectomy was combined with adjunctive procedures. On long-term follow-up with angiography or duplex ultrasonography, Rush and coworkers found that two thirds of ECAs closed primarily occluded or developed significant stenoses versus none with patch angioplasty.[292] In a review of 195 ECA endarterectomies and 23 ECA bypasses, the resolution of symptoms was seen in 83% of patients, with another 7% showing marked improvement. The perioperative mortality rate was 3%, mostly secondary to stroke, and the overall neurologic complication rate was 5%. A diseased contralateral carotid artery was associated with higher neurologic morbidity, whereas disease in the vertebral arteries had no impact on outcome. The best results were obtained when surgery was performed to relieve specific hemispheric or retinal symptoms as opposed to nonspecific neurologic complaints or previous stroke.[292] However, there is no evidence that ECA endarterectomy should be performed prophylactically for asymptomatic disease.

Impact of Radiation Therapy

Cervical irradiation is a known risk factor for carotid artery stenosis and cerebrovascular ischemic events. Carotid artery lesions secondary to irradiation therapy tend to occur at unusual locations, such as in the proximal or mid-common carotid artery. In addition to a predisposition to significant atherosclerotic disease, the effects of radiation include a fibrotic reaction and obliteration of normal tissue planes. This makes dissection and mobilization of the carotid vessels and identification of the cranial nerves more difficult. Although development of an appropriate endarterectomy plane may be more difficult than

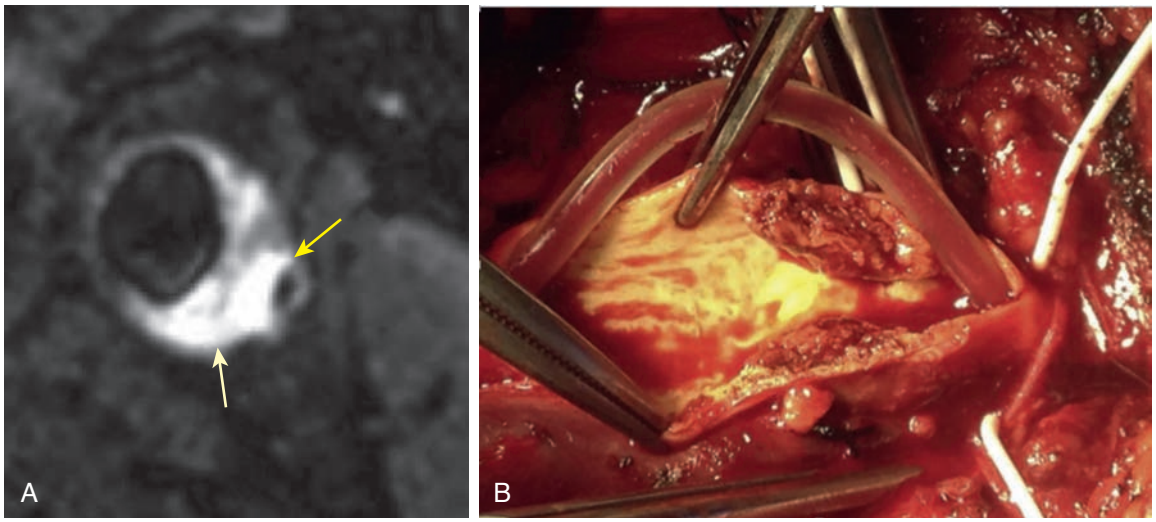

Figure 91.11 Axial reconstruction of three-dimensional high-resolution blood and calcium gradient-echo sequence of magnetic resonance imaging/magnetic resonance angiography in a 72-year-old man with a history of three right hemispheric cerebral vascular accidents. A routine duplex scan revealed a less than 50% right internal carotid artery stenosis but a contrast-enhanced duplex revealed hemorrhagic plaque. (A) The *dark yellow arrow* indicates calcification and *light yellow arrow* indicates hemorrhagic plaque. (B) The operative photograph demonstrates hemorrhagic plaque.

usual, in most cases conventional endarterectomy can be successfully carried out. In the uncommon case where conventional endarterectomy cannot be performed, the obstruction may be relieved simply by placement of a patch, or vessel resection and placement of an interposition graft with placement of the anastomoses outside of the radiated field. There also may be more potential for impairing wound healing in the patient with prior irradiation therapy. In the patient with particularly abnormal tissues, or if there is wound breakdown, closure with a muscle flap is an excellent option.

The reported clinical experience with CEA in this clinical scenario has been excellent, and appears superior to the results of CAS. Lesèche and associates published a series 30 cases from France, and also summarized 77 cases published by other authors.[293] The overall stroke and mortality rate for this entire cohort was 2%. Restenosis and recurrent stroke were not commonly encountered. The mean interval between cervical irradiation and CEA was 10 years. Bypasses from either the CCA or the subclavian artery were required to reconstruct the carotid artery in one third of their cases. In another early series including 26 cases, bypasses were rarely performed, although some patients required tissue flaps.[294] The mean time interval between irradiation and CEA in that series was even longer: 17 years. In a more recent series of 24 patients who underwent 27 carotid revascularization procedures, including 23 vein and 3 PTFE interposition bypass grafts, and one eversion endarterectomy from 1996 to 2004, there were no perioperative strokes or deaths, and only three patients experienced transient cranial nerve dysfunction.[295] Follow-up ranged from 6 to 120 months (mean, 28). There were 11 deaths—all unrelated to cerebrovascular disease. There were three (4.2%) strokes within the first 3 months of follow-up, with no additional strokes thereafter. A meta-analysis including 172 patients who underwent CEA and 361 who underwent CAS following neck irradiation, the periprocedural rates of stroke and TIA were 3.5% and 3.9% for CEA and CAS ($P = .77$), respectively. The rate of cranial nerve injury was 9.2% following CEA. The long-term rates of ≥50% restenosis or occlusion were 5.4 per 100 person-years and 2.8 per 100 person-years ($P = .003$) following CAS and CEA, respectively.[296] The long-term clinical outcome was also superior following CEA. Specifically, the rate of late strokes and TIAs was 4.9 per 100 person-years following CAS and 2.8 per 100 person-years following CEA ($P = .014$).

Hospital/Surgeon Volume

In contemporary practice, many have advocated regionalization of specialized care or high-risk procedures (or both) to higher volume centers and high-volume surgeons. A meta-analysis published in 2007 suggests that the CEA stroke and death rate is significantly lower in high-volume centers, with a critical volume threshold of 79 CEAs per year. Interestingly, this study demonstrated that patients undergoing operations performed by lower volume surgeons operating in higher volume centers also experienced lower stroke and death rates, thus suggesting that the hospital infrastructure and available resources rather than surgeon experience were more important in lowering complication rates.[297] Other population-based studies have shown similar trends of mortality being inversely proportional to volume. In California between 1982 and 1994, mortality rates decreased for CEA, and higher hospital volume was found to be an important determinant of outcome.[298]

Conversely, a retrospective review of CEAs performed in Oregon over a 2-year period examined the outcomes between two low-volume institutions (total of 156 CEAs) and one high-volume institution (404 CEAs). There was no significant difference in 30-day stroke and death rates between the low- and high-volume centers.[299] This was observed despite the fact that the low-volume centers had significantly older patients, more smokers, and fewer asymptomatic patients. This paper makes a legitimate point that an individual surgeon in a low-volume institution may perform more individual high-risk procedures than another individual surgeon at a higher volume center.

Ultimately, it is surgeons and not hospitals that perform surgery. Furthermore, the ideal break point to define a suitably "high-volume" caseload remains to be defined. Data published on CEA outcomes from institutional series, as well as large hospital and government databases, much of which has been summarized in this chapter, would suggest that vascular surgeons both individually and as a group have been tremendously successful in achieving published guidelines of a perioperative CVA/death rate ≤3% for asymptomatic and ≤6% for symptomatic CEA cases.[299] Therefore, CEA continues to be an effective treatment of carotid disease more than 60 years after it was introduced, and it is the treatment with which all future therapies must be compared.

BACKGROUND

The concept of using endovascular therapy for the treatment of carotid artery stenosis was first proposed in 1977 by Mathias, who reported successful results of carotid artery angioplasty using adapted peripheral arterial angioplasty technology.[1,2] Balloon-expandable stents for the treatment of cerebrovascular disease were introduced 10 years later, when Marks et al. reported the successful deployment of carotid artery stents in two patients with aneurysms and stenosis of the distal cervical carotid artery.[3]

Abstract

With the increasing interest in carotid artery stenting (CAS) as a means to treat carotid artery stenosis, a number of randomized controlled trials (RCTs) comparing outcomes after CAS versus the "gold standard" of carotid endarterectomy (CEA) were designed. Herein, we provide an overview of the major RCTs investigating CAS. We also provide a summary of the current societal recommendations for CAS versus CEA, and summarize the major patient characteristics that must be considered when planning the procedure. Finally, we discuss major technical considerations for optimizing result, including use of an embolic protection device, access considerations, and perioperative medications.

Keywords

carotid artery stenting
carotid artery stenosis
cerebrovascular disease
embolic protection

This experience was subsequently adapted for the use of treating high-grade symptomatic carotid artery stenosis. However, the initial enthusiasm with the procedure was dampened by high perioperative stroke rates ranging from 6% to 9%.[4–8]

In 1990 Theron et al. published their technique of performing carotid angioplasty using cerebral protection to prevent brain embolism.[9] This led to the development of embolic protection devices (EPDs), which drastically reduced stroke rates and revitalized interest in the use of endovascular therapy for carotid artery stenosis.

LANDMARK CLINICAL TRIALS

With the increasing interest in carotid artery stenting (CAS) as a means to treat carotid artery stenosis, a number of randomized controlled trials (RCTs) comparing outcomes after CAS versus the "gold standard" of carotid endarterectomy (CEA) were designed (Table 92.1).

SAPPHIRE

The Stenting and Angioplasty With Protection in Patients at High Risk for Endarterectomy (SAPPHIRE) is a multicenter, randomized, noninferiority US trial designed to compare CAS versus CEA for patients with greater than or equal to 50% asymptomatic or greater than or equal to 80% asymptomatic carotid artery stenosis, based on angiography.[10,11] Nearly all CAS patients (97%) underwent stenting with an EPD. The primary endpoint was a composite of death, stroke, or myocardial infarction (MI) within 30 days after the intervention or death

TABLE 92.1 Summary of Major Completed Randomized Controlled Trials Comparing Carotid Artery Stenting vs. Carotid Endarterectomy

Trial	Publication Date	Sample Size	Carotid Stenosis Criteria	Study Design	EDP Use for CAS	Primary Outcome	Results CAS vs. CEA	Conclusion
SAPPHIRE[10,11]	2004, 2008	334	≥50% symptomatic or ≥80% asymptomatic	Noninferiority RCT United States	97%	Composite death, stroke, MI within 30 days or ipsilateral stroke up to 1 year	1 year: 12.2% vs. 20.1% 3 years: 24.6% CAS vs. 26.9%	CAS noninferior to CEA
EVA-3S[7,12]	2006, 2008	527	>60% symptomatic carotid artery stenosis	Noninferiority RCT Europe	92%	Any stroke or death within 30 days	30 days: 9.6% vs. 3.9% 6 months: 11.7% vs. 6.1% 4 years: 11.1% vs. 6.2%	Worse periprocedrual stroke/death outcomes with CAS
SPACE[8,13]	2006, 2008	1,200	≥70% symptomatic carotid stenosis	Noninferiority RCT Europe	27%	Ipsilateral stroke or death within 30 days	30 days: 6.8% vs. 6.3% 2 years: 9.5% vs. 8.8%	Higher risk of periprocedural adverse events with CAS
ICSS[6,14]	2010, 2015	1,713	>50% symptomatic carotid artery stenosis	Noninferiority RCT Europe	72%	3-year fatal or disabling stroke in any territory	120 days: 8.5% vs. 5.2% 4.2 years: 6.4% vs. 6.5%	Long-term risk of disabling stroke is similar for CAS and CEA
CREST[15,16]	2010, 2016	2,502	Symptomatic or asymptomatic carotid artery stenosis ≥70% (ultrasound) or symptomatic ≥50% (angiography)	Noninferiority RCT North America	96%	Composite stroke, MI, or death within 30 days or ipsilateral stroke within 4 years	4 years: 7.2% vs. 6.8% 10 years: 11.8% vs. 9.9%	No significant long-term differences for CAS vs. CEA in composite endpoint or risk of stroke
ACT-I[19]	2016	1,453	>80% asymptomatic carotid stenosis	Noninferiority RCT United States	100%	Composite of death, stroke, or MI within 30 days or ipsilateral stroke within 1 year	30 days: 2.9% vs. 1.7% 1 year: 3.8% vs. 3.4%	CAS not inferior to CEA for

or ipsilateral stroke between 31 days and 1 year. SAPPHIRE enrolled 334 patients total (167 in each group), and demonstrated that CAS was noninferior to CEA both at 1 year (12.2% CAS vs. 20.1% CEA; $P = .004$)[10] and 3 years (24.6% CAS vs. 26.9% CEA; $P = .71$)[11] postoperatively.

EVA-3S

The Endarterectomy Versus Angioplasty in Patients With Symptomatic Severe Carotid Stenosis (EVA-3S) trial is a multicenter, randomized, noninferiority French trial designed to compare CAS versus CEA for patients with greater than 60% symptomatic carotid artery stenosis, as diagnosed by either angiography or both duplex scanning and magnetic resonance angiography.[7,12] EPDs were used in 92% of stent patients. The primary endpoint was any stroke or death within 30 days of the procedure. EVA-3S enrolled 527 patients total (265 CAS and 262 CEA) but was stopped prematurely due to significantly worse stroke/death outcomes with CAS at both 30 days (9.6% CAS vs. 3.9% CEA; $P = .01$) and 6 months (11.7% CAS vs. 6.1% CEA; $P = .02$).[7] Of note, outcomes with CAS were much worse among patients without cerebral protection (7.9% with EDP vs. 25% without EDP; $P = .03$).[7] Follow-up out to 4 years demonstrated worse outcomes with CAS (11.1% CAS vs. 6.2% CEA; $P = .03$), but this was largely attributable to higher periprocedural stroke/death.[12] Based on this data, the authors concluded that CAS might be a reasonable alternative to CEA in patients with symptomatic carotid artery stenosis if the periprocedural risk of stenting can be minimized.[12] This trial was heavily criticized for unbalanced training requirements between both groups; although the vascular surgeon had to have performed at least 25 endarterectomies in the year before enrollment, the interventional physicians only had to have performed 12 carotid-stenting procedures or 35 supraaortic trunk stenting procedures, of which 5 were in the carotid artery.

SPACE

The Stent-Supported Percutaneous Angioplasty of the Carotid Artery Versus Endarterectomy (SPACE) trial is a German multicenter, randomized, noninferiority trial designed to compare CAS versus CEA among patients with greater than or equal to 70% symptomatic carotid stenosis on duplex ultrasound.[8,13] In this trial, EDP was only used in 27% patients who underwent stenting. The primary endpoint was ipsilateral stroke or death between randomization and 30 days after treatment. SPACE enrolled 1200 patients total (605 CAS and 595 CEA) but was stopped prematurely due to cost issues and futility. The 30-day rate of stroke or death was 6.8% for CAS versus 6.3% for CEA ($P = .09$), which failed to meet criterion for noninferiority.[8] There were no differences in stroke rates comparing patients who underwent CAS with versus without EDP (7% in both groups at 30 days). After 2 years of follow-up, there were no significant differences in cumulative 30-day stroke/death and 2-year ipsilateral stroke between treatment groups (9.5% CAS vs. 8.8% CEA; $P = .62$), although recurrent stenosis greater than or equal to 70% was more common in the CAS group (10.7% CAS vs. 4.6% CEA; $P < .001$).[13] Similar to EVA-3S, the authors concluded that CAS could not be proven to be noninferior to CEA due to concerns over a higher risk of periprocedural adverse events with CAS.

ICSS

The International Carotid Stenting Study (ICSS) is a multicenter, randomized, British trial designed to compare CAS versus CEA for patients with greater than 50% symptomatic carotid artery stenosis based on angiography.[6,14] EPDs were used in 72% of cases. The primary endpoint was the 3-year rate of fatal or disabling stroke in any territory, but the authors also published an interim safety analysis comparing the 120-day rate of stroke, death, or procedural MI rate between groups. ICSS enrolled 1713 patients (855 CAS and 858 CEA). At 120 days, adverse outcomes were higher in the CAS group (8.5% CAS vs. 5.2% CEA; $P = .006$).[6] However, after a median of 4.2 years of follow-up, the risk of fatal or disabling stroke was similar between groups (6.4% CAS vs. 6.5% CEA; $P = .77$), leading the authors to conclude that the long-term functional outcomes and risk of disabling stroke are similar for CAS and CEA.[14]

CREST

The Carotid Revascularization Endarterectomy Versus Stenting Trial (CREST) is the largest multicenter, randomized trial designed to compare outcomes for CAS versus CEA to date.[15,16] It is a North American trial sponsored by the National Institutes of Health and an industry partner that compared CAS versus CEA for patients with carotid artery stenosis greater than or equal to 70% for asymptomatic or asymptomatic patients (based on ultrasound criteria) or greater than or equal to 50% for symptomatic patients (based on angiographic North American Symptomatic Carotid Endarterectomy Trial criteria). The primary composite endpoint was stroke, MI, or death from any cause during the periprocedural period up to 30 days or any ipsilateral stroke within 4 years after randomization. EPDs were used in 96% of patients, and all surgeons and interventionalists involved in the trial were required to meet robust training and experience requirements.[17] CREST enrolled 2502 patients (1262 CAS and 1240 CEA). At a median follow-up of 2.5 years, there was no significant difference in the estimated 4-year rates of the primary endpoint between groups (7.2% CAS vs. 6.8% CEA; $P = .51$).[15] However, CAS had a higher risk of periprocedural stroke (4.1% CAS vs. 2.3% CEA; $P = .01$), whereas CEA had a higher risk of periprocedural MI (1.1% CAS vs. 2.3% CEA; $P = .03$). Notably, the periprocedural risk of stroke/death was only significantly higher after CAS for symptomatic patients (6.0% CAS vs. 3.2% CEA; $P = .02$). The risk of restenosis following CAS versus CEA at 2 years was similar between groups (6.0% CAS vs. 6.3% CEA; $P = .58$).[18] CREST has the longest follow-up period of all CAS RCTs. After 10 years of follow-up, there were no significant differences between CAS versus CEA in either the composite primary endpoint (11.8% CAS vs. 9.9% CEA) or long-term ipsilateral stroke (6.9% CAS vs. 5.6% CEA).[16]

ACT-I

The Carotid Angioplasty and Stenting Versus Endarterectomy in Asymptomatic Subjects Who Are at Standard Risk for Carotid Endarterectomy With Significant Extracranial Carotid Stenotic Disease (ACT-I) trial is a randomized noninferiority trial designed to compare outcomes after CAS (with EDP) versus CEA among patients with severe asymptomatic carotid stenosis, were younger than 80 years, and were not considered to be at high risk for surgical complications.[19] The primary endpoint was a composite of death, stroke, or MI within 30 days or ipsilateral stroke within 1 year after the procedure. ACT-I was terminated early due to slow enrollment, with 1453 of a planned 1658 participants enrolled (88%). The rate of stroke or death within 30 days was 2.9% in the CAS group and 1.7% in the CEA group. The primary outcome was not significantly different between groups (3.8% CAS vs. 3.4% CEA; $P = .01$ for noninferiority). After 5 years the cumulative rate of stroke-free survival was 93.1% in the CAS group and 94.7% in the CEA group ($P = .44$). Based on these findings, the authors concluded that stenting was noninferior to endarterectomy for asymptomatic patients with severe carotid stenosis who were not at high risk for surgical complications.

CURRENT GUIDELINES

Because of the perceived higher periprocedural risk of stroke with CAS compared with CEA, based on results from the previously described RCTs, the current guidelines for use of CAS for treating carotid artery stenosis are limited. A consensus supports the use of CAS in symptomatic patients with high-grade stenoses who are deemed too high medical risk to undergo open surgery. There are also some data to support the use of CAS in a lower medical risk population of patients with higher anatomic risk factors for CEA such as restenosis or neck radiation.[20] The use for CAS for patients who are low or moderate risk without prior neck radiation or surgery, or those who have asymptomatic carotid artery disease, is less well supported. Many cite concerns about the long-term viability of CAS as a reason to use this technique judiciously. As such, societal guidelines around the appropriate use of CAS are cautious.

Symptomatic Carotid Artery Stenosis

Current guidelines are fairly consistent regarding the use of CAS in patients with symptomatic carotid artery stenosis. Based on available RCT data, in 2011 the American College of Cardiology/American Heart Association (ACC/AHA),[21] the Society for Vascular Surgery (SVS),[22] and the European Society of Cardiology (ESC)[23] each published guidelines for the use of CAS (Table 92.2). Each of these guidelines calls for CEA over CAS except in symptomatic patients who were deemed to be surgically unsuitable for CEA. In these cases, CAS is recommended for use only by experienced operators with a documented risk of death or stroke less than 6%.[24]

Similarly, the Centers for Medicare and Medicaid Services (CMS) support the use of CAS with embolic protection for patients with symptomatic carotid artery stenosis greater than or equal to 70% who are deemed to be high risk for CEA or patients with symptomatic carotid artery stenosis between 50% and 70% who are enrolled in CMS-approved clinical trial.[25] CMS also published a list of minimum standards pertaining to the evaluation, procedure, and follow-up of patients treated by CAS that are now required for an institution to be deemed eligible to perform the procedure.[25]

Asymptomatic Carotid Artery Stenosis

The use of CAS for patients with asymptomatic carotid artery stenosis is less clear (Table 92.3). Based on the ACT-I trial, it appears to be safe at least among patients with severe carotid artery stenosis.[19] Currently, ACC/AHA guidelines support the use of CAS in select patients with asymptomatic carotid stenosis (minimum 60% by angiography, 70% by duplex ultrasound), but note that the evidence supporting CAS over best medical therapy (BMT) is not convincing.[21] The SVS also notes that there are insufficient data for the use of CAS over BMT in patients with asymptomatic carotid artery stenosis between 70% and 99% but does recognize that in experienced hands the risk of stroke with CAS may be equivalent to that of CEA.[22] In contrast, the ECS endorses the use of CAS as an alternative to CEA as long as the procedure is performed in a high-volume center with a documented death or stroke rate less than 3%.[23] CMS recognizes CAS only for patients with asymptomatic carotid artery stenosis greater than or equal to 80% who are enrolled in a CMS-approved clinical trial.[25]

PATIENT SELECTION

Based on the guidelines noted previously, it is clear that CAS is currently supported only for use in a group of highly select patients meeting appropriate diagnostic criteria. According to CMS criteria (Table 92.4),[25] all patients must have a diagnosis of high-grade carotid artery stenosis based on duplex ultrasound or carotid artery angiography; if the diagnosis is based on duplex findings, the degree of stenosis must be confirmed via angiography at the time of the procedure prior to stenting. Patients must also be symptomatic, as determined by a history of transient ischemic attacks with distinct focal neurologic dysfunction last <24 hours, a prior cerebrovascular incident resulting in a nondisabling stroke, and/or amaurosis fugax; and at high risk for open surgical intervention, as determined by the presence of either a significant medical comorbidity (see Table 92.4) or prior neck radiation therapy or a previous CEA. Other considerations when selecting a patient who might be appropriate for CAS are as follows.

Age

Given the less invasive nature of CAS over CEA, the use of carotid stents for treating elderly patients with carotid artery stenosis was initially considered one of the main indications of the procedure. Unexpectedly, data from a multitude of RCTs on CAS demonstrated that the opposite was true; the risk of

TABLE 92.2 Recommendations of the 2011 Carotid Guidelines for Patients With Symptomatic Carotid Artery Stenosis

Society	Recommendation	Strength
ACC/AHA[21]	CAS is indicated as an alternative to CEA for symptomatic patients at average or low risk of complications associated with endovascular intervention when the diameter of the lumen of the internal carotid artery is reduced by more than 70% as documented by noninvasive imaging or more than 50% as documented by catheter angiography and the anticipated rate of periprocedural stroke or mortality is less than 6%.	Class I; level of evidence B
	Among patients with symptomatic severe stenosis (≥70%) in whom the stenosis is difficult to access surgically, medical conditions are present that greatly increase the risk for surgery, or when other specific circumstances exist, such as radiation-induced stenosis or restenosis after CEA, CAS may be considered.	Class IIb; level of evidence B
	CAS in the above setting is reasonable when performed by operators with established periprocedural morbidity and mortality rates of 4%–6%, similar to those observed in trials of CEA and CAS.	Class IIa; level of evidence B
SVS[22]	In most patients with carotid stenosis who are candidates for intervention, CEA is preferred to CAS for reduction of all-cause and periprocedural death.	Grade I; level of evidence B
	CAS is preferred over CEA in symptomatic patients with ≥50% stenosis and tracheal stoma, situations where local tissues are scarred and fibrotic from prior ipsilateral surgery or external beam radiotherapy, prior cranial nerve injury, and lesions that extend proximal to the clavicle or distal to the C2 vertebral body.	Grade II; level of evidence B
	CAS is preferred over CEA in symptomatic patients with ≥50% stenosis and severe uncorrectable coronary artery disease, congestive heart failure, or chronic obstructive pulmonary disease.	Grade II; level of evidence C
ESC[23]	In patients with symptomatic 70%-99% stenosis of the internal carotid artery, CEA is recommended for the prevention of recurrent stroke.	Class I; level of evidence A
	In symptomatic patients at high surgical risk requiring revascularization, CAS should be considered as an alternative to CEA.	Class IIa; level of evidence B
	In symptomatic patients requiring carotid revascularization, CAS may be considered as an alternative to CEA in high-volume centers with documented death or stroke rate <6%.	Class IIb; level of evidence B

TABLE 92.3 Recommendations of the 2011 Carotid Guidelines for Patients With Asymptomatic Carotid Artery Stenosis

Society	Recommendation	Strength
ACC/AHA[21]	Prophylactic CAS might be considered in highly selected patients with asymptomatic carotid stenosis (minimum 60% by angiography, 70% by validated Doppler ultrasound), but its effectiveness compared with medical therapy alone in this situation is not well established.	Class IIb; level of evidence B
SVS[22]	Neurologically asymptomatic patients with ≥60% diameter stenosis should be considered for CEA for reduction of long-term risk of stroke, provided the patient has a 3- to 5-year life expectancy and perioperative stroke/death rates can be ≤3%.	Class I; level of evidence A
	There are insufficient data to recommend CAS as primary therapy for neurologically asymptomatic patients with 70%–99% diameter stenosis. In properly selected asymptomatic patients, CAS is equivalent to CEA in the hands of experienced interventionalists with a combined stroke and death rate <3%.	Grade II; level of evidence B
ESC[23]	In asymptomatic patients with carotid artery stenosis ≥60%, CEA should be considered as long as the perioperative stroke and death rate for procedures performed by the surgical team is <3% and the patient's life expectancy exceeds 5 years.	Class IIa; level of evidence A
	In asymptomatic patients with an indication for carotid revascularization, CAS may be considered as an alternative to CEA in high-volume centers with documented death or stroke rate <3%.	Class IIa; level of evidence B

TABLE 92.4 Medicare Decision Summary for Carotid Artery Stenting[25]

CAS with embolic protection is reasonable and necessary for the following:
1. Patients who are at high risk for CEA and who also have symptomatic carotid artery stenosis ≥70%. Coverage is limited to procedures performed using US Food and Drug Administration (FDA)-approved carotid artery stenting systems and embolic protection devices.
2. Patients who are at high risk for CEA and have symptomatic carotid artery stenosis between 50% and 70%, in accordance with the Category B IDE clinical trials regulation, as a routine cost under the clinical trials policy, or in accordance with the National Coverage Determination on CAS post approval studies.
3. Patients who are at high risk for CEA and have asymptomatic carotid artery stenosis ≥80%, in accordance with the Category B IDE clinical trials regulation, as a routine cost under the clinical trials policy, or in accordance with the National Coverage Determination on CAS post approval studies.
Patients who are at high risk for CEA include those with any of the following:
Congestive heart failure class III/IV
Left ventricular ejection fraction <30%
Unstable angina
Contralateral carotid occlusion
Recent myocardial infarction
Previous CEA with recurrent stenosis
Prior radiation treatment to the neck
Other conditions that were used to determine patients at high risk for CEA in the prior carotid artery stenting trials and studies

CAS, Carotid artery stenting; *CEA*, carotid endarterectomy; *IDE*, Investigational Device Exemption.

an adverse event with CAS was significantly higher than that with CEA in older patients.[26-30]

In a post hoc analysis of data from the SPACE trial, ipsilateral stroke or death after CAS occurred in 2.7% of patients 68 years or younger versus 10.8% in patients older than 68 years, whereas outcomes after CEA were not significantly different.[26] Similarly, an analysis of CREST data examining the treatment-specific impact of age demonstrated the risk of adverse events (i.e., stroke, MI, or death) increased by 1.77 times per 10-year increment increase in age after CAS but was stable for CEA.[27] These findings are confirmed by a meta-analysis of 4754 patients enrolled in CREST and the Carotid Stenting Trialists' Collaboration trials, which demonstrated a significant pattern of increased periprocedural risk with increasing age in patients assigned to CAS versus CEA starting at 70 years and older ($P < .001$).[31]

Population database analyses examining the effects of age on adverse events after CAS and CEA report similar findings. Data from the SVS Vascular Registry demonstrated inferior 30-day composite outcomes in patients 65 years or older undergoing CAS, regardless of symptomatic status.[29] Data from the Nationwide Inpatient Sample demonstrated worse stroke rates and cardiac complications among patients 70 years or older who underwent CAS.[28]

A Cochrane Database Systemic Review from 2012 including 16 trials involving 7572 patients supported these findings; the overall risk of perioperative death or any stroke was significantly higher for CAS versus CEA among patients 70 years or older (OR 2.20, 95% confidence interval [CI] 1.47 to 3.29) but not significantly different for patients younger than 70 years (OR 1.16, 95% CI 0.80).[30] Taken together, these data suggest that CAS should be reserved for younger patients,[29] the age of which varies between 65 and 70 years, depending on the data source used.

Sex

There are well-described differences in outcomes between women versus men in both the cardiovascular and CEA literature.[32-34] However, the sex-specific effects on outcomes after CAS are less clear. A secondary analysis of data from the CREST trial suggested that the perioperative risk of an adverse event (i.e. stroke, MI, or death) was higher in women who underwent CAS versus those who underwent CEA (6.8% vs. 3.8%) but similar among men regardless of revascularization approach (4.3% vs. 4.9%).[33] These findings were largely attributable to an increased stroke rate in females underdoing CAS (5.5% vs. 2.2%).[33] In contrast, a meta-analysis of patients enrolled in the European Carotid Stenting Trialists Collaboration, which includes the EVA-3S, SPACE, and ICSS trials, demonstrated equivalent outcomes with CAS and CEA for both males and females.[35] A subsequent meta-analysis using data from both CREST and CSTS in combination with data from the CAVATAS trial supported the latter conclusion that sex had no real effect on the risks of either treatment.[36]

Interestingly, observational data evaluating the embolic debris captured in EPDs after CAS suggested that symptomatic women have a greater mean debris particle size compared with asymptomatic women, whereas the difference in debris size after carotid stenting is not statistically different between symptomatic versus asymptomatic men.[37] Accordingly, CREST data suggest that the main difference in stroke/death rates with CAS versus CEA occurred among symptomatic women (7.5% vs. 2.7% in CAS vs. CEA, respectively).[33] Although data on this topic from other RCTs are not convincingly worse for women compared with men, it should be noted that symptomatic women may have a different plaque morphology with greater embolic potential than their asymptomatic counterparts.

Hostile Neck

Patients with prior neck surgery or radiation should be considered for CAS to reduce risks of cranial nerve injury. Based on a systemic review of available literature through 2012, Kasivisvanathan et al. reported that CAS is technically feasible in postradiotherapy carotid stenosis and has a similar safety profile to that of nonirradiated necks when performed at a high-volume center.[38] Furthermore, in a meta-analysis of 27 articles reporting data on 533 patients with prior cervical irradiation undergoing carotid revascularization for carotid artery stenosis, Fokkema et al. demonstrated that the perioperative

risk of any cerebrovascular adverse event was similar for CAS versus CEA (3.9% vs. 3.5%) but the risk of cranial nerve injury was substantially higher after CEA (9.2% vs. 0%).[39] Societal guidelines now include the presence of neck scarring and fibrosis from prior ipsilateral surgery such as radical neck dissection or prior CEA or external beam radiotherapy as one indication for considering CAS over CEA.[21-23]

Combined Carotid and Coronary Artery Disease

Due to the systemic nature of atherosclerotic disease, the presence of combined significant carotid artery stenosis and coronary artery disease is common. CAS has been considered as a noninvasive option by which to treat patients with carotid artery stenosis just prior to coronary artery bypass grafting (CABG). In 2009 Naylor et al. published a meta-analysis of 11 studies reporting data on (predominantly asymptomatic) patients undergoing CAS plus CABG procedures and demonstrated a 30-day death/stroke/MI rate of 9.4%.[40] This risk was not significantly different for patients undergoing CAS within 48 hours of CABG versus those where CABG was delayed.

More recently Velissaris et al. reported results from a prospective nonrandomized study evaluating outcomes among 90 consecutive patients with carotid stenosis (≥60% in symptomatic patients and ≥70% in asymptomatic patients) who were treated using CAS under local anesthesia immediately before CABG.[41] In this series the 30-day death/stroke rate was only 2.2%. Similarly, Barrera et al. reported no deaths, strokes, or MI among 15 consecutive patients with severe asymptomatic carotid artery disease in need of urgent coronary revascularization who underwent synchronous CAS and urgent CABG.[42] Notably, EPDs were used in both of these two series cases.

Based on these data, it appears that CAS is at least equivalent if not safer than CEA for patients in need of combined carotid and coronary revascularization. CAS offers the benefit of being less invasive, to the point that it can be performed immediately prior to open heart surgery under local sedation, assuming that appropriate cerebrovascular protection is used. One question that remains is how to best manage patients' postoperative antiplatelet therapy, which is essential to preventing in-stent thrombosis and stroke (see section "Postoperative Medications: Antiplatelet Therapy," later) but may put patients at higher risk of intraoperative and/or postoperative hemorrhage following cardiac surgery.

Restenosis

Based on data from the CREST Trial, approximately 6% of patients undergoing CAS or CEA will demonstrate restenosis (i.e., reduction in diameter of the carotid artery by ≥70%) by 2 years postoperatively (see section "Complications: Restenosis," later).[18] Restenosis is associated with increased risk of stroke similar to native carotid artery stenosis. Preliminary data from the Vascular Quality Initiative suggest that CAS after prior CEA or CAS is safe, with an estimated 30-day risk of stroke of 1.4% (Arhuidese et al., in press). However, the clinical relevance of restenosis, as well as the associated risks of adverse events after CAS in patients with prior carotid revascularization, is currently unclear. At this time, we would recommend that only patients with severe restenosis should be considered for CAS using embolic protection performed by an expert at an institution with substantial CAS experience.

Contraindications

Absolute contraindications to CAS include the presence of a visible thrombus within the carotid lesion, active infection, and inability to gain vascular access. The presence of thrombus puts the patient at high risk for embolic stroke, and use of CAS should be aborted if noted prior to the procedure. Active infection confers a substantial risk of stent infection and should be avoided in all cases. Access difficulties can be minimized by using different approaches as indicated based on the patients' history, including femoral access, brachial access, or transcervical access (see section "Technique: Arterial Access," later). If none of these options are feasible, CEA should be considered over CAS.

Relative contraindications to CAS include older age (see section "Patient Selection: Age," earlier), the presence of a circumferential carotid plaque with severe calcification, severe carotid artery tortuosity (two 90-degree angles), near occlusion of the carotid artery (i.e., string sign), and an inability to deploy a cerebral protection device (see section "Technique: Embolic Protection Devices," later). The high rate of periprocedural stroke noted with CAS in the previously mentioned European RCTs is largely attributed to the variable use of EDPs in those studies. CREST, which used EDPs in 96% of cases, reported a 4.1% periprocedural stroke rate,[15] compared with notably higher rates in prior trials (6.8% stroke in SPACE[8] 8.65% stroke in ICSS,[6] and 9.6% stroke/death in EV-3S [7,12]), which implemented EDPs less frequently. As such, the use of EDPs is now considered standard of care in the deployment of a carotid stent.[25]

ANATOMIC CONSIDERATIONS

Several anatomic factors can influence outcomes after CAS. A comprehensive understanding of patient anatomy can help with appropriate selection and operative planning. Specifically, the presence of a type III aortic arch or an aortic arch with extensive wall irregularities or calcifications may benefit from transcarotid artery access for stent placement in an effort to avoid the maneuvering of wires and catheters in this area (see section "Arterial Access," later).

Aortic Arch Morphology

Aortic arch morphology can be classified into three different types depending on the position of the takeoff of the great vessels (Fig. 92.1). In type I aortic arches the great vessels arise at or above the same horizontal place as the outer curvature of the arch. In type II aortic arches the origin of the innominate artery lies between the horizontal plane of the inner and outer curve of the aortic arch. In type III aortic arches the innominate

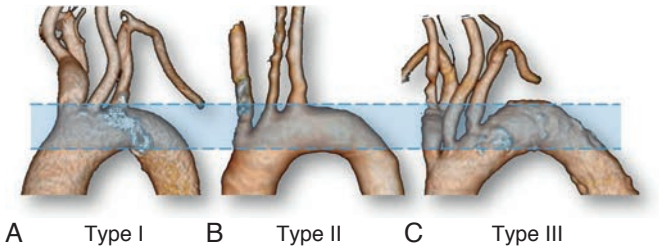

Figure 92.1 Aortic Arch Classification. (A) Type I: the great vessels arise above or in the same horizontal plane of the outer curvature of the arch. (B) Type II: the origin of the innominate artery lies between the horizontal planes of the outer and inner curvatures of the aortic arch. (C) Type III: the innominate artery lies below the horizontal plane of the inner curvature of the arch.

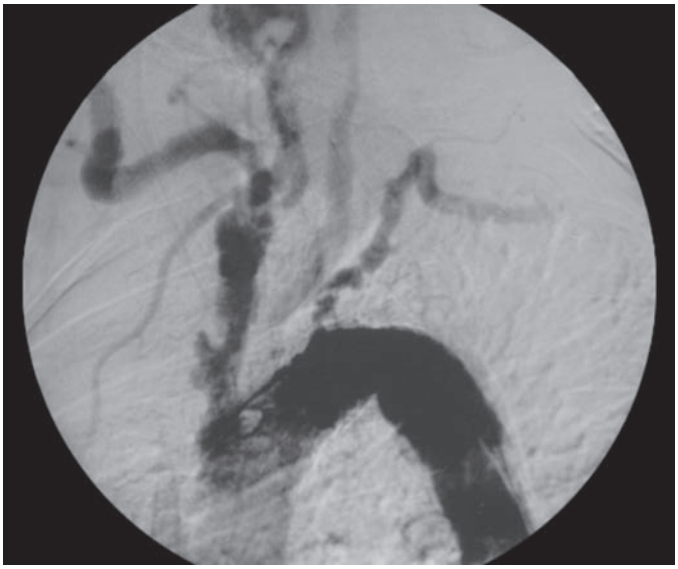

Figure 92.2 Severe Atherosclerosis and Calcification in Aortic Arch (Shaggy Aorta). The procedure should be terminated immediately; accessing the great vessel from a shaggy aortic arch should not be attempted due to potential catastrophic neurologic complications. Alternatively, a transcarotid approach will avoid the severe atheromatous arch.

artery lies below the horizontal plane of the inner curvature of the aortic arch. As the takeoff of the supraaortic vessels moves more inferiorly (i.e., type II and type III configurations), vessel selection and the manipulation of sheath, balloon, and stent delivery system become more difficult because the origin of the arteries becomes more oblique. Type III aortic arch morphologies are particularly challenging and can lead to a higher risk of embolic events due to repeated and/or prolonged wire and catheter manipulation leading to the disruption of aortic plaques.

Aortic arches with extensive aortic wall atheroma and irregularities (i.e., shaggy aorta) and those with severe calcification (eggshell aorta) may also increase the technical complexity of performing CAS and subsequently increase the patient's risk of stroke (Fig. 92.2). Shaggy aortas are composed of multiple atheromas that can break off upon contact with a wire or catheter, leading to atheroembolism to either the brain or the renal or visceral arteries. An eggshell aorta has poor compliance and thus is at risk for dissection or embolism that can similarly lead to devastating neurologic or visceral sequelae. The stiffness of an eggshell aorta can also make wire and catheter torqueability a challenge, leading to difficulty manipulating the stent delivery system into appropriate position within the target lesion.

Of note, bovine aortic arches, where two of the three great vessels share a common origin, are relatively common, occurring in approximately 27% of the population.[43] The most common type 2 form of this variant, the innominate artery and left common carotid artery (CCA) share a common origin. Somewhat less commonly, the common carotid branch takes off from the innominate artery. A "pure" bovine arch, where a common brachiocephalic trunk originates off the aortic arch and then branches into the right and left subclavian arteries and a single bicarotid trunk, is very rare. Although the bovine aortic arch variants are not necessarily contraindications for CAS, they should be noted when present because they may increase the difficulty of obtaining endovascular carotid access.

Carotid Artery Morphology

Carotid artery tortuosity and plaque burden can greatly affect the deliverability of both the EPD and the stent delivery system into the appropriate positions. Data from the EVA-3S trial suggests that the internal carotid artery (ICA)-CCA angulation of greater than or equal to 60 degrees increases the relative risk of death or stroke after CAS by 4.96 times (95% CI, 2.29 to 10.74).[44] ICAs that are particularly tortuous, especially distally, can cause difficulty positioning the EDP sufficiently far enough away from the lesion to allow for stent deployment. Internal carotids with severe angulation at the distal end of the stenotic lesion can cause flow limitations after the procedure due to significant changes in carotid morphology after stent deployment (Fig. 92.3). Tortuous vessels are also more prone to vasospasm at the end of the procedure.

Carotid arteries with circumferential plaque burdens and atheroma are noncompliant and thus can be difficult to access and can increase the risk of embolization during manipulation (Fig. 92.4). In addition, highly stenotic lesions with only a small area of flow (i.e., string sign; Fig. 92.5) may make stent delivery difficult and can result in inadequate stent expansion after deployment and subsequent early restenosis due to recoiling of the stenosis.

Plaque Morphology

Both qualitative and quantitative aspects of carotid artery plaque morphology play a role in determining post-CAS outcomes. Based on data from the EVA-3S trial, ICA stenoses greater than 10 mm in length are associated with a 2.36 (95% CI 1.28 to 3.38) increased risk of death or stroke after CAS.[44] Data from CREST show similar findings; in patients with longer lesion lengths (≥12.85 mm), the risk of CAS was significantly higher than CEA (OR 3.42; 95% CI, 1.19 to 9.78).[45]

Carotid plaque echolucency, as assessed by duplex ultrasonography, has also been shown to increase the risk of stroke in CAS.[46,47] Unfortunately, user variability with this technique results in poor reproducibility and reliability with these measurements, and as such plaque morphology characteristics are not standardly used for risk-stratifying patients undergoing CAS.[48]

Figure 92.3 Severe tortuosity in the ICA: double 90-degree bends increase the difficulty of EPD placement and reduce its effectiveness and can cause a significant kick after stent placement.

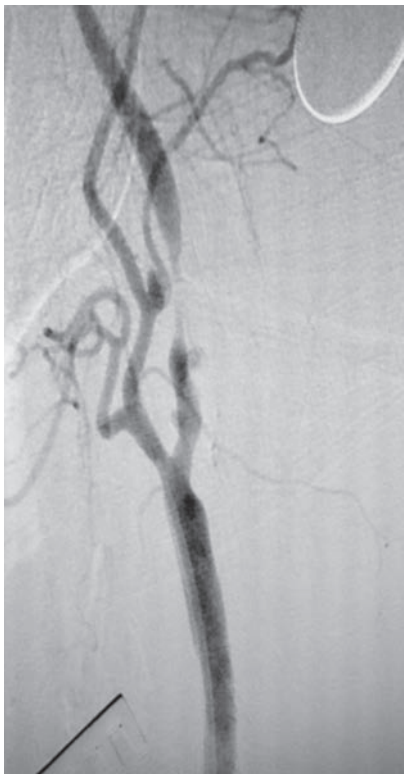

Figure 92.5 Carotid artery string sign: these complex lesions should not be stented.

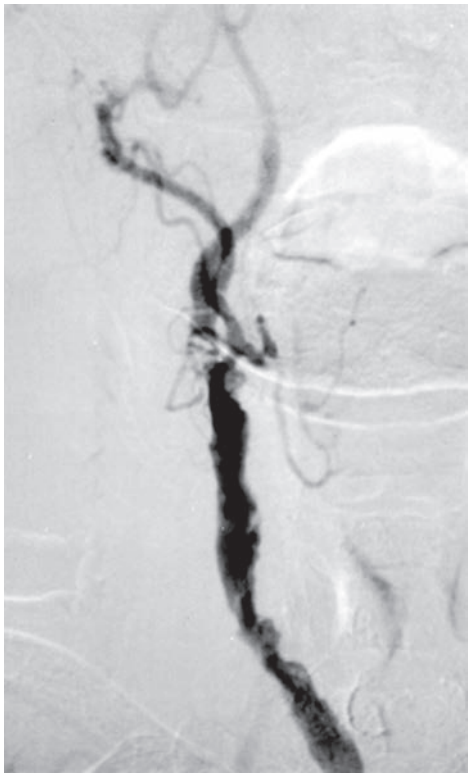

Figure 92.4 Severe plaque and atheroscleroma burdens increase the risk of neurologic complications during access of the common carotid artery. These lesions should not be treated with stenting.

Contralateral Carotid Artery Occlusion

The presence of contralateral carotid artery occlusion should not influence the decision to perform CAS. A subgroup analysis of 3137 patients undergoing CAS who were enrolled in a German Carotid Artery Stent registry (ALKK-CAS) demonstrated a low rate of periprocedural death or major strokes among patients with contralateral carotid occlusion versus those without (1.6% vs. 1.4%).[49] Separate retrospective reviews of in-hospital data from both Northwestern University and Emory University similarly demonstrated that both CAS and CEA can both be performed with good perioperative results and acceptable midterm (approximately 2 year) mortality in patients with carotid artery stenosis and contralateral carotid artery occlusion.[50,51] As such, current recommendations suggest that, although a preexisting contralateral carotid artery occlusion does not appear to adversely impact CAS outcomes, there are no data to suggest the use of CAS over CEA in this setting in the absence of other indications.

PREOPERATIVE CONSIDERATIONS

Preoperative Imaging

As mentioned previously, per CMS requirements, all patients require proof of diagnosis of carotid artery stenosis using angiography prior to stent placement.[25] In nonclinical trial patients, this can occur either preoperatively or intraoperatively,

as long as the patient has appropriate duplex ultrasound imaging to support a diagnosis of high-grade carotid artery stenosis. Duplex ultrasound allows for a comprehensive evaluation of extracranial anatomy and the hemodynamic significance of the CCA, ICA, and external carotid artery (ECA) lesions in most patients. In patients with extensive atherosclerotic disease in which duplex ultrasound findings are inconclusive or unclear, magnetic resonance imaging or computed tomographic angiography (CTA) may be helpful. Both of these imaging modalities allow for a more comprehensive assessment of carotid anatomy, as well as aortic arch morphology and carotid tortuosity. CTA specifically can be helpful in patients in whom carotid plaque morphology or extent is unclear and can be used to measure the diameter of the CCA and the ICA to allow for preoperative planning of stent sizing. Regardless of whether a preoperative CTA is obtained, the CCA and ICA diameters should be remeasured via angiography intraoperatively prior to definitive device selection.

Timing of Surgery

Data on the appropriate timing for surgery among patients with recent stroke who require carotid revascularization are conflicting. Patients who undergo urgent CEA within a week of TIA or minor (nondisabling) stroke do not have worse outcomes than patients who undergo delayed surgery, and thus the use of early carotid revascularization to prevent recurrent stroke is appealing in this population.[52] In contrast, data reporting outcomes after early CAS are inconsistent. An analysis of pooled dated from the EVA-3S, SPACE, and ICSS trials demonstrated that the risk of stroke or death with CAS compared with CEA was highest among patients treated within 7 days of symptoms.[53] The Carotid Acculink/Accunet Post-Approval Trial to Uncover Unanticipated or Rare Events (CAPTURE) registry also reported worse outcomes among patients undergoing CAS within 0 to 13 days of symptom onset, with an odds ratio of having 30-day complications of 2.52 (95% CI, 1.33 to 4.78).[54] In contrast, data from a prospective institutional registry has shown that 30-day stroke, MI, or death rates were similar for CAS performed early (≤4 weeks, 6%) and late (>4 weeks, 8%) after symptom onset.[55] These findings are supported by Groschel et al., who report equivalent outcomes with early versus late CAS based on a cohort of 320 patients from two centers in Germany.[56] Given the conflicting data, no firm conclusions can be made about the safety of CAS following recent stroke. However, given the poor outcomes associated with early CAS as reported by RCT data, use of early stenting in patients with recent cerebrovascular events should probably be approached with caution.

TECHNIQUE

General Principles of Stenting

The concept of CAS is based on the premise of dilating the carotid plaque that is responsible for the stenosis and preventing embolization or restenosis by scaffolding the ruptured, dilated plaque against the vessel wall with the stent. The exact techniques of achieving this outcome vary based on the user, but there are a number of general principles that have been shown to improve outcomes with this procedure and which should be considered standard of care. These include adequate periprocedural monitoring with frequent neurologic assessment, stable sheath access to the proximal CCA, use of EPDs, completion angiography, and perioperative antiplatelet therapy. In addition, the use of a hybrid operating suite with a high-resolution image intensifier, a large inventory of both endovascular and operative supplies, and a multidisciplinary approach to postoperative patient care can help to prevent poor outcomes before they occur.

Periprocedural Monitoring

Adequate hemodynamic monitoring in the operating room is essential to success during CAS. All patients should have continuous electrocardiographic, pulse oximetry, and intraarterial pressure monitoring throughout the procedure, the latter of which can be obtained via the side arm of the introducer sheath. Hypotension and hypertension and any changes in oxygenation or cardiac tracings should be treated immediately.

All procedures should be performed with the patient awake, using local anesthesia. This allows for continuous evaluation of neurologic function in the form of speech, alertness, and motor function, which can be monitored by asking the patient frequent questions and having him/her squeeze a plastic toy in the contralateral hand. If necessary, mild sedation may also be used but only to make the patient comfortable without altering level of consciousness because the awake neurologic exam is the cornerstone of periprocedural monitoring during CAS.

Adjunct methods of assessing neurologic status include continuous electroencephalogram (EEG) and/or transcranial Doppler (TCD). EEG can help to identify subclinical cerebrovascular changes that may aid in the early identification of a periprocedural stroke. However, the clinical utility of some of these changes is questionable and thus, as with CEA, EEG is not essential for performing CAS. Although TCD is purported to differentiate the size and composition of emboli during cerebroembolic events, the accuracy of this technology is inconsistent and thus its use during CAS is surgeon and center specific.[57]

Arterial Access

The most common access used for CAS is transfemoral. In a right-handed operator, retrograde right transfemoral access using a 6-F introducer allows for the easiest catheter manipulation. Left transfemoral access should be the second choice for access if the right groin is inaccessible due to severe peripheral arterial disease, prior interventions, or other reasons. Once the working sheath is in place, a full dose of heparin should be administered as with any endovascular procedure.

Transcarotid access may also be used successfully in patients with hostile groin or aortic arch anatomy (see section "Anatomic Considerations," earlier). Percutaneous transcervical carotid artery access can be obtained using ultrasound guidance, with

care taken to puncture the CCA at the base of the neck well below the carotid bifurcation to allow for a stable working platform.[58] Alternatively, access to the CCA can be obtained using a surgical cutdown. This allows for direct visualization of the CCA puncture site and may be the safest option. The Safety and Efficacy Study for Reverse Flow Used During Carotid Artery Stenting Procedure (**ROADSTER**) trial reported 30-day results of the ENROUTE neuroprotective system (Silk Road Medical Inc, Sunnyvale, California), which is deployed through direct common carotid cutdown access.[59] In this trial that enrolled 208 patients with symptomatic carotid artery stenosis greater than or equal to 50% stenosis and asymptomatic carotid artery stenosis greater than or equal to 70% stenosis, the overall stroke rate with transcarotid artery revascularization (TCAR) was 1.4%, which is lower than any prior prospective multicenter clinical trial of CAS. Based on these data, the authors conclude that direct TCAR with flow reversal may be a safe, less invasive alternative to CEA.[59,60] Based on the safety results of the **ROADSTER** trial, the US Food and Drug Administration approved use of the ENROUTE device for patients who qualify for CAS for both commercial and RCT purposes.[61]

Less commonly, transbrachial or transradial access may be used. In these cases a 6-F sheath should be used to access the artery using ultrasound guidance. Upper extremity access is indicated in patient who have either severe abdominal aortoiliac disease or shaggy or eggshell aortas and a hostile neck. Recently, a right transradial approach for patients with a bovine-type aortic arch or type III aortic arch morphology has been shown to be a safe and technically feasible approach to perform CAS for left and right carotid artery lesions, respectively.[62]

Target Lesion Access

For successful deployment of the carotid artery stent, stable sheath access in the CCA must be obtained. In patients with remote (i.e., trasfemoral, transbrachial, or transradial) arterial access, this can be achieved via two different platforms.

In a sheath-based platform a 6-F 90-cm Shuttle Select sheath (Cook, Inc. Indianapolis, Indiana) is placed in the descending aorta. A preshaped compatible 125-cm catheter (e.g., JB1, VTK, Headhunter, Simmons 1) is used to cannulate the CCA, and an exchange-length 0.035 guide wire is passed into the mid CCA. The catheter is advanced carefully over the wire and positioned a few centimeters below the carotid bifurcation. At this point the sheath is advanced into position over the catheter. This telescopic technique provides better support and fewer working maneuvers. However, due to a recent end of production of the 6-F compatible catheters, the size mismatch between the 6-F sheath and the 5-F catheter can increase the risk of the sheath scraping plaque off or dissecting the arterial wall as the catheter is advanced ("snowplowing"), which can result in embolization. Alternatively, the older technique of advancing a stiff glide wire into the ECA, followed by catheter withdrawal and dilator placement, can be used. The sheath and dilator are then advanced together into the mid CCA. This technique carries a number of risks, including crossing the carotid bifurcation unprotected with a stiff wire, the dilator crossing the plaque at the bifurcation, and the need for several exchanges and manipulations.

In a guiding catheter–based platform, the CCA is directly accessed with a preshaped 6- or 7-F guiding catheter (e.g., multipurpose curve, vertebral or reversed-angle Vitek catheter) that is left in place for the duration of the procedure. The benefit of this approach is that it minimizes the number of wire and catheter exchanges needed to get the system in place, making it ideal for patients with shaggy aortic arches. The disadvantage of this approach is that the platform can be easily dislodged from the CCA during stent advancement if it is not positioned far enough into the vessel. To avoid this from happening, a 0.014-inch coronary artery buddy wire can be placed into the ECA to assist with platform stabilization.

Angiography

As noted previously, adequate intraoperative carotid artery angiography should be obtained in all patients to assist with stent measurements and procedural planning prior to stent delivery. Once the working platform has been advanced into the CCA, an angiogram should be obtained through the guiding catheter or sheath using anteroposterior (AP) and lateral projection to try and minimize ICA and ECA overlap. If the carotid branches overlap with this approach, adjunct oblique views should be obtained to allow for complete visualization of the CCA, ICA, ECA, and intracranial carotid vessel distribution (Fig. 92.6). Occasionally, rotational angiography can help to detect the true degree of stenosis. Precerebral and postcerebral images can help to detect distal branch embolization.

Embolic Protection Devices

After carotid artery angiography is obtained, an EPD should be placed in the distal ICA for cerebral protection against intraoperative embolism. Data from the EVA-3S trial demonstrated a significant protective effect with EPDs against 30-day risk of stroke (7.5% with EPD vs. 25% without EPD; $P = .03$).[7] Although data from the SPACE trial did not support this finding,[63] a pooled analysis of 12,263 protected CAS patients and 11,198 unprotected CAS patients demonstrated a relative risk for stroke of 0.62 (95% CI 0.54 to 0.72) in favor of protected CAS.[64] The CREST trial mandated the use of EDP whenever feasible (95% of patients), and the ubiquitous use of cerebral protection is one of the reasons cited for the low number of adverse events reported in that study.[15] Accordingly, current clinical guidelines all support the use of EPDs during CAS,[21-23] and CMS mandates use of an EPD to qualify for reimbursement.[25]

Because of the current widespread use of EPDs with CAS, a number of different models have been developed. Each of the available EDPs is based on one of three conceptually different methods.

Filter-type EDPs are the most commonly used and are designed to allow antegrade cerebral flow throughout the entire CAS procedure (Fig. 92.7). The filter is passed across the carotid lesion over a wire and deployed distally in the ICA to capture

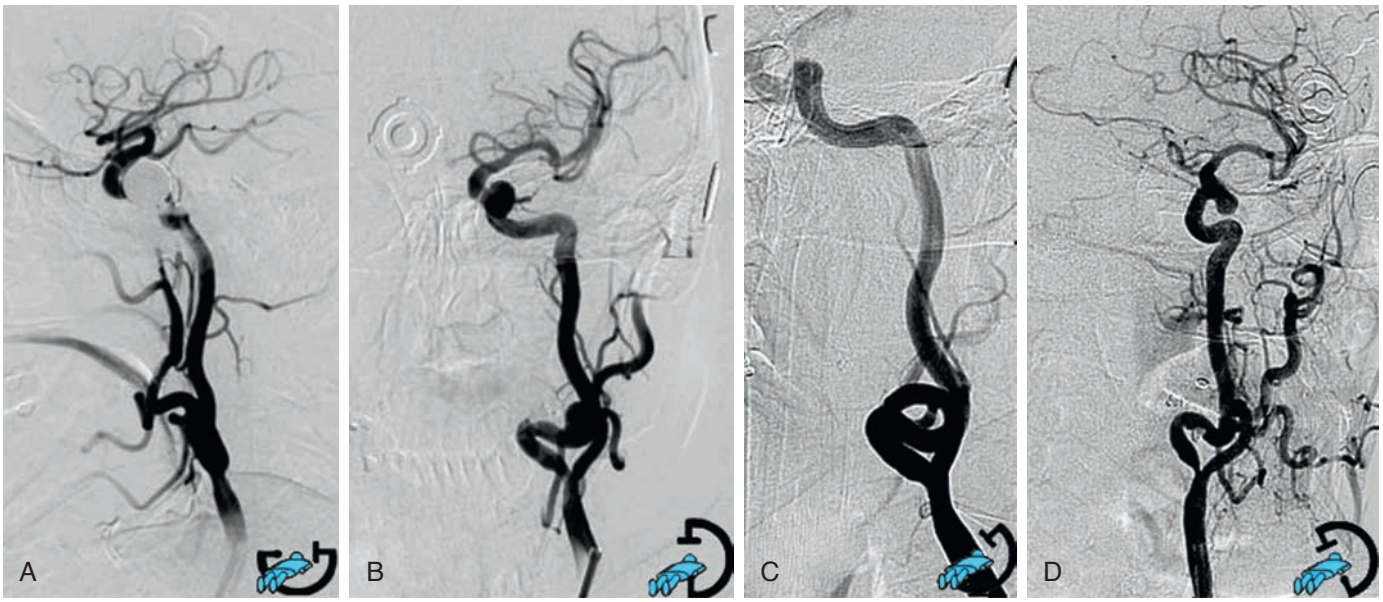

Figure 92.6 Standard projections showing mild to moderate stenosis. The projection selected with rotational angiography shows severe stenosis. (A) Laterolateral. (B) Anteroposterior. (C) Left anterior oblique. (D) Right anterior oblique.

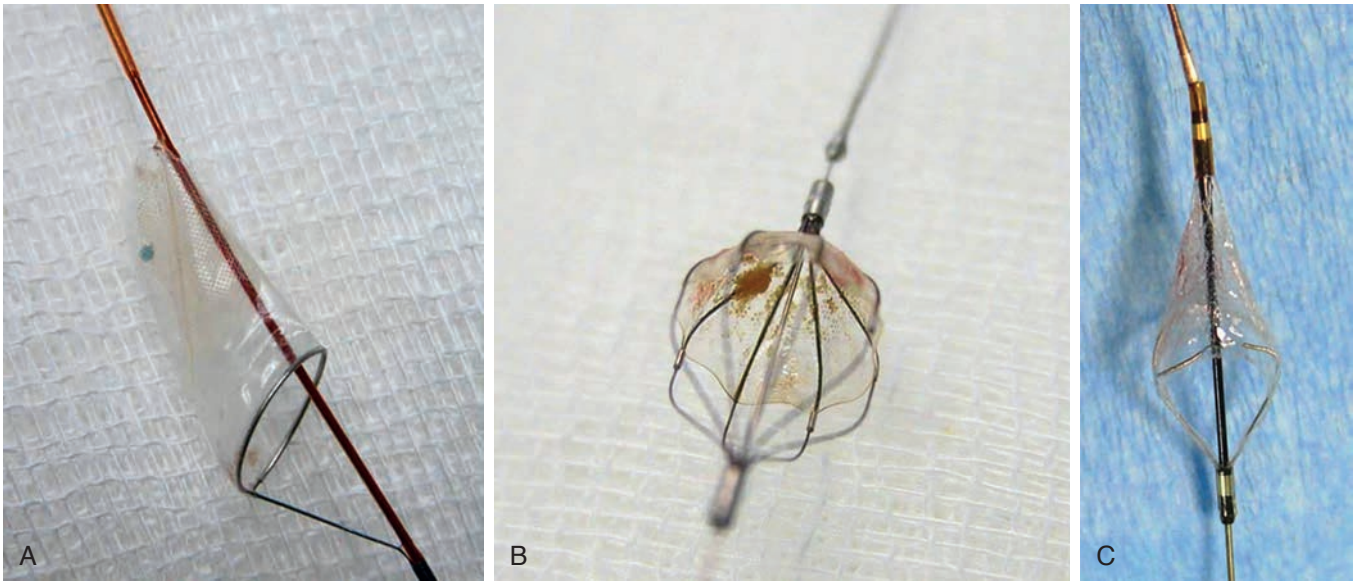

Figure 92.7 Filter-type embolic protection devices. Different types of filters containing debris after retrieval. (A) EPI FilterWire. (B) Angioguard. (C) Emboshield. ([A] Courtesy Boston Scientific, Natick, MA. [B] Courtesy Cordis, Somerville, NJ. [C] Courtesy Abbott Vascular, Redwood City, CA.)

any debris that may come loose during stenting. After the stent is successfully deployed, the filter is recaptured using a dedicated filter-retrieval system. The advantages of this EDP design are uninterrupted cerebral blood flow, continuous access to angiography throughout the procedure, and a low number of manipulations required within the carotid vessels. The main disadvantage is that the filter must be passed through the carotid lesion prior to deployment, which can be challenging in high-grade lesions and carried a risk of plaque dislodgement or rupture prior to filter deployment.

The distal occlusion balloon is the EDP that was originally used by Theron et al.[9] but which has been largely abandoned nowadays. With this device, a balloon is inflated in the distal ICA, preventing antegrade blood flow during the procedure. After stent deployment, the blood and any debris material are flushed and suctioned endovascularly, and then the balloon is deflated and removed. Like distal filter-type EDPs, this model requires passage of the carotid lesion prior to placement of embolic protection. There is also risk of incomplete evacuation of debris, and distal ICA vasospasm or damage as a result of

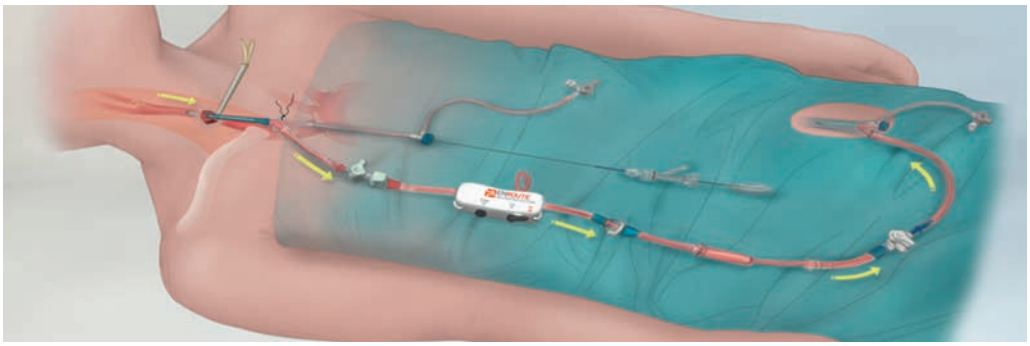

Figure 92.8 Transcarotid artery revascularization with cerebral flow reversal using the Enroute Neuroprotection System. In this system the arterial sheath placed in the common carotid artery via cutdown, and a low pressure venous sheath is placed in the femoral vein.

balloon deployment. Few patients are unable to tolerate occlusion with resulting neurologic changes that can mandate balloon deflation in the middle of the procedure.

Proximal protection EDPs provide protection against embolic events prior to crossing the lesion using either flow stasis or flow reversal. One proximal protection EDP, the Mo.Ma (Invatec, Roncadelle, Italy), deploys an occlusion balloon in the CCA and the ECA using a single delivery catheter. This causes flow stasis during stent deployment. Debris is aspirated after the stent is deployed using intermittent syringe aspiration through the introducer sheath, after which the distal occlusion balloon is deflated.[65] Flow reversal systems similarly employ the principles of CCA and ECA occlusion, but an external shunt containing a filter to capture any debris is placed between the long introducer sheath in the carotid artery and a shorter introducer in the femoral vein, allowing for continuous arteriovenous flow throughout the procedure.[66,67] The recent ENROUTE system for TCAR allows for effective cerebral flow reversal at low and high flow, avoiding the arch and ECA ballooning (Fig. 92.8). The main advantage to proximal protection EDPs is that they prevent the need for crossing the carotid lesion prior to obtaining cerebral protection. The main disadvantage is that a larger sheath is required to accommodate the EDP system (9 F for transfemoral access, 8 F for TCAR access) and the need for EDP device manipulation in close proximity to the target lesion. In addition, approximately 5% to 9% of patients will not tolerate flow stasis or reversal for prolonged periods of time; in these cases, short periods of balloon occlusion can be used to minimize neurologic intolerance and still maintain a degree of cerebrovascular protection during stent deployment.[68]

There is no obvious clinical advantage to one EDP design over another. In the Prevention of Cerebral Embolization by Proximal Balloon Occlusion Compared to Filter Protection During Carotid Artery Stenting (PROFI) study, which is the only RCT designed to compare EDP approaches to date, proximal balloon occlusion was shown to have a lower incidence of silent new cerebral ischemic lesions on postoperative magnetic resonance imaging compared with filter protection (6.5% vs. 29%; $P = .05$), but there were no significant differences in the 30-day risk of major adverse cardiovascular and cerebral events (0% vs. 3.2%; $P =$ NS).[69] A small benefit with proximal protection EDPs over filter EDPs has similarly been shown in smaller nonrandomized trials,[70,71] but many of these studies have substantial industry influence. Currently, it is most important that surgeons practicing CAS use the EDP that they are most familiar with to minimize complications related to user error or excessive device manipulation.

Predilation

After the EDP is in place, a decision must be made as to whether the carotid lesion requires predilation prior to stent deployment. When the stenosis is severe, predilation with a small (2.5 to 4.0 mm) coronary artery balloon to 4 to 6 atm of pressure may assist in stent positioning and deployment. Rarely, predilation may be necessary to pass a filter-type EDP. In these cases a proximal protection EDP should be considered as an alternative in an effort to avoid dilation of the lesion without cerebral protection.

Stent Selection and Delivery

Carotid artery stents are self-expandable stents made of either stainless steel (a cobalt alloy) or nitinol (a nickel-titanium alloy). There are two main configurations of carotid artery stent construction. In closed cell stents, all of the stent struts are interconnected, whereas in open cell stents they are not. As a result, closed cell stents have a smaller free cell area and those provide better scaffolding of the vessel wall. In contrast, open cell stents more conformable or flexible.

Stent selection depends on the carotid anatomy and plaque characteristics of the lesion in question. For tortuous carotid arteries, flexible stents may be preferred to prevent kinking. In contrast, stents with better scaffolding may be preferable for plaques at risk of protruding through the stent struts and causing distal embolization. In general, nitinol stents have a higher radial force than stainless steel stents and may be more effective for highly calcified plaques with poor compliance. However, there are no definitive data to support the use of one self-expanding stent over another.[72-75]

The diameter of the stent to be placed should be based on angiographic measurements taken at the time of the procedure. Preoperative CTA can assist in this and may be helpful for ensuring the availability of appropriate stent inventory, but all measurements should be confirmed in real time. The diameter of the stent should be sized to the largest portion of the carotid artery, which is usually the distal CCA.

Once an appropriate stent has been selected, it should be deployed using road mapping or, alternatively, using vertebral bones as landmarks, depending on the surgeons' comfort with either technique. The stent should be placed across the carotid bifurcation because in most cases the carotid lesion extends to the carotid bulb. Of note, recent stents under clinical investigation use a cover mesh to cover the lesion.[76] This is particularly important because the principle of successful CAS is to stabilize the plaque with minimal manipulation of the lesion.

Postdilation

When CAS was first adapted for the treatment for the carotid artery stenosis, it was performed using the basic tenants of peripheral arterial interventions. To that end, balloon dilation of the lesion being treated was performed both prior to and after the stent was placed. The theory behind this practice was that prestenting balloon dilation disrupts the plaque causing the lesion and allows the stent to be placed, and poststenting ballooning allows for full expansion of the stent. However, an analysis using data from the Vascular Quality Initiative suggests that poststent balloon dilation may increase perioperative hemodynamic depression and stroke and death rates in patients undergoing CAS. Compared with prestent ballooning only, the prestent and post-stent ballooning technique was associated with a 2.1-odds increase in hemodynamic depression (95% CI 1.51 to 3.01) and 2.4-odds increase in perioperative stroke and death (95% CI 1.01 to 5.620).[77] Accordingly, continued artery stent expansion has been demonstrated by duplex up to 30 days after deployment even without post-stent ballooning.[78] Based on these data, we suggest that post-stent balloon dilation be reserved for lesions with severe residual stenosis after stent deployment.

Completion Angiography and Retrieval of Embolic Protection Device

After the stent is deployed, a completion angiogram should be performed with the EPD in place to evaluate for accuracy of stent positioning, residual stenosis, vasospasm at the distal stent endpoint, and filling defects inside the stent due to plaque protrusion. After the EDP is retrieved, a final angiogram capturing both the cervical and intracranial circulation should be obtained to evaluate all aspects of cerebral blood flow. Careful attention should be paid to the distal ICA, which may spasm after a filter-based EDP is removed. In these cases, waiting a few minutes usually allows for spasm resolution. Rarely, small volumes of nitroglycerin (100 to 200 μg) can be instilled through the guiding sheath into the CCA to assist in vasorelaxation if needed.

Access Hemostasis

Heparin reversal with protamine has not been shown to increase the risk of MI, stroke, pulmonary embolism, or death in a number of CEA studies.[79-81] It is the authors' preference to administer a small dose of protamine slowly to reverse half the heparin dose given during the case (based on 1 mg per 100 unit of intravenous heparin). This allows for adequate access hemostasis and may reduce the potential for intracranial hemorrhage (ICH) postoperatively. Access hemostasis should be obtained using percutaneous closure assist devices and/or manual pressure as with any endovascular procedure.

PERIOPERATIVE MEDICATIONS

Anticoagulation

As noted previously, all patients should be fully anticoagulated with unfractionated intravenous heparin (70 to 100 units/kg) once sheath access is obtained and before starting catheter manipulation within the aortic arch. Activated clotting times (ACTs) should be followed and should not exceed 300 seconds to prevent hemorrhagic stroke secondary to reperfusion following the procedure.

Atropine

Hypotension with bradycardia, or HD, may occur after balloon dilation in response to stretching of the carotid baroreceptors. This is particularly common in older patients with long, heavily calcified plaques.[82,83] Hemodynamic depression may be associated with an increased risk of adverse periprocedural events including stroke[82] and thus should be avoided whenever possible. To prevent hemodynamic depression, the senior author avoids post-stent ballooning and the resulting stretching of carotid baroreceptors. In patients who develop severe hypotension and bradycardia after balloon dilatation and/or stent deployment, aggressive volume expansion and intravenous atropine (0.4 to 1 mg) may be administrated. Less commonly, use of vasopressors, including intravenous phenylephrine (1 to 10 μg/kg per minute) or dopamine (5 to 15 μg/kg per minute) infusion, may be necessary.[21] Persistent hypotension after cardiac stenting can occur, lasting 24 to 48 hours postoperatively. Risk factors for persistent hypotension include distance from the carotid bifurcation to maximum stenotic lesion (≤10 mm), type of stenosis (eccentric), plaque morphologic features (echogenic), and calcification at carotid bifurcation.[84] In these cases, management generally involves pharmacologic support until the carotid baroreceptors adapt to the radial force of the stent and the resulting hemodynamic depression is resolved. There are reports of using transcutaneous temporary cardiac pacing in carotid stenting in patients who are deemed to be high risk for postoperative bradycardia (i.e., older patients, those taking beta blockers or digoxin, or who are bradycardia at baseline),[85,86] but this is rarely indicated.

Vasodilators

Intravenous vasodilators should be used throughout the procedure to maintain a systolic blood pressure less than 180 mm Hg to minimize risk of ICH.[21] As mentioned, small volumes of nitroglycerin (100 to 200 μg) may also be instilled through the guiding sheath into the CCA to assist in vasorelaxation in cases of persistent ICA spasm after EDP removal. However, both of these therapies should be used judiciously because excessive vasodilation in combination with hemodynamic depression after balloon dilation may exacerbate the prolonged hypotension that can be observed in some CAS patients postoperatively.

Beta Blockers

The use of beta blockers to improve outcomes after CAS is somewhat controversial. Although once considered universally cardioprotective, the initiation of perioperative beta blockers for major elective vascular surgery may not be advisable in some subgroups.[87,88] Recent data from the Vascular Quality Initiative suggest that preprocedural beta blocker use for more than 30 days was associated with a 34% reduction in the stroke/death risk compared with nonuse[89] and is associated with an increased risk of postprocedural hypotension.[89,90] Taken together, these data suggest that if beta blockers can be initiated well in advance of a planned intervention, they may have a role in CAS therapy. In contrast, the use of periprocedural beta blockers in beta-blocker naïve patients may carry an increased risk of perioperative cardiac morbidity.[88]

Antiplatelet Therapy

The use of dual antiplatelet therapy has not been shown to have a significant benefit for reducing stroke, MI, or death as a preventative treatment strategy among patients who are at high-risk atherothrombotic events.[91,92] However, data from coronary revascularization studies have demonstrated a protective benefit with clopidogrel and aspirin for patients undergoing percutaneous coronary intervention, particularly in high-risk populations.[93,94] Given that periprocedural stroke is the highest concern in CAS, current guidelines recommend dual-antiplatelet therapy with aspirin (81 to 325 mg daily) plus clopidogrel (75 mg daily) at least 4 days before and for a minimum of 30 days after surgery for those patients undergoing CAS.[21,23,95] For patients intolerant of clopidogrel, ticlopidine (250 mg twice daily) may be used instead.

Antithrombotic Therapy

The routine use of antithrombotic therapy after CAS is not indicated. In an RCT designed to compare dual antiplatelet therapy (aspirin plus clopidogrel) versus aspirin and 24-hour heparin for patients undergoing CAS, neurologic complications were significantly higher in the heparin group (25% vs. 0% with dual antiplatelet therapy), causing the trial to be terminated prematurely.[96] The use of systemic antithrombotic therapy with warfarin among patients with recent stroke has also not been shown to be beneficial compared with aspirin.[97] As such, antithrombotic therapy after CAS should be restricted to those patients who were on it preoperatively due to cardiac or thromboembolic indications. In this group, warfarin may be converted to low-molecular-weight heparin prior to the procedure.

Statins

All patients undergoing evaluation for CAS should be initiated on statin therapy preoperatively. In a meta-analysis of 12 retrospective and 3 prospective trials representing 223,010 patients, preoperative statin therapy was shown to be associated with a 59% reduction in risk of mortality after vascular surgery.[98] Statins have also been shown to be effective at reducing the risk of cardiovascular events in both women and men[99] and that the protective benefit likely occurs within a month of starting treatment.[100] Consistent with this notion, patients undergoing CAS who are on preprocedural statin therapy have been shown to have a lower incidence of stroke, MI, and death within 30 days surgery; based on a prospectively maintained intuitional database composed of 180 consecutive CAS patients, the incidence periprocedural cardiovascular events was shown to be significantly lower among statin users (4% with statin vs. 15% without).[101] These findings have been corroborated by a large retrospective review of 1,083 CAS patients that demonstrated a significantly lower incidence of perioperative stroke and death among those taking statins (1.5% statin vs. 4.0% no statin).[102] Although the optimal timing, dosing, and agents are unclear at this time, consensus guidelines suggest that all patients undergoing carotid revascularization should be initiated on statin therapy as early as possible.[103]

COMPLICATIONS

Technical Complications

Acute stent thrombosis is an emergency because it carries a substantial risk of clot propagation and subsequent thromboembolic stroke. It can be caused by stent misplacement, severe carotid artery recoiling due to annular calcification, or massive plaque protrusion through the stent struts. When acute thrombosis occurs, the procedure should be immediately converted to CEA. Rapid reestablishment of cerebral perfusion via endarterectomy is associated with a good neurologic outcome.[104]

Kinking may occur at the endpoints of the stent, especially when placed in vessels with severe tortuosity. Usually, this is visible on the completion angiogram. In these cases the patient can be observed if the kink is mild, as long as there is good antegrade blood flow, because carotid remodeling occurs up to 3 to 6 months postoperatively and may reduce or eliminate the kink over time.[105]

Carotid dissection can also be observed on completion angiogram and may be managed by observation, balloon

apposition of the stent (i.e., poststent dilation), or placement of an additional stent, depending on the location and extent of the dissection flap. If the dissection is flow-limiting, use of an additional stent is indicated.[95]

Neurologic Complications

Neurologic complications are the most common complications following CAS and include embolism, ICH, hyperperfusion, and neurocognitive effects.

Embolism is the most common and feared complication following CAS and is usually the result of an atherosclerotic plaque or catheter-generated thrombus. The diagnosis is usually made as a result of changes in the intraoperative neurologic exam; when this occurs, an angiogram should be obtained immediately to visualize the offending occlusion. Depending on the location of the embolus, potential neurorescue procedures include catheter-directed chemical thrombolysis with urokinase or recombinant tissue plasminogen activator, thrombus maceration, aspiration thrombectomy, snare removal, and glycoprotein IIb/IIIa receptor inhibitor administration. The results of each of these salvage therapies are variable, and embolus prevention remains the mainstay of CAS therapy, predominantly by use of EPDs.[106]

Intracranial hemorrhage is a rare complication of CAS but can have devastating consequences. In a review of CAS versus CEA using data from the Nationwide Inpatient Sample, CAS was found to be associated with a sixfold higher risk of ICH than CEA.[107] However, these finding have not been confirmed with RCTs. Data from the EVA-3S, SPACE, and CREST trials have all shown relatively equivalent risk of ICH after CAS versus CEA (<1%).[7,8,18] There is some suggestion from CREST that when ICH occurs after CAS they are more severe, which may be attributable to the use of dual antiplatelet therapy before and after this procedure.[18] Groups that have been recognized as being high risk for developing ICH after CAS include patients with symptomatic carotid stenosis and those with bilateral severe carotid stenosis with associated hypertension.[108]

Hyperperfusion is also a relatively uncommon complication of CAS, occurring in an estimated 1% to 2% of patients.[108,109] Hyperperfusion is diagnosed when a patient develops a neurologic change and CT imaging reveals ipsilateral cerebral edema without evidence of stroke.[109] Headaches or transient ischemic attacks are not included. Symptoms usually develop at a mean of 10 hours postoperatively and are more common in patients with hypertension or a recent history of transient ischemic attacks.[109] The risk of hyperperfusion syndrome is progression to ICH. The treatment is largely supportive, with a focus on blood pressure control.

