Another limitation of typical contrast-enhanced MRA methods is that they average the appearance of a vessel over a long acquisition time, typically 20 seconds to 2 minutes, thus providing a static view without insight into the dynamic physiology of blood flow. For example, one may not be able to tell whether an artery distal to a high-grade stenosis is filling in an antegrade fashion or retrogradely through collaterals. Long acquisition times may also result in venous contamination if there is rapid transit of contrast through an organ with early venous filling, such as in the kidney. In addition, if two extremities are imaged simultaneously, the optimal imaging time may be different for each if one extremity has early arteriovenous shunting related to cellulitis, varicose veins, or arteriovenous malformations. Time-resolved MRA methods obtain multiple, more rapid acquisitions throughout passage of the contrast from arteries to veins.[122] Typically, time-resolved methods

Figure 28.26 Coronal maximum intensity projection of a continuous table motion magnetic resonance angiography runoff examination acquired at 3 T with parallel imaging from the abdomen to the toes in a patient with bilateral iliac stenoses and segmental left superficial femoral artery occlusions. The acquisition time was approximately 90 seconds. Note the lack of venous contamination in the calves and feet.

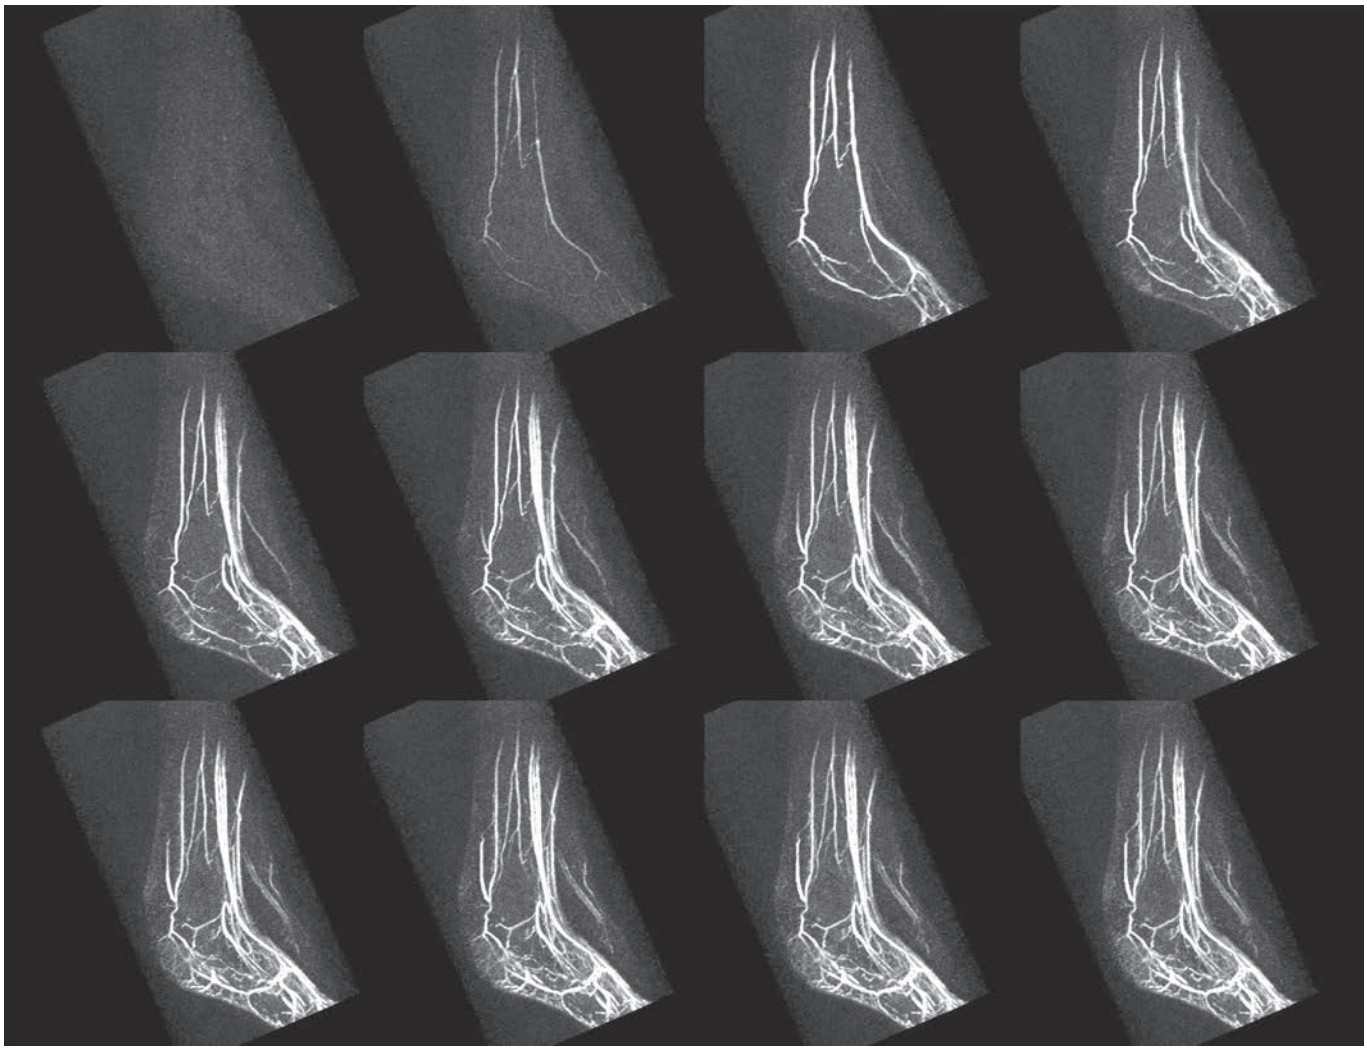

Figure 28.27 Coronal maximum intensity projection images of successive frames from a time-resolved magnetic resonance (MR) angiography examination of the feet. Each frame requires approximately 6 to 8 seconds to acquire, and thicker slices are obtained than with a static MRA.

acquire thicker slices than static high-resolution MRA does; some spatial information is sacrificed for improved temporal resolution, but complete 3D data sets are acquired in 2 to 10 seconds instead of 20 to 120 seconds. In this way, images can demonstrate the dynamic flow of contrast into an artery, followed by venous filling. The multiple frames of the resulting time-lapse movie can be viewed to choose the time with optimal arterial filling and minimal venous contamination (Fig. 28.27).

Blood Pool Contrast Agents

Gd-DTPA– and Gd-BOPTA–based contrast agents are extracellular or interstitial contrast agents (i.e., they do not enter cells with intact membranes); however, they rapidly equilibrate in the extracellular space after intravascular injection, with predominantly renal clearance, although some hepatic clearance also occurs. This property results in a narrow time window for MRA before the decreased concentration of contrast in the vessels and the increased background tissue signal make further imaging of little value, thus limiting the spatial resolution that can be obtained.

Blood pool contrast agents (BPCAs) remain intravascular for extended periods, which allows longer high-resolution imaging, albeit at a static steady state in which both arteries and veins are filled with contrast. Two principal types of BPCA have been developed—compounds of gadolinium bound to macromolecules and ultrasmall superparamagnetic iron oxide (USPIO) particles[123,124]—both of which may allow up to 1 hour of imaging time. Gadofosveset (Ablavar in the United States, Vasovist outside the United States), previously known as MS-325, is the only BPCA currently approved for clinical use. Gadofosveset binds noncovalently to albumin in plasma and results in an increased degree of enhancement for the same concentration when compared with Gd-DTPA compounds, so a lower dose may be used in imaging (0.03 mmol/kg gadofosveset

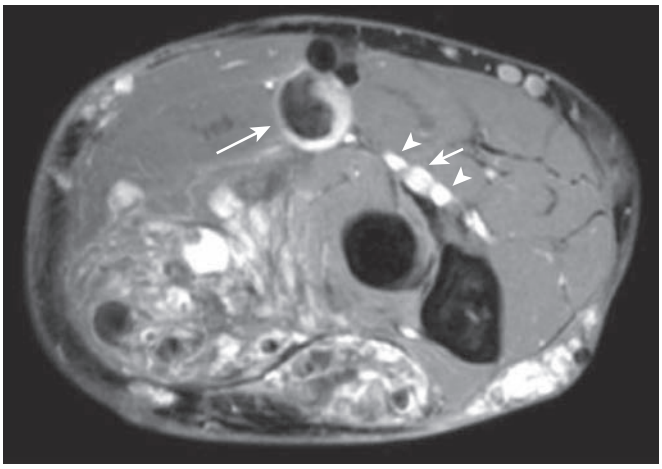

Figure 28.28 High-resolution axial T1-weighted image obtained more than 5 minutes after the administration of a blood pool contrast agent demonstrates contrast filling both arteries and veins, and outlining thrombus in an enlarged draining vein *(arrow)* in a patient with a large forearm vascular malformation.

vs. 0.1 mmol/kg Gd-DTPA).[124] One advantage of gadofosveset over some other BPCAs is the ability to obtain a dynamic arterial-phase acquisition in addition to steady-state imaging.

BPCAs have been evaluated for imaging of many vascular territories.[125,126] In most applications, steady-state imaging is performed at isotropic high spatial resolution, from 1 mm to 0.5 mm or less—such high resolution is necessary to be able to distinguish adjacent arteries and veins, both of which are filled with contrast. Imaging of abdominal and thoracic vessels (e.g., the renal arteries) is currently limited by breath-hold length and may not benefit as much from a BPCA, although the non–breath-hold respiratory or navigator-gated techniques currently used for non–contrast-enhanced MRA could be applied in these situations.[127] Fig. 28.28 shows a high resolution axial image T1-weighted image obtained through the forearm in a patient with a large vascular malformation more than 5 minutes after administration of a BPCA; contrast remains in both arterial and venous structures. Unfortunately, it was announced in early 2016 that Ablavar would no longer be available for purchase in the United Staes because of manufacturing difficulties.

Iron-based superparamagnetic nanoparticle MR contrast agents, SPIONS are used in scanning patients who have infection or inflammation. These agents are safe to be used in patients who have chronic renal failure where gadolinium-based contrast are contraindicated. SPIONS when injected are phagocytosed by macrophages and show prolonged T2 and T2* effects on contrast-enhanced MR images in macrophage-infiltrated tissues.[123] These agents are beginning to be studied for use in MRA, showing promising initial results.

Imaging of Blood Flow

All of the above discussion has concentrated on anatomic imaging of blood vessels, using native or exogenous contrast to allow visualization of the vessel lumen. In these techniques, signal within a vessel is relatively independent of flow, although vessels with poor flow may not fill with exogenous contrast or provide enough signal for noncontrast methods. However, MRI can also be used to visualize and measure flow velocities in a vessel using phase-contrast techniques, in which signal intensity is actually proportional to flow velocity. In cardiac MRI, 2D methods have long been used to measure valvular flow and regurgitation and to calculate shunt fraction, using ECG gating to acquire velocity maps through the cross-section of a vessel such as the aortic root. The instantaneous flow at each phase of the cardiac cycle is determined by multiplying the average velocity by the area of the cross-section, which is then integrated over the cardiac cycle to provide total flow.[128] The same 2D methods were used in the precontrast enhanced MRA era as an alternative to TOF imaging, allowing both anatomic and physiologic characterization of the significance of a stenosis.[129] Generalizing these methods to 3D velocity measurement over time has become possible, with acquisition times dramatically decreased by application of acceleration methods such as parallel imaging and compressed sensing.

After the complete 4D dataset has been acquired, it can be visualized in a variety of different ways. One popular method creates time-resolved 3D particle traces or pathlines, following the fate of a massless particle released from a specific point over the cardiac cycle (Fig. 28.29). This method has been applied to many different vessels; however, the ascending aorta has received the most study, allowing visualization and characterization of altered flow dynamics in patients with aneurysms, bicuspid valve, coarctation, and disorders such as Marfan syndrome.[130] Although 4D flow has proven useful for generation of hypotheses concerning a variety of pathophysiologies, whether it will demonstrate value in clinical routine remains to be seen.[131]

Plaque Imaging

A primary aim of MRA throughout the body is to image arterial stenosis caused by atherosclerotic disease; for this application, the principal advantages of MRI over catheter angiography are its noninvasive character and lack of ionizing radiation. However, stenosis imaging by itself fails to use one of the most powerful capabilities of MRI, soft tissue contrast imaging, which potentially allows visualization of the cause of the arterial stenosis (i.e., atherosclerotic plaque).[132] Several methods are available for imaging plaque, including non–contrast-enhanced techniques, the use of Gd-DTPA and other typical contrast agents, and imaging with contrast agents that concentrate specifically in atherosclerotic plaque.