Subclinical neurocognitive complications represent microembolic events after CAS that do not result in a clinical deficit. In a small prospective study including 82 patients, new brain lesions were identified by diffusion-weighted imaging in 71% of CAS patients, compared with only 4% of CEA patients.[110] Although not immediately symptomatic, the concern is that these microembolic events could lead to accelerated cognitive loss and premature senescence.[111] To date, existing data on this topic do not suggest that microembolic events after CAS result in worse long-term neurocognitive function. Data from ICSS demonstrate no differences in cognitive performance following CAS versus CEA.[112] Analyses of smaller institutional series support these findings, demonstrating no significant differences in cognitive function up to 6 months after CAS versus CEA despite a substantially higher rate of new ischemic lesions after CAS.[110,113] The longer-term effects of microembolic events that may occur with CAS remain to be seen.[114]

Cardiovascular Complications

The risk of periprocedural MI after CAS is consistently lower than that after CEA based on RCT data.[7,8,15] As such, CAS may be a good option for carotid revascularization in patients who are at high risk for having an adverse cardiac event with open surgery. Hemodynamic depression can occur (see section "Intraoperative Medications: Atropine," earlier), but this rarely results in ischemic events or alterations in blood pressure in the long term.[115,116]

Renal Dysfunction

The contrast load associated with CAS can cause contrast-induced nephropathy, particularly in patients who have baseline chronic renal insufficiency. This risk is equivalent to any generic endovascular procedure, and patients should be counseled accordingly. The total amount of contrast injected during the procedure should be minimized as much as possible and in most cases should not exceed 60 mL. Adequate fluid resuscitation is the cornerstone to avoiding acute kidney injury and should be managed with attention to the patients' other risk factors (i.e., congestive heart failure). Of note, patients with baseline chronic renal insufficiency are at risk of having higher major adverse events after CAS in general and should be approached with caution.[117]

Access Complications

As with any endovascular procedure, access complications, including hematoma formation, pseudoaneurysm, peripheral embolization, and access site infections, can occur. Of the 1262 patients in the CAS cohort of the CREST trial, there were 24 cases of major bleeding requiring blood transfusion and 12 cases of retroperitoneal major bleeding or femoral hematoma requiring revision.[15] Most access site complications resulting from CAS are self-limited and can frequently be managed expectantly. In our practice the use of duplex ultrasound to guide access, reversing anticoagulation at the end of the case, and the use of closure devices have all contributed to minimizing access site bleeding and pseudoaneurysm complications.

Stent Fracture

Stent fracture has been reported after CAS with an incidence of approximately 9%.[118] It has been reported to occur any time

from 0 to 37 months after surgery. In a review of 201 carotid stents in 10 case reports and 3 clinical studies, less than one-third of patients with stent fractures became symptomatic, but carotid artery restenosis occurred in 55% of cases.[118] The majority of these fractures were successfully treated by de novo stent placement, although balloon angioplasty, CEA, carotid bypass, and observation alone have also been reported.

Restenosis

One of the major concerns with CAS is that of long-term restenosis. The Carotid and Vertebral Artery Transluminal Angioplasty Study (CAVATAS) trial reported a 10-year restenosis rate of 30.7% following an endovascular treatment approach to patients with caroti artery stenosis, compared with 11% in the CEA group.[119] However, the endovascular arm of CAVATAS used carotid stents in only 26% of the patients treated endovascularly; the remainder underwent balloon angioplasty alone.[120] More recent data from the CREST trial suggest a much lower incidence of restenosis following CAS; at 2 years postoperatively, carotid artery restenosis or occlusion occurred in 6.0% of CAS patients and 6.3% of CEA patients.[18] The longer-term risks of restenosis with CAS are unknown, but high-risk features include diabetes, female sex, and dyslipidemia.[18] Patients with carotid stenosis that is longer than 0.65 times the CCA diameter have also been shown to be at increased risk of restenosis following CAS.[121]

POSTOPERATIVE SURVEILLANCE

Duplex ultrasound should be performed in all CAS patients 3 to 6 weeks postoperatively.[122] This allows for the establishment of new baseline flow for the patient to be used in future comparisons, which is particularly important because the presence of stents have shown to alter duplex flow velocity measurements.[123] Although no definitive RCT data exist on this topic, currently repeat duplex surveillance is recommended 6 months after the initial postoperative study and then annually thereafter for all patients undergoing CAS.[122]

LONG-TERM OUTCOMES

Randomized Controlled Trials

Ten-year outcomes after CAS versus CEA were recently reported by the CREST trial investigators.[16] Among 2502 patients, 10-year postprocedural ipsilateral stroke rates were not significantly different between the CAS versus CEA group (6.9% CAS vs. 5.6% CEA). The incidence of periprocedural stroke, MI, or death and subsequent ipsilateral stroke also did not differ between groups. Similarly, 5-year outcomes were reported for the ACT-I trial, which demonstrated no significant differences between CAS versus CEA in the rates of non–procedure-related stroke, all stroke, and survival in patients with high-grade asymptomatic stenosis.[19] These trials represent the first data on long-term outcomes after CAS, and based on reported findings the results are encouraging.

Ongoing Trials

There are currently a number of trials that have recently closed or are still in progress that were designed to compare CAS versus CEA versus BMT for the treatment of asymptomatic carotid stenosis.[124]

The Stent-Protected Angioplasty Asymptomatic Carotid Stenosis Versus Endarterectomy 2 (**SPACE-2**) trial was recently designed to compare the superiority of BMT versus intervention (CAS or CEA), as well as the noninferiority of CAS versus CEA.[125] The primary outcome of the study is the cumulative rate of any stroke or death within 30 days plus ipsilateral ischemic stroke within 5 years of follow-up. SPACE-2 was recently closed prior to completion due to slow enrollment, but the data are expected to be part of a meta-analysis comparing BMT versus carotid revascularization for asymptomatic carotid stenosis.[124]

The Asymptomatic Carotid Surgery Trial-2 (**ACST-2**) was designed to compare CAS versus CEA for the prevention of stroke in patients with asymptomatic carotid artery stenosis.[126] The primary outcomes are 30-day MI, stroke and death, and 5-year stroke rates. ACST-2 currently open for randomization, with an expected enrollment of more than 5000 patients.

The European Carotid Surgery Trial 2 (**ECST 2**) is a randomized trial designed to compare BMT versus carotid revascularization (CAS or CEA) in patients with greater than or equal to 50% carotid artery stenosis.[127] In this trial, patients can either be asymptomatic or symptomatic with associated factors indicating intermediate or lower risk of ipsilateral stroke (5-year ipsilateral stroke risk of <20%). The primary outcome for ECST 2 is any stroke at any time plus nonstroke death within 30 days of intervention. The trial targets enrollment of 200 patients in the United Kingdom and is currently open for randomization.

The Carotid Revascularization for Primary Prevention of Stroke (**CREST-2**) trial is actually composed of two independent multicenter RCTs designed to compare BMT versus carotid revascularization in patients with asymptomatic high-grade (≥70%) carotid artery stenosis.[128] One trial will randomize patients to BMT versus CAS+BMT, and the second trial will randomize patients to BMT versus CEA+BMT. The primary outcome for CREST-2 is a composite outcome of stroke plus death within 44 days after randomization and ipsilateral stroke thereafter up to 4 years. The trial is currently active and estimates a total enrollment of 2480 patients.

Based on the safety results of the **ROADSTER** trial,[59] the Reverse Flow Used During Carotid Artery Stenting Procedure 2 (ROADSTER 2) trial is now underway. ROADSTER 2 is a postapproval, multicenter study designed to assess the efficacy of TCAR using the ENROUTE Transcarotid Neuroprotection and Stent System from Silk Road Medical (Silk Road Medical Inc, Sunnyvale, California).[129] The primary outcome of the study is rate of procedural success through 30 days following stent implant. ROADSTER 2 is aiming for a minimum enrollment of 600 patients with symptomatic carotid artery stenosis greater than or equal to 50% or asymptomatic carotid artery stenosis greater than or equal to 80% at up to 100 sites.

TABLE 92.5 Recommended Techniques to Reduce Periprocedural Adverse Events During Carotid Artery Stenting

Timing	Technique	Comment
Preoperative	Statin therapy	All patients undergoing carotid revascularization should be initiated on statin therapy as early as possible[103]
	Beta blocker therapy	Preprocedural beta blocker use for >30 days is associated with a reduction in periprocedural stroke/death risk compared to nonuse[89]
	Adequate imaging	Consider computed tomography angiography in patients with potential complex aortic or carotid anatomy to allow for better operative planning
Intraoperative	Frequent awake neurologic assessment	Allows for early detection of stroke
	Stable sheath access	Consider transcarotid artery revascularization in patients with challenging aortic anatomy to reduce stroke risk[59]
	Embolic protection devices	Consider proximal protection EDPs to reduce risk of embolic lesion caused by initial crossing of the lesion[69]
	Atropine	Intravenous atropine (0.4-1 mg) may be administrated before balloon inflation to suppress the hemodynamic response to stretching of carotid baroreceptors
	Appropriate stent sizing	The diameter of the stent should be sized to the largest portion of the carotid artery, which is usually the distal common carotid artery
		All sizing should be confirmed by intraoperative angiography even if preoperative computed tomography angiography is obtained
	Avoid post-stent dilation	Hemodynamic depression and perioperative stroke and death have been shown to be lower without post-stent dilation[77]
	Completion angiography	Confirm stent placement and check for distal internal carotid artery spasm
Postoperative	Antiplatelet therapy	Aspirin (81-325 mg daily) plus clopidogrel (75 mg daily) 4 days before and for a minimum of 30 days after carotid artery stenting is recommended[21,23,95]

CONCLUSIONS

The implementation of EPDs, continued development of newly designed stent options, use of dual antiplatelet therapy, and a better understanding of the appropriate criteria for use of a noninvasive approach to carotid revascularization have substantially improved outcomes with this procedure over time (Table 92.5). The long-term results of CAS remain to be established, especially with regard to stent patency, but 10-year data from the CREST trial appear promising.[16]

Bonati LH, Dobson J, Featherstone RL, et al. Long-term outcomes after stenting versus endarterectomy for treatment of symptomatic carotid stenosis: the International Carotid Stenting Study (ICSS) randomised trial. *Lancet*. 2015;385(9967):529–538.

The International Carotid Stenting Study (ICSS) is a multicenter, randomized, British trial designed to compare CAS versus CEA for patients with >50% symptomatic carotid artery stenosis. This paper describes the long-term outcomes of the study (median follow-up time 4.2 years), which demonstrated that the risk of fatal or disabling stroke was similar for CAS and CEA.

Brott TG, Hobson RW 2nd, Howard G, et al. Stenting versus endarterectomy for treatment of carotid-artery stenosis. *N Engl J Med*. 2010;363(1):11–23.

This paper describes the original outcomes of the Carotid Revascularization Endarterectomy versus Stenting Trial (CREST), which is the largest multicenter, randomized trial designed to compare outcomes for CAS versus CEA to date. At a median follow-up of 2.5 years, there was no significant difference in the estimated 4-year rates of the primary composite endpoint (stroke, MI, or death from any cause during the periprocedural period up to 30 days or any ipsilateral stroke within 4 years after randomization) between groups. However, notably, the data from CREST demonstrated that CAS had a higher risk of periprocedural stroke, whereas CEA had a higher risk of periprocedural MI.

Brott TG, Howard G, Roubin GS, et al. Long-term results of stenting versus endarterectomy for carotid-artery stenosis. *N Engl J Med*. 2016;374(11):1021–1031.

This paper describes the long-term follow-up data from the CREST trial. After 10 years of follow-up, there were no significant differences between CAS versus CEA for the risk of periprocedural stroke, myocardial infarction, or death and subsequent ipsilateral stroke. The rate of postprocedural ipsilateral stroke also did not differ between groups.

Eckstein HH, Ringleb P, Allenberg JR, et al. Results of the Stent-Protected Angioplasty versus Carotid Endarterectomy (SPACE) study to treat symptomatic stenoses at 2 years: a multinational, prospective, randomised trial. *Lancet Neurol*. 2008;7(10):893–902.

The Stent-Supported Percutaneous Angioplasty of the Carotid Artery versus Endarterectomy (SPACE) trial is a German multicenter, randomized, noninferiority trial designed to compare CAS versus CEA among patients with ≥70% symptomatic carotid stenosis. This paper describes the 2-year follow-up outcomes for the study, which demonstrated no significant differences in cumulative 30-day stroke/death and 2-year ipsilateral

stroke between treatment groups. However, CAS failed to meet criterion for noninferiority compared with CEA at 30 days, and the study was stopped prematurely due to cost issues and futility.

Gurm HS, Yadav JS, Fayad P, et al. Long-term results of carotid stenting versus endarterectomy in high-risk patients. *N Engl J Med*. 2008;358(15):1572–1579.

This paper describes the 3-year results for the Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy (SAPPHIRE) trial, which is a multicenter, randomized, noninferiority US trial designed to compare CAS versus CEA for patients with ≥ 50% symptomatic or ≥ 80% asymptomatic carotid artery stenosis. SAPPHIRE enrolled 334 patients total (167 in each group) and demonstrated that CAS was noninferior to CEA both at 1 year and 3 years postoperatively.

Mas JL, Trinquart L, Leys D, et al. Endarterectomy Versus Angioplasty in Patients with Symptomatic Severe Carotid Stenosis (EVA-3S) trial: results up to 4 years from a randomised, multicentre trial. *Lancet Neurol*. 2008;7(10):885–892.

The Endarterectomy Versus Angioplasty in Patients with Symptomatic Severe Carotid Stenosis (EVA-3S) trial is a multicenter, randomized, noninferiority French trial designed to compare CAS versus CEA for patients with >60% symptomatic carotid artery stenosis. This paper describes the trial's 4-year follow-up, which demonstrated worse outcomes with CAS due to significantly higher rates periprocedural stroke/death.

Ricotta JJ, Aburahma A, Ascher E, et al. Updated Society for Vascular Surgery guidelines for management of extracranial carotid disease. *J Vasc Surg*. 2011;54(3):e1–e31.

This paper outlines the official Society for Vascular Surgery guidelines regarding use of CAS and CEA and patients with carotid artery stenosis. Based on available RCT data, these guidelines suggest that CAS be reserved for symptomatic patients with stenosis of 50%–99% at high risk for CEA for anatomic or medical reasons; CAS is not recommended for asymptomatic patients. For asymptomatic patients undergoing CEA, the perioperative risk of stroke and death must be <3% to ensure benefit for the patient. These guidelines are supported by similar guidelines published by the American College of Cardiology/American Heart Association and the European Society of Cardiology in the same year.

Rosenfield K, Matsumura JS, Chaturvedi S, et al. Randomized trial of stent versus surgery for asymptomatic carotid stenosis. *N Engl J Med*. 2016;374(11):1011–1020.

The Carotid Angioplasty and Stenting Versus Endarterectomy in Asymptomatic Subjects Who Are at Standard Risk for Carotid Endarterectomy With Significant Extracranial Carotid Stenotic Disease (ACT-I) trial is a randomized noninferiority trial designed to compare outcomes after CAS versus CEA among patients <80 years of age with severe asymptomatic carotid stenosis who were not considered to be at high risk for surgical complications. The primary outcome (composite of death, stroke, or MI within 30 days or ipsilateral stroke within 1 year) was not significantly different between groups, and after 5 years of follow-up the cumulative rate of stroke-free survival was similar for CAS and CEA.

Carotid artery dissection is a relatively uncommon entity that results from either traumatic injury or can be spontaneous without a clear etiology. This chapter summarizes the current state of knowledge about carotid dissection, with a focus on spontaneous dissection.

CAROTID ARTERY DISSECTION

Arterial dissection occurs when disruption of the intima allows blood to extravasate between layers of the vessel wall. The resulting intramural hematoma usually extends distally and can lead to acute stenosis or occlusion (Fig. 93.1) and later to aneurysmal change with an increased risk for thromboembolic events. Dissection of the carotid artery either is spontaneous or has a precipitating mechanical event (traumatic or iatrogenic). Although each type of dissection is relatively uncommon, both are important clinically because they can be a source of stroke and occur particularly in young people. Cervical carotid artery dissections are responsible for only 2% of all ischemic strokes but account for 10% to 20% of strokes in young and middle-aged patients.[1] Spontaneous and traumatic carotid dissections differ in their pathophysiology and will be reviewed separately.

Spontaneous Carotid Artery Dissection

Epidemiology

The overall incidence of clinically apparent spontaneous carotid dissection is reported to be between 1.7% and 2.6%.[2,3] Spontaneous cervical carotid artery dissection occurs most frequently in the third through the fifth decades of life, and the mean age at diagnosis is 45 years. There is no gender predilection for spontaneous dissection, but women are affected at an average of 5 years younger than men.[4,5]

Pathogenesis

Spontaneous dissection can occur in any artery but is more likely to occur in the extracranial carotid and vertebral arteries than in other vessels of similar size (see Chapter 97). These arterial segments are mobile and can potentially come into contact with the bony structures of the head and neck.[4] A history of antecedent minor trauma is often elicited in patients with "spontaneous dissection," but the significance of these events is unclear and the course is distinctly different from dissection caused by definite and severe trauma.[5] Chiropractic manipulation has been implicated as an etiology of "spontaneous"

Abstract

Carotid artery dissection is a relatively uncommon entity that results from either traumatic injury or can be spontaneous without a clear etiology. This chapter summarizes the current state of knowledge about carotid dissection, with a focus on spontaneous dissection. Etiology, natural history, and treatment options and outcomes are discussed.

Keywords

Carotid
Dissection

Figure 93.1 Dissection of the Cervical Segment of the Internal Carotid Artery. Note the elongated, narrowed, and tapered luminal stenosis *(solid arrows)*, a finding frequently seen in association with extracranial dissections. Another common feature of this entity, fairly abrupt reconstitution of the carotid lumen at the base of the skull *(open arrow)*, is also shown. (From Mokri M. Dissection of the cervical and cephalic arteries. In: Meyer FB, ed. *Sundt's Occlusive Cerebrovascular Disease*. Philadelphia, PA: WB Saunders; 1994:51.)

dissection of the carotid and vertebral arteries, but a true relationship is elusive because 25% of these patients also have connective tissue disorders and neck pain, which may or may not be related to the dissection.[4,6]

Atherosclerosis and other known risk factors for vascular disease such as smoking, diabetes, hypercholesterolemia, and oral contraceptive use are usually absent in patients with spontaneous dissection. These patients do have a higher incidence of hypertension, and a migraine disorder has also been shown to have an independent association with spontaneous dissection.[7,8] Spontaneous cervical carotid artery dissection occurs more frequently in the winter, and recent infection is present in up to 58% of patients. There is a preponderance of respiratory infections, but mechanical factors such as coughing, sneezing, and vomiting do not seem to be independent risk factors.[9] Winter peaks in hypertension and infection may contribute to seasonal variability.[10]

Underlying abnormalities of the vasculature have been implicated in spontaneous cervical carotid artery dissection, including fibromuscular dysplasia, Ehlers-Danlos syndrome, cystic medial necrosis, Marfan syndrome, autosomal dominant polycystic kidney disease, and osteogenesis imperfecta type I.[4] Associated vascular anomalies implicated in spontaneous dissection include arterial redundancy, intracranial aneurysms, aortic root dilatation, and increased arterial distensibility.[11] Familial occurrences of spontaneous carotid dissection are also described, which further supports the possibility of an inherited disorder,[8] but definitive proof is lacking.

Clinical Findings

The most common initial symptom in patients with spontaneous dissection of the carotid artery is headache, whereas "classic" patients have a partial Horner syndrome. Nausea occurs more often with vertebral dissections, and hemispheric symptoms more often with carotid dissections.[12] Patients with cervical carotid artery dissection also suffer from neck pain, amaurosis fugax, anisocoria, pulsatile tinnitus, and cranial nerve palsy.[4,12] Cranial nerves IX through XII and in particular the hypoglossal nerve are most commonly involved.[13]

The classic clinical description of patients with spontaneous carotid dissection is ipsilateral head or neck pain, ipsilateral partial Horner syndrome (also referred to as oculosympathetic palsy), and cerebral or retinal ischemia. Oculosympathetic palsy refers to miosis and ptosis caused by involvement of the sympathetic fibers accompanying the internal carotid artery but does not include the facial anhidrosis of Horner syndrome, which is mediated by sympathetic fibers running along the external carotid artery. The onset of cerebral or retinal ischemia can occur hours or days after the initial symptoms. The classic triad of symptoms is present in less than a third of patients with spontaneous carotid dissection, and the diagnosis must obviously be considered in patients with more subtle manifestations and isolated symptoms.[4]

Traumatic Carotid Artery Dissection

Epidemiology

The incidence of traumatic carotid artery dissection in all patients seeking medical care after blunt traumatic injury is 0.08%,[14] but it is higher in patients with specific patterns of injury.[15] After blunt head and neck trauma, the incidence of internal carotid dissection is 0.86%,[16] and patients with head and neck injury and an altered level of consciousness have a reported incidence of carotid injury of up to 3.2%.[17]

Improved imaging modalities and increased awareness of cervical carotid arterial injury may have contributed to an apparent rise in incidence over the past decade. It is suggested that cervical carotid artery dissection is underdiagnosed, and several groups have reported a much higher incidence than was previously noted when all patients with severe head and cervical spine injuries are screened.[17,18] Screening may have particular value in trauma patients because neurologic deficits can have a delayed manifestation or be attributed to associated injuries, and some data suggest that early anticoagulation in asymptomatic patients with blunt carotid injury detected by screening leads to improved neurologic outcome.[19,20]

Pathogenesis

Traumatic cervical carotid artery dissection can occur after blunt or penetrating trauma, and both direct and indirect forces

contribute to injury. The most common mechanism of injury is extreme cervical hyperextension or lateral hyperflexion associated with severe blunt head and neck trauma caused by a motor vehicle collision.[15,16]

Clinical Findings

Most series reporting patients who experienced traumatic dissection are small or retrospective, describe clinical manifestation that vary from exclusively asymptomatic patients to patients with lateralizing symptoms appearing after a latent period of 4 hours to 75 days, and combine outcomes for injury and dissection of all cervical vessels.[15,17,21] Head and neck pain, hemiparesis, hemiplegia, dysphasia, aphasia, Horner syndrome, lateralizing transient ischemic attack (TIA), and stroke have all been described as initial symptoms of traumatic cervical carotid artery dissection. Some advocate routine screening (ultrasonography) in all patients with head and neck trauma.[17,18] Mandatory diagnostic evaluation is advocated for active bleeding in the head and neck, expanding neck hematomas, cervical bruits in patients older than 50 years, imaging suggesting acute brain infarction, central or lateralizing neurologic deficits, Horner syndrome, head or neck pain, cervical spine fracture, Glasgow Coma Scale score less than 6, petrous bone fracture, diffuse axonal injury, basilar skull fracture, Le Fort II or III fracture, or any combination of these findings.[16,21]

Diagnostic Evaluation

Diagnostic modalities are the same for spontaneous and traumatic carotid artery dissection. Although ultrasound is readily available and thus commonly used as the initial test, four-vessel selective cerebral angiography remains the "gold standard." Angiography allows visualization of the arterial lumen and characterization of the lesion. An intimal flap or double lumen is pathognomonic for dissection. The internal carotid stenosis caused by dissection is usually irregular, originates 2 to 4 cm distal to the bulb, and has a long tapering stenosis that usually ends before the internal carotid artery enters the petrous portion of the temporal bone.[4,22] Occlusions are characteristically tapered and have a flamelike appearance (Fig. 93.2), whereas aneurysms, often a later development, are usually fusiform and most commonly occur in the distal subcranial segment, although more proximal saccular pseudoaneurysms are also seen (Fig. 93.3). Angiography carries a 1% to 2% risk of hematoma or pseudoaneurysm at the access site, a 1% to 2% risk of contrast-induced nephropathy, and a 1% risk of stroke,[23] but it may also provide opportunities for endovascular intervention or surgical planning.

Computed tomographic angiography (CTA), magnetic resonance angiography (MRA), and ultrasound are increasingly used noninvasive alternatives for diagnosing and monitoring carotid artery dissection. CTA and MRA are particularly attractive for diagnosis because their resolution approaches that of conventional angiography in detecting direct signs of vascular injury, such as irregular vessel margins, filling defects, changes in caliber, extravasation of contrast material, and occlusion,[24] and they are superior to angiography for evaluation of intramural

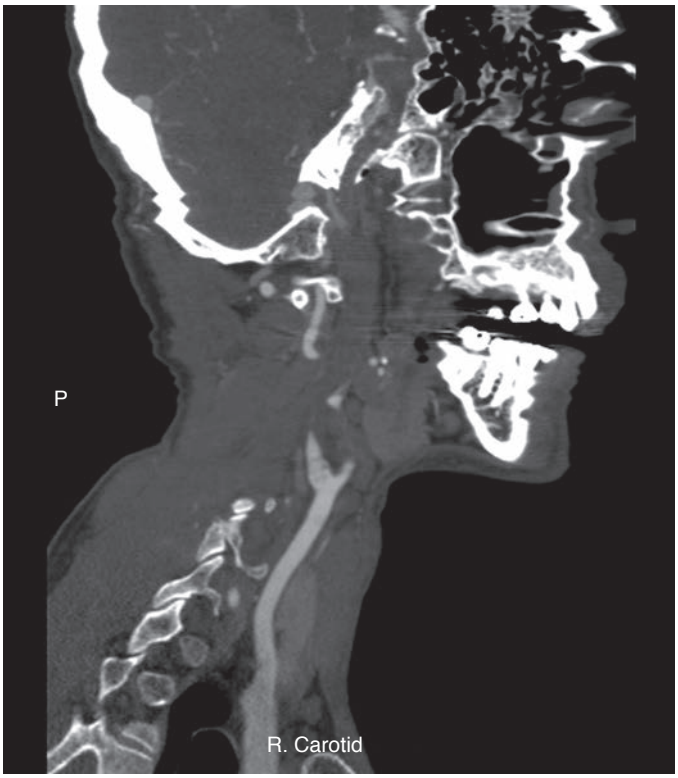

Figure 93.2 Computed tomographic angiography (centerline trace, right carotid artery) of a patient with a spontaneous dissection. Note the tapered occlusion with reconstitution near the skull base.

Figure 93.3 Angiogram showing residual stenosis and proximal pseudoaneurysm formation after traumatic carotid dissection.

hematoma and injury to surrounding structures. It should be noted that the initial results from two prospective studies in the trauma literature comparing CTA and MRA with angiography were disappointing and showed poor sensitivity and specificity.[25,26] CTA technology has improved, however, and more recent studies show 97.7% sensitivity and 100% specificity for 16-slice CTA in the diagnosis of blunt carotid and vertebral artery injuries.[27] These results suggest that CTA is a reliable, safe, fast, and cost-effective means of diagnosing cerebral artery dissections. Potential problems with CTA include artifact from metal (including projectiles) and bone, effective timing of the administration of contrast material, and the high doses of contrast material needed.

In addition to demonstrating the hyperintense crescent-shaped mural hematoma and eccentric flow typical of dissection, MRA shows a characteristic evolution of signal intensity over time and is the modality able to detect ischemic changes in the brain the earliest. Disadvantages of MRA are lack of availability, longer time required for imaging, and interference from extrinsic structures such as external fixation devices in trauma patients. Nephrogenic systemic fibrosis is a potential complication in patients with renal insufficiency who receive gadolinium for MRA.

Ultrasound does not evaluate the surrounding tissue or define the actual site of dissection as well as other noninvasive modalities do, but it does effectively detect resulting flow abnormalities. In experienced hands it is up to 95% sensitive in the diagnosis of carotid dissection when extracranial Doppler, transcranial Doppler, and duplex ultrasonography are appropriately combined.[28] Advantages of ultrasound are accessibility and convenience, which are particularly valuable in an acutely injured patient and for purposes of monitoring disease progression and resolution over time.

Natural History

Cerebral infarction is documented in 42% of spontaneous carotid dissections, and 58% of patients have persistent neurologic deficits.[12] Higher incidences of stroke appear in earlier reports,[13] and this may be the result of improved diagnosis and treatment.[4] More recently, studies of blunt traumatic carotid injury report mortality rates of up to 30% (in many cases related to associated injuries) and rates of permanent severe neurologic deficits of up to 20%.[19,20]

In patients with spontaneous dissection managed medically, the incidence of recurrent dissection is 0.3% to 1.4%, and recurrent dissection is more frequent in the first month and more common in patients with connective tissue disease or a family history of cervical carotid artery dissection. The annual risk of recurrent stroke ranges from 0.3% to 3.4%. Dissection is the most common cause of extracranial internal carotid aneurysm, but two-thirds of carotid aneurysms resolve, and complications related to aneurysm are rare.[29]

The prognosis is worse for traumatic carotid dissection. Patients with traumatic dissection are more likely to develop aneurysms and progress to occlusion, and are less likely to show improvement or resolution of aneurysms and stenoses than patients with spontaneous dissection.[30] The prognosis after stroke caused by dissection is worse than the prognosis after stroke caused by atherosclerosis. Dissection patients have more global middle cerebral artery involvement and severe clinical impairment.

A recent analysis of the Cervical Artery Dissection in Stroke Study (CADISS) trial evaluated the natural history of dissecting aneurysms and whether they are associated with an increased recurrent stroke risk, and whether the type of antithrombotic drugs (antiplatelets vs. anticoagulants) modifies the persistence or development of carotid aneurysms.[31] A total of 264 patients with extracranial cervical artery dissection were included from the CADISS, a multicenter prospective study that compared antiplatelet with anticoagulation therapy. Logistic regression was used to estimate age- and sex-adjusted odds ratios (ORs). The authors also conducted a systematic review of published studies assessing the natural history of dissecting aneurysms and stroke risk in patients with non-surgically-treated extracranial carotid dissection with a carotid aneurysm. A dissecting aneurysm was present in 24 of 264 patients at baseline. In 36 of 248 patients with follow-up neuroimaging at 3 months, 12 of the 24 baseline aneurysms persisted, and 24 new ones had developed. There was no association between treatment allocation (antiplatelets vs. anticoagulants) and whether an aneurysm at baseline persisted at follow-up or whether a new one developed. During 12 months of follow-up, stroke occurred in 1 of 48 patients with a dissecting aneurysm and in 7 of 216 patients without (age- and sex-adjusted OR 0.84; 95% confidence interval [CI] 0.10 to 7.31; $P = .88$). Published studies, mainly retrospective, showed a similarly low risk of stroke and no evidence of an increased stroke rate in patients with a dissecting carotid aneurysm. The authors concluded that the results of CADISS provide evidence suggesting that dissecting carotid aneurysms may have benign prognosis and therefore medical treatment should be considered.

Patients with strokes caused by dissection are younger with fewer vascular risk factors.[32] Although the overall functional prognosis in patients with stroke caused by dissection may be the same in young patients with stroke from other causes,[29] the overall implications of permanent impairment are greater because younger people are involved.

Treatment

Medical Therapy

Carotid artery dissection is thought to cause stroke as a result of ischemic stenosis or embolism from the site of the intimal tear. Microemboli have been detected acutely after dissection and correlate with the presence of stroke in patients with spontaneous and traumatic dissections.[33] Because of these factors, antithrombotic therapy has logically been the mainstay of medical treatment of carotid artery dissection. Concerns regarding anticoagulation include possible worsening of intramural bleeding at the site of dissection, bleeding from associated injuries in the case of trauma, and bleeding from unrelated sources. A

Cochrane Database Systematic Review in 2003 unfortunately found no randomized trials that compared antiplatelet drugs with anticoagulants or either type of agent with controls for the treatment of dissection. Although nonrandomized studies do not show a difference in mortality between patients receiving antiplatelet medications and patients receiving anticoagulation, the intracranial hemorrhage rate of anticoagulated patients is 0.5%, as opposed to 0% in those receiving antiplatelet medications alone.[34] An ongoing prospective trial is currently comparing antiplatelet therapy with anticoagulation for the treatment of acute cervical carotid artery dissection. The primary endpoint is ipsilateral stroke or death within 3 months of randomization, and secondary endpoints include any TIA or stroke, major bleeding, and residual stenosis.[35]

Despite the lack of level I evidence, most patients with spontaneous or traumatic dissection are treated with systemic heparin followed by warfarin for 3 to 6 months. Therapy after this is typically individualized and depends on vascular imaging.[33]

More recently, the CADISS trial was designed to be a prospective multicenter randomized-controlled trial in acute (within 7 days of onset) carotid and vertebral artery dissection. Intracerebral artery dissection was excluded. Patients were randomized to antiplatelet therapy (aspirin, dipyridamole, or clopidogrel alone or in dual combination) or anticoagulation therapy (heparin followed by warfarin aiming for an International Normalized Ratio [INR] in the range 2 to 3) for at least 3 months. The primary endpoint was ipsilateral stroke or death within 3 months of randomization, and secondary endpoints included any TIA or stroke, major bleeding, and residual stenosis.[23]

The results of the nonrandomized arm of the CADISS-NR trial, along with a meta-analysis of these results with previously published studies comparing the two therapeutic strategies were recently published. A total of 88 patients from 22 centers with extracranial carotid and vertebral dissection were recruited within 1 month of symptom onset.[24] At the primary endpoint of 3 months, three (5.08%) patients treated with antiplatelet had recurrent TIA, compared with none in the anticoagulation group. For meta-analysis, there were data from 40 nonrandomized studies including 1636 patients. There was no significant difference between the two treatments in recurrent stroke risk, or risk of death. These data suggested no superiority of anticoagulation or antiplatelet therapy in prevention of stoke after carotid and vertebral artery dissection.[36]

The results of the randomized trial showed similar findings. Two hundred and fifty participants (118 carotid, 132 vertebral) were enrolled, with a mean time to randomization of 3·65 days (SD 1·91). The major presenting symptoms were stroke or TIA (n = 224) and local symptoms (headache, neck pain, or Horner syndrome; n = 26). One hundred and twenty-six participants were assigned to antiplatelet treatment versus 124 to anticoagulant treatment. Overall, four (2%) of 250 patients had stroke recurrence (all ipsilateral). Stroke or death occurred in three (2%) of 126 patients versus one (1%) of 124 (OR 0.335, 95% CI 0.006 to 4.233; $P = .63$). There were no deaths, but one major bleeding (subarachnoid hemorrhage) in the anticoagulant group. Central review of imaging failed to confirm dissection in 52 patients. Preplanned per-protocol analysis excluding these patients showed stroke or death in three (3%) of 101 patients in the antiplatelet group versus one (1%) of 96 patients in the anticoagulant group (OR 0.346, 95% CI 0.006 to 4.390; $P = .66$).[37] The authors found no difference in efficacy of antiplatelet and anticoagulant drugs at preventing stroke and death in patients with symptomatic carotid and vertebral artery dissection, but stroke was rare in both groups, and much rarer than reported in some observational studies, questioning the clinical practice of using anticoagulation in patients with carotid dissection.

Surgical Treatment

Indications for surgical treatment of acute carotid artery dissection are fluctuating or deteriorating clinical neurologic symptoms despite medical treatment, compromised cerebral blood flow, contraindications to antithrombotic therapy, and a symptomatic or expanding aneurysm.[38-40] Indications for surgery after 6 months of medical treatment are persistent high-grade stenosis and a new or persistent aneurysm greater than twice the diameter of the normal internal carotid segment.[38] Aneurysms rarely (if ever) enlarge or rupture but may be a source of distal thromboembolization.[41] A cerebral embolus is an appropriate indication for repair, but there are no data regarding the need for repair in an asymptomatic patient with an aneurysm.

Exposure of the internal carotid artery for treatment of dissection is more difficult than exposure for atherosclerotic disease because lesions are more distal. Most dissections are superior to the bulb in the transition zone, where the artery becomes elastic rather than muscular. Distal exposure can require maneuvers that include division of the digastric muscle, mandibular subluxation, fracture of the styloid bone, and subtotal petrosectomy (see Chapter 91). Reports of distal balloon control in this setting could not be found, but it might be considered. Once exposure is obtained, surgical options include carotid ligation, interposition saphenous vein graft to a cervical or intracranial segment, and patch angioplasty. Ligation is considered safe, if necessary, in patients with systolic stump pressure greater than 70 mm Hg,[42] and the response to preoperative temporary balloon occlusion is also helpful in predicting whether ligation will be tolerated.

Postoperative complications are common after surgery for carotid dissection. In one group's experience, mortality was 2%, ipsilateral stroke occurred in 8%, 20% of reconstructions did not have primary patency at discharge, and 58% of patients experienced cranial nerve dysfunction (although 41% had a cranial nerve palsy preoperatively).[38] Another group reported a 9% rate of postoperative stroke and a high rate of cranial nerve palsy after high cervical exposure, but no sequelae at a mean follow-up of 6.2 years.[41] Most providers continue antithrombotic medication postoperatively if there are no contraindications, but confirmatory data do not exist.

Endovascular Therapy

Indications for endovascular intervention are essentially the same as for surgery. Given the morbidity and mortality associated

with open procedures, endovascular therapies for carotid dissection are increasingly being applied to treat the carotid dissection itself, or a resulting expanding aneurysm with the use of stents and/or other catheter based interventions. Two trials have compared intravenous thrombolysis and stent-assisted intraarterial thrombolysis for symptomatic middle cerebral artery occlusion secondary to carotid dissection. The larger series (N = 18) showed no difference between the groups at 3 months,[43] and the smaller series (N = 10) showed a better outcome at 3 months with endovascular treatment.[44] The authors of both papers agree that larger randomized controlled trials are needed.

Endovascular treatment is increasingly being applied to a number of acute cerebrovascular conditions, including stroke secondary to atherosclerosis or dissection,[45] carotid "blowout" syndrome, aneurysm, stenosis,[46] and arteriovenous fistulae.[47] Endovascular treatment of cervical carotid artery dissection is also being explored, and multiple case reports have documented encouraging outcomes.[48-50] An early small series from 1999 reported the results of carotid stents placed for four acutely symptomatic traumatic dissections and one spontaneous dissection.[51] There were no procedural complications, all patients improved clinically within the first 24 hours, and all remained well at follow-up. Another group reported placement of stents in seven patients with acute and chronic spontaneous carotid dissection. All patients exhibited improvement or resolution of symptoms, and the patency rate was 100% on follow-up imaging.[39] The only complication was an asymptomatic intraprocedural dissection (one patient died after heart transplantation 4 months after stent placement). All patients were pretreated for at least 4 days with clopidogrel and aspirin, received heparin intraoperatively, and took clopidogrel for at least 6 weeks postoperatively and aspirin indefinitely. All procedures were performed under local anesthesia without the use of cerebral protection devices. Equally favorable results have been reported for the treatment of traumatic dissection[40] and in series combining patients with traumatic and spontaneous dissection.[52]

Intraarterial or intravenous thrombolytic agents can also be used for the management of dissection associated with ischemic symptoms caused by thromboembolism, but data are still controversial. Excluding the contraindicated traumatic dissection, lytic therapy in spontaneous dissection can presumably increase the risk of expansion of the subintimal hematoma and subsequent dissecting aneurysm formation, vascular rupture, luminal narrowing, or even vessel occlusion, and can also increase the risk of subarachnoid bleeding. Yet there is no evidence to support these concerns. In a systematic review including studies on both intravenous and intraarterial thrombolysis in CeAD, the symptomatic intracranial hemorrhage rate was 3.1% with an overall mortality of 8.1%. The authors concluded that the outcome from thrombolysis for CeAD seems to be similar to that of other ischemic stroke causes. Most recently, the Cervical Artery Dissection and Ischaemic Stroke Patients (CADISP) multicenter study showed that thrombolysis was not associated with unfavorable outcomes or with an increased rate of symptomatic bleeding.[53,54]

Given the morbidity and mortality associated with open procedures, preliminary results describing endovascular treatment of carotid dissection seem promising.

Endovascular management strategies include stenting of the dissection with bare metal or covered stents, coiling of dissecting aneurysms, stent-assisted coiling, and embolization or occlusion of dissected vessels. Among these technical alternatives, bare metal stenting is the procedure of choice that will eventually restore the normal carotid contour (Fig. 93.4). A recent systematic review confirmed the safety and technical feasibility of stenting of carotid dissection in the setting of failed medical management, stroke, hemodynamic instability, or pseudoaneurysm formation. No distal protection devices were used in any of the studies reviewed. The technical success rate was 99%, with a 1.3% procedural complication rate. At a mean angiographic follow-up of 12.8 months, in-stent stenosis or occlusion was seen in 2% of patients.[55] While some authors report endovascular treatment for asymptomatic dissections, currently there is no evidence to support such a strategy, given the high rate of spontaneous clinical and angiographic resolution with medical management alone.[56]

Selection of Treatment

At present, there are no randomized trials comparing open and endovascular treatment of patients with acute or late sequelae of carotid dissection, and no clear indications regarding when either approach might be preferred. There is concern that endovascular interventions at the skull base could be compromised by bony resistance to stent deployment or bending and rotational forces at the point where the skull constrains the vessel. Although the results from recent endovascular series are promising, the case numbers are small and do not conclusively support endovascular intervention over open repair or medical management.

While the best treatment modality remains to be elucidated by large randomized trials, most patients can be safely treated with either anticoagulation or antiplatelet therapy and have good clinical and anatomic outcomes over long-term follow-up.

Surgical outcomes, including carotid ligation, have been inferior to conservative management with unacceptably high rates of stroke and cranial nerve injury.[57] Thus surgery should be limited to those cases with progression of symptoms in anatomically accessible lesions.

Endovascular interventions represent an attractive minimally invasive alternative, with potentially less cranial nerve injury compared with surgery. While recent data suggest that they are indeed safe,[58-61] they can pose potential hazards, including stroke and perforation in these thin-walled acutely dissected arteries, with unproven long-term benefit.

Thus larger series and longer-term follow-up are needed to determine whether such interventions provide low risk-to benefit ratio compared with conservative medical management alone.

Spontaneous carotid dissection seems to follow a relatively benign course and can be safely managed conservatively with short-term antiplatelet therapy. While invasive interventions are available, mainly in the form of endovascular interventions, the majority of patients are expected to make a full recovery with medical therapy alone.

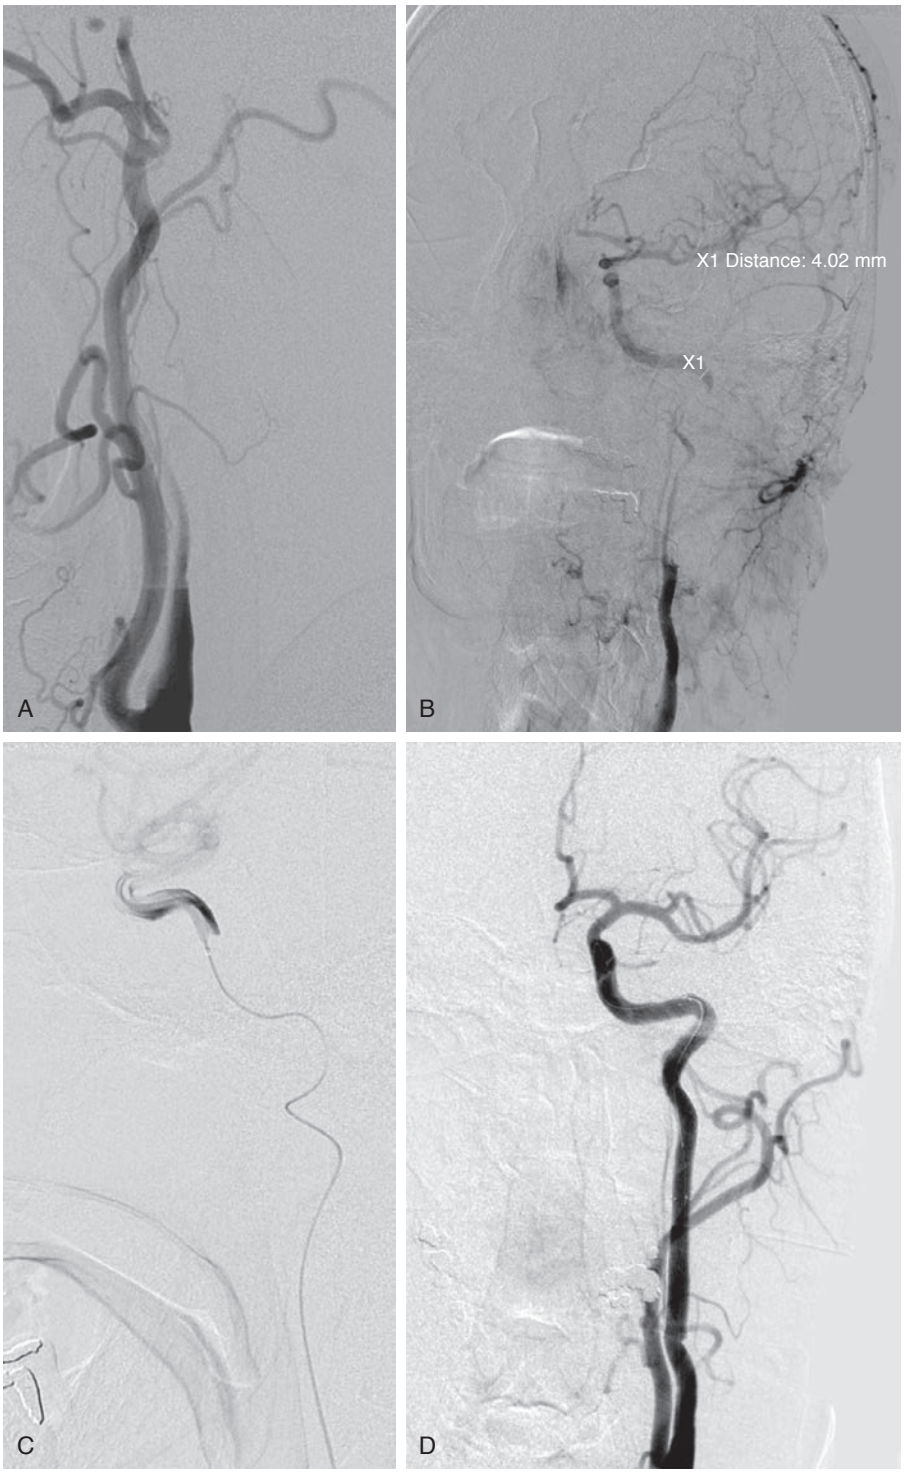

Figure 93.4 The patient is a 55-year-old male who presented with after left eye visual loss and right sided weakness. He was found on noninvasive imaging to have concern for an occlusion of the internal carotid artery likely secondary to dissection. He had a fluctuating neurological exam and this lesion was suspected to be flow-limiting. A) Selective injection through the guiding catheter positioned in the left common carotid artery demonstrates he flame-shaped tapering of the distal cervical carotid suggestive of a dissection at the skull base; B) Selective injection through the guiding catheter positioned in the left proximal internal carotid artery demonstrates occlusion but reconstitution of the supraclinoid carotid artery as well as middle cerebral artery and anterior cerebral artery branches; C) Using an 0.14" microwire and a microcatheter the occlusion has been traversed; D) Two overlapping 6mm self-expanding stents were deployed and the internal carotid artery intracranially as well as the anterior and middle cerebral artery branches fill well without evidence of branch vessel occlusion.

Aneurysms of the extracranial carotid arteries can occur as a result of atherosclerotic degeneration, traumatic injury, dissection, local infection, or as a complication after carotid endarterectomy (CEA). Extracranial carotid artery aneurysm (ECAA) is an uncommon but important clinical entity. Carotid aneurysms are extremely rare in comparison with atherosclerotic occlusive disease of the same location. These aneurysms are also rare in comparison with aneurysms involving the *intracranial* carotid arteries and their branches. The reported incidence of incidental intracranial aneurysms discovered in autopsy studies ranges from 0.8% to 18%.[1,2] The incidence of ECAA is largely unknown, but repair represents only 1% to 1.5% of procedures performed for extracranial cerebrovascular disease at major referral centers.[3-5] The true incidence of ECAA is well less than 1% of all carotid diseases. This chapter updates the contemporary management of ECAAs, including both open surgery and the evolving experience with endovascular therapy.

DEFINITION

The normal carotid bifurcation is typically 40% greater in diameter than the more distal internal carotid artery (ICA). The accepted definition of most arterial aneurysms is "an artery having at least a 50% increase in diameter compared to the

Abstract

Extracranial carotid artery aneurysms (ECCA) are rarely entities, often occurring secondary to atherosclerosis, traumatic injury, intimal dissection with subsequent degeneration, infection, or post-endarterectomy. Both endovascular techniques as well as traditional open surgical resection have been described, albeit in small series due to the low incidence of this disease process.

expected normal diameter of the artery."[6] Given this definition, it does not require much dilation of the carotid bulb to reach this threshold, a fact that has led to disagreement about what constitutes an ECAA. De Jong et al.[7] proposed that ECAA be defined as bulb dilation greater than 200% of the diameter of the ICA or greater than 150% of the diameter of the common carotid artery. This strict definition is used in many of the contemporary reports of ECAA and is helpful, given the normal physiologic dilation of the carotid bulb.

HISTORICAL REVIEW

Sir Astley Cooper[8] is credited with the first unsuccessful and first successful operations for ECAA in London in 1806 and 1808, respectively. Ligation of the common carotid artery was the sole treatment. Winslow[9] reported an exhaustive review of 124 reported cases through 1925, including 82 patients treated by carotid ligation with a mortality rate of 28%. The first report of resection of a carotid aneurysm with primary anastomosis was described by Shea in 1955.[10] The first successful procedure of this type was performed by Dimitza in 1952.[11] When inadequate length of vessels precludes primary anastomosis, an interposition graft must be used. Beall et al.[12] performed the first prosthetic graft replacement for this lesion in 1959. By the 1970s, direct arterial reconstruction or autogenous vein grafting (or both) had supplanted carotid ligation. Endovascular techniques were first applied as a treatment strategy for ECAAs in the 1990s.

EPIDEMIOLOGY

Population Affected

The population affected and age at diagnosis are directly related to the cause of the aneurysm. The relative frequency of the various potential causes of ECAA has changed over the years. Syphilis, tuberculosis, middle ear, and tonsillar infections were the most common causes of carotid artery aneurysms before the advent of antibiotics. In Winslow's review, the majority of these early cases were pseudoaneurysms related to trauma or "erosions" from middle ear infections and tonsillitis, rather than true atherosclerotic aneurysms.[9] Therefore the majority of patients were between 20 and 40 years of age, and the surgical morbidity and mortality associated with treatment, were excessive. Although mycotic ECAAs were thought to be a problem of the past, a modern series reported from Durban, South Africa, found 22 patients presenting with ECAAs to have human immunodeficiency virus (HIV) and/or tuberculosis, suggesting that (mycotic) ECAAs are more commonly encountered in the immunocompromised patient population.[13]

In contemporary practice, atherosclerotic degeneration, dissection, trauma, and previous carotid surgery have supplanted infection as the most frequent causes of ECAA, so the age at initial evaluation tends to mirror that of patients with carotid occlusive disease (Table 94.1).[3,14-26] Increasing the use of antibiotics for head and neck infections has significantly reduced the incidence of mycotic arterial infections involving the carotid artery from local extension of a septic process. ECAAs have also occurred in patients who have undergone extensive surgery and radiation therapy for head and neck cancer.[27]

Blunt trauma, dissection, and penetrating injury to the neck can result in a carotid pseudoaneurysm. Such lesions are typically encountered in a younger population. Pseudoaneurysms after CEA performed for occlusive disease usually affect individuals in their sixth or seventh decades of life.

True degenerative carotid aneurysms affect men twice as often as women,[17,28] and there does not seem to be a predilection for the right or left side. Most patients are older than 60 years, but true degenerative carotid artery aneurysms have also been reported in children.[29] There does not seem to be a specific racial distribution of true degenerative carotid aneurysms. Earlier reports suggested that the incidence of ECAAs coexisting with other aneurysmal disease ranged from 14% to 25%.[9,15] Most modern series, however, have not reported similar findings. There have been several reports of ECAAs in patients with connective tissue disorders, including Ehlers-Danlos syndrome, neurofibromatosis, and Behçet disease. It should be noted that in such patients, it is unwise to use autologous vein for arterial reconstruction because there has been late aneurysmal degeneration of the repairs using this conduit. Synthetic conduits to replace the ECAA appear to be the best option at this point in this patient population.

Incidence

A 1979 report of a search of the world's literature from 1687 to 1977 found only 853 ECAAs.[4,5] Pooled data from the 13 largest single-center series from 1960 to 1995 demonstrated 392 aneurysms involving the extracranial carotid arteries. Including only series that reported concurrent CEA volume during that same period, a total of 17,854 carotid procedures were performed, 276 of which were for ECAA, for a relative

incidence of 1.54%. The largest single-center series reported, that by El-Sabrout and Cooley[3] from the Texas Heart Institute, included 67 ECAAs treated between 1960 and 1995. During the same period, 7394 peripheral aneurysm and 4991 carotid operations were performed at the same institution. This 1.31% relative incidence is mirrored in several other published series.[16,30] These single-center series are from large referral centers, so the true incidence of ECAAs is probably less than 1% of all carotid disorders. Because these aneurysms are rare, it is impossible to define their true incidence or to determine whether their frequency is increasing. However, advances in vascular and soft tissue imaging have contributed to their greater recognition, especially in victims of trauma.[31]

PATHOGENESIS

Etiology

Degenerative/Atherosclerotic

Currently degenerative (or atherosclerotic) is the most frequently reported pathology associated with ECAAs (40% to 70% of cases). These are true aneurysms. The histologic features include disruption of the internal elastic lamina and thinning of the media. Although most true carotid aneurysms exhibit arteriosclerosis, it is considered a secondary event rather than a primary etiologic factor. Grossly, these aneurysms tend to be fusiform rather than saccular and are most commonly located at the bifurcation of the common carotid artery or the proximal ICA, where atherosclerotic plaque is common (Fig. 94.1). Atherosclerotic aneurysms that do not involve the carotid bifurcation are frequently saccular and occur in patients with severe arterial hypertension. Most bilateral, nontraumatic ECAAs are of the saccular type.

Posttraumatic Causes

Penetrating injuries involving the extracranial carotid arteries can have two important vascular sequelae: arteriovenous fistula and pseudoaneurysm formation. The incidence of carotid artery injury in civilian trauma series ranges from 12% to 17% of the total penetrating neck injuries. The internal jugular vein is most frequently involved in penetrating injuries of the neck. The common carotid artery is the most frequent site of arterial injury from penetrating trauma in this location. The incidence of pseudoaneurysm development after penetrating carotid injury is not known. Iatrogenic injury to the carotid artery during attempted placement of a catheter in the internal jugular vein is another frequent cause of carotid pseudoaneurysm.

Blunt cerebrovascular injury (BCVI) is rare, occurring in 0.18% to 2.7% of blunt trauma patients, and typically involves the distal ICA just below the skull base. Traumatic dissections can degenerate into persistent pseudoaneurysms, which can enlarge, embolize thrombus, or even rupture. Some authors advocate treatment of Grade 3 pseudoaneurysms that persist beyond a week.[32] Many of these patients have associated head injuries precluding antiplatelet therapy and anticoagulation initially. In the rare instances of enlarging or symptomatic pseudoaneurysm, the patients are typically diagnosed at a later time point from their original injury and can safely be treated with clopidogrel and treated intraprocedurally with heparin.

Post-Endarterectomy Aneurysms

CEA-related pseudoaneurysms are some of the most frequently reported aneurysms of the extracranial carotid arteries. El-Sabrout and Cooley[3] demonstrated that 57% of their 67 cases were a result of previous CEA. Zhou et al.,[26] in a later series from the Baylor College of Medicine, found post-CEA pseudoaneurysm

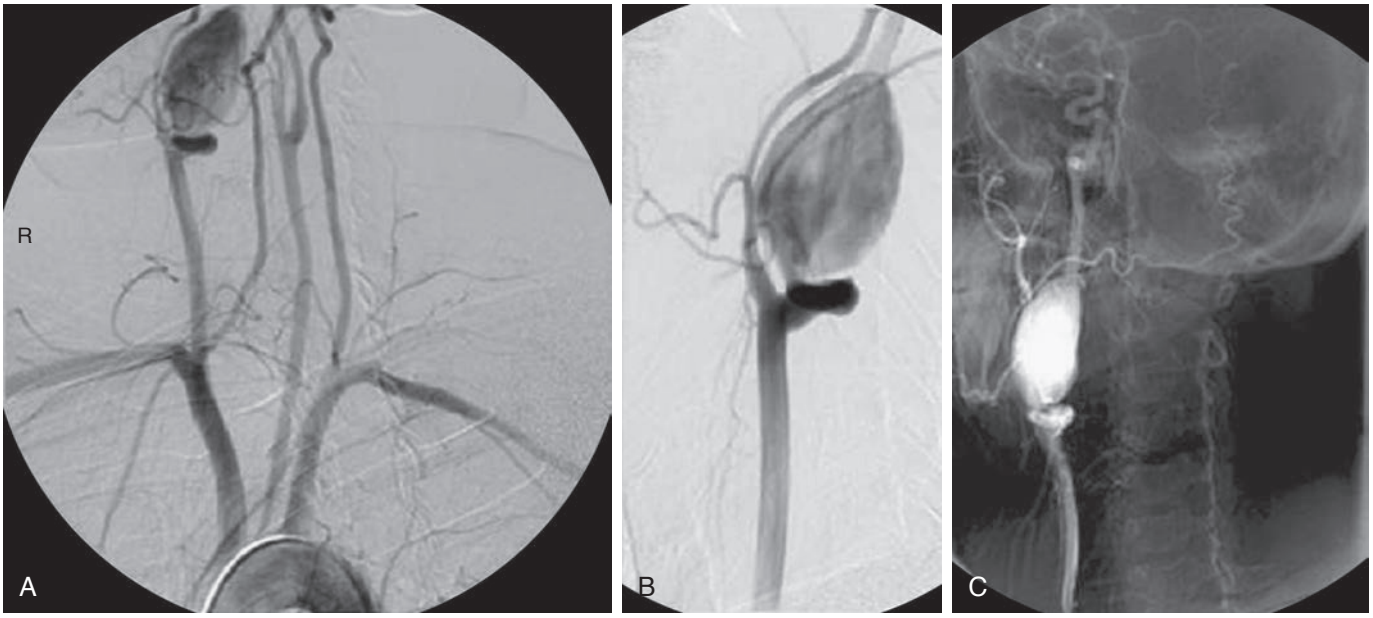

Figure 94.1 Arch (A) and right carotid (B and C) arteriograms showing a large extracranial carotid artery aneurysm involving the proximal internal carotid artery.

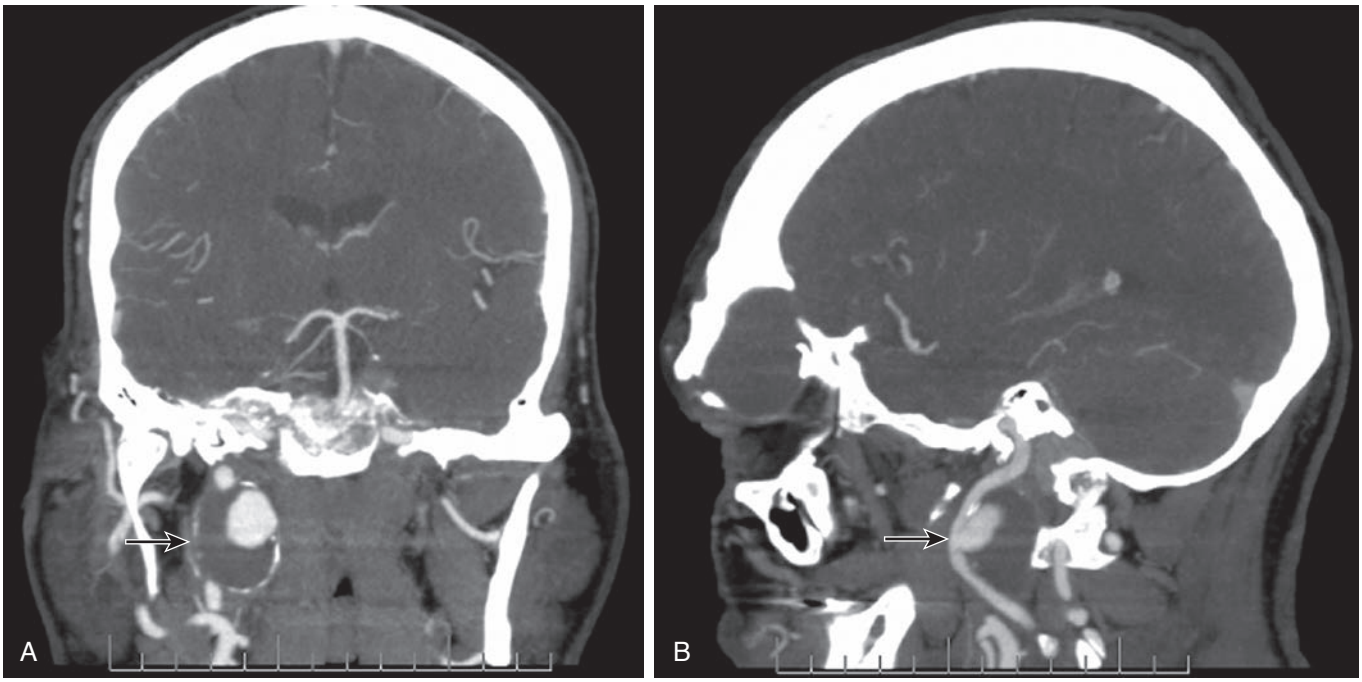

Figure 94.2 Anterior (A) and lateral (B) computed tomography arteriogram reconstructions of a 4-cm distal internal carotid artery aneurysm *(arrow)*. This aneurysm was treated with a covered stent graft with good result. (Courtesy Steven Oweida, MD, and John Parp Jones, MD.)

to be the principal etiology in 15 (36%) of 42 cases. The development of post-CEA pseudoaneurysm is related to either suture line failure or infection. Aneurysmal degeneration of saphenous vein patches has also been reported. El-Sabrout and Cooley[3] reported seven patients in whom the silk sutures (used for patch angioplasty before the advent of monofilament sutures) degenerated. Infectious complications were seen in a third of all post-CEA pseudoaneurysms. The patients typically have local signs and symptoms of infection, including pain and erythema at the operative site or draining neck sinuses. Infection of the synthetic patch is identified at the time of removal, with *Staphylococcus* species being the most commonly cultured causative organism (Figs. 94.2 and 94.3).

Arterial Dysplasia

Arterial dysplasia, usually a fibromuscular variant, was the most frequent pathologic cause of ECAAs reported in the series by Faggioli et al.[22] and also by several others.[30,33] However, this finding has not been the experience documented in most other reported large series. The arteries of patients with fibromuscular dysplasia typically display a beaded appearance (alternating stenotic webs and dilations). These dysplastic lesions may lead to ICA dissection and pseudoaneurysm formation.

Pathology

Although ECAAs are frequently associated with atherosclerotic pathologic changes, the pathologic process is much more complex. The rarity of primary carotid artery aneurysm in comparison with carotid occlusive disease makes it difficult to accept atherosclerosis as the sole cause. Histologic study of carotid artery aneurysms, however, does reveal many of the findings seen in atherosclerotic specimens: fragmentation of the elastic lamina, lipid-laden foam cells, extracellular accumulation of cholesterol, deposition of hemosiderin, degeneration of the media, and neoangiogenesis. Thinning of the media and fragmentation of the internal elastic lamina are also seen, as in aging arteries. Just as many authorities propose for abdominal aortic aneurysms, atherosclerosis is a coexisting finding but may not be the primary cause.[34,35]

CLINICAL FINDINGS

Physical Features/Symptoms

Pulsatile Mass

The symptoms of ECAAs vary according to their location, size, and etiology. The most common symptom is a usually painless pulsatile neck mass, which was the initial symptom in 93% of patients in the series reported by Zhou et al.[26] Tenderness and overlying erythema, especially if associated with fever, should raise suspicion for an infected aneurysm.

ICA aneurysm is occasionally recognized as a pulsating mass in the tonsillar fossa or pharynx with little or no manifestation of its presence externally in the neck. The classic analytic study by Shipley et al.[36] emphasized that aneurysms of the ICA are directed inward into the throat, whereas those of the common carotid artery are directed outward into the neck. The absence of cervical swelling in the former is attributed to the dense, deep cervical fascia and muscles attached to the styloid process anteriorly and the cervical vertebrae posteriorly, which crowd the gradually dilating aneurysm inward toward the tonsillar

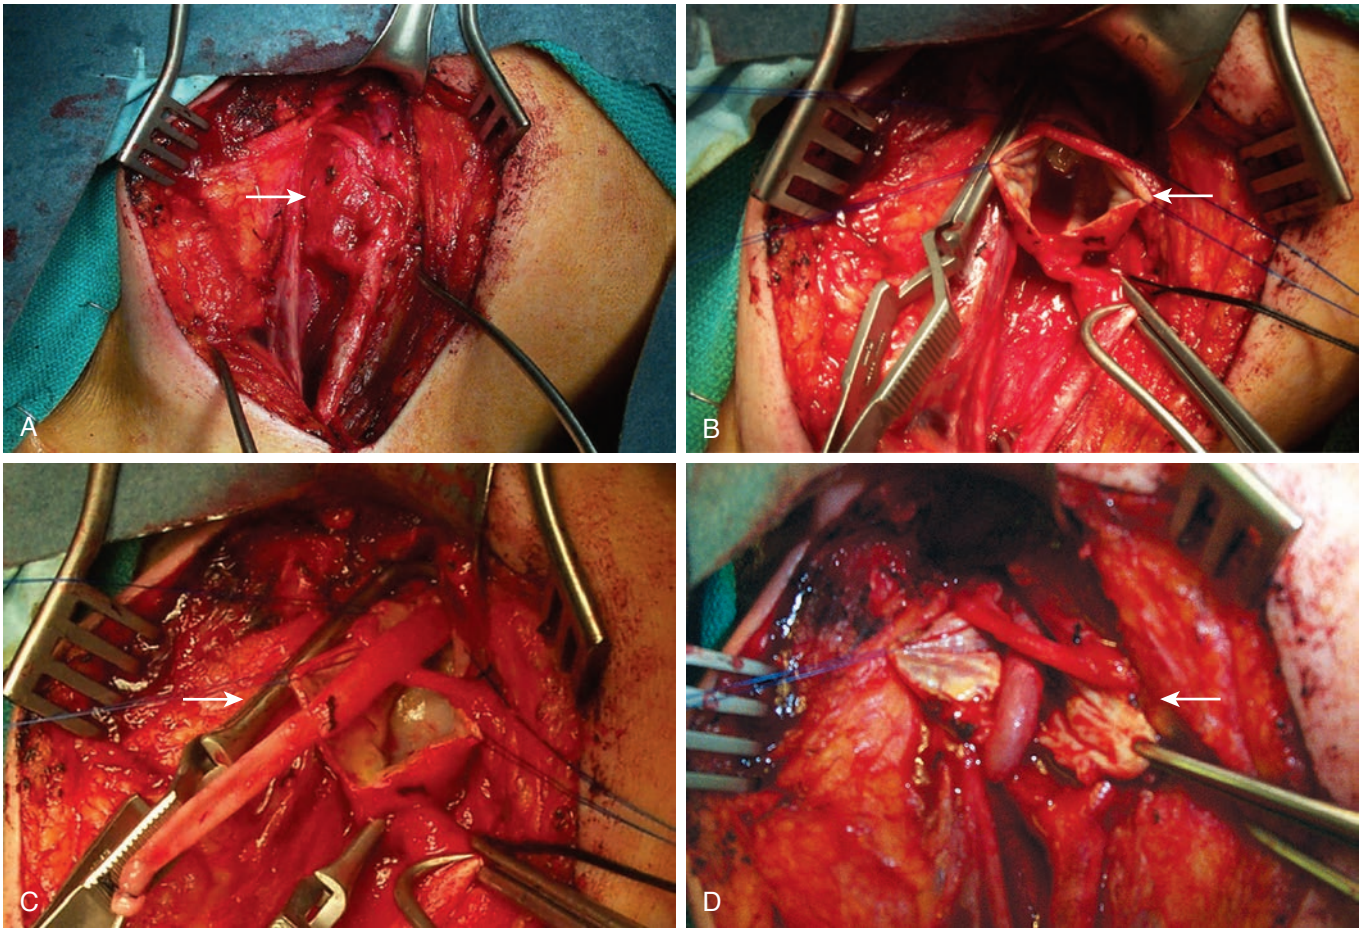

Figure 94.3 (A to D) Open repair of the extracranial carotid artery aneurysm seen in Fig. 94.1 via reversed–saphenous vein interposition.

fossa, where the thin superior pharyngeal constrictor muscle and mucous membrane offer only minimal resistance to inward protrusion.

Aneurysms that arise at or proximal to the carotid bifurcation are readily palpable and usually pose no diagnostic difficulty. Those arising from the ICA near the base of the skull can cause diagnostic problems. A chronic unilateral swelling of the posterior pharynx should raise the level of suspicion, especially when other physical signs are lacking, bizarre, or atypical. Otolaryngologists are often the first to see these lesions. A high index of suspicion usually leads to computed tomography angiography (CTA), magnetic resonance angiography (MRA), or catheter-based angiography, any of which is nearly always diagnostic when an aneurysm is present.

Neurologic Symptoms

Many series report hemispheric neurologic events as the initial symptom of carotid artery aneurysms. In the Texas Heart Institute series, 28 of the 65 patients (43%) had neurologic symptoms, including amaurosis fugax and transient ischemic attacks.[3] Three of the 28 patients suffered a stroke preoperatively. Zhou et al.[26] reported six patients (14%) with transient ischemic attack, stroke, or Horner syndrome. Most neurologic events are secondary to embolization of thrombotic material from within the aneurysm wall, but some could be potentially related to diminished flow and compression of the ICA from the mass effect of large aneurysms. Transient ischemic attacks appear to occur twice as often as completed strokes.[15,17,37]

Cranial Nerve Dysfunction

Distal ICA aneurysms are more frequently associated with cranial nerve dysfunction than are aneurysms located more proximally, but clearly nerve injury or compression can occur with large proximal carotid aneurysms as well. The ICA enters the cranium through the foramen lacerum and traverses the carotid canal in the petrous portion of the temporal bone. Accompanying the ICA are the sympathetic nerve fibers of the carotid plexus. Compression of these fibers can result in Horner syndrome. Aneurysms located more proximally can result in hoarseness from compression of the vagus or recurrent laryngeal nerve. Compression of the facial nerve can cause severe facial pain. Compression of the fifth (trigeminal) and sixth (abducens) cranial nerves has been reported as well.

Dysphagia

Occasionally, the mass of a large aneurysm can cause difficulty swallowing. Protrusion of the aneurysm into the pharyngeal constrictor muscles can produce the sensation of dysphagia, as

well as compression of the nerves involved in the swallowing mechanism. On occasion these aneurysms are discovered during evaluation for dysphagia.

Hemorrhage and Rupture

Fortunately, hemorrhage and rupture are now infrequent manifestations of carotid artery aneurysms. There have been descriptions of herald bleeds before massive rupture. When these aneurysms do rupture into the oropharynx, the bleeding is profound and death is usually due to suffocation and aspiration. Mycotic aneurysms are especially susceptible to rupture and bleeding.

Another group of patients at risk for the so-called carotid blowout syndrome[27] consists of those who have received extensive head and neck surgery and/or radiation therapy for head and neck cancer. Lesley et al.[27] reported their experience with 16 actual or impending carotid ruptures in 12 patients. Ten of these patients had undergone extensive treatment of head and neck cancer. Risk factors identified for the development of carotid blowout as a complication of treatment of head and neck cancer included thrombosis of the vasa vasorum secondary to wound infection, direct exposure and desiccation of the carotid artery, stripping of the carotid sheath, exposure of the artery to saliva, adjacent tissue necrosis, pharyngeal fistula formation, and previous irradiation.

Differential Diagnosis

The differential diagnosis for a pulsatile neck mass is extensive. The most common cause is a tortuous, kinked, or coiled carotid artery. Duplex ultrasound and occasionally CTA are required to help differentiate this finding from an ECAA. Other entities in the differential diagnosis include a prominent carotid bifurcation in a thin neck, cervical lymph nodes overlying the carotid bifurcation, carotid body tumors, glomus jugulare tumors, cervical metastatic disease, branchial cleft cysts, and cystic hygromas.

DIAGNOSTIC EVALUATION

Duplex ultrasound is the initial diagnostic imaging modality of choice for the evaluation of ECAAs emanating low enough in the neck to be evaluated by this modality. Aneurysms located high in the distal ICA, such as those related to blunt cervical carotid dissection, are notoriously missed by ultrasound. Such aneurysms require further imaging with CTA or MRA. MRA has the advantage of being able to distinguish old from recent thrombus, a differentiation that is particularly helpful in cases of carotid dissection. Knowledge of the strengths and weaknesses of the imaging modalities at one's institution should direct the next noninvasive imaging study chosen.

CTA has the benefit of visualizing the relationships of bony anatomic landmarks, which are critical in deciding whether a lesion is considered "surgically inaccessible" and requires an endovascular intervention (see Fig. 94.2A and B). MRA, when obtained in conjunction with head and brain imaging, provides indispensable information regarding the circle of Willis and collateral cerebral circulation. CTA can also provide similar intracranial imaging views, depending on the protocol utilized.

Catheter-based angiography was previously considered mandatory in the evaluation of ECAAs to obtain the detailed vascular anatomy information necessary to planning surgical treatment.[38] We currently find diagnostic arteriography is usually unnecessary, and reserve catheter-based angiography for endovascular interventions because of the potential stroke risk associated with this invasive diagnostic procedure.

The utility of diagnostic angiography in the current management of ECAAs involves the rare case in which open or endovascular arterial reconstruction are not considered to be feasible options, and carotid ligation may be necessary. Combined preprocedure noninvasive imaging of the circle of Willis anatomy and a balloon occlusion test of the ipsilateral ICA have been recommended before carotid ligation. The latter examination involves a period of occlusion with an end-hole balloon occlusion catheter in patients who are awake, anticoagulated, and at baseline blood pressure. The end-hole catheter also allows measurement of carotid artery "stump" pressure or back-pressure. A stump pressure greater than 50% of mean systemic pressure indicates adequate cerebral blood flow during the carotid balloon occlusion test.[39] Occlusion of the ICA is typically performed for 30 minutes, and the awake patient is assessed for neurologic changes. Blood pressure is also pharmacologically lowered to assess tolerance of hypotension. Several reports have detailed the inadequacy of the balloon occlusion test to accurately predict tolerance of carotid occlusion in 10% to 20% of patients.[40,41] In patients in whom ipsilateral hemispheric neurologic events developed after carotid occlusion, thromboembolic events secondary to disturbed flow were thought to be the cause. These reports stress the importance of anticoagulation with warfarin for 6 weeks to 3 months after carotid ligation.

NATURAL HISTORY

Based on prior case series demonstrating high risk of TIA, stroke, or rupture associated with nonoperative treatment, recommendations have been to intervene on essentially all carotid aneurysms once found.[9,15,17,18,26] As mentioned previously, the etiology of ECAAs has shifted from mycotic or traumatic to degenerative or postprocedural, with a more benign natural history. Furthermore, given our advances in medical therapy with statins, antiplatelet, and anticoagulation as well as improved imaging techniques, medical management in properly selected high-risk patients with small true aneurysms may prove to be a reasonable option. This was demonstrated in the Mayo Clinic study by Fankhauser et al., where 75/141 ECAAs over a 15-year period were treated nonoperatively. This series included 25 true aneurysms and 116 pseudoaneurysms. Medical management with antiplatelet therapy or anticoagulation as well as serial imaging occurred in 10 patients with true aneurysms and 65 patients with pseudoaneurysms. The size of the ECAA, as well as the age of the patient, symptomatic status, and comorbidities played a major role in the decision to pursue conservative treatment. True aneurysms undergoing observation had a mean diameter of 12.0 mm compared with 21.2 mm in those that were treated

with open surgery. Pseudoaneurysms treated medically had a diameter of 10.2 mm compared with 20.9 mm treated with open surgery and 14.5 mm undergoing endovascular intervention. During a mean follow-up of 77 months, none of these patients progressed to needing an intervention and none of them suffered death or major morbidity related to the ECAA. This is the largest series published to date and the first to demonstrate the safety of medical management in patients with small ECAAs. Clearly more research into proper patient selection based on size, presenting symptoms, etiology, associated comorbidities, aneurysm location, and associated thrombus morphology is needed to guide treatment decisions.

In cases of ECAA greater than 2 cm, any mycotic aneurysm, the presence of thrombus within the aneurysm, symptomatic aneurysm, or evidence of enlargement on serial imaging, operative intervention is warranted in the vast majority of cases. Serial observation of small, asymptomatic ECAA, especially in the elderly, is likely safe and justified.

TREATMENT

The primary objective in the treatment of such aneurysms is to prevent the permanent neurologic deficits that can arise from atheroembolism and thromboembolism. This objective is best accomplished by exclusion of the aneurysm from the arterial circulation and restoration of antegrade flow. The choice of therapy must be tailored to the individual and based on the location, size, and underlying cause of the aneurysm as well as the overall condition of the patient.

Open Surgical Approaches

Ligation

The subsequent development of modern reconstructive vascular techniques has eliminated ligation as a standard therapy for ECAAs. Ligation was performed in just 1 of the 65 patients with carotid aneurysms treated at the Texas Heart Institute over a 35-year period.[15] Ligation of the carotid artery may still be necessary in emergency situations of arterial rupture, especially if infection is the cause and the artery is deemed unreconstructable. If an elective carotid ligation is being considered, preoperative evaluation with the carotid balloon occlusion test and stump pressure measurement is necessary. Aneurysms involving the external carotid artery alone are typically ligated without reconstruction or significant sequelae.

It is recommended that patients undergoing carotid ligation be started on heparin therapy and then switched to warfarin anticoagulation for a period to prevent distal embolization because the ICA progressively fills with thrombus, with the risk of stump embolization. This approach is analogous to management of carotid artery trauma that might require ligation of the ICA. The duration of such anticoagulation is not standardized, but several groups have recommended a 2-week to 3-month course of therapy.[42,43]

Adjunctive Measures

Extracranial-to-intracranial (EC-IC) bypass, wrapping the aneurysm in fascia or mesh, and saphenous vein bypass through the aneurysm to the petrous portion of the carotid have all been described but largely abandoned due to failure to improve patient outcomes or decrease stroke risk.[44,45]

Resection and Reconstruction

Resection of the aneurysm with restoration of antegrade flow has been the conventional treatment of ECAAs in contemporary practice (see Fig. 94.3A–D). This surgical option is applicable to lesions involving the common carotid artery and proximal third of the ICA. Aneurysms involving distal portions of the ICA require further adjuncts to gain distal exposure and control.[30,46] Complete excision of large carotid aneurysms risks injury to the cranial nerves, including the facial, vagus, spinal accessory, hypoglossal, and glossopharyngeal nerves. The literature demonstrates cranial nerve injury rates between 4% and 20%. Similar dissection principles to CEA should be adhered to, with minimal aneurysm manipulation prior to vascular control, to decrease embolization risk.

Reconstruction Options

After resection of a carotid artery aneurysm, several reconstruction options are available. Small saccular aneurysms with narrow necks can be resected, and the artery closed primarily or with a patch. Mobilization of a tortuous carotid artery can frequently allow resection with primary end-to-end anastomosis. Autologous or prosthetic interposition grafts can be used with excellent results (Fig. 94.4). Autologous grafts are preferred if infectious etiology is suspected. A novel technique of using a Gore Hybrid graft was reported in 2014.[47] In this case report, the 6 mm nitinol stent portion was inserted into the distal ICA after resection of the ECAA; then a shunt was placed within the graft while the proximal anastomosis was performed.

In cases of true ECAA, it would seem intuitive to replace the entire aneurysmal segment to prevent the risk of further aneurysmal degeneration with partial excision. In the treatment of patch pseudoaneurysm following prior CEA, resection back to normal arterial wall plus redo patch angioplasty with autologous conduit when infection is a possibility is an acceptable alternative to interposition grafting.

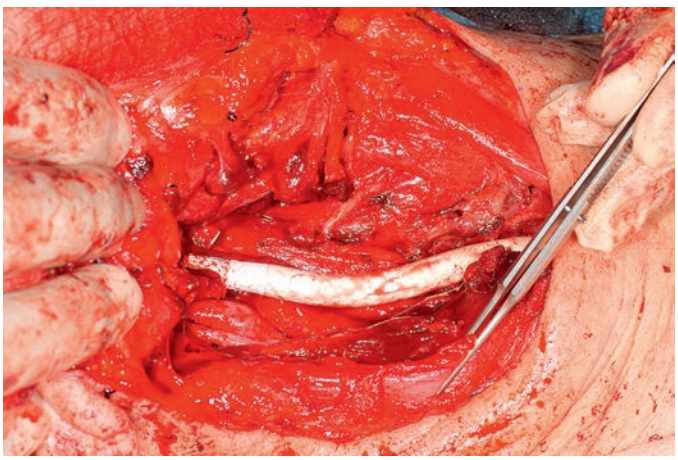

Figure 94.4 Treatment option of surgical exclusion with a prosthetic interposition graft for a large extracranial carotid artery aneurysm to prevent rupture and embolic sequelae.

Pseudoaneurysm Repair After Previous Carotid Endarterectomy

Patch angioplasty during CEA has become routine in an effort to decrease the restenosis rates seen after primary closure of the arteriotomy (see Chapter 91). Materials currently used for patch angioplasty include Dacron, polytetrafluoroethylene, and bovine pericardium. In current practice, patch pseudoaneurysm after CEA is more frequently related to infection than to degeneration of the patch. In one series, 28/141 ECAAs were pseudoaneurysms from prior CEA, 79% of whom had a Dacron patch. This trend was also seen in another large case series where 58% of pseudoaneurysms were related to Dacron patch use, and some of these used silk suture or were associated with infection.

Open Surgical Technique

Methods of cerebral monitoring and protection during carotid cross-clamping are the same as those used during conventional CEA and include electroencephalographic waveform analysis, selective shunting based on carotid stump pressure, and routine shunting. General anesthesia is usually recommended because of the difficult exposure and longer operative times for aneurysm repair than for CEA. As part of our usual practice, we routinely use shunting during CEA in patients under general anesthesia, although other authors may advocate selective shunting in these cases based upon cerebral monitoring.

Large aneurysms and aneurysms extending to the most distal ICA are technically challenging. Nasotracheal intubation should be used because it allows complete closure of the jaw which opens the space around the distal ICA. Several techniques can be used to improve distal operative exposure, including the ones described herein.

1. The first step in obtaining distal exposure should always be extension of the incision to curve in a posterior fashion behind the ear to the mastoid process.
2. Divide the ansa cervicalis to allow gentle retraction on the hypoglossal nerve.
3. Divide the posterior belly of the digastric muscle.
4. Divide the occipital artery and adjacent venous branches.
5. Divide the ascending pharyngeal artery.
6. Divide the sternocleidomastoid muscle from its mastoid attachment and elevate or resect the parotid gland. Careful dissection of the facial nerve and its branches is mandatory.
7. Remove the styloid process and its attached muscles.
8. Subluxate the mandible to increase the width of exposure at the skull base by approximately 1 cm. This maneuver is in general performed by an oral surgery team after nasotracheal intubation and prior to carotid exposure.
9. Drill and remove portions of the inferior surface of the petrous portion of the temporal bone. This process usually requires a multidisciplinary approach, including the participation of nonvascular surgeons with experience in skull base surgery.
10. Use of intraluminal balloons, usually as part of a shunt (e.g., the Pruitt-Inahara shunt), to control distal internal carotid back-bleeding can be a useful adjunct when distal control is difficult.

Once proximal and distal control is obtained, the decision must be made whether to perform complete aneurysm exclusion or partial resection. With a true atherosclerotic aneurysm, we typically replace the entire aneurysm with a saphenous vein interposition graft harvested from the groin. We typically use an endoaneurysmorrhaphy technique so that the cranial nerves are not injured during excision of the aneurysm wall. As with repair of abdominal aortic aneurysms, the sac of the aneurysm is used to cover the interposition graft. Use of a prosthetic graft in this situation has been reported. No large series have compared use of the two conduits, but a prosthetic graft is a reasonable alternative.

In situations of prosthetic patch pseudoaneurysm, El-Sabrout and Cooley[3] have reported good results with resection of the pseudoaneurysm back to normal arterial wall and repeat patch angioplasty. In such circumstances we would also recommend autologous material to patch the artery because infection is frequently encountered in this situation. Painter et al.[28] recommended the use of an in-line straight shunt, as opposed to the Javid type, during vein interposition to tailor the vein graft to the appropriate length so that kinking could be avoided. In such cases, the vein interposition graft is telescoped over a straight shunt. After the distal anastomosis is performed, the vein graft is pulled to length over the shunt and trimmed accordingly. The shunt is then removed just before completion of the proximal anastomosis, and flushing maneuvers are performed in the usual fashion. We routinely use intraoperative duplex ultrasound to evaluate carotid reconstructions.

Endovascular Therapy

Endovascular management of ECAAs offers the advantages of avoiding a potentially difficult dissection and eliminating the need for high cervical exposure, thus reducing the risk for cranial nerve injuries and other procedure-related complications. Although most cranial nerve dysfunction is temporary, the incidence of such injuries is significant, reaching 20% in some series.[26] Although rare, permanent significant cranial nerve injuries can be devastating.

Several endovascular techniques for the treatment of ECAAs have been reported, including bare-metal stents with and without trans-stent coiling (Fig. 94.5A and B),[48] placement of double stents,[49] autogenous vein graft–covered stents,[50] endovascular coil or balloon occlusion,[51] and placement of covered stent-grafts (Fig. 94.6).[52]

Percutaneous injection of thrombin under ultrasound guidance has become the treatment of choice for traumatic pseudoaneurysms of the common femoral artery. Holder et al.[53] reported successful thrombosis of a traumatic carotid pseudoaneurysm by endovascular balloon occlusion of the neck of the aneurysm followed by percutaneous injection of thrombin after inadvertent central venous catheter puncture. We have had no personal experience with this technique and have concerns about the risk for embolization once the balloon is deflated.

In 2006, the Baylor College of Medicine group reported their development in the treatment of such aneurysms, including 14 patients managed by endovascular means.[26] Stent-grafts were

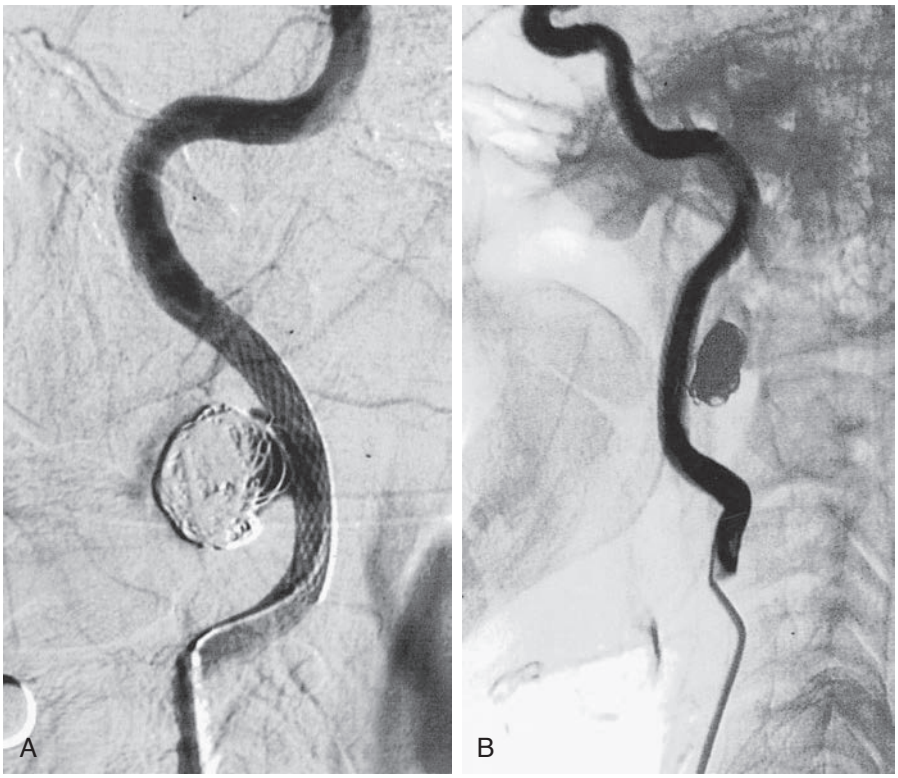

Figure 94.5 After placement of a self-expanding stent across the neck of the aneurysm, a microcatheter is used to introduce coils into the aneurysm sac. (A) Completion arteriogram documented a patent internal carotid artery (ICA) with aneurysm exclusion. (B) Arteriography after 5 months showed excellent flow through the ICA with exclusion of the pseudoaneurysm. (From Bush RL, Lin PH, Dodson TF, et al. Endoluminal stent placement and coil embolization for the management of carotid artery pseudoaneurysms. *J Endovasc Ther*. 2001;8:53–61.)

used in seven patients, carotid stenting with trans-stent coiling in six, and endovascular balloon occlusion in one. In most series of endovascular treatment of carotid artery aneurysms, a variety of endovascular therapies have been used, and thus the small numbers in each group have precluded any meaningful comparison of the various treatments.

We currently use a 6-Fr Flexor Shuttle Select Sheath (Cook Medical, Inc., Bloomington, Indiana) in the majority of carotid interventions performed from a femoral approach. If one is contemplating the use of a covered stent, such as the Gore Viabahn Endoprosthesis (W.L. Gore and Associates, Inc., Flagstaff, Arizona), larger sheaths may be needed (Table 94.2). We typically use a 0.014-inch wire to cross the aneurysm and have used a distal embolic protection device as long as there is reasonable length to land such a device above the aneurysm neck. In a circumstance of difficult transfemoral access, a cervical direct common carotid cutdown can be utilized.

Trans-Stent Coil Embolization

The technique of trans-stent coiling involves initially crossing the neck of a saccular aneurysm with a self-expanding stent. If a distal embolic protection device is deployed on the 0.014-inch wire, there is adequate room to introduce a second wire ("buddy wire") to track a 3-Fr RAPIDTRANSIT Microcatheter (Cordis Endovascular) into the aneurysm sac between the stent interstices. Coil embolization of the entire aneurysm sac is performed with detachable or platinum coils. The stent prevents migration of the coils into the distal carotid circulation.

Stent-Graft Coverage

In patients who have a fusiform aneurysm without a discrete neck, a stent-graft prosthesis is a better treatment option as long as there is adequate length of artery for proximal and distal sealing. How much proximal and distal seal zone is considered adequate, however, is unknown. Typically a larger introducer sheath is required for a stent-graft prosthesis. The stents are oversized to the artery per the instructions for use of the individual device. The stent-graft with the shortest length that will have adequate seal is chosen so that a distal kink is not created in the carotid artery. We angioplasty only within the stent graft and avoid angioplasty of the normal adjacent proximal and distal intima of the carotid artery.

Hori et al.[49] described a novel double-stent technique in which overlapping uncovered stents are placed within each other. The greater surface area coverage of the two stents is thought to increase the chance of immediate aneurysmal thrombosis through decreased flow into the sac. We have no personal experience with this technique but are concerned that if aneurysm sac flow is persistent, it may be impossible to track a catheter across the double latticework of stents to place coils if an additional procedure becomes necessary.

Selection of Treatment

The location and size of a carotid aneurysm also play a critical role in determining which therapy to offer. Large aneurysms and those involving the distal ICA, because of the difficult surgical exposure and significant morbidity, are probably best managed with endovascular techniques. On the other hand, the presence of unstable-appearing thrombus within an aneurysm or pseudoaneurysm or the occurrence of preoperative embolic symptoms may be considered a relative contraindication to endovascular repair. Aneurysms in very tortuous carotid arteries also present a relative contraindication to endovascular therapy because of the difficulty of stent tracking and conformability to the artery wall. In fact, many tortuous arteries lend themselves to aneurysm excision and primary end-to-end repair of the artery.

TREATMENT OUTCOME

Open Surgical Repair

Results vary widely depending on the type, size, and location of the aneurysm. Carotid ligation was previously associated with a 30% to 60% risk of stroke, and half of such patients died after stroke.[9,54,55] In a 2000 review of the 13 largest single-center series since 1950, El-Sabrout and Cooley[3] found that the combined stroke/death rate associated with carotid ligation had decreased to 12%. This change probably represents improvements in anesthetic technique and medical management as well as an understanding of the importance of anticoagulation after carotid ligation. Carotid ligation is reserved in current surgical practice for the unusual circumstance of an unreconstructable carotid artery.

In general, surgical reconstruction is associated with a combined stroke and mortality rate of about 10%.[3] Transient cranial nerve dysfunction occurs in about 20% of patients.[3] Pooled data reported by El-Sabrout and Cooley,[3] including 392 cases of ECAA, showed a combined stroke and death rate of 21% in those managed nonoperatively, 12% in those treated by carotid ligation, and 9% in those treated by surgical reconstruction (Table 94.3).[14-26]

Endovascular Therapy

The early results of endovascular repair of ECAAs appear favorable in comparison with those of open surgical repair. In a series of 141 ECAAs spanning 14 years, including 18 repaired using endovascular techniques for pseudoaneurysms, 4 covered stents, 11 uncovered stents with trans-stent coiling, and 3 carotid emoblizations were described, with no cranial nerve injury or strokes reported.[56]

In another series of 24 ECAAs in 19 patients, including 8 who underwent endovascular repair, one patient underwent coil embolization and 7 were treated with bare metal stents. Of note, three patients required open carotid exposure with manual straightening of the artery to deploy the stents from a common carotid puncture site due to tortuosity in the ICA. No strokes were described, but two patients did have transient cranial nerve palsies from traction during the open carotid exposure.[57]

Saatci et al.[58] reported using stent-grafts to treat 25 distal ICA pseudoaneurysms, the majority of which were posttraumatic. Endoleak, which occurred in two patients, resolved spontaneously in one and required the additional placement of a bare-metal stent in the other. Twenty-three aneurysms were immediately excluded from the circulation after stent-graft placement. No technical adverse events—vessel dissection, vessel perforation, or thromboembolism—occurred. No mortality or morbidity developed during or after the procedure or during the follow-up period. Follow-up angiography in 21 patients showed patent reconstruction of the ICA with no aneurysm recanalization. All symptoms resolved after treatment in patients who initially had mass effect complications.

In a report of 14 patients with traumatic pseudoaneurysms after BCVI, all patients with evidence of blunt carotid dissection underwent anticoagulation with heparin for 7 days, followed by repeat arteriography. Those with flow-limiting dissections or pseudoaneurysm formation were treated with self-expanding WALLSTENT endoprostheses (Boston Scientific Corporation, Natick, Massachusetts) and warfarin anticoagulation. In the follow-up period of 2.5 years, no strokes occurred and arteriography showed all lesions to have healed by 4 months.[32]

Zhou et al.[26] compared two different treatment periods: 22 cases all treated by open repair before 1995 and 20 cases treated after 1995. Of the 20 later cases, 14 were treated with endovascular therapy by a variety of techniques. During the second treatment period, hospital length of stay was significantly shorter, the rate of cranial nerve injury was diminished, and 30-day combined stroke/death rates were lower (14% vs. 5%, $P < .004$). No strokes occurred in the endovascular group at 30 days. At a mean follow-up of 4.6 years, 11 of 16 deaths were thought be related to cardiovascular causes, and continued aneurysm exclusion was confirmed in all patients.

Treatment of Carotid Blowout

Lesley et al.[27] reported a series of 16 carotid blowout events occurring in 12 patients, the majority of whom had undergone radiation therapy or surgery (or both) for head and neck cancer. All patients were deemed to be at high risk for cerebral ischemic complications because of a negative balloon occlusion test result or known incomplete circle of Willis. These patients were managed with a variety of stent devices and techniques. Adjunctive embolization of carotid pseudoaneurysms with platinum coils or acrylic glue was performed in five patients. Hemostasis was achieved in all cases, although one patient with traumatic carotid blowout and three patients with aggressive head and neck cancer–related carotid blowout syndrome required retreatment with endovascular therapy. Rates of recurrent carotid blowout were similar to those reported in other studies using percutaneous balloon occlusion. Overall, no treatment-related strokes or deaths occurred.

Li et al.[59] systematically reviewed all available published data of the endovascular treatment of ECAA during 1995 through 2010. There were 113 studies comprising 224 patients undergoing treatment for ECAA. Procedural success was 92.8%. Endoleaks occurred in 8.1%. The periprocedural stroke and death rates were 1.8% and 4.1%, respectively. The rate of cranial nerve injury was 0.5%. Follow-up of these patients averaged 15 months, and the stent patency rate was reported to be 93.2%. The investigators concluded that these intermediate results suggest that low complication and high success rates make endovascular treatment of ECAAs favorable. As with all meta-analyses, selection bias may contribute to the favorable results reported.

MEDICAL MANAGEMENT

Mycotic Aneurysms

Medical management of suspected or known mycotic carotid aneurysms involves the perioperative administration of antibiotics specific for the organism or organisms responsible. *Staphylococcus aureus* and *Staphylococcus epidermidis* are the most frequently encountered organisms. Gram-positive "coverage" with either vancomycin or linezolid is recommended until definitive culture and susceptibility results are available. *Escherichia coli*, *Klebsiella* species, *Corynebacterium* species, *Proteus mirabilis*, and *Yersinia enterocolitica* have also been reported. Therefore initial broad gram-negative coverage is warranted as well. Once the standards for treating vascular infection have been completed, including graft removal, autologous reconstruction, débridement of perigraft tissue, muscle flap coverage, and drainage, a course of parenteral antibiotics is recommended. There are no clinical trial data on which to base recommendations for the length of antibiotic therapy, but patients are typically treated with parenteral culture-specific antibiotics for 4 to 6 weeks followed by oral antibiotics for 3 to 6 months or for life.

SPECIAL CONSIDERATIONS

Pediatric Patients

Pourhassan et al.[29] reviewed their experience of ECAAs in children, including 27 case reports of ECAAs occurring in the pediatric population within the past 25 years. The usual initial symptom of carotid artery aneurysm in children is a pulsatile mass in the neck. The greater frequency of aneurysm rupture seen in children is probably a manifestation of the etiology. Traumatic and mycotic aneurysms seem to have the highest risk for rupture, and these causes represent the majority of cases occurring in childhood.

Given the higher rates of rupture seen in children, aggressive surgical intervention is warranted. As in adults, resection plus interposition grafting is the treatment of choice. In the pediatric population, resection of the aneurysm should be followed by interposition grafting with saphenous vein. An autologous conduit is recommended because of the infectious etiology in many cases. It also allows longitudinal growth of the vessels as the child ages.

INTRODUCTION

The carotid body tumor, first described in 1743 by Von Haller, is the only known pathologic condition of the carotid body. The tumor is extremely rare. In 1971, only about 500 cases had been reported in the literature; this figure doubled to more than 1000 by the early 1980s. Due to the infrequency of this disorder, very little is known about its etiology, clinical, and biologic behavior, or its malignancy potential. In 1903, the first successful resection of a carotid body tumor was performed by Scudder in the United States. He was able to preserve the carotid artery and there were no significant complications. Despite over a century of literature describing surgical treatment, significant controversy remains surrounding the details in the management of carotid body tumors.

EPIDEMIOLOGY AND ETIOLOGY

The exact incidence is unknown. Although they may be discovered in patients of all ages, they are usually diagnosed in the third to fifth decades of life. Patients with family histories of carotid body tumors may present at an earlier age. Gender predominance has not been established.

Carotid body tumors may be classified as sporadic, familial, or hyperplastic. Sporadic is the most common form. Familial patterns may occur in up to 10% of cases with apparent autosomal dominant inheritance. In addition to lower age of presentation for familial cases, rates of bilateral tumors have been reported in up to 30% of cases, in contrast to bilateral disease in 2% to 20% of nonfamilial cases. Hyperplastic lesions, although not true neoplasms, are more prevalent in patients exposed to prolonged hypoxia, including those living at high altitudes and those suffering from chronic obstructive pulmonary disease or cyanotic heart disorders. This association has suggested chronic hypoxia as a potential etiology of carotid body tumors.

ANATOMY AND PHYSIOLOGY

The carotid body is the largest mass of chemoreceptor tissue in the body. It is located within the periadventitia of the posterior surface of the carotid bifurcation. The normal carotid body is ovoid in shape and approximately 5 mm in its longest dimension. It usually receives its blood supply through branches of the external carotid artery. Blood returns through tributaries of the lingual and laryngopharyngeal veins. The carotid body derives sensory innervation through small nerve fibers from the glossopharyngeal nerve.

The embryologic origins of the carotid body are both neural crest ectoderm and mesodermal tissue from the third branchial arch. The neural crest cells migrate in close association with autonomic ganglion cells; thus they are often referred to as

Abstract

Carotid body tumors are rare paragangliomas that arise from the chemoreceptive tissue located at the carotid bifurcation. Most carotid body tumors are benign; although, aggressive local invasion or malignant transformation have been observed. Carotid body tumors are typically discovered as asymptomatic neck masses. Diagnosis is confirmed with imaging studies, such as duplex ultrasound, computed tomography scanning, magnetic resonance imaging, and conventional angiography. Surgical resection is the recommended treatment for patients with acceptable perioperative risk.

Keywords

Carotid body tumor
Paraganglioma
Shamblin classification

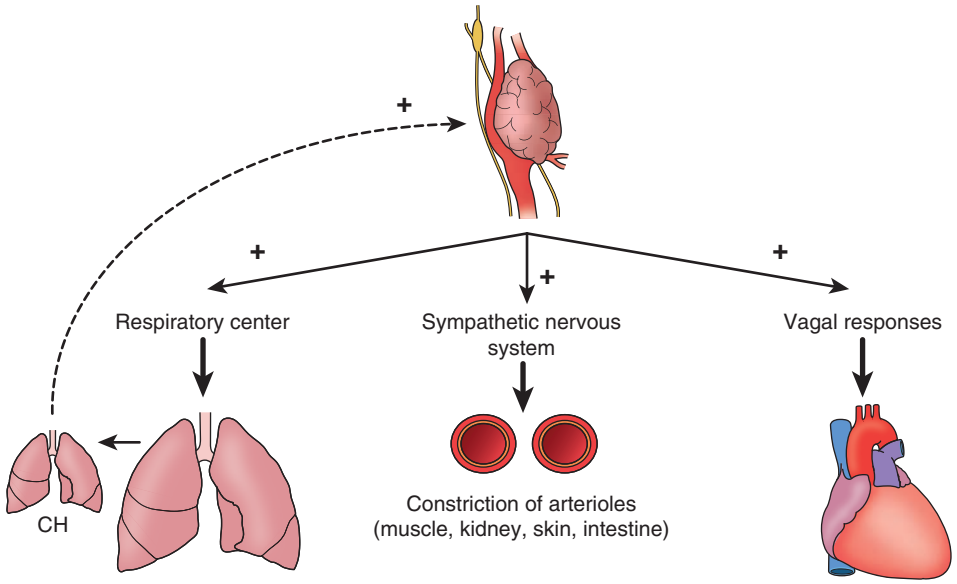

Figure 95.1 The carotid body tumor is stimulated by partial pressure of O_2, partial pressure of CO_2, and arterial pH. It sends signals to multiple body systems including cardiopulmonary centers that regulate breathing and blood pressure.

paraganglioma cells. These cells differentiate into the chemoreceptors, also known as type I glomus cells. The mesoderm forms the rich vascular stroma, made up of type II glomus cells, which support the chemoreceptor cells.

The carotid body is stimulated primarily by the partial pressure of O_2, and to a lesser degree the partial pressure of CO_2 and arterial pH. In response, the type I glomus cells release neurotransmitters that act on the receptors of afferent nerve fibers. Signals are carried through the glossopharyngeal nerve to the medulla oblongata, affecting a number of the body's systems (Fig. 95.1). Most notable are cardiopulmonary centers in the brain that regulate breathing and blood pressure. For example, hypoxia, hypercapnia, or acidosis can stimulate the carotid body, resulting in increases in respiratory rate, tidal volume, and blood pressure with vasoconstriction.

PATHOLOGY

Carotid body tumors are also known as carotid chemodectomas, carotid paragangliomas, and glomus tumors. They represent neoplastic growths of the chemoreceptive tissue. These tumors belong to the family of paragangliomas, which are neoplastic tumors that occur along the autonomic ganglion chain from the head to pelvis. Within the head and neck, carotid body tumors are the most common type. Other cervical paragangliomas include the glomus tympanicum, glomus vagale, and glomus jugulare (Fig. 95.2).

Macroscopically, carotid body tumors resemble normal carotid body tissue. They are reddish brown, rubbery, and well circumscribed, although they lack a true capsule. They are highly vascular, and can invade the adventitia of adjacent carotid vessels. As the tumors enlarge, they distort the carotid bifurcation and splay the internal and external carotid arteries, known as the "lyre sign" seen on angiography (Fig. 95.3). Frequently, large tumors will encase the external carotid artery, but they rarely wrap around the internal carotid artery, which is likely attributable to the blood supply from branches of the external carotid artery.

Microscopically, carotid body tumors tend to resemble normal carotid body architecture with a well-differentiated benign appearance. Only very rarely does histology demonstrate degenerative malignant characteristics, such as nuclear polymorphism, vascular invasion, increased mitotic activity, and necrosis. Malignant transformation cannot be predicted based on histologic findings. Advanced immunohistochemical studies have revealed that carotid body tumors can produce numerous neuroendocrine substances, often with granules rich in catecholamines seen in the cytoplasm. These tumors, in contrast to retroperitoneal paragangliomas, are usually nonfunctional and stain negative for chromaffin.

Most carotid body tumors are benign. Malignant transformation has been reported, but the exact incidence is unknown. In contrast to many other types of cancer, malignancy of carotid body tumors and other neuroendocrine tumors is based on clinical behavior instead of histology. Even benign tumors are capable of aggressive invasion into adjacent structures, as well as nodal and distal metastatic spread. Local growth may include adherence or encasement of neurologic and vascular structures, and even extension into the skull. Metastatic disease usually spreads into regional lymph nodes. If carotid body cells are found in lymph nodes biopsied during surgery, this is diagnostic for malignancy. Metastases have also been seen in the cerebellum, thyroid, brachial plexus, lungs, kidney, pancreas, bones, and breast.

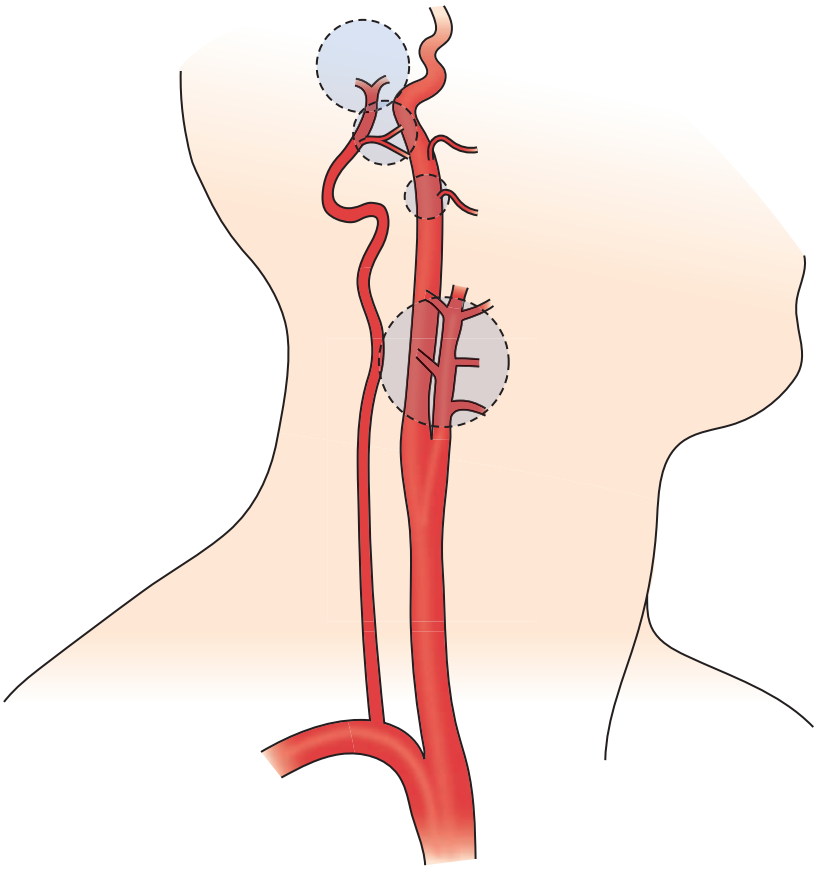

Figure 95.2 Carotid body tumors belong to the family of paragangliomas, which are neoplastic tumors that occur along the autonomic ganglion chain from the head to pelvis. Carotid body tumors are the most common of the cervical paragangliomas. Others include the glomus tympanicum, glomus vagale, and glomus jugulare. The circles represent the relative incidences of these cervical paragangliomas.

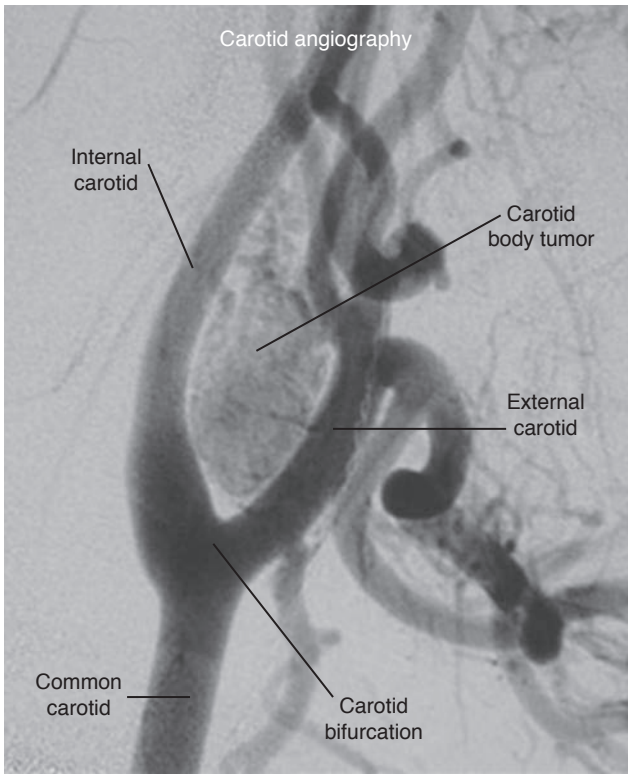

Figure 95.3 As carotid body tumors enlarge, they distort the carotid bifurcation and splay the internal and external carotid arteries, known as the "lyre sign" seen on angiography. Large tumors often encase the external carotid artery, but rarely wrap around the internal carotid artery.

CLINICAL PRESENTATION

Carotid body tumors most commonly present as asymptomatic neck masses located below the angle of mandible. On palpation, the lesions are firm, smooth, and lobulated, and are characteristically mobile laterally but fixed longitudinally due to their association with the carotid artery. Carotid pulsation may be transmitted through the mass, and approximately 30% to 40% of patients may have an audible bruit over the tumor. Very large carotid tumors may cause compression or local invasion, leading patients to present with nonspecific symptoms, such as localized tenderness, fullness, numbness, dysphagia, hoarseness, chronic cough, and tinnitus. Tumors rarely produce cranial nerve dysfunction, and if there is involvement, symptoms are typically associated with the vagal, hypoglossal, and cervical sympathetic nerves. Occasionally, Horner syndrome has been reported with this tumor. Patients may complain of dizziness, but lateralizing neurologic signs are uncommon.

Despite possessing apparatus to synthesize and secrete catecholamines and hormones, carotid body tumors are almost never functional. In extremely rare cases, tumors demonstrate neuroendocrine activity and patients may complain of headaches, dizziness, palpitations, tachycardia, arrhythmias, flushing, diaphoresis, and photophobia. Some cases have been reported of patients with hypertension that resolves after tumor resection, which may be caused by tumor-related catecholamine release.

These neoplasms tend to grow slowly over several years, although occasional cases of rapid growth have been reported.

Although the risk of malignancy is believed to be relatively low, these tumors do progress in size and become locally invasive. Patients may live many years without treatment; however, due to the morbidity and mortality associated with progressively enlarging tumors, the low but unpredictable risk of malignancy, and the ease of excising small tumors, most surgeons recommend early diagnosis and surgical resection.

DIAGNOSIS

The workup begins with a history and physical examination. The differential diagnosis for neck masses is broad, and includes congenital lesions (vascular malformations, branchial cleft cysts, hygromas), inflammatory disorders (chronic lymphadenitis, reactive lymphadenopathy), infection (viral, bacterial, and parasitic lymphadenopathy), benign lesions (lipomas, cysts, parotid, and salivary tumors), and malignancies (metastatic head and neck cancer, lymphoma). Other vascular lesions (carotid artery aneurysms, kinks, and coils) and cervical paragangliomas (glomus jugulare and glomus vagale) may also present as neck masses.

Radiographic imaging is a critically important modality in the diagnostic confirmation and preoperative evaluation. Conventional angiography was traditionally the gold standard, and provides excellent details about the overall size, extent, and vascularity of the lesion. It also shows variation in blood supply and encasement of carotid vessels, both of which can significantly affect operative planning. It can also identify synchronous and contralateral tumors, carotid atherosclerotic or ulcerative disease, and other anatomic variations (aneurysms, kinks, and coils). It can also identify intracranial vascular lesions that may affect management. Finally, angiography provides the opportunity for preoperative embolization (see below). Limitations of angiography include high costs, risk of access complications, wound complications (hematoma, dissection, pseudoaneurysm), distal embolization with stroke, and contrast problems (allergic reaction and renal failure).

Duplex ultrasound has emerged as the most important, noninvasive method for examining carotid body tumors. It subjects the patient to minimal discomfort and essentially no risk. Ultrasound can provide excellent anatomic detail, estimate tumor vascularity with color Doppler, and determine tumor size, vessel encasement, and atherosclerotic disease. Finally, compared to angiography, ultrasound is significantly less expensive. Its limitations include an inability to clearly visualize the proximal (chest) and distal extent (intracranial) of the carotid artery and the possible extent of the tumor. The level of detail is lower compared to angiography, and it may not be as sensitive for small lesions. Like other duplex studies, the reliability of carotid ultrasound is highly operator dependent.

Recently, computed tomography angiography (CTA) and magnetic resonance angiography (MRA) have supplanted conventional angiography. These methods are noninvasive but provide high levels of anatomic and vascular detail when duplex ultrasound is insufficient. CTA and MRA more clearly show the proximal and distal portions of the neck compared to duplex ultrasound and avoid the access/wound and embolic risks of conventional angiography. Both also have the advantage of 3D reconstruction. CTA has radiation exposure and contrast risks that are similar to conventional angiography, and MRA risks include nephrogenic systemic fibrosis associated with gadolinium contrast in patients with renal failure.

Due to the highly vascular nature of the carotid body tumor, percutaneous needle biopsy and incisional biopsies are *contraindicated*. Risks include hemorrhage, hematoma, pseudoaneurysm, and injury to adjacent neurovascular structures. Furthermore, the ability to confirm the diagnosis with high-quality imaging renders further diagnostic tests, including biopsy, unnecessary.

Shamblin and colleagues at the Mayo Clinic developed a classification system for carotid body tumors based on tumor extent and neurovascular involvement (Fig. 95.4). Group I tumors are smaller and can be dissected easily off the walls of the carotid arteries in the periadventitial plane. Group II tumors are larger, more adherent to the adventitia, and partially surround the carotid vessels. Group III tumors have more intimate adherence to the vessels and encase the internal and external carotid arteries. Modern imaging allows staging of carotid body tumors according to the Shamblin classification, and can assist in preoperative planning.

TREATMENT

Surgical resection is the mainstay of treatment for carotid body tumors. Although these lesions tend to be small and slow growing, they are best treated early for several reasons: smaller tumors are easier to remove; most tumors can become locally invasive; lesions may grow distally into the skull or involve cranial nerves, complicating resection; and these tumors may develop malignant behavior. In the absence of prohibitive comorbidities, perioperative risks, or limited life expectancy, patients with carotid body tumors should undergo surgical resection as soon as the diagnosis is made.

Radiation therapy is another treatment modality for carotid body tumors, although its use as a primary or adjunct therapy remains controversial due to conflicting studies and lack of long-term follow-up. Carotid body tumors are traditionally considered not radiosensitive, and radiation is used for suppression. Preoperative radiation may render surgery more difficult due to fibrosis. Radiation therapy is usually reserved for patients deemed poor operative candidates, and for bulky, unresectable, or recurrent tumors.

There are currently no effective chemotherapy treatments for carotid body tumors.

PREOPERATIVE PREPARATION

Planning should start with the evaluation of the patient's general medical condition, following current perioperative guidelines for vascular, and specifically carotid artery disease. Because the operation is elective, reasonable steps should be taken to optimize the patient's health and reduce their risk factors for perioperative adverse events.

Appropriate imaging should be performed to determine the tumor size and extent, and to identify other cervical

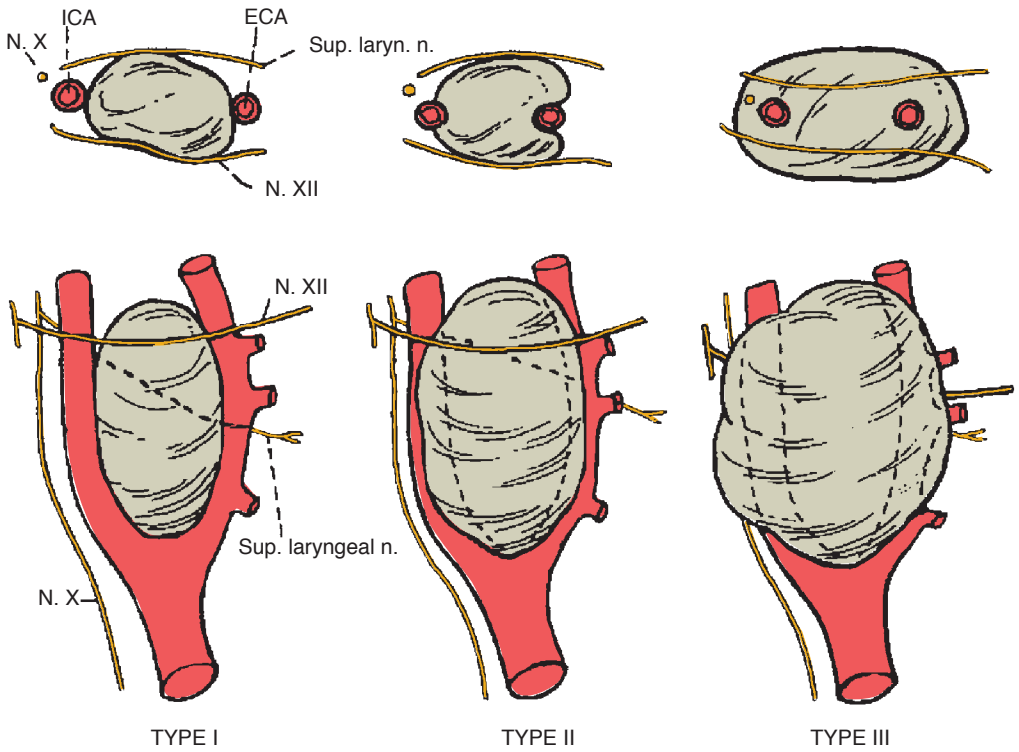

Figure 95.4 The Shamblin classification describes the staging of carotid body tumors and can assist in preoperative planning. Type I tumors are smaller and can be easily dissected from the walls of the carotid arteries in the periadventitial plane. Type II tumors are larger, more adherent to the adventitia, and partially surround the carotid vessels. Type III tumors have more intimate adherence to the vessels and encase the internal and external carotid arteries.

paragangliomas. Extension into the cranium and synchronous lesions can change operative planning. In addition, any existing cranial nerve involvement and neurologic deficits should be carefully and thoroughly documented. Although neuroendocrine activity from carotid body tumors is rare, if endocrine dysfunction or hormone imbalance is suspected, appropriate laboratory tests, including urinary catecholamines, should be ordered. Positive workup may also indicate an active synchronous lesions, such as adrenal pheochromocytomas. Medical and surgical treatment for these lesions should precede treatment for the carotid body tumor.

Preoperative embolization remains controversial. Some surgeons routinely perform embolization on Shamblin group II and III tumors. Carotid angiography is performed with selective catheterization of the ECA and embolization (Gelfoam or coils) of branch vessels feeding the tumor. Several studies demonstrate conflicting results regarding reduction in blood loss, surgical time, length of stay, and perioperative complications. The senior author does not advocate preoperative embolization. The disadvantages include the risk of inadvertent cerebral embolization and stroke. It also adds an additional invasive procedure with associated patient discomfort and increases the overall cost of care.

SURGICAL TECHNIQUE

Carotid body tumors are highly vascular lesions that carry a massive hemorrhage risk during resection. The lesions may also adhere to or envelop neurovascular structures, increasing the risk of complications. The surgeon must plan his or her operative approach according to the tumor characteristics, and attempts must be made to reduce blood loss and preserve vital structures.

Anesthesia for this operation could potentially be either cervical block or general anesthesia, as is the case for other carotid artery operations. However, resection of carotid body tumors usually requires more time than carotid endarterectomy and tends to be more invasive, particularly with large tumors. As a result, it is difficult to maintain patient comfort and compliance during a technically demanding operation that requires all of the surgical teams' attention to the operative field without the distraction that can occur with patient discomfort and restless movement. Therefore most surgeons prefer the more controlled setting of general anesthesia, with better airway management and reduced patient movement during the operation.

Cerebral monitoring and protection should be used for carotid body tumor resection due to potential or planned internal carotid artery occlusion or reconstruction. The choices are to use EEG monitoring or routine shunting of the internal carotid artery. Internal carotid artery back pressure is not an option due to the inability to clamp the external carotid artery due to tumor involvement. If continuous EEG monitoring shows ischemic changes with clamping of the carotid artery, a Pruitt-Inahara shunt can be inserted through an arteriotomy in the common carotid artery. The distal shunt is passed into the internal carotid artery and held in place by gentle inflation of the distal balloon. The proximal shunt is passed retrograde into the common carotid artery and can be held in place with the proximal balloon or a Rummel tourniquet. Some surgeons have advocated doing

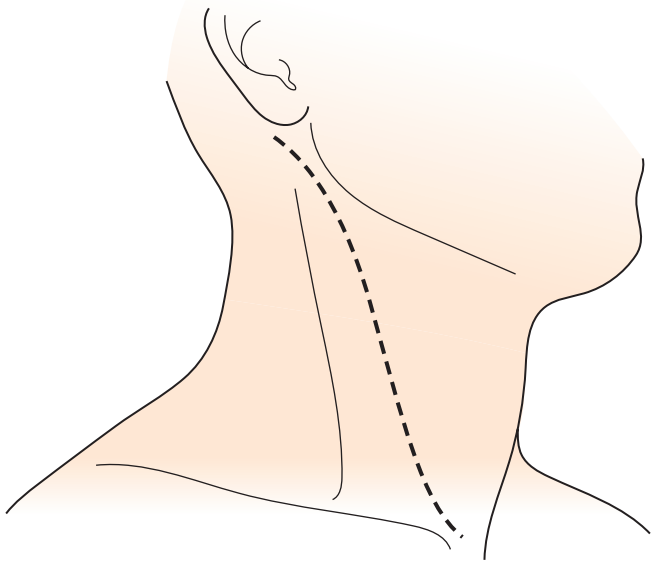

Figure 95.5 The skin incision for carotid body tumor resection is longitudinal along the anterior border of the sternocleidomastoid muscle. The incision should be centered over the carotid bifurcation.

this in all cases of carotid body tumor resection because the placement of the shunt effectively blocks inflow to the external carotid artery and may make tumor resection and hemostasis more effective.

POSITIONING AND EXPOSURE

The setup and dissection of carotid body tumors are similar to that of carotid endarterectomy (see Chapter 91). The patient is supine with the head rotated to the contralateral side. Depending on the patient's body habitus, a shoulder roll may be placed to extend the neck. The head of the table can be elevated 10 to 15 degrees to reduce venous pressures and incisional blood loss.

A longitudinal incision is made through the skin and subcutaneous tissues along the anterior border of the sternocleidomastoid muscle. The incision should be centered over the carotid bifurcation. If necessary, the incision can be extended proximally toward the sternal notch and distally toward the mastoid process (Fig. 95.5). Additional techniques for extended exposure include continuing the incision across the mastoid process behind the ear, detachment of the posterior belly of the digastric muscle from the mastoid process, division of the stylohyoid muscle with or without the styloid process, and subluxation or division of the mandible.

RESECTION OF TUMOR

The dissection continues along the anterior border of the sternocleidomastoid until the muscle can be reflected off the carotid sheath. If the parotid gland is encountered, it can be mobilized and reflected anteriorly. The carotid sheath should be opened along the anterior border of the jugular vein. The common facial vein typically joins the jugular vein near the level of the carotid bifurcation and is a useful landmark that can be divided. The jugular vein can be reflected laterally to expose the carotid arteries (Fig. 95.6). The surgeon should identify and protect the hypoglossal, vagus, and laryngeal nerves. These structures may be displaced by large tumors.

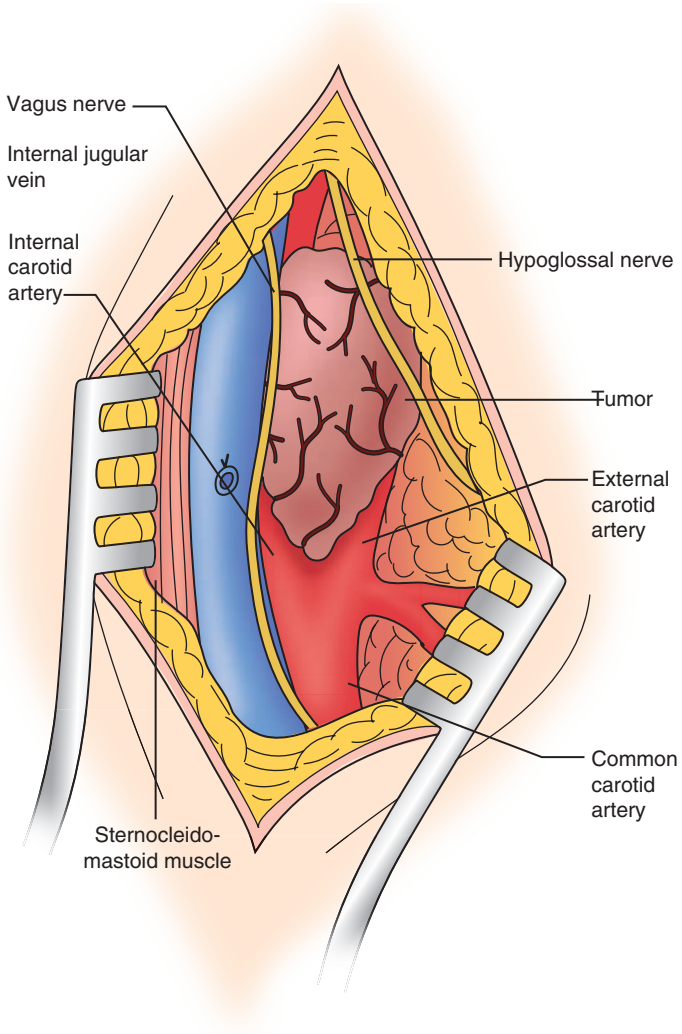

Figure 95.6 For the exposure of the carotid body tumor, the carotid sheath should be opened along the anterior border of the jugular vein. The common facial vein, which typically joins the jugular vein near the level of the carotid bifurcation, is divided to allow lateral reflection of the jugular vein. The hypoglossal, vagus, and laryngeal nerves are identified and protected. These structures may be displaced by large tumors.

The proximal common carotid artery should be circumferentially mobilized in the perivascular plane, with sufficient length obtained for possible bypass shunt (Fig. 95.7). At this point it is usually possible to see the vagus nerve. The dissection proceeds distally on the lateral aspect of the common carotid artery, in the perivascular plane, separating the artery from the vagus nerve, until a point at the upper end of the tumor mass where the internal carotid artery can be circumferentially mobilized. It is during this maneuver that the hypoglossal nerve may be encountered and must be carefully separated from the tumor mass and protected (Fig. 95.8).

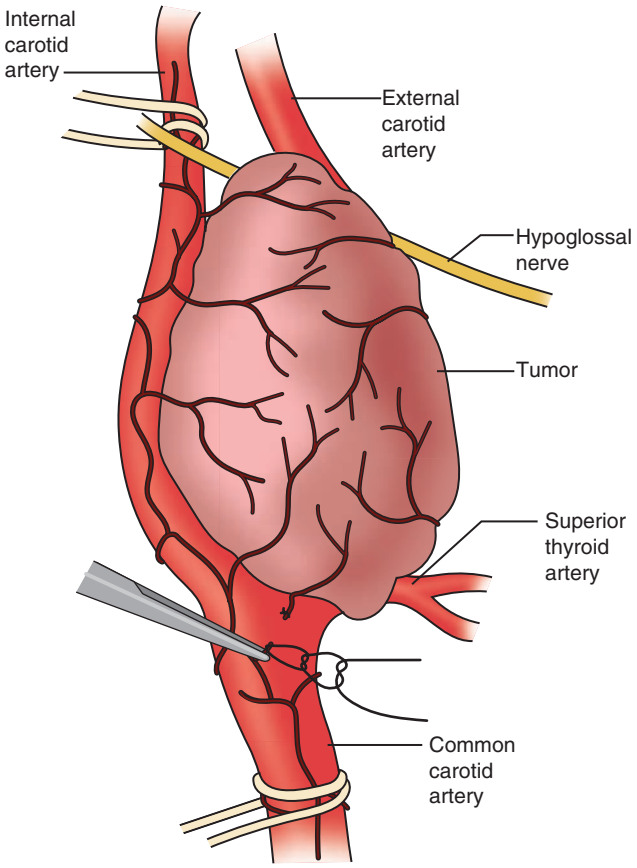

Figure 95.7 The common carotid artery is circumferentially mobilized in the perivascular plane to obtain proximal control of the artery. Dissection proceeds distally on the lateral aspect of the common carotid artery in the perivascular plane to a point beyond the tumor. The vagus nerve is separated from the artery and protected.

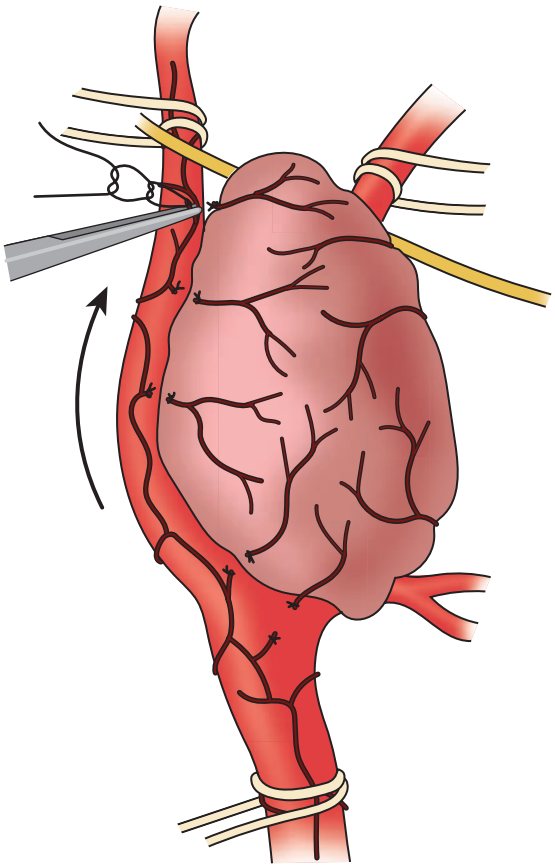

Figure 95.8 The internal and external carotid arteries are circumferentially mobilized for distal control. The hypoglossal nerve may be encountered during the dissection; it is separated from the artery and mass and protected.

Because carotid body tumors rarely encase the internal carotid artery, attempts are made to preserve it. The dissection is continued down the medial aspect of the internal carotid artery in the same perivascular plane, separating the tumor from the internal carotid artery to the bifurcation (Fig. 95.9). At this point, the external carotid artery can be circumferentially mobilized. For small tumors (Shamblin group I), the external carotid artery can be preserved. The dissection should stay on the tumor pseudocapsule; branches of the external carotid artery that supply the tumor can be divided and ligated with care to protect the hypoglossal nerve. Once the posterior, lateral, and medial aspects of the tumor are mobilized, the superior extent is divided between the ligature and the mass removed (Fig. 95.10).

For larger tumors that are adherent to the external carotid artery (Shamblin group II), the vessel can be divided at its origin, and the proximal stump is oversewn at the point where it was circumferentially mobilized. This maneuver is useful in reducing blood loss, and it provides a handle to rotate the tumor and aid in the dissection. The external carotid artery is resected en bloc with the tumor (Fig. 95.11).

For tumors that cannot be dissected from the bifurcation (Shamblin group III), the bifurcation and possibly the internal and external carotid arteries must be removed with the tumor. Vascular reconstruction for the internal carotid can be performed with a prosthetic or autologous vein interposition graft (Fig. 95.12). However, it is our preference to use a 6-mm PTFE graft, because long-term patency in this position is well documented as opposed to vein grafts. If a carotid shunt is required, the vascular reconstruction can be performed by passing the shunt through the graft and removing the shunt before the second anastomosis is completed. In addition, if clamping of the common or internal carotid arteries must be performed, the patient should receive systemic heparin. If the neoplasm adheres to or encases nerves, attempts should be made to preserve the nerves, even by splitting the tumor. If it is necessary to split the tumor to preserve a cranial nerve, use of bipolar forceps is helpful for hemostasis.

The wound is irrigated and meticulous hemostasis is obtained. The platysma is reapproximated, and the skin is closed with subcuticular sutures or skin staples. Drains are rarely needed, but if used, they can be placed beneath the platysma layer and brought out through the skin through a separate stab wound. A sterile dressing is placed.

POSTOPERATIVE CARE

A preliminary neurologic assessment should be performed when the patient awakens from anesthesia. The patient is brought to the

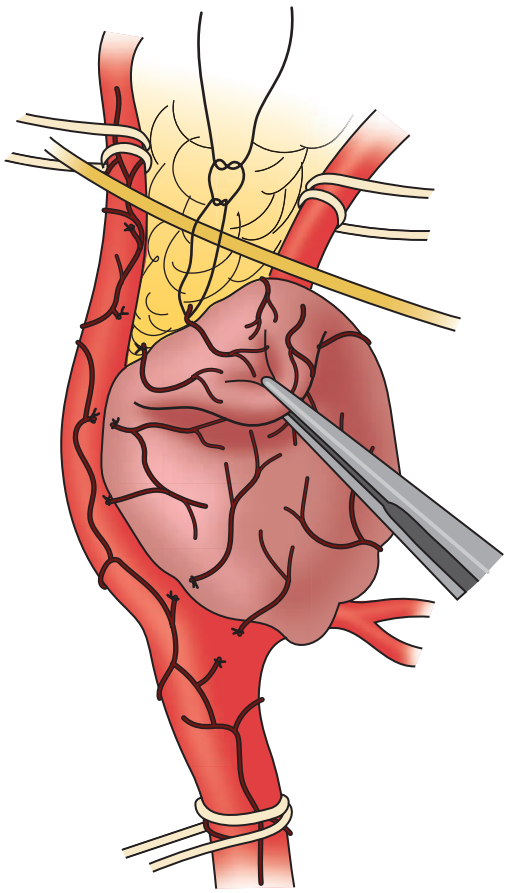

Figure 95.9 Dissection is continued along the medial aspect of the internal carotid artery in the same perivascular plane. The carotid body tumors rarely encase the internal carotid artery, and attempts should be made to separate and preserve the internal carotid artery.

recovery room where the blood pressure and neurologic function can be carefully monitored. The care team should be vigilant for neck hematomas, which can lead to an airway emergency, as well as stroke symptoms and evidence of cranial nerve injuries. If a drain is placed, it can be removed after 24 hours. Most patients are discharged 24 to 48 hours postoperatively.

Although recurrence is rare, patients should be followed closely after discharge.

RESULTS

In experienced hands, the perioperative mortality should be significantly less than 0.5%, and cerebrovascular, cranial nerve, or other minor complications occur very rarely. Particularly for tumors that appear and behave benignly, perioperative mortality and morbidity rates must be low. Other complications include hemorrhage and hematoma, especially when vascular control is inadequate. As described, several important cranial nerve structures lie within the tumor and dissection regions. Higher rates of nerve injury are seen with larger tumors. Most cranial nerve dysfunction is transient. Most complications are considered technically preventable, and adequate planning by the surgeon can greatly reduce the rates of adverse events.

CONCLUSIONS

- Carotid body tumors are rare neoplasms.
- Patients usually present with asymptomatic neck masses.
- Carotid body tumors are usually slow-growing, benign lesions, but may exhibit locally aggressive behavior. Malignant transformation is rare.

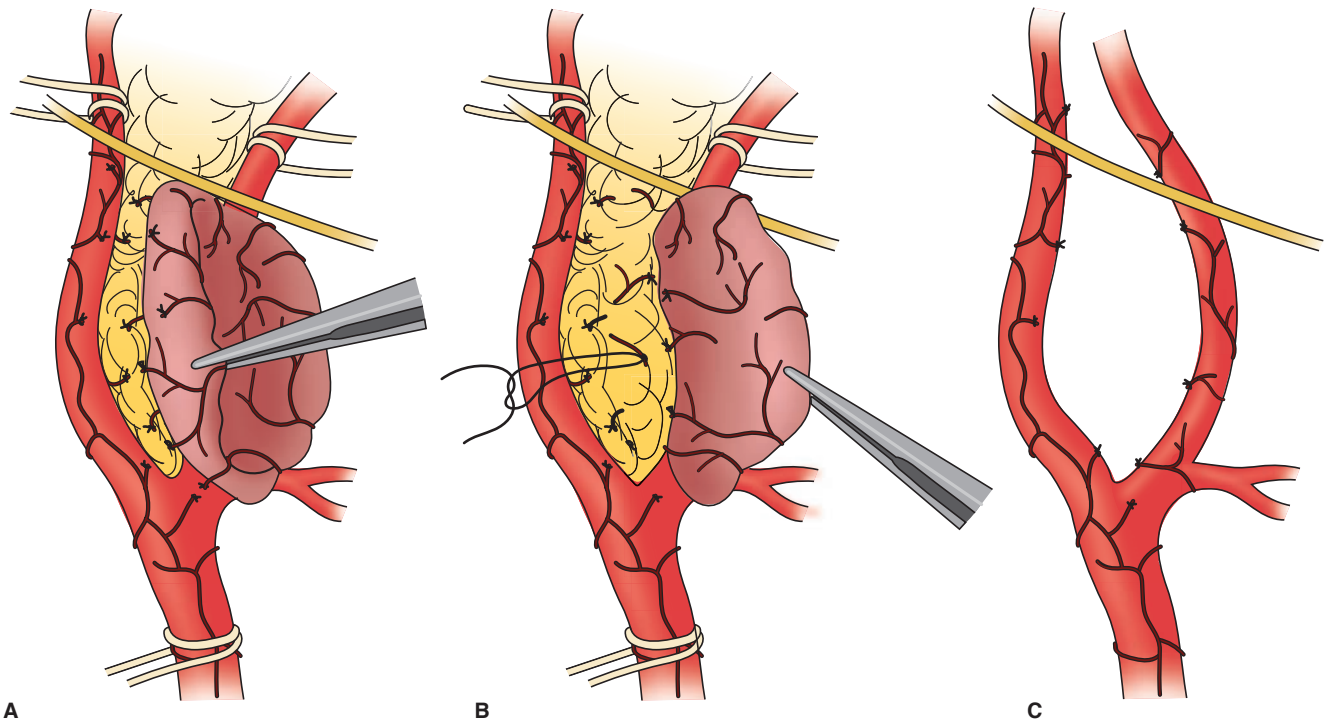

Figure 95.10 For small tumors (Shamblin group I), the external carotid artery can be preserved by mobilizing the carotid body tumor along the pseudocapsule (A). The blood supply to the tumor from branches of the external carotid artery can be divided and ligated (B).

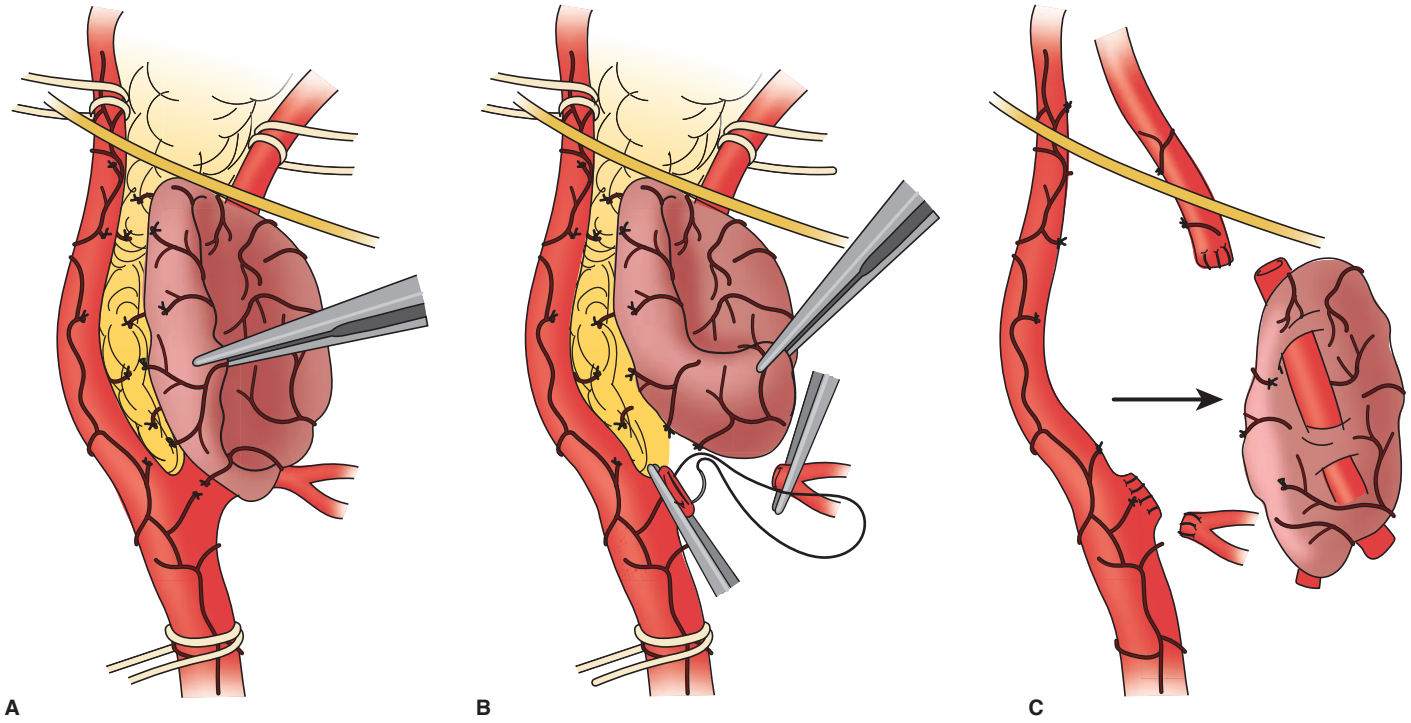

Figure 95.11 For larger tumors (Shamblin group II) that adhere to the external carotid artery, the vessel can be resected en bloc with the tumor. The carotid body tumor is mobilized from the internal carotid artery and carotid bifurcation (A). The external carotid artery is divided at its origin and the proximal stump oversewn (B). The tumor is then rotated to facilitate the remaining dissection. The distal external carotid artery and remaining branches are oversewn (C).

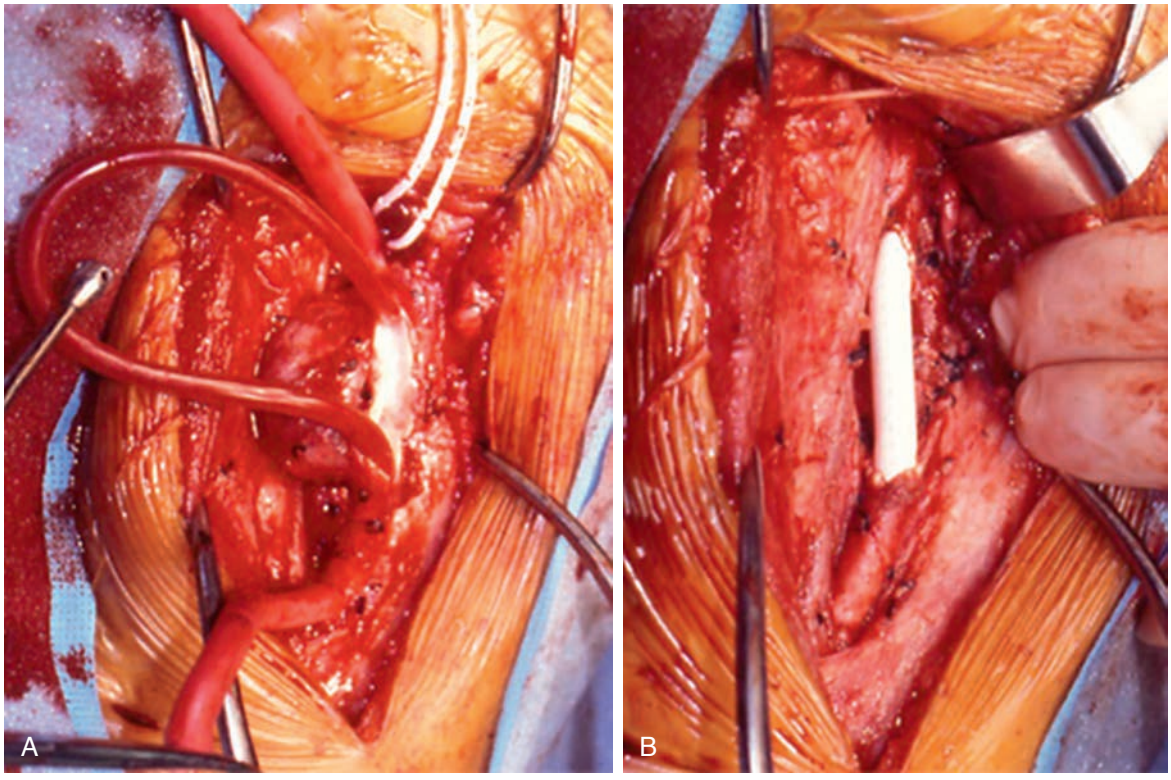

Figure 95.12 For tumors that involve the carotid artery bifurcation (Shamblin group III), the bifurcation and possibly the internal carotid artery, must be removed with the tumor (A). A carotid shunt may be required during the reconstruction. The internal carotid artery can be revascularized with a prosthetic or autologous vein interposition graft (B).

- Carotid body tumors are highly vascular structures.
- Imaging (conventional angiography, duplex ultrasound, CTA, and MRA) is the primary tool for diagnosis.
- Early complete surgical resection is the mainstay of treatment.
- In experienced hands with adequate operative planning, perioperative mortality and complication rates are very low.

Atherosclerotic stenosis and occlusion of the extracranial vessels are the leading causes of the cerebrovascular diseases with which vascular surgeons have the most experience. There are several others disorders affecting carotid arteries and cerebral vessels that are underestimated and unacknowledged due to their rarity. For these uncommon pathologies, there is limited experience as well as few reports of best practices. This chapter addresses the clinical presentation and management of carotid sinus syndrome and carotid sinus hypersensitivity (CSS/CSH), Moyamoya disease, carotid artery kinks and coils, intracranial vascular stenosis, lacunar infarcts, cerebral vasculitis, and intracranial aneurysm with extracranial carotid stenosis.

BACKGROUND

There are several unusual diseases that affect the carotid arteries. These rare vascular conditions can cause disabling neurologic symptoms and deficits similar to atherosclerotic lesions (Box 96.1). This chapter discusses several of these rare cerebrovascular diseases including their presentations and risk factors as well as potential treatment modalities.

Abstract

There are many rare and unusual vascular diseases of the carotid artery; some occurring only in certain patient populations. Thus, physicians may not be familiar with their presentation or management. This chapter will review several carotid conditions, including epidemiology, clinical presentation, and available evidence for treatment.

CAROTID SINUS SYNDROME/ CAROTID SINUS HYPERSENSITIVITY

Background and Epidemiology

Carotid sinus syndrome (CSS) was first reported over 200 years ago and is a relatively common finding. The carotid sinus is a high-pressure baroreceptor located at the carotid bifurcation. CSS is most often associated with the elderly patient population; hypersensitivity of the carotid sinus develops for unknown reasons. CSS presents with syncopal symptoms triggered by manipulation of the carotid sinus that occurs in daily life, resulting in a neurally mediated reflex bradycardia and hypotension. It is likely underdiagnosed, and common presenting symptoms include dizziness, falls, and syncope in the elderly patient population.[1,2] Carotid sinus hypersensitivity (CSH) is defined as bradycardia or hypotension due to carotid sinus massage or manipulation in patients without a clinical history of such symptoms.[3]

Epidemiology

The prevalence of CSS is highest among the elderly, even those without a history of symptoms. Generally the lifetime prevalence of syncope is 35% (95% CI 31% to 39%) in individuals from 35 to 60 years of age; it occurs more often in women than in men (41%, compared with 28%, respectively).[4] There are controversial findings regarding sex association, however. A study by Kerr et al. found that male sex was associated with CSH.[2] Another study by Volkmann et al. similarly found higher rates among men than among women (28% vs. 10% in asymptomatic patients and 48% vs. 34% in symptomatic patients, respectively).[5] A third study, by Kumar et al., supports these findings as well, with higher rates for men than for women (26.3% vs. 13.1%).[6] This wide distribution of the prevalence of CSS by sex is potentially due to variations in stimulation method, nonmodifiable patient characteristics, and the relevant diagnostic criteria utilized in each study.[7]

Classification

There are three main types of CSH. Cardioinhibitory carotid sinus hyperactivity (CICSH) is characterized by ventricular pauses greater than or equal to 3 seconds. Vasodepressor carotid sinus hyperactivity (VDCSH) displays blood pressure drops of at least 50 mm Hg without concomitant bradycardia. Finally, mixed CSH shows ventricular pauses of greater than or equal to 3 seconds along with a decrease in systolic blood pressure of at least 50 mm Hg on rhythm resumption. It is important to differentiate these classifications clinically as they dictate the approach to treatment; CICSH is a class 1 indication for cardiac pacing, whereas VDCSH typically requires pharmacologic treatment.[8,9]

Physiology and Pathophysiology

In normal physiology, sudden increases in arterial blood pressure result in expansion of the carotid arterial wall. Triggering of the carotid sinus receptor sends an afferent signal via the glossopharyngeal and vagus nerves to the brain stem and an efferent signal via the vagus nerve to the heart and blood vessels. This results in increased vagal activity and decreased sympathetic activity. Therefore increases in blood pressure cause compensatory vasodilation, bradycardia, and hypotension. Similarly, decreases in blood pressure decrease stretch in the carotid arterial wall and result in decreased afferent signals, resulting in a relative increase in sympathetic activity.[10]

The pathophysiology of the disease is poorly understood, but several models have been proposed. The first is that an abnormality in the central nervous system due to upregulation of postsynaptic alpha-2 adrenoceptors causes an exaggerated efferent response. However, testing with yohimbine (an alpha-2 antagonist) indicated no findings of baroreflex attenuation.[11,12] Another theory is that chronic terminal denervation of the sternocleidomastoid increases baroreflex sensitivity, but no definitive cause and effect relationship has been established in this case either.[13]

Presentation and Risk Factors

Common symptoms include dizziness (presyncope) or syncope of sudden onset, short duration, and quick recovery; this can occasionally be more prolonged if hypotension is severe.[8] Complications are most serious in the elderly who have falls (typically without loss of consciousness) and sustain resulting trauma. Both CICSH and VDCSH can induce falls.[14,15] Neurologic symptoms, which are rare and transient, include abnormal sensorium, vision changes, paresthesia, paresis, and cognitive dysfunction.[16] Risk factors include provocative maneuvers such as head turning, shaving, wearing tight neck collars, and age itself.[6,17-19]

Diagnosis and Workup

Proper diagnosis requires a thorough history to differentiate spontaneous from provocation-induced CSS.[1] Carotid sinus massage (CSM) should be conducted to determine if a hypersensitive response occurs. There is debate regarding whether the ability to spontaneously reproduce a response is required for diagnostic purposes. CSM is a safe and low-cost procedure

to stimulate the carotid sinus by the application of pressure, but descriptions of the technique vary by practitioner with respect to patient positioning and timing. CSM is contraindicated in patients with previous transient ischemic attacks, but the presence of a carotid murmur is not a contraindication.[3,7,20,21]

The technique serves to reproduce spontaneously occurring symptoms during 10-second sequential right and left massage[10] performed in both the supine and erect position under continuous heart rate and blood pressure monitoring.[21] Current guidelines from the European Society of Cardiology state that the upright position is preferred, and this is supported by data reported by Morillo (diagnostic accuracy of CSM increased by 38%).[1,22] The guidelines recommend continuous electrocardiography and noninvasive blood pressure monitoring as a 5- to 10-second massage is conducted at the anterior margin of the sternocleidomastoid at the cricoid cartilage level. If the test is negative, it can be repeated on the contralateral side after 1 to 2 minutes. If the test is positive, eliciting a cardioinhibitory response, atropine is administered, and repeat massage is performed to determine the degree of vasodepression. The differential diagnosis should include vasovagal syncope, given the potential for the coexistence of common conditions in elderly patients. Unlike CSS, vasovagal syncope is typically triggered by prolonged standing, strong emotion, and pain.[1]

Treatment

Nonpharmacologic treatment includes adequate fluid and salt intake as well as avoidance of physical counterpressure maneuvers.[23] If the patient is not responsive to these conservative measures, medical or surgical management should be considered. Regarding pharmacologic treatment, several drug trials have been conducted. In midodrine drug trials, the proportion of patients with syncopal complaints induced by CSM was lowered by midodrine treatment as compared with placebo (RR 0.13; 95% CI 0.02 to 0.82).[24] Selective serotonin reuptake inhibitors (SSRIs) and fludrocortisone have been shown to be effective, but atropine and propranolol did not prevent the vasodepressor response. Norepinephrine was shown to diminish the vasodepressor responses without a hypertension response, whereas ephedrine attenuated hypotensive responses. Isoproterenol and amphetamine did not have efficacy and the sympathomimetic side effects were dangerous in older patients who have high rates of systolic hypertension and coexisting coronary artery disease.[10]

Permanent pacemaker implantation is the treatment of choice if bradycardia occurs in CICSH.[25,26] Pacemakers can be atrial, ventricular, or designed for dual-chamber sensing and pacing. Indications for pacemaker placement include a clinical history of syncope, a positive response to CSM (asystole and bradycardia, indicating a severe reflex response), and syncope during CSM.[27] There is sparse evidence from randomized controlled trials but one study found that patients with syncope and CICSH respond to permanent pacing with a reduction in symptoms. There is conflicting evidence on whether or not pacing actually helps with unexplained falls.[28]

The current literature indicates that single-chamber atrial-based pacing should not be used as it has led to high rates of AV block.[29] A study by Brignole compared dual pacing and sensing, inhibitory and triggered (DDD) with ventricular pacing and sensing, inhibitory (VVI) and found no significant differences in follow-up for CSS.[30] However, another study by McIntosh et al. noted that CSM-induced syncope was higher in patients with VVI than those with DDI pacemakers (RR 5.50; 95% CI 1.33 to 22.73)[31] DDD pacing is currently accepted as better for symptom reduction, and the guidelines reflect this by noting that dual-chamber pacing is better than single-chamber pacing.[1]

Surgical or radiologic denervation of the carotid sinus, involving adventitial stripping, has been conducted for 60 years (Fig. 96.1). One study found that in 39 procedures on 27 individuals from 1980 to 2007, the procedure was relatively effective, safe, and could be considered as an alternative to pacemaker therapy.[32] Another study reporting data from 130 procedures indicated 85% effectiveness in preventing CSS, with low complication rates. Postoperative monitoring is required

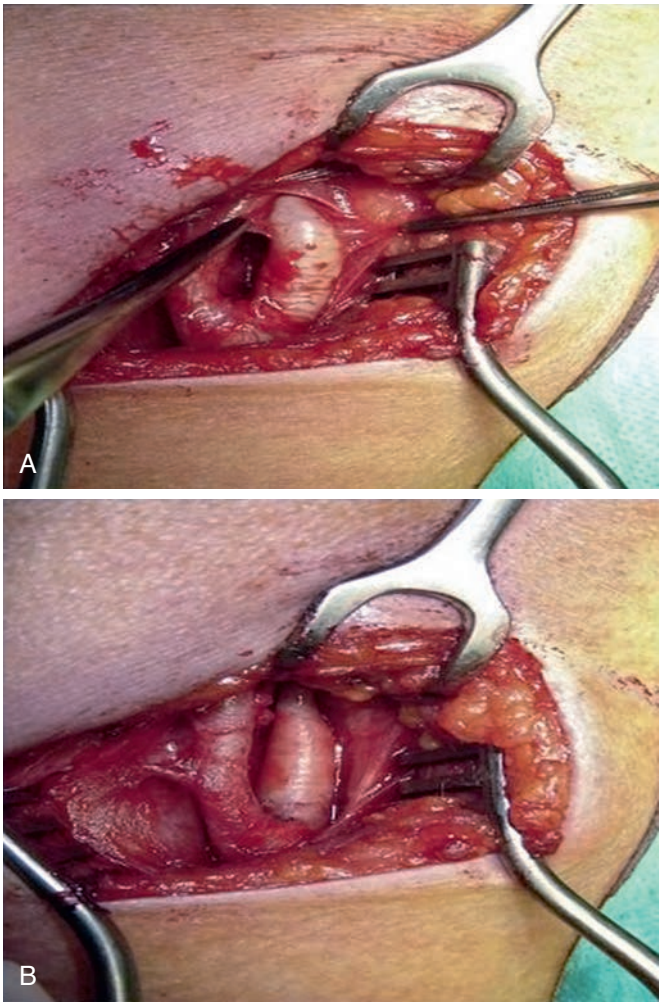

Figure 96.1 Operative Photographs Depicting Adventitial Stripping of the Left Carotid Artery. (A) The process of stripping with the forceps holding the nervous tissue. (B) The 3 cm of stripped proximal internal carotid artery after the procedure. (From Toorop RJ, Scheltinga MR, Huige MC, Moll FL. Clinical results of carotid denervation by adventitial stripping in carotid sinus syndrome. *Eur J Vasc Endovasc Surg*. 2010;39:146-152.)

due to transient alterations in blood pressure and heart rate.[33] A literature review following 28 patients undergoing carotid sinus denervation found that no patients experienced recurrent syncopal attacks or dizziness.[34] Therefore this is a potential therapy when pharmacotherapy is not effective.