The carotid bifurcation has been the subject of many investigations of plaque imaging techniques given its superficial location, lack of pulsatile motion, high prevalence of atherosclerotic disease, and clinical importance. So-called multispectral imaging, which combines information from sequences with T1, T2, and proton density weighting, has been shown to allow reliable discrimination of the various components of carotid atherosclerotic plaque, including the lipid core and fibrous cap, and distinction between necrotic, calcified, and hemorrhagic plaque.[133,134] Similar techniques have begun to be applied to

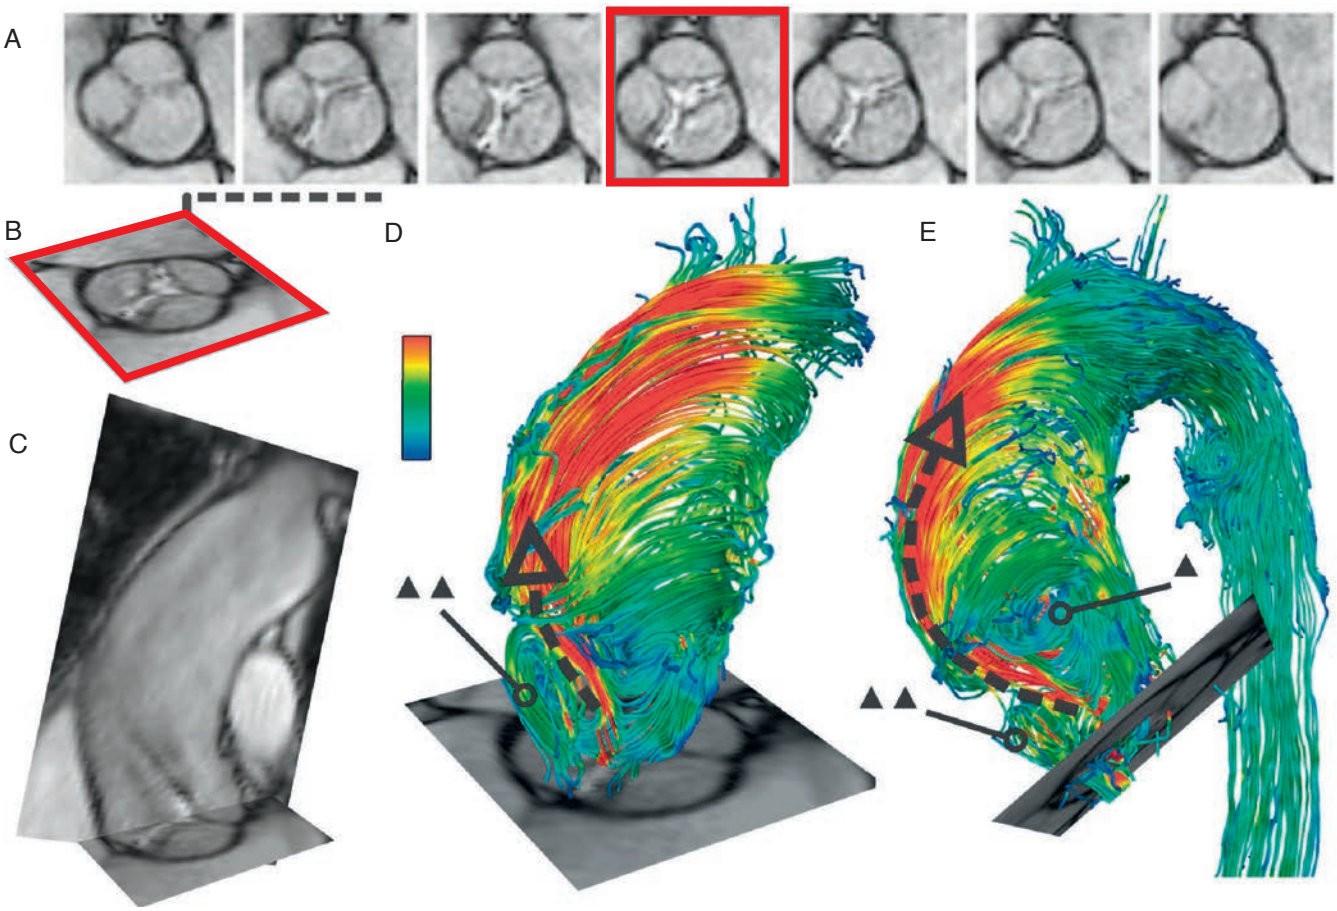

Figure 28.29 Several representations of data obtained during a single four-dimensional phase-contrast flow acquisition in a patient with a bicuspid aortic valve and dilated ascending aorta. (A and B) Two-dimensional cine images through the aortic valve demonstrate fusion of the left and right cusps and small opening area during systole. (C) Hybrid short-axis and oblique multiplanar reformatting long-axis anatomic view of dilated ascending aorta with high velocity flow jet visible. (D and E) Pathline reconstructions demonstrate high-velocity flow along the anterior border of the ascending aorta *(large arrow)* and abnormal flow vortices at the aortic root *(arrowheads)*. (Courtesy Alex J. Barker, PhD, Northwestern University.)

other vessels, including the aorta[135] and coronary arteries,[136] but imaging of atherosclerotic plaque in these vessels is limited by small diameter or pulsatile motion, or both.

Contrast-enhanced imaging has been used to quantify the degree of neovascularity of atherosclerotic plaque, which may be related to vulnerability to or likelihood of rupture.[137,138] In addition to their properties as BPCAs, injected USPIO particles are eventually taken up by macrophages and thus allow visualization of macrophage-laden plaque, which may be more vulnerable to rupture.[139] One preliminary study has demonstrated increased uptake of gadofosveset, the BPCA described earlier, in inflamed arterial walls adjacent to atherosclerotic plaque.[140] Currently under development are MR molecular imaging agents that specifically bind to components of atherosclerotic plaque or vessel walls, such as integrins.[141]

Recent studies have also shown that noninvasive MR angiography allows assessment of presence or absence of greater than 50% coronary artery stenosis with diagnostic accuracy comparable to that of multidetector computer tomography.[142]

Computed Tomographic Angiography Versus Magnetic Resonance Angiography

The development of multidetector CT technology over the past several years has led to a dramatic improvement in the quality and reproducibility of CTA examinations. The latest generation of 64-, 128-, 256-, and 320-slice scanners permit the rapid acquisition of high-resolution data over a large volume, which allows arterial-phase acquisitions at isotropic submillimeter resolution. Although the utility of CTA versus MRA for specific vascular applications will be discussed in later chapters, general advantages and disadvantages of each technique are mentioned here.

Acquisition Speed

Despite advances in MRI such as 3-T systems and parallel imaging technology (see earlier), a major advantage of CTA is speed of acquisition. Newer machines allow scanning of the entire aorta in under 2 seconds, scanning of the chest for

evaluation of pulmonary embolism in 1 second, imaging of peripheral runoff from the diaphragm to the toes in less than 10 seconds, and imaging of the coronary arteries in 150 ms. More important than the specific speed of acquisition is the fact that spatial resolution is independent of acquisition time and limited only by detector thickness, focal spot size, and the transit time of contrast down a vessel. Outrunning the contrast bolus is a potential complication in CTA,[143] especially in patients with poor cardiac output, large aneurysms with stagnant flow, or proximal occlusive disease. Unlike MRA, there is a cost associated with a repeat scan to allow filling of unopacified vessels, namely, increased radiation dose, although a second scan through the calves will not add much to the overall examination dose given their comparative insensitivity to radiation.[144]

Dynamic Imaging

Lack of dependence of spatial resolution on acquisition speed in CT can also be a disadvantage in that it is not possible to trade off these parameters for applications such as time-resolved imaging. As noted earlier, MRA can be performed in a dynamic fashion to provide physiologic information about direction and speed of blood flow, albeit at lower resolution, whereas CTA generally allows only static full-resolution snapshots at one or two time points during the contrast bolus. New wide detector CT systems can image up to 16 cm at each gantry rotation (< 0.3 seconds), thereby potentially allowing full-resolution dynamic imaging as well. Although this technique has shown some initial promise in neurovascular imaging, where it can also capture brain perfusion, it is not yet clear that the information gained will be worth the substantial penalty in radiation dose engendered by repeated scans.

Calcification and Other Imaging Artifacts

MR is limited in its ability to image vascular calcification because it tends to have very low signal on all pulse sequences used for MRA. Although this disadvantage limits the utility of MRI for detection of vascular calcification, it also means that MRA is in general not subject to the artifacts from vascular calcification seen with CTA. Therefore MRA may be more appropriate for patients with known or a high likelihood of heavily calcified vessels,[145] particularly for distal runoff imaging in diabetics. However, because these patients are also more likely to have renal disease, all options should be carefully considered, including non–contrast-enhanced MRA. Dual energy CT, also known as spectral CT, is a novel technique in which CT data are acquired at two different x-ray energies, exploiting the fact that the difference in x-ray attenuation at the two different energies is characteristic of an element, with chemical binding exerting only a small effect. By examining the difference in attenuation for each pixel at the two different energies, one can determine the material in that pixel. Using this method, pixels containing calcium can be separated from those containing iodine, even if their attenuation (in Hounsfield units) is very similar, allowing more accurate subtraction of calcium in bones and vessels from CT angiographic studies.[146] However, although these methods may allow improved removal of vascular calcification, they do not decrease the artifacts associated with the calcification, and therefore the degree of stenosis may still be overestimated in a vessel adjacent to a large calcified lesion.

As discussed earlier, MRA may be suboptimal in the presence of vascular stents, filters, or coils, depending on their composition. CTA also is subject to artifacts in these circumstances, although to a lesser degree.[147-150] Fig. 28.30 demonstrates the ability of CT to visualize the stent lumen, as well as the presence of stent artifact on MRA. Specific exceptions include coils containing platinum and stents or other metallic implants made of titanium or gold, all of which can cause severe streak artifacts on CTA.[151,152] Orthopedic hardware can cause artifacts in both modalities, but MRA may provide a better option, depending on the specific device and anatomy being imaged. As noted,

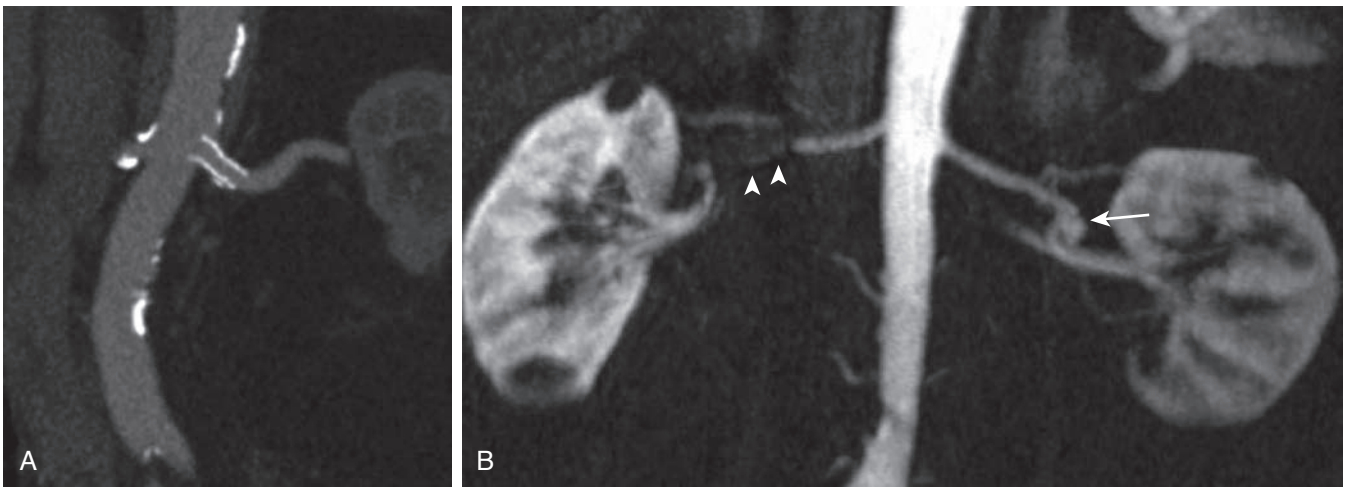

Figure 28.30 (A) Coronal multiplanar reconstruction (MPR) from a computed tomographic angiography examination demonstrating a patent stent in the left renal artery. (B) Coronal maximum intensity projection from three-dimensional magnetic resonance angiography in a patient with history of previous stent placement for right renal artery aneurysm. Note artifact from the stent obscuring the midportion of the renal artery *(arrowheads)*; we can infer stent patency from enhancement of right kidney. A left renal artery aneurysm is also present *(arrow)*.

CTA is almost always preferred in patients with implanted pacemakers or defibrillators.

Radiation Dose and Contrast Concerns

With increasing use of CT, and of CTA in particular, has come increased concern for the effects of exposure to ionizing radiation. Several high-profile journals and the mainstream media have published reports evaluating the cancer risk engendered by exposure to radiation from CT.[153,154] Although one can disagree with the assumptions behind many of the calculations of cancer risk in these reports, it is clear that repeated CT studies do come with some risk. Therefore consideration should be given to the use of MRA in radiation-sensitive populations (children, young women, etc.) and in those who will undergo repeated surveillance studies over many years.

As discussed previously, gadolinium contrast agents are not without risk, particularly in patients with renal dysfunction. However, the incidence of contrast-induced nephropathy (CIN) is still greater with iodinated contrast (at the doses of each used for clinical imaging), and there is a higher rate of reactions and complications after iodinated contrast agents.[16,18,19] As stated earlier, contrast-enhanced MRA should not generally be performed in dialysis-dependent patients without a compelling clinical need.

Dual energy CT may provide an opportunity for both radiation and contrast dose reduction in CT angiography. As mentioned previously, this technique can be used to determine the material content of an object (e.g., the amount of iodine in a specific pixel). The amount of iodine can then be subtracted, leaving what is called a "virtual noncontrast" or water image. This has two potential benefits: (1) obviating the need for an actual precontrast acquisition (e.g., saving radiation dose in stent-graft follow-up exams)[155] and (2) improving the contrast-to-noise ratio (CNR) of contrast enhanced exams, allowing the reductions in iodinated contrast dosage.[156]

Ease of Use and Convenience

CTA examinations are generally performed much more quickly than MRA, in less than 5 minutes of table time versus 30 minutes or more. This is a result of increased positioning and setup time before data acquisition, increased duration of each acquisition performed during the study, and the increased number of acquisitions per study for MRA versus CTA. The increased number of acquisitions is related both to the ability to acquire multiple phases during the contrast bolus without a radiation penalty and to the multiple pulse sequences acquired to obtain the different soft tissue contrast (T1 versus T2) that are available with MRI. Our typical CTA protocol requires four breath-holds (topogram, precontrast, arterial phase, and delayed phase), whereas a typical MRA protocol would entail approximately 10 (localizers [2], axial T1 in- and out-of-phase imaging [2], axial T2 in- and out-of-phase imaging [2], precontrast imaging [1], arterial- and delayed-phase MRA [2], and postcontrast T1-weighted imaging [1]), which can be completed in less than 15 minutes in most patients. However, CT would still be the recommended initial study for acutely symptomatic vascular disease, such as acute aortic syndromes.

Until recently, CTA gantries were larger and more "open" than MR systems; however, the availability of short-bore MRI machines and 64-slice and greater CT has virtually erased that gap, with 70-cm openings and 450-lb or higher table capacity being standard on most CT and MR systems. The presence of the magnetic field does continue to limit the types of monitoring equipment and patient attachments that can be brought into the scan room, as well as ease of access for staff to respond to medical emergencies in the magnet room. Although MR systems tend to be more expensive and less available than CT systems, these differences have also narrowed recently.

MR angiograms tend to be easier to interpret and postprocess than CT angiograms because of the background suppression techniques used in MRA pulse sequences. This allows rapid 3D visualization without the need for the bone removal techniques used in CTA. In addition, there are usually many fewer images in 3D Gd-MRA than in corresponding CTA of the same volume because the MR angiogram can be acquired in the plane that is most advantageous for the specific anatomy, such as oblique sagittal for the aorta, whereas all CT images are acquired axially and then reformatted to the desired orientation.

Both CTA and MRA can provide excellent-quality imaging in almost all clinical circumstances. In the end, the decision concerning whether to perform CTA or MRA may often be most influenced by the local availability of the technology and expertise in performing and interpreting these studies, as well as the experience and comfort of the referring vascular surgeon with the two modalities and the interpreting radiologists.