MOYAMOYA DISEASE

Background and Epidemiology

Moyamoya disease (MMD) was first described by Suzuki and Takaku in 1969 and is now characterized as a chronic, idiopathic, progressive cerebrovascular disease presenting with internal carotid artery stenosis and occlusion.[35,36] The condition displays abnormal vascular networks at the brain base and is a common cause of stroke or transient ischemic attack; hemorrhages are possible as well (Fig. 96.2). It is most commonly seen in East Asian countries (i.e., Korea, Japan, China, Taiwan). Several large epidemiologic studies have been conducted in these regions[37-41] noting an incidence ranging from 3 to 14 in 100,000 and prevalence ranging from 0.35 to 2.3 in 100,000. These ranges are potentially due to improvements in diagnostic procedures. There is a bimodal age distribution to the disease, occurring in pediatric patients 5 to 15 years of age and adults in the third and fourth decades of life. Females are also more likely to have the disease than males. A US study found similar results, with a bimodal age distribution, increased prevalence in females, and higher prevalence in Asian American subpopulations.[42]

Presentation and Risk Factors

Pediatric MMD commonly presents with transitory repetitive cerebral ischemia, paroxysmal hemiplegia, paresthesia and facial paralysis, paroxysmal headaches, fine involuntary movements of the extremities, and progressive mental impairment.[35,43] In contrast, adult-onset MMD is characterized by sudden

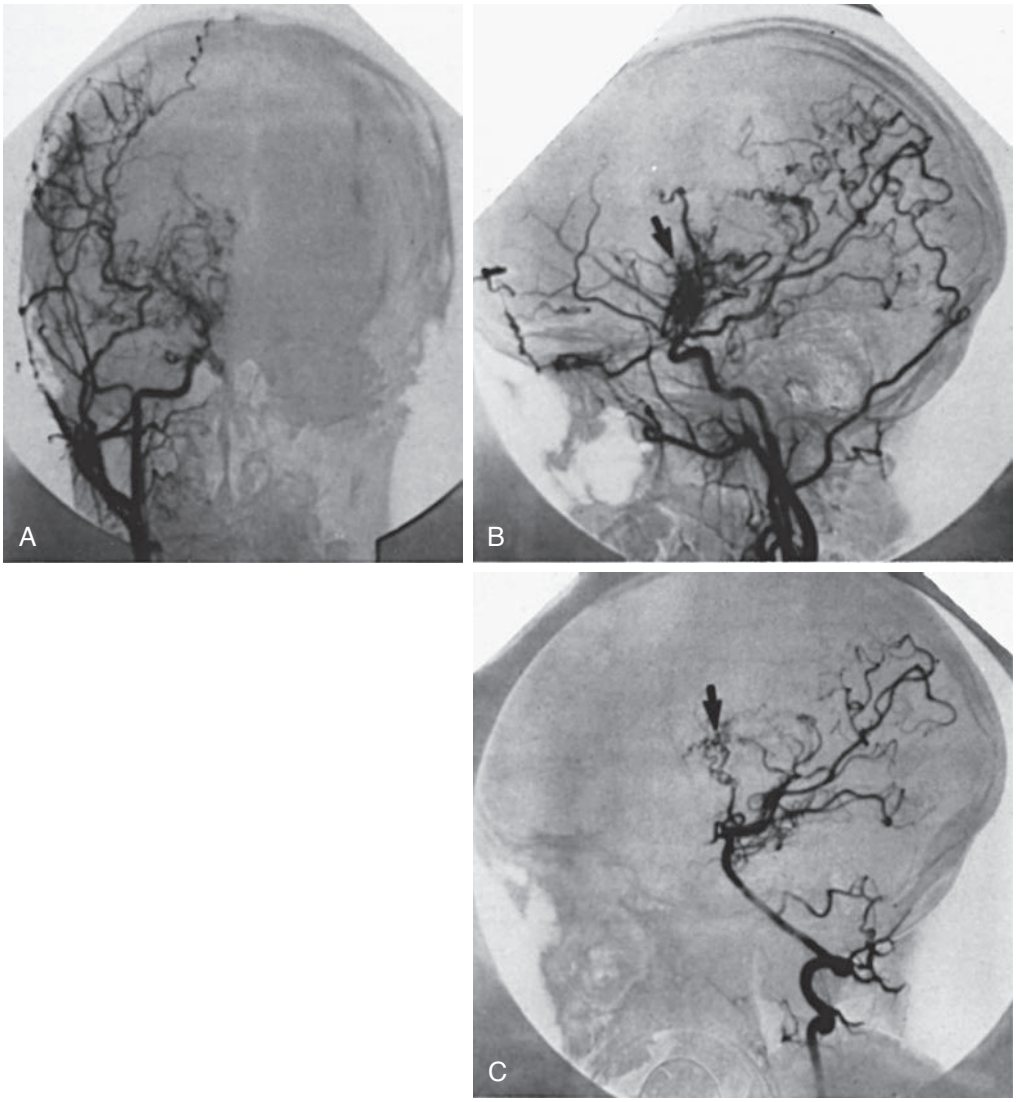

Figure 96.2 Cerebral Angiograms of a Patient With Moyamoya Disease. The collateral networks *(arrows)* around the sites of the occlusive disease. (A) Anterior and (B) lateral injections of the anterior circulation. (C) A selective angiogram of the vertebral and posterior circulation.

disturbances of consciousness, intracranial hemorrhage, bleeding into the ventricles, and subarachnoid hemorrhage.[43] Patients often present due to headache, dizziness, palpitations, syncope, or hyperventilation.[44] Risk factors include Japanese/East Asian heritage, female gender, family history, age, Graves disease, and genetic factors, as discussed in the following section.[38-41]

Pathology and Genetics

Epidemiologic data may point to a familial form of MMD, which constitutes 10% of cases.[45] The etiology of sporadic MMD is currently unknown, but many models have been proposed: infectious (viral and bacterial), autoimmune, protein abnormality, and genetic.[46] The genetic theory posits an autosomal dominant pattern of inheritance with low penetrance.[47] The following genetic loci are implicated: 3p24-26, 8q23, 6q25, 17q25, and 10q23.31.[48-52] The strongest candidate for gene susceptibility in patients of Asian descent with MMD is RNF213 from the 17q25-ter region.[53,54]

Pathophysiology

In MMD, progressive bilateral or unilateral stenosis of the internal carotid artery is seen, leading to thickening of the intima. Smooth muscle cell proliferation results in eventual arterial stenosis or occlusion; there is a notable lack of inflammation and atherosclerosis. Arterial stenosis due to fibrocellular thickening of the intima and occlusion due to smooth muscle cell accumulation occurs; ultimately potential thrombosis can result in regional cerebral hypoxia. As a result, collateralization by so-called Moyamoya vessels occurs; these vessels are characterized by a thin media, fibrin deposition in the vessel walls, fragmented elastic laminae, and an increased tendency to form microaneursyms. Neovascularization occurs due to the expression of HIF-1, VEGF, TFG-B, hepatocyte growth factor, and MMP.[46,55-58]

Histologically, the internal carotid artery shows concentric fibrocellular thickening of the intima, inducing vascular luminal stenosis, intimal elastic lamina undulation, a thickened layer of smooth muscle, and a lack of inflammation. Cerebrocortical microvascularization (an increase in microvascular density and diameter) is a potential compensatory mechanism for reduced blood flow or absent neovascularization prior to frank occlusion. However, MMD pediatric patients often show this neovascularization prior to hemodynamic impairment.[59]

Diagnosis and Workup

Based on recent changes in care management, there is no requirement for bilateral steno-occlusive changes in the internal carotid artery as a diagnostic criterion; instead, it can be a unilateral presentation leading to subsequent bilateral presentation.[60] Unilateral changes require diagnostic catheter angiography to assess for prominent basal collaterals. Bilateral changes can be evaluated with either catheter angiography or magnetic resonance imaging (MRI) studies. Angiography is very sensitive, although MRI can have decreased diagnostic sensitivity in early-stage Suzuki grading (stage 1) due to a lack of the characteristic vascular network. However, three-dimensional constructive interference in steady-state MRI and high-resolution MRI can both demonstrate constrictive remodeling in the affected segments and concentric enhancement of symptomatic segments; these techniques can therefore provide increased accuracy of diagnosis in the early stages of the disease.[61,62] Genetic testing should be considered as tests become more rapidly available and genetic associations are clarified.

Grading of MMD is done by the Suzuki and Takaku scales, with a six-stage evolutionary model indicating stepwise progression. However, the disease does not always present exactly in this order, so the clinical relevance of this scale has been debated.[35,63] The stages are as follows: (1) narrowing of the carotid fork, with no other abnormalities demonstrated; (2) initiation of Moyamoya vessels, where dilation of intracerebral main arteries is seen—the blood vessels are thick but no collateral circulation from the external carotid artery to the intracranial vessels has occurred; (3) the Moyamoya process intensifies, affecting the middle and anterior cerebral arteries; (4) the Moyamoya vessels are minimized, with occlusion of the internal carotid artery to the level of the posterior communicating artery junction; (5) further reduction of the Moyamoya vessels while the main internal carotid arteries disappear; and (6) the Moyamoya process disappears and the internal carotid artery is completely gone. The original Moyamoya vessels at the base of the brain are not visualized; only collateral circulation from external carotid artery or vertebral artery enters the intracranial region.

Treatment

There is an elevated risk of both ischemic and hemorrhagic stroke in asymptomatic patients.[64] Antiplatelet therapy is contraindicated in asymptomatic patients due to the risk of bleeding (50% of patients experience hemorrhage).[65] Therefore modifiable risk factors should be managed and lifestyle guidance provided to prevent recurrence of stroke. Hyperventilation can induce symptoms, so patients should avoid hot meals and strenuous exercise.[65] Furthermore, the patients should also start the following medical treatment plans: antihypertensive medication, lipid-lowering therapy, diabetic glycemic control, smoking cessation, weight reduction, and the elimination of oral contraceptive agents.[66,67]

Surgical management is indicated in individuals with symptomatic cerebral ischemia.[65] Pediatric cases tend to be more progressive, and this is another potential indication for surgical management.[68] The goal of revascularization is to allow normalized cerebral perfusion, and this treatment has been noted as the standard of care to prevent recurrent stroke. Furthermore, revascularization has been shown to reduce the risk of transient ischemic attacks (TIAs) and cerebral infarction, to improve activities of daily living, and to ameliorate overall brain function as tracked over time.[69]

Surgical techniques include direct bypass (surgical revascularization) and indirect bypass (pial synangiosis). Direct bypass is indicated under the following conditions: availability of a highly trained and experienced surgeon as well as the presence

of sufficient diameter in the superficial temporal artery and cortical arteries, given that later stages lead to cortical arterial shrinkage and vessel wall fragility. The donor artery is most often the superficial temporal artery, which is harvested and treated with papaverine to prevent vasospasm. The recipient artery is usually the middle cerebral artery, and Chater's point is used as a landmark in searching for a large cortical branch.[70]

Indirect bypass is typically a more expedient procedure with decreased operative times and a lower complication rate; it is also a technically less demanding procedure. In these cases, distal anastomoses are not directly performed to the intracerebral vasculature. However, indirect bypass may be difficult in pediatric patients as well as advanced-stage adult patients due to the reduced diameter of cortical arteries and longer neovascularization times. The most common types are encephalomyosynangiosis, where the deep temporal artery is the neovascularization supply, and encephaloduroateriosynangiosis, where the superficial temporal artery's parietal branch is harvested instead.[70]

Management and Prognosis

In the postoperative period, blood pressure should be carefully monitored and fluid balance should be assessed to prevent ischemic or hemorrhagic stroke. This is due the fact that postoperative neurologic sequelae are often caused by hyperperfusion syndrome, which involves increased blood flow in vessels that are unable to autoregulate.[71] Regarding the prognosis, Kim et al.[70] have reported the perioperative stroke rate after revascularization for ischemic MMD patients. They note that with conservative management, stroke rates are as high as 3.2% to 15% annually. In direct/combined revascularization in adults, there is a 0% to 1.6% rate annually, whereas in pediatric patients it is 0.2% annually (rate reported from an aggregate average of three studies). For indirect bypass, the stroke rates (0% to 14.3%) are higher than with direct revascularization. Specifically it was noted that pediatric patients have similar stroke rates with direct or indirect revascularization, whereas adults benefit more with direct revascularization.[72,73] The management of hemorrhagic MMD remains controversial.[70]

CAROTID ARTERY KINKS AND COILS

Background

The association between kinking and coiling of the internal carotid artery (ICA) and cerebrovascular insufficiency was first noted in 1951.[74] Coiling is defined as elongation and redundancy of the ICA resulting in an exaggerated S-shaped curvature or even in a circular configuration of the vessel (Fig. 96.3). Kinking is the angulation of one or more segments of the ICA associated with stenosis in the affected segment (Fig. 96.4). The degree of kinking has been defined as mild (>60 degrees), moderate (30 to 60 degrees), and severe (<30 degrees).[75] Unlike coiling, kinking is associated with clinically relevant stenosis that has led to neurologic symptoms in 4% to 20% of patients, even in the absence of atherosclerotic plaques at the carotid bifurcation[76]; kinking generally occurs in the proximal ICA.[77,78]

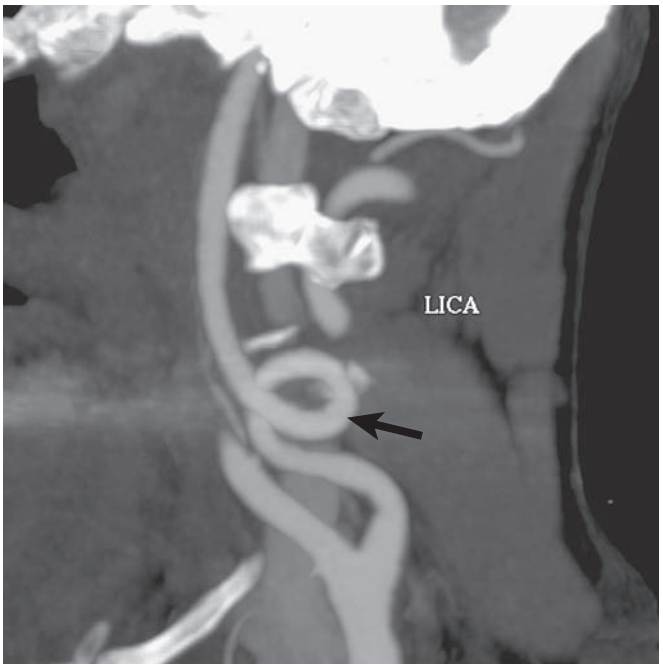

Figure 96.3 Computed axial tomography angiogram with sagittal reconstruction identifying a complete 360-degree coil of the internal carotid above the carotid bulb. *Arrow* indicates looping carotid artery resulting in "coil". *LICA,* Left internal carotid artery.

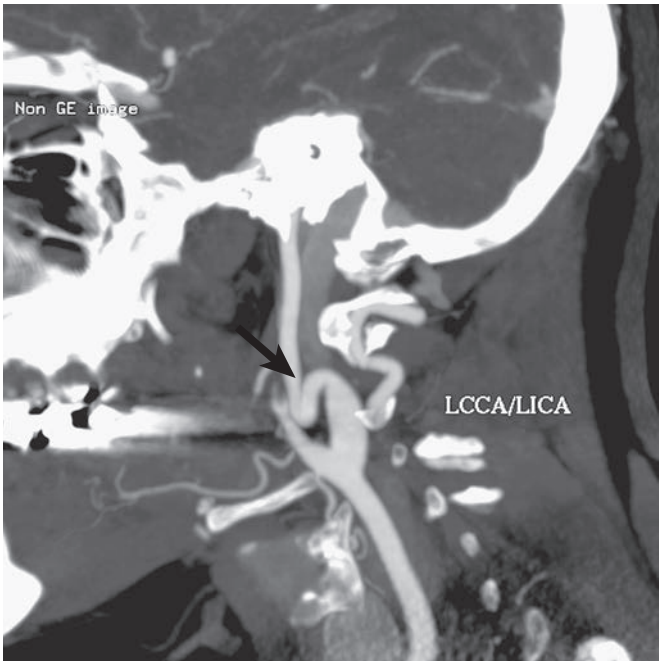

Figure 96.4 Computed axial tomography angiogram with sagittal reconstruction identifying two kinks that represent angulations of less than 90 degrees of the internal carotid just above the carotid bulb. *Arrow* indicates redundant carotid artery resulting in "kink". *LCCA,* Left common carotid artery; *LICA,* left internal carotid artery.

Epidemiology

The incidence of these carotid anomalies has been studied primarily in adults. Variations in incidence rates of internal carotid abnormalities are likely due to varying diagnostic

modalities. Arteriographic methods indicate that the incidence of these anomalies can range from 10% to 25% or even 43%.[75,78] A study by Togay-Isikay et al. using duplex ultrasound indicated a 24.6% rate. The overwhelming majority of patients with these carotid abnormalities were female (70.6%) and most were over 60 years of age. The most common abnormality noted was kinking (56%), followed by tortuosity (38%) and then coiling (6%).[79] Infantile carotid anomalies have also been reported, with associated symptoms. A study by Sarkari et al. identified nine infants with cerebrovascular disease and unilateral or bilateral looping or kinking.[80] Parrish and Byrne similarly reported five cases of infant hemiparesis and seizures in those with ICA kinking.[81]

Etiology and Clinical Presentation

There is controversy regarding the underlying cause of this condition, but two theories predominate.[82] The first describes an embryologic etiology: the internal carotid artery arises from the third aortic arch and dorsal aorta. In the embryo, the vessel is naturally coiled or kinked. The heart receding into the thorax during normal development causes arterial stretching and the disappearance of kinks. Therefore failure of this process might allow for persistence of the original coils or kinks. This could explain the kinking found in infants by Sarkari et al.[80] and Parrish and Byrne.[81] It is generally believed that coiling is associated with embryologic causes, whereas kinking is more likely to be linked to atherosclerosis or fibromuscular dysplasia.[83] These findings may explain the low rates of coiling with respect to kinking, as embryologic causes are less likely than the common risk factors that can lead to atherosclerosis. Other studies indicate the possibility that carotid coiling and kinking may be sequelae of prior carotid endarterectomy, age-related degeneration, normal deviation, or hypertension.[84-86]

Most patients are symptomatic later in life, and the symptoms demonstrated are caused by the vessel course deviations that result in hemodynamic changes.[82] Consequently embolism formation can eventually cause occlusion of intracerebral vessels. One study found that the hemodynamic conditions in a region of coil concavity are similar to those of aneurysms and can lead to endothelial denudation and the formation of embologenic material.[87] Several studies have also found that carotid kinking may be the source of cerebral emboli or that the kinked vessel may be temporarily occluded by rotation of the head and neck.[78,88,89] It should be noted that kinking of the ICA is more often associated with symptomatic cerebrovascular disease than is coiling. In this case, patients often present with hemispheric stroke or TIA. Physical findings vary and are based on where occlusion occurred in the cerebral vasculature.[90,91]

Treatment

Clinical evaluation can include carotid ultrasonography, duplex ultrasound scan of arteries supplying brain, CT with imaging of the brain, biplane carotid angiography, and multislice CT of the arteries to the brain. Medical treatment is limited to antiplatelet therapy (typically aspirin) to reduce platelet coagulation; however, this has been found to be significantly less effective than surgical correction of isolated carotid elongations with coiling or kinking.[92]

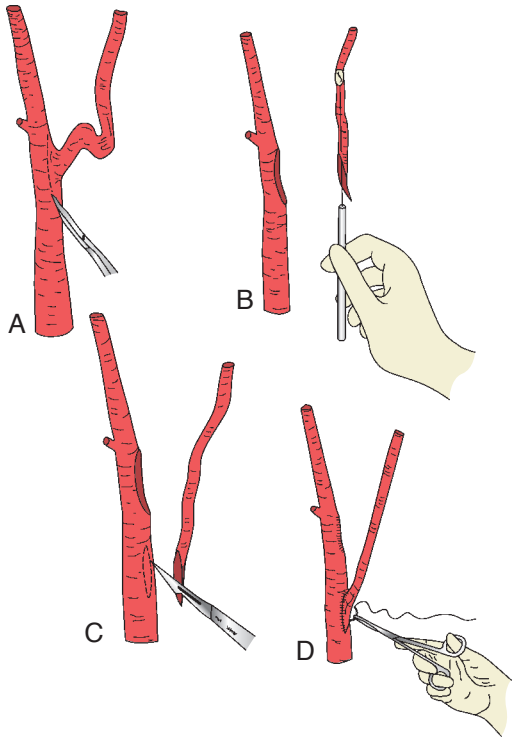

Figure 96.5 Management of a Highly Redundant Internal Carotid Artery. (A) Transection of the internal carotid artery from the bulb. (B) Transluminal dilation of any internal webs or fibrous bands. (C and D) Reimplantation of the internal carotid artery lower on the common carotid artery with repair of the original orifice. (From Ballotta E, Thiene G, Baracchini C, et al. Surgical vs medical treatment for isolated internal carotid artery elongation with coiling or kinking in asymptomatic patients: a prospective randomized clinical study. *J Vasc Surg*. 2005;42:838-846.)

With respect to surgical treatment, many small studies exist but few are randomized, and the anecdotal nature of existing data makes it challenging to draw firm conclusions with respect to the patient population at large. However, a randomized clinical study by Ballotta et al. in patients with symptomatic ICA coiling and kinking without atheromatous lesions demonstrated that surgical treatment was significantly better than antiplatelet therapy alone for the relief of neurologic symptoms and the prevention of ICA thromboses and stroke (Fig. 96.5).[92] Another study by Illuminati et al. indicated that operative correction of ICA elongation is safe and effective in patients with isolated stenotic kinking and hemispheric symptoms that persisted even with antiplatelet therapy.[93]

Simple kinking is an indication for shortening angioplasty. The ICA is sectioned at its site of origin on the common carotid artery and then the adhesions are released, followed by kink straightening. Next, proximal extension of the arteriotomy on the common carotid artery (CCA) is conducted, and then oblique transection at the base of the ICA. The distal arteriotomy on the ICA is elongated, and the ICA is reimplanted more proximally on the CCA. Distal dilation of the ICA should be performed if the lumen of the kinked artery does not return to normal after straightening.[93]

Double kinking should be addressed with resection of the diseased arterial segment and the distal ICA reconstructed either by transposition with side-to-end anastomosis onto the external carotid artery (ECA) or by interposition bypass grafting. The ICA is transposed to the ECA when the diameter of the ECA is suitable. In this case, the ICA is transected distal to the kinked segment and transposed onto the ECA using an end-to-side anastomosis. If transposition is not possible, bypass grafting should be performed using the greater saphenous vein as the bypass conduit; if it is unavailable, synthetic conduits may be considered.[93]

Management and Prognosis

In their study, Ballotta et al. found that the surgical treatment group experienced lower rates of TIAs, stroke, amaurosis fugax, deaths, carotid occlusion, and nonhemispheric symptoms than did the medically treated group; the follow-up period varied from 1 month to 10 years (median 5.9 years).[92] Illuminati et al. found that after 83 surgical procedures, there were no postoperative deaths and a postoperative stroke rate of 1%. At 5-year follow-up, primary patency of the carotid revascularizations was 89% ± 4%, and freedom from neurologic symptoms was 92% ± 4%.[93] Therefore surgical treatment conferred a significantly improved prognosis with minimal perioperative or postoperative side effects compared with medical management.

INTRACRANIAL VASCULAR STENOSIS

Background and Epidemiology

Intracranial arterial stenosis (ICAS) is defined as large intracranial arterial luminal narrowing. The etiology of the condition has not been entirely determined, but several causes are noted.[94] Primary atherosclerosis is the most common condition linked to ICAS, and emboli can be a source of stenosis as well. Other causes—such as arterial dissection, vasculitis, central nervous system infections, radiation, sickle cell disease, and Moyamoya disease—should be considered. ICAS is one of the most common causes of stroke worldwide and has been associated with an increased risk of recurrent stroke. The potential sequelae of this condition were relatively underappreciated until noted in brain biopsy studies, cerebral angiographic studies in racially mixed populations, and the extracranial-intracranial bypass trial.[95-98]

In the United States, ICAS causes approximately 100,000 strokes each year. Worldwide, 20 to 40 individuals per 100,000 are affected yearly.[99] The true burden of the condition might be considerably underappreciated. Several multiracial studies have focused on symptomatic individuals and have noted that the condition extensively affects Asians, accounting for 20% to 50% of strokes in Chinese, Korean, Thai, and Japanese populations. ICAS also accounts for approximately 5% to 10% of strokes in Caucasians, and 15% to 29% of TIAs in African Americans, Additional studies indicate that a large proportion of strokes in the Hispanic population are attributable to ICAS.[95,100-103]

These studies show that the lack of prevalence studies among asymptomatic patients in highly affected racial populations might explain the underestimation of the true burden of this condition on a global scale. Furthermore, genetic, environmental, and lifestyle influences likely play roles in the development of ICAS. Finally, it should be noted that subanalyses of the Warfarin-Aspirin Symptomatic Intracranial Disease (WASID) study have demonstrated that women with symptomatic ICAS are at higher risk for recurrent stroke, leading to death.[104]

Pathophysiology and Risk Factors

Hypertension, smoking, and other risk factors culminate in endothelial injury and increased vascular permeability. Subsequent monocyte and lymphocyte adhesion to damaged endothelium causes white blood cell migration into the surrounding subendothelial tissue. Macrophage activation and cytokine and growth factor release induce smooth muscle cell migration and proliferation. Fibrous cap formation occurs next, covering the leukocyte, lipid, and necrotic mass; cap rupture leads to platelet aggregation and the formation of emboli. The vascular changes create turbulent flow, creating flow separation and oscillatory shear stress that propagates endothelial and arterial wall damage. Ultimately luminal stenosis and the generation of emboli result in ischemic stroke due to tissue hypoperfusion.[105]

Modifiable risk factors include hypertension, smoking, diabetes mellitus, and dyslipidemia.[106] Nonmodifiable risk factors include race, age, and a variety of genetic variations (angiotensin converting enzyme polymorphisms, increased plasma endostatin/vascular endothelial growth factor, plasma homocysteine levels, glutathione S-transferase omega-1 gene polymorphism).[103] Interestingly, Turan et al. noted that the location of intracranial stenosis varied based on the patient's risk factors and demographics; this implies some type of pathophysiologic difference among the typically affected intracranial arteries.[106]

Diagnosis

Catheter digital subtraction angiography is the gold standard due to its ability to quantify precisely the degree of intracranial luminal stenosis.[107] The benefits of the modality include excellent visualization of the intracranial vasculature; however, recent commentary has raised the question of whether it is actually superior to CTA with respect to visualization of the posterior circulation in low-flow conditions. The limitations include the high operator skill required and the fact that intra-arterial catheterization has led to increased morbidity and mortality.[108] Given these considerations, the modality is best used for in patients when considering endovascular intervention and not as a screening tool.

There is currently a shift toward the use of noninvasive or minimally invasive neuroimaging techniques, including transcranial Doppler (TCD) ultrasound, MRA, CTA, and high-resolution MRI owing to their noninvasive nature and reduced cost. However, limitations have been explored in the Stroke Outcomes and Neuroimaging of Intracranial Atherosclerosis (SONIA) trial. This study found that both TCD and MRA can identify 50% to 99% intracranial stenosis noninvasively with a high negative predictive value (86% and 91%,

respectively). However, the positive predictive value was far lower (36% and 59%, respectively).[107] The conclusion from this study is that these modalities should be used in tandem with formal arteriography. The former two methods are better for screening purposes, but the latter should still be primarily employed for confirmatory diagnosis or intervention.

Treatment

Medical therapy for ICAS is limited to antiplatelet treatment; its use was first reported in the treatment of symptomatic ICAS in 1955.[109] Since then, a number of trials have been conducted to determine the efficacy of recurrent stroke prevention in symptomatic patients.

The Warfarin and Aspirin for Symptomatic Intracranial Arterial Stenosis (WASID) trial in 2005, a double-blind randomized trial comparing the efficacy of aspirin versus warfarin, determined that there was no statistically significant benefit from warfarin over aspirin for stroke or death prevention in ICAS patients. It was noted that a high risk of recurrent stroke existed for patients on medical therapy alone.[110] The Clopidogrel plus Aspirin for Infarction Reduction (CLAIR) study in 2010 found that the combination therapy of clopidogrel and aspirin was more effective than aspirin alone in the reduction of microemboli formation (relative risk reduction of 42.4%).[111] The Stenting versus Aggressive Medical Therapy for Intracranial Arterial Stenosis (SAMMPRIS) study was conducted to compare the benefits of medical treatment with intracranial endovascular treatment. Medical management with aspirin and clopidogrel (followed by aspirin alone) was better than medical management plus angioplasty and stenting using the Wingspan stent system.[112] Of note in this study is the lower stroke recurrence rates in the medically treated group, which also highlighted the benefits of dual antiplatelet therapy compared with aspirin alone.

Despite the results of these studies, surgical and endovascular interventions have shown promise in the prevention of recurrent stroke. Medical management alone does not produce optimal results, as supported by the high rates of recurrent stroke risk in the WASID trial and the short-term ability of using dual antiplatelet therapy (considering the risk of hemorrhage).

Surgical treatment for ICAS was introduced in the 1960s and was popular until the EC/IC bypass study group demonstrated that extracranial-intracranial anastomosis was not efficacious in preventing stroke in carotid and middle cerebral arterial atherosclerotic disease as compared with aspirin therapy.[98]

Endovascular intervention has generated interest in the treatment of ICAS. In 2005, the US Food and Drug Administration (FDA) approved the Wingspan self-expanding nitinol stent designed for use in the cerebral vasculature in the treatment of ICAS. Initially, its use was limited to patients with greater than 50% stenosis, but in 2012, the usage was again further restricted to patients with 70% to 99% stenosis and recurrent stroke despite medical management. This change was linked to the following reported data. In 2007, a US multicenter study using the Wingspan stent system found that angioplasty and stenting for symptomatic ICAS had high technical success rates, with a pretreatment degree of stenosis of 74.6% improving to 43.5% after angioplasty and 27.2% after stenting. However, there was a 6.1% periprocedural rate of neurologic complications, 80% of which resulted in death within 30 days.[113] In 2008, the National Institutes of Health (NIH) Wingspan registry, which was limited to data from patients with 70% to 99% stenosis, found similar rates of technical success, with greater improvement of stenosis (82% to 20%).[114] These findings were the catalyst for the 2011 SAMMPRIS trial, which, as noted earlier, found that aggressive medical management was indeed still more effective than treatment with the Wingspan stent in reducing 30-day rates of stroke or death.[112] Nevertheless, as endovascular techniques continue to be refined, there is a possibility that endovascular treatment may confer greater benefits to patients than medical treatment, especially in the case of severe stenosis. Currently medical treatment remains the treatment of choice.

INTRACRANIAL ANEURYSM WITH EXTRACRANIAL CAROTID STENOSIS

Background and Epidemiology

Intracranial aneurysms are often asymptomatic and undetected (Fig. 96.6); when patients present, it is most often acutely with a subarachnoid hemorrhage.[115] Based on current guidelines, treatment of unruptured intracranial aneurysms should be via surgical clipping or endovascular coiling to prevent potential hemorrhage. The appropriate management when unruptured aneurysms exist concomitantly with extracranial carotid stenosis presents a more complex situation. Debate exists regarding the treatment approach for the conditions in tandem.

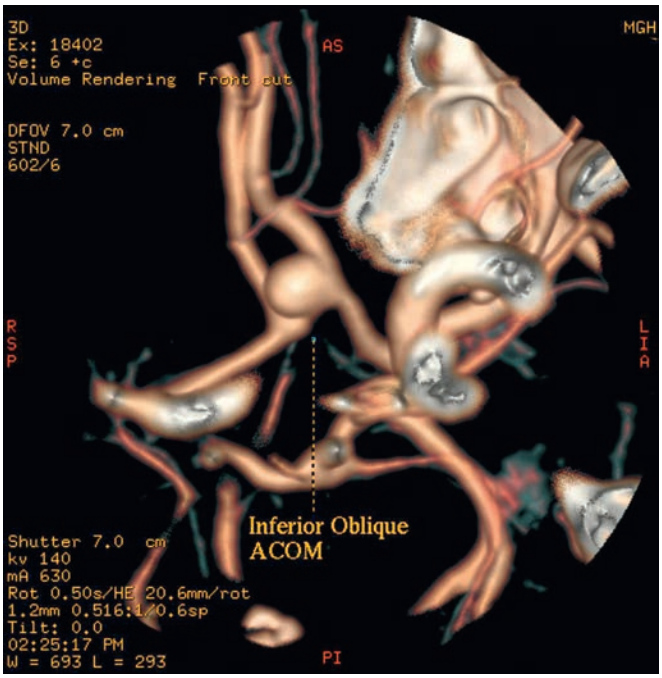

Figure 96.6 CTA reconstruction in the inferior oblique orientation of an intracranial aneurysm of the anterior communicating artery *(ACOM)*.

There is a low prevalence of carotid stenosis presenting with intracranial aneurysm (3.2% based on a literature review of 4251 patients), and most cases are diagnosed during imaging to assess the degree of stenosis in symptomatic carotid arteries.[116] Studies of the prevalence of intracranial aneurysms in healthy populations note the prevalence to be approximately 1.8%.[117] There are several reasons postulated as to why the incidence of ICA in patients with carotid stenosis may be increased as compared with the general population. Confounding factors among studies, such as age and sex, may account for rate disparities between healthy populations and those with carotid stenosis. The two conditions clearly do share several risk factors, including but not limited to age, hypertension, and tobacco use.[118]

Treatment and Management

The hemodynamic relationship between the conditions when they coexist underlies the continuing controversy regarding appropriate management. If one chooses to treat severe carotid stenosis prior to the ipsilateral intracranial aneurysm, several changes can occur within the cerebral vasculature. Given that carotid stenosis typically occurs progressively over a period of time, the intracranial vasculature can demonstrate compensatory vasodilation. With acute treatment and revascularization of the carotid artery, the subsequent increase in cerebral blood flow and pressurization can lead to shear stress on the aneurysm's wall, with resulting rupture.[119,120] This is one potential argument against addressing ipsilateral carotid stenosis first, especially in a multiprocedure treatment plan spaced across several weeks.

If aneurysm repair is conducted first with the patient under general anesthesia, there are also potential perioperative complications. These include hypoperfusion due to the ipsilateral carotid stenosis, which can lead to hypoxia and stroke. Additionally, endovascular access to the aneurysm itself may be challenging, and movement of the coiling device through the stenotic carotid plaque can lead to thromboembolic events.[121]

The following factors should be considered in considering treatment of patients with symptomatic carotid stenosis and asymptomatic intracranial aneurysm. In the literature, there is no conclusive evidence suggesting that all intracranial aneurysms must be treated.[115] Size and location are key factors involved in aneurysm risk and should be considered with an endovascular approach. Life expectancy is an important factor as well. One study noted that in patients with a remaining life expectancy that was less than 15 to 35 years or those who were aged 45 to 70, repair of aneurysms smaller than 7 mm in the anterior circulation conferred no significant benefit when considering surgical risk. The treatment of symptomatic carotid stenosis is appropriate based on current guidelines, but again, one should consider the potential intracranial hemodynamic changes that may incurred as a result when deciding on the appropriate approach to a particular patient.[122]

As noted earlier, there is no consensus on the treatment of choice in concomitant lesions. Recent studies discuss a variety of approaches to this clinical scenario. Single-stage endovascular treatment may be considered with stenting of the carotid stenosis performed prior to coiling of the aneurysm. The major concern with this approach is the loss of a potentially protective effect of carotid stenosis on an ipsilateral intracranial aneurysm, which could result in postoperative cerebral hyperperfusion.[121,123] However, one study indicates that close monitoring of blood pressure could reduce risks associated with sudden changes in cerebral blood flow.[124] At the same time, the risk of acute carotid stent thrombosis secondary to the trauma of subsequent catheter manipulation during secondary aneurysm treatment should be considered. Even with these potential complications, the benefits of single-stage treatment include reduced cost to the patient as well as reduced time of aneurysm exposure as well as increased perfusion after carotid revascularization. Furthermore, stenting before coiling facilitates aneurysmal access and decreases the risk of thromboembolism from stenotic plaque rupture.

The opposite sequence of treatment during endovascular management may also be considered. Endovascular coiling for aneurysm repair followed by carotid stent placement was conducted by Iwate et al. in a single elderly female patient.[125] The rationale for aneurysm coiling proport to stenting was based on the aneurysmal sac pressure being equivalent to mean systolic blood pressure. Therefore this procedure purported to decrease the risk of turbulence during proximal carotid stenosis treatment, which might cause the aneurysm to rupture; this is a potential choice in dealing with large aneurysms in locations of high shear stress. In this case report, both lesions underwent successful treatment over a 1-month period with no complications or stroke. Given that this occurred in an elderly female, a patient at higher risk for stroke complications, this may suggest support for staged endovascular treatment. It should be noted again that this procedure was successfully performed in only one patient and that operator experience and other unknown factors could have led to the favorable outcome.

Based on the current literature, no single treatment can be advocated above others. The benefits of aneurysm treatment versus carotid stenosis treatment must be balanced based on the degree of risk associated with each individual lesion as well as the patient profile.

CEREBRAL VASCULITIS

Background and Epidemiology

Vasculitis is blood vessel inflammation that occurs due to a heterogeneous set of etiologies. Due to the variety of patterns, classification systems focus on identifying the origin of pathology (immunologic, infectious, neoplastic, etc.), vessel size, presence of granulomas or vessel wall necrosis, and the involvement of peripheral or cerebral vessels. Vasculitis affecting the cerebral vessels is a rarer condition than systemic vasculitis, as evidenced by the annual incidence of 1 to 2 per million in the former compared with 39 per million in the latter.[126]

Presentation and Diagnosis

Cerebral vasculitis can be a mild to potentially life-threatening disease entity given the clinical and pathologic presentation,

which can be acute, subacute, chronic, or relapsing-remitting. Specific symptoms depend on the vessels affected and can include headaches, seizures, cranial nerve neuropathies, encephalopathy, ischemic stroke, intracranial hemorrhage, cognitive changes, and aseptic meningoencephalitis.[127] These features, along with lab testing, can aid in diagnosis. Diagnostic examinations include electroencephalography and cerebrospinal fluid (CSF) analysis (detecting pleocytosis and intrathecal immunoglobulin synthesis). Imaging studies including conventional digital subtraction angiography, MRA, and CTA are also critical to ascertain the degree of cerebral involvement. However, all of these studies remain secondary to histopathologic examination, which is the gold standard and is required for definitive diagnosis.[128]

Treatment

Vasculitides that may include the cranial arteries include Takayasu arteritis, Wegener granulomatosis, and temporal lesions. As with other central nervous system (CNS) vasculitides, ischemia may result in neurologic functional loss; this can be due to frank luminal obstruction or proinflammatory cytokines that result in increased coagulation on the endothelial surface. Generally the lesions are nongranulomatous in nature.[129] Patients of all ages can be affected, but the majority are between 40 and 60 years of age.[130] Potential therapies include the use of glucocorticoids, which are also used in other small, medium, and large cerebral vasculitides. However, in the case of systemic vasculitis with CNS involvement, revascularization procedures should be considered when extracranial arteries or proximal intracranial vessels are diseased.[131]

LACUNAR INFARCTS

Background

Lacunar infarcts were first described by Dechambre in 1838 in identifying subcortical regions of softening on brain autopsy.[132] They are currently defined as noncortical infarcts resulting from single penetrating branch occlusion of larger cerebral arteries; infarct diameters can range from 0.2 to 15 mm, with the size of lacunae potentially correlating to clinical features.[133] Risk factors for lacunar infarct are similar to those for ischemic stroke and include hypertension, cardiac disease, smoking, high levels of low-density lipoprotein cholesterol, and age.[134] These insults account for 20% of ischemic strokes and are mostly asymptomatic.[135] If symptomatic, the most common presentations are as follows: motor hemiparesis, aphasia, dysarthria, change in level of consciousness, mutism, and sensorimotor dysfunction.[134]

Pathophysiology

Lacunar infarcts most often affect the putamen, pallidum, pons, thalamus, internal capsule, corona radiate, and caudate nucleus. These are regions where the collateral circulation is typically limited. The pathophysiology for these infarcts is currently postulated as involving one of two potential mechanisms. The first posits that chronic hypertension or uncontrolled diabetes results in arterial media thickening due to fibrinoid deposition and smooth muscle hypertrophy, ultimately resulting in localized ischemia. The second notes that parental artery intimal plaques can result in penetrating artery obstruction. Both result in focal brain ischemia and edema due to blood-brain barrier damage.[136]

Diagnosis

The differential diagnosis should include intracranial hemorrhages, infections (syphilis and cysticercosis), tumors, cerebral vasculitis, and cardiac emboli. Imaging studies are often employed, with CT and MRI being the most common. The Stroke Data Bank found that CT scans identified only 35% of lesions in lacunar stroke patients, whereas MRI was found to identify at least one lacuna correlating with signs and symptoms in 73 patients out of 100.[137,138] However, a direct comparison between the sensitivity of CT versus MRI is not truly feasible between these studies given that CT is often performed sooner than MRI after symptom onset.

Treatment

Medical therapy is similar to other nonhemorrhagic stroke management, with current guidelines indicating administration of intravenous tissue plasminogen activator within 3 hours of stroke onset.[139] Preventative treatment should focus on attenuating medical conditions that contribute to increased stroke recurrence. Surgically, carotid endarterectomy is indicated for lacunar stroke, with patients with 70% stenosis or greater in the ipsilateral internal carotid artery achieving the most benefit. A relatively low perioperative risk of stroke and death has been reported (1.5% to 5.6%), but a higher number needed to treat (83 individuals) to prevent one stroke in 2 years has also been noted.[140]

SELECTED KEY REFERENCES

Kerr SR, Pearce MS, Brayne C, Davis RJ, Kenny RA. Carotid sinus hypersensitivity in asymptomatic older persons: implications for diagnosis of syncope and falls. *Arch Intern Med*. 2006;166:515–520.

Carotid sinus hypersensitivity is quite common (up to 40%) in older persons, many of whom may not have had overt symptoms including syncope and falls. Its finding on physical examination should be investigated.

Romme JJ, Reitsma JB, Black CN, et al. Drugs and pacemakers for vasovagal, carotid sinus and situational syncope. *Cochrane Database Syst Rev*. 2011;(10):Cd004194.

Forty-six randomized controlled trials on vasovagal syncope (n = 40) and carotid sinus syncope (n = 6) were evaluated. Most studies were small and results varied, with no consensus. Thus there is limited evidence to recommend any specific pharmacologic treatment or pacemaker placement without larger randomized and standardized trials.

This is a good overview of Moyamoya disease, populations at risk, and diagnostic criteria.

Kim T, Oh CW, Bang JS, Kim JE, Cho WS. Moyamoya disease: treatment and outcomes. *J Stroke*. 2016;18:21–30.

Surgical revascularization for moyamoya disease is described as well as postoperative complications.

Koskas F, Bahnini A, Walden R, Kieffer E. Stenotic coiling and kinking of the internal carotid artery. *Ann Vasc Surg*. 1993;7:530–540.

This study is a relatively large (174 procedures in 166 patients) retrospective single-center outcomes study of carotid reconstructions for stenotic coiling and kinking of the internal carotid artery. Most cases were symptomatic and associated with other carotid artery lesions such as occlusive disease or fibromuscular dysplasia.

Togay-Isikay C, Kim J, Betterman K, et al. Carotid artery tortuosity, kinking, coiling: stroke risk factor, marker, or curiosity? *Acta Neurol Belg*. 2005;105:68–72.

This study evaluated ultrasound findings related to carotid abnormalities including kinking, coiling, and tortuosity and found no relationship to stroke or atherosclerotic lesions. The authors conclude that these abnormalities are more of a curiosity than a risk factor for stroke or atherosclerotic disease.

Ballotta E, Thiene G, Baracchini C, et al. Surgical vs medical treatment for isolated internal carotid artery elongation with coiling or kinking in symptomatic patients: a prospective randomized clinical study. *J Vasc Surg*. 2005;42:838–846, discussion 46.

This prospective randomized trial evaluated symptomatic patients with either medical or surgical therapy including carotid artery elongation (straightening). The authors had a lower stroke and transient ischemic attack rate in the surgical arm and thus concluded that there was a benefit to elongation.

Gorelick PB, Wong KS, Bae HJ, Pandey DK. Large artery intracranial occlusive disease: a large worldwide burden but a relatively neglected frontier. *Stroke*. 2008;39:2396–2399.

This is an epidemiologic review of large artery intracranial disease as an important but poorly understood or recognized cause of stroke worldwide.

The EC/IC Bypass Study Group. Failure of extracranial-intracranial arterial bypass to reduce the risk of ischemic stroke. Results of an international randomized trial. *N Engl J Med*. 1985;313:1191–1200.

This large (n = 1377) multicenter randomized clinical trial evaluated the benefit of extracranial-intracranial anastomosis in preventing stroke in patients with symptomatic atherosclerotic disease in the carotid and middle cerebral arteries. There was no additional benefit of surgery over medical management.

Chimowitz MI, Lynn MJ, Derdeyn CP, et al. Stenting versus aggressive medical therapy for intracranial arterial stenosis. *N Engl J Med*. 2011;365:993–1003.

In this NIH-funded trial, the investigators found that for patients with symptomatic intracranial arterial stenosis, aggressive medical management combined with percutaneous angioplasty and stenting was associated with a higher risk of early stroke compared with medical management alone (14.7% vs. 5.8%, P = 0.002). In fact, enrollment was teminated early because of the differential stroke rates.

Heman LM, Jongen LM, van der Worp HB, Rinkel GJ, Hendrikse J. Incidental intracranial aneurysms in patients with internal carotid artery stenosis: a CT angiography study and a metaanalysis. *Stroke*. 2009;40:1341–1346.

This meta-analysis of over 4000 patients with symptomatic internal carotid artery stenosis found a 1% incidence of intracranial aneurysms at a size associated with possible rupture, with women being at higher risk than men. This is a much higher incidence than in the general population, although the authors do not recommend routine screening for intracranial aneurysms in patients with ICA stenosis.

Vindlacheruvu R, Mendelow A, Mitchell P. Risk–benefit analysis of the treatment of unruptured intracranial aneurysms. *J Neurol Neurosurg Psychiatry*. 2005;76:234–239.

Intracranial aneurysms should be repaired when the benefit to life expectancy exceeds the risk of repair. Definitely no repair is indicated for aneurysms less than 7 mm in diameter and outcomes are worse for those located in the anterior circulation.

Berlit P. Diagnosis and treatment of cerebral vasculitis. *Ther Adv Neurol Disord*. 2010;3:29–42.

A review article presenting a thorough synopsis of various large and small cell systemic vasculitides that may involve the cerebral vasculature.

CONCLUSION 1291

The vertebrobasilar system supplies blood to the brain stem, cerebellum, and occipital lobes via paired vertebral arteries. Posterior circulation ischemia is most often the result of the atherosclerotic process involving the vertebrobasilar arteries but may also the related to a number of other vasculidities. Although vertebrobasilar ischemia is less common than ischemic episodes related to internal carotid artery disease, approximately 25% of all ischemic strokes do occur in the distribution of the posterior brain circulation; these events should be diagnosed appropriately as they may be the result of a treatable vasculopathy. For patients who experience vertebrobasilar transient ischemic attacks, disease in the vertebral arteries portends a 22% to 35% risk of stroke over a 5-year period.[1-4] The mortality associated with a posterior circulation stroke is 20% to 30%, higher than that for an anterior circulation event.[5-7]

PATHOGENESIS AND ANATOMY

The surgical anatomy of the paired vertebral arteries has traditionally been divided into four segments: segment V1 includes the origin of the vertebral artery as it arises from the subclavian artery to the point at which it enters the C6 transverse process; segment V2 includes the segment of the artery buried deep within the intertransversarium muscle and the cervical transverse

Abstract

Interventional procedures for symptomatic vertebral artery disease should be considered in when appropriate lesions are encountered and in patients where medical therapy has failed. Open techniques for revascularization of the vertebral artery have proven clinical durability and acceptable surgical morbidity in experienced hands. Endoluminal techniques have yet to deliver on durability benchmarks set by open surgical revascularization. For each individual patient who suffers from medically refractive vertebrobasilar ischemia, practitioners must carefully balance the risks of surgery versus the limitations of endoluminal intervention before recommending intervention.

Vertibrobasilar stroke

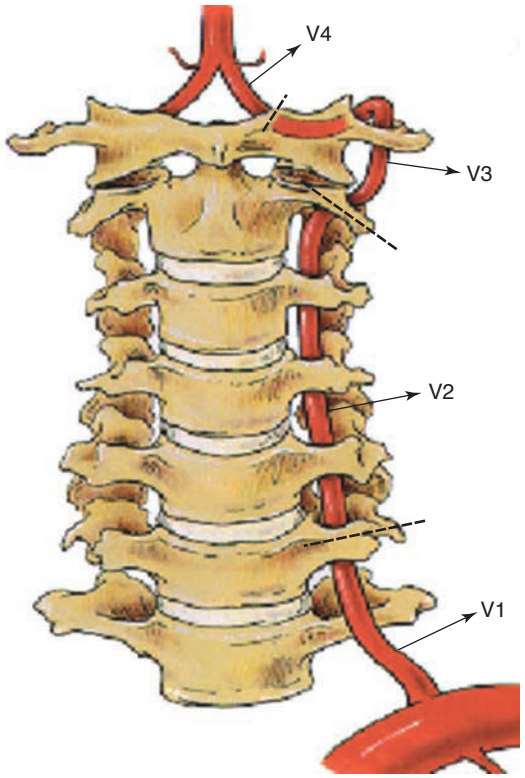

Figure 97.1 The four segments of the vertebral (V) artery. (From Berguer R. Surgical management of the vertebral artery. In: Moore WS, ed. *Surgery for Cerebrovascular Disease*, New York: Churchill Livingstone; 1986.)

processes of C6 to C2; segment V3 includes the segment of the vertebral artery that extends from the top of the transverse process of C2 to the atlanto-occipital membrane at the base of the skull; and segment V4 includes the intracranial, intradural portion of the vertebral artery beginning at the atlanto-occipital membrane and terminating as the two paired vertebral arteries that converge to form the basilar artery (Fig. 97.1).

Ischemia affecting the temporo-occipital areas of the cerebral hemispheres or segments of the brain stem and cerebellum characteristically produces bilateral symptoms. The classic symptoms of vertebrobasilar ischemia are dizziness, vertigo, drop attacks, diplopia, perioral numbness, alternating paresthesia, tinnitus, dysphasia, dysarthria, and ataxia. When patients have two or more of these symptoms, the likelihood of vertebrobasilar ischemia is high (Box 97.1).

Posterior circulation ischemia and strokes occur most commonly in relation to large-artery diseases (Table 97.1), with the vertebral artery being the most common large vessel with occlusive lesions that lead to stroke in this distribution (Table 97.2). The most common disease affecting the vertebral artery is atherosclerosis. Less common pathologic processes include dissection, trauma, fibromuscular dysplasia, Takayasu disease, osteophyte compression, aneurysms, and other arteritides.

Ischemic Mechanisms

In general, the ischemic mechanisms can be broken down into those that are hemodynamic and those that are embolic. In contrast to ischemia resulting from carotid artery occlusive disease, the low-flow hemodynamic mechanism of ischemia is better recognized and more frequent than the embolic one in the case of vertebral artery disease.

Low Flow

Patients with low-flow hemodynamic ischemia have transient symptoms in the cerebral territories supplied by the basilar artery because they lack appropriate inflow from the vertebral

arteries and have inadequate compensation from the carotid artery territory. Hemodynamic symptoms occur as a result of transient end-organ (brain stem, cerebellum, occipital lobes) hypoperfusion and can be precipitated by postural changes or a transient reduction in cardiac output. Ischemia from hemodynamic mechanisms rarely results in tissue infarction. Rather, symptoms are short-lived, repetitive, and more of a nuisance than a danger. Some patients may be prone to traumatic injuries from loss of balance or consciousness, resulting in falls. For hemodynamic symptoms to occur in direct relation to the vertebrobasilar arteries, significant occlusive disease must be present in both paired vertebral vessels or in the basilar artery itself. In addition, compensatory contribution from the carotid circulation via the circle of Willis must be incomplete. Alternatively, hemodynamic ischemic symptoms may result from proximal subclavian artery occlusion and the syndrome of subclavian/vertebral artery steal.

Embolic

Embolic causes of vertebrobasilar ischemia are generally the result of microembolization from the heart or aortic arch or from the subclavian, vertebral, or the basilar artery. Approximately one-third of vertebrobasilar ischemic episodes are caused by distal embolization from plaque or mural lesions of the subclavian, vertebral, or basilar arteries (or any combination of these vessels).[8] Arterial-to-arterial emboli can arise from atherosclerotic lesions, intimal defects caused by extrinsic compression or repetitive trauma, and rarely fibromuscular dysplasia, aneurysms, or dissections. Although fewer patients suffer from embolic phenomena than from hemodynamic mechanisms, actual tissue infarction is most often the result of an embolic event. As compared with the hemodynamic mechanisms of ischemia, emboli are much more likely to cause fatal events or debilitating strokes. The importance of the embolic mechanism as a cause of vertebrobasilar symptoms has been emphasized in clinical and anatomicopathologic studies. This information has been derived from autopsy and magnetic resonance imaging (MRI) studies, which have identified small infarcts in the brain stem and cerebellum and shown their source, via arteriography, to be lesions in the subclavian or vertebral arteries. As opposed to patients with hemodynamic symptomatology, multiple and multifocal infarcts in the brain stem, cerebellum, and occasionally the posterior cerebral artery territory more often develop in patients with embolic ischemia.[9,10]

DISEASE DISTRIBUTION

V1 Segment

The most common atherosclerotic lesion of the vertebral artery is stenosis of its origin. The prevalence of such lesions is approximately 20% to 40% in patients with cerebrovascular disease.[8] The atherosclerotic lesions are usually smooth and fibrotic and have low embolic potential. Redundancy and kinks are also common in the V1 segment, but only very severe kinks associated with poststenotic dilatations can be responsible for hemodynamic symptoms.

V2 Segment

The most common pathology of the V2 segment is extrinsic compression by either bone or tendon. Compression can be caused by osteophytes,[11] the edges of the transverse foramina (Fig. 97.2), or the intervertebral joints. Rotation or extension

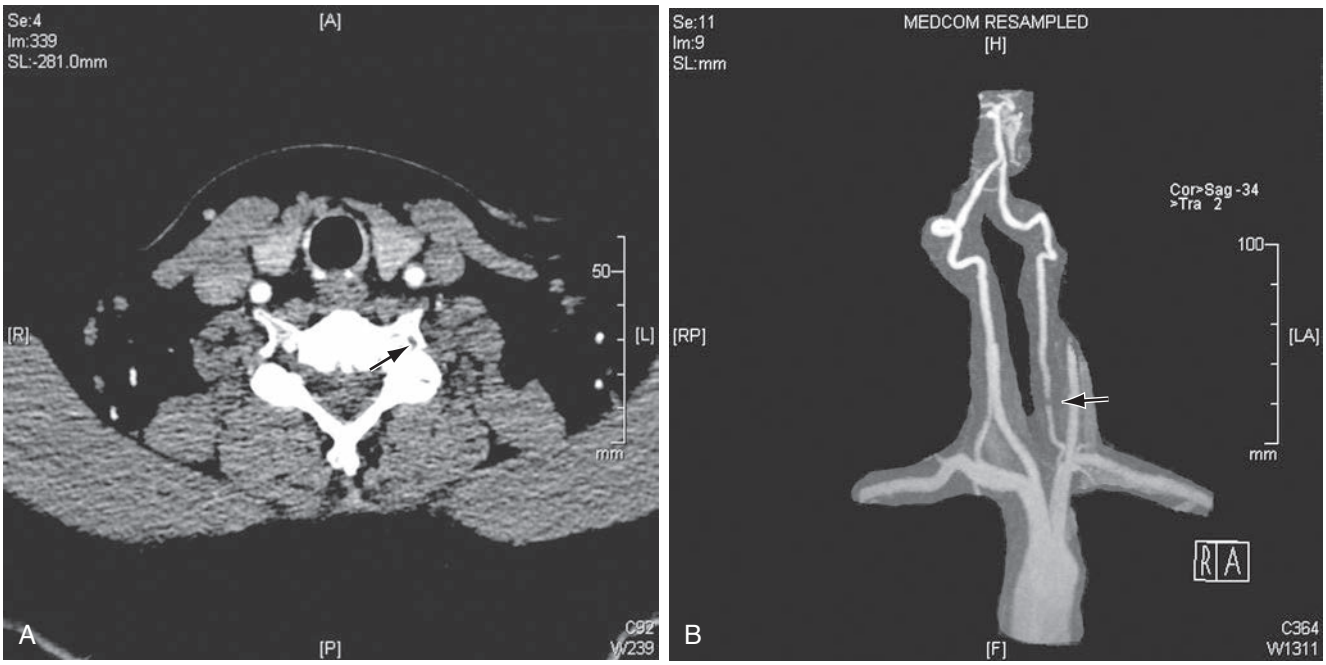

Figure 97.2 Computed tomography (CT) (A) and magnetic resonance angiography (MRA) (B) images demonstrating large osteophytes occluding the vertebral artery at C5.

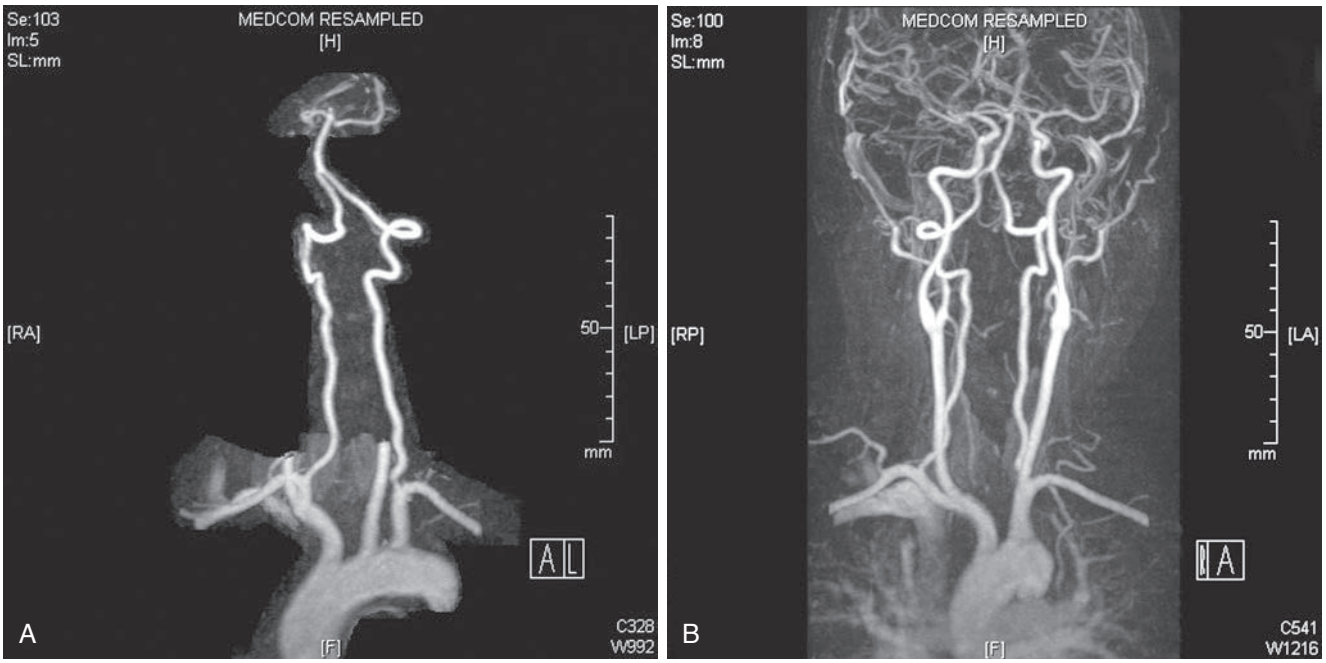

Figure 97.3 (A) Vertebral magnetic resonance angiography (MRA) (with the carotid image subtracted). (B) Arch and four-vessel MRA.

of the neck usually triggers compression of the vertebral artery in this segment. Extrinsic vertebral artery compression by musculotendinous structures is common in patients with an abnormally high level of entry into the transverse processes of the spine, usually C4 or C5, due to the sharp angulation resulting from the abnormal level of entry (Fig. 97.3).

The V2 segment is a frequent site for the development of traumatic or spontaneous arteriovenous fistulas. Fistulas occur in the V2 segment because fixation of the adventitia of the vertebral artery to the periosteum of the foramina makes the former vulnerable to luxation/subluxation injuries. The close proximity of the artery to its surrounding venous plexus results in an arteriovenous fistula when the artery and vein are damaged in continuity. The vertebral artery may tear completely or incompletely (dissection) as a consequence of stretch injury after brisk rotation or hyperextension of the neck.

Although most vertebral artery aneurysms occur intracranially, the V2 segment is the most common site of extracranial aneurysmal degeneration (Fig. 97.4). Two-thirds of all extracranial vertebral artery aneurysms involve the V2 segment, and most form as pseudoaneurysms secondary to trauma or dissection.[12] True degenerative extracranial vertebral artery aneurysms are rare, accounting for less than 1% of all vertebral artery lesions.[13] In one review, all patients with a true extracranial vertebral artery aneurysm had some form of connective tissue disorder.[12] Most extracranial vertebral aneurysms are asymptomatic and found incidentally. Some present with symptoms that can include a palpable neck mass, dizziness, headaches, and/or neurologic deficit from cerebral ischemia or nerve compression. Rupture is rare. Because the natural history is unknown, vertebral ligation with or without reconstruction is most often recommended for large extracranial vertebral aneurysms.[12]

Figure 97.4 V2 segment true aneurysm *(arrow)* in a patient with connective tissue disorder. Also note the left common right subclavian and right external carotid aneurysms.

In addition to aneurysms and fistulas, dissection, fibromuscular disease, arteritis, and embolizing atherosclerotic plaque can be identified in the V2 segment. Disease in the second segment of the vertebral artery can result in extracranial occlusion or stenotic lesions in the intraforaminal segment, which commonly give rise to emboli.

V3 Segment

The most common problems at the V3 level are related to trauma and arterial dissection; they include occlusive lesions, arteriovenous fistulas, and pseudoaneurysms. Extracranial

Figure 97.5 Intramural dissection of the vertebral artery at the V3 segment in a 40-year-old woman with Klippel-Feil syndrome and subluxation of the atlantoaxial joint.

Figure 97.6 Distal V2 segment pseudoaneurysm resulting from dissection.

vertebral artery dissection occurs most commonly in the V3 segment because the artery is most mobile in this location and therefore vulnerable to mechanical injury. The first two cervical vertebrae are the most mobile of the spine. Approximately 50% of neck rotation occurs between C1 and C2. The vertebral artery is redundant at this level to allow the arc of displacement of the transverse process of the atlas (80 degrees), to which the vertebral artery is attached. Clinically, extracranial vertebral dissection may present with severe occipitocervical neck pain with associated dizziness, vertigo, double vision, ataxia, and dysarthria.[14] Dissection may be associated with fibromuscular dysplasia; it can also occur in a normal artery after seemingly trivial trauma (Fig. 97.5). Vertebral artery dissection often follows hyperextension or rotation of the neck and has been associated with, among other activities, practicing yoga, painting a ceiling, coughing, vomiting, sneezing, and cervical chiropractic manipulation.[15,16] Vertebral dissection is rare, with an overall incidence of 1 per 100,000, but it is a significant cause of stroke in a young and otherwise healthy population.[17] In one study, 62% of dissections observed serially with angiography went on to heal with complete resolution.[18] The remaining dissections went on to vessel occlusion, remained stenotic, or developed pseudoaneurysmal dilation and/or AV fistulas (Fig. 97.6). One-half of the patients diagnosed with extracranial vertebral artery dissection will develop no neurologic symptoms, whereas 21% will experience mild neurologic sequelae, 25% will suffer moderate to severe deficits, and 4% will die.[19] Notably, there appears to be no relationship between recanalization rates and neurologic outcome.[20]

An arteriovenous fistula results from rupture of the wall of the vertebral artery into its surrounding venous plexus. In long-standing fistulas, the pulsatile mass formed by the fistula and its dilated venous channels is called an arteriovenous aneurysm.

The vertebral artery may be compressed in the pars atlantica of the third segment between the occipital ridge and the arch of the atlas. In these patients the symptoms of low-flow posterior circulatory systems are usually precipitated by head extension or rotation. The V3 segment is rarely affected by significant atherosclerosis.

When the vertebral artery is occluded proximally in the V1 or V2 segments, it usually reconstitutes at the V3 segment by forming collateral blood vessels from the external carotid via the occipital artery (Fig. 97.7) or collaterals from the ipsilateral subclavian artery via branches of the thyrocervical trunk (Fig. 97.8).[21] Because of this collateral network, the distal vertebral and basilar arteries usually remain patent despite a proximal vertebral artery occlusion. This anatomic finding is crucial for developing the appropriate surgical strategy.

V4 Segment

Similar to the V3 segment, the fourth segment (V4) is infrequently affected by atherosclerosis. This segment is also prone to arteriovenous fistula formation and aneurysmal degeneration. Advanced atherosclerotic disease of the basilar artery is generally a contraindication to the reconstruction of vertebral artery lesions.

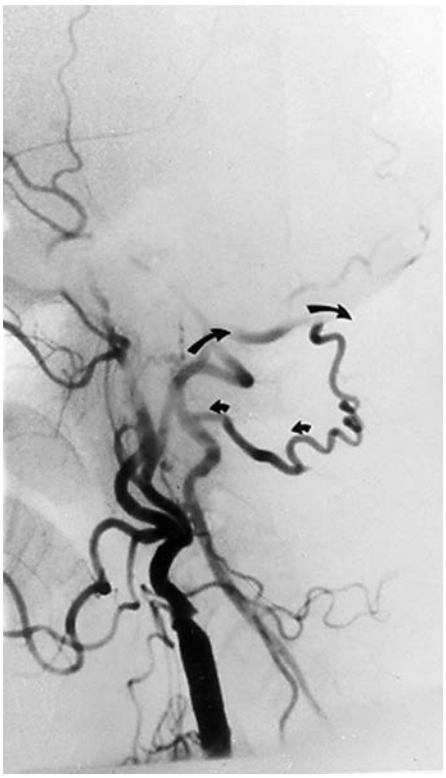

Figure 97.7 The distal vertebral and basilar arteries being fed by an occipital artery collateral in a patient with proximal vertebral artery occlusion.

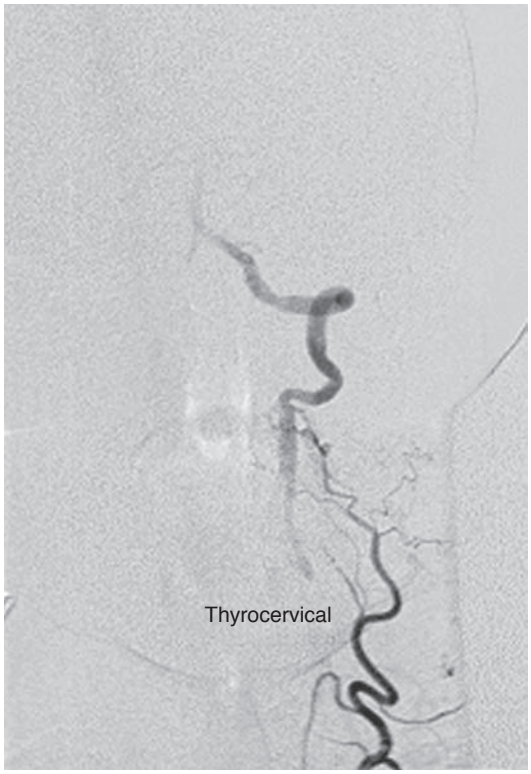

Figure 97.8 The distal vertebral and basilar arteries fed by a thyrocervical trunk collateral in a patient with proximal vertebral artery occlusion.

PATIENT SELECTION FOR VERTEBRAL ARTERY RECONSTRUCTION

Anatomic Considerations

The minimal anatomic requirement to justify vertebral artery reconstruction for hemodynamic symptoms would be greater than 60% diameter stenosis in both vertebral arteries if both are patent and complete or the same degree of stenosis in the dominant vertebral artery if the opposite artery is hypoplastic, ends in a posteroinferior cerebellar artery, or is occluded. A single normal vertebral artery is typically sufficient to adequately perfuse the basilar artery regardless of the patency status of the contralateral vertebral artery. Unlike carotid artery disease, the mere presence of vertebral artery stenoses in an asymptomatic patient would not be an indication for reconstruction because these patients are well perfused from the contralateral vertebral or the carotid circulation through the posterior communicating vessels.

Etiologic Considerations

Low Flow

For patients with hemodynamic symptoms, it is essential to rule out systemic causes of ischemia before advising evaluation of the vertebrobasilar arteries as the definitive etiology. In the later years of life, vertebral artery stenosis is a frequent arteriographic finding and dizziness in the elderly is a common complaint. The presence of both cannot necessarily be assumed to have a cause-effect relationship. The indication for intervention in patients with hemodynamic symptoms depends on the ability to demonstrate insufficient blood flow to the basilar artery. Other common systemic causes of hemodynamic ischemia, aside from vascular occlusion, include orthostatic hypotension, poorly regulated antihypertensive therapy, arrhythmias, heart failure, malfunction of pacemakers, and anemia.

Embolic

In contrast to individuals with low-flow states, patients who present with posterior circulation ischemia secondary to embolization from lesions in a vertebral or subclavian artery should be considered for medical or surgical treatment regardless of the status of the contralateral artery. Surgical or endoluminal intervention is warranted if medical treatment fails. Surgical intervention is not indicated in asymptomatic patients who present only with radiographic findings.

Patients who present with nonatherosclerotic lesions such as aneurysm, dissections, and fistulas may also be considered as potential candidates for vertebral artery reconstruction depending upon their presentation.

Differential Diagnosis

The identification of patients who could benefit from vertebral artery reconstruction begins with an accurate assessment of the symptom complex, followed by efforts to exclude other causes of the symptoms (Box 97.2). These other medical conditions

BOX 97.2 Routine Testing for the Potential Diagnosis of Vertebrobasilar Ischemia

Cardiology consultation
Echocardiography
Holter monitoring
Medication review

BOX 97.3 Nonvascular and Cardiac Conditions That Cause or Mimic Vertebrobasilar Ischemia

Cardiac arrhythmia
Pacemaker malfunction
Cardioemboli
Labyrinthine dysfunction
Tumors of the cerebellopontine angle
Use of antihypertensive medications
Cerebellar degeneration
Myxedema
Electrolyte imbalance
Hypoglycemia

commonly include inappropriate use of antihypertensive medications, cardiac arrhythmias, anemia, brain tumors, and benign vertiginous states. A thorough investigation consists of ruling out (1) inner ear pathology, (2) cardiac arrhythmias, (3) internal carotid artery stenosis/occlusion, and (4) inappropriate use of medications (Box 97.3).

The evaluation of patients with posterior circulation ischemia should include assessment of the precise circumstances associated with the development of symptoms. Any systemic mechanism that decreases the mean pressure of the basilar artery may be responsible for hemodynamic symptomatology, and affected individuals may or may not have concomitant vertebral artery stenosis or occlusion. Symptoms from orthostatic hypotension often appear upon standing in older individuals with poor sympathetic control of their venous tone. This causes excessive pooling of blood in the veins of the leg and resulting transient hypotension. A drop of 20 mm Hg in systolic pressure on rapid standing is a criterion for the diagnosis of orthostatic hypotension causing low flow in the vertebrobasilar system.

Because certain prescription medications can mimic vertebrobasilar ischemia, patient medications require thorough review. In fact, excessive use of antihypertensive medications is the most common etiology of posterior circulation symptoms and can also cause hemodynamic posterior circulation ischemia by decreasing perfusion pressure and inducing severe orthostatic hypotension.

A cardiac source is the second most common cause of brain stem ischemia, especially in older adults; a thorough evaluation should include 24-hour Holter monitoring for arrhythmias and echocardiography to assess heart valve function. Arrhythmias commonly cause symptoms as a result of decreased cardiac output. In addition, transesophageal echocardiography may be useful in patients with a suspected embolic mechanism of ischemia to rule out a cardiac source.

In some patients, the cause of the drop in mean arterial pressure can be corrected simply by readjusting their antihypertensive regimen, by the administration of antiarrhythmic drugs, or by inserting a cardiac pacemaker. In patients with a combination of orthostatic hypotension and occlusive lesions, the hemodynamic problem may not respond to medical treatment; in such cases only reconstruction of a diseased or occluded vertebral artery will render the patient asymptomatic in the presence of persistent oscillations in blood pressure.

Investigation must also be undertaken to exclude inner ear pathology, including rare tumors of the cerebellopontine angle. In addition, neurologic evaluation to rule out benign vertiginous states should be considered.

When patients present with a combination of anterior and posterior hemispheric symptoms, investigation of the great vessels and the carotid circulation is usually warranted. Significant great vessel or carotid occlusive lesions may warrant reconstruction to alleviate symptoms.

An important aspect of the history is identifying triggering events, such as positional or postural changes. This is followed by a thorough physical examination, which includes palpation, auscultation, pulse examination, and comparative arm blood pressures (recumbent and standing). Physical examination can alert the physician to the possibility of subclavian steal in patients with differences in brachial blood pressure greater than 25 mm Hg or with diminished or absent pulses in one arm. The diagnosis of reversal of vertebral artery flow can be made accurately by noninvasive indirect methods and demonstrated directly by duplex imaging of the reversal of flow in the vertebral artery (see Chapter 88).

Patients may relate their symptoms to turning or extending the head. These dynamic symptoms usually appear on turning the head to one side and are caused by extrinsic compression.[11] To differentiate this mechanism from dizziness or vertigo secondary to labyrinthine disorders that appear with head or body rotation, the patient should attempt to reproduce the symptoms by first turning the head *slowly* and then repeating the maneuver *briskly*, as in shaking the head from side to side. In labyrinthine disease, the sudden inertial changes caused by the latter (brisk) maneuver result in immediate symptoms and nystagmus. Conversely, with extrinsic vertebral artery compression, a short delay occurs before imbalance develops.

Diagnostic Testing

Once a suspicion of vertebrobasilar ischemia has been entertained, only a few diagnostic tests are available to clearly ascertain the vertebral anatomy.

Duplex Ultrasonography

Although duplex ultrasound is an excellent tool for detecting lesions in the carotid artery, it has significant limitations when

it is used to detect vertebral artery pathology. Direct visualization of the second portion of the vessel is difficult because of its intraosseous course through the transverse processes of C2 to C6. The usefulness of duplex ultrasound lies in its ability to confirm reversal of flow within the vertebral arteries and detect changes in flow velocity consistent with a proximal stenosis.[22] In addition, ultrasound imaging can diagnose pathology of the great vessels and confirm subclavian steal.

Computed Tomography and Magnetic Resonance Imaging

MRI is another modality that provides a safe, noninvasive, detailed evaluation of both the extracranial and intracranial vasculature as well as structures within the posterior fossa. Contrast-enhanced magnetic resonance angiography (MRA) with three-dimensional reconstruction and maximum image intensity techniques provides full imaging of the vessels, including the supra-aortic trunks and the carotid and vertebral arteries (see Fig. 97.3). MRA can also diagnose reversal of flow in the vertebral artery.

In contrast to traditional computed tomography (CT) scans, transaxial MRI can readily diagnose both acute and chronic posterior fossa infarcts. Brain stem infarctions are often missed by CT because they tend to be small and the resolution of CT in the brain stem is poor. In patients who are candidates for vertebral artery reconstruction, brain MRI is performed preoperatively to ascertain whether infarctions have taken place in the vertebrobasilar territory. Transaxial MRI is particularly important in patients suspected of having suffered embolic infarction in the distribution of the posterior circulation.

CT angiography can readily identify occlusive lesions and has the advantage of being able to demonstrate significant osteophytic lesions that may impinge on vertebral flow.

Arteriography

Despite the technologic advances in MRI and CT evaluation, selective subclavian and vertebral angiography remains the best imaging modality for the preoperative evaluation of patients with vertebrobasilar ischemia. Some surgeons still consider angiography mandatory before endovascular intervention or surgical reconstruction. Arteriographic investigation of vertebral artery pathology necessitates systematic positions and projections to evaluate the vertebrobasilar system from its origin to the top of the basilar artery. Such an evaluation begins with an arch view, which determines the presence or absence of a vertebral artery on each side. Angiography shows whether one vertebral artery is dominant (generally the left) and can clearly define aberrant vessel anatomy. The most common anomalous origin involves the left vertebral artery, which can originate from the aortic arch in 6% of patients. A much rarer variant involves the right vertebral artery, which can be seen to arise from the innominate or right common carotid artery. This anatomy usually occurs in patients with an aberrant retroesophageal right subclavian artery. Arch views must be obtained in at least two projections: right and left posterior oblique views. Usually these two projections will sufficiently display the first segment (V1) of the vessel from its subclavian origin up to the transverse process of C6. The most common site of disease, the vertebral artery origin, may not be well imaged with ultrasound or MRA and, in fact, can often be displayed only with oblique projections that are not part of the standard aortic arch evaluation. A vertebral origin stenosis may be missed in standard arch views because of superimposition of the subclavian artery over the first segment of the vertebral artery. Additional oblique projections may be needed to "throw off" the subclavian artery to obtain a clear view of the origin of the vertebral artery. The presence of poststenotic dilation in the first centimeter of the vertebral artery suggests that there may be a significant stenosis at its origin hidden by an overlying subclavian artery. Visualization of the second segment (V2) of the vertebral artery, from C6 to the top of the transverse process of C2, is accomplished in the oblique arch views in conjunction with selective subclavian injections. An effort should be made to attempt to angiographically identify the point of entry of the vertebral arteries into the transverse processes of the cervical spine. Whether a patient has an abnormally low entry at the level of C7 instead of C6 should be noted. This finding is associated with a short V1 segment of the artery. In this circumstance, the short extraosseous length can create challenges for reconstruction at the V1 level.

Patients with suspected vertebral artery compression should undergo dynamic angiography, which incorporates provocative positioning. Arteriography is required to demonstrate extrinsic dynamic compression of the vertebral artery. This is performed either with the patient sitting up, by means of bilateral brachial injections, or, if the transfemoral approach is used, with the patient supine in the Trendelenburg position with the head resting against a block. The reason for positioning the patient either sitting up or in a 25-degree Trendelenburg position is to mimic the effects of the weight of the head on the spine. With the patient standing, the weight of the head acting on the cervical spine changes its curvature and decreases the distance between C1 and C7. This longitudinal compression of the spine often enhances the extrinsic compression effects caused by osteophytic spurs. In these positions, intended to exert axial compression on the cervical vertebrae, the angiographer should obtain the specific rotation or extension of the head that provokes the symptoms. When the patient is rendered symptomatic, arteriographic injection should demonstrate the extrinsic compression that developed with the head in rotation or extension.[23] The vertebral artery may be normal in one position and occluded by extrinsic compression in the other (Fig. 97.9). Finally, delayed imaging should be performed to demonstrate reconstitution of the extracranial vertebral arteries through cervical collaterals. Delayed angiographic views are of the utmost importance in identifying a patent V3 segment, which can be exploited as a distal target for revascularization. Finally, the basilar artery should be seen clearly in a lateral projection. Subtracted views are needed to eliminate the temporal bone density in the lateral projection. In the Towne anteroposterior view, routinely used in neuroradiology, the basilar artery is foreshortened and therefore the resolution is poor.

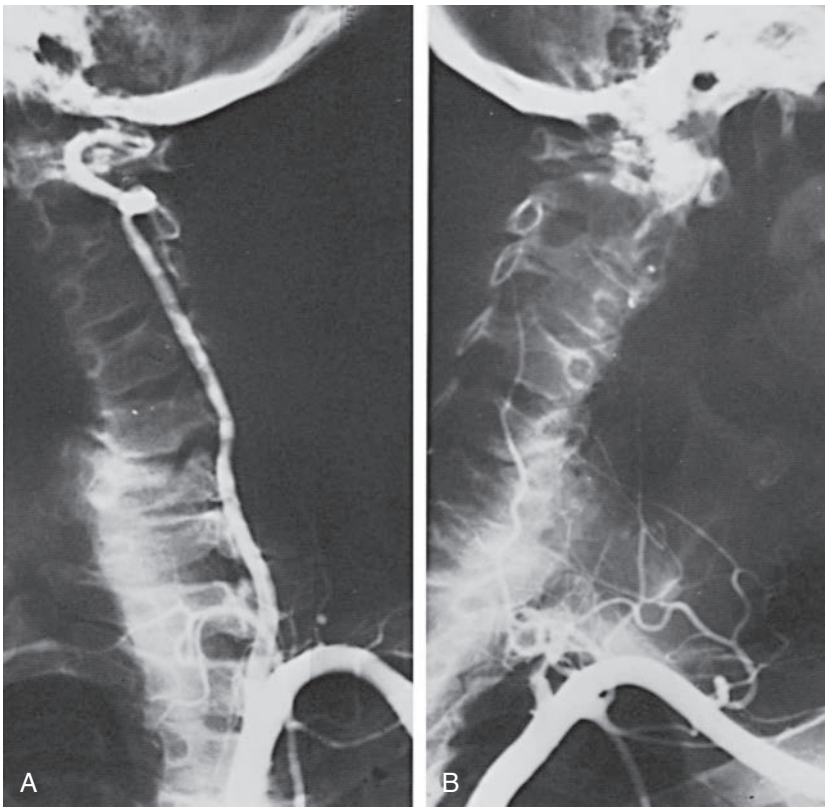

Figure 97.9 A patient with a single vertebral artery showing minimal extrinsic compression (A) when the neck is rotated to the right and occlusion (B) when the neck is rotated to the left. VERTEBRAL ARTERY RECONSTRUCTIVE PROCEDURES

Accumulated experience has shown that with appropriate surgical intervention, predictable resolution of hemodynamic symptoms and cessation of embolic events can occur.