FUTURE ADVANCES 367

Traditional imaging modalities for the assessment of blood vessels have focused on size, irregularity of the vascular lumen, and anatomic changes in adjacent structures. The ability of these morphologic imaging techniques to identify physiologic changes such as active inflammatory processes and plaques at risk for rupture is, however, limited. Molecular imaging has the advantage of enabling noninvasive physiologic assessment of these processes with radionuclides, very often early in the course of disease. Such early assessment can lead to subsequent changes in clinical management, potentially affecting patients' outcomes. The limitations of traditional nuclear medicine techniques, mainly low spatial resolution and lack of anatomic details, have been overcome in the last decade with the introduction of the hybrid single-photon emission computed tomography/computed tomography (SPECT/CT) and positron emission tomography (PET)/CT imaging devices. A large body of evidence has accumulated on the use of molecular probes for the assessment of vascular inflammation and infection (especially in vascular graft infections and vasculitis), early diagnosis, precise determination of the extent of disease, and assessment of response to therapy.

BASIC PRINCIPLES

Single-Photon Emission Computed Tomography, Positron Emission Tomography, and Hybrid Imaging

In nuclear medicine imaging, radiopharmaceuticals are administered to the patient intravenously. Images are obtained from radiation, which is emitted at the location of disease processes in the patient's body. Two main camera systems, the gamma camera and the PET camera, convert this radiation into images.

The gamma camera forms the basis of conventional nuclear medicine and provides two-dimensional imaging of the body.

Abstract

This chapter provides an overview of the basic principles of nuclear medicine, the most commonly used tracers, and the clinical applications of these tracers in atherosclerosis, aortic pathology, vasculitis and vascular graft infections.

Keywords

Nuclear Medicine
PET/CT
SPECT/CT
atherosclerosis
vasculitis
vascular graft infection

Image contrast of this planar imaging is rather low due to the presence of overlying structures that interfere with the region of interest. This limitation can be overcome by collecting images from different angles around the patient, the so-called SPECT, which leads to better spatial resolution, higher contrast, and improved sensitivity.

PET is an imaging tool based on radionuclides that emit positrons to become stable. For example, decay of the radioisotope fluorine-18 (18F) leads to emission of a positron that collides with an electron after traveling a short distance in tissue, thereby generating a pair of 511-keV annihilating photons (in opposite directions) that can be detected by the PET imaging device. The major advantage of PET over SPECT is that the PET camera system is more effective in detecting photons and provides better spatial resolution (around 3-4 mm). Furthermore, quantification is easier with PET. Uptake of PET radiopharmaceuticals can be quantified by standardized uptake values (SUVs), which measure the tracer uptake within a region of interest in relation to the injected dose and patient's body weight.[1]

However, both modalities provide only very limited morphologic information. Therefore PET as well as SPECT are now combined with CT in a single imaging modality. Hybrid SPECT/CT, PET/CT, and now also emerging PET/magnetic resonance imaging (MRI) improve the sensitivity by anatomic detection of small structures, such as plaques, and may also improve the specificity, confirming active disease in these small lesions.[2] Other advantages of combining radiologic and nuclear medicine techniques in one imaging modality are reduced costs, perfect correlation of pathophysiologic with anatomic information, and the one-stop-shop principle, which is convenient for the patient and reduces waiting time.

Most Commonly Used Tracers for Vascular Diseases

^{18}F-Fluorodeoxyglucose

Fluorodeoxyglucose (FDG) is an analogue of glucose, taken up by and accumulating in cells in proportion to their metabolic activity. The transfer of glucose into cells is facilitated by glucose transporters (GLUTs) and sodium glucose cotransporters (SGLTs). After entering the cell, glucose undergoes phosphorylation by hexokinase, forming glucose-6-phosphate. After its glycolysis by hexose-6-phosphate isomerase, fructose-6 phosphate is formed. In contrast, the analogue 2-deoxy-D-glucose cannot undergo conversion by hexose-6-phosphate isomerase; therefore, FDG becomes trapped in the cytosol. Glucose and FDG have otherwise similar properties, and the rates of phosphorylation in vivo are proportional to each other, reflecting the general rates of glucose metabolism.[3]

FDG imaging is today the "gold standard" in the assessment of patients with cancer, for staging tumors, monitoring response to treatment, and diagnosing recurrence. FDG can also be used in infectious and inflammation diseases, since many cells involved in infection and inflammation (activated leukocytes, monocytes, lymphocytes, macrophages, and giant cells) use glucose for their metabolism. This tracer is extensively used in vascular imaging.

^{18}F-Sodium Fluoride

Sodium fluoride (NaF) is mainly used for skeletal imaging, since it has the desirable characteristics of high and rapid bone uptake accompanied by a very rapid blood clearance, which results in a high bone-to-background ratio.[4] Its use in vascular imaging is, however, at this time limited to plaque imaging. Since NaF is not physiologically taken up in the myocardium and blood vessels, it could also potentially be a better agent than FDG in assessing the coronary vessels.

Labeled White Blood Cells

Scintigraphy using autologous white blood cells—also called leukocyte scintigraphy—is still considered the gold standard nuclear imaging modality for infections. In using the correct acquisition protocols and interpretation criteria, this technique is highly accurate. Limitations, however, are the needs for a laborious labeling procedure and for imaging at several time points. White blood cell scintigraphy is primarily used in musculoskeletal infections but has also been extensively evaluated in vascular diseases, such as vascular graft infections.

Other Available Tracers

Besides the already mentioned commonly used tracers, various other radiopharmaceuticals have been developed and tested, most of them in atherosclerosis. SPECT and PET imaging of atherosclerosis takes advantage of the wide array of biologic mechanisms involved in the different stages of atherosclerosis and plaque formation. Tracers have been developed for targeting the atherosclerotic lesion components, such as technetium-99m (^{99m}Tc)–labeled low-density lipoprotein (LDL), ^{99m}Tc-labeled oxidized LDL, and labeled antibodies against plaques and degradation products. Since an unstable plaque with rupture or erosion of the fibrous cap demonstrates activation of platelets and of the clotting cascade, other studies have focused on labeled platelets and fibrins. Apoptosis has also been demonstrated in macrophages as well as in smooth muscle cells of atherosclerotic plaques and is often observed in the fibrous cap of a ruptured plaque. Therefore ^{99m}Tc-labeled annexin V has also been used for specifically targeting the atherosclerotic plaque. Also matrix metalloproteinases (MMPs), excreted by macrophages and activated by plasmin as part of the inflammatory process in active atherosclerotic lesions, were labeled and tested. Many of the molecular probes developed for plaque imaging are linked with inflammation, a major component of vulnerable plaques. Labeled macrophages, monocytes, and lymphocytes were all used for imaging the inflammatory process. An overview of all the possible radiopharmaceuticals for imaging atherosclerosis can be found in a recent review.[5]

Challenges

There are a number of challenges in the molecular imaging of vascular plaques. Their small size (most are less than 5 mm in diameter) is close to the resolution limit of SPECT and

PET. Also, some arteries are located deep within the body, and in some regions, such as the coronary arteries, imaging is of lower quality because of artifacts related to cardiac and respiratory motion.[6] Most of the radiopharmaceuticals labeled with single-photon emitters have unfavorable imaging properties, including slow blood clearance and a low ratio of target (atherosclerotic plaque) to background (blood pool); they may also demonstrate affinity with nonspecific binding sites. Despite the large variety of probes labeled with single-photon emitters, none is being widely used in the clinical setting to identify vulnerable plaques. More research is needed to identify a suitable probe that will also yield a robust clinical imaging tool.

CLINICAL APPLICATIONS

Molecular Imaging of Atherosclerosis

Fluorodeoxyglucose Uptake in Carotid Plaque

In patients undergoing FDG PET/CT scans for cancer imaging, increased FDG uptake was reported in the vascular walls of 31% to 59% of patients older than 50 years,[7-9] the uptake being more evident with advancing age, male sex, and the presence of cardiovascular risk factors such as hypertension and hypercholesterolemia.[7,8,10,11] Rudd et al.[12] were the first to show, in a prospective study in eight patients imaged shortly after a transient ischemic attack (TIA), that FDG uptake was 27% higher in the symptomatic carotid artery than in the asymptomatic contralateral artery. Autoradiography confirmed the location of uptake in macrophages.[12] Coregistration of FDG PET and MRI indicated the presence of increased tracer uptake in arterial plaques in 10 of 12 patients with an embolic event, consistent with clinical symptoms. In addition, 25% of lesions determined to be nonstenotic by magnetic resonance angiography (MRA) in symptomatic patients had increased FDG activity in significantly inflamed plaques.[13] Plaques with unstable features, such as a large lipid core and intraplaque hemorrhage on MRI or echolucency on ultrasound, show higher FDG uptake than more stable lesions.[14-17] Lipid-rich necrotic plaques show higher FDG uptake than collagenous or calcified plaques.[14] In patients with severe carotid stenosis imaged prior to endarterectomy, an excellent correlation of FDG activity was reported with macrophage staining but not with plaque thickness, plaque area, or smooth muscle staining. This confirms that FDG can be used to assess the severity of inflammation in patients with carotid plaques.[18,19] Significantly increased carotid FDG activity had been demonstrated in patients with stroke.[20,21] FDG uptake in carotid vessels correlates with serum levels of C-reactive protein, a marker of systemic inflammation.[22,23] This observation is consistent with the definition of the "vulnerable patient" rather than "vulnerable plaque": the finding of one vulnerable lesion may increase the likelihood of other vulnerable lesions.[24] FDG activity in vessels was greater in patients with more than one cardiovascular risk factor and known coronary artery disease.[23] In addition, patients with type 2 diabetes mellitus and/or metabolic syndrome also demonstrated increased carotid FDG uptake.[25,26]

Monitoring Treatment With Fluorodeoxyglucose Uptake

Sequential PET/CT studies can be used to monitor the effect of lipid-lowering treatment on FDG uptake in atherosclerotic plaques. Reduced plaque inflammation after treatment with probucol, a lipid-lowering antioxidant, has been shown in an experimental rabbit model.[27] In human studies, high-resolution MRI has demonstrated that more than 12 months of simvastatin treatment were required to show regression of atherosclerotic plaques.[28-30] In a group of 43 patients with cancer who had increased FDG activity in the thoracic aorta or carotid arteries, half of the subjects who were subsequently randomly assigned to treatment with simvastatin showed reduced FDG uptake in the arterial wall as well as a decrease in LDL cholesterol by 30% and an increase in high-density lipoprotein (HDL) cholesterol by 15%. The second half of the study group received dietary management and did not show any change in FDG uptake.[30] On the other hand, dietary and lifestyle modifications in asymptomatic subjects caused a 65% reduction in the number of FDG-positive vascular regions.[31]

Fluorodeoxyglucose-Avid Arterial Wall Calcifications

Colocalization of FDG on PET and arterial calcifications on CT has been previously studied using PET/CT, with FDG-avid arterial wall calcifications observed in 2% to 14% of lesions.[7-9] Findings in the vascular wall of patients more than 50 years of age showed three different patterns: PET-negative and CT-positive, PET- and CT-positive, and PET-positive and CT-negative. Although there were many CT-positive atherosclerotic lesions (in 82%-92% of patients), FDG uptake indicating active inflammation was variable (15%-74%). Lesions with evidence of both past (CT-positive) and current (PET-positive) inflammation were seen in 10% of patients.[8,32] Other researchers have described none or a negative correlation between areas of calcification and FDG uptake.[33] The incongruence between FDG PET and CT findings may represent variations in the stage of the atherosclerotic process. The presence and extent of calcifications on CT define morphologic changes likely consistent with advanced disease, whereas FDG avidity demonstrates transient plaque inflammation, possibly indicating future complications.

Change in Plaque Fluorodeoxyglucose Uptake Over Time

Changes in vascular wall uptake over time in 50 patients with cancer and a mean age of 68 years who had repeat PET/CT scans 8 to 26 months apart were also reported. Changes in the pattern of vascular findings were observed in 48% of FDG-positive sites, compared with 4% of PET-negative foci and 7% of CT-positive lesions (Fig. 29.1).[32] Transient FDG uptake in the arterial wall was found in a group of 205 studies from 50 patients with a mean age of 49 years who underwent at least four PET/CT scans for a mean follow-up of 27 months.[33] The variable FDG uptake in the vascular wall suggests that inflammation may be a transient feature of a dynamic process, whereas calcifications may represent a chronic process or stable atherosclerosis.[32] This

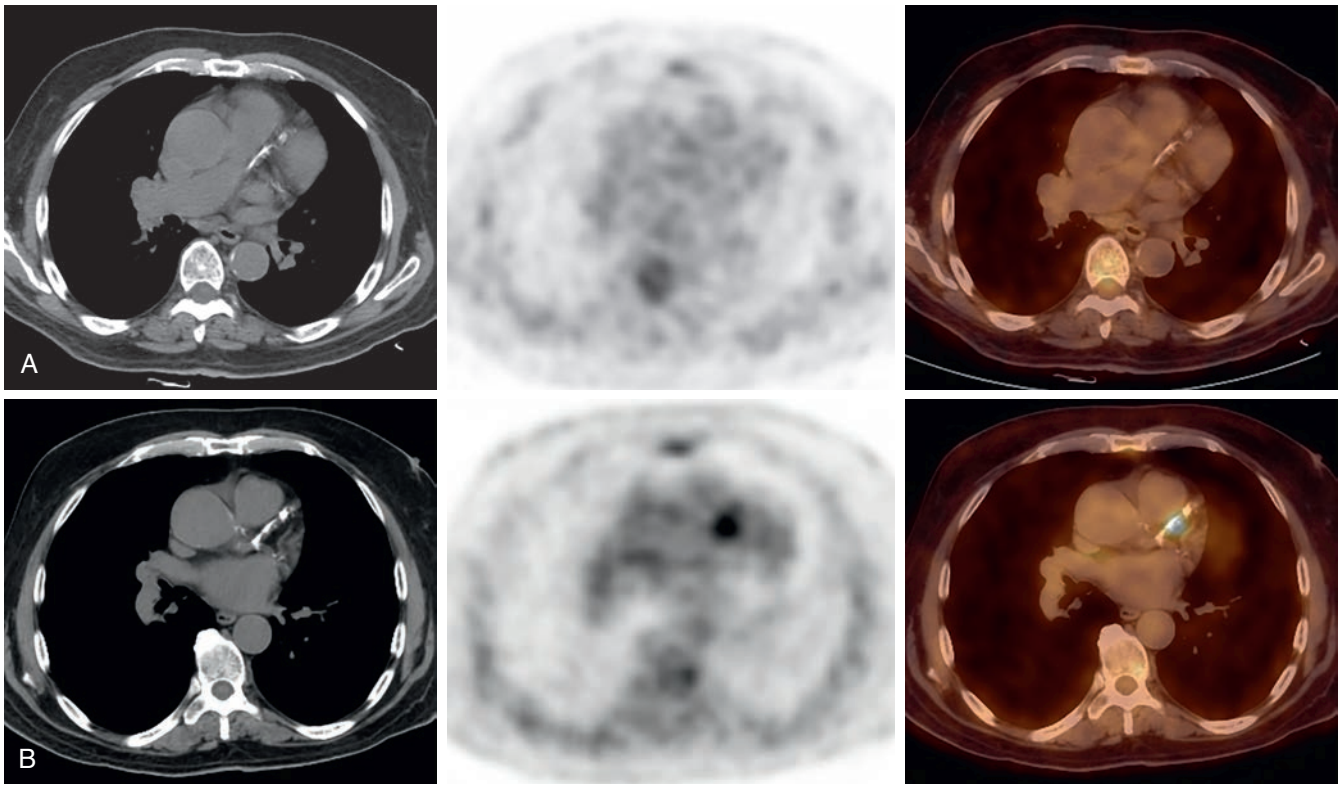

Figure 29.1 Changing pattern of vascular wall fluorodeoxyglucose (FDG) uptake in 70-year-old patient referred for routine follow-up after completion of chemotherapy for diffuse large B-cell lymphoma. Whole-body FDG positron emission tomography/computed tomography (PET/CT) images showed no evidence of FDG-avid disease. (A) Selected axial slice shows left anterior descending (LAD) coronary artery calcifications on CT *(left)* with no focal increased FDG activity on PET *(center)* or on the fused PET/CT image *(right)*. (B) On follow-up scanning 8 months after the previous study, CT shows that LAD calcifications have progressed *(left),* and there is also focal FDG activity in the LAD calcifications on the PET *(center)* scan and localized activity on the fused PET/CT scan *(right)*.

observation may have potential future implications for the design of trials for monitoring the response of vascular inflammation to therapeutic interventions.