Disease Location

The location of disease will dictate the type of surgical reconstruction that is required. With rare exceptions, most reconstructions of the vertebral artery are performed to relieve an orificial stenosis (V1 segment) or stenoses, dissection, or occlusion of its intraspinal component (V2 and V3 segments).[24]

V1 Segment

Several operations have been described for treating ostial lesions in V1.[25,26] Transposition of the proximal vertebral artery onto the adjacent carotid artery is the most common reconstruction. Less commonly, a bypass using saphenous vein can be performed from either the common carotid artery or the adjacent subclavian artery.[27,28] Alternatively, a subclavian–vertebral artery endarterectomy can be performed, but this operation is fraught with technical challenges.

V2 Segment

Although the second segment of the vertebral artery is the site of a wide variety of pathologic conditions, the V2 segment is rarely accessed surgically due to its interosseous position. The most common indication for exposure of the V2 segment is hemorrhage, which, when untreatable endoluminally, is best managed by proximal and distal ligation of the artery. After complete V2 occlusion, patency of the distal extracranial segment is often maintained by collaterals from the external carotid or subclavian artery. Ligation (at the C1-C2 level) and bypass to the distal (V3 segment) vertebral artery may be indicated for embolizing V2 pathology.

V3 Segment

Reconstruction of the distal (V3 segment) vertebral artery is usually performed at the C1-C2 level. The technique most often used to reconstruct the distal vertebral artery includes saphenous vein bypass from the common carotid, subclavian, or proximal vertebral artery.[21,25] Alternatively, the radial artery can be used as a conduit in the absence of suitable vein. Transposition of the external carotid or hypertrophied occipital artery into the distal vertebral artery, as well as transposition of the distal vertebral artery into the side of the internal carotid artery, has also been described.

Suboccipital Segment

For more distal pathology, the vertebral artery can also be accessed surgically above the level of the transverse process of C1. Surgical exposure at the suboccipital segment requires resection of the C1 transverse process and part of its posterior arch. Reconstruction at this level is limited to saphenous vein bypass from the distal internal carotid artery. Bypasses above the level of C1

(suboccipital) are technically demanding and have been required in only 4% of cases of distal vertebral artery reconstruction.

Transposition of the Proximal Vertebral Artery Into the Common Carotid Artery

The approach to the proximal vertebral artery is the same as the approach for a subclavian-to-carotid transposition. The incision is placed transversely one fingerbreadth above the clavicle and directly over the two heads of the sternocleidomastoid muscle (Fig. 97.10). Subplatysmal skin flaps are created to provide adequate exposure. Dissection is carried down directly between the two bellies of the sternocleidomastoid, and the omohyoid muscle is divided. The internal jugular vein is retracted laterally and the carotid sheath entered. The carotid artery should be exposed proximally as far as possible, which is facilitated if the surgeon temporarily stands at the head of the patient and looks down into the mediastinum. The vagus nerve should be left with the common carotid to prevent traction injury from lateral displacement.

After the carotid artery has been mobilized, the sympathetic chain is identified running behind and parallel to it. On the left side, the thoracic duct is divided between ligatures. Accessory lymph ducts—often seen on the right side—are identified, ligated, and divided. The entire dissection is confined medial to the prescalene fat pad that covers the scalenus anticus muscle and phrenic nerve.

The vertebral vein is next identified emerging from the angle formed by the longus colli and scalenus anticus and overlying the vertebral artery and, at the bottom of the field, the subclavian artery. The vein is ligated in continuity and divided. Below the vertebral vein lies the vertebral artery. It is important to identify and avoid injury to the adjacent sympathetic chain. The vertebral artery is dissected superiorly to the tendon of the longus colli and inferiorly to its origin from the subclavian artery. The vertebral artery is freed from the sympathetic trunk resting on its anterior surface without damaging the trunk or the ganglionic rami. Preserving the sympathetic trunks and the stellate or intermediate ganglia resting on the artery usually requires freeing the vertebral artery from these structures, and after dividing its origin, the latter is transposed anterior to the sympathetics.

Once the artery is fully exposed, an appropriate site for reimplantation in the common carotid artery is selected. The patient is given heparin systemically. The distal portion of the V1 segment of the vertebral artery is clamped below the edge of the longus colli with a microclip placed vertically to indicate the orientation of the artery and to avoid axial twisting during its transposition. The proximal vertebral artery is closed by transfixion with 5-0 polypropylene suture immediately above the stenosis at its origin. The artery is divided at this level and

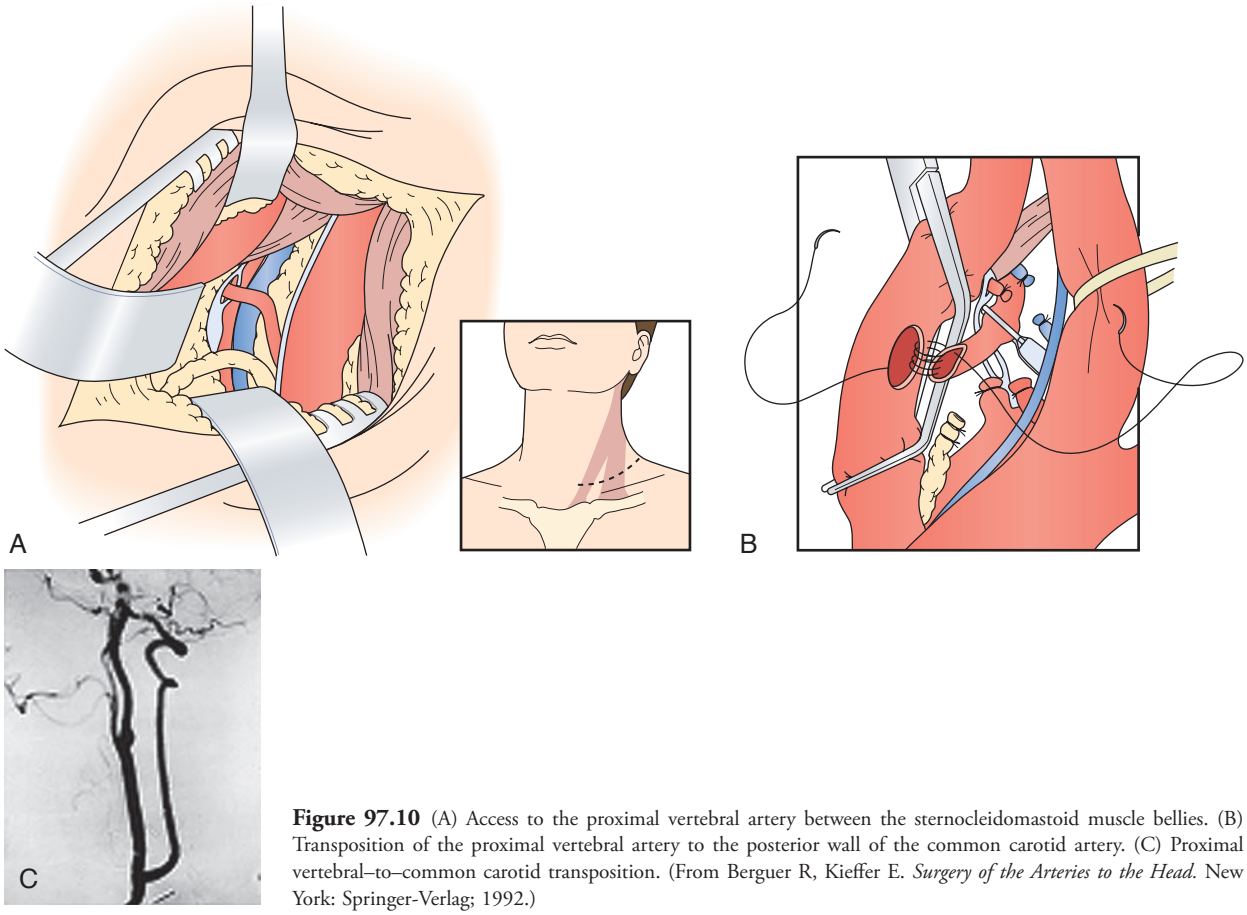

Figure 97.10 (A) Access to the proximal vertebral artery between the sternocleidomastoid muscle bellies. (B) Transposition of the proximal vertebral artery to the posterior wall of the common carotid artery. (C) Proximal vertebral–to–common carotid transposition. (From Berguer R, Kieffer E. *Surgery of the Arteries to the Head.* New York: Springer-Verlag; 1992.)

then brought to the common carotid artery, and its free end is spatulated for anastomosis.

The carotid artery is then cross-clamped. An elliptical 5- to 7-mm arteriotomy is created in the posterolateral wall of the common carotid artery with an aortic punch. The anastomosis is performed in open fashion with continuous 6-0 or 7-0 polypropylene suture while avoiding any tension on the vertebral artery, which tears easily. Before completion of the anastomosis standard flushing maneuvers are performed, and the suture is tied to reestablish flow (Fig. 97.10C).

When simultaneous carotid endarterectomy is planned, the vertebral artery is approached through the standard carotid incision extended inferiorly to the head of the clavicle. With this approach, the sternocleidomastoid muscle is lateral and the field is a bit narrower than when the vertebral artery is approached between the heads of the sternocleidomastoid. The remaining steps of the operation are performed as described previously.[29]

Distal Vertebral Artery Reconstruction

Common Carotid–Vertebral Artery Bypass

Reconstruction of the distal vertebral artery is generally done at the C1-C2 level. Rarely, the reconstruction is done between C1 and the base of the skull via a posterior approach. Although various techniques can be applied to revascularize the vertebral artery in its V3 segment (between the transverse processes of C1 and C2), the approach to the vertebral artery at this level is the same for all procedures.[21,30]

The incision is made anterior to the sternocleidomastoid muscle, the same as for a carotid operation, and is carried superiorly to immediately below the earlobe (Fig. 97.11). The dissection proceeds between the internal jugular vein and the anterior edge of the sternocleidomastoid to expose the spinal accessory nerve. The nerve is followed cranially as it crosses in front of the transverse process of C1, which can easily be felt by the operator's finger. The levator scapulae muscle is identified by removal of the fibrofatty tissue overlying it. With the anterior edge of the levator scapulae identified, the surgeon searches for the anterior ramus of C2. With the ramus as a guide, the levator scapulae is transected from its origin on the C1 transverse process (Fig. 97.12). The C2 ramus divides into three branches after crossing the vertebral artery. The artery runs below, in contact with the nerve and perpendicular to it. The surgeon cuts the ramus (Fig. 97.13) before its branching; underneath it, the vertebral artery can be identified. A small minority of patients may develop noticeable but self-limiting posterior scalp numbness as a result of cutting the ramus. The artery is freed from the surrounding veins with care, as venous bleeding is difficult to control at this level. Before encircling the artery with fine silicone vessel loops (Fig. 97.14), one must ensure that a branch from the occipital collateral artery does not enter the posterior aspect of the vertebral artery at this location. Tearing of this important collateral vessel complicates preparation of the distal vertebral artery. Once the vertebral artery has been encircled, the distal common carotid artery is dissected and prepared to receive a saphenous vein graft. There is

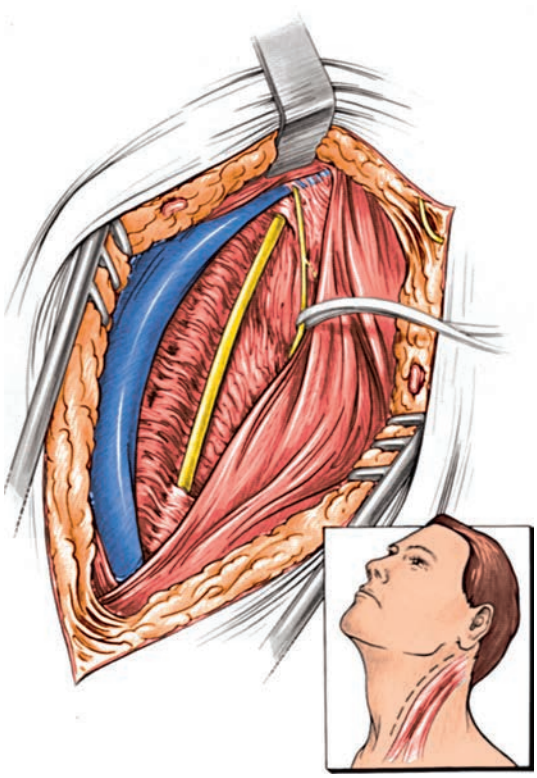

Figure 97.11 Retrojugular approach and isolation of the spinal accessory nerve. (From Berguer R, Kieffer E. *Surgery of the Arteries to the Head.* New York: Springer-Verlag; 1992.)

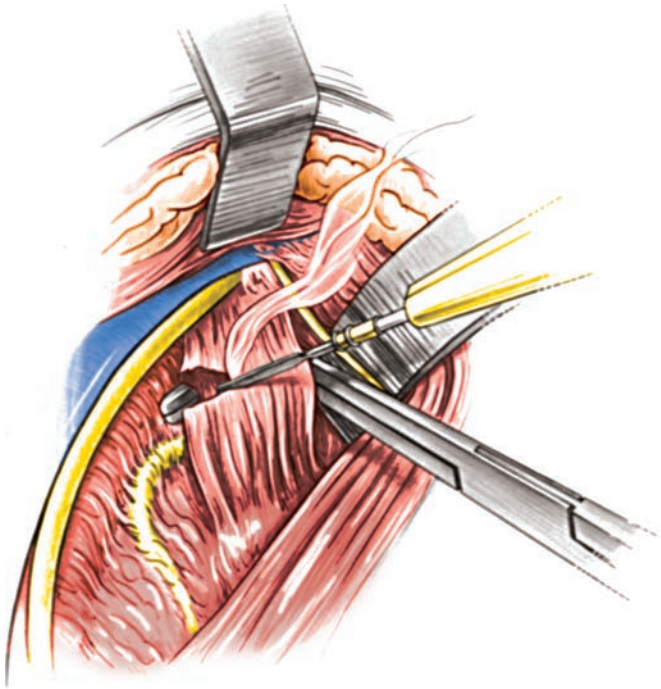

Figure 97.12 Dividing the levator scapulae over the C2 ramus. The vagus, internal jugular vein, and internal carotid artery are anterior to the muscle. (From Berguer R, Kieffer E. *Surgery of the Arteries to the Head.* New York: Springer-Verlag; 1992.)

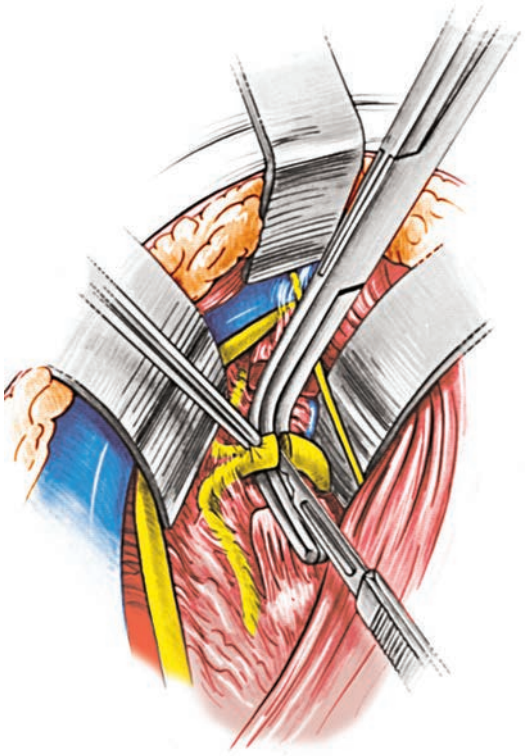

Figure 97.13 Dividing the anterior ramus of C2 to expose the underlying vertebral artery running perpendicular to the anterior ramus. (From Berguer R, Kieffer E. *Surgery of the Arteries to the Head.* New York: Springer-Verlag; 1992.)

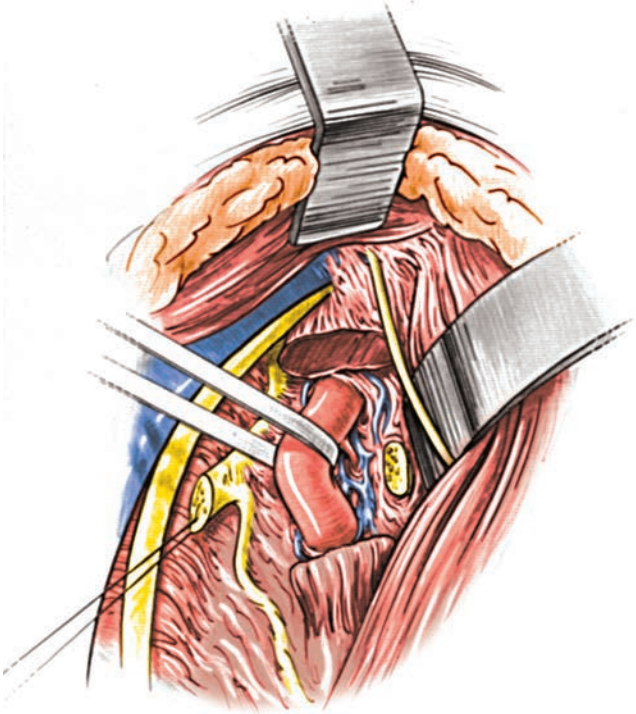

Figure 97.14 After the vertebral venous plexus is dissected away, the vertebral artery is slung with a polymeric silicone (Silastic) loop for clamping and anastomosis. (From Berguer R, Kieffer E. *Surgery of the Arteries to the Head.* New York: Springer-Verlag; 1992.)

no need to dissect the carotid bifurcation. The location selected for the proximal anastomosis of the saphenous vein graft on the common carotid artery should not be too close to the bifurcation, because cross-clamping at this level may fracture any underlying atheroma.

A saphenous vein graft or other suitable conduit of appropriate length is prepared. A valveless segment facilitates back bleeding of the vertebral artery after completion of the distal anastomosis. The patient is given intravenous heparin. The vertebral artery is elevated by gently pulling the loop and is occluded with a small J-clamp to isolate this segment for an end-to-side anastomosis. The vertebral artery is opened longitudinally with a coronary knife for a length adequate to accommodate the spatulated end of the vein graft. The end-to-side anastomosis is performed with continuous 7-0 polypropylene and fine needles. The distal anastomosis is assessed for backflow, and if satisfactory, a small clamp is placed in the vein graft proximal to the anastomosis and the J-clamp removed to restore flow through the vertebral artery.

The proximal end of the graft is passed beneath the jugular vein. The common carotid artery is then cross-clamped, an elliptical arteriotomy is made in its posterior wall with an aortic punch, and the proximal vein graft is anastomosed end to side to the common carotid artery with continuous 6-0 polypropylene. Before the anastomosis is completed, standard flushing maneuvers are performed, the suture is tied, and flow is reestablished. Next, the vertebral artery is occluded with a clip immediately below the anastomosis to functionally create an end-to-end configuration. In the absence of suitable common carotid artery, the ipsilateral subclavian artery can be used as a donor vessel.

Alternative Options for V3 Reconstruction

The distal vertebral artery may also be revascularized via the external carotid artery (ECA), either directly by means of transposition of the ECA to the distal vertebral artery or by anastomosis of the proximal end of a graft to the ECA (Fig. 97.15). Another method of revascularization of the distal vertebral artery is transposition of this vessel into the distal cervical internal carotid artery below the transverse process of C1. This technique is particularly applicable for patients with inadequate saphenous vein or those in whom the ECA cannot be used because of unsuitable anatomy or disease of the carotid bifurcation.

A small number of patients have disease that extends up to the level of C1 and require revascularization in the most distal segment of the extracranial vertebral artery.[31-33] To accomplish this, the vertebral artery must be exposed in its pars atlantica, where the artery runs parallel to the lamina of the atlas before entering the foramen magnum.

Posterior Suboccipital Vertebral Artery Bypass

For more distal pathology, the vertebral artery can also be accessed surgically above the level of the transverse process of C1. Surgical exposure at the suboccipital segment requires resection of the C1 transverse process and part of its posterior arch. Reconstruction at this level is limited to saphenous vein bypass from the distal internal carotid artery. Bypasses above the level of C1

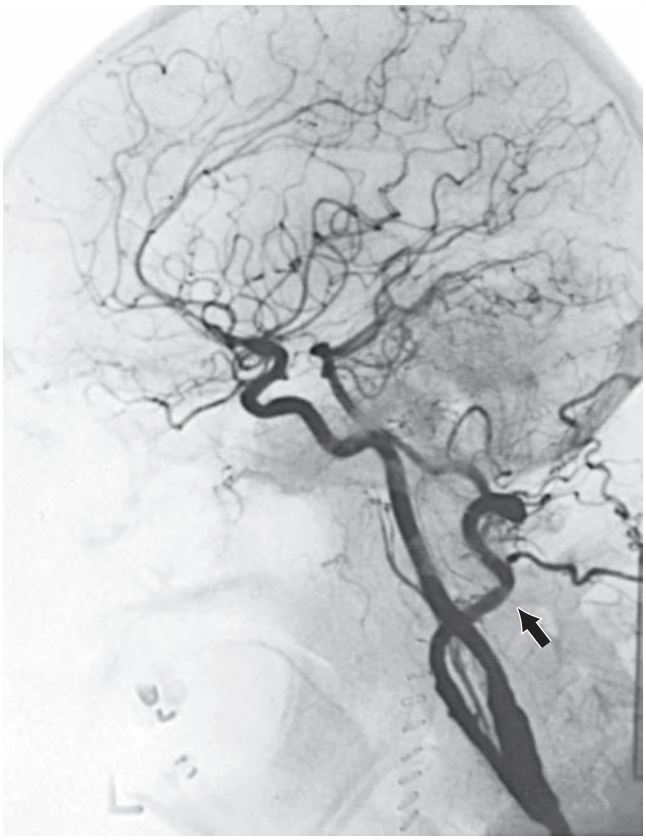

Figure 97.15 Arteriogram of a transposition of the external carotid artery to the distal vertebral artery. This patient had previously undergone internal carotid endarterectomy. (From Berguer R, Kieffer E. *Surgery of the Arteries to the Head.* New York: Springer-Verlag; 1992.)

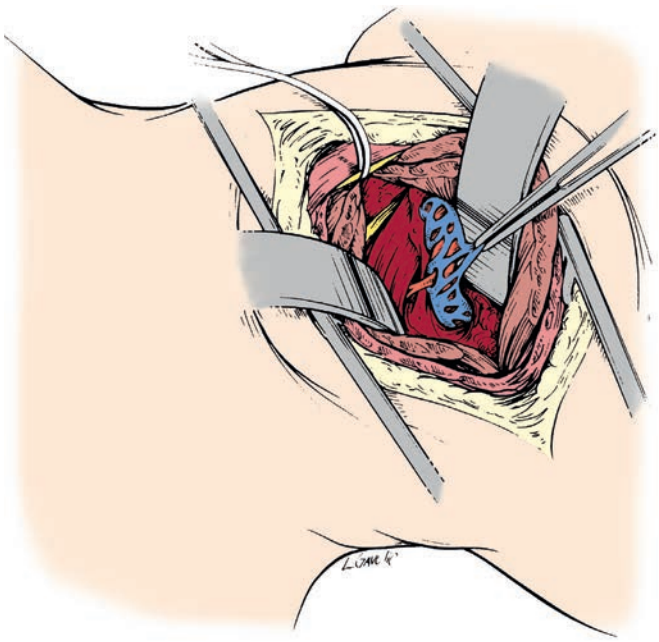

Figure 97.16 The pars atlantica of the distal vertebral artery exposed and surrounded by a dense venous plexus.

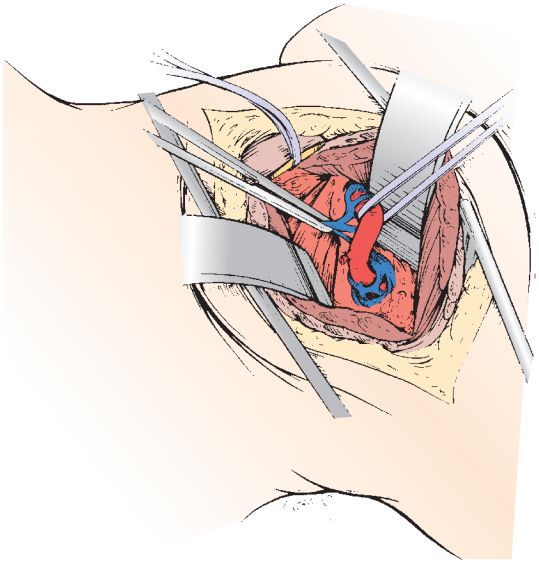

Figure 97.17 Exposure of the pars atlantica of the vertebral artery from its exit from the transverse foramen of C1 to its entrance into the dura mater.

(suboccipital) are technically demanding and have been required in only 4% of cases of distal vertebral artery reconstruction.

A small group of patients have disease up to the level of C1 and require revascularization in the last segment of the extracranial vertebral artery. To accomplish this, the vertebral artery must be exposed in its pars atlantica, where the artery runs parallel to the lamina of the atlas before entering the foramen magnum (Figs. 97.16 and 97.17).

OPERATIVE RESULTS

Perioperative Outcomes

Perioperative complication rates differ for proximal versus distal vertebral artery reconstruction. Perioperative complications that can follow any reconstruction include stroke, bleeding, thrombosis, and nerve injury. Intraoperative completion imaging with digital angiography is useful and should be considered for all types of vertebral artery reconstruction. Reparable technical flaws may be identified, and repair can prevent reconstruction failure.

Proximal Reconstructions

The technically easier proximal operations have been reported to have a combined stroke and death rate of 0.9%.[22] Among patients undergoing proximal operations in one report, no deaths or strokes occurred in those who underwent only a vertebral reconstruction. When the proximal vertebral artery reconstruction was combined with a carotid operation, the observed stroke and death rates increased to 5.7%.[22] Berguer et al.[22] reported four instances of immediate postoperative thrombosis (1.4%). Three of the four patients had vein grafts interposed between the vertebral artery and the common carotid because of a short V1 segment. The grafts kinked and thrombosed. Other complications that are particular to proximal reconstruction include vagus and recurrent laryngeal nerve palsy (2%), Horner's

syndrome (8.4%-28%), lymphocele (4%), and chylothorax (0.5%).

Distal Reconstructions

Operations on the distal vertebral artery carry higher stroke and death rates than do operations on the proximal vertebral artery. Distal reconstructions have a combined stroke and death rate of 3%.[34] The immediate graft thrombosis rate has been reported at 8%, and spinal accessory nerve injury occurs in 2% of patients.[35]

Long-Term Outcomes

Results after both proximal and distal vertebral artery reconstruction are generally equal to or better than those reported in series reviewing other forms of extracranial cerebrovascular reconstruction.[34,36] After proximal vertebral–to–common carotid transposition, patency rates at 5 and 10 years equal or exceed 95% and 91%, respectively. When selected appropriately, more than 80% of patients will have relief of their symptoms after proximal surgical reconstruction.[36]

For distal bypass reconstruction, patency rates of 87% and 82% should be expected at 5 and 10 years.[34,36] Seventy percent of patients undergoing distal vertebral artery reconstruction are dead at 5 years of follow-up, mostly from cardiac disease, whereas 97% of survivors are free of stroke at 5 years. Symptoms are expected to be cured in 71% of patients and improved in an additional 16%.[34,36]

Predictably, in patients treated for severe hemodynamic symptoms who also suffer from compensatory high blood pressure, appropriate reconstruction and reperfusion of the brain stem results in significant improvement in their hypertension.

ENDOVASCULAR THERAPY

Endovascular Treatment

In the last two decades, a growing number of case reports and small nonrandomized case series suggest that endovascular intervention in the posterior circulation may be safe and technically feasible.[37-48] Endovascular access to the vertebral artery is relatively straightforward. Patients are pretreated with dual-therapy aspirin and clopidogrel. The procedure can be performed under local anesthesia, enabling continuous neurologic monitoring of the patient. Most cases are performed from a femoral approach (93%), although transbrachial (3%) and transradial (5%) access have also been used (see Chapter 92).[49] The stenotic lesions are crossed and treated with 0.014- or 0.018-in. guidewires and small coronary-diameter balloons and stents. Procedures can be performed with or without the assistance of embolic protection, although vertebral arteries are usually too small to accommodate most distal protection devices. One large review found distal protection used in only 2% of cases.[49]

Periprocedural risks include access complications, distal embolization and stroke, arterial rupture, stent malposition and vessel thrombosis or dissection. Later, restenosis and stent fracture are not uncommon.

Overall, retrospective reviews suggest that endoluminal vertebral artery intervention is reasonably safe, although a selection bias exists. A 2005 Cochrane review identified 313 interventions for vertebral artery stenosis, with just over half using stent placement as part of the treatment. The technical success rate was 95%, and the 30-day stroke and death rate was 6.4%.[50] The Cochrane group concluded that although angioplasty with stenting for vertebral artery stenosis is technically feasible, evidence is currently insufficient to support its routine application.

A subset of 16 patients treated within the Carotid and Vertebral Artery Transluminal Angioplasty Study (CAVATAS 2001) represents the only report of a randomized controlled trial comparing endoluminal therapy with best medical care for symptomatic vertebral stenosis. No 30-day strokes or deaths occurred in either group, although two of eight patients who underwent endoluminal therapy experienced transient ischemic symptoms. Furthermore, with a mean follow-up of 4.5 years, no posterior circulation strokes were noted in either group.

Despite high technical success rates, vertebral artery angioplasty alone, especially when used for the treatment of disease at the origin of the vessel, appears to have an unacceptably high rate of restenosis. Adjuvant stent placement seems to add to the clinical durability, although stents carry inherent morbidity of their own, such as malposition and potential stent fracture. In their series of 105 patients who underwent endovascular stenting for symptomatic vertebral artery disease, Jenkins et al. achieved 100% radiographic improvement (residual stenosis ≤30%). The authors reported an immediate (30-day) periprocedural risk of death of 1% and periprocedural complication rate of 4.8%. Complications included transient ischemic attack, flow-limiting dissection, hematoma, and access-site problems. At 1 year of follow-up, six patients had died and five had experienced a vertebrobasilar stroke; at approximately 2.5 years of follow-up, 70% of patients remained symptom-free, but 13% had restenosis requiring retreatment.[51]

In the Stenting of Symptomatic Atherosclerotic Lesions in the Vertebral or Intracranial Arteries (SSYLVIA) trial, 18 patients with extracranial vertebral artery disease underwent angioplasty and stenting. Technical success (determined as less than 50% residual stenosis following treatment) was achieved in 17 (94%) of the 18 patients. No periprocedural neurologic complications were observed. The investigators, however, reported 6-month restenosis rates of 50%. These recurrences were symptomatic in 39% of cases.[52]

A recent systematic review of the available literature noted a weighted mean technical success rate of 97%. The authors estimated the mean periprocedural stroke and death rate from combined angioplasty and stenting to be approximately 1.1%. Transient ischemic events occurred in 1.5% of patients. Recurrent symptoms occurred in 8% of patients within a reported follow-up range of 6 to 54 months, and greater than 50% restenosis developed in 23% of the subset of patients who underwent follow-up imaging.[49]

Late stent fracture with concomitant in-stent restenosis may be a problem plaguing endoluminal therapies that target lesions at the vertebral artery origin. Anatomically, the vertebral artery

takes origin from the subclavian artery at a near right angle. In addition, the first portion of the subclavian artery has relative mobility, whereas the vertebral artery becomes fixed as it passes into the transverse foramen of C6. This particular anatomy may create unique mechanical forces that make stent fracture more likely than it is for other parts of the body.

The use of drug-eluting stents to impede neointimal hyperplasia and prevent restenosis has been well established in the coronary arteries and may be beneficial in the treatment of vertebral disease.[53] Ogilvy et al. reported a series of patients with the longest follow-up thus far (21 months); for these patients, drug-eluting stents were used in stenosis of vertebral artery origin. The authors found that the incidence of in-stent restenosis (>50% diameter) decreased from 38% in patients who received non–drug-eluting stents to 17% in those who received drug-eluting stents.[54] Other reports also suggest decreased restenosis rates with drug-eluting stents; however, many of those studies have mean patient follow-up times of less than 1 year.[55,56] Treatment with drug-eluting stents requires long-term dual antiplatelet therapy. It remains unclear whether differing stent makeup will have a significant impact in the outcomes of patients who undergo interventions of the vertebral artery.

With the exception of the small subset of patients from CAVATAS 2001, only retrospective case series exist for endoluminal therapies for the treatment of vertebral artery disease, as with open surgical techniques. Currently no level I data support the routine application of angioplasty and stenting of the vertebral artery over best medical therapy. The multicenter, randomized Vertebral Artery Stenting Trial (VAST), which was designed to prospectively analyze the impact of percutaneous vertebral interventions over medical therapy for stenting of intracranial or extracranial vertebral artery stenosis was stopped due to regulatory requirements but after enroling 115 subjects the authors were able to conclude that stenting of symptomatic vertebral artery stenosis is associated with a major periprocedural vascular complication in about one in 20 patients and that the risk of recurrent vertebrobasilar stroke under best medical treatment alone was low, questioning the need for and feasibility of a phase 3 trial.[57]

CONCLUSION

Surgical or endovascular reconstruction of the vertebral artery is often a viable option and should be considered in symptomatic patients with appropriate atherosclerotic lesions or other vasculopathy in whom medical therapy has failed. Open techniques for revascularization of the vertebral artery have proven clinical durability and acceptable surgical morbidity in experienced hands. Endoluminal techniques, which have gained momentum over the past decade, have shown clinical feasibility but have yet to deliver on durability benchmarks set by open surgical revascularization. For each individual patient who suffers from medically refractive vertebrobasilar ischemia, practitioners must carefully balance the risks of surgery versus the limitations of endoluminal intervention before recommending intervention.

INTRODUCTION

The innominate, left common carotid, and left subclavian arteries originate at the transverse aortic arch and are collectively referred to as the supraaortic trunk or the brachiocephalic arteries. Brachiocephalic arterial occlusive disease can cause transient ischemic attacks, stroke, and upper extremity ischemia. The most common occlusive etiology is atherosclerosis. Other pathologies include arterial dissection (either extending from the aortic arch or in isolation), vasculitides, and radiation arteritis. Other entities affecting the brachiocephalic arteries include infection, trauma, and aneurysm. Revascularization options include endovascular techniques, extraanatomic bypass, and direct access via median sternotomy.

ANATOMIC VARIANTS

The most common configuration of the aortic arch is to have three distinct origins of the innominate, left common carotid, and left subclavian arteries. However, a variety of congenital alterations to the aortic arch exist (Table 98.1). Up to 20% of normal patients have the so-called "bovine arch" variation, where the left common carotid artery originates from a shared trunk with the innominate artery (Fig. 98.1). There is some evidence of association between anomalous brachiocephalic arteries and thoracic aortic disease requiring intervention.[1] Most commonly, the vertebral arteries originate from the subclavian arteries but the left vertebral artery occasionally originates directly from the aortic arch between the left common and

Abstract

Brachiocephalic artery disease can cause transient ischemic attacks, stroke, and upper extremity ischemia. The most common occlusive etiology is atherosclerosis. Other pathologies include arterial dissection, vasculitides, and radiation arteritis. In this chapter, we examine the various surgical treatments for brachiocephalic artery disease and report postoperative results. We first look at anatomic variants and the key indications for surgical intervention, highlighting the best diagnostic tools. We outline the different means for revascularization, including endovascular techniques, extraanatomic bypass, and direct access via median sternotomy. We report operative results, including those from Berguer and colleagues who reviewed 182 cervical reconstructions in 1999. They found that stroke, myocardial infarction, and mortality rates were 3.8%, 3%, and 0.5%, respectively. Five- and 10-year survival rates were 72% and 41%, with 5- and 10-year patency rates of 91% and 82%. In 2007, Byrne and colleagues reported a 5-year cumulative patency rate of 92% in 143 patients with cervical brachiocephalic artery revascularization. They had stroke, myocardial infarction, and mortality rates of 1.4%, 4.3%, and 0.7%, respectively. We conclude the chapter with our postoperative management protocols, which typically include discharge after 1 or 2 days and plan follow-up visits where we monitor graft patency by duplex ultrasound examination every 6 months for the first year and annually thereafter.

Brachiocephalic artery disease
atherosclerosis
aortic arch

TABLE 98.1 Aortic Arch Anomalies

Arch Anomaly	Description	Prevalence (%)
Normal aortic arch configuration	Consists of three great vessels originating from the aortic arch. The first branch is the innominate artery, which branches into the right subclavian artery and right common carotid artery. The second branch is the left common carotid artery. The third branch is the left subclavian artery.	70-74
"Bovine aortic arch" subtype II	Left common carotid artery and innominate artery share a common origin. More common in African Americans (25%) versus whites (8%).	13-20
"Bovine aortic arch" subtype I	Left common carotid artery arises directly from the innominate artery, most often <1 cm from aortic arch. More common in African Americans (10%) versus whites (5%).	9
Aberrant left vertebral artery	Left vertebral artery arises from the aortic arch. The most common location is between the left common carotid and subclavian arteries.	2-6
Aberrant right subclavian artery	Right subclavian artery is the last branch of the aortic arch arising distal to the origin left subclavian artery. It courses posterior to the esophagus (80%), between the esophagus and trachea (15%), or anterior to the trachea or mainstem bronchus (5%).	0.5-2
Aberrant left subclavian artery	Left subclavian artery is the second branch of the aortic arch, arising before the left common carotid artery.	<0.5
Right aortic arch	Vessels originate in the following order: left common carotid, right common carotid, right subclavian artery, and left subclavian artery.	<0.1

left subclavian arteries. An aberrant right subclavian artery may originate distal and posterior to the left subclavian artery. In treating aortic arch pathology, it is critical to recognize these anomalies.

INDICATIONS FOR INTERVENTION IN OCCLUSIVE DISEASE

Brachiocephalic arterial occlusive disease can be unifocal, multifocal, single vessel, or multivessel. In the series of 282 transthoracic and transcervical brachiocephalic revascularizations reported by Berguer et al.,[2,3] there was a 40% incidence of multivessel disease. Repair is clearly indicated in symptomatic lesions, such as causing stroke, transient ischemic attacks, subclavian steal syndrome, upper limb ischemia, and other thromboembolic phenomena.

There is limited data regarding treatment of asymptomatic severe lesions defined as causing more than 75% stenosis.[2,4,5] With few exceptions, asymptomatic lesions of the subclavian arteries should be medically managed, regardless of severity. Invasive treatment of asymptomatic lesions involving the innominate or common carotid arteries is controversial and is based on extrapolation from carotid bifurcation studies. In general, the risks of open transthoracic surgical repair for asymptomatic occlusive lesions likely outweigh the benefits in most patients (Table 98.2). Reasonable exceptions to this include severe subclavian stenosis with patent internal mammary-coronary bypass, preservation of arteriovenous accesses, preservation of axillary artery-based peripheral bypass grafts, planned sternotomy and reconstruction of the aortic arch or other brachiocephalic artery lesions.

OTHER INDICATIONS FOR INTERVENTION

Infection

Infectious processes (including syphilis and tuberculosis) can lead to aneurysmal degeneration of the brachiocephalic arteries and, in particular, the subclavian artery. These are rare causes of proximal (intrathoracic) aneurysm. Aberrant right subclavian artery aneurysms (Kommerell diverticulum) can fistulize into the esophagus.[6,7] When diagnosed, infectious brachiocephalic aneurysms or pseudoaneurysms should be repaired, regardless of size. All patients should receive long-term systemic antibiotics. Depending on organism virulence and anatomy, treatment includes resection, debridement, and extraanatomic or in situ repair.

Trauma

Blunt traumatic injuries can lead to brachiocephalic pseudoaneurysm formation, especially involving the origin of the innominate artery.[8] Penetrating trauma may affect the brachiocephalic vessels in any location (Fig. 98.2). Urgent repair of traumatic brachiocephalic artery injury is indicated for patients with hemorrhage, critical extremity ischemia, and compression of vital structures. Minor asymptomatic injuries can be medically managed if patients can adhere to a surveillance program. Most asymptomatic, clinically occult injuries will remain stable or resolve.[9,10] Most strokes from blunt cerebrovascular injuries occur at the time of injury, or soon afterward. Few patients have recurrent stroke on medical management with anticoagulation

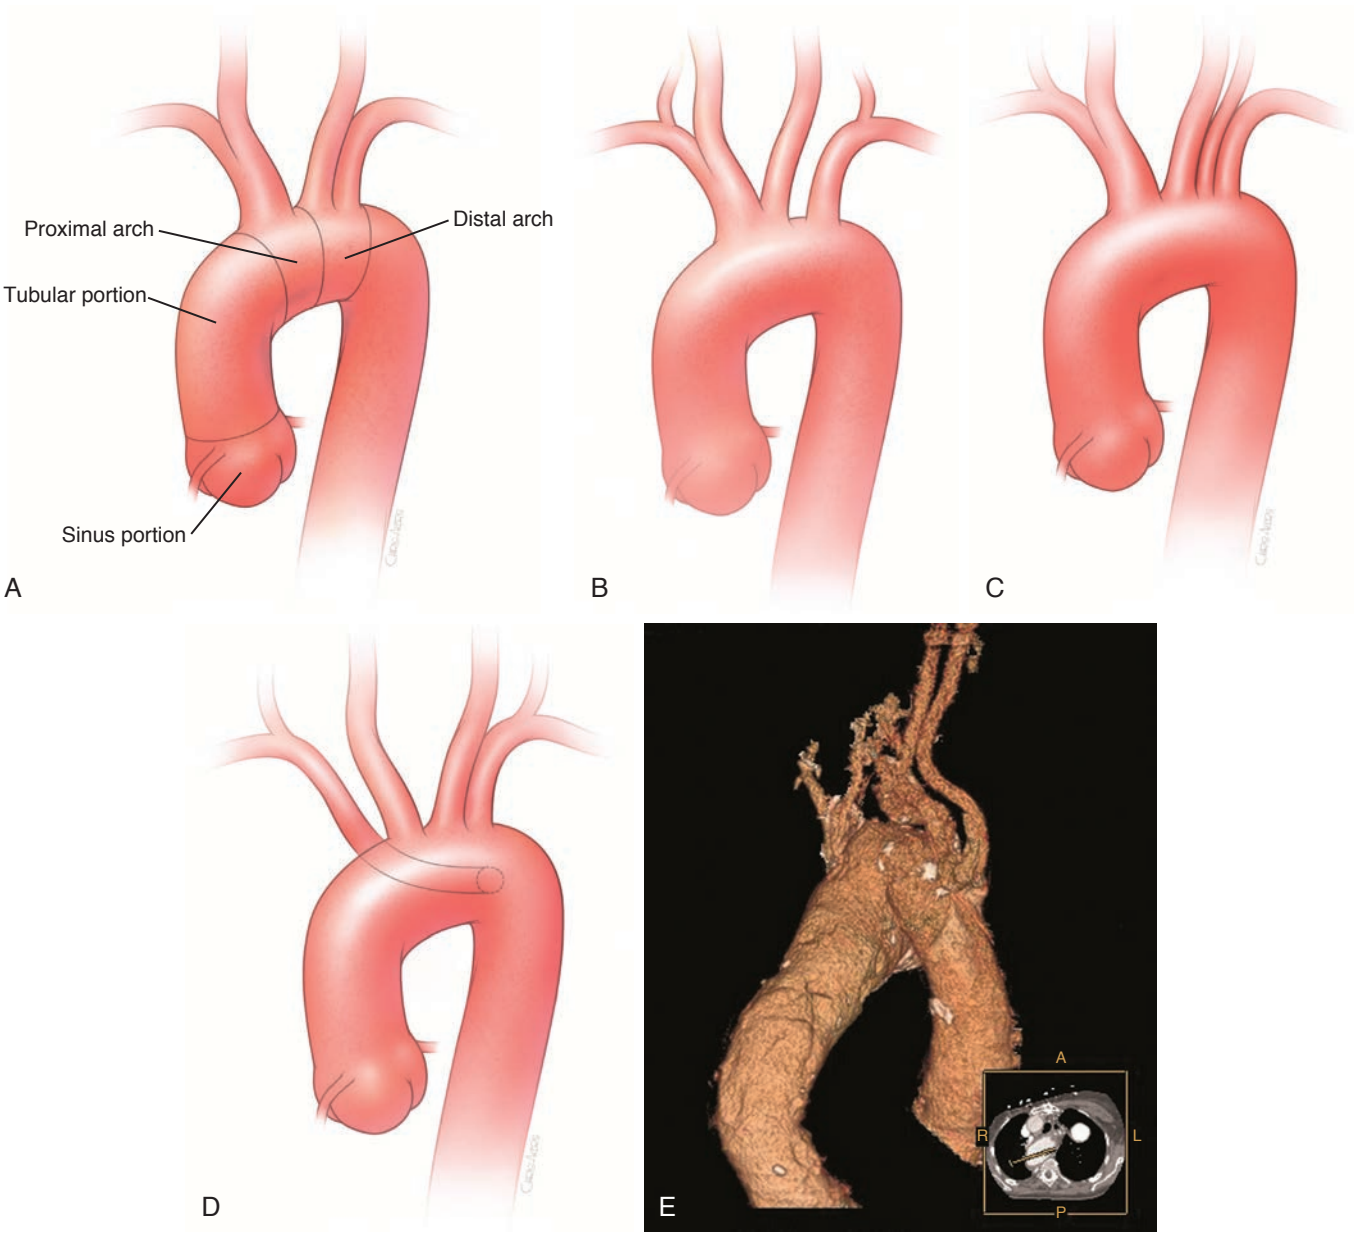

Figure 98.1 Normal and Variant Aortic Arch Anatomy. (A) The normal aortic arch configuration (70%-74% prevalence) consists of three great vessels originating from the arch of the aorta. The first branch is the innominate artery, which branches into the right subclavian artery and right common carotid artery. The second branch is the left common carotid artery. The third branch is the left subclavian artery. (B) The "bovine aortic arch" subtype II (13%-20% prevalence) consists of the left common carotid and innominate arteries sharing a common origin. This is more common among African Americans (25% vs. 8% of whites). In the "bovine aortic arch" subtype I, the left common carotid artery arises directly from the innominate artery, most often less than 1 cm from the aortic arch. It is also more common among African Americans (10% vs. 5% of whites 5%). (C) The aberrant left vertebral artery (2%-6% prevalence) arises directly from the aortic arch, most commonly between the left common carotid and subclavian arteries. (D) The aberrant right subclavian artery (0.5%-2% prevalence) occurs as the last branch of the aortic arch, arising distal to the origin of the left subclavian artery. It typically courses posterior to the esophagus (80%), between the esophagus and trachea (15%), or anterior to the trachea or mainstem bronchus (5%). The aberrant left subclavian artery occurs less frequently (<0.5% prevalence), and manifests as the second branch of the aortic arch, arising proximal to the left common carotid artery. (E) The right-sided aortic arch is a rare variant (<0.1% prevalence) whereby the arch vessels originate in the following order (proximal to distal): left common carotid, right common carotid, right subclavian artery, and left subclavian artery. The following represents a three-dimensional reconstruction of a contrast-enhanced computed tomography scan depicting a patient's right-sided aortic arch.

or antiplatelet therapy.[11-13] In follow-up, surgical repair should be limited to patients with new symptom onset; recurrent thromboembolic events, despite medical therapy; and enlarging or symptomatic pseudoaneurysms.

Dissection

Dissection of the brachiocephalic arteries occurs spontaneously or as an extension from the aortic arch. In patients with aortic dissection and extension into the common carotid arteries, nearly 19% of cases initially present with stroke. Even with aortic repair, the dissection of the carotid arteries usually persists. However, subsequent thromboembolic events are rare.[14] Medical management includes antithrombotic agents for 3 to 6 months, and is the initial treatment of choice. A recent randomized trial confirmed the low rate of recurrent stroke with either anticoagulant or antiplatelet agents.[15] Only patients with active hemorrhage, enlarging pseudoaneurysm, or recurrent thromboembolic events, despite medical therapy, are offered surgical or endovascular repair.

Arterial Thoracic Outlet Syndrome

Distal (extrathoracic) subclavian artery aneurysms are commonly related to a cervical rib that causes arterial thoracic outlet syndrome (Fig. 98.3) (see Chapter 122). The pathogenesis of the aneurysm is thought to be related to repetitive trauma to the artery at the level of the thoracic outlet.[16] Bony abnormalities, such as a cervical rib, are usually present. The clinical consequences of aneurysmal degeneration are usually related to distal thromboembolization causing arm claudication, rest pain, and digital ischemia. Most subclavian artery aneurysms are repaired at the time of thoracic outlet decompression. In experienced centers, the procedure is safe and provides excellent functional outcomes.[17]

Aneurysm

True, isolated, brachiocephalic artery aneurysms are rare in the absence of adjoining aortic arch aneurysm. Patients younger

Figure 98.3 Innominate and Subclavian Artery Aneurysms. Intraoperative photo representing distal right subclavian artery aneurysm *(white arrow)* in a patient with arterial thoracic outlet syndrome exposed via an infraclavicular incision. The patient's head is at the top, left corner; the feet are to the bottom, right corner.

than 50 years should be screened for genetic disorders, such as Loeys-Dietz and Marfan syndromes. Because of the risk of nerve compression and thromboembolic events, most brachiocephalic artery aneurysms should be repaired, regardless of size or presence of symptoms. Pairolero reported thromboembolism in 16% of axillary and subclavian artery aneurysms.[18] However, open repair is associated with significant mortality and morbidity. Kieffer and colleagues reported an 11% perioperative mortality after open repair of innominate artery aneurysm, although this also included ruptured and infected cases.[19] Patients had a heterogeneous etiology and most also had aortic aneurysm. In patients with high surgical risk, small asymptomatic aneurysms less than 2 cm in diameter, without intraluminal thrombus, may be observed. Proximal occlusion with cervical revascularization may be an option in some cases. Unfortunately, it is rare that the anatomy is suitable for endovascular repair. However, it may be a reasonable option in selected cases.[20]

DIAGNOSTIC EVALUATION

In addition to a comprehensive physical examination, careful assessment of the upper extremity pulses, and bilateral upper extremity blood pressure measurements, Duplex ultrasound examination may be of some utility in identifying flow reversal in the vertebral arteries and excluding significant disease in the extracranial carotid arteries. Axial imaging modalities, such as magnetic resonance imaging and computed tomography (CT) scans, provide excellent imaging of the aorta and great vessels. These imaging techniques have mostly replaced conventional aortography as a diagnostic tool. Body habitus, claustrophobia, and metallic implants may limit the use of these imaging techniques.

Transesophageal echocardiography (TEE) is another important diagnostic tool because of its ability to accurately identify atherosclerotic disease in the proximal ascending and descending portions of the thoracic aorta. Disadvantages of TEE are that accurate evaluation requires an experienced sonographer and that the patient needs conscious sedation during the procedure. If transthoracic revascularization is planned, the proximal ascending aorta should be devoid of any atheromatous plaque or dissection. If accurate preoperative or intraoperative TEE is not available, a handheld (epiaortic) ultrasound probe can be used intraoperatively, once the aorta is exposed, to assess for atheromatous plaque in the ascending aorta at the potential clamp site.

REVASCULARIZATION

Transthoracic revascularization is preferred for patients with multivessel disease and reasonable surgical risk. Proximal aneurysms and traumatic injuries are also best treated with a bypass from the ascending aorta to the involved brachiocephalic arteries (Fig. 98.4), especially when not anatomically suitable for endovascular repair. Infections involving the innominate and proximal common carotid arteries can be resected and revascularized via a median sternotomy. Adjunctive techniques, such as pedicled omental flaps, can easily be added with this approach.

Extraanatomic cervical revascularization is ideal for single-vessel subclavian disease or in high-risk patients. This approach is often combined with endovascular treatment of thoracic aortic aneurysms (see Chapter 78). Left subclavian-carotid transposition or carotid-subclavian bypass may be required for a suitable proximal landing zone for thoracic aortic endografts. A right-to-left carotid bypass can further extend the proximal landing zone to the level of the innominate artery. The recent introduction of branched aortic endografts will reduce the need for cervical brachiocephalic artery bypasses (see Chapter 80).

Transthoracic Revascularization

The ascending aorta and transverse aortic arch are approached through a median sternotomy. The procedure is initiated with a skin incision from just below the sternal notch. The incision can extend to the xiphoid process for complete sternotomy, if needed. A mini-sternotomy also allows for exposure of the ascending aorta and proximal brachiocephalic arteries. The mini-sternotomy incision extends from the sternal notch to the fourth intercostal space. Electrocautery is used to divide the soft tissues down to the sternum. The lateral sternum is exposed between the third and fourth ribs. A sternal saw is used to create the osteotomy and a sternal retractor is used to gently free the mediastinal structures from the undersurface of

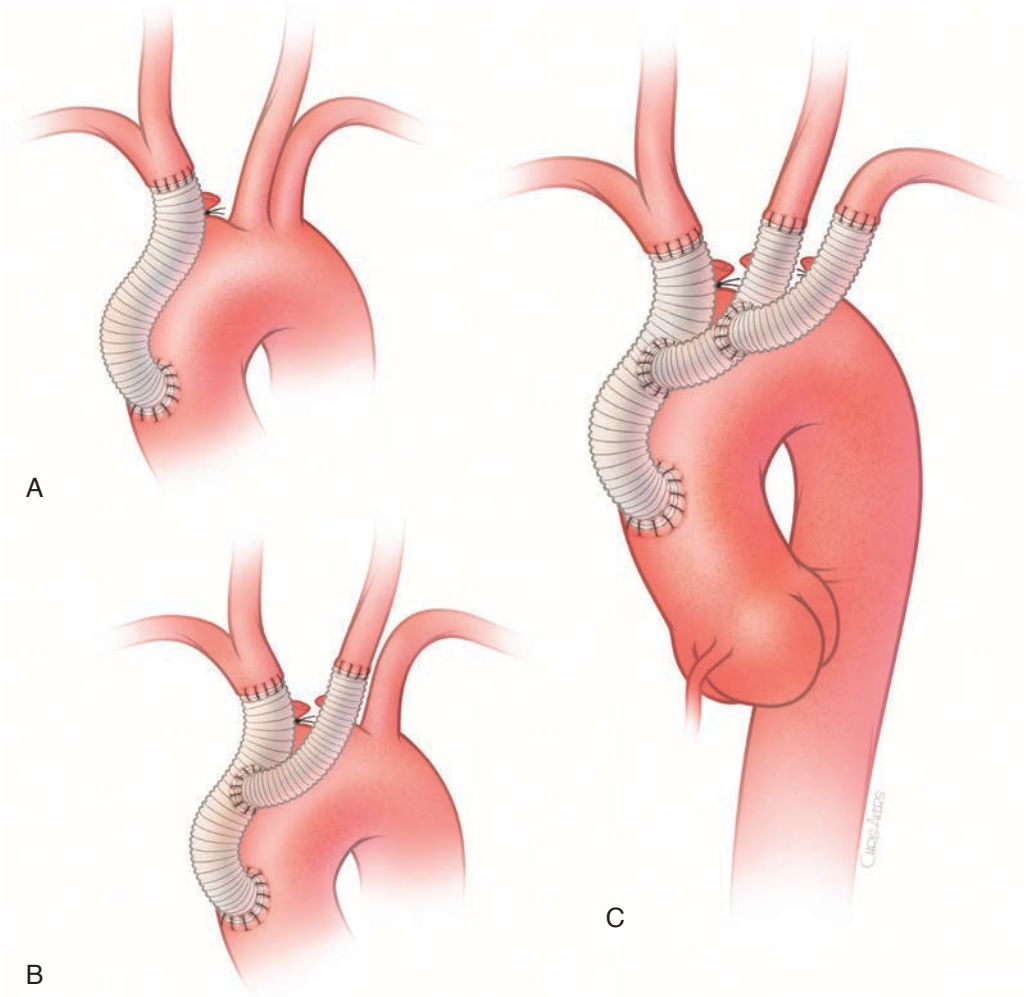

Figure 98.4 Technical Approach for Transthoracic Revascularization. (A) Creation of an aorto-innominate bypass. (B) Sidearm bypass graft to the left carotid artery. (C) Sidearm bypass graft to the left subclavian artery.

the bone. Incision of the superior portion of the pericardium exposes the heart and ascending aorta. Anatomic revascularization of the brachiocephalic arteries can be accomplished by endarterectomy or bypass.

Endarterectomy

Endarterectomy is an effective strategy for focal lesions involving the midsection of the proximal innominate or common carotid artery. When the atherosclerotic lesion is located at the orifice of the brachiocephalic trunk, the transverse arch is usually involved in this process. In this setting, endarterectomy can be fraught with the dangers of embolization, incomplete endarterectomy, and aortic dissection. Also, endarterectomy is not suitable for patients with disease involving a bovine arch variant because clamping of the innominate artery would cause ischemia to both cerebral hemispheres.

Bypass Grafts

Bypasses generally originate from the ascending aorta to the brachiocephalic arteries if the ascending aorta is free of atherosclerotic disease (see Fig. 98.4). The presence of atheroma can be confirmed by intraoperative TEE or epiaortic ultrasound. The patient is anticoagulated and a partial-occlusion clamp is applied. A 12- to 14-mm woven Dacron tube graft impregnated with collagen or gelatin is sewn to the ascending aorta in end-to-side fashion with 4-0 polypropylene suture. The partial-occlusion clamp is released with the patient in the Trendelenburg position, and a clamp is placed distally on the graft. The innominate artery is then transected distal to the diseased portion and the proximal stump is oversewn with 4-0 polypropylene suture. The distal anastomosis is completed in an end-to-end fashion with 4-0 or 5-0 polypropylene suture.

When the left common carotid or subclavian artery is involved, we avoid the use of a premade bifurcated graft, such as an aortoiliac or aortofemoral graft, because the volume of this graft near the proximal anastomosis creates difficulty in closing the sternotomy. We use a separate sidearm graft sewn to the innominate bypass graft in an end-to-side fashion with 4-0 polypropylene suture. This graft is then sewn end-to-end to the left common carotid artery with 5-0 polypropylene suture. If the left subclavian artery also has a proximal lesion, a separate bypass is constructed in a similar fashion. Exposure of the proximal left subclavian artery is facilitated by downward retraction on the ascending aorta and the transverse arch. After

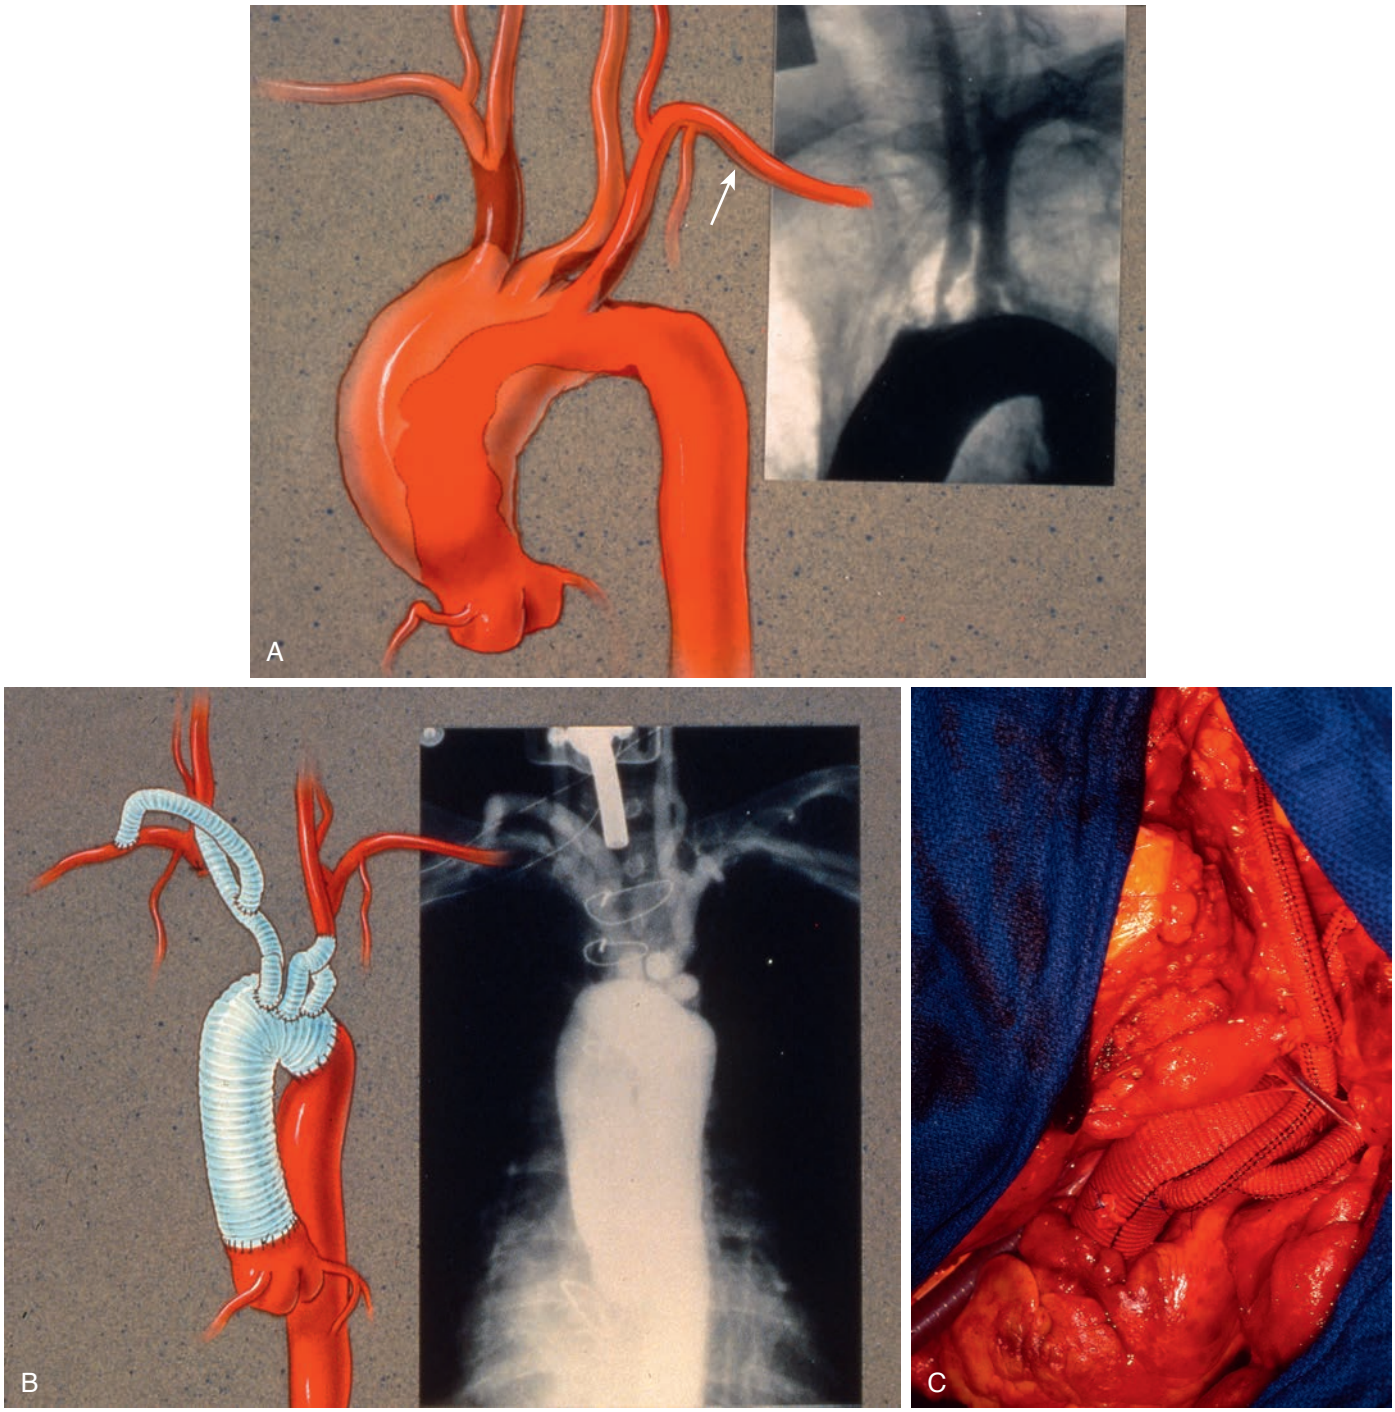

Figure 98.5 Total Aortic Arch Replacement. Replacement of ascending aorta and transverse aortic arch, with reconstruction of brachiocephalic arteries using a prefabricated branched graft. (C) Intraoperative photo representing the completed replacement of the ascending aorta and aortic arch with individual bypasses to the brachiocephalic arteries.

revascularization, anticoagulation is reversed and we insert 2 (32 or 36 Fr) chest tubes in the mediastinum for drainage.

Total Aortic Arch Replacement

Patients with severe atheromatous plaque involving the ascending and transverse aortic arch have a significant risk of stroke from atheroembolic debris with manipulation. We replace the ascending aorta with the transverse arch and reconstruct the brachiocephalic arteries with a prefabricated branched graft (Fig. 98.5). Our center has low mortality and neurologic morbidity in total arch replacement with use of retrograde cerebral perfusion, cardiopulmonary bypass, profound hypothermia, and circulatory

arrest.[21,22] Endovascular total aortic arch repair using brachiocephalic debranching and thoracic aortic endografting is an alternative approach.

Transthoracic Operative Results

DeBakey and colleagues performed the first aorto-innominate bypass in 1957.[23] Crawford and colleagues subsequently published results of direct brachiocephalic revascularization (combining endarterectomy and bypass) in 1962 and reported a 30-day mortality of 7.5%.[24] In 1983, the group updated their series and reported stroke and 30-day mortality rates of 6.9% and 4.7%, respectively.[25] Since that time, there have been several reports of excellent initial and long-term results after transthoracic revascularization of the brachiocephalic arteries (Table 98.3). Kieffer and colleagues reported 2.9% stroke, 1.5% myocardial infarction, and 5.2% mortality rates, with 5- and 10-year patency rates of 98.4% and 96%, respectively.[26] Rhodes and colleagues reported 7% stroke, 3% myocardial infarction, and 3% mortality rates, with a 5-year patency rate of 80%.[27] Berguer and colleagues reported 8% stroke, 3% myocardial infarction, and 8% mortality rates, with 5- and 10-year patency rates of 94% and 88%, respectively.[2] Nevertheless, despite outstanding long-term patency rates, the mortality and stroke rate is probably too high for treatment consideration in most asymptomatic patients.

Postoperative Management

In the immediate postoperative period, patients are observed in a monitored unit for the first 24 hours. Mediastinal drains are removed once the drainage is less than 200 mL/day. Patients are discharged with poststernotomy precautions, including not lifting more than 5 to 10 lb, avoiding upper extremity or chest weight-bearing exercises, and limiting arm abduction to less than 90 degrees for 6 weeks postoperatively. After the initial postoperative visit, we monitor patients with duplex ultrasound of the extracranial carotid system and the graft itself every 6 months for the first year and annually thereafter.

Extraanatomic Revascularization

Extraanatomic reconstructions are suitable for patients with single-vessel disease or patients in whom median sternotomy presents prohibitive risk. A bypass can be constructed between the carotid and subclavian, bilateral carotid, bilateral subclavian, or bilateral axillary arteries. The most common lesion is isolated proximal subclavian artery stenosis, and there are several options for revascularization.

Subclavian-Carotid Transposition

Subclavian-carotid transposition carries the advantage of avoiding prosthetic material and is performed with a single anastomosis. However, it requires more extensive dissection of the proximal subclavian artery and isolation of the vertebral and internal mammary artery origins (Fig. 98.6). The procedure is initiated via a transverse supraclavicular incision between the two heads of the sternocleidomastoid muscle. Platysmal flaps are created, with care taken to avoid injury to the external jugular vein. The omohyoid is divided and the common carotid artery is circumferentially dissected and mobilized. If a left-sided exposure is being performed, the thoracic duct is identified and ligated; accessory lymphatic channels on either side are also meticulously identified and ligated to avoid lymph leak. The internal jugular vein and vagus nerve are retracted laterally, and exposure of the subclavian artery and its proximal branches proceeds after division of the vertebral vein.

Once the vertebral internal mammary arteries and thyrocervical trunk are controlled, the patient is anticoagulated and the proximal subclavian artery is transected proximal to the origin of the vertebral artery. Absolute control must be maintained until the proximal stump can be oversewn because a transected stump lost in the thoracic cavity can be disastrous. For this reason, we place two pledgeted, 4-0 polypropylene sutures under the proximal subclavian clamp before transecting the artery. The sutures are tied, left long, and attached to a hemostat. If the clamp is accidentally released after transection, the sutures can be elevated, preventing the artery from retracting into the chest. Once the subclavian stump is ligated with running suture, the artery is released and allowed to fall back into the chest.

The common carotid artery is then clamped, and a longitudinal lateral arteriotomy is made. The free, transected subclavian artery is brought next to the common carotid artery. With proper mobilization, there is usually ample subclavian length for a tension-free anastomosis. An end-to-side anastomosis is created with 5-0 or 6-0 polypropylene suture. Because of the tight spaces and acute angles involved, a parachute technique can be used to facilitate the anastomosis. Shunting is cumbersome

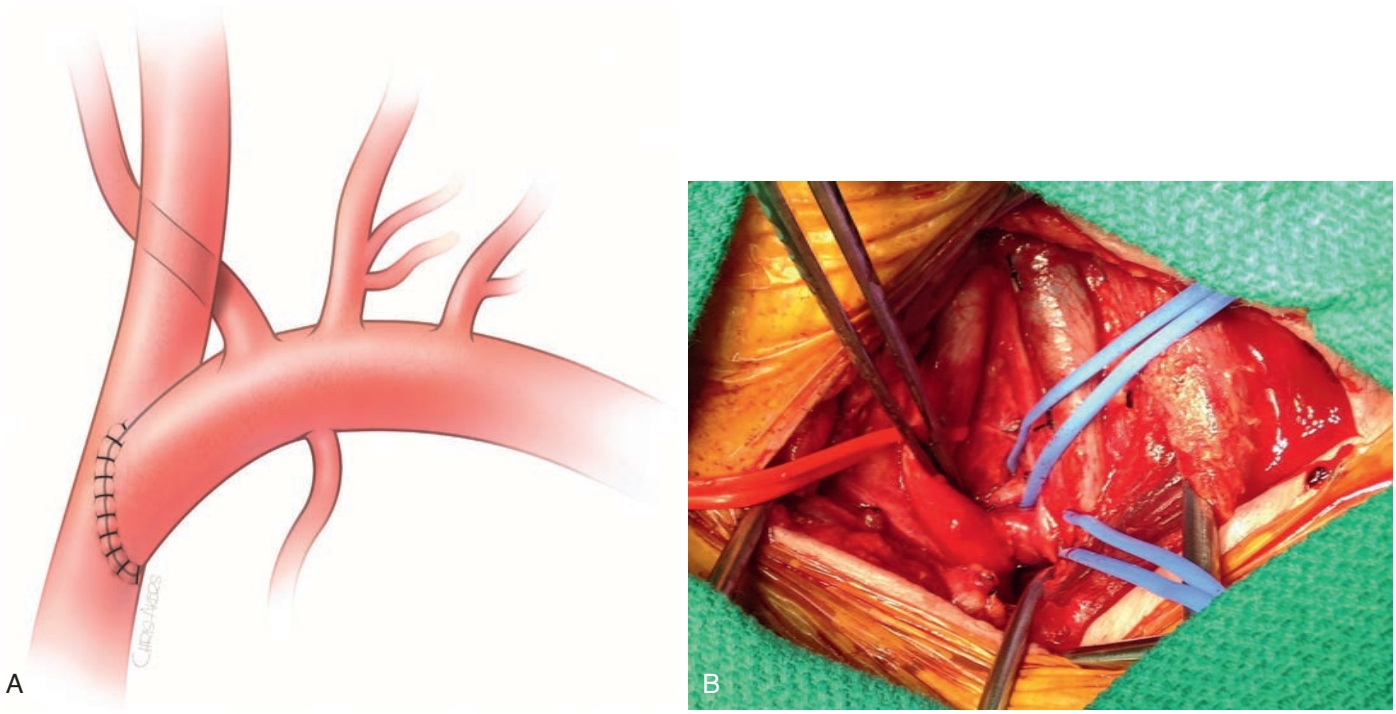

Figure 98.6 Subclavian-Carotid Transposition. (A) Illustration depicting left subclavian-carotid artery transposition using an end-to-side anastomosis. (B) Intraoperative photo depicting left subclavian-carotid artery transposition using an end-to-side anastomosis. The patient's head is at the top, right corner; the feet are to the left. The red vessel loop encircles the left common carotid artery.

and usually not necessary because collateral flow to the internal carotid is maintained from the external carotid artery. The incision is closed after reapproximation of the platysma.

Transposition is contraindicated in patients with an early origin of the vertebral artery and in patients with patent internal mammary-coronary artery bypass grafts. Care should be taken to preserve the vertebral artery whenever possible during transposition. In patients unable to tolerate temporary vertebral artery clamping, such as with contralateral vertebral artery occlusion, bypass may be preferred over transposition. This also applies in cases of aberrant termination of the vertebral artery into the posteroinferior cerebellar artery.

Most reports cite very low mortality and good midterm patency rates. Duran and colleagues reported results after 126 cases with no perioperative deaths and a 2.4% stroke rate.[28] Early thrombosis occurred in 4% with cumulative patency of 96% at mean follow-up of 54 months. Earlier results in 178 cases by Edwards and colleagues showed an early mortality rate of 2.2%, stroke in 1%, and patency of 99% over a mean follow-up of 46 months.[29] Several authors report improved patency, lower early thrombosis, and better hemodynamics with subclavian-carotid transposition compared to bypass. The difference in patency rates within single-center series are generally minor and not statistically significant.[30,31] However, a systematic review by Cina and colleagues analyzed 1027 cervical subclavian revascularizations (511 transpositions and 516 bypasses) and found that transpositions had lower early thrombosis ($P = .01$) and better midterm cumulative patency ($P < .0001$).[32] Cumulative patency was 99% over a mean follow-up of 61 ± 15 months.

Carotid-Subclavian Bypass

Carotid-subclavian bypass is a straightforward procedure with good results. It does not require extensive dissection of the proximal subclavian artery. However, a conduit (usually prosthetic) must be used (Fig. 98.7). A transverse supraclavicular incision extending lateral to the clavicular head of the sternocleidomastoid muscle provides exposure for both the carotid and subclavian arteries. The platysma is divided and the sternocleidomastoid is retracted medially. The jugular vein is dissected free and retracted to expose the common carotid artery, which is encircled and mobilized sufficiently to obtain proximal and distal control. The scalene fat pad is ligated medially and retracted laterally. Care must be taken to identify and protect the phrenic nerve.

The anterior scalene muscle is divided at its attachment on the first rib. Meticulous attention should be given to careful ligation of the thoracic duct and all its tributaries and to avoid trauma to the surrounding brachial plexus. The thyrocervical trunk can be divided for further mobilization of the subclavian artery. Sufficient length is obtained for control of the artery and space for an arteriotomy.

Prosthetic conduit appears to have superior patency over autologous conduit[32,33] and we typically use an 8-mm polytetrafluoroethylene (PTFE) or Dacron graft. The subclavian anastomosis is created first in an end-to-side fashion with 5-0 or 6-0 polypropylene suture. The graft is passed under the jugular vein, flushed, and cut to the appropriate length. Carotid clamps are then applied, and a clamp is

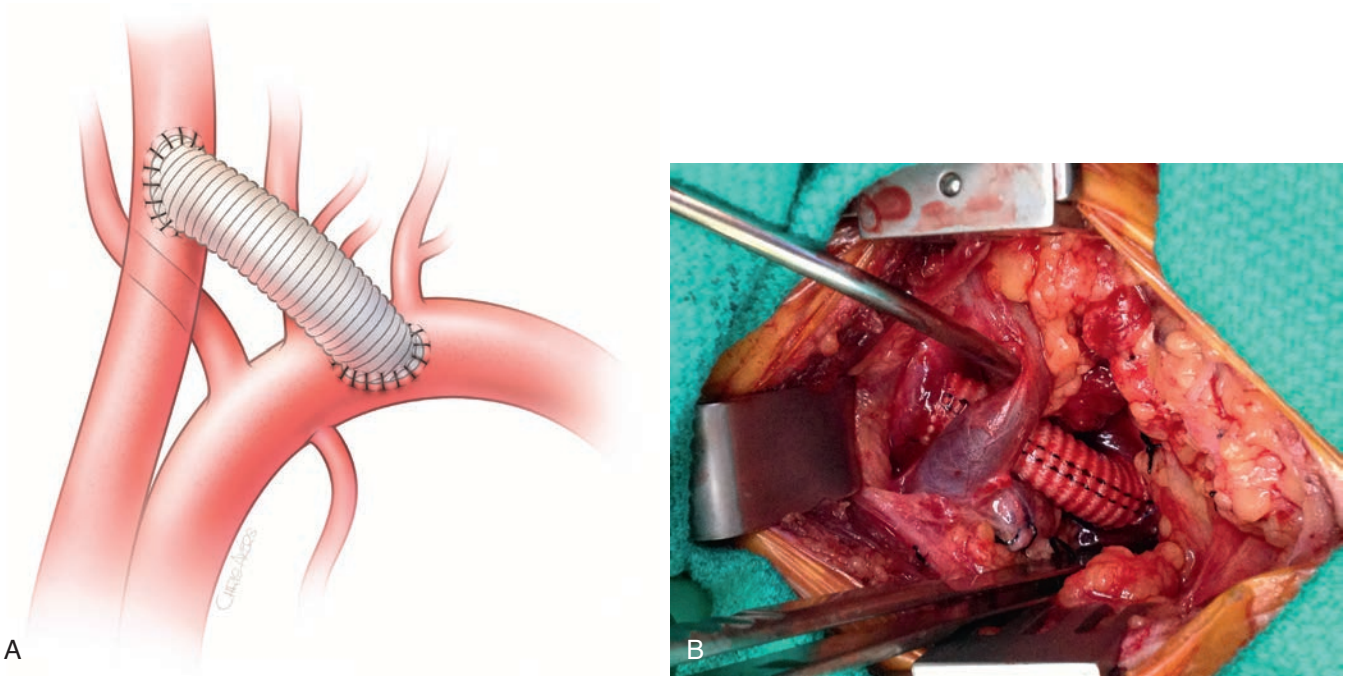

Figure 98.7 Carotid-Subclavian Bypass. (A) Illustration depicting a left carotid-subclavian artery bypass using an 8-mm woven Dacron graft configured with end-to-side anastomoses to both the common carotid and subclavian arteries. The bypass graft courses under the jugular vein.

placed on the graft near the subclavian anastomosis. The carotid anastomosis is completed in an end-to-side fashion with 5-0 or 6-0 polypropylene suture. If the procedure is being performed for proximal common carotid artery disease involving ulcerated plaque, we transect the carotid artery distal to the plaque and perform an end-to-end anastomosis with the graft.

Most of the recent, larger series report perioperative mortality and stroke at less than 2%.[34-36] Takach and colleagues recently reported their results after 287 bypasses with 1% perioperative mortality, 2.1% stroke, but with 94% 5-year patency.[37] In a systematic review, vein grafts had lower patency compared to prosthetic grafts (P = .0006).[32] Cumulative patency using prosthetic bypass grafts was 86% over a mean follow-up of 58 ± 18 months.

Carotid-Carotid Bypass

Occasionally, no ipsilateral source artery is suitable for bypass. In these situations, the contralateral carotid artery can provide inflow for carotid or subclavian revascularization (Fig. 98.8). Bilateral exposure of the carotid artery is achieved through a longitudinal incision overlying the anterior border of the sternocleidomastoid muscle on each side. The carotid sheath is opened and the common carotid artery is dissected free bilaterally. The pharynx is identified medially, and blunt dissection is used to create a tunnel posterior to the pharynx and anterior to the prevertebral fascia. This retropharyngeal tunnel, as described by Berguer et al.,[38] eliminates the risk of skin erosion, enables transposition of the carotid artery, and places any graft safely away from possible future tracheostomy.

Once the tunnel is created, the inflow common carotid artery is clamped proximally and distally. A medial longitudinal arteriotomy is created, and a prosthetic graft is sewn end-to-side with 5-0 or 6-0 polypropylene suture. The graft is passed through the tunnel, the carotid clamps are released, and the graft is clamped. The target carotid artery is then clamped, and an end-to-side anastomosis with 5-0 or 6-0 polypropylene suture is performed. If the proximal plaque on the target carotid artery is at risk of distal thromboembolization, we transect the artery distal to the plaque. The proximal stump is oversewn, and an end-to-end anastomosis is performed with 5-0 or 6-0 polypropylene suture.

In one report, there was no perioperative mortality, 4.1% stroke, and a 3-year cumulative patency rate of 92% in 24 carotid-carotid bypass patients.[39] However, the reported stroke rates of 4% to 6%[38,39] are higher compared to subclavian or axillary-based bypasses. When performing total arch debranching, a carotid-carotid bypass is often combined with a carotid-subclavian bypass prior to zone 0 aortic endografting.[36,40]

Axilloaxillary and Subclavian-Subclavian Bypass

Another option to revascularize the subclavian artery is via axilloaxillary bypass (Fig. 98.9). The axillary artery is exposed bilaterally by transverse infraclavicular incisions along the lateral third of the clavicle. The pectoralis major is retracted between the muscle fibers, and the axillary artery is identified just inferior to the clavicle, posterior to the deep pectoral fascia. A

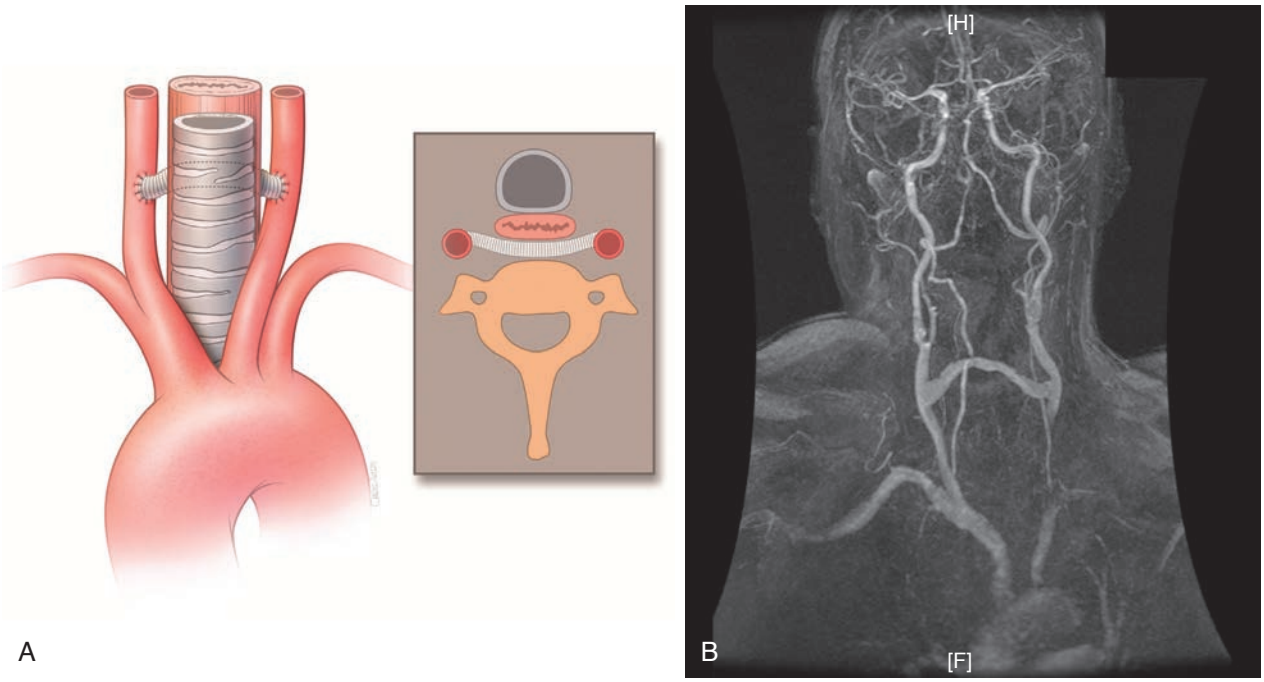

Figure 98.8 Carotid-Carotid Bypass. (A) Illustration depicting a right-to-left carotid-carotid artery bypass using an 8-mm ringed prosthetic graft configured with end-to-side anastomoses to both common carotid arteries. (B) Completion angiogram after carotid-carotid bypass.

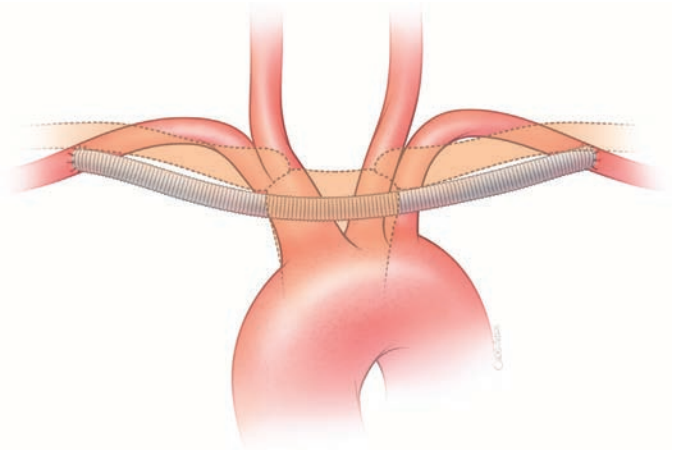

Figure 98.9 Axilloaxillary Bypass. Illustration depicting axilloaxillary artery bypass using an 8-mm ringed prosthetic graft configured with end-to-side anastomoses to both axillary arteries.

subcutaneous tunnel is created between the two arteries, and an end-to-side anastomosis with prosthetic graft is performed bilaterally. The axilloaxillary bypass can be used to maintain cerebral flow during total aortic arch debranching prior to zone 0 aortic endograft deployment.[41]

Although good results have been reported,[42,43] the potential risks of graft infection, skin erosion, and need for possible future sternotomy have limited widespread use of this technique. Aziz and colleagues summarized 16 studies with 426 patients.[36] The perioperative mortality was 0.5% with stroke in 1.1%. A cervical subclavian-subclavian bypass avoids tunneling across the chest.[44]

Carotid-Contralateral Subclavian Bypass

If the target vessel is the contralateral subclavian artery, exposure of the subclavian artery is performed as described earlier for subclavian transposition, and the graft is sewn end to end with 5-0 or 6-0 polypropylene suture. If transposition is contraindicated, the graft can be sutured end-to-side at a more distal location on the subclavian artery.

Operative Results

In general, perioperative mortality and stroke rates are lower with cervical revascularization compared to transthoracic reconstructions. Long-term patency rates are also slightly lower. Berguer and colleagues reviewed 182 cervical reconstructions in 1999.[3] Stroke, myocardial infarction, and mortality rates were 3.8%, 3%, and 0.5%, respectively. Five- and 10-year survival rates were 72% and 41%, with 5- and 10-year patency rates of 91% and 82%. In 2007, Byrne and colleagues reported a 5-year cumulative patency rate of 92% in 143 patients with cervical brachiocephalic artery revascularization.[45] They had stroke, myocardial infarction, and mortality rates of 1.4%, 4.3%, and 0.7%, respectively. Analysis of registry data comparing transthoracic and cervical revascularizations showed similarly low perioperative composite stroke, myocardial infarction, and death rates but a slightly higher complication rate in median sternotomy patients.[46]

Postoperative Management

The physiologic stress after extraanatomic revascularization is less than that after transthoracic revascularization. The primary postoperative concern is the presence of neurologic deficits in

patients in whom the carotid artery was clamped. All patients are observed in the operating room for gross motor function before transfer to the recovery room. Patients are usually discharged after 1 or 2 days. After the initial postoperative visit, graft patency is monitored by duplex ultrasound examination every 6 months for the first year and annually thereafter.

Although early treatment for this disease process involved open surgical reconstruction,[1,2] more recently endovascular therapy has assumed a more important role in the treatment of patients with brachiocephalic artery disease.[3-6] New developments in the technology available for interventional therapies and strategies for dealing with these complex lesions from an endovascular approach have improved risks and recovery times related to these procedures. For the experienced interventionalist, the risks remain low and the morbidity acceptable; however, the consequences of inadequate preparation and poor technique can be devastating.

PROCEDURE PLANNING

A great deal of the information on patients with occlusive disease of the arch vessels comes from reports of open surgical series.[7-10] A detailed understanding of the anatomy of the aortic arch along with knowledge regarding the positions of the vessel origins is a necessity for planning these procedures. The most common cause of arch vessel stenosis is atherosclerosis, but even this occurs relatively infrequently. In evaluations for carotid bifurcation occlusive disease, only 5% to 15% of patients are found to have concomitant disease in the arch vessels.[11-14] The prevalence in patients without cerebrovascular disease is lower, but it is not insignificant even in the general population, where it is found in approximately 1.5% to 2.0%. In patients with coronary artery disease, prevalence can be as high as 4% to 7%[15-18] and greater (up to 11%) in those with more significant coronary disease. The left subclavian artery is involved most often, followed by the innominate and left common carotid arteries, which are both affected approximately 30% of the time.[12,19] Less common causes of arch vessel disease include

Takayasu arteritis, radiation-induced injury, aneurysm, and dissection.

IMAGING STUDIES

Duplex Ultrasound

Ultrasound imaging of the vessels of the aortic arch is often the initial imaging modality. The velocity information obtained can provide insight into the degree of stenosis, and often the visualization (or lack thereof) of calcification can provide information regarding the nature of the occlusive process.[20-22] However, the anatomic discrimination necessary to guide intervention can be obtained only with more detailed imaging.

Computed Tomography and Magnetic Resonance Angiography

The most commonly used methods for assessing the anatomy of the aortic arch are computed tomographic angiography (CTA) and magnetic resonance angiography (MRA), along with standard angiography. The axial imaging modalities have the obvious advantage of avoiding catheter manipulation within the aortic arch and its potential complications; they can detect both aneurysmal disease and mural atherosclerotic debris. These studies can also assess the extent of calcification at the origins of the vessels. When the imaging region includes the brain, they can define the intracranial circulation as well. In most instances the source images can be reformatted into three-dimensional models of the aortic arch and its branches to allow excellent visualization of the relevant anatomy. The information obtained from these studies can often allow complete procedural planning before conventional angiography is performed.

The normal anatomic makeup of the aortic arch involves three arch vessels: the innominate or brachiocephalic artery, which normally gives rise to the right subclavian and right common carotid arteries; the left common carotid artery; and the left subclavian artery. However, in up to 20% of individuals, the left common carotid artery originates from the innominate artery in a "bovine" configuration, thus leaving only two main trunks off the aortic arch (Fig. 99.1).[23] In as many as 6% of individuals, the left vertebral artery originates from the aortic arch directly, between the left common carotid and left subclavian arteries. Finally, aberrant origin of the subclavian arteries, with or without an associated Kommerell diverticulum (see Chapter 98) and/or a right-sided aortic arch, are best displayed on preprocedural axial imaging studies.

Arteriography

For most patients, procedural planning and determination of the degree of stenosis can be achieved with axial imaging alone; angiography is typically performed as part of the therapeutic intervention to treat identified disease. In performing catheter-directed imaging, care must be utilized, as disease of the arch vessels is often associated with disease of the aortic arch itself. Manipulations in this area provide the opportunity to dislodge plaque or debris, which can lead to emboli in the cerebrovascular or other circulatory beds. Flush aortography is normally performed with a pigtail or halo flush catheter to prevent high-pressure injections via a straight-end catheter, which can cause arch dissection. Imaging of the arch is best performed in a left anterior oblique projection to "open up" the arch on the imaging screen, while the flush catheter is best positioned proximal to the origin of the innominate artery. Frequently it is helpful to rotate the imaging acquisition arm with a wire in the catheter placed across the arch to allow optimization of the imaging plane for maximum visualization. Images obtained from aortography are used to help identify vessel origins, degree of vessel stenosis, and the type of catheter or guide that may be necessary to cannulate and image the individual arch vessels.

Angiographic imaging of the bifurcation of the innominate artery is best performed in a right anterior oblique projection of approximately 20 degrees with a selective catheter positioned in the proximal innominate artery. This orientation will often maximally separate the origins of the branches of the innominate

artery, allowing individual assessment of the right common carotid and subclavian artery origins and ideal visualization for treatment of either vessel.

Transesophageal Echocardiography

Transesophageal echocardiography can be used to image the aortic arch, but it has not often been used in planning arch interventions.[24] This imaging modality can provide real-time information regarding the presence and extent of dissection in this region and the mobility of atheromatous plaque near the arch vessel origins. Although it is not commonly used for interventional planning, transesophageal echocardiography can provide important information, especially in the setting of complex arch disease.

Anatomic Considerations

For interventions in this location, it is particularly important to understand the high-risk anatomic features, as missteps in performing these procedures can lead to terrible consequences for the patient. High- and low-risk lesion features are noted in Table 99.1. Axial imaging with either CT or MR can now provide a functional three-dimensional model of the relevant anatomy, which can allow the calculation of ideal imaging angles for viewing the aortic arch and the branch vessel origins as well as the ability to select the preferred catheter for vessel access preoperatively.

Normal arch anatomy with vessel origins at the peak of the arch offers the ideal situation for vessel access. In this scenario the left subclavian artery is often cannulated with ease and antegrade recanalization can be performed even in the setting of complete occlusion; forward pressure on the occlusion can be achieved with nearly a direct path of the catheter and sheath combination. In the most common variant of arch anatomy, with the left common carotid artery originating from the innominate artery, access to this same vessel can be challenging; in situations where the origins of these vessels have rotated around the arch such that they are located in the ascending aorta, it may be so challenging to access the vessels that either open surgical reconstruction or hybrid endovascular and/or open repair may be easier and safer and thus preferable to a completely endovascular approach.

TABLE 99.1 Favorable and Unfavorable Characteristics of Arch Vessel Disease

Favorable	Unfavorable
Stenosis	Occlusion
Concentric lesions	Eccentric lesions
Vessel origin at top of arch or distal	Vessel origin in ascending aorta
Absence of calcium	Heavy calcification
Nonulcerated plaque	Ulceration
Asymptomatic	Symptomatic
Nonostial lesions	Ostial lesion
	Plaque abutting vertebral artery origin

Disease Distribution

Knowledge of disease extent in the arch vessels is important before beginning the intervention. Occlusions of these vessels can be crossed and intervention successful; however, there is wide variability in the technical success rates in reported series of treatment of arch vessel occlusions, with reported failure rates ranging from 0% to 40%.[25-28] Knowledge of the anatomic relationships of the disease to other vessel origins is critical. For example, when intervening in the left subclavian artery, it is imperative to know the location of the origin of the left vertebral artery and its proximity to disease to avoid injury to the vessel, whether originating directly off the arch, near the subclavian origin, or at the normal anatomic position off the proximal subclavian artery. Additionally, it is essential to recognize that intervention in the origin of any arch vessel can have an impact on the orifice of closely located neighboring vessels. In all arch interventions, knowledge of the status and location of neighboring vessels allows planning to prepare for and mitigate risk of occluding or injuring closely located arch branches.

OPTIONS FOR ENDOVASCULAR THERAPY

Angioplasty

Initial descriptions of endovascular intervention in the supra-aortic trunks involved balloon angioplasty alone.[3-6,29-33] Initial success rates reported in these series varied from 80% to 95%, and recurrence rates were acceptable at 8% to 25% at 1 to 2 years. Initial failures were commonly related to an inability to pass the balloon itself across the lesion rather than an inability to gain wire access. Currently lower-profile balloons make this scenario an uncommon problem. A recent report has documented a technical failure rate of less than 10%,[34] with a meta-analysis showing technical success rates of 94% for stenosis and 64% for complete occlusions.[35] The use of angioplasty with selective stenting rather than primary stenting has been argued by some to be a reasonable alternative. A recent meta-analysis of series comparing angioplasty with selective stenting with primary stent placement revealed mean technical success rates for angioplasty and/or stent of 87% as compared with primary stenting, which was successful in 92% of reported cases.[36] Despite the improved initial success rate with primary stenting, midterm primary patency rates for angioplasty and/or selective stent and primary stent were similar at 89.9% and 88.7%, respectively, at 24 months. Similar patency rates were noted at later time periods as well (79.6% vs. 76.9%). From these data one can infer reasonable outcomes with angioplasty alone, with good initial success. Nevertheless, since the introduction of stents for treatment of this disease, the principal interventional therapy approach has become primary stent placement.

Medicated balloons have been utilized for the treatment of recurrent stenosis,[37] but the widespread use of this technology is difficult to justify without definitive outcome data.

Stents

Since the introduction of stents for treating arch vessel disease, this technology has been the mainstay of interventional therapy in this location.[26,38-43] These studies report technical success rates from 91% to 100%, with failures occurring only in patients with total occlusions. Follow-up in the larger of these series has demonstrated patency rates of 77% to 100% over an 18- to 24-month period. It remains unclear whether primary stenting of all arch vessel lesions is clearly beneficial, and some authors have suggested that a selective approach to stenting may be a better alternative.[44,45] The most common approach reported today involves the routine use of stents in treating these vessels. It appears that in treating occlusions or complex stenoses, primary stenting should be the preferred approach. There remains little information regarding the use of medicated stents for the treatment of supra-aortic trunk[46] occlusive disease.

Covered Stents

Covered stents for the treatment of arch vessel disease have been reported for conditions involving aneurysms and traumatic injury,[47-49] but no meaningful data are available on the use of these devices for the treatment of arch vessel occlusive disease. Reports document excellent acute success of these devices in the setting of trauma or aneurysm treatment and patency of the devices has been maintained; repeat interventions have occasionally been necessary for the treatment of either kinks or angulation within the prosthesis. It is conceivable that the use of covered stents for occlusive disease in this anatomic location may prove helpful in reducing the incidence of neointimal hyperplastic recurrent stenosis, but at present there is inadequate information to make a recommendation for their routine use in this setting.

PERIOPERATIVE MEDICAL MANAGEMENT

Antiplatelet Agent

There are few data regarding the use of antiplatelet therapies for specific intervention in the supra-aortic trunks. Recommendations are currently based on inference from the use of these agents in patients with peripheral and cerebrovascular disease and those requiring carotid bifurcation intervention (see Chapters 40 and 89). The benefit of the use of aspirin in patients with peripheral vascular disease is well documented, and it is recommended that all patients with peripheral or cerebrovascular disease be maintained on aspirin.[46] The routine use of aspirin is mandatory, and aspirin should be considered part of standard therapy for aortic arch interventions. The use of clopidogrel for the treatment of patients with atherosclerotic vascular disease has also been well documented; it provides a reduction in risk compared with aspirin use alone in this population.[50] The combination of this agent with aspirin for the treatment of symptomatic carotid disease is beneficial in reducing embolic episodes, as documented by transcranial Doppler examinations,[51] and the combination of aspirin and clopidogrel has shown benefit when used as the periprocedural antiplatelet regimen in carotid stenting.[52,53] The addition of glycoprotein IIb/IIIa inhibitors to the dual antiplatelet therapy has not been shown to reduce embolic events and may significantly increase intracranial hemorrhagic complications.[54-56] Based on this information, dual aspirin and clopidogrel therapy is recommended as the standard antiplatelet regimen for arch intervention.

Intraprocedural Heparin

Heparin is normally used as the intraoperative anticoagulant for intervention in the arch vessels, and there are no meaningful data assessing alternative anticoagulant strategies in this clinical setting.[57] The use of bivalirudin in carotid interventions has been reported,[58] and this approach may prove to be a safe alternative to the routine use of unfractionated heparin. Without additional data, however, the routine use of bivalirudin cannot be recommended. Currently heparin administration adequate to maintain activated clotting times of greater than 250 to 300 seconds is recommended, and reversal of the heparin with protamine after intervention is reasonable.

Technical Details

After angiography of the arch, selective catheterization must be performed to gain adequate imaging of the relevant arch vessels and allow intervention. In most instances, this is best achieved with a forward-facing catheter with minimal angulation. Options for this initial access include the vertebral (Cook, Inc., Bloomington, IN), Headhunter (Cook, Inc.), and angled Glide (Terumo, Tokyo, Japan) catheters. These less complex catheters allow simple access to the vessels, and if advancement of the catheter is necessary, it may be performed easily. When the angulation of the vessel origin mandates an increased angle on the catheter, alternatives include the C2 (Cook, Inc.), JR4 (Cordis, Mexico), and internal mammary (Boston Scientific, Mexico) catheters. The use of complex or reverse-curve catheters necessitates formation of the catheter within the aortic arch, which can increase the risk for embolic complications and may complicate access to these vessels. Nevertheless, use of these reverse-curve catheters may be essential because of the angulation of the vessel origin. Once selective access has been obtained, the vessel can be imaged and intervention can be performed.

One positive aspect of endovascular intervention in this vascular distribution is the potential for an alternative access site for treatment. Brachial access for intervention in the subclavian arteries and the innominate artery can provide an approach to treat an obstructive lesion that might otherwise prove impossible to revascularize from the femoral route. These

other access routes also provide alternative methods for imaging or the insertion of protective devices while attempting to intervene for the treatment of stenotic lesions.

Left Subclavian Artery Intervention

Many of the techniques described in this section are applicable to interventions in the other arch vessels and can be helpful to keep in one's armamentarium. Other arch vessels less frequently undergo intervention because they are less often affected by occlusive disease. However, because of the increased angulation noted at the origin of these vessels, these interventions can prove to be more challenging, especially when performed from a groin approach.

Of the three vessels, access to the left subclavian artery is usually the easiest to obtain. Often only a mildly angled catheter is required, and most interventions can be performed with a sheath rather than an angled guide catheter. Typically, after arch aortography with either a 4- or 5-Fr flush catheter, an exchange is made for a selective catheter. After accessing the origin of the vessel, a 0.035-in. Glidewire (Terumo Cardiovascular Systems, Ann Arbor, MI) is passed across the lesion into the distal vessel. If a stiff Glidewire is used, it can be left in place, and a long 6-Fr sheath can be advanced from the groin over this wire. If the Glidewire used has less support, wire exchange for either a Rosen (Infiniti Medical, Menlo Park, CA) or Storq (Cordis, Bridgewater, NJ) wire can be performed, and the sheath then advanced over this wire. The sheath is positioned at the origin of the vessel and just below the level of disease. The vessel origin and the area of disease are positioned within the center of the imaging field to minimize distortion from parallax. Predilation with a 4- to 6-mm angioplasty balloon allows accurate determination of size and will ensure free passage of the stent. Frequently this predilation is performed with a balloon that is longer than the lesion itself to allow fixation of the balloon at either end of the stenosis. The balloon diameter chosen for predilation should be slightly smaller than the vessel distally so that dissection of the distal vessel is not induced. In the case of proximal subclavian lesions, this will limit the potential for damage to the origin of the vertebral artery. This technique also allows imaging of the distal extent of the lesion to gauge the proximity of the vertebral and internal mammary artery origins, because preservation of these vessels is critical. The length and diameter of the stent selected should be sufficient to ensure that the lesion is covered fully and the vessel is expanded to its true size and not that of a poststenotic dilated segment. The stent should not extend beyond the origin of the vertebral artery. Ideally, for lesions located proximally in the vessel, the stent should additionally extend approximately 1 to 2 mm into the aortic lumen. If a balloon-expandable stent is undersized, it will allow further expansion by dilation with a larger diameter balloon. It is important to know the limits of expansion of the stent while still retaining the strut architecture, which provides adequate radial resistance to compression. After adequate dilation of the stent in the vessel, if the proximal extent of the stent has been positioned partially in the aorta, it is helpful to "flare" this end of the stent by dilating it with an oversized balloon. This will further open the origin of the vessel and reduce protrusion of the stent into the aortic lumen, which can be an impediment to future interventions in either the arch vessels or the coronary arteries.

In some situations, the interventionalist may choose to place the stent in "protected" fashion through the lesion. To do so, the sheath and dilator are passed through the lesion and the sheath remains within the lesion itself. Typically, for orificial disease, a balloon-expandable stent is positioned just at the origin of the vessel; if the stent has been placed in protected fashion, the sheath is withdrawn to expose the stent within the lesion. In using this approach, the interventionalist must ensure that the stent is positioned appropriately before complete withdrawal of the sheath. This positioning can be difficult to achieve; thus it is not often used as the principal approach.

Vertebral Artery Protection

When the lesion approaches the origin of the vertebral artery and does not directly involve the origin of the subclavian artery, it is important to "protect" the vertebral artery origin. This can be done in two ways. The first is to use a slightly larger sheath and insert a second wire into the origin of the vertebral artery. If there is concern that the origin of the vessel may need to be partially covered once the sheath is within the subclavian artery, the 0.035-in. wire can be exchanged for a 0.014-in. wire placed antegrade via the axillary artery. A second 0.014-in. wire can then be positioned in the vertebral artery. If a balloon-expandable stent is used in this region, it may be possible to place a 0.035-in. system over both wires and position the stent over both wires as well. This ensures that the origin of the vertebral artery will be protected. In this region, a self-expanding stent may be preferable because some vessel torsion and flexion will occur outside the thorax. The delivery system of a self-expanding stent will not allow proximate placement to the vertebral origin if the delivery system is inserted over both wires. Therefore the stent delivery system must be placed over the wire in the axillary artery. Placement of this system on the wire in the vertebral artery poses a significant risk of dissecting the origin of the vertebral artery.

It is imperative in this situation to be able to adequately visualize the vertebral origin as the stent is being deployed. For this reason, brachial access should be considered. Ultrasound guidance can be used to obtain micropuncture access to the brachial artery, which is cannulated in a retrograde direction with a 5-Fr sheath. A straight catheter can be positioned in the proximal vessel just beyond the vertebral origin, and retrograde imaging via this catheter will allow precise visualization of the origin and positioning of the stent. An additional degree of safety can be afforded if a longer sheath (30-45 cm) is inserted into the brachial artery and wire access into the vertebral artery is obtained via this access. This will allow continuous simultaneous angiographic imaging of the vertebral origin and protective wire access.

Embolic protection of the vertebral artery system during endovascular intervention has been described, but its routine use is not advocated. The baseline risk of embolic complications

with intervention in this region is very low; the risks of adverse events related to insertion of a protection device in this area remains undefined.[59] Complex lesions proximal to the origin of the vertebral artery pose an increased risk of posterior cerebral embolization; therefore, care should be taken in crossing and treating these lesions. In the setting of subclavian steal, it is clear that normalization of flow takes some time to occur, and there is inherent protection related to the preexisting reversed flow in the vertebral artery.[60]

Brachial Access

Retrograde brachial access can be important for traversing proximal occlusions in the left subclavian artery. With flush occlusion of the vessel origin, it can be impossible to position a catheter at the origin to allow traversal of the occlusion via aortic access. In certain difficult situations, through-and-through access may be necessary to ensure access across the lesion and adequate purchase within the vessel for delivery of the device. Access to the brachial artery is similarly obtained as noted earlier, and a long 5- or 6-Fr sheath is positioned in the vessel just distal to the extent of the occlusion. A Glidewire is used in conjunction with either a straight or mildly angled catheter to traverse the occlusion. It is important to ensure reentry into the aorta because it is relatively easy to enter a dissected plane within the aortic arch. Once it appears that the wire is traversing through the arch or the descending aorta, the catheter can be introduced, and the wire removed; blood should exit the catheter freely. In the absence of free flow of blood, the catheter can be assumed to be in a plane outside the vessel lumen; therefore a different path must be created for access into the aortic lumen. Once access into the aortic lumen has been obtained, treatment of the lesion can be completed from the brachial approach. In this situation, it is imperative that the stent be positioned 1 to 2 mm into the aorta, because this is almost certainly an ostial lesion. When positioning the stent, imaging can be difficult from the brachial sheath. In this situation, the groin access that has been obtained for arch aortography can be extremely helpful. The wire is positioned within the flush catheter around the aortic arch. This wire then creates a fluoroscopic marker for the aortic wall, so that the location of the subclavian artery origin can be identified. This technique can be used to assist in identifying the level of the origin of any of the arch vessels, but it is particularly helpful in performing a retrograde intervention.

Radial Access

Increasingly, the radial artery is being utilized for percutaneous coronary interventions. This approach has proven to decrease bleeding complications and diminish renal dysfunction.[61] Reports have demonstrated that the use of this access site as an alternative for the retrograde treatment of subclavian and innominate disease provides safe results, comparable wih those achieved via brachial access.[62,63] Particularly in situations where femoral and upper extremity access is being considered or utilized, transradial access can be considered as a reasonable alternative.

Innominate Artery Interventions

Interventions in the innominate artery expose the patient to a risk of embolization in both the carotid and vertebral distributions. Although the risk of embolization should be low, there are options to minimize the potential for embolization, including protection during intervention (see the section titled Carotid Protection, further on). However, in most circumstances innominate interventions completed from a retrograde femoral access do not use protection devices.

In treating innominate artery disease it is important to understand where the origins of the branches of this vessel are in relation to the disease process. Frequently, imaging of the vessel in the left anterior oblique projection will be needed to image the origin of the innominate artery from the aortic arch. Imaging of the vessel in the right anterior oblique projection will also be required to isolate the origins of the innominate branches. It may be necessary to add either caudad or cephalad angulation to the right anterior oblique projection to isolate the origins of these branches. However, it is imperative to ensure that the distal aspect of the stent placement be understood in relation to the bifurcation of the innominate artery

Access

The most challenging of the arch vessels to access from the groin, even in the normal arch configuration, the innominate artery may pose an additional challenge in the situation where the left common carotid artery originates from this vessel, as the left anterior cerebral circulation may be potentially exposed to embolic risk from vessel cannulation. One must also ensure that the origin of the left common carotid artery is not compromised by stent placement across the origin of the innominate artery. In some instances, it may be better to perform extra-anatomic revascularization of the left common carotid artery and then treat the innominate vessel as needed with an interventional approach. This option will avoid the possibility of "jailing" the left common carotid artery with stent placement.

Because the innominate artery often has the most difficult angulation off the aortic arch, it can be very challenging to engage its orifice adequately to allow interventional access. As with the left subclavian artery, access via the brachial artery on the right side can allow excellent interventional access and visualization of the distal aspect of the plaque. Access via a through-and-through technique can also be used by snaring the wire and bringing it through the alternative access site. In some instances it may be helpful to have a second access so that a protection device can be used to protect the right common carotid distribution. Normally, if access to the innominate origin from the groin has not been achieved easily within 15 to 20 minutes of initiating the attempt, brachial access should be used. Extensive attempts in patients with significant disease at the origin expose them to unnecessary risk when there is an easy alternative site for interventional access. In most situations, when the brachial approach is used, the distal brachial wire is left in the ascending aorta so that the angle of stent placement

is closer to the angle of blood flow within the proximal aorta and the innominate artery.

Carotid Protection

If there is concern about the need for protection in the carotid distribution and access from the groin has proved challenging, the wire from the arm can be snared and brought out through the femoral access. This will allow a catheter to be brought through the lesion from below and a guide to be positioned at the origin of the vessel. The through-and-through wire can be used to provide support, holding the guide in place, and a protection device can be placed from either the brachial or femoral approach to within the right carotid distribution; the lesion can then be treated from the groin. If the protection device has been placed from the groin, the intervention should be performed over the protection device's wire. This will allow capture and removal of the protection device through the stent rather than around it.

In most instances, however, there is a low risk of embolization, and the lesion can be treated using the simplest approach, without protection. As discussed earlier, when access from the arm is used, the femoral wire can be left around the arch to assist in identifying the origin of the arch vessel. Finally, many surgeons approach innominate lesions via a cervical common carotid cutdown, affording both simple access to the lesion and providing embolic protection by direct carotid clamping and flushing.

Innominate Branches

Disease in branches of the innominate artery usually occurs at the vessel origins; in many instances it will require a kissing-stent technique to avoid impingement of the origin of the other vessel (Fig. 99.2). This approach can be performed from single access in the groin but requires a larger sheath for the introduction of two-stent delivery systems. An alternative approach involves simultaneous access from the groin and arm to allow separate introduction of the devices. Wire access to the carotid artery is obtained through the groin, and the arm approach provides access through the subclavian artery. Simultaneous positioning of stents in the origin of each vessel can thus be achieved, and imaging from the sheaths in both locations allows excellent visualization of the proximal and distal aspects of the occlusive lesion. Simultaneous deployment of the stents allows preservation of the ostia of both vessels.

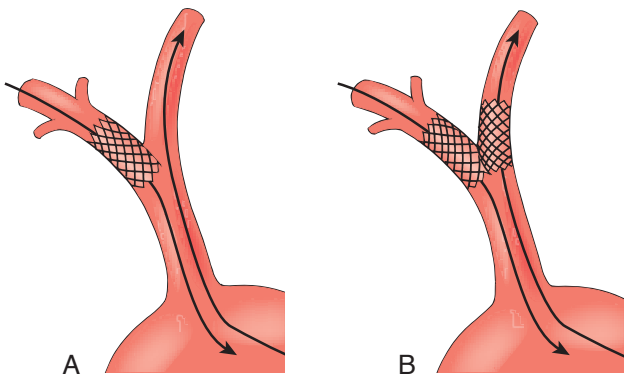

Figure 99.2 (A) Treatment of the right subclavian artery origin can result in "jailing" the origin of the right common carotid artery when the proximal end of the stent projects into the common carotid lumen, as shown. (B) Treatment of the innominate artery branch origins with a kissing-stent technique to preserve both origins.

Left Common Carotid Artery Interventions

Interventions in the left common carotid artery most commonly involve the origin of the vessel as it arises from the aortic arch, but intervention may also be necessary because of disease at the vessel origin as it arises from the innominate artery. When the vessel originates from the arch, the intervention is performed similarly to the previously described femoral approach to the left subclavian artery. Access to the vessel is obtained with the least angled catheter possible, and a decision is made regarding the use of either a guide catheter or sheath to deliver the stent. In some instances access to the origin of this vessel is tenuous because of its angle off the aorta; in this situation a "buddy wire" can be positioned in the external carotid artery distally to maintain the position of the guide or sheath at the origin of the vessel. A protection device is then advanced and deployed within the internal carotid artery. Intervention is performed over the protection device wire, which can subsequently be captured and removed. The buddy wire is removed last to ensure that the access sheath or guide remains stable throughout the treatment.

When access to the origin of this vessel proves challenging, the interventionalist must decide whether to attempt retrograde interventional access through open carotid artery exposure or to proceed to surgical revascularization. Several factors contribute to this decision, including the extent of disease in other arch vessels, in particular the left subclavian artery; the presence of significant disease in the ipsilateral carotid bifurcation, which may be addressed at the same time by simultaneous carotid endarterectomy (CEA) and retrograde intervention; and a history of operations or radiation therapy to the neck. When attempting intervention in this vessel, it is important to remember that changing to an alternative approach may be safer than persisting in attempting access in a very diseased arch.

Innominate and Left Common Carotid Interventions in Combination With Carotid Endarterectomy

As stated earlier, patients with cerebrovascular disease have a higher rate of brachiocephalic occlusive disease than the general population. It remains rare that both lesions will be significant enough to require treatment. This occurs in approximately 5% of patients who require carotid intervention.[64,65] In those who need both innominate or common carotid intervention in conjunction with internal carotid intervention, a hybrid approach has emerged as a safe and efficacious option. Clinical decision making as to whether a proximal intervention must be added

to a CEA is generally straightforward; only flow-reducing lesions need treatment, and with the proliferation of CTA and MRA, lesions at the arch vessels origins are commonly detected. One clinical clue is the presence of a palpable common carotid pulse in the neck, which implies that the proximal lesion is not flow-limiting; in addition, the duplex image of the cervical common carotid waveform will be blunted in proximal flow-reducing lesions. Finally, it is a simple maneuver to obtain an intraoperative intra-arterial pressure measurement to assess the hemodynamic significance (or lack thereof) of the proximal lesion.

Technique

The hybrid approach as described by Moore et al.[66] involves proceeding with surgical exposure of the carotid bifurcation and internal carotid in the standard fashion for endarterectomy. Once exposed, the internal carotid can be clamped above the level of disease to avoid cerebral embolization, and intervention on the common or innominate lesion is performed under that protection. Access is gained into the common carotid below the level of disease, and a hydrophilic wire is passed through the lesion. This is then exchanged for a stiff wire, and angioplasty and/or stenting conducted in the normal fashion. After the intervention has been performed, a clamp is placed on the common carotid above the stent but below the bifurcation disease. The artery is opened and any embolic debris is cleared with endarterectomy. An alternative option is to first perform the endarterectomy, which allows for avoidance of stagnant flow in a newly placed stent for any significant period of time.

Results

A recent meta-analysis of 13 studies, in which tandem lesions were treated in the fashion reported earlier, a technical success rate of 97% was achieved.[67] Stents were used in 61% of procedures, whereas the remainder underwent simple balloon angioplasty alone. Thirty-day mortality and stroke rates were 0.7% and 1.5%, respectively. These studies had a mean follow-up of 12 to 36 months. During this time, 10 of the 129 total patients developed restenosis of the proximal lesion, and 2 patients were found to have asymptomatic restenosis of the endarterectomy site. With regard to proximal restenosis, 70% of these patients did not have stents placed at the initial operation. Four of these patients were symptomatic, and a total of 7 underwent reintervention, including repeat angioplasty ($n = 4$) and bypass graft ($n = 3$). The favorable results seen so far in published series for this approach seem to indicate that it is both a reasonable and efficacious option, but further study is justified prior to widespread application. A more recent review of a large single-center series reported less optimistic outcomes.[68] These authors reported their experience with 23 patients undergoing combined endarterectomy with proximal intervention and noted dissection in the proximal intervention site in 3 patients, 2 of whom required additional stent placement and one of whom sustained stroke and death. There were two early strokes (9%) and one death (4%), along with five patients having restenosis (4 at the endarterectomy site and 1 at the proximal intervention site) at a mean follow-up of 30 months. These authors advised caution in utilizing this approach and, as noted previously, they advised that performance of this combined procedure should be limited to those with hemodynamically significant proximal stenosis.

RESULTS

Initial descriptions of endovascular treatment of arch vessel disease involved limited numbers of patients treated with angioplasty alone.[3,4,69,70] Since that time, however, extension of the experience of these and other authors has increased the information available regarding perioperative complications and longer-term outcomes.[24,71,72] These investigators have noted a low complication rate with reasonable initial success and acceptable long-term results. In these patients, stents were applied selectively.

The introduction of stents has markedly changed the interventional options available for treating lesions; they have more commonly been used as a primary method of treating occlusive lesions in this region. As primary stenting is the more commonly utilized technique, the initial technical results of reports of primary stenting are noted in Table 99.2**.** Complication rates in these series ranged from 0% to 20% with the majority consisting of access-related problems, including hematoma, pseudoaneurysm formation, and vessel thrombosis. Importantly, there were very few neurologic sequelae in these series, with two strokes occurring in a single series[42]; both occurred in patients undergoing combined endarterectomy and proximal branch intervention. In one of the larger series reported, Karpenko et al.[73] noted an incidence of TIA in 1 (0.8%) of patients with stenosis and 3 (2.5%) of patients with occlusion, and no strokes were identified. In an additional large study, the SCALLOP investigators[74] noted no TIA in patients with stenosis and two (1.2%) in patients with occlusion. Stroke rates were similar in both groups at 1.8%; however, in the SCALLOP registry, over 15% of patients had stents placed across the origin of the vertebral artery, a technique we would not recommend because of the neurologic risk, which would seem to be inherent in this approach. In most of these series, the incidence of death and neurologic morbidity was extremely low with no deaths noted in the two largest studies.

Rupture is a rare but recognized risk when using endovascular means to treat brachiocephalic occlusive disease. There are few reports on the incidence or management of brachiocephalic rupture. Options for management are similar to those in the event of rupture in other vessels during angioplasty and/or stenting.[76] This would typically include the use of balloon occlusion to immediately control the injury and treatment with covered stent placement to control hemorrhage.

Patency

From the reported series published to date, endovascular patency rates appear to be lower than those reported for surgical

[a]Secondary patency.

reconstruction in these vessels (Table 99.3). One-year patency rates vary from 88.5% to 97%, and 5-year patency rates vary from 77% to 89%. Importantly, recurrent stenosis can be treated by reintervention, with improvement in primary patency rates as noted by Rodriguez-Lopez et al.[43] and the SCALLOP registry investigators.[74] These investigators reported a 36-month secondary patency rate of 90%[38] and a 60-month secondary patency rate of 97.7%,[74] which is comparable to data from open surgical bypass series.

There are currently four retrospective studies that have compared the results of endovascular therapy for subclavian occlusive disease with outcomes from surgical reconstruction.[77-80] In the first of these studies, AbuRahma et al.[77] compared data on procedures performed over a 13-year period at a single institution. During this period, 121 patients underwent intervention with angioplasty and stenting for subclavian artery occlusive disease, whereas 51 patients underwent operative reconstruction via carotid-subclavian bypass grafting. The diagnosis of restenosis was based on the presence of an arm pressure differential together with appropriate duplex criteria. In the endovascular group, two completely occlusive lesions could not initially be crossed. Complication rates were 5.9% in the bypass group versus 14.9% in the endovascular group. Bypass complications included two phrenic nerve injuries, from which patients recovered within several months, and one nonfatal myocardial infarction. Endovascular complications included two distal embolic events treated by intervention, congestive heart failure, brachial artery thrombosis treated by thrombectomy, reperfusion arm edema, pseudoaneurysm, procedure-related dissection and/or thrombosis treated by thrombolysis and stenting, and 11 minor complications (8 hematomas not requiring transfusion, 2 cases of headache and/or syncope, and 1 superficial wound infection). Overall the patients treated via an endovascular approach experienced a major complication rate of 5.8%, which was very similar to the major complication rate of surgical bypass. Primary patency rates for bypass at 1, 3, and 5 years were 100%, 98%, and 96%, respectively, versus 93%, 78%, and 70%, respectively, for endovascular therapy.

Another report compared the outcomes of 114 patients who underwent 137 procedures for subclavian artery stenosis

treated by either primary stent placement (67 lesions) or carotid-subclavian bypass grafting (70 lesions).[78] Among lesions that underwent endovascular therapy, 62 were successfully treated. The five patients in whom endovascular attempts failed underwent bypass. Primary patency rates in the interventional patients were 78%, 72%, and 62%, respectively, at 1, 3, and 5 years, with assisted-primary patency rates at the same time points of 84%, 76%, and 76%. For patients who underwent surgical therapy, 1-, 3-, 5-, and 10-year patency rates were 95%, 92%, 90%, and 90%, respectively, and primary-assisted patency rates at the same time points were 97%, 97%, 95%, and 95%, respectively. There was no mortality in either group, and complication rates were similar: 20% in the open surgery group and 10% in the endovascular group. Furthermore, no cerebrovascular events occurred in either group.

In another study of 76 patients treated over a 20-year period at a single institution, 35 underwent surgical reconstruction with bypass and 41 had attempted angioplasty.[79] The surgical group had a total of four complications, including an early graft occlusion treated by thrombectomy, two brachial plexus neurapraxias that resolved fully, and one hematoma in the neck, with no perioperative neurologic events or deaths. The 5-year secondary patency rate in this group was 97%. In the endovascular group, there were eight failed attempts at treatment. Six of these failures occurred in the setting of total occlusions, and one failure occurred because of the development of a cerebellar infarct, at which point further interventional attempts were abandoned. There were four complications among these patients, including the one cerebellar infarct noted, two subclavian artery dissections requiring stenting, and one covered stent protruding into the aorta to an extent that necessitated surgical removal of the stent. The primary patency rate of successfully treated lesions was 82% at 4 years.

The most recent notable report[80] evaluated outcomes over a 20-year period in 252 patients who underwent balloon-expandable stent placement ($n = 148$) or extrathoracic bypass grafting ($n = 104$). Of the bypass patients, 71 underwent axilloaxillary bypass and 33 had carotid-subclavian bypass. There were no perioperative deaths and no permanent neurologic deficits in either group. The overall complication rates were 6.1% in the endovascular group and 9.6% in the surgical bypass group. Cumulative 1-, 3-, 5-, and 10-year primary (secondary) patency rates in the stent group were 91%, 78%, 67%, and 49% (95%, 91%, 86%, and 64%), whereas those same values in the bypass group were 99%, 97%, 95%, and 89% (99%, 99%, 98%, and 94%). The authors concluded that although both therapies were safe and effective, surgical bypass was a more durable solution for this entity. Importantly, for those patients with endovascular therapy failure, all were able to undergo surgical revascularization with a technical success rate of 100%.

It appears notable from these reports that long-term patency seems to be better with open surgical reconstruction than with endovascular therapy (see Chapter 98). However, the option of endovascular therapy remains reasonable because it offers extremely low risk at the time of intervention, rapid recovery, hospitalizations that are normally no longer than 1 to 2 days, early resumption of normal activities, and preservation of surgical options if needed.

Arch Intervention in Inflammatory Conditions

Interventional therapy for inflammatory diseases (e.g., Takayasu arteritis) of these vessels mandates an understanding of the nature of the inflammatory process (see Chapter 139). For stenosis of an arch vessel that is severe enough to cause symptoms, the inflammatory disease process must have been active for some time. In most cases, treatment with anti-inflammatory medications is aimed at reducing the inflammatory state and not at decreasing the amount of stenosis in the vessel. Because revascularization procedures in these disease states are hampered by cell overgrowth and neointimal hyperplasia, it is important to ensure that the patient's disease is quiescent before vascular reconstruction by any route. This should include normalization of inflammatory serum markers and improvement in systemic symptoms such as fevers and malaise. Nevertheless, occasionally cerebral ischemic symptoms develop that mandate acute attention to revascularization, even with an active inflammatory state. In this setting, reconstruction ideally with autogenous material carries the lowest risk of recurrence. Endovascular intervention in the setting of acute inflammation can be achieved, although immediate and long-term success rates appear lower than those achieved in patients with atherosclerotic disease, and recurrence rates are related to the degree of ongoing inflammation.[81] There is a suggestion that covered stents may be of some benefit in treating lesions in this scenario.[82]

Once the inflammatory state has diminished, the residual lesion in question should be assessed. Improved endovascular outcomes are obtained with the treatment of short focal stenoses. Stent placement appears to have a distinct advantage over angioplasty alone. For complex lesions, especially long occlusions, it appears that autogenous reconstruction via arch vessel transposition offers recurrence rates that are about half those of endovascular therapy. Little information is available regarding the use of either covered stents or medicated stents in this setting, but it would seem likely that they might play a more significant role in treating these problems in the future.

Long-Term Management

Long-term management of this patient population includes appropriate medical therapy to address the underlying atherosclerotic process to limit their overall risk for cardiovascular complications. This will involve appropriate medical therapy for their comorbid conditions, including hypertension, hyperlipidemia, and diabetes. Smoking cessation should be a major component of therapy aimed at reducing this risk as well (see Chapter 11).

Medical Therapy

Medical therapy for patients treated by stenting for arch vessel disease should include antiplatelet therapy, which should be initiated before any procedure, as noted earlier. The antiplatelet

therapy is continued for at least 1 month as a combination of both aspirin (325 mg) and clopidogrel (75 mg) with a transition normally to clopidogrel alone after 1 month. However, there are currently no data to objectively define the optimal time frame for continuing aggressive antiplatelet therapy.

Surveillance Protocol

After intervention in the arch distribution, it is important to maintain continued follow-up. These patients have a 15% to 25% risk for recurrent stenosis within the first 3 to 5 years, with about half of these recurrences being symptomatic. Follow-up should consist of an office evaluation with a history and physical examination including bilateral arm pressure determination. In addition, duplex assessment of the arch vessels should be done every 6 months for the first 18 to 24 months, with annual evaluation thereafter.

In some instances, duplex examination will be unable to assess the degree of stenosis within these vessels because of the difficulty encountered when trying to insonate at this depth behind the bony anatomy of the chest. In this situation, CTA can be helpful in assessing the degree of stenosis. Repeat evaluations are recommended at 6-month intervals for the first 2 years after intervention and then annually. This recommendation is based on the fact that recurrent stenosis in a number of the previously published studies appears to occur at significantly diminished frequency more than 2 years after interventional therapy.

Acute ischemia of the limb represents one of the toughest challenges encountered by vascular specialists. The diagnosis and initial assessment are largely clinical, and diagnostic errors can result in a high price to the patient—amputation or even death. Amputation and death rates remain high despite intervention, which is in contrast to major advances in the treatment of many other vascular diseases. Acute ischemia is often an end-of-life condition that presents in a patient with multiple medical comorbidities. Therefore careful clinical assessment of the individual is as important as assessment of the limb. Unlike many other vascular conditions, there is no one definitive treatment; a variety of modalities are available, including anticoagulation, operative intervention, thrombolysis, and mechanical thrombectomy. Selection of the most appropriate intervention or combination of interventions can be critical to the eventual outcome.

ETIOLOGY AND PATHOLOGY

Acute ischemia is the result of a sudden deterioration in the arterial supply to the limb. Excluding trauma and iatrogenic causes, there are two main reasons for acute ischemia to occur: arterial embolism and thrombosis. The distinction between thrombosis and embolism is important in terms of diagnosis and prognosis, but it may not be crucial when deciding on the form of treatment.

Embolism

Embolism (from the Greek *embolos*, or "plug") is the result of material passing through the arterial tree and obstructing a peripheral artery. Usually the source of the embolus is the heart, and the material is mural thrombus that has accumulated and detached. The other main cause is atherosclerotic debris from a diseased proximal artery, often the thoracic aorta, in individuals with a heavy burden of atherosclerotic disease.

Once the embolus detaches, it passes easily through large arteries and lodges peripherally, usually at an arterial bifurcation, where vessels naturally narrow. Emboli can occlude any artery, but in the legs, the common femoral and popliteal arteries are commonly obstructed. Only large emboli, so-called saddle emboli, occlude the normal aortic bifurcation. In the upper extremity, the brachial artery bifurcation and the brachial artery at the takeoff of the profunda brachialis artery are frequent locations for emboli.

Embolic ischemia is usually catastrophic because it often occurs in otherwise normal arteries, without any established collaterals. Typically, the patient presents with an acute white leg, including a complete neurosensory deficit. Embolic occlusion is also progressive; the ischemia worsens as secondary thrombus forms both proximal and distal to the occlusion. The secondary thrombus is the plum-colored clot removed at embolectomy (Fig. 100.1). It is particularly important that this secondary thrombus be removed because it may be responsible for obstruction in smaller distal vessels. If the presentation is delayed, the secondary thrombus adheres to the arterial wall, making it particularly resistant to removal with an embolectomy catheter and less easily lysed by thrombolytic drugs.

Figure 100.1 Embolic Fragment in the Centre of the Image, With the Tail of Secondary Thrombus Shown Around It.

Cardiac Embolism

Atrial and Ventricular

Embolism may occur in patients with otherwise normal arteries, with the embolic material usually arising from the heart. Embolic material from the heart usually consists of platelet-rich thrombus. Often it is organized, giving it the characteristic white surface on removal at embolectomy. The most common cause is atrial fibrillation; thrombus forms in the left atrial appendage as a result of stasis due to incoordinate contractions of the atrium and ventricle.

Mural thrombus, as a result of acute myocardial injury due to infarction, is a particularly dangerous cause of embolism. The patient has not only an ischemic extremity but also a high-risk medical condition (Fig. 100.2). Left ventricular aneurysm is also a high-risk cause of embolism, because these patients have a low cardiac output as a result of the previous infarcts that caused the aneurysm.

In the past, cardiac valve disease was the main cause of arterial embolism, but advances in the management of these patients have virtually eliminated this as a cause.[1-3] Instead, many patients now have artificial heart valves, and those with prosthetic valves are usually anticoagulated. Embolism is rare in patients with porcine replacement heart valves.

Paradoxical

Paradoxical embolism occurs when a clot from the venous system, usually deep venous thrombosis, travels through a patent foramen

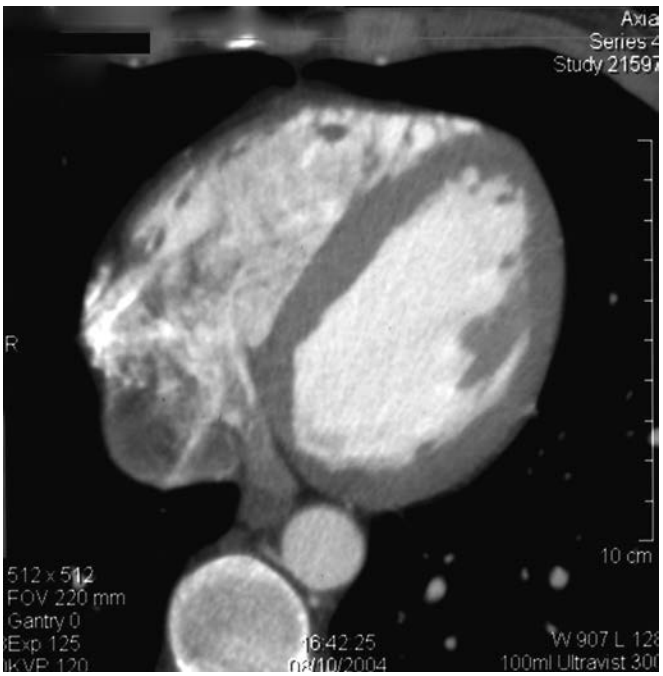

Figure 100.2 Computed Tomogram of the Heart Showing Mural Thrombus That Caused Brachial Embolus (Same Patient as in Fig. 100.9).

ovale into the arterial system. The clinical clue is acute arterial ischemia in a young patient with simultaneous deep venous thrombosis.[4]

Endocarditis

Bacterial endocarditis is an infrequent diagnosis since the introduction of widespread echocardiography and antibiotics. However, certain patient groups are at risk, including intravenous drug users, patients with indwelling arterial or venous lines, and those who are immunocompromised.

Cardiac Tumor

Atrial myxoma is a benign tumor of the left atrium that may fragment as it enlarges. Surgeons are advised to send the embolic material for histology if there is anything atypical about the material removed at embolectomy, or if the patient is young with no obvious reason for embolic disease.[5]

Noncardiac Embolism

Atheroembolism

Another source of embolism is the native arteries themselves. Particularly in patients with extensive atherosclerotic disease in major arteries such as the aortic arch or the descending thoracic aorta, fragments of plaque or adherent thrombus may detach and cause symptoms that mimic cardiac embolism (Fig. 100.3). The embolic material may consist entirely of platelet-rich thrombus, similar to embolism. More sinister are fragments of atheromatous plaque that detach (Fig. 100.4); these are more difficult to remove at embolectomy and may irreversibly occlude small distal vessels (see Chapter 164). Atheroembolism may occur spontaneously or may be precipitated by intraarterial manipulation of wires or catheters during cardiac or peripheral arterial interventions.

Aortic Mural Thrombi

Occasionally patients with hypercoagulable conditions develop an aortic mural thrombus in the absence of aortic pathology, which then embolizes to a limb. This should be suspected in a patient without atherosclerotic vascular disease and in whom

Figure 100.3 Ulcerated Aortic Atheroma at Autopsy.

Figure 100.4 Angiogram Showing Aortic Plaque (A) Causing Distal Popliteal Thromboembolism (B).

the cardiac evaluation is negative. Although the acutely ischemic limb may need urgent treatment, the underlying aortic pathology can often be treated simply by anticoagulation, with resolution of the thrombus.[6]

Thrombosis

Thrombosis results from blood clotting within an artery, which can be caused by progressive atherosclerotic obstruction, hypercoagulability, or arterial dissection.

Atherosclerotic Obstruction

Thrombotic occlusion is most commonly the result of progressive atherosclerotic narrowing in peripheral arteries of the leg. Once a stenosis becomes critical, platelet thrombus develops on the stenotic lesion, leading to an acute arterial occlusion. The clinical manifestations are seldom as dramatic as those of embolization, because the progressive process of atherosclerotic narrowing results in the development of robust collateral circulation. Patients with atherosclerosis deteriorate in a stepwise fashion, as thrombosis supervenes on an arterial stenosis. The resulting symptoms of ischemia (usually the acute onset of claudication) improve as collateral vessels expand. Critical ischemia is the end result when this process occurs at multiple levels. Acute stroke or myocardial infarction is the result of atherosclerotic plaque disruption, which may be confirmed by plaque inspection at carotid endarterectomy or autopsy.[7] In the extremities, it is not known whether plaque disruption is a cause of acute-on-chronic arterial thrombosis, because the offending plaque is rarely available for examination. It is possible, however, that the process of plaque disruption is the etiology in certain cases.

In patients with extensive atherosclerotic peripheral vascular disease, a reduction in cardiac output may produce acute limb ischemia by a global reduction in limb arterial perfusion. For example, if a patient with severe claudication develops complicated diverticulitis, the onset of shock may cause low cardiac output and result in acute critical limb ischemia in the absence of thrombosis. It is important to recognize this phenomenon because it is the underlying disease, not the leg, that needs urgent treatment.

Hypercoagulable States

In situ vessel thrombosis can also occur in the absence of atherosclerotic disease in states of hypercoagulability, low arterial flow, or hyperviscosity. These hypercoagulable states are associated predominantly with venous thrombosis, but thrombocythemia in particular can cause arterial occlusion, usually in small vessels. Malignant disease is also linked mainly to venous thrombosis, but several authors have observed an association with acute arterial ischemia.[8] It may be worth screening patients with acute leg ischemia without obvious atherosclerosis for an underlying malignancy. Because the vessel thrombosis is often a marker of advanced malignancy, the outcome in these patients is poor, despite active treatment.

Vascular surgeons occasionally encounter heparin-induced thrombocytopenia, in which a patient on heparin develops progressive vessel thrombosis with a falling platelet count. Other hypercoagulable conditions that may cause arterial thrombosis and result in acute limb ischemia are discussed in Chapter 38.

Vasospasm

Primary Raynaud disease rarely, if ever, causes acute ischemia. Secondary Raynaud's, due to underlying connective tissue disorder, can be acute and may present with digital ischemia. Open revascularization is seldom possible, and the key to a successful outcome is prompt diagnosis and treatment with intravenous or intraarterial infusion of a vasodilator or prostanoid. Digital ischemia can also follow intraarterial injection, most commonly as a result of inadvertent injection of illicit drugs. Ischemia may be profound and irreversible, particularly if particulate material is injected. Treatment consists of anticoagulation to prevent secondary thrombosis and infusion of thrombolytics, vasodilators, or prostanoids, as appropriate.

Aortic Dissection

Another condition that requires a high index of suspicion for diagnosis is aortic dissection, which may involve the aortic bifurcation and give the appearance of iliac artery thrombosis.[9] These patients typically have chest or back pain and may be hypertensive. Another clinical clue is renal failure if the dissection involves the renal arteries. Arterial dissection of other arteries supplying the lower extremity is uncommon but may follow trauma, or could be a sign of underlying fibrodysplasia.

Bypass Graft Occlusion

Another significant cause of acute limb ischemia is the occlusion of an existing patent bypass graft. Clearly the rate depends on how many bypass grafts exist in a community.[10,11] In areas that are well endowed with vascular services, patients frequently present emergently with graft thrombosis. In the United Kingdom, a national survey in 1996 reported that graft or angioplasty occlusion was responsible for 15% of acute limb ischemia.[12] The diagnosis is usually easy, and the cause is more likely to be thrombosis than embolism. Assessment and treatment are similar to that for native vessel ischemia, but decisions about treatment can be much more difficult because of the variety of options available (see Chapter 113).

CLINICAL PRESENTATION

The symptoms caused by vascular occlusion depend on the size of the artery occluded and whether collaterals have developed beforehand. Sudden occlusion of a proximal artery without existing collaterals leads to an acute white leg, whereas occlusion of the superficial femoral artery in the presence of well-established collaterals may be entirely asymptomatic. This is borne out by the number of individuals who are found to have occult femoropopliteal occlusive disease on population screening. Acute ischemia affects sensory nerves first; therefore loss of sensation is one of the earliest signs of acute leg ischemia. Motor nerves are affected next, causing muscle weakness; then skin and finally muscles are affected by the reduction in arterial perfusion. This is why muscle tenderness is one of the end-stage signs of acute leg ischemia. Once ischemia is established, the skin's initial

pallor becomes dusky blue as capillary venodilatation occurs. At this stage, pressure over the discolored skin leaves it white because the vessels are still empty (Fig. 100.5). The terminal stage of skin ischemia is caused by extravasation of blood owing to capillary disruption; digital pressure over the discolored skin produces no blush. At this stage, the skin is nonviable, and revascularization of necrotic tissue risks compartment syndrome and renal failure without salvaging the extremity (Fig. 100.6).

Historical series of patients with acute leg ischemia reveal a preponderance of embolic occlusion, usually secondary to valvular heart disease; however, this cause has essentially been eradicated owing to modern cardiovascular surgical expertise.[1-3] Today the usual cause of cardiac emboli is atrial fibrillation as a result of ischemic heart disease. This means that the affected population tends to be much older than it was 50 years ago, and patients often have established atherosclerotic disease of the arteries. This can produce the confusing picture of a patient with an embolus as well as peripheral arterial disease. Another effect is the gradual increase in the incidence of acute ischemia as the population ages.[13,14]

Figure 100.5 Acute Ischemia, Class IIb—Immediately Threatened.

Figure 100.6 Acute Ischemia, Class III—Irreversible.

CLINICAL ASSESSMENT

The initial assessment of acute critical ischemia involves an evaluation of both the limb and the patient as a whole.

History

The initial symptoms depend on the severity of ischemia and can range from incapacitating pain to the sudden onset of mild claudication. Obviously, the more severe the ischemia, the faster the patient seeks medical attention. Severe acute ischemia is usually obvious, with extreme pain and loss of sensation and power in the limb. Less severe ischemia can be difficult to diagnose and may be confused with musculoskeletal pain, sciatica, and other causes of limb discomfort. The duration of symptoms is the most important part of the history; in patients with severe ischemia, irreversible muscle necrosis occurs within 6 to 8 hours if the condition is untreated. Patients with an acute white leg require urgent intervention. The symptoms of sensory loss and muscle pain are also evidence of critical ischemia.

The history should include an attempt to define the cause of the ischemia. Historically, patients with emboli had valvular heart disease but no evidence of peripheral vascular disease or other atherosclerotic conditions; however, the presence of atherosclerosis no longer rules out embolism. Patients with acute-on-chronic thrombosis often give a history of prior intermittent claudication in the ipsilateral or contralateral leg. A full medical history is important because it may reveal other associated diseases such as diabetes mellitus. Risk factors for atherosclerotic disease should be sought, including smoking, hypertension, hyperlipidemia, and family history.

Physical Findings

Examination of the leg is used to define the severity of the ischemia and is therefore fundamental. The well-known rule of Ps—pain, pallor, paresis, pulse deficit, paresthesia, and perishing with cold—remains a good guide to both symptoms and signs. The color of the skin reflects its vascular supply. Marble-white skin is associated with acute total ischemia. Slow capillary refill is a sign that at least a small degree of distal flow is present and runoff vessels are probably patent. Sensation may be lost completely and the foot may be numb, but more often there is loss of fine touch and proprioception, which should be tested specifically. Muscle tenderness, particularly in the calf, is a sign of advanced ischemia. Acute ischemia is associated with the loss of peripheral pulses, which also helps define the level of the occlusion. Palpable normal pulses in the contralateral leg point toward embolism as the cause.

A full vascular examination reveals the level of the occlusion by the loss of arterial pulsation. A strong pulse can, however, mask an occlusion at that level because of the water-hammer effect. Other possible sources of embolization may become apparent, such as aortic or popliteal aneurysm or cardiac abnormalities such as atrial fibrillation. Patients with acute leg ischemia are often older adults with multiple comorbidities, and a full physical examination should be undertaken because

the final outcome may depend as much on associated conditions as on the severity of the leg ischemia.

Handheld Doppler examination is also a basic part of the examination. Pedal arterial signals may be absent or reduced. The presence of normal biphasic signals excludes the diagnosis. Soft monophasic signals are associated with patent distal vessels but proximal arterial occlusion. Absent Doppler signals in the ankle arteries is a poor prognostic sign. The arteries may be patent but with little flow, or they may be occluded with thrombus. In severe ischemia, ankle Doppler pressures are impossible to measure, partly owing to the lack of signal but also because of muscle tenderness. In less severe ischemia, an ankle pressure of 30 to 50 mm Hg can be expected, and an ankle-brachial index of about 0.3 is diagnostic of subcritical acute ischemia. Doppler can also be used to examine the extremity veins. In particular, a lack of a venous signal in the popliteal fossa suggests popliteal venous occlusion, which is a particularly poor prognostic sign in a patient with acute arterial ischemia.

CLASSIFICATION OF ACUTE LIMB ISCHEMIA

Acute limb ischemia used to be classified according to cause—thrombosis or embolism—because this had implications for treatment and prognosis. Patients with thrombosis tended to be younger but had a higher risk of major amputation. Patients with emboli tended to be older and had a higher risk of dying after treatment.[15,16] It has become clear that this is not a useful classification, because there is no way of proving definitively whether an occlusion is thrombus or embolus. A more valuable method of classification is based on the severity of the arterial ischemia, which is helpful in determining the urgency of intervention and has implications for outcome.[17,18]

The Society for Vascular Surgery and the International Society for Cardiovascular Surgery have published definitions of acute leg ischemia that are valuable for treatment and prognosis (Table 100.1).[19,20] These standards were modified in 2007 by a larger group—the Trans-Atlantic Inter-Society Consensus—which defined acute ischemia as any sudden decrease in limb perfusion causing a potential threat to limb viability.[21] They may be modified again in the future, but they have stood the test of time, and are unlikely to change significantly. The categories of ischemia are based on clinical findings and Doppler measurements, which can be performed at the bedside and are immediately available. In patients with class I ischemia (viable) or acute-onset claudication, intervention, particularly with thrombolysis, may be risky, and there is an argument for conservative treatment consisting of exercise and best medical therapy. In class III or irreversible ischemia, there is no indication to improve the blood supply, which may risk rhabdomyolysis, so the decision is between major amputation and conservative treatment.

Patients with class II ischemia require intervention, and the distinction between IIa (marginally threatened) and IIb (immediately threatened) is crucial. Any delay in treating the latter risks irreversible muscle necrosis, whereas in patients with IIa ischemia, there is time for investigation and semielective intervention. Class II ischemia encompasses the majority of patients with acute leg ischemia, and it may be helpful to think of class IIa as acute subcritical ischemia and class IIb as acute critical ischemia.[18] As outlined in Table 100.1, the three findings that best differentiate IIa from IIb ischemia are pain at rest, sensory loss, and muscle weakness.[21]

DIAGNOSIS

Following clinical assessment and classification, the anatomic location of the arterial occlusion can be diagnosed with a high degree of reliability.

Aortic Occlusion

The diagnosis of an aortic occlusion is usually obvious. Paralysis of the legs is often the presenting feature; patients are unwell, with mottled skin discoloration that often extends above the inguinal ligament onto the lower abdomen and no palpable

TABLE 100.1 Classification of Acute Limb Ischemia

Category	Description/Prognosis	FINDINGS		DOPPLER SIGNALS	
		Sensory Loss	Muscle Weakness	Arterial	Venous
I. Viable	Not immediately threatened	None	None	Audible	Audible
II. Threatened					
a. Marginally	Salvageable if promptly treated	Minimal (toes) or none	None	Inaudible	Audible
b. Immediately	Salvageable with immediate revascularization	More than toes, associated with rest pain	Mild, moderate	Inaudible	Audible
III. Irreversible	Major tissue loss or permanent nerve damage inevitable	Profound, anesthetic	Profound, paralysis (rigor)	Inaudible	Inaudible

From Rutherford RB, Baker JD, Ernst C, et al. Recommended standards for reports dealing with lower extremity ischemia: revised version. *J Vasc Surg*. 1997;26:517–538.

extremity pulses. This is a particularly high-risk condition, and urgent treatment is indicated.[22] The kidneys are especially at risk, particularly if the aortic occlusion is due to an aortic dissection. The dissection or occlusion may already involve the renal arteries, in which case the patient presents in established renal failure. Successful revascularization restores the blood supply to a large muscle mass, and the effects of ischemia-reperfusion may cause further renal damage.

Iliac Occlusion

The findings are similar to those for aortic occlusion, but unilateral. The femoral pulse is lost on the affected side, and mottling usually extends to the inguinal level. Aortic dissection should be excluded if there is time for investigation or if symptoms are suggestive.

Femoropopliteal Occlusion

Femoropopliteal occlusion is the most common situation in those with acute leg ischemia. The severity of the ischemia depends on whether the profunda femoris remains patent. The symptoms are more severe if the profunda is involved. Although the femoral pulse may be strongly palpable (owing to the water-hammer effect), the artery may be occluded.

Popliteal and Infrapopliteal Occlusion

In popliteal and infrapopliteal occlusion, the calf muscles are ischemic with a palpable femoral pulse. In young patients, rare diagnoses include popliteal thrombosis due to muscular entrapment or cystic adventitial disease. The most sinister cause is popliteal aneurysm thrombosis or embolization. This diagnosis should be suspected if a generous popliteal pulse is palpable in either leg or there is a nonpulsatile mass in the popliteal fossa of the affected leg. The outcome of this condition is particularly poor, despite aggressive treatment.[23] Chronic embolization of thrombus from within the aneurysm gradually occludes the distal vessels and arterial outflow; the aneurysm then thromboses, leaving no distal arterial targets for revascularization. Tibial embolism is an infrequent diagnosis, because most emboli that produce symptoms are large and obstruct proximal arteries (Fig. 100.7). Very distal emboli can be challenging to treat because the embolectomy catheter is least effective in small distal vessels. Some authors recommend retrograde embolectomy of tibial emboli via pedal arteries.[24]

INVESTIGATION

Investigation may be valuable in confirming the clinical diagnosis and planning the appropriate treatment for patients with acute ischemia. However, when the ischemia is critical, there may be no time for investigation if direct operative intervention is required. It is possible to employ on-table angiography to assist in decision making in the operating room. In a modern vascular service, treatment in a hybrid operating theater with access to the full range of interventional and surgical procedures is optimal.

Figure 100.7 Distal Ischemia Due to Occlusion of Small Vessels (Acute Blue Toe Syndrome).

Time permitting, a number of methods can be used to definitively determine the site and nature of the arterial occlusion.

Computed Tomographic Angiography

New-generation computed tomography (CT) scanners acquire images at very high speed and are available in most emergency suites. CT angiography has thus become the investigation of choice for urgent investigation of acute arterial ischemia. Intravenous contrast injection with current CT technology provides images that are similar in quality to intraarterial arteriography. The images sometimes require manipulation to produce the best results, but this is an acquired skill of many young vascular specialists. These images are particularly good for aortoiliac occlusions but give adequate information to plan treatment of infrainguinal occlusions. One concern is that the contrast material may have a deleterious effect on renal function, so intravenous fluids should be considered for prehydration at this stage.

Ultrasound

Imaging with duplex ultrasonography is the mainstay of investigation for chronic arterial ischemia. It may not be available in all hospitals after hours, but it can be employed in cases of acute ischemia to define the level of the arterial occlusion and the patency of other vessels. Portable ultrasound machines may permit rapid, bedside imaging by vascular specialists trained in duplex imaging.

Transfemoral Arteriography

Arteriography was the mainstay of investigation for acute leg ischemia, but it is less accessible than CT angiography in many hospitals without a hybrid theater. Brachial puncture can be used in the absence of femoral pulses. The angiogram documents the level of occlusion and sometimes its nature. Thrombotic occlusion is likely if there are established collateral arteries and evidence of arterial atherosclerosis. Sometimes emboli can be

Figure 100.8 Angiogram Showing Popliteal Embolus. Note the Meniscal-Type Cutoff, With No Existing Collaterals.

seen in several vessels, establishing the diagnosis (Fig. 100.8). Angiography is the best choice when an endovascular solution to the arterial occlusion is likely, because thrombolysis, percutaneous thrombectomy, angioplasty, or stenting can be performed during the same operative session. Arteriography may not visualize all the distal vessels in the acute situation, because the lack of collaterals and associated spasm limit visualization. It may still be worth exploring distal vessels surgically when contemplating a distal bypass in this situation, although an alternative would be to consider intraarterial thrombolytic therapy (see Chapter 162).

Magnetic Resonance Angiography

Magnetic resonance angiography with gadolinium enhancement is less useful than either CT or ultrasound in the context of acute limb ischemia. It is often unavailable at off hours, takes time for images to be acquired, and is generally inconvenient for sick patients.

Echocardiography

Debate continues about the role of echocardiography. In practical terms, the investigation seldom alters management, because most patients are anticoagulated for life after successful treatment for acute ischemia. Some surgeons, however, regard the investigation as a vital part of the postoperative management. There are certainly some conditions that require echocardiography to make a diagnosis, such as valvular disease (including vegetations), septal defect, and cardiac tumor. Problems associated with the routine application of echocardiography include the variability in results between transthoracic and transesophageal techniques and among different technicians, the inability to visualize the left atrial appendage, the fact that failure to visualize the source of an embolus does not rule out its existence, and the test's lack of influence on overall management.[25] A pragmatic view would be that echocardiography is indicated in young patients, those in whom a cardiac diagnosis is suspected, and those in whom the results might affect decisions about long-term anticoagulation.[26]

INITIAL MANAGEMENT

Once the diagnosis of acute ischemia has been established and its severity classified, a number of immediate interventions are possible. These are discussed briefly here and addressed in greater detail in Chapter 162.

Anticoagulation

The threat to the limb escalates with secondary thrombosis of underperfused distal vessels, particularly in patients with emboli. Therefore, immediate anticoagulation with intravenous calcium heparin can stabilize the condition of the leg and prevent deterioration. Whereas low-molecular-weight heparin is a valuable therapy for many conditions, the potential for immediate reversal with protamine makes calcium heparin the drug of choice in this situation. Protocols using a weight-based bolus and infusion rates facilitate rapid therapeutic anticoagulation. If urgent operation is not undertaken, the infusion should be monitored using the activated partial thromboplastin time, aiming for a ratio of 2 to 3. It is vital not to assume that anticoagulation is being accomplished while heparin is being administered; there is a wide variation in response to the drug, and careful monitoring by protocol is needed.

Ancillary Supportive Measures

Other first-aid measures that are beneficial in patients with leg ischemia include the use of oxygen delivered by facemask. This has been shown to improve skin perfusion, even in the ischemic limb.[27] Patients with acute ischemia are often dehydrated and at risk of renal dysfunction, so an intravenous infusion of fluid and monitoring of urine output is appropriate. Many radiologic maneuvers involve the use of contrast agents that can damage the kidneys, and adequate renal perfusion is important. As part of the diagnostic workup, a full blood screen for blood urea nitrogen and a full blood count are indicated. In patients with recurrent thrombosis, a full thrombophilia screen should be performed at this stage, if indicated, because therapeutic anticoagulation renders these investigations inaccurate.[28,29] These tests are indicated in patients with a strong family history of arterial and venous thrombosis or those with recurrent disease.[30,31] Patients are often in severe pain, and adequate analgesia is important. Intramuscular opiates are contraindicated in a patient

who may receive thrombolysis, and patient-controlled intravenous analgesia is a good alternative.

TREATMENT

Options

Once the initial assessment is complete, a decision should be made about the intervention required and its timing. The following options are available: anticoagulation alone, operative intervention, and endovascular intervention via mechanical thrombectomy or thrombolysis.

Anticoagulation

Heparin anticoagulation has no direct thrombolytic effect; it is used to stabilize clot formation and prevent further secondary thrombosis. Use of anticoagulation alone as a treatment implies that the limb is likely to remain viable or that other therapeutic options are limited, perhaps by age or comorbidity. Before anticoagulants were available, treatment of acute leg ischemia was largely expectant, and historical series documented high morbidity and mortality rates, despite amputation. Heparin and then warfarin made an immediate impact after their introduction.[32,33] Anticoagulation for stable class I ischemia, followed several weeks later by intervention (usually endovascular) if collaterals do not become established, is safe and effective. Anticoagulation has been shown to improve results after embolectomy.[34] In class III irreversible ischemia, anticoagulation allows stabilization of the patient while his or her medical condition is improved, pending major amputation at a later date. Otherwise, anticoagulation may be a component, but does not constitute definitive treatment for acute leg ischemia.

Operative Intervention

After Fogarty et al. described the embolectomy catheter for the remote removal of a clot via a groin incision in 1963, surgery became the main treatment for acute leg ischemia.[35] Over the years, the pattern of disease has changed, and emboli now occur in patients with ischemic heart disease, often in association with peripheral vascular disease. Thus the embolectomy procedure has become more complicated, and the results are inferior in patients who may have an acute thrombosis.[36,37] Increasingly, surgical bypass techniques are required in this situation, and a modern vascular surgeon should be able to offer a full range of bypass and endovascular procedures to patients with acute leg ischemia in a specialized environment to achieve optimal outcomes.[38]

Endovascular Intervention

Endovascular interventions offer an expanding range of alternative treatments for acute limb ischemia. Options include mechanical thrombectomy with homemade (aspiration embolectomy) or commercially available custom-built devices. In expert hands, mechanical thrombectomy can yield good results in selected patients, particularly those with bypass graft occlusions. If unsuccessful, it can be followed promptly by surgical intervention or thrombolysis.[39]

Percutaneous thrombolysis is also an established intervention for all forms of acute arterial occlusion (see Chapter 36). A potential advantage of thrombolysis is that unlike surgical embolectomy, which simply removes the thrombus from the large arteries, thrombolysis lyses clot in both large and small arteries and arteriolar and capillary beds.[40]

Selection

The choice of intervention depends on the available expertise and the severity of the leg ischemia.[41] The most recent evidence summary[42] and a recent Cochrane review[43] found little difference in outcomes to guide treatment selection between surgery and thrombolysis. There is a suggestion that endovascular first treatment may be more expensive overall,[44] but even in modern series, open vascular reconstruction for acute limb ischemia carries a significant risk of major morbidity (20%) or limb loss (22%).[45] The management of other vascular emergencies such as ruptured abdominal aortic aneurysm benefits from treatment in a hybrid operating theater, where endovascular or surgical treatment can be individualized. Similarly, treatment of acute limb ischemia could benefit from this approach; early indications are that this flexible approach has the potential to reduce the morbidity of a dangerous condition.[46] UK hospital process data show an increasing burden of acute limb ischemia (bucking the downward trend of other cardiovascular diseases), but no increased use of endovascular treatments.[47] Clearly a sea change in attitude is required to take advantage of new facilities, and the skill set of a modern vascular specialist. The severity of ischemia, however, remains the fundamental factor affecting choice of intervention.

Acute Critical Ischemia

Patients with acute critical (class IIb) ischemia need urgent intervention. In institutions where vascular and endovascular services are limited, the choice may be restricted to surgical intervention. Where expertise is limited, consideration should be given to transferring the patient to an institution with a full range of vascular and endovascular services. This clinical setting has been shown to improve outcomes.[38]

If endovascular treatment is offered for acute critical ischemia, there should be no delay. Percutaneous thrombectomy is a valuable option in cases where expertise exists. Low-dose intraarterial thrombolysis is contraindicated because it usually takes 12 to 24 hours to be effective. Accelerated thrombolysis may be an option in experienced units, using either high-dose bolus infusion techniques[48] or pulse spray thrombolysis.[49] However, with these few exceptions, most patients with acute class IIb critical limb ischemia are best treated in the operating room. In the operating room or hybrid theater, numerous interventions are available, ranging from embolectomy to reconstruction to on-table angioplasty or thrombolysis.