Other Tracers for Plaque Imaging

The majority of data related to metabolic imaging of atherosclerosis refer to the use of FDG, mainly because of its wide availability and the vast clinical experience with its use accumulated over the last few decades. Because of the limitations of FDG, including the nonspecific nature of its uptake in various types of cells that metabolize glucose as well as the technically challenging imaging of the coronary vessels, other tracers are being sought and evaluated.

Active plaque calcification can contribute to plaque instability[34] and can be assessed with NaF, which can potentially better assess the coronary vessels than FDG owing to the lack of significant physiologic myocardial uptake and its high target-to-background ratio. It has been shown that NaF adsorbs to calcified deposits within plaque with high affinity and is selective and specific.[35] NaF PET/CT imaging can distinguish between areas of macro- and microcalcification. A group of 45 patients with cancer were assessed with FDG, NaF, and CT for the presence of inflammation, active calcium deposition, and calcifications, respectively. Of 105 lesions with NaF uptake, 77% showed calcification on CT and 14% showed increased FDG activity.[36] It has been hypothesized that in early atherosclerosis, only inflammatory changes and therefore only FDG uptake can be seen, whereas later during the course of this process, there is also active calcification, reflected by uptake of both FDG and NaF. At a late stage, when the density of calcium deposits exceeds a certain threshold, calcifications would also become visible on CT. When calcification and mineralization exceed the inflammatory process, uptake of NaF but not of FDG would be found in calcified lesions seen on CT. At the final stage of dense calcification with no significant calcium turnover, lesions would be seen only on CT.[24]

^{99m}Tc-labeled LDL has been shown to accumulate in experimental atherosclerotic plaques in rabbits.[37] In clinical studies, a fourfold greater uptake was found in carotid endarterectomy macrophage-rich specimens than in fibrotic specimens.[38] Owing to slow blood clearance, however, this tracer was not suitable for in vivo imaging. ^{99m}Tc-labeled oxidized LDL is taken up by macrophages and has a more rapid blood clearance. It was detected at 150% higher levels in 10 of 11 plaques than in normal arterial segments and therefore provides better image quality.[39] Indium-111 (^{111}In)- or ^{99m}Tc -labeled antibodies against plaque and its degradation products, fibrin and platelets, have also been used for the imaging of atherosclerosis in an experimental setting.[40] ^{111}In–labeled polyclonal human immunoglobulin (Ig) G contains an Fc unit that binds to macrophage receptors.

It showed a poor target-to-background ratio in rabbits, whereas in humans uptake was found in carotid atheromas in 86% of patients, with no correlation with ultrasound findings.[41]

In patients with known cardiovascular events, imaging with ^{111}In-labeled platelets correlated with plaque burden and ulcerations seen on ultrasound.[42,43] However, blood clearance of labeled platelets is slow, so imaging cannot be performed until 48 hours after the injection. In addition, discontinuation of antiplatelet medication is needed, which cannot be considered in patients with suspected vascular events. Fibrin fragment E1 labeled with ^{123}iodine and ^{99m}Tc can detect thrombi in animals with deep venous thrombosis.[44] This agent clears rapidly from the circulation and has good imaging qualities. At present there are no reports on the use of this tracer in the evaluation of atherosclerosis.

^{99m}Tc–labeled annexin V has been used for specific targeting of active atherosclerotic lesions. Uptake of ^{99m}Tc–annexin V has been reported in experimental models of aortic lesions[45] as well as in patients with carotid artery disease.[46] The role of this substance to assess apoptosis is limited by the lack of specificity. ^{99m}Tc–annexin V binds to phosphatidylserine on platelets within the thrombus, but because thrombosis occurs in vulnerable plaques, this feature represents only a relative limitation for imaging with ^{99m}Tc–annexin V.[47]

Lymphocytes constitute at least 20% of infiltrating cells in vulnerable plaques. Therefore the interleukin-2 (IL-2) receptor, being overexpressed on activated T lymphocytes, may represent an attractive biomarker for plaque vulnerability. Radiolabeled IL-2 was therefore tested for imaging the lymphocytic infiltration in carotid plaques. ^{99m}Tc-IL-2 was found specific for imaging activated T lymphocytes in the carotid plaque. A significant correlation was found between the number of CD25+ lymphocytes and the total number of CD25+ cells in the plaque and the tracer uptake in the plaque.[48]

Preliminary work using ^{11}C-PK11195, a selective ligand of a translocator protein with 20 times greater density expression on macrophages than on vascular smooth muscle cells, has been reported. This tracer binds to macrophage-rich regions in human carotid plaques,[49] and promising results have been reported in patients with vasculitis.[50]

Other potentially useful tracers include ^{68}Ga-DOTATATE, which binds to somatostatin receptors subtype 2 expressed by macrophages,[51] and ^{11}C– or ^{18}F–labeled choline, which is taken up by macrophages, undergoes phosphorylation and metabolism to phosphatidyl choline, and is incorporated into the cellular membrane.[52,53] In an experimental model, ^{18}F–labeled choline uptake correlated better than FDG uptake with fat staining and macrophage-positive areas.[53] In patients with cancer, ^{11}C–labeled choline was not taken up by the normal vascular wall or by calcified vascular wall lesions.[52]

Molecular Imaging of Aortic Pathology

Abdominal Aortic Aneurysm

Increased FDG activity has been reported in patients with asymptomatic abdominal aortic aneurysms (AAAs), probably owing to the presence of transmural inflammation and the accumulation of FDG in macrophage aggregates.[54,55] A possible association between increased FDG uptake and AAA expansion and rupture has been suggested.[56] Higher FDG uptake in AAA has been associated with higher wall stress[57] and correlated with instability and macrophage infiltration.[58] Aneurysmal dilatation develops after an inflammatory phase with increased FDG activity.[59] An inverse relationship between FDG uptake and future expansion of the aneurysm, as measured by Doppler ultrasound, was found in 25 patients with AAAs who underwent routine surveillance over a period of 12 months.[60] In patients with asymptomatic AAAs, no increase in FDG uptake was observed in large lesions referred to surgery.[61] A marked reduction in cell density in AAAs correlated with low FDG activity.[61] Increased FDG activity is more frequent in small aneurysms and in lesions with inflammatory changes, which are more often symptomatic and require direct surgical intervention (Fig. 29.2).[58]

Aortic Dissection

Thoracic aortic dissections are uncommon but are associated with high mortality rates, 10% to 30% within 30 days of diagnosis.[62,63] The disease is mediated by inflammatory changes.[64] In one study, FDG PET/CT was performed in 33 patients with acute aortic syndrome. Increased FDG activity (positive result) was seen in one-third of the patients, 82% of whom showed progression of disease; 55% of patients with negative PET results showed stable disease on follow-up.[65] In another study, FDG uptake in 28 patients with acute or chronic dissection was compared with that in a group of 14 age-matched controls for prediction of adverse outcomes. Patients were followed for up to 6 months after PET/CT. Within a subgroup of eight patients with unfavorable outcomes (death from cardiovascular causes, rupture or progression of aortic dissection, requirement for surgical repair, or cardiovascular events during or after initial hospitalization), FDG uptake was significantly higher in those with acute dissecting aneurysms than in controls. It was also higher at the site of maximum dissection in patients with unfavorable outcomes than in those with favorable outcomes. Multivariate analysis showed that the mean SUV of FDG uptake at the site of maximum dissection independently predicted an unfavorable outcome. The investigators concluded that FDG PET/CT may play a role in predicting the prognosis of patients with type B aortic dissection and may also be useful in selecting patients at high risk for near-term complications requiring early surgery.[66]

More clinical data from larger and longitudinal patient cohorts will establish the role of FDG PET/CT in guiding patient selection for surgery and for follow-up of patients with aortic pathology.

Molecular Imaging of Vasculitis

In vasculitis, molecular imaging techniques can assist in the early diagnosis of inflammatory changes in the vascular walls, which are potentially reversible. This inflammatory process precedes anatomic changes; therefore, at the early stage, anatomic imaging modalities are unreliable. MRI is probably the best method to