Acute Subcritical Ischemia

The treatment of patients with stable (class IIa) acute ischemia should be individualized, given the number of options and the greater time available for deliberation. These decisions are often

best made by multidisciplinary teams reflecting local expertise. Obvious emboli may be treated most appropriately by embolectomy. With this exception, the primary alternative to surgery for class IIa ischemia is intraarterial thrombolysis, with or without adjunctive mechanical thrombectomy. There has been much debate about the advantages and disadvantages of thrombolysis versus a surgical approach, and a number of large randomized trials have compared the two modalities.[50] Premier vascular units are familiar with both surgery and thrombolysis, and can make treatment decisions on an individual basis.[51] If a good surgical option exists, it is probably best that this is undertaken in a fit patient. Many patients with acute leg ischemia are in poor general health and at high risk of complications following operative intervention, particularly if general anesthesia is required. Thrombolysis is particularly indicated when the surgical options are poor and the runoff vessels in the leg appear occluded. An early meta-analysis of the available trials suggested that thrombolysis was best for short-duration ischemia and bypass graft occlusions.[52]

In Gloucestershire, a clinical pathway has been used for the past two decades that requires urgent embolectomy or thrombectomy in a patient with the acute onset of ischemia (<24 hours), an obvious embolic source, class IIb ischemia, and normal pulses in the contralateral leg. All other patients with class IIb acute critical ischemia require consultation with a specialist vascular surgeon on admission. The remainder with subcritical (class IIa) ischemia are anticoagulated overnight and treated by a vascular specialist in daylight hours.[53]

PROGNOSIS

The medical state of a patient who presents with acute leg ischemia is a good prognostic index of survival.[54] In particular, patients with acute myocardial infarction or poor cardiac output have a high mortality rate.[55,56] Outcome can also be predicted from pretreatment POSSUM (Physiological and Operative Severity Score for the Enumeration of Mortality and Morbidity) physiology scores.[57] Despite active intervention, the outcome after treatment for acute limb ischemia is often poor. In some patients, limb ischemia is a manifestation of the end of life. Such agonal thrombosis may be recognized in the very elderly with multiple comorbidities, particularly in hospitalized patients,[58] and is an indication for palliative care rather than active intervention.[59] Another very high-risk group in whom palliation might be appropriate is patients with acute ischemia due to hypercoagulable blood as a consequence of advanced malignancy. Prognosis is dependent on cancer stage, which is usually advanced; most of these patients succumb from their cancer within 6 months, even if treated actively.

UPPER LIMB ISCHEMIA

A number of significant differences exist between acute ischemia of the arm and leg. Patients with acute arm ischemia tend to be, on average, about 4 years older than those with acute leg ischemia (mean age, 74). Arm ischemia seldom threatens the limb, and treatment decisions are less urgent.[60,61] The main reason for treating arm ischemia is to prevent late complications such as activity-induced arm fatigue and pain.[62] Most arm ischemia is due to cardiac embolism (Fig. 100.9); atherosclerosis is rare in upper limb arteries.

Patients often present with a cold feeling and numbness rather than pain in the arm. The diagnosis is clinical and can be confirmed by duplex imaging. The arm often improves after initial anticoagulation, and decisions about whether to perform embolectomy can be difficult. Up to 50% of patients have late symptoms of arm pain if untreated; consequently, if limb viability is in doubt, there should be a low threshold to perform embolectomy under local anesthesia.[62] A small number of patients present with class IIb critical ischemia and should undergo urgent surgical intervention.[61] Failed surgery in this situation risks ischemic contracture (Fig. 100.10) or even arm amputation on occasion. The threat to the arm is generally low, but up to 20% of patients with acute arm ischemia do not survive the acute event, usually owing to cardiac complications.[63] Like acute leg ischemia, the attrition rate after successful treatment is high; only 60% of patients survived 3 to 5 years in one typical series.[63]

Figure 100.9 Acute Arm Ischemia Due to Brachial Embolus of Cardiac Origin (Same Patient as in Fig. 100.2).

Figure 100.10 Failed Embolectomy with Wound Dehiscence Resulting in Ischemic Contracture.

Rare causes of arm emboli include thoracic outlet syndrome and proximal subclavian artery aneurysm. Arteriovenous fistulae for dialysis may also cause a number of complications, including thrombosis and aneurysm formation.

Pediatric Population 1342
UPPER LIMB ISCHEMIA 1342

Acute limb ischemia (ALI) results from a sudden decrease in limb perfusion that threatens limb viability and often requires urgent revascularization.[1] Historic rates of amputation and mortality range from 10% to 25%, emphasizing the need for prompt evaluation and treatment.[2,3] The initial evaluation and decision making in the management of ALI are discussed in detail in Chapter 100. This chapter focuses on percutaneous endovascular, open surgical, and hybrid treatment options for the management of acute arterial ischemia.

INITIAL MANAGEMENT

Once the diagnosis of acute ischemia has been established and its severity classified, a number of immediate interventions are critical to optimize patient outcomes.

Anticoagulation and Supportive Measures

Systemic anticoagulation with unfractionated heparin should be initiated to minimize the risk of further clot propagation and to prevent microvascular thrombosis of underperfused distal vessels. An initial weight-based bolus of 100 units/kg is appropriate for most patients, followed by an intravenous infusion of 1000 units/h. If urgent operation is not undertaken, the heparin dose should be titrated to maintain an activated partial thromboplastin time (aPTT) between 50 and 80 seconds or 2.0 to 3.0 times normal values. For those patients with a known heparin allergy, a direct thrombin inhibitor can be used and titrated to an aPTT of 50 to 80 seconds.

Other measures that may be beneficial in patients with ALI include intravenous hydration, supplemental oxygen, and intravenous analgesia. Patients with acute ischemia are often relatively volume depleted, and careful fluid resuscitation is necessary, with fluid administration titrated to urine output. The potential for myoglobinuria due to ischemia-reperfusion, combined with the use of contrast agents during diagnosis and treatment of ALI, increases the risk of acute renal insufficiency, which may be mitigated with appropriate fluid resuscitation.

Results of a full serum chemistry panel, including blood urea nitrogen and creatinine, complete blood count, and baseline coagulation studies, will guide further therapy. A baseline plasma creatine phosphokinase will be helpful to follow for evidence

Abstract

This chapter focuses on the initial treatment options for the management of acute arterial ischemia of the extremities.

TABLE 101.1 Clinical Categories of Acute Limb Ischemia

Category	Description/Prognosis	FINDINGS		DOPPLER SIGNAL	
		Sensory Loss	Muscle Weakness	Arterial	Venous
I: Viable	Not immediately threatened	None	None	Audible	Audible
II: Threatened					
a. Marginally	Salvageable if promptly treated	Minimal (toes) or none	None	Inaudible	Audible
b. Immediately	Salvageable with immediate revascularization	More than toes, associated with rest pain	Mild, moderate	Inaudible	Audible
III: Irreversible	Major tissue loss or permanent nerve damage inevitable	Profound, anesthetic	Profound, paralysis (rigor)	Inaudible	Inaudible

From Rutherford RB, Baker JD, Ernst C, et al. Recommended standards for reports dealing with lower extremity ischemia: revised version. *J Vasc Surg*. 1997;26: 517-538.

of rhabdomyolysis after reperfusion of the extremity. In patients with recurrent thrombosis, a full hypercoagulability workup should be considered, including evaluation for a history of previous heparin exposure and the possibility of a thrombophilia due to heparin-induced thrombocytopenia.

TREATMENT SELECTION

Treatment for ALI depends largely on the extent of limb ischemia present clinically. Rutherford et al.[4] developed a classification of ALI that is helpful in determining the appropriate therapeutic intervention and overall prognosis (Table 101.1).

Class I ALI may require only medical therapy, such as anticoagulation. Revascularization, if contemplated, can be performed electively and can consist of either thrombolytic or open surgical intervention. Treatment selection depends on the duration of ALI, the location and cause of the occlusion, the presence or absence of underlying atherosclerotic occlusive disease, and the patient's overall medical condition.

Class II ALI requires a flexible approach to intervention. All patients with class II ALI require revascularization to preserve the functional integrity of the affected extremity. For patients with class IIa ischemia, immediate revascularization is not necessary. Consequently, either endovascular or surgical options may be considered. In the planning of therapy for a patient with class IIa ALI, the duration of symptoms is of prime importance. Percutaneous endovascular options are more effective in patients with ischemia of less than 2 weeks' duration, whereas ischemic symptoms of more than 2 weeks' duration are better served by surgical revascularization.[5] For a duration of symptoms less than 14 days, prospective studies comparing thrombolytic and surgical intervention favor the initial use of thrombolytic therapy, with surgical intervention reserved for those limbs that do not show response to lytic therapy. Because the ischemic insult in class IIa ALI is mild, therapy may be performed on an urgent, rather than emergency, basis.

More severe ALI (class IIb), manifested by both sensory and motor deficits, requires emergency revascularization. Because time is a factor, surgical revascularization has been preferred. However, advances in catheter-based thrombolytic delivery and percutaneous mechanical thrombectomy (PMT) devices have shortened the time to reperfusion. Consequently, these techniques are increasingly being used as first line therapy in patients with class IIb ALI. In addition, the availability of hybrid operating rooms has allowed physicians to perform diagnostic imaging, endovascular intervention, and open surgical revascularization in single settings as necessary.

Class III ALI manifests as a profound neurologic deficit (insensate, paretic limb), muscle rigidity, and the absence of arterial and venous Doppler ultrasound signals in the affected vascular bed. In patients with class III ALI, revascularization is usually futile and may have adverse systemic effects such as cardiac arrest due to acidosis and hyperkalemia, and primary amputation should be considered.

ENDOVASCULAR TREATMENT

Endovascular procedures offer less invasive revascularization strategies for sick or elderly patients with decreased morbidity and mortality. Currently available percutaneous endovascular procedures include catheter-directed thrombolysis (CDT), pharmacomechanical thrombolysis, catheter-directed thrombus aspiration, and PMT.[1,3] These techniques clear the occluding thrombus from a peripheral artery with a minimally invasive approach, restore blood flow to the extremity, and allow the identification of underlying lesions responsible for the occlusive event. Culprit lesions may then be addressed in a directed fashion with an endovascular procedure such as angioplasty, stenting, or atherectomy.

Catheter-Directed Thrombolysis

CDT has become the preferred treatment in many centers for the management of most viable or marginally threatened limbs (classes I and IIA) after recent occlusive events in native arteries and for thrombosed grafts and acutely occluded stents. One potential exception is cardioembolic events to either the brachial artery or the common femoral artery, which can be expeditiously removed with surgical embolectomy and use of local anesthesia, or to the aortic bifurcation, where expeditious revascularization

BOX 101.1 Contraindications to Pharmacologic Thrombolytic Agents

Absolute Contraindications

Active bleeding disorder
Gastrointestinal bleeding within 10 days
Cerebrovascular event within 6 months
Intracranial or spinal surgery within 3 months
Head injury within 3 months

Relative Contraindications

Major surgery or trauma within 10 days
Hypertension (systolic >180 mm Hg or diastolic >110 mm Hg)
Cardiopulmonary resuscitation within 10 days
Puncture of noncompresssible vessel
Intracranial tumor
Pregnancy
Diabetic hemorrhagic retinopathy
Recent eye surgery
Hepatic failure
Bacterial endocarditis

may be important to minimize risks from metabolic systemic complications. Of the previously used thrombolytic agents, streptokinase, urokinase and tissue plasminogen activators (tPAs), only tPAs are in active use in the United States. A complete discussion of the available pharmacologic lytic agents and their actions is provided in Chapter 41.

Peripheral thrombolytic therapy is administered through a catheter-directed approach to achieve regional thrombus dissolution with minimal systemic fibrinolysis. However, a moderate systemic proteolytic state often results from the use of thrombolytic agents, limiting their use to patients without contraindications to such a state (Box 101.1).[6-8]

Technique

Most physicians prefer a retrograde contralateral femoral approach when dealing with ALI. We routinely use a micropuncture needle to perform a single wall puncture of the common femoral artery and always use ultrasound guidance. Multiple attempts at blind puncture are discouraged due to the risk of access site hemorrhage during thrombolytic infusion. Antegrade ipsilateral femoral access carries a higher risk of hemorrhagic complications and increases the risk of wound infection if an open vascular procedure becomes necessary. Once access is obtained, a short 5 Fr sheath is introduced and diagnostic angiography is performed. A complete evaluation of the runoff vessels is obtained before an attempt is made to cross the occlusion with the sheath. This evaluation assists in the recognition of embolic events and identifies a potential target vessel for bypass in the event of failed thrombolytic therapy. We routinely place a 45- or 55-cm 6 Fr sheath over the aortic bifurcation into the contralateral femoral artery to provide support for crossing the occlusion and later intervention. A straight 4 Fr Glidecath catheter (Terumo Interventional Systems, Somerset, New Jersey) with a 0.035-inch angled Glidewire (Terumo Interventional Systems) and liberal fluoroscopic "road-mapping" techniques are used to cross the occlusion. A 0.035-inch QuickCross Support Catheter (Spectranetics Corporation, Colorado Springs, Colorado) may be useful for crossing the occlusion if more support is needed. An alternative is to use a smaller hydrophilic V-18 ControlWire guide wire (Boston Scientific Corporation, Natick, Massachusetts) to cross the occlusion. The "guide wire traversal test," the ease with which a guide wire is able to cross the occlusion, is a good predictor of technical success in CDT. However, one must take care to avoid intimal dissection in traversing the occlusion.[9]

In the treatment of a thrombosed bypass graft, multiple oblique angiographic views may be required to visualize the proximal stump of the graft. If a bypass graft cannot be entered from the native artery, ultrasound-guided direct puncture of the graft may be helpful. Open cutdown is required to remove the sheath and repair the graft once thrombolysis is complete. Direct graft puncture is also useful in treating thrombosed axillofemoral grafts. Two separate sheaths are placed directly into the midportion of the occluded graft, approximately 5 cm apart in crossing fashion so that the sheath tips are directed toward each other. Two separate thrombolysis catheters are then used to cross the occluded graft from opposite directions and treat the entire occluded graft segment.

After the occlusion has been crossed, a distal angiogram is performed to confirm the catheter location in the true lumen of the native vessel. A catheter exchange is performed to place a specifically designed, 0.035-inch compatible infusion catheter across the occluded segment. We prefer to use the Fountain Infusion Catheter (Merit Medical Systems, Inc., South Jordan, Utah), which is a 4 Fr catheter with a working length of 90 or 135 cm and infusion lengths of 5 to 50 cm (Fig. 101.1A and B).

Multiple side holes in this infusion catheter are designed to distribute the lytic agent throughout the thrombus. A ball-valve occlusion wire included with the catheter directs flow out the side holes and temporarily occludes the end of the catheter. The distal sidehole marker should be placed at the end of the thrombus, and the proximal side hole located just proximal to the thrombus origin. A list of various infusion catheter sizes and designs is shown in Table 101.2. Both low-dose and high-dose regimens can be used with recombinant tPA (rtPA) (Alteplase, Genentech, Inc., South San Francisco). The low-dose regimen prescribes a 1-mg bolus, followed by a continuous infusion of 0.5 to 1 mg/h. The infusion can run for 10 to 12 hours or overnight with another arteriogram performed the following day. Heparin is administered through the proximal side port of the 5 Fr sheath at 300 to 500 units/h to prevent perisheath thrombosis.

We currently use a high-dose tPA regimen for shorter periods. In our experience, this protocol has been very effective, with no increase in bleeding complications. This regimen involves delivering a 10-mg pulse-spray bolus of tPA over 5 minutes, followed by a continuous infusion at 0.05 mg/kg per hour with a maximum dose of 4 mg/h.[9-11] The high-dose infusion is continued for 6 hours before angiography is again performed. We routinely check the serum fibrinogen level every 4 hours and discontinue the infusion if the fibrinogen level drops to less than 100 mg/dL. If the thrombolytic agent is discontinued due to hypofibrinogenemia, it is usually best to remove the

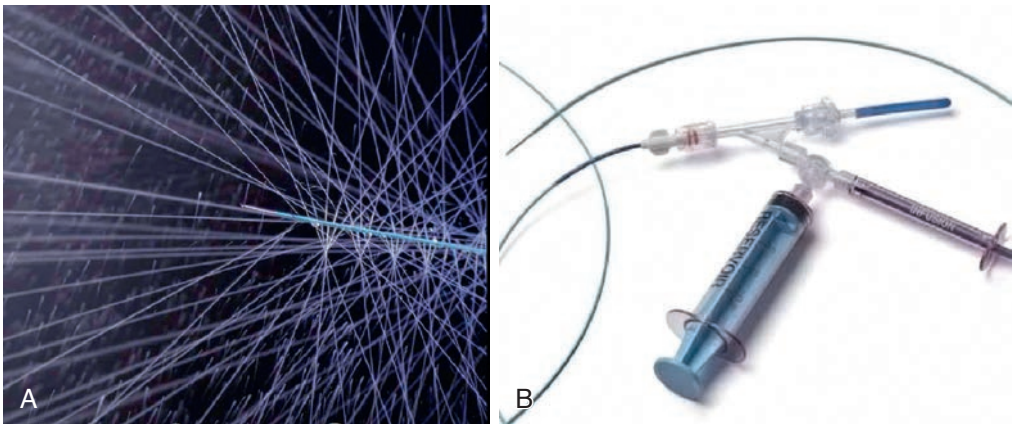

Figure 101.1 (A) Distal end of fountain infusion catheter (Merit Medical Systems, Inc., South Jordan, Utah), which has multiple side holes, with test infusion demonstrated. (B) Proximal end of the fountain catheter.

thrombolytic catheter to prevent thrombosis around the catheter. All patients are kept nothing by mouth and at bed rest in a critical care setting so they can be observed for clinical or laboratory evidence of local or systemic bleeding.

Results

In the 1990s three multicenter randomized trials were published comparing thrombolysis with operation for arterial occlusion (Table 101.3).[12–14]

The first trial, the Rochester study, randomly assigned 114 patients with acute limb-threatening ischemia to thrombolysis with urokinase (57 patients) or to immediate operation (57 patients).[12] At 1 year the amputation-free survival rates were 75% and 52%, respectively, a statistically significant difference. A closer analysis revealed this finding to be the result of a higher mortality rate in the operative group caused by perioperative cardiopulmonary complications. It appeared that taking patients with severe limb ischemia directly to operation without the opportunity for preparation resulted in a high frequency of complications that culminated in death.

The second large multicenter evaluation was the Surgery versus Thrombolysis for Ischemia of the Lower Extremity (STILE) trial.[13] In this study 393 patients were randomly assigned to surgery or to thrombolysis with either rtPA or urokinase. Clinical outcomes for the rtPA and urokinase groups were similar, so the data were combined for an overall comparison of thrombolysis and surgery. Post hoc stratification of patients into two subgroups on the basis of duration of symptoms before enrollment (more or less than 14 days) showed that among patients with symptoms of longer duration, the surgical group had lower amputation rates

TABLE 101.3 Outcome of Patients Treated With Initial Thrombolytic Therapy or Primary Operation for Acute Limb Ischemia

			THROMBOLYTIC THERAPY		PRIMARY	
Series	Number of Patients	Period (Months)	Amputation (%)	Death (%)	Amputation (%)	Death (%)
University of Rochester[9]	114	12	18	16	18	42
STILE Trial[13]	393	6	12	6.5	11	8.5
TOPAS Trial-II[14]	544	12	15	20	13.1	17

STILE, Surgery versus thrombolysis for ischemia of the lower extremity; *TOPAS*, thrombolysis or peripheral arterial surgery.

than did the thrombolysis group at 6 months (3% vs. 12%). In contrast, among patients with symptoms of shorter duration, patients assigned to thrombolysis had lower amputation rates than surgical patients (11% vs. 30%).

The third multicenter trial to evaluate thrombolytic therapy was the Thrombolysis or Peripheral Arterial Surgery (TOPAS) trial.[14] Recombinant urokinase (rUK) therapy (4000 IU/min for 4 hours, followed by 2000 IU/min) was compared with primary operation in 544 patients with lower extremity native artery or bypass graft occlusions of 14 days' duration or less. There was no significant difference in amputation-free survival rates or mortality rates between the two groups at the time of discharge from the hospital. Likewise, the amputation-free survival rates 6 months after randomization were not significantly different: 71.8% in the rUK group and 74.8% in the operative group. At the end of 6 months, 31.5% of the patients in the rUK group had avoided amputation or death without the need for anything more than a percutaneous procedure. By contrast, 94.2% of the patients who had had primary operation underwent open surgery, a rate that was not unexpected owing to the design of the trial. The median length of hospitalization was 10 days in both treatment groups. Among the patients assigned to thrombolysis, those with occlusions in bypass grafts had better clinical outcomes, better rates of clot dissolution, and lower rates of major hemorrhagic complications than did those with native artery occlusions.

In patients with ALI, CDT leads to resolution of thrombus with satisfactory clinical results in 75% to 92% of patients.[1] The factors that portend a higher likelihood of success are: (1) recent graft occlusion (<14 days), (2) guide wire traversal of the occluded graft, (3) graft patency of at least 1 year prior to the thrombotic event, and (4) the presence of a remediable lesion that may be treated. Factors associated with a poor outcome after thrombolysis include diabetes, current smoking, and prosthetic graft material. The reported 24-month vessel patency rate after thrombolysis for native arterial occlusions was 79% if an underlying lesion was identified and treated compared with 9.8% when no lesion was identified. For bypass graft thrombotic events, post-thrombolysis graft patency rates are between 10% and 40% at 2 years, making a case for replacement of a failed graft, especially if an anatomic lesion is not identified as an etiology of graft thrombosis.

Suffice it to say that there is not a "one-size-fits-all" standard of care for the initial treatment of ALI. Successful treatment depends on experience, judgment, skill, and the willingness to modify treatment based on evolving clinical information.

Complications

Hemorrhagic complications are the primary cause of morbidity following CDT. In the TOPAS trial, major hemorrhagic complications occurred in 32 patients (12.5%) in the rUK group, compared with 14 patients (5.5%) in the surgery group.[14] Patient age, duration of infusion, and aPTT at baseline were unrelated to the risk of bleeding. Intracranial hemorrhage occurred in four patients in the rUK group (1.6%), one of whom died. There were no instances of intracranial hemorrhage in the surgery group. The risk of bleeding was significantly greater when therapeutic heparin was used. In 102 patients who received therapeutic heparin, bleeding occurred in 19 patients (19%). By contrast, of the 150 patients in whom therapeutic heparin was not used, bleeding occurred in only 13 (9%). These data are the basis for the use of low-dose heparin infusions via the sheath, rather than therapeutic heparin dosing, in current protocols. Other complications include compartment syndrome after reperfusion, in 5% to 25% of patients, and acute renal insufficiency in up to 20% of patients.

Although not widely reported, distal embolization during CDT is commonly observed in real world practice. Symptoms may worsen or a distal Doppler ultrasound signal may be lost during the initial phase of lytic infusion. This is often managed by continued treatment with the thrombolytic agent and pain medication. More significant distal embolization that does not resolve in a few hours requires immediate arteriography, with the occasional need to reposition the catheter to a more distal location. The use of glycoprotein IIb/IIa inhibitors has been proposed as a mechanism to reduce distal embolization but does not appear to improve outcomes and may increase the risk of hemorrhagic side effects.[15]

Pharmacomechanical Thrombectomy

Several of the mechanical clot removal devices are intended to be used in conjunction with thrombolytic agents. Ultrasound energy (EkoSonic Endovascular System, BTG Corporation, Bothell, Washington) or "power pulse injection" (AngioJet, Boston Scientific, Marlborough, Massachusetts) are used to accelerate the speed of thrombolysis. The resultant decrease in

the dose of lytic agents and duration of thrombolysis has the potential to minimize the bleeding risk associated with standard CDT and to shorten the time to reperfusion.

EKOS EkoSonic Endovascular System

The EKOS Catheter (EKOS Corporation/BTG, Bothell, Washington) uses ultrasound to facilitate clot penetration by the lytic agent, thereby accelerating thrombolysis. The device consists of a 5.2 Fr multiple-lumen drug delivery catheter and a coaxial ultrasound core wire. The active treatment zone of the catheter is available in lengths from 6 to 50 cm; catheter selection is based on the length of the occlusion.

After the thrombus has been crossed with a standard 0.035-inch guide wire, the drug delivery catheter is placed over the guide wire. The guide wire is exchanged for the ultrasound core wire, which contains a series of transducer elements (2.2 MHz, 0.45 W) spaced approximately 1 cm apart. In addition to the guide wire (ultrasound core) lumen, the back end of the catheter has two additional ports—one for infusion of the lytic agent and the other for infusion of normal saline as a coolant. The ultrasound energy is delivered via the core wire simultaneously with the infusion of lytic agent and coolant. The EkoSonic system's control unit monitors the temperature and alters the ultrasound power to prevent overheating. Theoretically, maximal ultrasound power is reached with complete thrombus dissolution because the free flow of blood and coolant prevents the thermocouples from overheating. The control unit displays a continuous graph of the power generated, which may help to determine when the patient needs to have a recheck angiogram.

In preclinical studies, thrombus exposed to ultrasound absorbed 48% more tPA in 1 hour, 84% more in 2 hours, and 89% more in 4 hours than did thrombus not exposed to ultrasound.[16] This phenomenon is thought to be secondary to thrombus deformation by the ultrasound waves, which exposes a greater surface area to the infused lytic agent. The pharmacomechanical approach using the EkoSonic system decreases the procedure time and the amount of lytic used while increasing the clinical success rate to 90% in some studies.[17,18]

AngioJet Thrombectomy System

The AngioJet Thrombectomy System (Boston Scientific, Marlborough, Massachusetts) has been approved by the U.S. Food and Drug Administration for use in the peripheral arterial circulation. Of the mechanical thrombectomy devices available, the AngioJet has the longest clinical history.[5,19] With use of "power pulse-spray" mode, tPA is actively injected into the thrombus, allowed to dwell there for a short time (5 to 20 minutes), and aspirated, along with liquefying the thrombus. The AngioJet system has three major components: the catheter, pump set, and drive unit. The pump set and drive unit are responsible for producing a controlled, high-velocity saline jet (350 to 450 km/h) that is redirected at the tip of a dual-lumen catheter back into the effluent lumen of the catheter. The inflow lumen is a low-profile stainless steel tube that forms a transverse loop at the distal end of the catheter and has multiple 25- to 50-µm-diameter orifices directed retrograde toward the inflow lumen. Saline solution from the pump drive unit is driven at 50 to 60 mL/min and 8000 to 10,000 pounds per square inch, resulting in a high-velocity jet at the catheter tip. The velocity of the saline jets produces an area of extremely low pressure (Venturi effect) that is exposed to the intraarterial lumen only at the catheter tip. Thrombus surrounding the catheter tip is fragmented[20] and rapidly evacuated through the effluent lumen in an isovolumic manner (fluid instilled equals fluid and blood removed). Embolization and hemolysis are known complications of this technique. In addition, the use of this device can lead to bradyarrhythmias and renal insufficiency related to hemolysis.[21]

Percutaneous Mechanical Thrombectomy Without Thrombolysis

PMT devices can be classified as hydrodynamic, rotational/mechanical, or aspiration thrombectomy catheters (Table 101.4).

Hydrodynamic Devices

Percutaneously delivered devices can remove thrombus from the peripheral arteries through the use of a stream of fluid and hydrodynamic forces to extract the thrombotic material from the lumen.[20,21-23] The AngioJet system as described previously uses a dedicated fluid delivery machine to achieve thrombus removal without the use of adjunctive TPA.

Rotational/Mechanical Devices

A variety of "brushes," rotating wires, and mechanical thrombectomy devices that fragment thrombus with or without aspirating the fragments have been designed to establish arterial recanalization. This class of devices includes the Cleaner rotational thrombectomy system (Argon Medical, Plano, Texas) and the Arrow-Trerotola thrombectomy device (Teleflex Inc., Morrisville, North Carolina).[24-27] Although these devices have gained a foothold in the treatment of dialysis access graft occlusion, clinicians have been reluctant to use them in native arteries for fear of injuring the vessel wall. The Cleaner system has also been used for treatment of iliac and IVC deep venous thrombosis. Another potential limitation of this class of device involves the risk of distal embolization of macroparticles of thrombus. Currently none of these devices is routinely used in the management of peripheral arterial disease. A new class of retrievable stent thrombectomy devices such as the Stryker Trevo (Stryker, Kalamazoo, Michigan), the Medtronic Solitaire (Medtronic, Minneapolis, Minnesota), and the Revive thrombectomy device (Codman Neuro/Johnson and Johnson, Raynham, Massachusetts) have proven to be very effective in the treatment of acute thrombotic stroke by removing acute thrombus from the intracranial circulation. However, these devices have not been tested extensively in the peripheral arterial system.[28,29]

Thrombus Aspiration Devices

Percutaneous aspiration thrombectomy involves moving a catheter over a wire while aspirating thrombus with a large

Company Name	Product Name	Sheath Size (F)	Guide Wire (inch)	Working Length (cm)	Mode of Operation	U.S. FDA Indicated Use
Ekos Corporation, a BTG International group company	EkoSonic Endovascular System	6	0.035	106 catheter length; treatment areas: 6, 12, 18, 24, 30, 40, 50; 135 catheter length; treatment areas: 12, 30, 40, 50	The treatment offers a minimally invasive system for the acceleration of thrombus dissolution; the ultrasonic core generates a localized acoustic field that targets the entire thrombus; this greatly accelerates lytic dispersion by driving the drug deeper into the clot and unwinding the fibrin to expose plasminogen receptor sites	Indicated for the ultrasound-facilitated, controlled, and selective infusion of physician-specified fluids, including thrombolytics, into the vasculature for the treatment of pulmonary embolism; the controlled and selective infusion of physician-specified fluids, including thrombolytics, into the peripheral vasculature; and the infusion of solutions into the pulmonary arteries; Instructions for Use, including warnings, precautions, potential complications, and contraindications can be found at www.btg-im.com/ekos; Caution: Federal (USA) law restricts these devices to sale by or on the order of a physician
Medtronic	Mindframe Capture LP Revascularization Device 3 × 15, 3 × 23, 4 × 15, 4 × 23	Balloon guide (8, 9)	0.010	Capture push wire (178)	Compatible with a catheter in the 10/14 class. It is designed to navigate, access, and treat distal zone occlusions, and has distal and proximal markers for accurate positioning and a proprietary cell geometry that minimizes deformation and maximizes entrapment	Indicated for endovascular temporary use in patients with acute ischemic stroke and to restore blood flow in patients who are experiencing symptoms of an acute ischemic stroke caused by an embolus in a cerebral vessel
Medtronic	Solitaire 2 Revascularization Device 4 × 15, 4 × 20, 4 × 40, 6 × 20, 6 × 30	Balloon guide (8, 9)	0.014	Solitaire push wire (180)	Designed to restore blood flow in patients experiencing ischemic stroke due to large intracranial vessel occlusion and for use in the neurovasculature, such as the internal carotid artery, M1 and M2 segments of the middle cerebral artery, basilar, and the vertebral arteries	Indicated for use to restore blood flow in the neurovasculature by removing thrombus for the treatment of acute ischemic stroke to reduce disability in patients with a persistent, proximal anterior circulation, large vessel occlusion, and smaller core infarcts who have first received IV tPA; endovascular therapy with the device should be started within 6 hours of symptom onset; indicated to restore blood flow by removing thrombus from a large intracranial vessel in patients experiencing ischemic stroke within 8 hours of symptom onset; patients who are ineligible for IV tPA or who fail IV tPA therapy are candidates for treatment
Medtronic	Solitaire Platinum Revascularization Device 4 × 20, 4 × 40, 6 × 20	Balloon guide (8, 9)	0.014	Solitaire push wire (180)	Designed to restore blood flow in patients experiencing ischemic stroke due to large intracranial vessel occlusion and for use in the neurovasculature, such as the internal carotid artery, M1 and M2 segments of the middle cerebral artery, basilar, and the vertebral arteries	Indicated for use to restore blood flow in the neurovasculature by removing thrombus for the treatment of acute ischemic stroke to reduce disability in patients with a persistent, proximal anterior circulation, large vessel occlusion, and smaller core infarcts who have first received IV tPA; endovascular therapy with the device should be started within 6 hours of symptom onset; indicated to restore blood flow by removing thrombus from a large intracranial vessel in patients experiencing ischemic stroke within 8 hours of symptom onset; patients who are ineligible for IV tPA or who fail IV tPA therapy are candidates for treatment

Penumbra, Inc. (Neurovascular)	3D Revascularization Device	6 (long sheath [Neuron MAX])	0.020	200 (delivery wire; compatible with Velocity Delivery microcatheter [160 cm] and 3MAX Reperfusion catheter [153 cm])	Designed to successfully treat large vessel occlusion in combination with Ace Reperfusion catheters; the architecture provides maximum clot capture capability through four intraluminal chambers and is optimized for use with aspiration delivered by Ace catheters	Indicated for use in the revascularization of patients with acute ischemic stroke secondary to intracranial large vessel occlusive disease (within the internal carotid and middle cerebral [M1 and M2 segments] within 8 hours of symptom onset; patients who are ineligible for IV tPA or who fail IV tPA therapy are candidates for treatment
Penumbra, Inc. (Neurovascular)	Penumbra System Reperfusion Catheter ACE, 5MAX, 4MAX, 3MAX, 026	6 (ACE and 5MAX require 8 Fr short sheath or 6 Fr long sheath)	0.014-0.016	Reperfusion catheter lengths 132, 139, 150, 153	Direct aspiration clot removal with ADAPT technique	Intended for use in the revascularization of patients with acute ischemic stroke secondary to intracranial large vessel occlusive disease within 8 hours of symptom onset
Penumbra, Inc. (Neurovascular)	Penumbra System Separator and Separator Flex 5MAX, 4MAX, 3MAX, 026	—	—	Separator and Separator Flex length 175-200	Separator-assisted clot debulking, if needed	Intended for use in the revascularization of patients with acute ischemic stroke secondary to intracranial large vessel occlusive disease within 8 hours of symptom onset
Penumbra, Inc.	Indigo System Separator	—	—	90-190	The Indigo Separator is (Peripheral Vascular)	SEPD, SEP8, SEP6, advanced and retracted SEP5 and SEP3 through the CAT
Penumbra, Inc. (Peripheral Vascular)	Indigo System Catheter CATD, CAT8, CAT6, CAT5, and CAT3	CATD (8 Fr Sheath), CAT8 (8 Fr sheath), CAT6, CAT5 (6 Fr sheath)	0.014-0.038	50-150	Separator-assisted mechanical extraction of thrombus/debris with constant vacuum aspiration. Available in a selection of sizes, the CAT family can provide access to distal peripheral vessels of the upper and lower extremities, including below the knee catheter at the proximal margin of the primary occlusion to facilitate clearing of the thrombus from the catheter tip Intended for the removal of fresh, soft emboli, and thrombi from vessels of the peripheral arterial and venous systems	Intended for the removal of fresh, soft emboli, and thrombi from vessels of the peripheral arterial and venous systems

syringe. This technique has been used more frequently in the coronary system to retrieve thrombus. The size of thrombus fragments that can be removed with this device is limited by the distal diameter of the catheter tip (Fig. 101.2).

This technique has been very useful when small amounts of fresh thrombus are identified in the distal circulation or to treat embolization after recent angioplasty, particularly when combined with the use of low-dose tPA. However, this technique has a low success rate when used as stand-alone therapy.[30] A list of currently available catheters and their sizes is provided in Table 101.5. More recently Penumbra, Inc. has developed a line of neurovascular aspiration catheters for the treatment of acute stroke and have now begun to promote a series of larger-diameter Indigo System catheters, which are designed to remove fresh peripheral thrombi.[31]

Results

The ability of percutaneous devices to rapidly restore arterial perfusion is an attractive addition to pharmacologic thrombolysis alone. In patients with significant ischemia that precludes the obligatory delay associated with pharmacologic thrombolysis, percutaneous thrombectomy devices may rapidly clear a channel through the occluded segment. Partial reperfusion of the extremity may provide enough improvement to allow complete removal of thrombus with thrombolytic infusions thereafter. Initial thrombus debulking may also significantly reduce the dose and duration of thrombolytic agents, thereby decreasing the risk of hemorrhagic complications associated with pharmacologic thrombolysis.[5,19,22,32,] Finally, the devices may be used as sole therapy in patients with contraindications to thrombolytic administration, such as those who have recently undergone major surgical procedures.

It appears unlikely that mechanical thrombectomy devices will completely eliminate the need for pharmacologic thrombolysis or open surgery.[19,22,31] In all but one clinical report,[23] a significant number of patients required adjunctive thrombolytic therapy for complete thrombus removal. However, the advantage of mechanical devices lies in the ability to rapidly debulk the thrombus (Fig. 101.3), significantly reducing the duration of ischemia and increasing the exposure of the residual thrombus and distal vessels to pharmacologic thrombolytic agents. The reductions in dose and in time needed to achieve complete thrombolysis may result in considerable cost savings and fewer bleeding complications.[14]

In patients with contraindications to pharmacologic thrombolysis and at high risk with open surgery, mechanical thrombectomy may represent the best therapeutic option. Braithwaite et al.[31] managed 15 patients with ALI due to infirmity or surgical or thrombolytic contraindications with anticoagulation alone, resulting in dismal 30-day limb salvage and mortality rates of 33% and 60%, respectively.

Kasirajan et al.[33] compared patients with ALI treated with the AngioJet catheter with historic controls treated with standard open surgical techniques. The 65 patients in the AngioJet group received stand-alone treatment ($n = 21$) or subsequent adjunctive pharmacologic thrombolysis ($n = 44$). They were compared with 79 patients who underwent open surgical revascularization. No difference was noted in the 1-month amputation rate (11%

TABLE 101.5 Thrombus Aspiration Devices

Company Name	Product Name	Type	Maximum Tip Diameter (mm)	Minimum Guide Catheter Size (Fr)	Catheter Length (cm)
Control Medical Technology	Aspire Max 5 Mechanical Thrombectomy System	5 Fr braided large-lumen OTW	1.65	6	55, 135
Control Medical Technology	Aspire Max 6 Mechanical Thrombectomy System	6 Fr braided large-lumen OTW	1.91	7	55, 135
Control Medical Technology	Aspire RX-LP6 Mechanical Thrombectomy System	Rapid-exchange low-profile system	1.7	6	136

vs. 14%; $P = .57$); however, a lower rate of early mortality was observed in the AngioJet group (7.7% vs. 22%; $P = .037$). A lower rate of local ($P = .002$) and systemic ($P < .001$) complications was observed for the AngioJet treatment group.

The EKOS Infusion Catheter has also been investigated as an option for treating ALI. In a series of 25 patients presenting with ALI and undergoing treatment with the EKOS total clot removal was achieved in 22 (88%) after 16.9 hours (range, 5 to 24 hours) using a mean dosage of 17 mg (range, 5 to 25 mg) rtPA. In eight patients, total clot removal of the main lesion was achieved after 6 hours with 6 mg of rtPA.[6] A prospective randomized study comparing the EKOS system with standard CDT, the Dutch Randomized Trial (DUET), included 32 patients randomized to standard thrombolysis and 28 randomized to ultrasound-accelerated thrombolysis. Although the time to achieve complete lysis and the overall lytic dose were significantly less in the ultrasound-accelerated thrombolysis group, there was no difference in technical success, 30-day death or serious adverse events and no difference in 30-day patency.[34] Fig. 101.4 demonstrates a successful EKOS thrombolysis case.

Complications

With any mechanical thrombectomy device, there is always the possibility of inducing distal embolization as the device is passed through the thrombus. The use of distal filters typically used in the carotid circulation has been suggested as one possible solution but seem cumbersome and ineffective at this time. The efficacy of the thrombectomy devices are also limited by the diameter of the cylindrical "core" of thrombus that can be extracted with each pass of the catheter—a property dependent on the size of the device. A larger size device might remove more thrombus but would also increase the risk of trauma to the arterial wall. Thus the size limitation must be balanced by the convenience of placing the device through a relatively small-bore sheath, as well as by the greater safety associated with the use of a smaller device in the tibial vessels. Another limitation of current devices is the amount of potential red blood cell damage. Hemolysis with hemoglobinemia and hemoglobinuria can occur, especially with repeated passes of the device. Finally, volume overload can develop if one does not carefully monitor the volume of intravascular irrigation instilled. Despite these theoretical limitations, fluid overload and hemolysis have not proven to be problems in preliminary clinical trials.[20,22,32,35]

In vitro studies comparing endothelial denudation with the AngioJet and the Fogarty thrombectomy catheter have demonstrated significantly greater mean endothelial loss in vessels treated with the Fogarty balloon catheter (58.0% vs. 88.0%).[24] Particulate embolization was uncommon, and 99.83% of particles were smaller than 100 µm. Hemolysis equivalent to that resulting from lysis of 75 mL of blood was seen after a standard pump run, but no elevation in blood urea nitrogen or creatinine was noted.[24]

SURGICAL REVASCULARIZATION

Balloon catheter thrombectomy, first introduced by Fogarty et al.[36] in 1963, has been the cornerstone of therapy for the surgical management of ALI.[37] Severe ALI (class IIb), manifested by both sensory and motor deficits, requires urgent intervention, and surgical therapy has remained the treatment of choice. With the increasing availability of hybrid operating rooms, surgeons can now perform diagnostic imaging, endovascular intervention, open surgical revascularization, and hybrid procedures in single settings.

Techniques

Techniques for salvage of an ischemic limb include: (1) balloon catheter thrombectomy or embolectomy, (2) bypass procedures to direct blood flow beyond the occlusion, (3) endarterectomy with or without patch angioplasty, and (4) hybrid procedures combining open and endovascular techniques.

Balloon Catheter Thrombectomy or Embolectomy

Balloon thrombectomy is routinely used to deal with an embolic event or chronic graft thrombosis. The technique involves direct cutdown over either the common femoral artery or the brachial

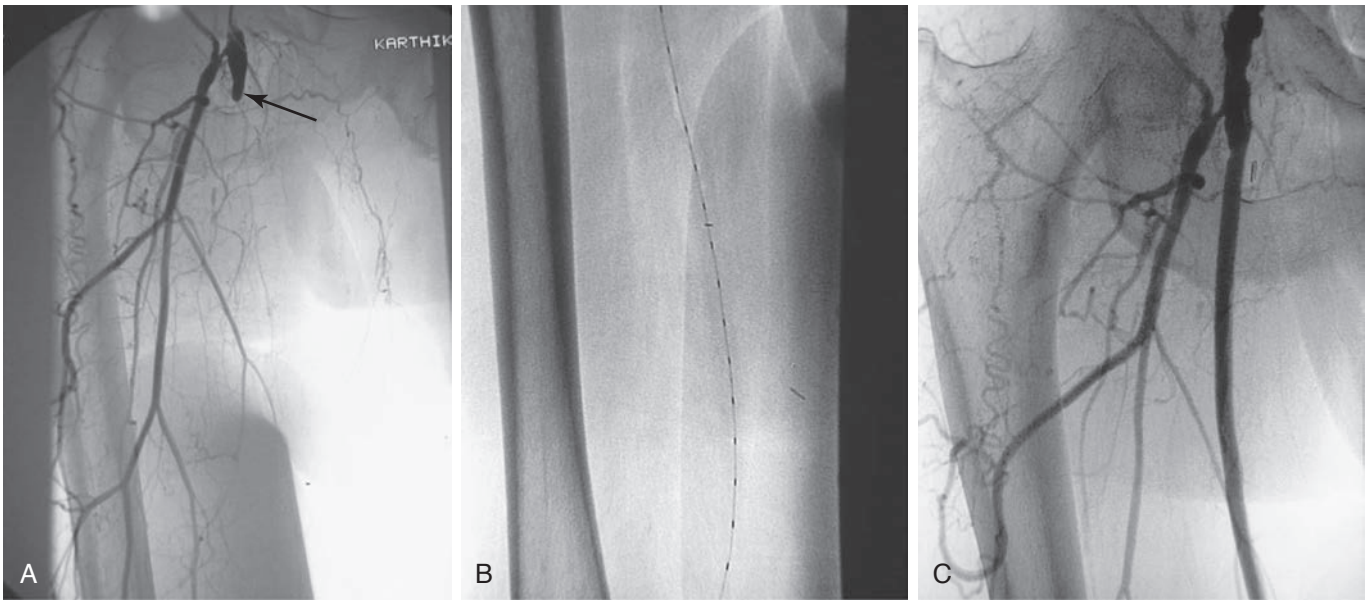

Figure 101.4 (A) Patient with a right femoropopliteal artery graft occlusion *(arrow)*. (B) EKOS ultrasound catheter (EKOS Corporation, Bothell, Washington) placed in the femoropopliteal graft. (C) After 8 hours of lytic infusion, complete thrombus resolution is noted.

artery with proximal and distal control of the major branches. A transverse arteriotomy is performed immediately proximal to the common femoral artery or brachial artery bifurcation to allow for direct visualization of the distal branches, with the ability to directly pass an appropriate-sized embolectomy catheter into those branches. A longitudinal arteriotomy is made when there is concern that endarterectomy with patch angioplasty closure will be required. Balloon embolectomy catheters are passed proximally and distally until no visible thrombus is removed and a pulse or backflow is established. Completion angiography is important to evaluate the effectiveness of thrombus removal. Over-the-wire embolectomy catheters may also be used to direct the embolectomy catheter into the tibial branches. Fig. 101.5 demonstrates the treatment of a patient with acute-on-chronic arterial ischemia who presented with a threatened limb. Initial attempts at open thrombectomy from a femoral approach failed, and subsequent attempts at over-the-wire embolectomy were also unsuccessful. Due to the chronic-appearing nature of the thrombus on angiogram, the decision was made to explore the below-knee popliteal artery directly. An arteriotomy at the popliteal artery and tibioperoneal trunk revealed chronic thrombus. Thromboendarterectomy of the tibioperoneal trunk was performed with patch angioplasty closure using bovine pericardium. A common femoral artery to tibioperoneal trunk bypass graft with reversed saphenous vein was then placed for limb salvage.

Bypass Procedures

Bypass procedures are more commonly performed in patients with known peripheral arterial disease or after failed open balloon thrombectomy. Proximal and distal targets are evaluated by intraprocedural arteriography. If the clinical scenario permits, a preoperative angiogram from a contralateral femoral approach provides the best guide to open intervention. The ideal bypass conduit is an ipsilateral single-segment saphenous vein of adequate caliber (>3 mm). Otherwise, the contralateral saphenous vein, arm veins, or lesser saphenous vein is preferred if below-knee revascularization is required. For above-knee revascularization, synthetic grafts can be used.

Endarterectomy

Endarterectomy is uncommonly used for limbs with ALI but may be performed for in situ occlusion of the common femoral artery. After arteriographic confirmation of occlusion of the common femoral artery, the target vessel is usually approached via a longitudinal groin incision. The common femoral, deep femoral, and proximal superficial femoral arteries should be adequately exposed and controlled. Atherosclerotic plaque often extends into the superficial femoral and profundal femoris orifices. Distal endpoints that extend into the superficial femoral or profundal femoris artery may require tacking sutures. To prevent narrowing of the common femoral artery, we use bovine pericardium for patch angioplasty closure of the femoral artery.

Results

Although improvements in open surgical technique have diminished the rate of limb loss associated with ALI, the mortality rate remains unacceptably high (Table 101.6).[5] In fact, patient survival has not changed dramatically since the report by Blaisdell et al.[38] more than 30 years ago, with mortality as high as 25%. The discordance between limb salvage and patient survival is explained by the specific factors controlling the two events. Death occurs as a result of medical comorbidities and the fragile baseline medical state of patients presenting with ALI, whereas limb loss is related to an unsuccessful revascularization procedure.

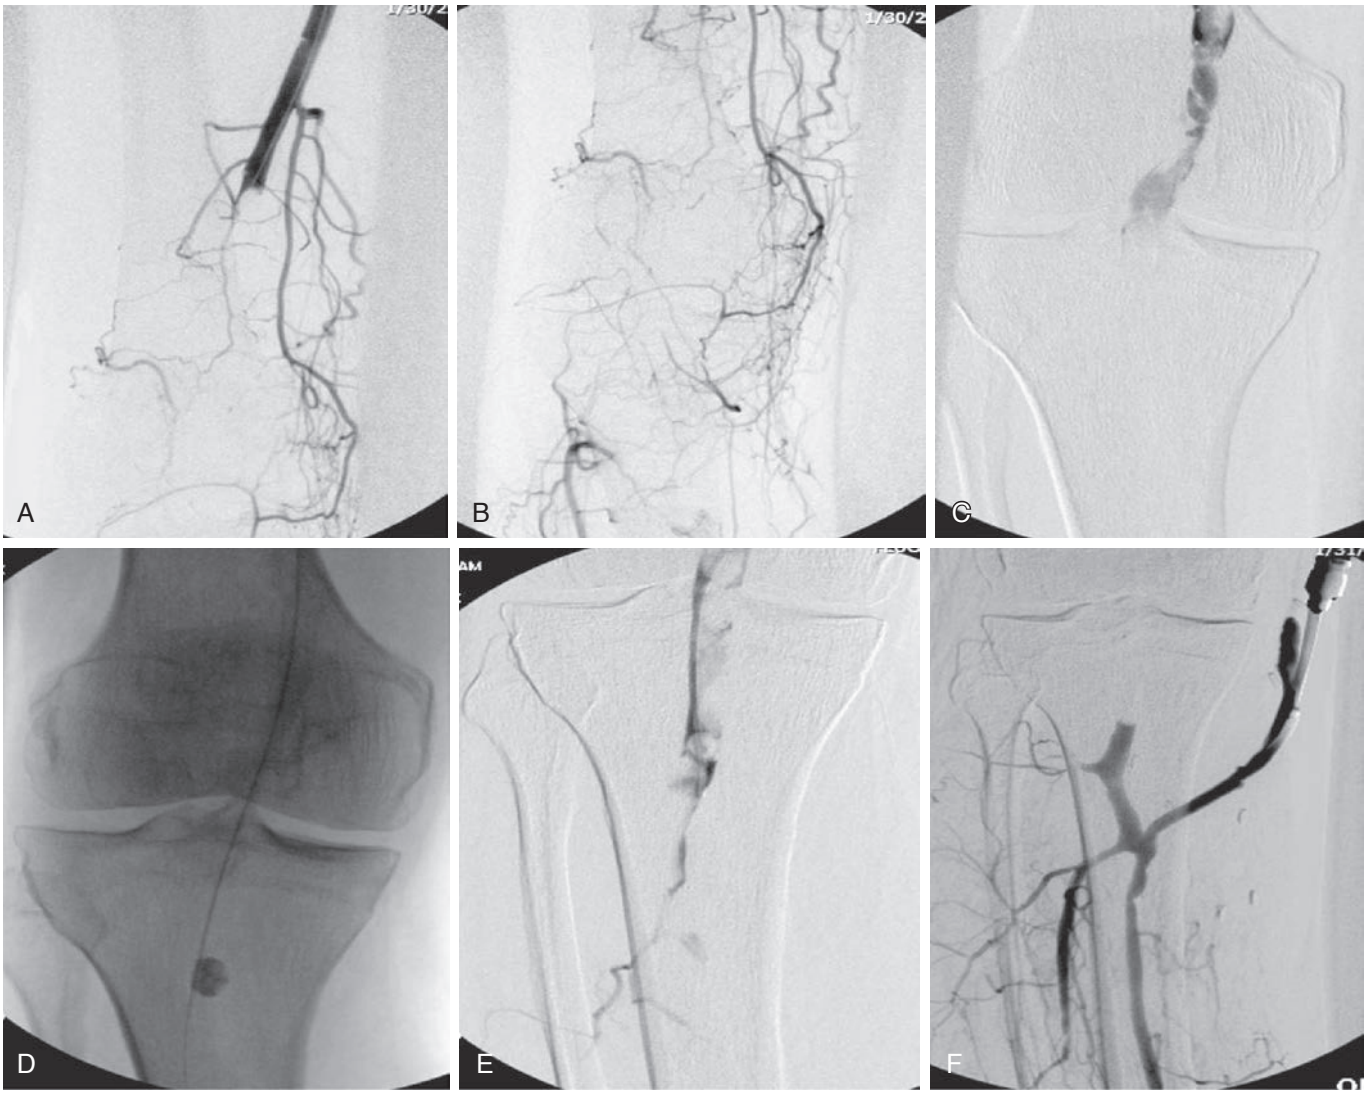

Figure 101.5 Thrombus is visualized at the superficial femoral artery (A) with occlusion of the popliteal artery (B). After embolectomy, residual thrombus was present (C). Over-the-wire thrombectomy was performed (D) with persistent popliteal artery thrombus (E). This finding necessitated a salvage bypass from the common femoral artery to the tibioperoneal trunk after endarterectomy and patch angioplasty of the distal target artery (F).

TABLE 101.6 Amputation, Mortality, and Long-Term Limb Salvage for Open Surgery for Acute Limb Ischemia

			RESULTS		
Series	Year	Number of Patients	Amputation (%)	Mortality (%)	Limb Salvage
Campbell et al.[6]	1998	474	16	22	Not reported
Nypaver et al.[7]	1998	71	7	10	62% at 1 year
Pemberton et al.[8]	1999	107	12	25	75% at 2 years

As such, the rate of amputation has diminished over the decades, presumably because of improvements in surgical technique. Unfortunately, the ability to rapidly restore arterial flow to the extremity with an operative procedure represents a significant insult to a medically compromised patient—one that all too frequently culminates in the patient's death.

SPECIAL CONSIDERATIONS

Myoglobinuria

Myoglobinuria is not uncommon after the treatment of ALI. It can be a significant problem in patients with preexisting renal

insufficiency and in patients who have received large volumes of iodinated contrast agents. Hemoglobinuria can be commonly seen after the use of some PMT devices such as the AngioJet, which cause lysis of red blood cells. Hemoglobinuria may also induce acute kidney injury. The incidence of hemoglobinuria with the AngioJet device appears to be correlated with treatment times exceeding 10 minutes and infusion volumes exceeding 300 mL. Patients with any of these risk factors are monitored for myoglobinuria, hemoglobinuria, and oliguria. A urine output of more than 100 mL/h is maintained. Alkalization of the urine is achieved by the addition of sodium bicarbonate to intravenous fluids. Acute renal failure may require temporary dialysis until the kidney function improves.

Fasciotomy

Compartment syndrome is most commonly seen in patients who have undergone open surgical revascularization and in those treated with PMT devices, owing to the speed of revascularization. Fasciotomy for compartment syndrome is less frequently required in patients undergoing CDT because of the more gradual resolution of ALI. Any patient with early motor changes (Rutherford class IIb or III) should undergo fasciotomy after open surgical revascularization or successful PMT. Further details regarding the diagnosis and treatment of compartment syndrome and indications for fasciotomy can be found in Chapter 102.

Pediatric Population

Currently, there are few studies relating to the management of ALI in the pediatric population, even though catheters are known to be responsible for more than 80% of venous-acquired and 90% of arterial-acquired thrombotic complications in children. Symptomatic secondary thromboembolic complications develop in approximately 2.4 per 1000 patients admitted to the neonatal intensive care unit, although asymptomatic catheter-related thrombi occur more frequently, on the basis of post mortem (3% to 59% of cases) and angiographic studies (10% to 90% of cases).[39]

The use of thrombectomy catheters, thrombolytics, and combinations of these approaches has been extensively reported in the adult literature. In the pediatric population, although rare reported cases exist, there are no studies supporting the use of these techniques. The writers of one report believe that a combination of CDT and percutaneous aspiration and/or mechanical thrombectomy, when feasible, may improve results in the treatment of ALI in children. Repeated interventions were necessary to improve results. In their five cases, the writers were able to resolve small proximal clots, but they were not able to reach distal clots if complete occlusions were present, especially in the absence of collateral circulation. On the basis of this limited report, it appears that aggressive management is warranted because tissue salvage was achieved in those five cases, even when initial gangrenous changes were present.[40]

UPPER LIMB ISCHEMIA

There are a number of significant differences between acute ischemia of the arm and that of the leg. Patients with acute arm ischemia tend to be, on average, approximately 4 years older than those with acute leg ischemia (mean age, 74 years). Arm ischemia is seldom limb threatening, and treatment decisions are usually less urgent.[41,42] The main reason for treating arm ischemia is to prevent late complications such as exercise-induced arm fatigue and pain.[43] Most arm ischemia is due to cardiac embolism. Rare causes of arm emboli include thoracic outlet syndrome and proximal subclavian artery aneurysm. Atherosclerosis is rare in upper limb arteries, and collateral vessels usually prevent ALI when atherosclerosis is present.

Patients with upper limb ischemia often present with a cold feeling and numbness, rather than pain in the arm. The diagnosis of ALI in the upper extremity is clinical and can be confirmed by duplex ultrasonography. The arm often improves after initial anticoagulation, and decisions about whether to perform embolectomy can be difficult. Up to 50% of patients have late symptoms of arm pain if untreated. Consequently, there should be a low threshold to undertake embolectomy if there is doubt about limb viability.[43] A small number of patients present with class IIb critical ischemia and require urgent surgical intervention.[42] In our practice these are often patients who have experienced arterial embolization due to a proximal subclavian artery aneurysm related to ongoing thoracic outlet syndrome. Failed surgery in this situation risks ischemic contracture or even arm amputation on occasion. The threat to the arm is generally low, but up to 20% of patients with acute arm ischemia do not survive the acute event, usually owing to cardiac complications.[44] As with acute leg ischemia, there is a high attrition rate after successful treatment; only 60% of patients survived 3 to 5 years in one typical series.[44]

Results of a prospective randomized trial evaluating surgery versus thrombolysis for ischemia of the lower extremity. The STILE Trial. *Ann Surg*. 1994;220:251–266.

One of the first large, randomized trials comparing open surgery to CDT. Failure of CDT was thought to be primarily due to the duration of ischemia, and many patients were treated for chronic limb ischemia (6 months' duration) with this technique. Currently, most physicians limit the use of CDT for symptoms of less than 2 weeks' duration. Additionally, the dose of tPA used in the STILE study is rarely administered with a cautious approach to systemic anticoagulation.

INTRODUCTION

Compartment syndrome is a surgical emergency and a recognized complication of several conditions treated by vascular surgeons. Failure to arrive at a timely diagnosis increases the risk of short- and long-term morbidity, including limb loss or permanent disability. Conversely, appropriate recognition and management of a compartment syndrome will optimize the chances of a full recovery. This chapter will address the pathogenesis, diagnosis, and treatment of compartment syndrome of the lower leg and other less common anatomic sites. Abdominal compartment syndrome is discussed in Chapter 183.

Abstract

Compartment syndrome is a surgical emergency and a recognized complication of several conditions treated by vascular surgeons. Early recognition and prompt treatment are critical to minimizing the risk of severe morbidity, including limb loss.

Typical symptoms include pain with passive motion of the muscles traversing the compartment, paresis or paresthesias referable to the compartment, or a tense compartment. Compartment syndrome is a clinical diagnosis, but measurement of intracompartmental pressures (ICP) may aid in decision-making. The most appropriate ICP criteria are ICP minus mean blood pressure < 40 mm Hg or ICP minus diastolic blood pressure < 10 mm Hg. This chapter includes descriptions of the surgical technique for fasciotomy of the lower leg and other less common anatomic sites for compartment syndrome.

Keywords

Compartment syndrome
fasciotomy
intracompartmental pressure

PATHOGENESIS OF COMPARTMENT SYNDROME

Local Hemodynamics of Compartment Syndrome

The unifying feature of all compartment syndromes, regardless of etiology or anatomic location, is an increase in intracompartmental pressure (ICP) within an unyielding fascial envelope that impairs tissue perfusion.[1] The adverse consequence of elevated ICP on tissue perfusion may be understood by applying Poiseuille's law ($F = \pi r^4 \Delta P/8\eta L$) to capillary blood blow within a muscle compartment. In this equation, F represents capillary blood flow, r is the radius of the capillary to the fourth power, and ΔP is the pressure gradient from the precapillary arteriole to the postcapillary venule. Increasing ICP alters two variables in this equation, ΔP and R. As ICP rises, pressure is transmitted to the postcapillary venules, increasing the venous pressure and decreasing the arterial-venous pressure gradient (ΔP). Furthermore, increased ICP may collapse capillaries, decreasing their radius and further increasing resistance to flow.[1,2]

Compartment Pressures

Several theories exploring the role of ICP in the development of compartment syndrome have been proposed. The concept of a critical closing pressure was one of the earliest concepts, whereas more recent research suggests that the dynamic ICP threshold more accurately predicts which muscle compartments will develop compartment syndrome.

Critical Closing Pressure

Matsen suggested that there is a "critical closing pressure" above which capillaries collapse from transmural pressure and blood flow is arrested.[1] The pressure at which capillary blood flow ceases has been debated over the decades. Using vital microscopy to observe the response of isolated rat cremasteric muscle to increased external pressure, Hartsock found that a pressure gradient between the ICP and mean arterial pressure (MAP) of 25.5 ± 14 mm Hg arrested capillary blood flow. Hartsock saw no significant collapse of arterioles, capillaries, or venules.[3] This study and others disproved the "critical closing theory" proposed by Matsen, suggesting instead that the arterial-venous pressure gradient (ΔP) is the critical determinant of capillary blood flow.[1,3,4] This conclusion has direct implications for determining the threshold ICP that defines compartment syndrome.

Absolute Intracompartmental Pressure Threshold

Defining the threshold ICP that produces tissue injury and cell death is an important step in determining the pressure at which fasciotomy is advisable. Hargens found that an absolute ICP of 30 mm Hg for 8 hours universally produced muscle necrosis in normotensive dogs, whereas pressures less than 30 mm Hg produced no muscle necrosis.[5] Tissues differed in their susceptibility to increased ICPs. Early signs of endoneurial injury were observed at pressures of 30 mm Hg for 8 hours.[6,7] The differential susceptibility to injury between tissues may provide an explanation for those cases in which a delayed fasciotomy fails to restore full neurologic function despite viable muscle in the compartment.

Dynamic Intracompartmental Pressure Threshold

Defining compartment syndrome based on an absolute pressure threshold is appealing in its simplicity but ignores the role of arterial blood pressure in affecting compartmental blood flow. Changes in arterial pressure affect the arterial-venous pressure gradient (ΔP), altering compartment blood flow. Some authors have proposed defining compartment syndrome using a pressure threshold relative to MAP or diastolic pressure. Heppenstall found that healthy muscle in dogs developed evidence of tissue ischemia on[8] P-magnetic resonance spectroscopy when the difference between MAP and ICP (MAP – ICP) dropped below 30 mm Hg.[9] Injured muscle showed greater sensitivity to ischemia, as tissue ischemia became evident when the difference between MAP and ICP was less than 40 mm Hg ([MAP – ICP] < 40 mm Hg).

Heppenstall found that a dynamic pressure threshold (MAP – ICP) < 40 mm Hg, prevented unnecessary fasciotomy in a number of patients with absolute ICP exceeding 30 mm Hg.[9] Another study found that use of a dynamic ICP threshold of 30 mm Hg less than diastolic pressure prevented unnecessary fasciotomies in most patients.[10] Using the diastolic blood pressure as their reference point, Heckman observed a dramatic increase in tissue injury and necrosis when the difference between the diastolic blood pressure and ICP was less than 10 mm Hg in dogs.[11] These studies offer compelling evidence that a dynamic ICP threshold *relative to MAP or diastolic pressure* is more appropriate for selecting patients for fasciotomy.

CLINICAL ETIOLOGIES

Vascular Causes

ICP is elevated by conditions that either increase compartment volume or produce external compression on the compartment. The most common vascular etiologies for compartment syndrome are ischemia-reperfusion (IR) injury associated with acute ischemia, arterial and venous traumatic injuries, crush injuries, phlegmasia cerulea dolens, and hemorrhage within a compartment.

Ischemia-Reperfusion

The IR phenomenon, described in detail in Chapter 6, plays a central role in the pathogenesis of compartment syndrome due to acute ischemia and crush injury. IR increases compartment volume by causing muscle tissue injury, which leads to increased microvascular permeability with efflux of plasma proteins and progressive interstitial edema.[12] With reperfusion, oxygen radical generation exacerbates microvascular permeability and resulting interstitial edema.[12] Papalambros identified several risk factors for compartment syndrome after acute arterial ischemia, including prolonged ischemia time (>6 hours), young age, insufficient arterial collaterals, acute time course for arterial occlusion,

hypotension, and poor back-bleeding from the distal arterial tree at embolectomy.[13]

Trauma

Both arterial and venous trauma may produce compartment syndrome. Occlusive arterial injuries result in distal ischemia that initiates the IR phenomenon, whereas venous injuries may compromise venous outflow. The impact of compromised venous outflow is discussed next (Venous Outflow Obstruction). Fasciotomy rates vary according to the type of vascular injury, ranging from 29.5% for isolated arterial injuries, 15.2% for isolated venous injuries, and 31.6% for combined arterial and venous injuries. Injuries to the popliteal artery are notorious for a higher risk of compartment syndrome (61% incidence), compared with injuries above the knee (19% incidence).[14]

Venous Outflow Obstruction

Uncomplicated deep venous thrombosis (DVT) often increases ICP, depending on the extent of DVT.[15] Only when there is extensive, multilevel DVT with occlusion of venous collaterals is the venous outflow obstruction sufficient to increase ICP and produce compartment syndrome. With increased venous hypertension the arterial-venous pressure gradient (ΔP) is altered and capillary blood flow is impaired. With reduced capillary blood, muscle cell injury ensues, exacerbating tissue edema. This cycle continues until eventually the postcapillary venules thrombose and venous gangrene develops.

Hemorrhage

Hemorrhage may be a source of rapid increases in compartment pressure. Thigh compartment syndrome has been described as the presenting symptom for rupture of a popliteal artery aneurysm[16] or postoperative hemorrhage after joint replacement surgery in an anticoagulated patient.[17]

Nonvascular Etiologies

Fracture

Tibial or forearm fractures are the most common orthopedic causes of acute compartment syndrome. These fractures injure the surrounding muscles and cause bleeding within the compartment, elevating ICP. The incidence of compartment syndrome with fractures ranges from 1% to 29%.[10,18-20] The anterior compartment of the leg and the flexor compartment of the forearm are most prone to this phenomenon. Comminuted fractures are more likely to result in a compartment syndrome, owing to the greater energy absorbed in such injuries.[19]

Crush Injury

Crush injuries are another form of trauma that may cause compartment syndrome. Reported mechanisms include crushing by equipment at industrial sites or large building structures during earthquakes and blunt trauma due to assault.[21,22] Compartment syndrome after crush injury results from a combination of direct muscle injury and IR due to direct compartment pressure with underlying muscle ischemia and subsequent reperfusion upon removal of the external compressive force. Large-volume crystalloid resuscitation can exacerbate the increase in ICP.[21]

Iatrogenic

Iatrogenic causes of compartment syndrome include extravasation of large volumes of fluid within a muscle compartment, extravasation of caustic medications such as contrast agents, inadvertent arterial injections, and hemorrhage related to arterial or venous punctures in coagulopathic or anticoagulated patients.[23-25] Additional mechanisms include the compression injuries associated with prolonged intraoperative immobilization, as occurs in the dorsal lithotomy position, and cast immobilization for fractures.[26,27]

Secondary Compartment Syndrome

Rarely a compartment syndrome develops in a trauma patient without overt evidence of extremity trauma. This phenomenon has been termed "secondary compartment syndrome" and is believed to be a consequence of diffuse microvascular permeability due to trauma-induced systemic inflammatory response syndrome in concert with massive fluid resuscitation.[28]

CLINICAL PRESENTATION

History and Examination

The diagnosis of an acute compartment syndrome begins with a high index of suspicion. Symptoms of a compartment syndrome include pain that is disproportionate to the magnitude of the injury and paresthesias in the distal extremity.[8] The pain is typically not relieved by immobilization or reduction of fractures and responds poorly to analgesic medications. Paresthesias represent an early symptom of ischemia of the nerves traversing the muscle compartment in question.

On examination, the most common findings are a tense, swollen compartment with pain elicited by passive movement of the muscles in that compartment. A careful neurologic examination should document sensory and motor function distal to the compartment, focusing especially on the nerves that traverse the compartment at risk. For example, a compartment syndrome afflicting the anterior compartment of the lower leg may be accompanied by dysfunction of the deep peroneal nerve, causing numbness at the first dorsal webspace of the foot or inability to extend the great toe. Loss of two-point discrimination is a relatively sensitive indicator of developing compartment syndrome.[29] The overall sensitivity of exam findings for compartment syndrome is dubious. In a meta-analysis of compartment syndromes related to tibial fractures, Ulmer found that the sensitivity of clinical findings for diagnosing compartment syndrome is low (13% to 19%). The positive predictive value is equally low (11% to 15%), and the negative predictive value is high (97% to 98%). Ulmer concluded that the "clinical features of compartment syndrome are more useful in their absence in excluding the diagnosis."

Measurement of Compartment Pressures

Measurements of ICP are not required to ascertain the diagnosis of a compartment syndrome in most cases. Pressure measurement should be reserved for equivocal cases, unconscious patients, and pediatric patients in whom a compartment syndrome is suspected. In cases in which the diagnosis is apparent from history or examination, measuring ICP is superfluous and risks delaying definitive therapy.

Technique

Measuring ICP requires an instrument for measuring compartment pressures and a working knowledge of the muscle compartments. ICP has been measured using a host of techniques and instruments, including simple manometers, wick catheters, slit catheters, side-ported needles, and fiberoptic transducers. There are two components to each system: (1) a needle to access the compartment and (2) a pressure measurement system. The most commonly used ICP measuring systems are the arterial line manometer and handheld Stryker system. The arterial line manometer is ideally suited for use in the intensive care unit and operating room where pressure transducers and monitors are readily available. In the emergency room the handheld Stryker system is particularly convenient.

The choice of compartments for pressure measurement should be guided by clinical exam. The most symptomatic or turgid compartment should be interrogated first, remembering that the anterior compartment of the lower leg and the flexor compartment of the forearm are most prone to compartment syndrome. Ultimately it is advisable to obtain compartment pressures from all compartments at risk. If necessary, multiple readings may be obtained. ICP, MAP, and diastolic pressure should be recorded for the medical record. The pressure criteria that define a compartment syndrome will be discussed later in this section. A normal compartment pressure is ≤10 to 12 mm Hg.

Unusual Presentations for Compartment Syndrome

Compartment syndrome may affect any myofascial compartment. Although less common than the lower leg, compartment syndromes have been described in the upper extremity, hand, thigh, foot, and buttock. For any of these compartment syndromes, pain out of proportion to examination and swelling remain the hallmarks of their clinical presentation. In some cases, pain with passive motion may exacerbate the pain. The presence of neurologic symptoms is highly variable and is not required to secure the diagnosis.

Hand compartment syndromes are usually associated with crush injuries or fractures of the carpal bones. Hand compartment syndrome may affect any of the 10 compartments of the hand. The classic symptoms are pain and local paralysis at the intrinsic muscles.[30] Forearm compartment syndromes are typically associated with direct blows, crush injuries, or fractures.[31] Pain, swelling, and neurologic symptoms are the classic symptoms of increased ICP in the forearm, especially after trauma.[31]

Thigh compartment syndrome is usually caused by blunt trauma from motor vehicle accidents, contusion,[32] or crush injury.[21] Reperfusion injury rarely results in a compartment syndrome of the thigh. The anterior thigh compartment is most commonly involved and universally presents with pain on passive motion. Paresthesias and paralysis may also be present.[32]

Gluteal compartment syndrome has been associated with hypogastric artery ligation or embolization during aortic aneurysm repair, hip arthroplasty, and prolonged compression during operative procedures.[33-36] Gluteal compartment syndrome has been cited as a cause of rhabdomyolysis, renal failure, and sciatic nerve palsy.[33]

ADJUNCTIVE MEASURES

Prevention of Compartment Syndrome

A variety of adjuncts have been proposed to mitigate muscle swelling and prevent compartment syndrome. The most common approach has been pharmacologic therapy to blunt oxygen radical formation during reperfusion of an ischemic limb to minimize IR injury. Mannitol, allopurinol, superoxide dismutase, deferoxamine, thromboxane A_2, and melatonin have shown promise in reducing oxygen radical formation and ICP in animal models.[37-41] The use of these agents in humans has been limited to anecdotal reports.[42,43]

In cases of impending compartment syndrome, Mars[44] proposed a protocol of "first aid to hypoxic cells." Mars' protocol included: (1) maintaining normal blood pressure because hypotension reduces perfusion pressure; (2) removing any constricting bandages; (3) maintaining the limb at heart level (with no elevation) to avoid reducing the arterial-venous pressure gradient; and (4) supplemental oxygen to optimize oxygen saturation.

Prevention of Systemic Sequelae

Myonecrosis associated with compartment syndrome may liberate intracellular potassium, phosphate, myoglobin, and creatine phosphokinase (CPK). Treatments designed to prevent systemic sequelae of compartment syndrome are aimed at preventing further complications related to the electrolyte disturbances or myoglobinuria that result from extensive myonecrosis.

Hyperkalemia

Hyperkalemia with cardiac arrest has been described among patients with significant myonecrosis, especially among patients with crush injuries.[21,22] Aggressive pharmacologic interventions, even hemodialysis or continuous hemofiltration, may be required to control severe hyperkalemia.[45]

Myoglobinuria

Myoglobinuria exerts its nephrotoxic effects by inducing renal vasoconstriction, tubular cast formation, and direct heme protein–induced cytotoxicity.[45] The management of myoglobinuria includes aggressive crystalloid infusion, forced diuresis

with mannitol, and alkalinization of the urine with bicarbonate. The rationale for crystalloid and bicarbonate infusion is based on the observation that heme proteins have minimal nephrotoxicity in the absence of hypovolemia and aciduria.[45] Clinical data affirm that early resuscitation with crystalloid diminishes the risk of progression to acute renal failure.[21,22,45] The data in support of mannitol and bicarbonate are more circumstantial. In a review of 1771 patients with acute renal failure due to myoglobinuria, Brown and colleagues found no difference in the incidence of acute renal failure, need for dialysis, or mortality between patients receiving mannitol and bicarbonate, compared with those receiving crystalloid infusion alone.[46] Current recommendations for the management of myoglobinuria include hydration with a goal urine pH of greater than 6.5, despite the fact that the use of sodium bicarbonate has not been shown to be superior to saline diuresis.[47]

Myoglobin is poorly cleared by conventional dialysis membranes due to its relatively large molecular weight (17,000 Da), so hemodialysis is not a useful adjunct in preventing renal injury due to myoglobinuria, although continuous venovenous hemofiltration has shown promise in preliminary studies.[48] Renal replacement therapy is currently reserved for standard indications, including the management of severe hyperkalemia.[47]

FASCIOTOMY

Criteria for Fasciotomy

The decision to proceed to fasciotomy may be dictated on clinical grounds or by ICP measurements (Table 102.1).

Clinical Criteria

Clinical criteria for fasciotomy include a swollen, tense compartment, pain with passive motion of muscle groups traversing that compartment, and neurologic findings referable to the compartment. Not all of these criteria are required to proceed to fasciotomy. The presence of a turgid compartment with either of the other two criteria (pain with passive muscle movement, neurologic changes) is sufficient to warrant fasciotomy. Any neurologic finding referable to a tense compartment is an absolute indication for expeditious fasciotomy because nerve injury is ongoing. The presence of a tense compartment alone places the limb in an equivocal category for which fasciotomy or continued serial examinations are options. Patients who are obtunded or require other operations are poor candidates for serial examination, making fasciotomy the best option. If serial examinations are pursued, they must be performed by an experienced surgeon. In equivocal cases, ICP measurement may assist in decision-making.

An important consideration is the likely evolution of muscle swelling over the next several hours. In an equivocal case in which additional muscle swelling is inevitable, a "prophylactic" fasciotomy may be prudent. Scenarios in which prophylactic fasciotomy may be reasonable include acute ischemia exceeding 6 hours, especially if there is inadequate collateral flow, and combined arterial and venous traumatic injuries.[13,49-51]

TABLE 102.1 Indications for Fasciotomy

Absolute Indications	Potential Indications
• Tense compartment *plus either*: • Pain with passive motion of muscles traversing the same compartment *or* • Paresis or paresthesias referable to the same compartment • Tense compartment in a patient who cannot be examined serially due to obtundation or need for other operations • ICP minus mean blood pressure <40 mm Hg • ICP minus diastolic blood pressure <10 mm Hg	• Acute ischemia >6 h with few collaterals • Combined arterial and venous traumatic injuries • Phlegmasia cerulea dolens • Tense compartment after crush injury • Tense compartment after fracture

ICP, Intracompartmental pressures.

Intracompartmental Pressure Measurements

The threshold ICP for the diagnosis of compartment syndrome remains controversial, but the data favor the use of a dynamic ICP threshold related to MAP or diastolic pressure.[9,11,10] Fasciotomy is warranted if the difference between the ICP and MAP falls to less than 40 mm Hg or the difference in ICP and diastolic pressure is less than 10 mm Hg.

Contraindications to Fasciotomy

Fasciotomy is contraindicated when the extremity is nonviable, due to extensive traumatic or ischemic injury. Crush injuries, in particular, may result in life-threatening complications from reperfusion because of the magnitude of the electrolyte shifts that result from reperfusion of ischemic muscle after fasciotomy.[21]

TECHNIQUE OF FASCIOTOMY

Fasciotomy is the only known treatment for acute compartment syndrome. Performing an adequate fasciotomy is critical to complete decompression of a compartment syndrome. Poor technique may lead to incomplete decompression or injury to anatomic structures within the compartment. Technical details and relevant anatomy for fasciotomy are outlined in this section.

Lower Extremity Technique

Lower Leg

Anatomic Considerations

The lower leg is the most common site for compartment syndrome. The lower leg is subdivided into four anatomic compartments: anterior, lateral, superficial posterior, and deep posterior compartments. The most commonly injured nerve during a fasciotomy of the lower leg is the superficial peroneal nerve, which branches from the common peroneal nerve at or below the proximal fibular head and descends in the lateral compartment along the intermuscular septum separating the anterior and lateral compartments.[52]

Skin Incisions

The length of the skin incisions is critical to ensuring that complete decompression of the compartments is achieved. Jensen et al. found that 12% of subcutaneous fasciotomies, using minimal incisions, had incomplete decompression requiring reoperation to extend the skin incision.[8] Jensen and Sandermann hypothesized that the skin itself could prevent adequate decompression of the compartment syndrome. Cohen noted that a skin incision of 8 cm decreased the mean ICP in the anterior compartment of the lower leg from 48 to 25 mm Hg; however, one-third of patients had compartment pressures that remained elevated. Full decompression of all compartments of the lower leg required incisions 12 to 20 cm in length.[53] Some authors have advocated using limited incisions when the muscle swelling is expected to be minimal, reserving extensive open incisions for cases in which the muscle swelling is dramatic.[54] Unfortunately it is often difficult to predict the extent of postoperative swelling that will evolve postoperatively.