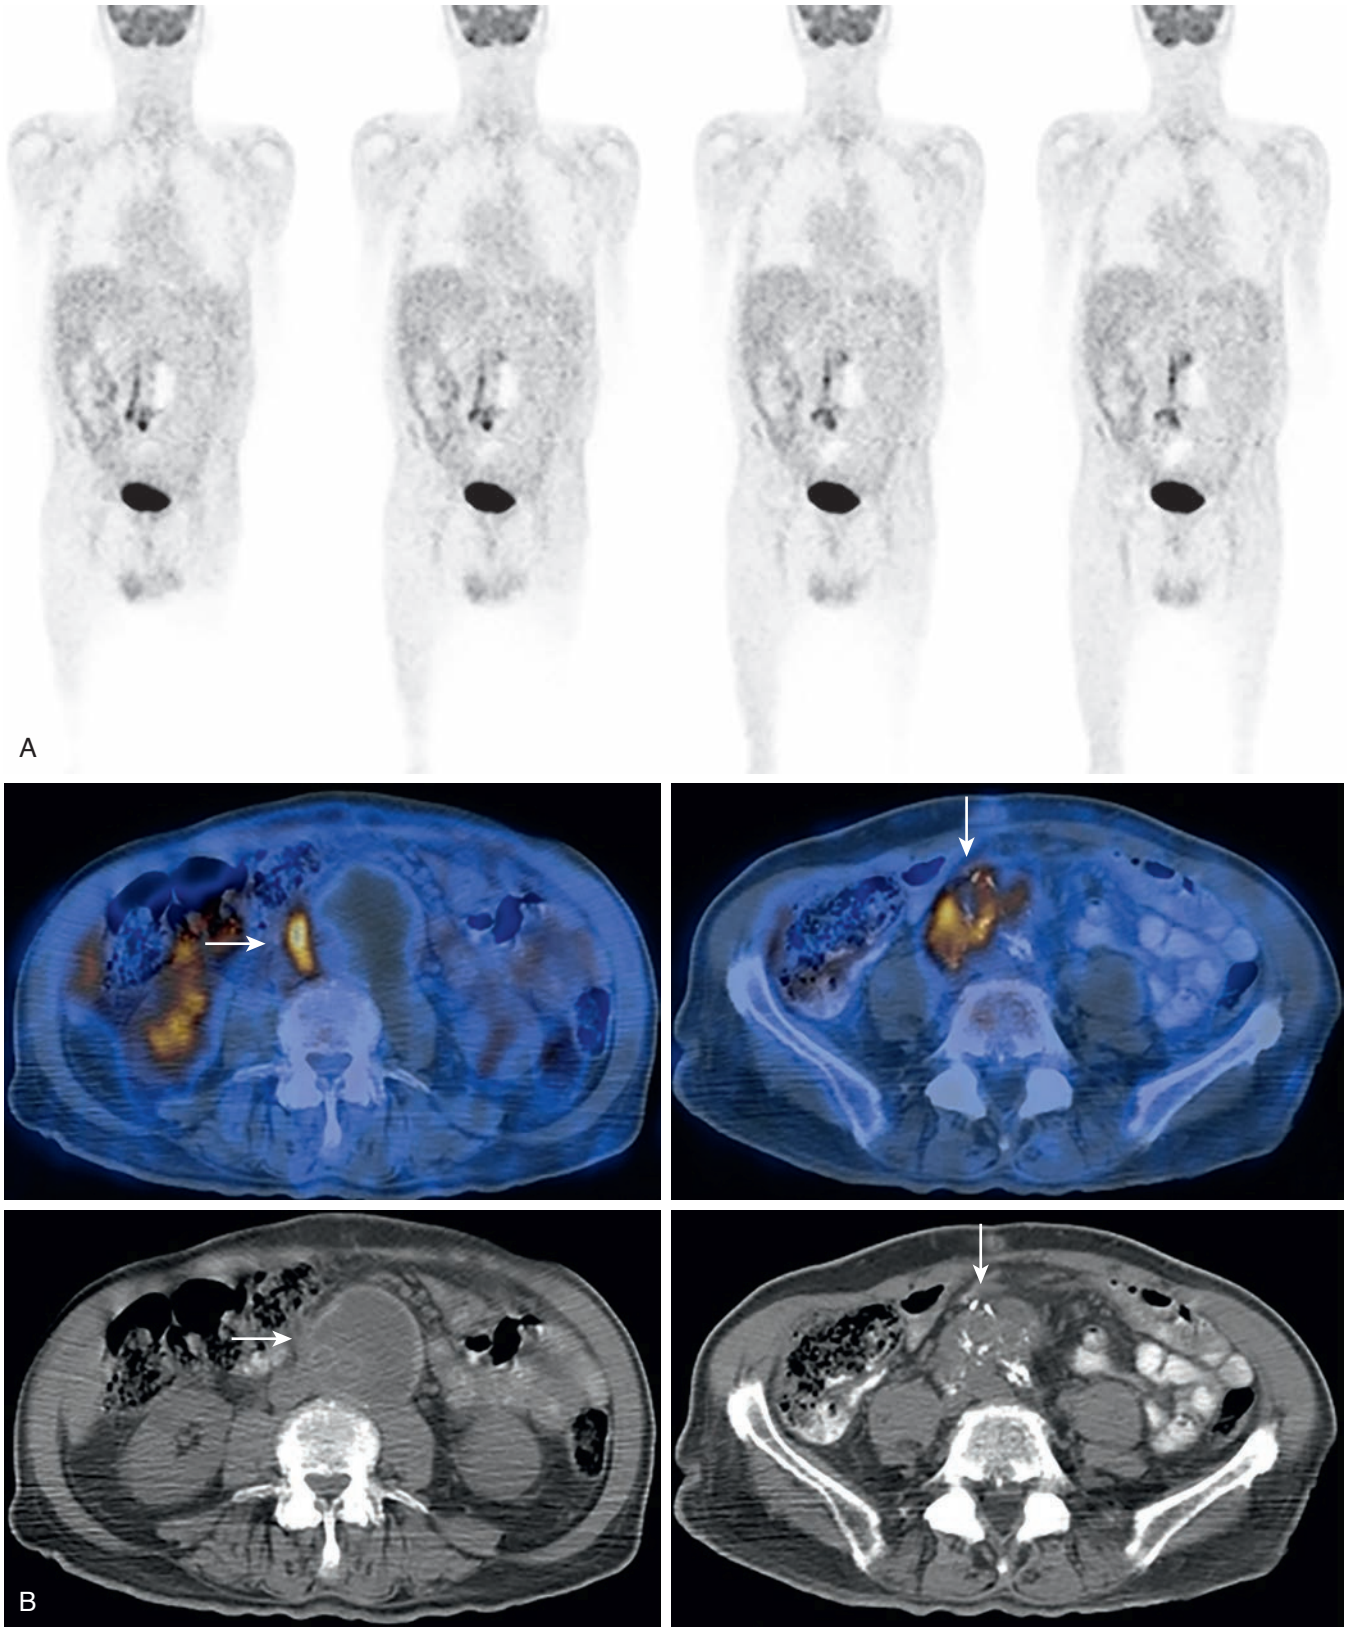

Figure 29.2 Fluorodeoxyglucose (FDG) uptake in an infected graft inserted in an abdominal aortic aneurysm (AAA). The patient, a 79-year-old diabetic man, had undergone surgical repair of a dissecting AAA and implantation of a bi-iliac vascular graft 10 years prior to the current examination. He presented with severe abdominal pain. Computed tomography (CT) angiography demonstrated a thickened posterior wall of the aneurysm. (A) Selected coronal positron emission tomography (PET) slices demonstrate a linear area of intense abnormal FDG uptake in the lower abdomen and upper pelvis. (B) The uptake is localized by PET/CT at its upper level to a thickened AAA wall (left column, *arrows*), consistent with active inflammation, and at the pelvic level to a soft tissue mass surrounding the right component of the graft and surgical clips (right column, *arrows*), consistent with an infected right vascular graft.

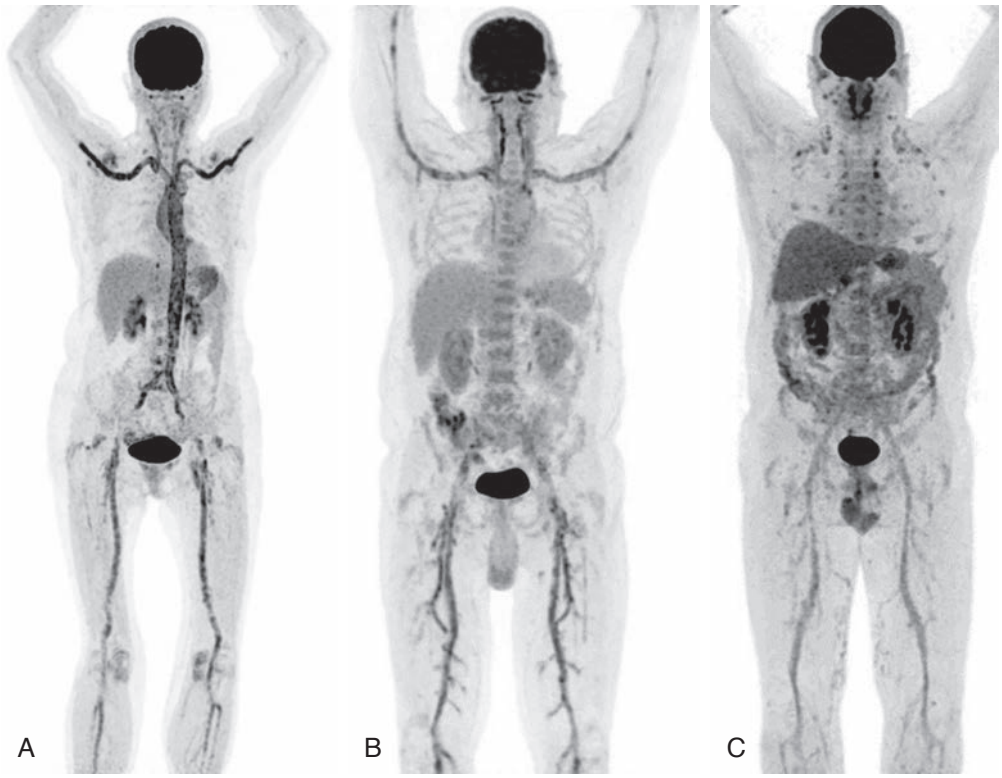

Figure 29.3 Fluorodeoxyglucose uptake patterns in different vasculitis types and associated diseases. (A) Giant cell arteritis with intense uptake in the aorta and all the large vessels. This scans also shows increased uptake in the shoulders, hips, and knees, pointing to polymyalgia rheumatica. (B) Uptake in both large (subclavian and femoral arteries) and medium-sized arteries in the legs, pointing to polyarteritis nodosa. (C) Another example of polyarteritis nodosa, but also notice the uptake in the costochondral and costovertebral joints and the ears, indicating polychondritis.

evaluate and reveal structural vascular abnormalities. However, in the early setting without anatomic changes, MRI cannot detect inflammation. FDG PET is able to identify vasculitis at an early stage, but because of the limited spatial resolution of the imaging device (4-5 mm), it is able to visualize only inflammation of the aorta and the large and medium-sized arteries. Based on which vessels are involved, FDG PET is able to diagnose giant cell arteritis (GCA) (involvement of the aorta and all large vessels), Takayasu arteritis (mainly involvement of the vessels in the thoracic region), and polyarteritis nodosa (involvement of the medium-sized arteries, which can be visible in the upper legs and arm (Fig. 29.3).[67] Moreover, FDG PET is able to diagnose associated diseases, such as polymyalgia rheumatica (PMRI) or polychondritis (see Fig. 29.3). For these reasons, FDG PET is accepted as a major imaging technique for the early detection of vasculitis.[68] In addition, FDG PET has been shown to be superior to anatomic imaging modalities and is being increasingly used to assess response to therapy in documented cases of vasculitis.[68,69]

FDG PET has become increasingly important for the diagnosis of large vessel vasculitis, particularly in cases with nonspecific presentation, such as fever of unknown origin, malaise, and weight loss. Vasculitis can be diagnosed early with FDG PET because the inflammatory process precedes morphologic changes.[68] Also, FDG PET detects more involved regions than MRI.[68,70] The overall reported sensitivity and specificity of FDG imaging in untreated patients with large vessel vasculitis and increased inflammatory markers are in the range of 77% to 92% and 89% to 100%, respectively.[69,71-74] In the largest prospective study involving 35 patients with biopsy-proven GCA, the sensitivity of FDG imaging was 83%.[75] Increased FDG activity at the level of the aortic arch and subclavian arteries has been reported in 56% and in the lower limbs in 64% of cases.[76-79] In TA, increased FDG activity was noted in the aorta and brachiocephalic, carotid, and subclavian arteries and less frequently in the pulmonary arteries.[80] False-negative results have been reported in patients with temporal arteritis, caused either by high physiologic FDG uptake in the brain or the adjacent skin or by the small diameter of the involved vessel.[73] One study compared FDG PET, contrast-enhanced CT, MRI, and angiography in 18 patients with biopsy-proven TA. FDG PET had a sensitivity of 92%, a positive predictive value of 85%, and specificity and negative predictive value of 100% and was superior to morphologic imaging both in early diagnosis of inflammatory changes and for monitoring treatment effectiveness.[73] In another study, the role of FDG PET/CT was assessed in 39 patients with TA and 40 controls; it correlated with disease activity as defined by clinical and biochemical markers. Maximum SUV (SUV_{max}) was significantly higher in patients with active disease than in those with inactive disease and controls. For an SUV_{max} cutoff of 2.1, active TA was detected with a sensitivity of 92.6%, specificity 91.7%, a

positive predictive value of 96.2%, and a negative predictive value of 84.6%. SUV_{max} was also significantly higher in patients in whom relapse occurred during treatment than in patients with stable disease during treatment.[80]

A correlation between the intensity of vascular FDG activity and inflammatory markers has been found in GCA.[81] In TA, SUV measurements were found to be useful only for serial follow-up studies, showing a decrease in patients whose disease responded to therapy.[82] FDG PET/CT was superior to MRI in monitoring GCA disease activity during immunosuppressive therapy. FDG imaging reliably detected the earliest improvement after treatment, in good correlation with inflammatory markers and clinical symptoms, whereas morphologic changes seen on MRI, such as wall thickening, resolved only later.[66] In a small number of patients with fever of unknown origin and negative workup results, FDG PET correctly diagnosed GCA, demonstrating findings that disappeared on follow-up studies after the administration of steroids (Fig. 29.4).[83] In patients who have previously received immunosuppressive therapy, FDG imaging is unreliable for assessment of inflammation.[74,81]

FDG PET/CT is a sensitive and specific imaging modality in the diagnosis of large vessel vasculitis. It can assist in visualizing early inflammatory changes in patients with active disease, earlier than morphologic imaging techniques, thus enabling prompt treatment and possibly preventing occlusive complications. It can also be used as an index of disease activity and response to immunosuppressive therapy, but it appears to be unreliable in diagnosing vasculitis in patients receiving steroids.

Molecular Imaging of Vascular Graft Infection

Molecular imaging modalities have a major role in the assessment of vascular graft infection; the basic principles already described for other vascular diseases apply also here.

Both labeled white blood cells (WBCs) and FDG PET have been used for the detection of infected vascular grafts, with FDG PET having several advantages over labeled WBC scintigraphy (higher target-to-background ratios, shorter study duration, no need for handling of the blood of potentially infected patients, and quantification possibilities).

Because of the relatively high incidence of nonspecific morphologic abnormalities in patients with infected vascular grafts, molecular imaging modalities have been used to assess the clinical and functional significance of anatomic findings with significant clinical consequences on optimized early diagnosis, defining the best therapeutic strategy. The major advantages of molecular imaging are related to its ability to define functional or metabolic alterations. However, it provides only scarce morphologic data. Therefore hybrid SPECT/CT and PET/CT are of particular value in patients with suspected infections of vascular prostheses.[84,85] Accurate spatial localization of abnormal radiotracer foci to a graft or only to the adjacent soft tissues may be impossible unless these highly specific functional or metabolic images with low background activity and therefore limited structural information are combined with an anatomic road map. Precise alignment of metabolic and anatomic images is crucial, particularly in the extremities and in regions prone to even involuntary patient motion between imaging sequences, which may harbor an infectious process in a structure located very close to several others (as is the case with vascular grafts).

Radiolabeled White Blood Cell Imaging

Scintigraphy with radiolabeled WBCs has been used for assessment of suspected prosthetic graft infection. The overall sensitivity of WBCs for diagnosis of infected grafts ranges between 53% and 100%.[86,87] Although the circumstances have not been described in detail, false-negative results may be related to previous or concomitant antibiotic treatment or to the duration of symptoms.[86] The specificity of WBC scintigraphy ranges between 50% and 100% as well.[86,87] False-positive results have been reported in the presence of uptake in lymphocele, hematoma, thrombosis, bleeding, and pseudoaneurysms. Physiologic tracer uptake can be found in recently placed noninfected grafts within 1 month after surgery.[88] Many of the false-positive or false-negative studies can be overcome by using the correct acquisition criteria (at least dual time-point imaging) and the correct interpretation criteria (only uptake increasing over time is consistent with infection).

A study of 40 patients with suspected infection of abdominal aortic grafts compared the performance indices of ^{111}In–labeled WBCs and MRI. The positive predictive value of MRI was higher than that of WBC scintigraphy, although the negative predictive values were similar, around 80%.[89] SPECT studies performed with ^{99m}Tc–labeled WBCs are of better quality and therefore easier to interpret than studies using ^{111}In-labeled WBCs. ^{99m}Tc WBC imaging has reported sensitivity and specificity in the range of 82% to 100% and 75% to 100%, respectively.[86,87] The modality is of significant clinical value in cases where findings of other imaging modalities are inconclusive. False-positive results can be due to cross-labeling of red blood cells and platelets and by nonspecific perivascular accumulation of granulocytes early after surgery in healing wounds or graft anastomoses.[86,87]

In a study involving 82 patients with suspected infection, the use of labeled WBC SPECT/CT contributed significantly to the precise anatomic localization of suspicious foci of increased tracer uptake, thus confirming the diagnosis of infection and subsequently the precise localization and delineation of its extent in up to half of the patients.[84] This study included 24 patients with suspected vascular graft infection who were scanned with ^{111}In WBCs, with confirmed infected vascular implants in 10 patients. Overall, SPECT/CT provided more accurate data than planar imaging and contributory information in 67% of patients with suspected vascular graft infection. In one patient, SPECT/CT was falsely positive, showing focal vascular graft uptake that was unconfirmed by further follow-up and clinical outcome.[84] The role of ^{99m}Tc WBC SPECT/CT was also assessed retrospectively in 11 patients with suspected arterial graft infection. On the basis of clinical outcome, ^{99m}Tc WBC SPECT/CT identified 6 patients as having infection (true-positive results) and 4 as not having infection (true-negative results). One false-positive result was seen in a patient imaged 2 years after insertion of a thoracoabdominal aortic endograft.[90]

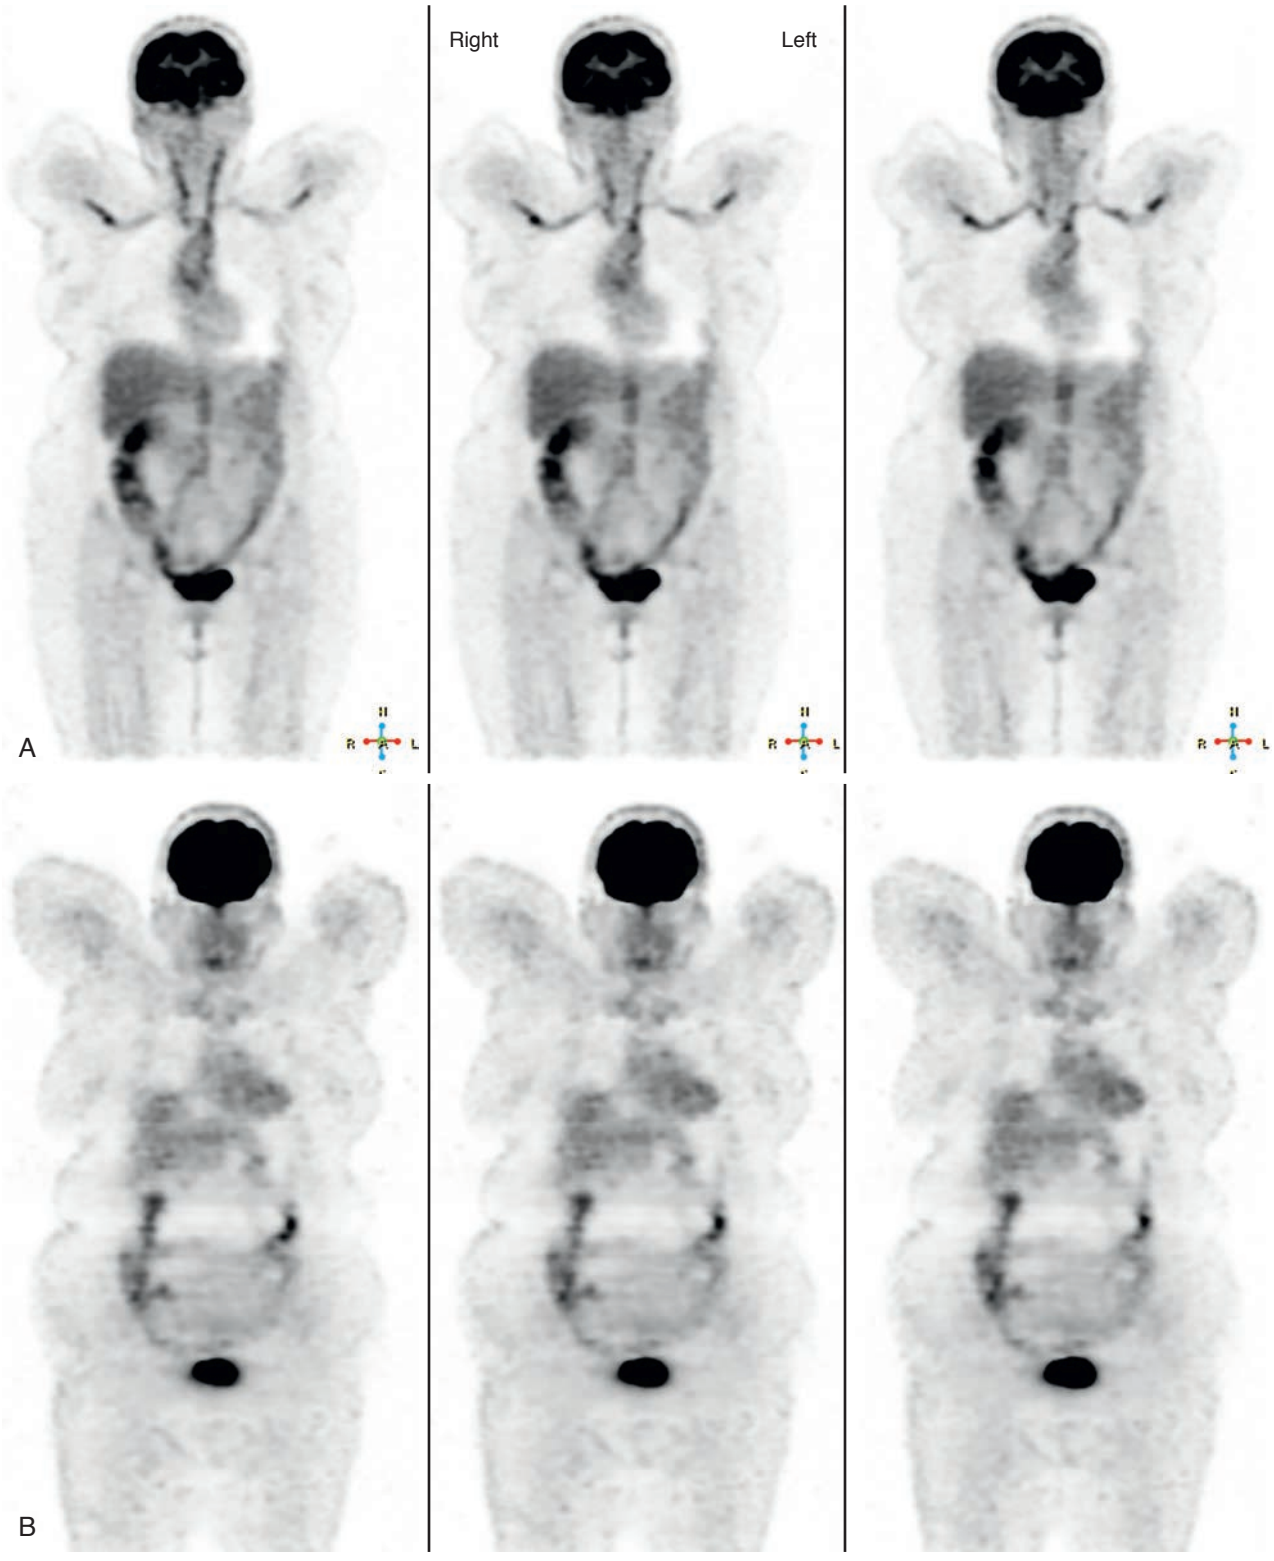

Figure 29.4 Fluorodeoxyglucose (FDG) uptake in the diagnosis and follow-up of vasculitis. A 65-year-old woman was referred for the assessment of fever of unknown origin. Results of computed tomography (not shown) were negative. (A) Selected coronal positron emission tomography slices demonstrate intense abnormal FDG uptake along the large vessels, including the ascending thoracic aorta, aortic arch, and subclavian and carotid vessels bilaterally. Less intense uptake can be seen along the abdominal aorta and iliac vessels, consistent with large vessel vasculitis. Biopsy confirmed Takayasu arteritis. (B) Follow-up imaging a year after treatment shows significant improvement.

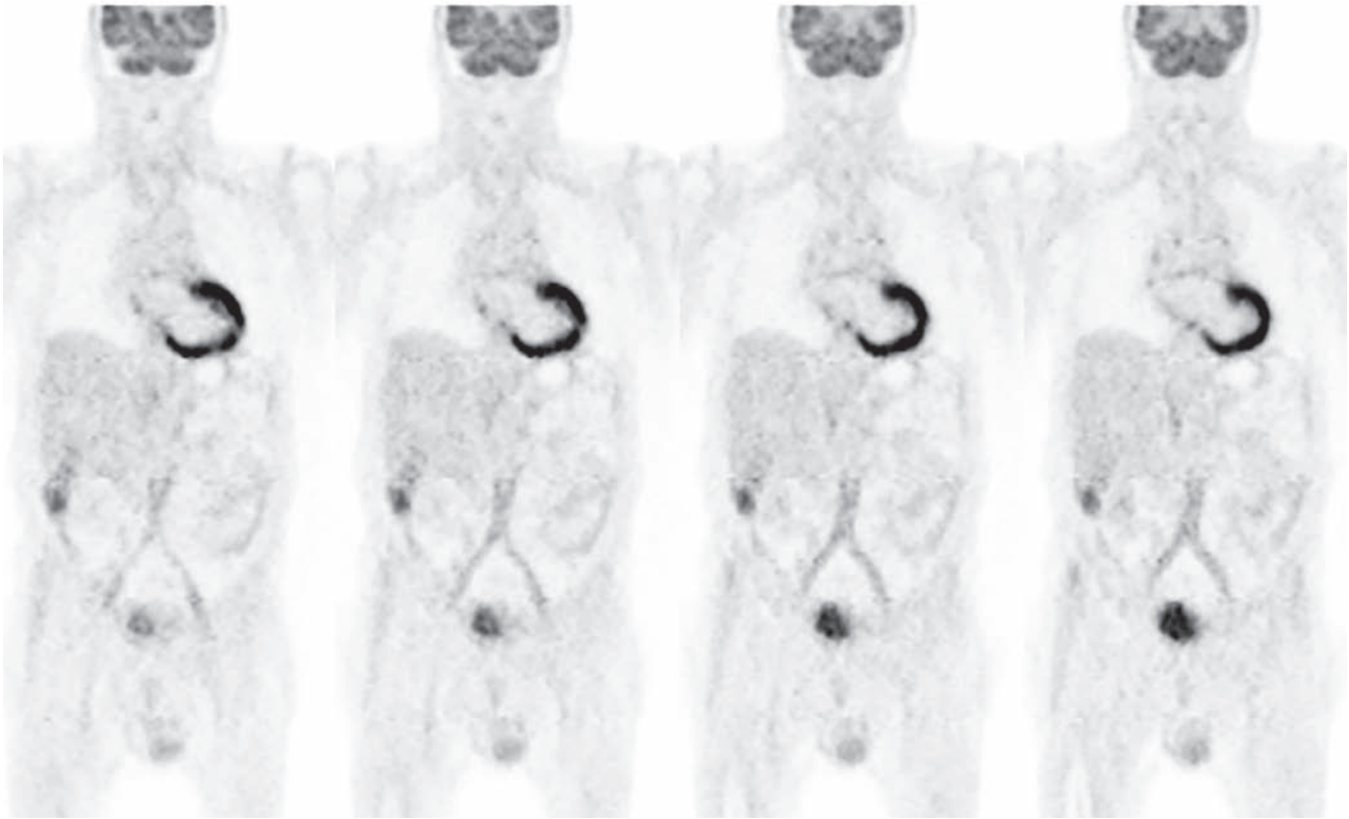

Figure 29.5 Diffuse linear fluorodeoxyglucose (FDG) uptake along a noninfected aortobifemoral graft. This 82-year-old man was diagnosed with cancer of the larynx 2 years prior to the current examination. He was referred for reevaluation at completion of radiochemotherapy. FDG positron emission tomography/computed tomography (selected serial coronal slices) does not demonstrate pathologic uptake consistent with residual viable tumor. There is increased linear FDG uptake in the abdominopelvic region along an aortobifemoral Dacron graft implanted 16 years earlier, representing an inflammatory "foreign-body reaction." The patient had no evidence of infection of the vascular prosthesis during a follow-up of 48 months. (Note also the physiologic FDG activity in the ascending colon.)

Fluorodeoxyglucose Positron Emission Tomography

Stand-alone FDG PET has a high sensitivity for vascular graft infection, but specificity is low in comparison with CT.[91] Increased FDG uptake may also occur in native vessels. False-positive results can be due to increased radiotracer activity along implants, grafts, and stents or in healing postoperative scars as well as to the presence of known or unknown malignant disease.[92] A pattern of linear FDG uptake of mild to moderate intensity found along a vascular graft with no evidence or suspicion of infection can be attributed to a chronic aseptic inflammatory reaction to a synthetic graft that is mediated by macrophages, fibroblasts, and foreign-body giant cells (Fig. 29.5). This pattern is observed more frequently in recently implanted grafts but can persist for years after surgery.[93] Keidar et al. studied FDG uptake in 107 noninfected vascular graft prostheses in patients scanned for other, mainly oncologic reasons. Diffuse, homogeneous uptake was found in more than half of the grafts, more prevalent in Gore-Tex than in Dacron grafts. The FDG uptake in these synthetic grafts showed no change in intensity for a follow-up of up to 16 years.[94] Although a focal pattern of intense abnormal FDG uptake is indicative of infection, the use of PET alone is limited for diagnosis of an infected vascular graft mainly by its inability to precisely define the anatomic location of the increased radiotracer focus. Correlation of functional information provided by FDG PET with the anatomic data of CT or MRI in separately performed imaging procedures of the lower limbs is not accurate enough for localizing a focus of increased FDG uptake to the vascular prosthesis itself or to the surrounding soft tissues.

Hybrid PET/CT has improved the specificity of FDG imaging. The presence, intensity, and pattern (focal or diffuse) of increased radiotracer activity is defined on the PET component, and the precise localization of abnormal FDG foci to the graft or to adjacent soft tissues is determined by the CT component (Figs. 29.6 and 29.7). In patients with complicated regional anatomy after multiple surgical procedures, PET/CT can pinpoint to the infected implant and differentiate between various suspicious findings on CT. In patients with multiple grafts, PET/CT can diagnose or exclude infection involving one or more specific prostheses.