Double-Incision Technique

The double-incision technique (Fig. 102.1) for lower leg fasciotomy involves a generous longitudinal incision on the lateral aspect of the lower leg between the fibular shaft and the crest of the tibia. The incision is oriented directly over the intermuscular septum between the anterior and lateral compartments, approximately 4 cm lateral to the crest of the tibia. Skin flaps are then raised medially and laterally to expose the fascia of the anterior and lateral compartments. The intermuscular septum between these compartments must be identified clearly to ensure that both compartments are thoroughly decompressed. The anterior and lateral compartments are opened via separate, parallel 12 to 20 cm fascial incisions using Metzenbaum or Cooley scissors, taking care to sufficiently elevate the posterior blade of the scissors off of the muscle to avoid injury to the common, superficial, and deep peroneal nerves. These nerves are most at risk of injury near the fibular head, so it is advisable to terminate the proximal extent of these fascial incisions 4 to 5 cm distal to the fibular head. A second incision is placed on the medial aspect of the leg 1 to 2 cm posterior to the tibia for decompression of the two posterior compartments. The saphenous vein and nerve should be avoided in the subcutaneous tissue. The superficial posterior compartment is decompressed via a longitudinal incision along the gastrocnemius fascia. The deep posterior compartment is decompressed by dividing the attachments of the soleus muscle to the tibia, exposing the fascia overlying the tibialis posterior and flexor muscles of the foot. This fascia is then incised longitudinally, avoiding injury to the posterior tibial artery. The advantage of the two-incision technique is its relative simplicity, allowing rapid decompression of the four compartments of the lower leg.[55]

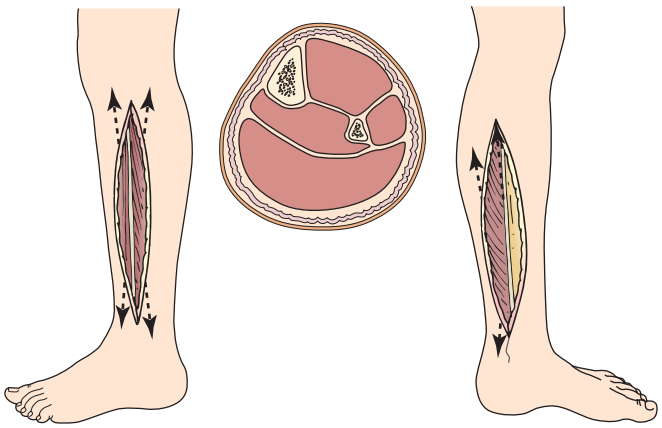

Figure 102.1 Double-incision fasciotomy of the lower leg.

Single-Incision Technique

The single-incision technique (Fig. 102.2) involves a lateral incision over the fibula from the fibular neck to 3 or 4 cm above the lateral malleolus.[56] A subcutaneous flap is developed in an anterior direction to access the anterior and lateral compartments. These compartments are decompressed using the same technique outlined previously for these compartments *(Double-Incision Technique)*. A posterior subcutaneous flap is developed to access the superficial posterior compartment for a longitudinal fascial incision. The interval between the lateral and superficial posterior compartments is exposed. The flexor hallucis longus muscle is identified and dissected off of the fibula in a subperiosteal plane. The peroneal vessels should be displaced posteriorly to avoid injury to these structures during the subperiosteal dissection. The fascial attachment of the posterior tibial muscle to the fibula is incision to open the deep posterior compartment. Most surgeons no longer perform a fibulectomy. The primary advantage of the one-incision approach is the ability to decompress all four compartments through a single-incision, but it is a relatively tedious approach to fasciotomy with a potential for injury to the peroneal artery and nerve. Most vascular surgeons now favor the double-incision technique.

Thigh

The thigh contains three compartments: anterior, posterior, and medial. The anterior compartment contains the sartorius and quadriceps muscles (rectus femoris, vastus lateralis, vastus intermedius, and vastus medialis). It receives its innervation from the femoral nerve. The posterior compartment contains the biceps femoris, semimembranous, and semitendinous muscles. The sciatic nerve innervates this compartment. The medial compartment contains the pectineus, obturator externus, gracilis, and adductor muscles (longus, brevis, magnus, and minimus). The obdurator nerve innervates the medial compartment.[57]

In most cases a single lateral incision may be used to decompress the posterior and anterior compartments (Fig. 102.3), whereas the medial compartment rarely requires decompression.[58] An incision is placed along the lateral thigh, beginning just distal to the intertrochanteric line and extending distally to the lateral epicondyle. The iliotibial band is exposed and incised longitudinally along the length of the skin incision to decompress the anterior compartment. The vastus lateralis is reflected medially to expose the lateral intermuscular septum. The intermuscular septum is incised over the length of the skin incision to release the posterior compartment. The medial compartment pressure

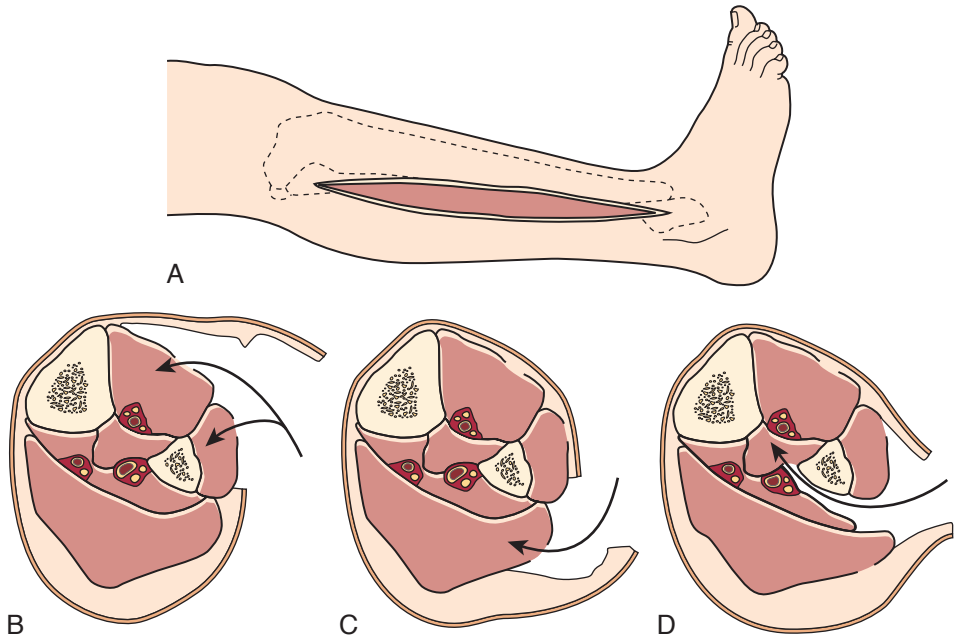

Figure 102.2 Single-incision fasciotomy of the lower leg. **A,** Lateral skin incision from the fibular neck to 3 to 4 cm proximal to the lateral malleolus. **B,** The skin is undermined anteriorly, and a fasciotomy of the anterior and lateral compartments is performed. **C,** The skin is undermined posteriorly, and a fasciotomy of the superficial posterior compartment is performed. **D,** An interval between the superficial posterior and lateral compartments is developed. The flexor hallucis longus muscle is dissected subperiosteally off the fibula and retracted posteromedially. The fascial attachment of the posterior tibial muscle to the fibula is incised to decompress the muscle. (From Davey JR, Rorabeck CH, Fowler PJ. The tibialis posterior muscle compartment: an unrecognized cause of exertional compartment syndrome. *Am J Sports Med* 12:391-397, 1984.)

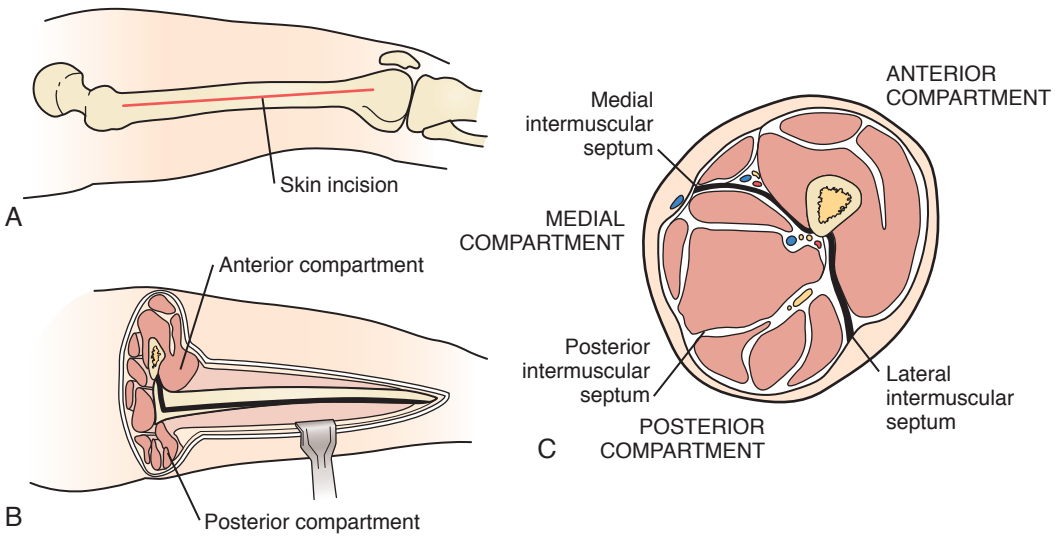

Figure 102.3 Fasciotomy of the thigh. **A,** The incision extends from the intertrochanteric line to the lateral epicondyle. **B,** The anterior compartment is opened by incising the fascia lata. The vastus lateralis is retracted medially to expose the lateral intermuscular septum, which is incised to decompress the posterior compartment. **C,** Thigh compartments and appropriate incision. (A and B, redrawn from Tarlow SD, Achterman CA, Hayhurst J, et al: Acute compartment syndrome in the thigh complicating fracture of the femur: a report of three cases, *J Bone Joint Surg Am* 68:1439, 1986.)

should be measured. Decompression of the medial compartment is rarely necessary, although a separate incision over the adductor muscle group will decompress this compartment.

Buttock

The buttock is composed of three major muscles, each with its own fascial compartment. There is no universally accepted standard incision for a buttock fasciotomy. However, a longitudinal incision is most frequently described in case series. Each of the muscle compartments requires decompression for a complete fasciotomy. Some authors have also recommended performing neurolysis of the sciatic nerve to prevent tension on the nerve from inflammatory adhesions.[59]

Foot

Currently, there is variability to the number of compartments ascribed to the foot. The most frequently named compartments are medial, lateral, superficial, and calcaneal compartments, with an additional compartment corresponding to each interosseous muscle.[60,61] Decompression of the foot is required infrequently and most commonly associated with crush injuries.[62] Two longitudinal dorsal incisions are fashioned. The first incision is oriented along the medial aspect of the second metatarsal, and the second incision is placed at the lateral margin of the fourth metatarsal bone. A separate incision is required to decompress the calcaneal compartment. Through these incisions, each of the muscle compartments can be incised, typically with fine scissors. Care must be taken to avoid the medial and lateral plantar neurovascular bundles that traverse the longitudinal axis of the foot.[62,63]

Upper Extremity

Forearm

The forearm is the most frequent site of compartment syndrome in the upper extremity. Within the forearm, there are volar (flexor, superficial, and deep), lateral (mobile wad), and the extensor (dorsal, superficial, and deep) compartments. The volar, or Henry, fasciotomy (Fig. 102.4) uses a single incision to decompress both the lateral and volar compartments.[29,64] A curvilinear incision begins proximal to the antecubital fossa, medial to the biceps tendon, crosses the antecubital crease, and extends to the radial side of the forearm where is extends distally along the medial border of the brachioradialis muscle. From the distal forearm the incision extends across the carpal tunnel along the thenar crease. The fascia overlying the superficial flexor compartment is incised along the entire length of skin incision. The radial nerve and brachioradialis muscle are retracted to the radial side of the forearm, and the flexor carpi radialis and radial artery are retracted to the ulnar side. The fascia overlying each of the muscles of the deep flexor compartment are incised to complete the volar fasciotomy. If the dorsal ICP is elevated, a long incision from the lateral epicondyle to the wrist is used to perform a fasciotomy between the extensor carpi radialis brevis and the extensor digitorum communis.[29] Carpal tunnel releases are controversial and may not be of benefit in isolated forearm compartment syndromes.[64]

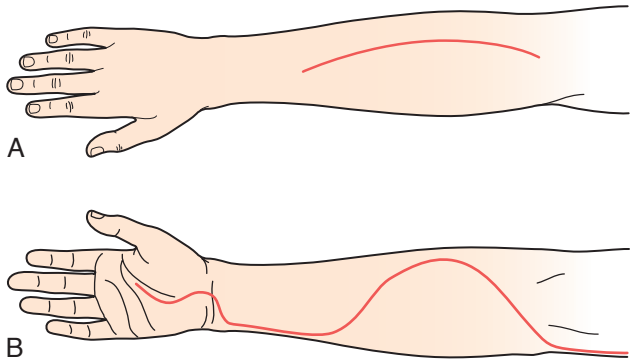

Figure 102.4 Fasciotomy of the volar forearm for severe Volkmann's contracture. **A,** Extensive opening of the fascia of the dorsum of the forearm for dorsal compartment syndromes. **B,** Incision used for anterior forearm compartment syndromes. The skin and underlying fascia are released completely throughout.

Hand

The hand is a rare location for compartment syndrome. There are 10 compartments of the hand: hypothenar, thenar, and adductor pollicis compartments; four dorsal interosseous compartments; and three volar interosseous compartments. The number of compartments in the hand complicates decision-making in performing a fasciotomy of the hand. The choice of fasciotomies for the hand should be tailored to symptoms.[23] All patients should have a carpal tunnel release, and most will require one to two dorsal interosseous fasciotomies. Many patients will also require thenar or hypothenar fasciotomy. All dorsal hand fasciotomies should be performed through longitudinal hand incisions.

FASCIOTOMY WOUND MANAGEMENT

Fasciotomy may solve the problem of increased ICP, but resulting wounds may be a source of considerable short- and long-term morbidity.[65,66] The goal of wound care early after fasciotomy is preventing further muscle injury or necrosis until muscle swelling subsides sufficiently to permit closure. When muscle viability is questionable, periodic saline dressings permit caregivers the opportunity to inspect and debride the wound at regular intervals. Vacuum-assisted closure (VAC) therapy is an alternative means of wound coverage, although the wound should be inspected at frequent intervals early after fasciotomy. After tissue viability is ensured and wound swelling has subsided, the priority shifts to wound closure.

Fasciotomy wound closure has been attained through a variety of approaches. The options include delayed primary closure, closure by secondary intention, gradual dermal apposition, split-thickness skin grafting (STSG), and myocutaneous flap coverage. Each of these approaches has a role, depending on the clinical circumstances. Delayed primary closure offers the simplicity of direct closure but should be reserved for those cases in which muscle swelling is minimal or nonexistent. Wiger found that 7 of 12 fasciotomy wounds had increased ICP

(>30 mm Hg) with attempted delayed primary closure on postoperative days 3 or 4, so early closure should be undertaken with caution.[67] Closure by secondary intention should be reserved for cases in which the patient is either medically or nutritionally ill-suited for any other option because this approach is the least expeditious in achieving wound closure. The addition of VAC therapy accelerates the process of closure by secondary intention and has been used with success for fasciotomy wounds.[68-70] To accelerate closure further, various forms of gradual dermal apposition have been advocated, including progressive closure with silastic vessel loops or cutaneous sutures placed at surgery or commercially available products.[71-75] Anecdotal reports have documented success with each approach.[72] Finally, several authors have proposed closure of fasciotomy wounds using STSG.[13,31,37,65,76] Myocutaneous flap coverage is generally reserved for coverage of neurovascular structures or exposed bone in a limb that remains functional. Early closure may decrease the rate of wound complications associated with closure by secondary intention and truncate the length of hospital stay.[13,65]

OUTCOMES

Early Outcomes

The mortality rate for patients undergoing calf fasciotomy ranges from 11% to 15%.[8,77,78] Major amputations are required in 5% to 21% of limbs.[8,77,78] Wound complications occur in 4% to 38% of patients.[65,66,77] Wound complications are more frequent if fasciotomy is delayed more than 6 hours (37%), compared with early fasciotomy (25%).[31,67,79] Renal failure is a rare complication after compartment syndrome, unless there is considerable myonecrosis.[45] Neurologic deficits occur in 7% to 36% of limbs[77,78,80] and are the most frequent early complications following a forearm fasciotomy.[31]

Late Outcomes

The late outcomes for fasciotomy are determined largely by the functional status of the patient at hospital discharge. Neurologic deficits or amputation in the early postoperative period are harbingers of long-term disability. Even in the subset of patients discharged without amputation or neurologic deficits, a fasciotomy predisposes the limb to future problems. Fitzgerald and colleagues noted at late follow-up that 77% of fasciotomy sites were associated with impaired sensation at the margins of the wound, 7% had tethered tendons, and 13% had recurrent ulcerations at the fasciotomy site.[81] Bermudez and colleagues[82] found that a significant proportion of patients (47%) had clinical evidence of chronic venous insufficiency after lower leg fasciotomy due to impaired calf muscle pump function. A small subset (7.5%) of patients will require late amputation (between 30 days and 1 year).[78,83]

Sequelae of Missed Compartment Syndrome

A delayed or missed compartment syndrome will have devastating consequences for the patient and the limb, increasing the risk of neurologic deficit, amputation, and renal failure. Sheridan and colleagues found that the overall complication rate increased dramatically if fasciotomy was delayed more than 12 hours (54%), compared with early fasciotomies (4.5%).[76] Nearly half of the patients with delayed fasciotomies required amputation and 92% had a significant neuropathy.[76] Not surprisingly, delay of fasciotomy for more than 36 hours almost invariably results in amputation. After 3 to 4 days, compartment syndrome is not indicated since the rate of infection and muscle necrosis is prohibitively high.

The classic late consequence of a missed compartment syndrome is a Volkmann contracture. In this state the ischemic muscle and nerve tissue are replaced by fibrosis, leaving the compartment firm, contracted, and dysfunctional.[84] Adjacent joints become stiff and immobile. Treatment consists of contracture and joint capsule release.[85] Orthopedic consultation for immediate- and long-term management is advisable.

CHRONIC EXERTIONAL COMPARTMENT SYNDROME

Clinical Presentation and Diagnosis

Chronic exertional compartment syndrome (CECS) is a syndrome of exercise-induced pain and tightness that usually affects the muscles of the lower leg, especially the anterior and lateral compartments, due to increased ICP and transient muscle ischemia.[86-88] The typical patient is a young (20- to 30-year-old), athletic patient who is a runner.[86] The syndrome is characterized by pain beginning 20 to 30 minutes after the onset of exercise, which abates with 15 to 30 minutes of rest. Paresthesias and muscle dysfunction often occur in the distribution of peripheral nerves traversing the compartment. Symptoms are bilateral in 82%. Physical examination often shows tenderness of the affected muscle compartment.

The differential diagnosis includes fascial hernias, medial tibial syndrome (for anterior compartment symptoms), and claudication due to popliteal entrapment syndrome (for calf symptoms). Although MRI and other tests may rule out other causes of leg pain, measurement of ICP is required to secure the diagnosis. Pedowitz and colleagues established pressure criteria for the diagnosis: (1) resting ICP >15 mm Hg; (2) ICP >30 mm Hg, 1 to 2 minutes after completion of exercise; or (3) ICP >20 mm Hg, 5 minutes after completion of exercise.[89] One or more of these criteria are sufficient for the diagnosis with the characteristic symptoms that are reproducible on exercise.

Fasciotomy for Chronic Exertional Compartment Syndrome

Treatment for CECS is either avoidance of the precipitating exercises or surgical decompression of the affected compartment. Avoidance is poorly accepted by athletic patients, so fasciotomy is typically the treatment of choice. The approach to compartment decompression for CECS differs from treating acute

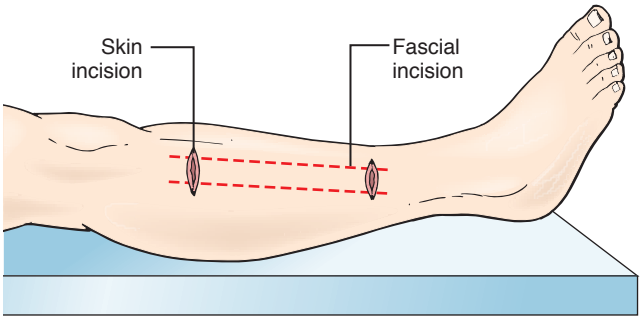

Figure 102.5 Fasciotomy of the anterior and lateral lower leg compartments for chronic exertional compartment syndrome.

compartment syndrome because only symptomatic compartments are decompressed. Both fasciotomy and fasciectomy have been proposed to decompress the symptomatic compartments. For subcutaneous fasciotomy (Fig. 102.5), two 2- to 4-cm transverse incisions are commonly used.[90] Both incisions are oriented over the intermuscular septum between the anterior and lateral compartments at the proximal and distal ends of the standard longitudinal fascial incisions of the anterior and lateral compartments. Two longitudinal fascial incisions are then performed between the two transverse skin incisions, akin to the fascial incisions used for a standard open fasciotomy (see *Double-Incision Technique*). For fasciectomy, a single longitudinal skin incision overlying the intermuscular septum between the anterior and lateral compartments is used. Two standard longitudinal fascial incisions are performed in the anterior and lateral compartments, followed by resection of a 2 × 6 cm ellipse of fascia. In his review of the treatment of 796 patients with CECS, Turnipseed advises fasciectomy as the treatment of choice in most cases of chronic compartment syndrome.[87]

Outcomes

Long-term results appear promising in case series, which describe significant reduction in pain at 2 years following anterior compartment fasciotomy in 83% of subjects.[90]

SUMMARY 1366

Atheromatous embolization is a poorly recognized and underdiagnosed multisystem disorder that is associated with high risk of all-cause and cardiovascular mortality.[1] There are a myriad of clinical manifestations that may occur across all specialties, making differential diagnoses broad and diagnosis difficult. In addition, atheromatous embolization is a confusing entity to many physicians because it is known by many different names: cholesterol embolization, cholesterol crystal embolization, blue toe syndrome, purple toe syndrome, atheroembolism, and pseudovasculitis. For the purposes of this chapter, these terms will be used interchangeably. After atheroembolism occurs, therapy involves three major strategies: treat the end organ that is undergoing embolization, prevent further embolization from occurring, and prevent future cardiovascular morbidity and mortality by risk factor modification. Therefore it is critical for clinicians to have a high index of suspicion and to recognize the clinical manifestations of this syndrome.

INCIDENCE

The prevalence of atheroembolism ranges from 0.18% to 2.4%, based on series of unselected autopsy studies.[2] However, in older patients with more severe atherosclerosis, the incidence is much higher, from 8.6% to 12.3%.[3,4] Autopsy studies performed in patients with known advanced atherosclerosis who have undergone cardiac or vascular surgical procedures before their deaths found 22% to 27% with evidence of atheroemboli.[5,6] Postmortem examination of patients who had abdominal aortic aneurysm resection found evidence of atheroembolism in 77% of this population.[7] In general, retrospective autopsy studies may overestimate the frequency of the disease because of the detection of subclinical cases and the selection bias inherent in obtaining information after necropsy. In contrast, clinically significant atheroembolic disease in clinical studies may be missed because of short-term follow-up. The prevalence of

atheroembolic disease in clinical studies has been estimated to be between 1% and 4%.[8-12] There are two factors that may be associated with either an increased prevalence of atheromatous embolization (the continuing increasing age of the population, and thus, more advanced atherosclerosis) or a decreased prevalence (better guide wires, catheters, and endovascular and surgical techniques). However, there have been no recent studies on current prevalence rates.

PATHOGENESIS

The first description of atheroembolism was published more than a century ago by the German pathologist, Panum. However, Flory[13] is credited for accurately describing the syndrome in 1945. Among 267 consecutive autopsies, he observed that the risk of atheroembolism is directly related to the severity of aortic atherosclerosis. There was no cholesterol crystal embolism when aortic ulceration was absent, 1.4% embolization with moderate aortic plaque erosion, and 12.8% with severe aortic plaque ulceration. The sources of atheroembolism are atherosclerotic plaques in large arteries such as the aorta, iliac, or carotid arteries which consist of a fibrous cap, under which are macrophages, necrotic debris, and cholesterol crystals. The vulnerable plaque, or the plaque at the highest risk of rupture, is the one with a thin fibrous cap surrounding a large lipid-rich core.[14] Plaque rupture caused by either spontaneous, traumatic, or iatrogenic maneuvers leads to embolization of cholesterol crystals, platelets, fibrin, and other detritus into arteries or arterioles and results in local mechanical obstruction, as well as an inflammatory reaction that contributes to end-organ ischemia and necrosis.[15]

Cholesterol crystals are white and rhomboidal or rectangular in shape. They can also be elongated, biconvex, and needle shaped, and range in size from 250 µm to less than 10 µm in diameter.[9] Because they are light in weight and hydrophobic, they pass quickly through blood vessels until they are stopped by arterial bifurcations, a narrowing of the vessel lumen, or when they reach the end of the arterial circulation.[9] Cholesterol crystals that lodge in the arterioles immediately incite an inflammatory response characterized by varying degrees of polymorphonuclear and eosinophilic infiltration.[9,13,16,17] By 2 to 4 weeks, a more chronic inflammatory infiltrate is seen where cholesterol crystals become embedded in multinucleated giant cells and smooth muscle cells.[16] Endothelial proliferation and fibrous tissue can be found surrounding the crystals, ultimately leading to luminal obliteration.[16,17] At 1 to 2 months, crystals may extrude out of the vessel lumen and be buried in the adventitia, or remain in the lumen, embedded within organized thrombus that may recanalize.[16] The crystals are resistant to breakdown by macrophages and have been shown to persist in tissue for up to 9 months.[18,19] Arterial lumina are eventually occluded by the accumulation of cells and fibrous material. These pathologic changes result in tissue effects distal to the cholesterol crystal emboli, including ischemia, and rarely, infarction, depending on the extent of organ involvement. This type of foreign body reaction is the reason it may take weeks to months for serum creatinine to rise in patients with atheroembolic renal disease and illustrates why renal function does not usually recover.[18,20-22]

RISK FACTORS

The major risk factor for atheromatous embolization is atherosclerosis of the thoracic and abdominal aorta.[23,24] Other risk factors include age (>60 years), coronary artery disease, peripheral arterial disease, and abdominal aortic aneurysms.[5,13,24] Patients with protruding mobile atheroma or aortic plaques greater than 4 mm in diameter have increased risk of embolic events.[25,26] Another feature that increases risk of atheroembolization is lack of plaque calcification.[24] It was hypothesized that the noncalcified plaques are probably lipid-laden plaques with a thin fibrous cap, which are unstable and prone to ulceration, rupture, and thrombosis.[27] Pedunculated, mobile plaques have also been associated with an increased risk of recurrent embolization (Table 103.1).[28-30]

Complex thoracic aortic plaques are not only valuable "markers" of severe widespread atherosclerosis[24,31] but also identify individuals at a high risk for cardiovascular disease such as peripheral arterial occlusive or coronary artery disease.[32] Although atheroembolism could occur spontaneously, precipitating factors are often invasive procedures that could potentially dislodge the plaques by mechanical trauma to the arterial wall either from endovascular intervention or from arterial clamping during cardiac/vascular surgeries.[8,33-37]

TABLE 103.1 Incidence of Events According to Plaque Thickness in the Aortic Arch Proximal to the Ostium of the Left Subclavian Artery

Endovascular Procedures for Coronary and Peripheral Arterial Occlusive Disease

Endovascular intervention is now the most frequent precipitating cause of the atheromatous embolization syndrome.[20,21,38-40] Manipulation of the aorta with rigid catheters or guide wires and the force of contrast injection can cause mechanical trauma, consequently dislodging atheromatous material from the arterial wall.[41] Nevertheless, the most important factor determining risk remains the severity of the atherosclerotic disease in the aorta. The reported incidence of atheromatous embolization from cardiac catheterization is from 0.15% to 2%.[11,21] Clinically apparent cholesterol embolism, such as livedo pattern on the feet, blue toe syndrome, digital gangrene, or renal failure, was found in 1.4% of patients who underwent left heart catheterization.[42] As with coronary angiography, catheter manipulation of the aorta in endovascular procedures for noncoronary arterial occlusive disease is also a serious concern. Embolic protection devices used in both renal and carotid artery stenting procedures frequently retrieved visible atherosclerotic debris.[43-50] Although spontaneous cholesterol emboli occurred in only 4.3% of patients who did not undergo arteriography, those who had arteriography had up to 27% incidence of cholesterol embolization.[6]

Cardiac Surgery

Atheroembolization is a well-recognized complication of cardiac surgery and has profound medical and economic consequences. Doty et al.,[34] in a retrospective analysis of 18,402 patients who underwent cardiac surgery, found evidence of atheroembolism in 0.2% of patients at autopsy. The clinical presentation of atheroembolism in this study was broad and included five distinct organ systems: heart, central nervous system, gastrointestinal (GI) tract, kidneys, and the lower extremities. In 21% of these cases, death was directly attributable to atheroembolism.[34] Kolh et al.[51] documented a significant increase in intensive care unit stay, overall hospital stay, and total hospital cost in patients with documented atheroembolism after cardiac surgery.

Vascular Surgery

The effect of atheroembolism after major vascular surgery was first recognized by Thurlbeck et al. in 1957.[7] In their series, atheroembolism was present at autopsy in more than 75% of the patients who died after aortic aneurysm surgery. Atheromatous embolization was the cause of death or significantly contributed to mortality in nearly half of the patients in this series. Vascular surgery procedures may disrupt plaque when the vessel is manipulated, cross-clamped, or incised during surgery. Other vascular surgery procedures known to precipitate cholesterol embolization include aortoiliac and aortofemoral bypass, carotid endarterectomy, and renal artery revascularization.[11] In a retrospective series of 1011 patients who underwent infrarenal aortic surgery or infrainguinal surgery, the diagnosis of cholesterol embolization was 2.9%.[52] Due to the advent of better surgical techniques and an awareness of the risk of surgery precipitating atheromatous embolization, this complication has become much less common than reported in the older literature.[53]

Anticoagulation

An increased risk of cholesterol embolization with anticoagulation and clinical improvement when anticoagulation was removed has been reported in case reports for nearly half a century.[8,11] One hypothesis is that anticoagulation may prevent thrombus formation over unstable atherosclerotic plaque, thus allowing exposed cholesterol crystals to embolize. Another hypothesis is that these agents may initiate the disruption of a complex plaque by causing intraplaque hemorrhage.[54-57] Based on these small case series and case reports, some investigators have recommended that warfarin be discontinued, when feasible, in patients who have had an episode of cholesterol embolization for which no other precipitant can be identified.

However, the data are not entirely clear in assessing anticoagulation safety in patients with a large amount of aortic plaque. The assumption that anticoagulation precipitates cholesterol emboli syndrome was not confirmed by the SPAF-3 trial, in which patients with documented aortic plaque who were assigned to warfarin therapy had a low annual rate of cholesterol embolization (0.7% per patient-year; 95% confidence interval, 0.1% to 5.3%).[58] Likewise, there was no report of cholesterol embolization in warfarin-treated patients with aortic arch plaque in The French Study of Aortic Plaques in Stroke Group.[32] As a matter of fact, Dressler et al.[30] found that patients with mobile aortic atheroma who did not receive warfarin had a higher incidence of vascular events than those who received warfarin treatment (27% had strokes vs. 0%). Whether the use of anticoagulation is associated with a higher incidence of atheroemboli remains controversial, but anticoagulation has been advocated for patients with crescendo transient ischemic attacks (TIAs), a syndrome caused by atheromatous embolization to the eye or brain. The current literature suggests that it is safe to continue anticoagulation therapy in patients with a compelling reason to do so, such as those with atrial fibrillation or venous thromboembolism.

Thrombolysis

Atheromatous emboli have also been associated with thrombolytic therapy in case reports and small series,[37,59] but again this is controversial. Thrombolytic agents act by converting plasminogen to plasmin; plasmin directly degrades fibrin. Theoretically, any therapy that causes the thrombus to undergo lysis may leave atherosclerotic plaque uncovered, placing the patient at risk for embolization. In one small prospective study, no relationship between the administration of thrombolytic therapy and cholesterol emboli syndrome was found.[60]

CLINICAL FEATURES

Atheroembolism may not result in any apparently clinical symptoms but could also present with a myriad of symptoms, including cardiovascular catastrophes such as myocardial infarction, stroke, acute renal failure, mesenteric ischemia, or peripheral

BOX 103.1 Clinical Manifestations of Atheromatous Embolization

Skin
- Purple or blue toes
- Gangrenous digits
- Ischemic ulcerations
- Livedo reticularis
- Nodules

Renal
- Acute, subacute, and chronic renal failure
- Severe uncontrolled hypertension
- Renal infarction (rare)

Neurologic
- Transient ischemic attack
- Amaurosis fugax
- Stroke
- Altered mental status

Eye
- Hollenhorst plaque

Cardiac
- Myocardial infarction or ischemia

Gastrointestinal
- Abdominal pain
- Gastrointestinal bleeding
- Ischemic bowel
- Acute pancreatitis
- Liver function abnormalities
- Cholecystitis
- Splenic infarcts

Constitutional Symptoms/Signs
- Fever
- Weight loss
- Malaise
- Anorexia

Modified from Bartholomew JR, et al. Atheromatous embolization. In: Young JR, et al., eds. *Peripheral Vascular Diseases.* 2nd ed. St. Louis: C.V. Mosby; 1996.

arterial occlusive disease (Box 103.1).[61-63] In general, the organs affected by cholesterol embolism depend on the location of the embolic source. Atheroemboli from the ascending aorta and proximal aortic arch usually manifest with central nervous system or retinal pathology, whereas cholesterol crystal emboli originating from the descending thoracic or abdominal aortas affect the visceral organs and extremities. In general, bilateral lower extremity atheroembolism signifies a source proximal to the aortic bifurcation, whereas unilateral emboli may originate either proximally or in any artery distal to the aortic bifurcation. Patients with one or more large atheromatous plaques in the aorta may present with a catastrophic event, such as an acutely ischemic limb, or renal or mesenteric infarction.[38,64] Conversely, patients with microemboli may have milder localized signs or a clinical picture that suggests a systemic illness. There may be a temporal delay in clinical findings (especially for renal failure) after the inciting event of up to 8 weeks.[62]

Cutaneous Manifestations

Skin manifestations are among the most common clinical manifestations of atheroembolism, and the common cutaneous features are livedo reticularis and blue toes.[65,66] The appearance of cutaneous signs can be delayed, with 50% of patients in one series showing skin signs of atheroembolism more than 30 days after their procedure or other inciting event.[65]

Livedo Reticularis

Livedo reticularis is a blue-red mottling or discoloration of the skin that occurs in a netlike pattern, most commonly seen on the buttocks, thighs, or legs (Fig. 103.1A). A detailed skin examination performed in both the supine and upright posture is necessary because livedo reticularis has been shown to be more readily demonstrable in the upright position.[67] Livedo reticularis is caused by obstruction of small arteries, capillaries, or venules in the deep dermis.[11,21] When the skin is biopsied in patients with atheromatous embolization, cholesterol crystals may be seen in the dermal blood vessels. However, livedo reticularis is not pathognomonic of atheroemboli and has an extensive differential diagnosis including, but not limited to, other causes of intravascular obstruction (i.e., antiphospholipid antibody syndrome, cryoglobulinemia, endocarditis, left atrial myxoma), vasculitis, or be drug induced (i.e., quinidine, quinine, amantidine, catecholamines).[68] Furthermore, there are also physiologic (Cutis marmorata) and idiopathic (livedoid vasculitis) forms of livedo reticularis. Livedo can occur in young healthy women and appears to be related to abnormal sensitivity of the dermal blood vessels to cold (primary livedo reticularis). This livedo reticularis pattern usually disappears on rewarming. Patients who exhibit this should be reassured that there is no serious circulatory abnormality present.

Blue Toe Syndrome

In its classic presentation, the blue toe syndrome presents as the sudden appearance of a cool, cyanotic, and painful toe in the presence of palpable distal pulses (see Fig. 103.1B).[54-56,65] Discoloration may also be seen on the sole of the foot. The discoloration may be patchy (see Fig. 103.1A), and comparison of both feet shows that the distribution is not symmetric. These lesions may progress to ulceration, necrosis, and frank gangrene (see Fig. 103.1C).[11] Accessory lesions may be present on the lateral and posterior aspects of the heels, which later develop into linear fissures with skin edge gangrene and a dark, necrotic base.

Other Skin Manifestations

Other skin manifestations include splinter hemorrhages, petechiae, purpura, ulcers,[69] and raised nodules that appear as the result of subepidermal inflammation surrounding cholesterol crystals.[11,65] These nodules are painful, violaceous in appearance with a necrotic center, and may mimic a necrotizing vasculitis, such as polyarteritis nodosa or leukocytoclastic vasculitis. Ulceration of the penis and scrotum have also been described.[70]

Renal Involvement

The kidneys are the second most common target for cholesterol crystal embolization, due to the enormous amount of blood that flows through the kidney and the close proximity of the proximal renal arteries to the plaque-bearing abdominal aorta.[20-22] The incidence of clinically detectable atheroembolism amounted to at least 4% of all inpatients examined, representing approximately 5% to 10% of the acute renal failure patients encountered.[10] This condition is significantly underdiagnosed because of delayed presentation.[1,20,22] The cholesterol emboli cause occlusion of the medium-sized arterioles (150 to 200 μm in diameter) and glomerular capillaries resulting in mechanical ischemia at the onset, but they also produce an inflammatory

Figure 103.1 Examples of Cutaneous Manifestations of Atheroembolism. Characteristic appearance of the foot in a patient with atheromatous embolization (A). There is a patchy distribution of livedo reticularis on the lateral aspect, plantar surface, and heel of the right foot (note the purple second toe). Typical appearance of blue or purple toes that may occur in atheromatous embolization (B). More severe cases may progress to gangrene (C).

reaction within the arterioles. The inflammatory infiltration of PMNs, macrophages, and multinucleated giant cells leads to thickening and fibrosis of the arterioles resulting in glomerular sclerosis, tubular atrophy, and interstitial fibrosis.[20,62,71]

It is important to recognize several different clinical presentations (Fig. 103.2)[11,20-22] of this disease, especially the differences between acute tubular necrosis (ATN) (see Fig. 103.2A) and atheroembolic renal disease (see Fig. 103.2B–D). Marked renal impairment with acute onset is the easiest form of atheroembolic renal disease to recognize. It has the closest temporal relationship to the inciting event and is generally considered the consequence of massive embolization, often resulting in catastrophic consequences. The subacute form of atheroembolic renal disease, the most frequently observed, is more insidious in onset, occurring a few weeks after the inciting event. Renal impairment may worsen over weeks to months due to an inflammatory response and foreign body reaction, or the cyclic occurrence of cholesterol crystal embolic showers (see Fig. 103.2B). Under this circumstance, atheroembolic renal disease can be diagnosed only by performing a renal biopsy. Atheroembolic renal disease may also be present with chronic stable renal impairment (see Fig. 103.2C) in an asymptomatic patient. Clinical features tend to be similar to those of ischemic nephropathy and nephrosclerosis. Recovery of dialysis-dependent renal failure (see Fig. 103.2D) may occur in 21% to 39% of patients who initially require renal replacement therapy.[22] Atheroembolic renal disease is often associated with severe and poorly controlled hypertension due to ischemic atrophy of the renal parenchyma and activation of the renin-angiotensin-aldosterone system as glomerular filtration declines.[56,62,72,73] As a result, atheroembolic renal disease should be strongly considered in patients who present with resistant hypertension.[73,74]

The renal outcome for patients with atheroembolic renal disease is quite variable. In early reports the renal outcome was uniformly dismal, with progression over weeks or months to end-stage renal failure.[55,72] However, over the past decade, spontaneous recovery of renal function in patients with atheroembolic renal disease have appeared in the literature, even after variable periods of dialytic support.[8,75-77] The improvement in renal function may be related to reversal of inflammation,

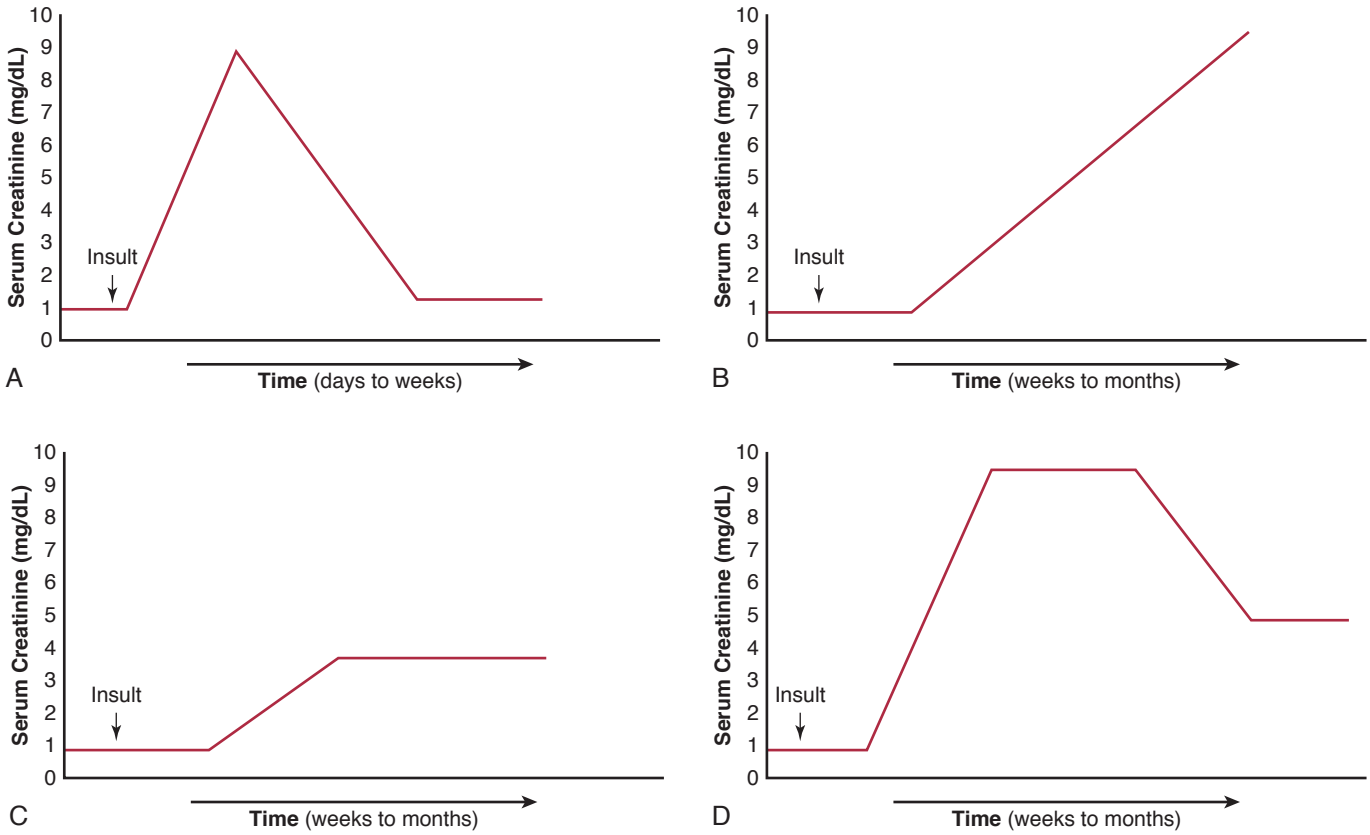

Figure 103.2 Patterns of Renal Failure in Patients With Acute Tubular Necrosis (ATN) and Atheroembolic Renal Disease. In ATN, the serum creatinine rises within 24 hours of the inciting event and progresses to a peak over a period of days to weeks. Under most circumstances, the creatinine slowly returns to normal or near normal (A). In atheroembolic renal disease, there is a delay of 1 week to several weeks from the inciting event until the creatinine begins to rise. This may progress to end-stage renal disease over a period of weeks to months (B). Another presentation of atheroembolic renal injury is also a delay from the inciting event, followed by a rise in the serum creatinine over a period of weeks to months eventually leveling out and leaving the patient with chronic stable renal disease (C). There have been an increasing number of reports in which the patient requires renal replacement therapy and after a period of time, the renal function improves to the point where the patient no longer requires dialysis (D). (From Bartholomew JR, et al. Atheromatous embolization. In: Young JR, et al., eds. *Peripheral Vascular Diseases*. 2nd ed. St. Louis: C.V. Mosby Co.; 1996:266.)

resolution of ATN in ischemic areas, and hypertrophy of surviving nephrons.[77] Despite these promising case reports, most patients with atheroembolic renal disease continue to have either advanced chronic renal insufficiency or progress to end-stage renal disease requiring dialytic support. In the large study by Scolari et al.,[21] of the 354 patients followed for an average of 2 years, 116 (32.7%) patients required dialysis therapy. Eighty-three patients remained on maintenance dialysis therapy, whereas 33 were able to discontinue dialysis. Five patients restarted dialysis within 2 to 6 months of stopping therapy. Cumulative renal survival probability was reduced by the presence of heart failure ($P < .001$), baseline chronic kidney disease categories ($P < .001$), age older than 70 years ($P < .039$), iatrogenic atheromatous embolization ($P < .001$), acute and/or subacute onset ($P < .001$), and leg ($P < .007$) or GI involvement ($P < .001$). Statin treatment was associated with protective effects both when already in place at the time of diagnosis and when initiated after diagnosis ($P < .001$). Multivariable analysis showed that the same factors plus diabetes were associated with a significant increased risk for end-stage renal disease.

Gastrointestinal Involvement

The GI tract is the third most common organ system involved according to autopsy findings, but it is frequently overlooked and rarely diagnosed premortem.[55,78,79] Sites of GI involvement include the colon, which is involved in up to 42% of cases, with the small bowel in 33%, and the stomach in 12%.[80] The preferential involvement of the GI tract is probably a result of its rich vascular supply. Other areas of digestive system involvement that have been reported include the pancreas, liver, gallbladder, and, less commonly, the spleen.[81] The pancreas and liver are frequent sites of cholesterol embolization, as indicated by autopsy reports, although clinically overt pancreatitis and hepatitis are an exceedingly rare presentation of cholesterol embolization.[81] In contrast, cholesterol embolization to the

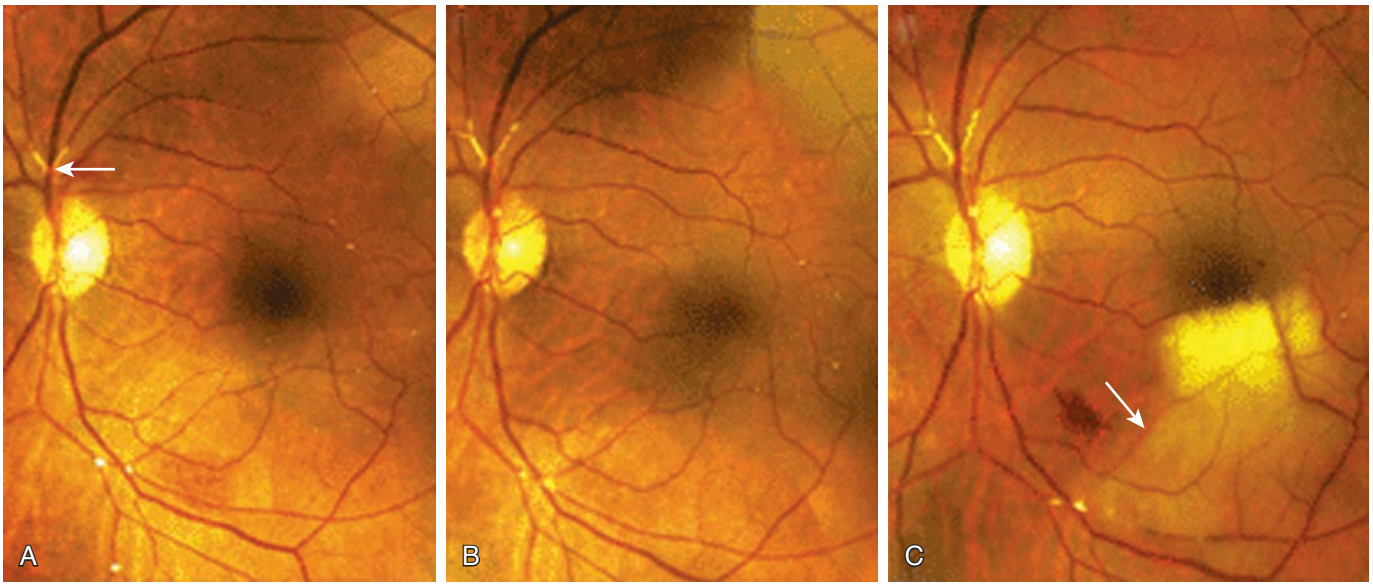

Figure 103.3 Examples of Hollenhorst Plaques. This 59-year-old man underwent stenting of the left internal carotid artery. Two months later, retinal examination of the left eye showed multiple, tiny refractile retinal arteriolar cholesterol emboli and a saddle embolus (A) superior to the optic nerve *(arrow)*. Repeated examination showed an increase in the number of cholesterol emboli (B). Four weeks later, a sudden, painless loss of the left superior visual field occurred. Examination revealed whitening in the inferior macular region (C) *(arrow)*, a finding that was consistent with an occlusion at the second major bifurcation of the inferior temporal branch of the retinal artery. (From Colucciello M. Images in clinical medicine. Retinal arteriolar cholesterol emboli. *N Engl J Med*. 2008;358:826.)

gallbladder, although even rarer, tends to be clinically significant when present, with a clinical presentation ranging from chronic acalculous cholecystitis to acute gangrenous cholecystitis.

The most common manifestations of GI tract involvement are abdominal pain, diarrhea, and GI bleeding. Abdominal pain may be caused by bowel ischemia with or without infarction, or by fibrous stricture with bowel obstruction as a consequence of tissue repair after repeated showers of atheroembolism.[11] The pathogenesis of diarrhea may be related to multiple mechanisms, including mucosal inflammation, accumulation of luminal blood, and malabsorption. GI bleeding is caused by superficial mucosal ulceration, erosions, and microinfarcts.[80]

The diagnosis of cholesterol embolism is rarely made by endoscopy alone because most endoscopic findings are nonspecific, including congestive or erythematous mucosa, erosions, ulcerations, necrosis, inflammatory polyps, or strictures.[2,8,80,81] Mucosal punch biopsies from the stomach, duodenum, or colon may be helpful in making the diagnosis occasionally, demonstrating the typical appearance of cholesterol crystals.[80]

The prognosis of patients with GI involvement tends to be poor; the overall death rate is high. Patients with GI involvement commonly have a multisystem cholesterol embolization syndrome. In a retrospective review of 10 patients with histologically proven cholesterol crystal emboli diagnosed by endoscopic GI biopsy, death due to atherosclerotic complications occurred in 5 patients (multisystem failure [3], stroke [1], and ruptured abdominal aortic aneurysm [1]) within 3 months after diagnosis. All of these patients also had cutaneous manifestations and end-stage renal disease.[80]

Central Nervous System and Eye Involvement

Cholesterol embolization commonly occurs in the brain and eye and causes significant morbidity and mortality.[2]

Retinal

The culprit atherosclerotic plaques are located in the ascending aorta, aortic arch, and/or carotid arteries.[82,83] Patients may develop visual disturbances such as amaurosis fugax or variable degrees of blindness caused by central or branch retinal artery occlusion.[9] Retinal cholesterol embolization is evident as yellow, highly refractile plaques (Hollenhorst plaques) at arterial bifurcations on ophthalmoscopic examination (Fig. 103.3).[9,84] From 2000 to 2005, 130 patients were analyzed with either Hollenhorst plaques or branch retinal artery occlusions.[85] This study found a low rate of significant extracranial carotid artery disease among these patients (<30% in 68%, 30% to 60% in 22%, and >60% in 8%). Only six patients underwent a carotid endarterectomy or received a stent. With a median follow-up of 22 months, no stroke or TIA occurred, and overall survival was 94% in this group of patients.[85] Among the 3654 survivors of the Blue Mountain Eye Study, the cumulative incidence of retinal emboli was only 2.9%.[86] The authors believed that this was an underestimation of the true incidence due to the transient nature of emboli and differential loss to follow-up. The same authors[87] assessed the relationship between retinal emboli and mortality in elderly patients. Of the 8384 patients with retinal photographs available, 2506 (30%) patients died over a 10- to 12-year period of time. The cumulative mortality was higher in patients with than without emboli (all-cause mortality: 56% versus 30%;

stroke-related mortality: 12% versus 4%; and cardiovascular mortality: 30% versus 16%).

Cerebral

Cerebral cholesterol embolism may be manifested as TIA, stroke, altered mental status, headache, dizziness, or organic brain syndrome.[8,82,88] In a retrospective review of 29 patients with autopsy-proven brain cholesterol emboli, encephalopathy was the predominant finding on neurologic examination.[89] This was most likely due to the diffuse and bihemispheric nature of cholesterol embolization. Involvement of the spinal cord artery, which can lead to lower extremity paralysis, has been rarely reported.[61] A case history that is composed of a procedure that involves the ascending thoracic aorta, acute renal failure, and encephalopathy in an elderly patient should raise the suspicion of cholesterol emboli to the brain. Radiologic studies can be helpful by showing multiple small ischemic lesions or border zone infarcts.

Other Areas

Cholesterol emboli can occur in virtually any organ. Cardiac manifestations include angina pectoris and myocardial infarction. The usual source in these circumstances is the aortic root or proximal coronary artery.[90] Pulmonary involvement has rarely been reported in the context of cholesterol embolism.[91,92] Hemoptysis and dyspnea are the most common respiratory symptoms described. The pathogenesis of pulmonary involvement in cholesterol embolism may be related to direct deposition of atheroemboli in the lungs[93] or de novo production of pulmonary lesions as a result of systemic inflammation associated with cholesterol embolism.[94] Atheromatous emboli have also been demonstrated in the spleen, bone marrow,[95] muscle, prostate, thyroid, and adrenal glands in autopsy studies.[2,54,55,72]

Nonspecific findings such as fever, weight loss, headaches, and myalgias have been reported and may suggest a multisystem illness (see Box 103.1).[8,75]

DIAGNOSIS

The diagnosis of cholesterol embolization syndrome remains a significant challenge for physicians. The symptoms and signs are nonspecific and diverse, which is why this disease is sometimes referred to as the "great masquerader."[12] For this reason, a high index of suspicion and a thorough understanding of the various clinical manifestations are needed to correctly make the diagnosis ante mortem. The diagnosis can often be made on clinical grounds alone, without histologic evaluation, in a patient who has a precipitating event, acute or subacute renal failure, difficult to control hypertension, and evidence of peripheral embolization.[8]

Laboratory Tests

Other than laboratory data that reflect specific organ injury such as elevations in serum levels of amylase, hepatic transaminases, blood urea nitrogen, creatinine, and creatinine phosphokinase which may be seen with involvement of the pancreas, liver, kidney, and muscles, respectively, there are no specific laboratory tests that are diagnostic of atheromatous embolization. Eosinophilia can be found in up to 80% of cases and is probably related to the generation of complement C5, which has chemotactic properties for eosinophils.[96] However, eosinophilia tends to be transient and short lived.[2,19] Laboratory markers of inflammation, including C-reactive protein, fibrinogen, and the erythrocyte sedimentation rate, have also been found to be elevated in many patients.[55] Other reported laboratory findings include leukocytosis, anemia, thrombocytopenia, and decreased complement levels.[54,55,97] Mild proteinuria, microhematuria, and hyaline or granular casts are the most common urinary findings in patients with confirmed cholesterol embolism.[55] Nephrotic range proteinuria, and eosinophiluria have also been reported less commonly.[18,98]

Imaging Modalities

Invasive vascular procedures requiring aortic instrumentation should be avoided as a diagnostic modality due to the potential risk for producing recurrent atheroembolism. Noninvasive imaging studies, such as multidetector CT angiography (Fig. 103.4), magnetic resonance angiography, and TEE (Fig. 103.5), can assist in confirming the diagnosis if a markedly irregular and shaggy aorta is demonstrated. It should be emphasized that these imaging modalities only demonstrate that the patient has significant underlying atherosclerosis but cannot discern whether the atherosclerotic lesions are responsible for the embolic events.

Histologic Findings

In the absence of obvious clinical clues, a definitive diagnosis may require a biopsy. The highest yield for histologic confirmation is in the skin in patients exhibiting livedo reticularis or in an affected organ, such as an amputated extremity in a patient with gangrenous toes, the kidney in a patient with new-onset renal failure, or in the GI tract in a patient with abdominal pain and GI bleeding. The cholesterol crystals dissolve in paraffin-fixed sections, leaving needlelike clefts (Fig. 103.6). Frozen or wet formalin-fixed sections reveal doubly refractile cholesterol crystals; with the Schultz histochemical stain, these crystals stain blue-green.[99]

DIFFERENTIAL DIAGNOSIS

Diseases that should be considered in the differential diagnosis include, but are not limited to, contrast nephropathy, ATN from ischemic injury, necrotizing vasculitis, leukocytoclastic vasculitis, thrombotic thrombocytopenic purpura, antiphospholipid antibody syndrome, and multiple myeloma. Thromboembolism from the heart or aneurysms, and other cardiac sources of emboli, such as an atrial myxoma, nonbacterial thrombotic endocarditis, and infective endocarditis,[100] should always be excluded.

No laboratory test uniformly helps in the diagnosis of atheroembolic disease. The peripheral blood eosinophilia, hypocomplementemia, elevated sedimentation rate, and increased

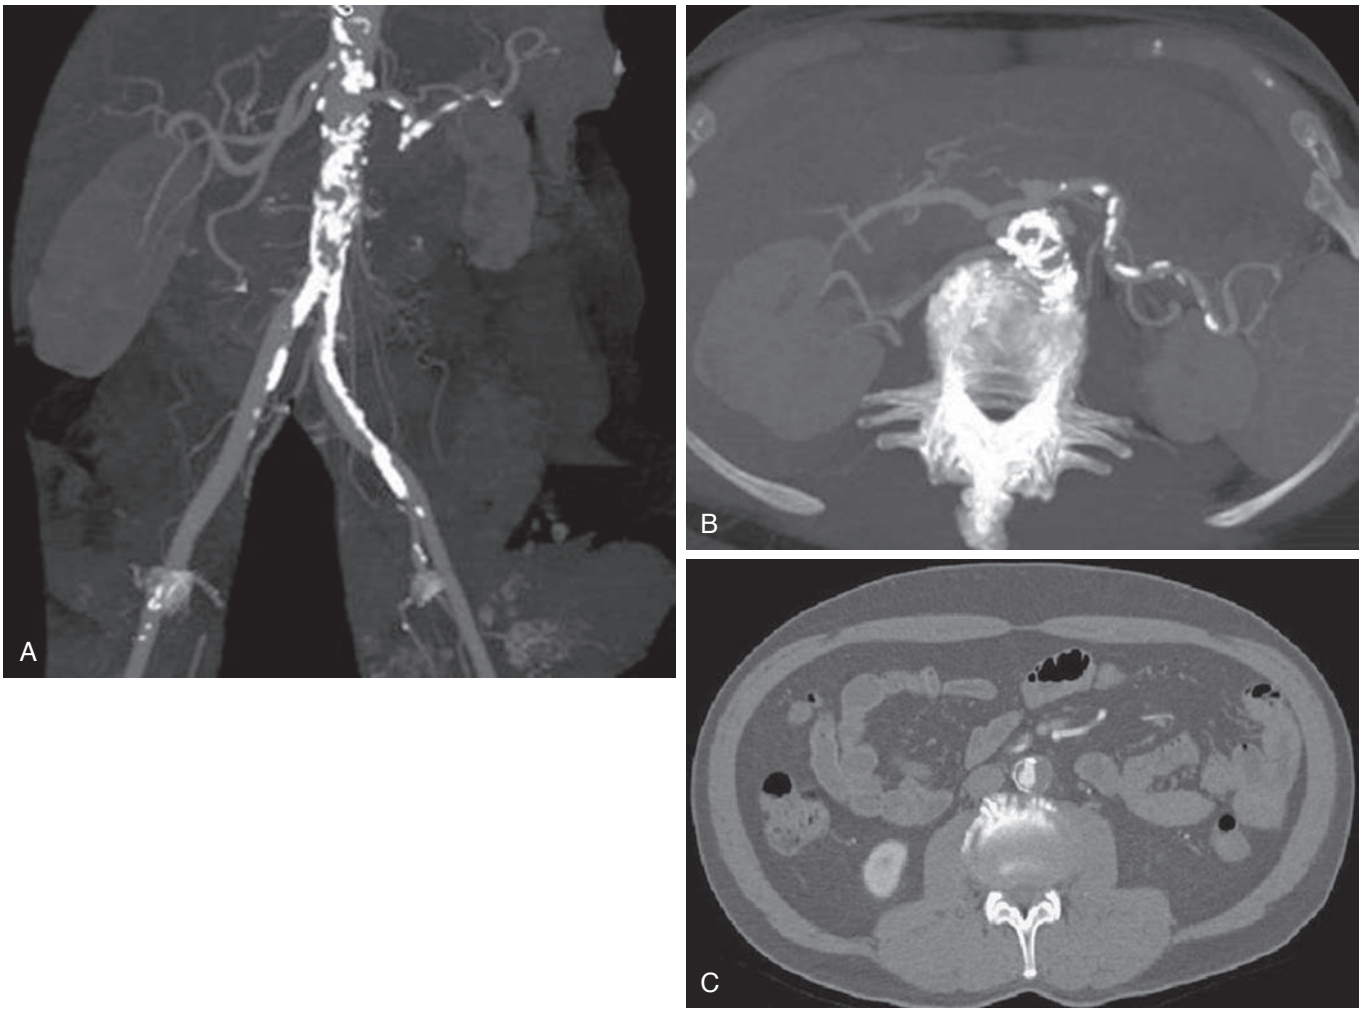

Figure 103.4 Multidetector computed tomography angiogram demonstrating marked calcified atherosclerotic disease in the infrarenal abdominal aorta in axial view (A) and reformatted view (B). Another example of infrarenal aorta with calcified plaque and extensive thrombus formation (C).

level of C-reactive protein seen in these patients are nonspecific findings that can also be found in patients with systemic or renal vasculitis.[101] Atheroembolic disease should be distinguished from vasculitis on the basis of other clinical findings and histology. The urine sediment in patients with atheroembolic renal disease is usually benign or shows only microhematuria. Rarely, eosinophiluria may be present.[102] In contrast, the urine sediment in patients with ATN often demonstrates pigmented casts (dirty brown casts) and renal tubular cells. Atheroembolic renal disease can further be differentiated from ATN or contrast nephropathy based on the time frame of renal impairment. In contrast nephropathy and ATN, renal failure occurs within 48 to 72 hours after the inciting event, whereas in patients with atheroembolic renal disease, the rise in creatinine is often delayed for 7 to 10 days.[20,21,61,62] In addition, full recovery of renal function is the rule for contrast nephropathy and ATN if the underlying precipitating factor is corrected, whereas it is the exception in atheroembolic renal disease.[11,62] However, there are examples of late recovery of renal function in patients with atheroemboli.[103] ATN is further characterized by normal blood pressure levels as opposed to the severe and refractory hypertension present in many patients with atheroembolic renal disease. The other previously listed disorders that may mimic cholesterol embolization due to their multisystem involvement should be excluded by appropriate diagnostic studies.

TREATMENT

Preventive Strategies

It is clear that the most effective strategy for the management of atheroemboli in vascular surgery is prevention. Imaging modalities such as MRI/MRA, TEE, or CTA are excellent techniques to screen for high-risk patients by detecting the presence of aortic atherosclerosis preoperatively. When a severely atherosclerotic aorta is visualized, alternative surgical procedures should be considered to minimize aortic manipulation. Utilization of long guide wire exchanges is recommended, and back bleeding from guiding catheters allows for removal of debris. Advancement and removal of catheters should occur over a

guide wire to straighten the catheter and minimize contact with the aortic wall. Brachial and radial access may minimize embolization from the abdominal aorta but not from the ascending aorta or arch.

Several studies showed that distal protection devices used at the time of renal artery stenting were associated with less deterioration in renal function compared with stenting without the use of these devices (Fig. 103.7).[45-47] In a small prospective randomized trial, Cooper et al.[46] demonstrated that during renal artery stenting, the combination of distal embolic protection and the use of the glycoprotein IIb/IIIa inhibitor abciximab resulted in an improvement in renal function compared with the use

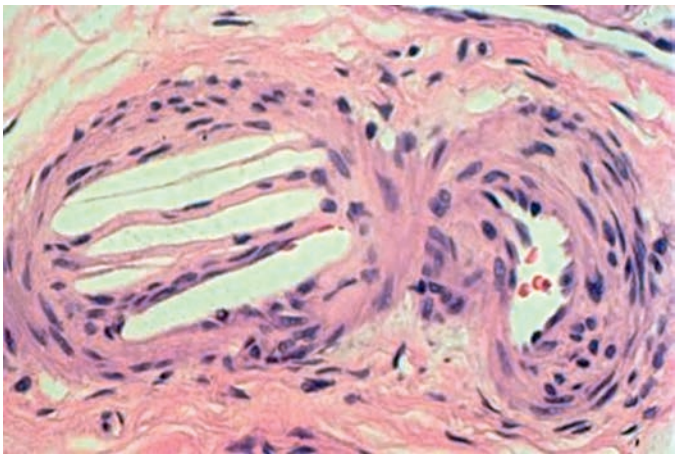

Figure 103.6 Typical Appearance of the Cholesterol Clefts in a Specimen from a Kidney Biopsy. The convex-shaped crystals within the small arterioles of the kidney dissolve during the fixation process leaving the ghosts *(left side)*, which is what is seen in the histopathology (hematoxylin and eosin stain, 200× original magnification). Note the three red blood cells in the arteriole *(right side)*.

of either of these modalities alone.[46] In addition, Paul et al.[104] showed that there is a much greater improvement in renal blood flow when a distal protection device was used during renal artery stent implantation compared with renal artery stenting without a distal protection device. Although distal protection devices are routinely used in carotid artery stenting, this is not the case in renal artery stenting. In the initial design of the Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL) trial, a distal protection device was used in every patient who was randomized to stenting. However, due to slow recruitment, this requirement was dropped from the protocol and the decision was left up to the discretion of the interventionalist.[105]

Medical Therapy

After atheromatous embolization has occurred, therapy is mostly supportive. Avoiding further inciting events (such as aortic manipulation), good control of hypertension and heart failure, dialytic support, and adequate nutrition are the mainstays of treatment.[8,56] Symptomatic care of the end organ where the emboli are located and risk factor modification to prevent myocardial infarction, stroke, and the progression of atherosclerotic disease are important treatment goals.[61,106]

Pathologic descriptions of cholesterol embolism highlight the severe inflammatory reaction that contributes to vascular obstruction. Although the inflammatory process caused by cholesterol embolism may suggest a role for antiinflammatory agents,[19] the use of corticosteroids has had conflicting results. Dahlberg et al.,[57] in a report of two patients given prednisone (60 mg daily) or methylprednisolone (80 mg daily) for 5 days, found a rapid and dramatic improvement in the manifestations of peripheral embolization.[57] More recent case reports described improvement in renal function in patients with suspected atheroembolism when corticosteroid therapy was used.[107-112] Corticosteroid administration has also been shown to be helpful in relieving symptoms related to mesenteric ischemia, such as

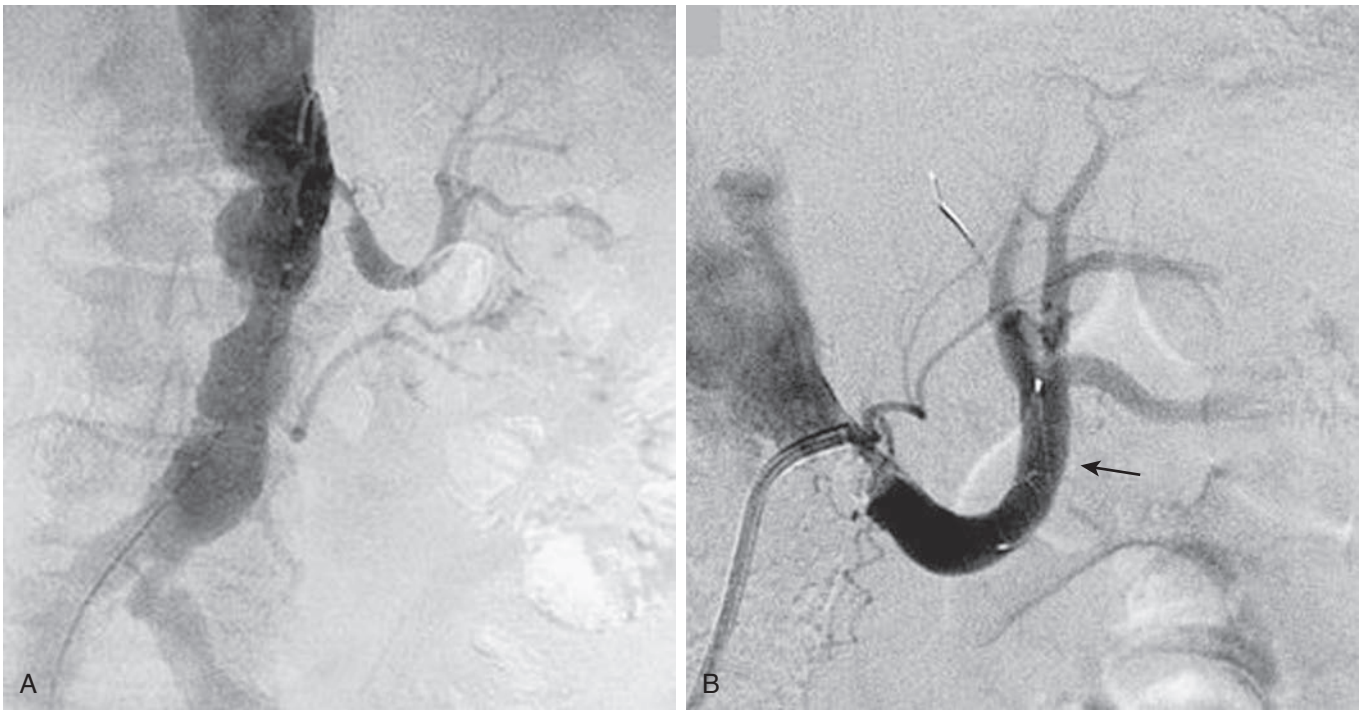

Figure 103.7 (A) Catheter-based angiogram demonstrating a severely atherosclerotic aorta with a severe stenosis of the left renal artery and an occluded right renal artery. A selective angiogram of the left renal artery shows the severity of stenosis (A). There was a 7-mm Spider embolic protection device *(arrow)* (ev3 Endovascular, Inc., Plymouth, Minnesota) placed before renal artery stenting (B).

abdominal pain and food intolerance, and for ischemic leg pain.[8] In contrast, in a series of 67 patients, of whom 18 were treated with corticosteroids, no survival benefit was attributed directly to this therapy.[8] Furthermore, in large retrospective series, Falanga et al.[65] found that corticosteroid use was associated with 100% mortality. Based upon the available literature, corticosteroid use cannot be recommended on a routine basis for this patient population, although some authorities have recommended corticosteroids in patients with multisystem atheroembolic disease.[22]

Statins have been reported to be beneficial in the treatment of livedo reticularis caused by cholesterol embolization[113] and for treatment of atheroembolic renal disease.[114] Furthermore, in a retrospective analysis of 519 patients with severe thoracic aortic plaque visualized on TEE, multivariate analysis showed that statin use was independently protective against recurrent embolic events ($P = .0001$).[115] The mechanism of the beneficial effects of statin therapy is most likely related to the plaque-stabilizing activity of these drugs.

Iloprost (Schering AG, France), a prostacyclin analogue, has been reported to be beneficial for treatment of atheromatous embolization. It is a potent vasodilator that inhibits platelet aggregation and also has cytoprotective properties. It has been used to treat pain at rest and nonhealing ulcers in patients with critical limb ischemia, as well as severe Raynaud phenomenon and thromboangiitis obliterans. In some reported individual cases or small series, patients who received iloprost infusions for ischemia of the distal extremities or kidneys reported a decrease in pain and improvement in their nongangrenous skin lesions, as well as renal function.[116-118]

Low-density lipoprotein (LDL) apheresis with or without the addition of steroids was shown to be effective in improving skin manifestations. Hasegawa et al.[119] showed that combining corticosteroids and LDL apheresis improved atheroembolism related to blue toe syndrome. The mechanism is unknown, although it was postulated to improve blood viscosity by removing large molecular weight substances and decreasing total and oxidized LDL, thus improving endothelial function and reducing circulating inflammatory cytokines and chemokines.[119]

Other forms of therapy that have been advocated include antiplatelet agents such as aspirin[54,55] and dipyridimole, low-molecular-weight dextran, intraarterial papavarine, and the use of platelet infusions to help stabilize the source of atheroemboli. However, no controlled trials have shown that any of these forms of therapy are of benefit. All patients should receive optimal risk factor modification with an antiplatelet agent (aspirin, clopidogrel, or both), a statin, and an angiotensin-converting enzyme inhibitor or angiotensin receptor blocking agent, all of which have been found to improve mortality in patients with underlying atherosclerotic disease.[61,120-125]

Surgical and Endovascular Therapy

Surgical or endovascular treatment is a viable option when a source of cholesterol emboli can be identified, and the source

is surgically or endovascularly accessible. However, it is often difficult to identify which of the many atherosclerotic plaques is the culprit lesion.

Surgical Therapy

The aims of surgical therapy for atheroembolic disease are, first and foremost, the elimination of the embolic source, and second, arterial reconstruction of any hemodynamically significant proximal occlusive disease to encourage healing through improved end-arterial bed perfusion. Given the frequent instability of these lesions, surgical treatment has been perceived to be safer than endovascular approaches because the surgeon can clamp the artery proximal and distal to the lesion before manipulating the diseased vessel in an attempt to decrease the risk of recurrent embolization.[126] Thromboendarterectomy or resection and graft replacement have been the surgical approaches most commonly used.[127] Two prospective series reported favorable outcomes with vascular resection of atherosclerotic segments of large arteries identified as being the source of previous cholesterol crystal embolism.[128,129] However, when the suprarenal aorta was involved, greater mortality rates were observed, likely related to the risk for visceral and renal ischemia and/or atheroemboli.[128] Thus, according to some investigators, surgical elimination of the presumed source of cholesterol embolization should be reserved for patients with lower limb ischemia and an infrarenal source of embolization.[11] In patients who are too weak for a major surgical intervention, ligation of the external iliac arteries or common femoral arteries, followed by an extra anatomic bypass (e.g., axillobifemoral bypass) has been advocated.[127,130] The ligation prevents further embolization from reaching the legs, although embolization to the kidneys and intestines may still occur.

Finally, surgical treatment of thoracic aorta atherosclerosis may be considered. Surgical therapy cannot be recommended routinely for the asymptomatic patient because the risks inherent in such a complex procedure outweigh the benefits.[131] However, performing aortic arch endarterectomy or aortic resection along with the planned cardiac procedure, if severe atheromatous disease is discovered, has been addressed. Stern et al.[132] reported a large increase in intraoperative stroke and mortality when surgery was performed to limit the risk of stroke after cardiopulmonary bypass. At this time, in the absence of randomized controlled trials, surgical indications for aortic endarterectomy should be restricted to highly selected patients who have multiple and documented embolic events with a low operative risk, despite optimal medical treatment.[29]

Endovascular Therapy

There are a few reports of intraarterial treatment of embolizing lesions, including thrombolytic administration,[52,133] percutaneous atherectomy,[134,135] balloon angioplasty,[52,133] and stent implantation.[136,137] Intraarterial thrombolytic administration in isolation is controversial. By destroying the platelet-fibrin thrombus that covers the atheromatous ulcerated plaques, thrombolysis may allow for the liberation of the cholesterol crystals into the arterial circulation with consequent microembolization. There are no data currently on the adjunctive use of tissue plasminogen activator in treating lesions believed to be responsible for atheroembolic events.

In percutaneous transluminal angioplasty, the intima is fractured and remolded, which could increase the risk of distal embolization. However, anecdotal reports using this approach have shown symptomatic improvement in leg pain, reestablishment of peripheral pulses, and no evidence of recurrent embolization. Stent placement, in conjunction with angioplasty, may provide a protective scaffold to help secure these lesions. However, a potential risk of recurrent atheroembolism may exist due to either plaque dislodgement or extrusion of atheromatous material through stent interstices at the time of stent placement.

The possibility of procedural-related distal embolization due to stent placement was highlighted in a recent study by Ohki et al.[138] that demonstrated a significant risk of distal embolization secondary to intraarterial stent placement in an ex vivo carotid endarterectomy model. In contrast, Matchett et al.,[136] in a retrospective report of 15 patients treated with stent placement for blue toe syndrome, found no procedure-related embolization and only one recurrent embolization during follow-up. Renshaw et al.[139] reported successful angioplasty with stenting in eight patients with unilateral blue toe syndrome. Symptoms resolved in all eight patients over the ensuing month, and there were no recurrences with a mean follow-up of 18.5 months.[139]

The short-term results in studies using percutaneous atherectomy, in which the plaque is shaved off the wall of the vessel and removed through a collection device, are similar to those of patients undergoing percutaneous transluminal angioplasty or surgery.[134,135]

The availability of covered stent-grafts in recent years has raised their potential utility in the management of patients with distal atheroembolic lesions. Covered stents offer the added advantage of completely excluding the diseased segment, preventing the escape of thrombus or plaque debris. Kumins et al.[140] reported on the successful use of the Wallgraft endoprosthesis in two patients with distal microembolism from common iliac artery pathology.

Carroccio et al.[141] recently reported on endovascular stent-graft repair for abdominal aortic aneurysms in 16 patients with atheromatous embolization syndrome. The 30-day mortality was 0%, and the abdominal aortic aneurysms were successfully excluded in 88% of patients. Resolution of foot ischemia and prevention of further atheromatous embolization occurred in 89% of the patients still alive at 1 year. Six patients died during a mean follow-up of 26 months, further illustrating the very high mortality in this patient population.

Distal embolic protection devices, especially filters, were originally designed to minimize atheroembolism during percutaneous coronary or carotid interventions. An off-label use of these devices is to protect the outflow arteries from atheroembolism during peripheral interventions. It would not be cost effective to use distal embolic protection for all peripheral interventions, and the arterial diameters compatible with these devices are limited. Nonetheless, distal embolic protection may be a useful adjunct for endovascular treatment of lesions deemed to be a high risk for embolization during the procedure, especially

in patients who have already experienced an atheroembolic event.

Because of the limited studies available in the literature regarding the role of endovascular therapy for atheromatous embolization, its clinical efficacy is difficult to compare with operative treatment strategies. Undoubtedly, further clinical evaluation is warranted to further validate endovascular therapy in the treatment of atheroembolism.

Pain Control

Pain control is a critical aspect of the management of peripheral cholesterol embolism. The degree of pain associated with lower extremity ischemic and necrotic lesions secondary to cholesterol embolism is generally severe and disproportionate to the extent of the tissue involved. Sympathectomy has received attention as a surgical measure for the palliation of atheroembolic lesions. Lee et al.[142] demonstrated that adjunctive sympathectomy resulted in improved healing of distal digital ischemic ulcers. Sympathectomy is easily performed during aortic procedures, or it can be achieved postoperatively through lumbar sympathetic block or laparoscopic techniques.

More recently, Ghilardi et al.[143] reported on two cases of inferior limb ischemia secondary to cholesterol embolism treated with the temporary surgical implantation of spinal cord stimulation devices. Spinal cord stimulation in this study was found to provide rapid and effective pain control in the reported cases and improvement in peripheral microcirculation manifested by the rapid resolution of the necrotic lesions within 4 to 6 weeks.[143] These surgical techniques may not only be an adjunct to direct surgical treatment of the offending arterial segment but also may be useful to control the pain of severe atheroembolic lower extremity lesions in patients who are not candidates for direct reconstruction of the embolic source. It is often helpful to ask a pain specialist to help in the management of the severe pain that may occur in these patients.

SUMMARY

Atheroembolism is a multisystem disease complicating advanced atherosclerosis. The clinical presentation varies from subtle to catastrophic manifestations. It is still often underrecognized and requires a high clinical suspicion to diagnose. The treatment is mainly supportive and risk factor modification to prevent further insults. Removal of the embolic sources is sometimes possible with surgical or endovascular intervention. In general, the prognosis of patients with atheroembolic disease is poor and most likely related to the severe and diffuse atherosclerosis that is present in this patient population. However, the course varies depending on type of clinical presentation. Patients with symptoms limited to an extremity tend to have a better prognosis compared with patients with disseminated cholesterol crystal embolization, particularly when there is evidence of visceral and renal involvement. The reported 1-year mortality in four different reports varied from 64% to 81% (Table 103.2).[18,55,57] Causes of death were multifactorial and included cardiac, central nervous system, and GI ischemia.