Keidar et al. studied 39 patients with suspected graft infections. FDG-avid foci were noted in 30 of 39 patients on PET/CT, allowing for the accurate localization of 16 foci to the grafts with a sensitivity of 93%, specificity of 91%, positive predictive value of 88%, and negative predictive value of 96% for the diagnosis of prosthetic involvement. This enabled accurate

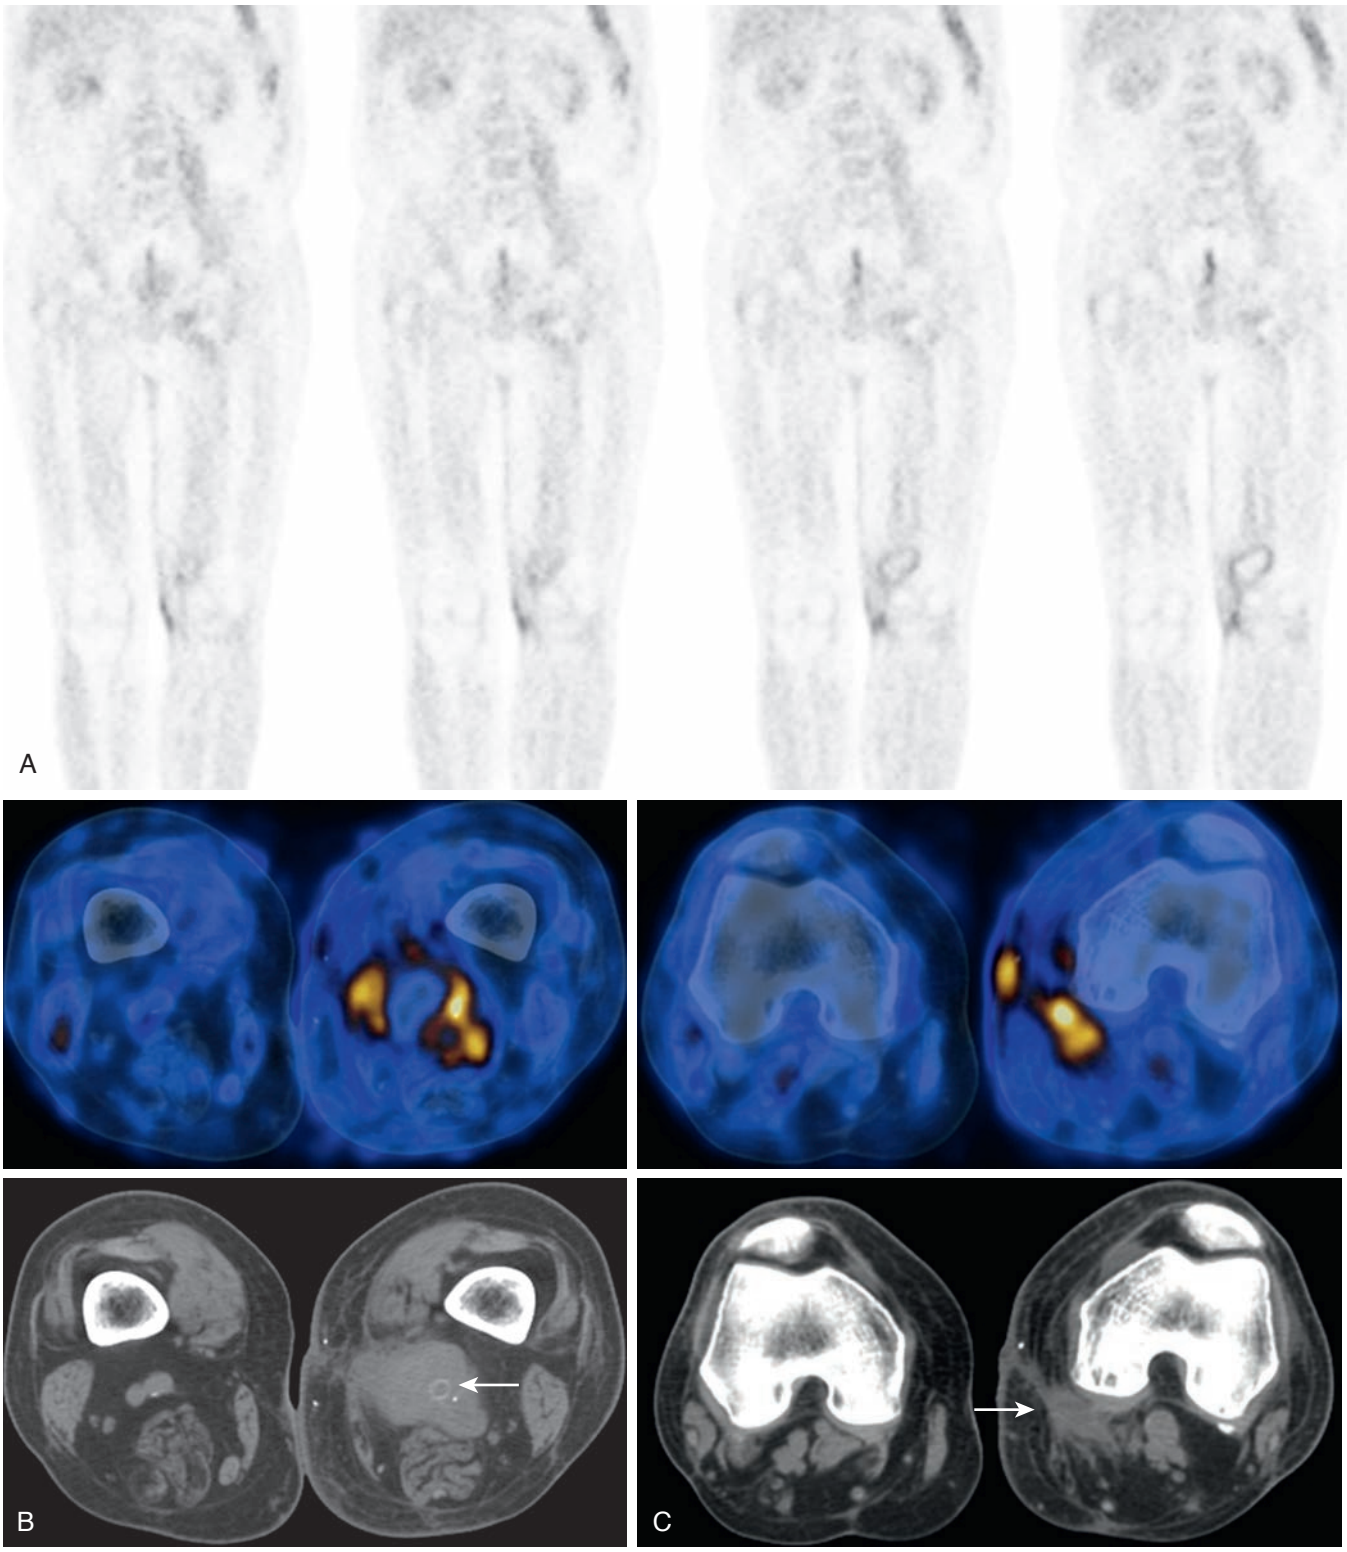

Figure 29.6 Abnormal focal fluorodeoxyglucose (FDG) uptake in an infected graft and soft tissue. The patient, a 65-year-old diabetic man with severe peripheral vascular disease, underwent implantation of a left femoropopliteal synthetic vascular graft 2 months prior to the current examination. The patient presented with pain and swelling and a pus-secreting surgical wound at the lower anastomosis of the graft at the level of the proximal left calf. (A) Coronal positron emission tomography (PET) slices demonstrate the presence of focal intense FDG uptake at the medial aspect of the proximal left calf. (B) and (C) The uptake is localized by PET/computed tomography to a soft tissue edematous mass surrounding and involving the lower end of the prosthesis (B, *arrow*) as well as in postsurgical soft tissue changes at the level of the infected surgical wound (C, *arrow*).

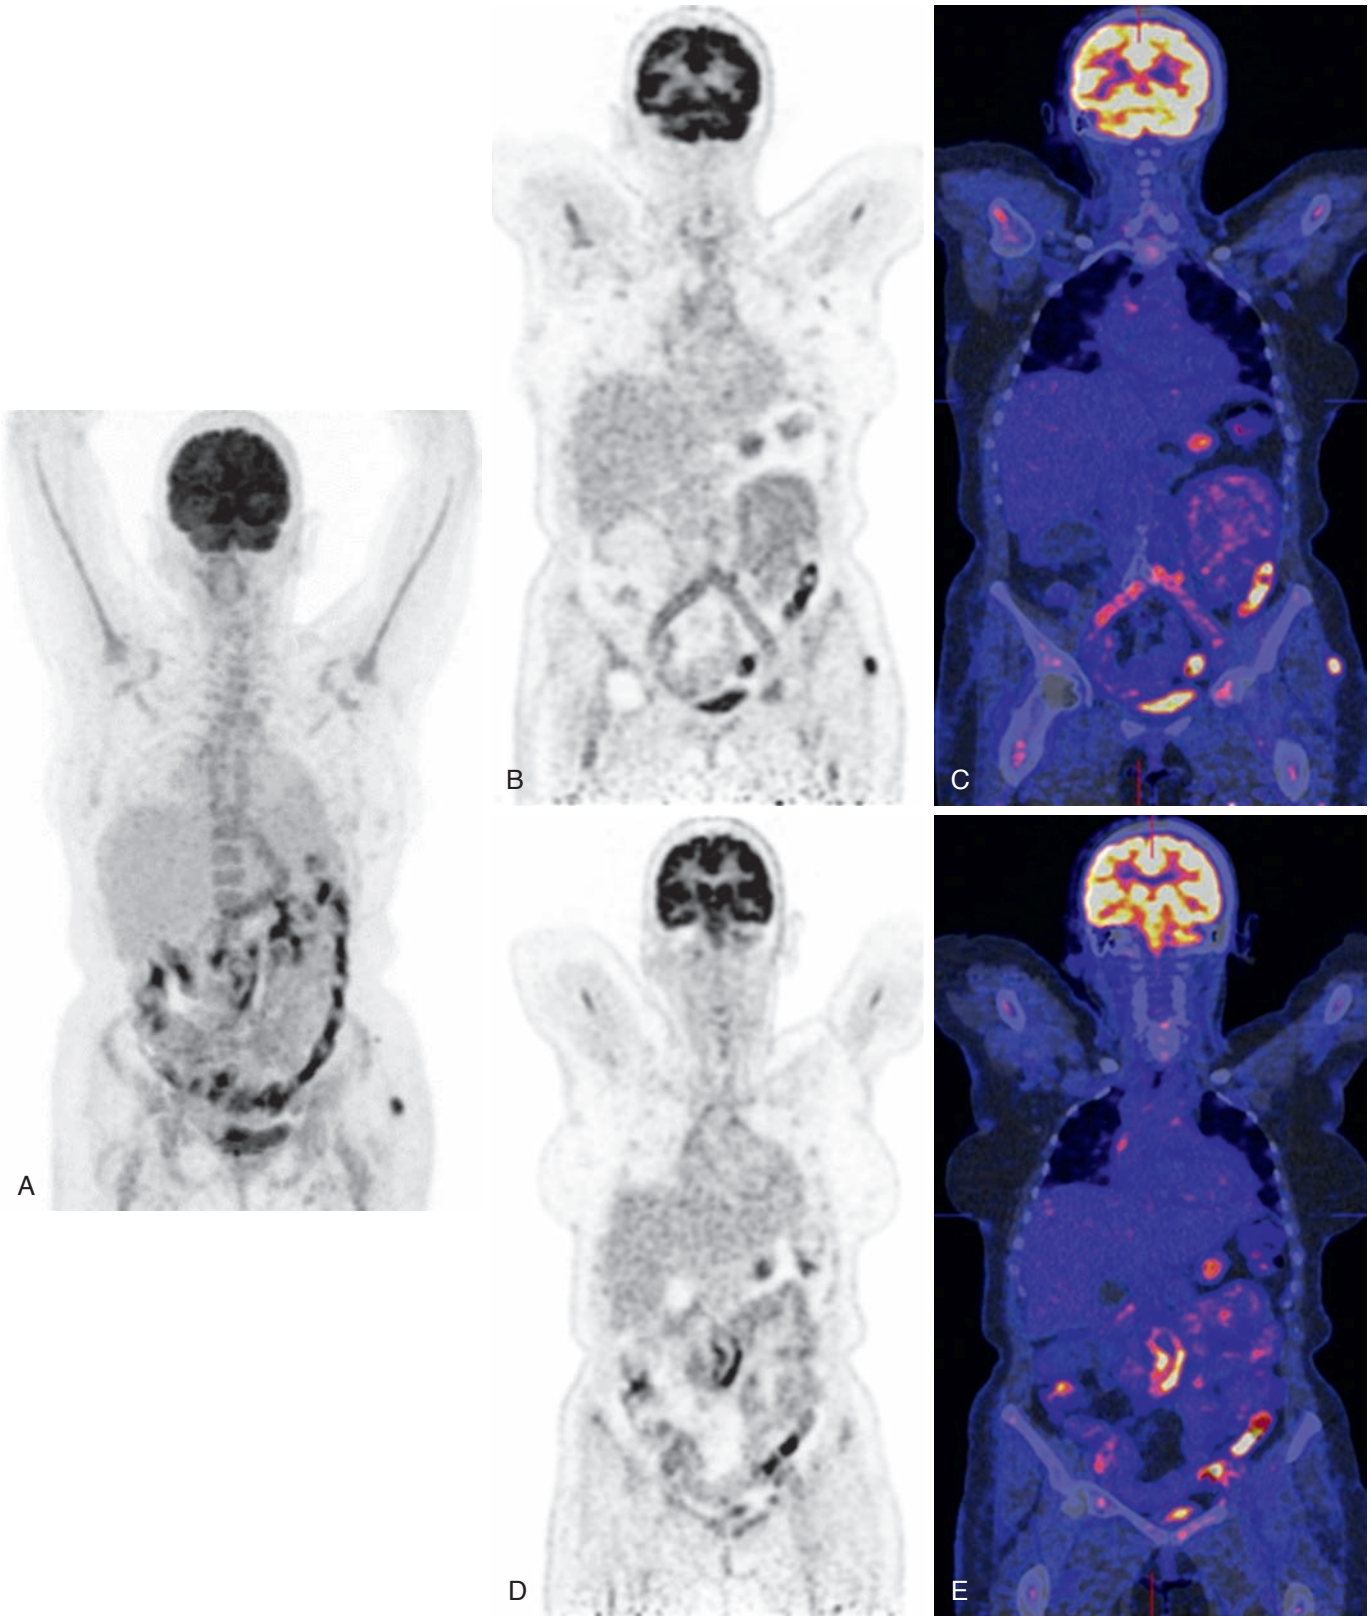

Figure 29.7 Normal and abnormal fluorodeoxyglucose (FDG) uptake in an aortobifemoral vascular graft. (A) Coronal maximum intensity projection showing heterogeneous uptake at the graft and diffuse physiologic uptake in the colon. (B and C) Selected coronal FDG positron emission tomography (PET) and fused PET-computed tomography (CT) images of the iliac part of the prosthesis showing homogeneous uptake because of reactive inflammation. (D and E) Selected coronal FDG PET and fused PET-CT images of the aortic part of the prosthesis showing heterogeneous focal and intense uptake. This part of the prosthesis is infected.

differentiation between graft and surrounding soft tissue infection.[95] In a prospective study of 96 suspected infected grafts in 76 patients, focal FDG uptake had a positive predictive value of 93% for the diagnosis of graft infection and a negative predictive value of 97%, compared with 89% and 67%, respectively, for a pattern of inhomogeneous tracer activity. Only focal FDG uptake and irregular graft boundaries on CT were significant predictors of vascular graft infection, whereas smooth lesion boundaries with no focal FDG uptake had a positive predictive value of less than 5%. The overall diagnostic accuracy of FDG PET/CT was more than 95% in 75% of vascular grafts.[96] The incremental value of fused images of FDG PET and CT was assessed in 25 patients with suspected vascular graft infections. In 15 patients, infection was proven by culture. FDG PET had a sensitivity of 93%, a specificity of 70%, a positive predictive value of 82%, and a negative predictive value of 88%; for CT, these values were significantly lower: 56%, 57%, 60%, and 58%, respectively. The results were improved when FDG and CT data were fused.[97]

LIMITATIONS AND RISKS

The limited resolution of the current technology of molecular imaging procedures, around 4 to 5 mm, is overcome by the unique information this technique offers on both function and structure, which is often unattainable with morphologic imaging.

Another important limitation is the development of new molecular probes for imaging. There is significant difficulty in the radiolabeling of new substrates and in the development of new radiopharmaceuticals for clinical indications. Novel molecular probes for SPECT and PET are currently in the pipeline of basic and clinical research.

The combined modalities, SPECT/CT and PET/CT, offer greater detail and a higher level of accuracy. These studies, however, are associated with higher radiation exposure for the patient. For instance, most molecular imaging procedures result in radiation doses between 1 and 10 mSv and the effective dose for FDG PET/CT is around 4 mSv. With the use of hybrid devices, the burden of radiation derives from both the radiopharmaceuticals and the CT component. Advances in PET/CT scanner technology allow reduced injected activity of FDG and hence lead to a decrease in the effective dose. In addition, advances in CT technology, as well as careful planning of CT for either attenuation correction or diagnostic purposes can further lower the overall radiation dose.

FUTURE ADVANCES

Vascular imaging is challenging to manage. It is therefore important to gather a wide expertise in a multidisciplinary vascular team approach involving vascular internal medicine and surgery and experienced nuclear (hybrid) imagers to perform the optimal diagnostics resulting in dedicated treatment and follow-up for each individual patient. It is also important to standardize the acquisition protocols and interpretation criteria throughout the world, not only to provide the nuclear medicine physicians with criteria indicating when to declare a scan positive but also to be able to better compare research results. Some efforts to provide this standardization have recently been taken.[98] Hybrid PET/MR technology has been developed and is now available for clinical use. The total radiation exposure in a combined PET/MR study is limited to that resulting from the administration of the PET tracer only. The combination of PET, with its sensitivity in the picomolar range, with the high soft tissue contrast offered by MRI may play an important role in future imaging algorithms.[99] Bini et al. have recently compared PET/MR with PET/CT for carotid artery imaging and have also assessed various technical variables associated with the new technology (i.e., MR-based attenuation correction, carotid coil for PET/MR). Excellent correlations were reported, supporting the use of PET/MR for quantitative assessment of the inflammatory burden of the carotid arteries.[100]

INTRODUCTION

Catheter-based endovascular techniques are increasingly being used in vascular surgery, with demand for detailed intraoperative imaging increasing accordingly. Intravascular ultrasound (IVUS) is a catheter-based endoluminal guidance system that was initially utilized in interventional cardiology in the 1980s.[1-5] Various trials and analyses of IVUS-guided versus angiographic-guided percutaneous coronary intervention (PCI) have concluded that IVUS-guided PCI results in similar or improved outcomes overall.[6-15] In fact, IVUS has been shown to be effective in improving procedural results and reducing restenosis and the need for reintervention in PCI. Since its initial clinical use in coronary artery interventions, IVUS has been shown to have a variety of applications in vascular intervention because of its ability to provide detailed pretreatment diagnostic information on the extent and severity of disease, to guide treatment intraoperatively, and to immediately assess the treatment's success.[16]

Abstract

The use of intravascular ultrasound (IVUS) has broadened from its initial use in percutaneous coronary interventions to become applicable and beneficial in the treatment of aortic, arterial, and venous pathologies as well. The benefits of IVUS include its ability to be used intraoperatively to provide superior visualization of arterial wall and plaque morphology, to aid in choosing appropriately sized balloons and stent-grafts by providing accurate luminal measurements, and its capacity to evaluate the effectiveness of treatment postoperatively.

BASIC PRINCIPLES

Creating the Image

Technology

IVUS creates axial images perpendicular to the long axis of the catheter by transmitting sound waves covering 360 degrees around the tip of the catheter, which is delivered into the lumen of the vessel over a guidewire. This is achieved either mechanically or electronically. The mechanical system, produced by Boston Scientific Corporation, utilizes a flexible high-torque catheter with a quickly rotating ultrasound transducer located at the tip. Electronic systems, produced by Volcano Corporation, utilize 64 miniaturized transducer elements located circumferentially around the tip of the catheter that are activated in sequence to produce an array of images. Information collected by IVUS transducers is reconstructed, displayed, and recorded visually on a separate console. This workstation facilitates the collection of measurements such as the diameter, circumference, and area of a vessel and allows for the capture of still images and video loops (Fig. 30.1).

In working with IVUS, it is important to choose the appropriate catheters and ultrasound frequencies to obtain

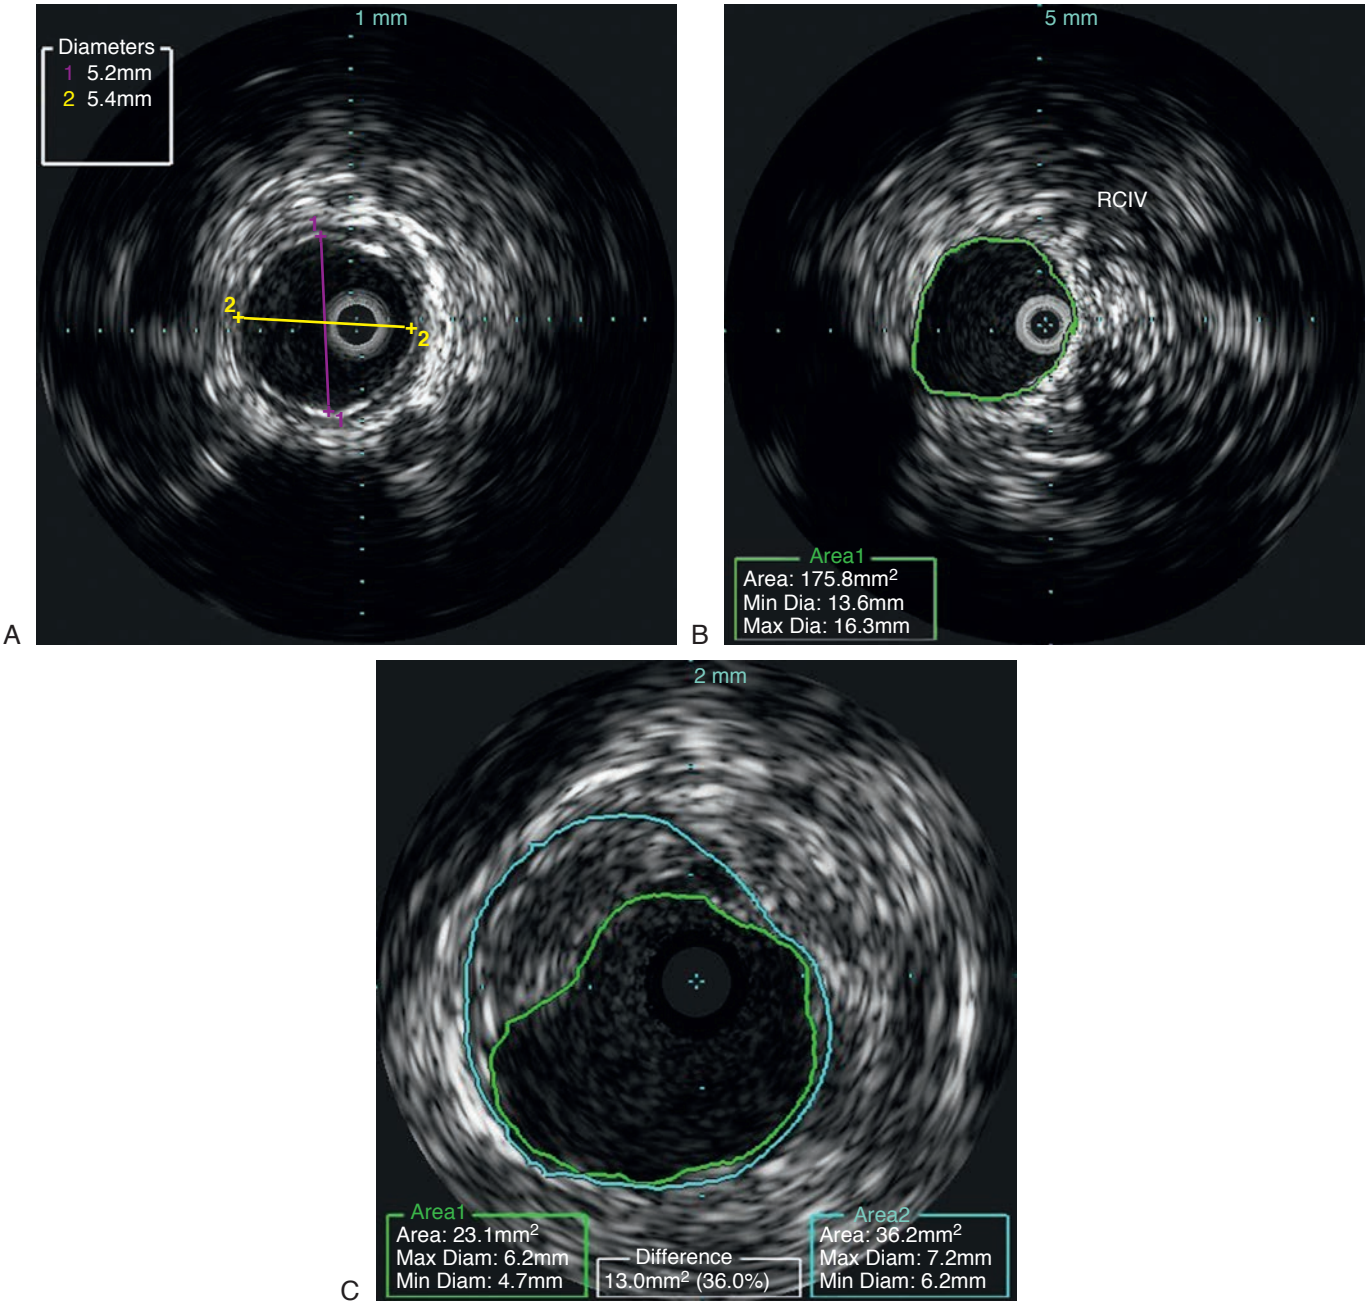

Figure 30.1 It is possible to take a variety of measurements on the intravascular ultrasound console, including diameters (A) and area (B). It is also possible to find the amount of thrombus present in a vessel by measuring the area of the lumen and the area of the vessel (C). *RCIV*, Right common iliac vein.

the best possible imaging.[17] Higher frequencies improve image resolution but decrease the depth of penetration. This makes them ideal for smaller vessels, as they provide more detail, with probes delivering 45 MHz being well suited to coronary vessels. Probes with frequencies around 20 MHz are ideal for larger peripheral vessels or occlusive branched vessels, whereas probes with lower frequencies around 10 MHz are well suited for imaging vessels such the aorta, inferior vena cava, and iliacs (Table 30.1). These catheters must be delivered with larger sheaths and provide less detail, but they can scan the entire circumference of a vessel.

Interpreting the Image

Gray Scale

As with other forms of ultrasound, IVUS displays two-dimensional images in gray scale. Ultrasound's ability to penetrate the material and the resultant amplitude of the returning signal determine the relative brightness or darkness of the vessel wall, reflecting its echogenicity or echolucency, respectively (Fig. 30.2).[18,19] It is also possible to visualize different types of plaques using IVUS. Heavily calcified plaques are highly echogenic and characterized by brightness and posterior shadowing. Fibrotic plaques are slightly less bright and lack the posterior shadowing of calcified plaques. Soft, lipid-filled plaques are echolucent and appear darker. Software allowing further characterization and analysis of vessels is also available with IVUS.

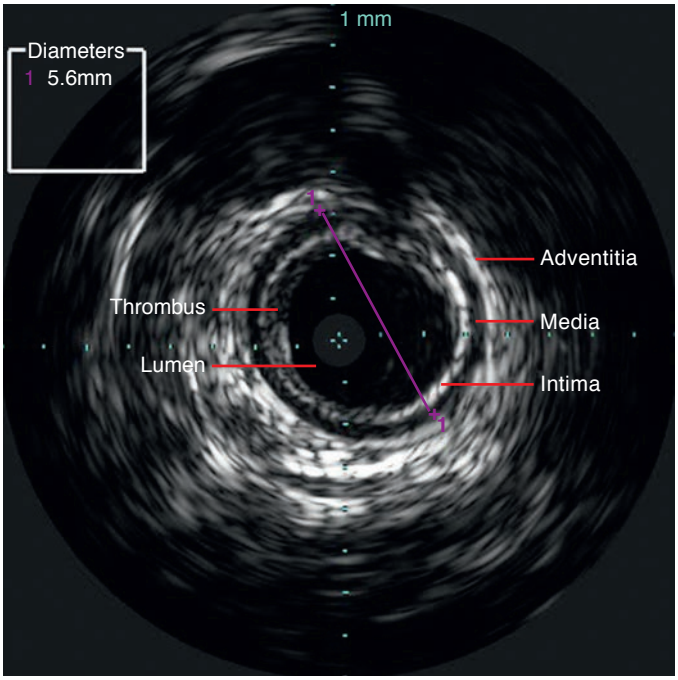

Figure 30.2 In gray scale, the layers of the arterial wall are visualized clearly, with the intima and adventitia appearing bright and echogenic, while the media is darker and echolucent. The blood-filled lumen appears very dark, with the clear demarcation between the arterial wall and the lumen allowing measurements to be obtained.

Volumetric Three-Dimensional Intravascular Ultrasound

In order to overcome the limitations of two-dimensional visualization, three-dimensional IVUS has been developed to more accurately describe arterial morphology and atheroma distribution. Conventional methods have relied on a longitudinal reconstruction similar to an angiogram, created through an automated "pullback" of the IVUS probe and compiling a pixel-based two-dimensional longitudinal reconstruction. Because the catheter tip is not reliably in the center of the lumen, it is difficult to obtain accurate diameter and length measurements in longitudinal reconstructions.[20] However, in recent years more sophisticated three-dimensional reconstruction algorithms have been developed, such as a novel method allowing for simultaneous registration of two IVUS pullbacks of the same vessel.[21] This type of technology is likely to continue to improve, offering fewer errors in location and orientation registration.

Color-Flow Intravascular Ultrasound

It is also possible to characterize blood flow with IVUS using color-flow software. This software, such as Volcano's ChromaFlo, compares adjacent frames at 30 frames per second and identifies the movement of blood cells, coloring any normal blood flow red and faster blood flow yellow. Unlike Doppler, color-flow IVUS cannot measure flow velocities. However, it does provide more information about the interface between the vessel wall and the bloodstream, allowing for more accurate volumetric measurements and the ability to assess completeness of treatment (Fig. 30.3 and Video 30.1).[22,23]

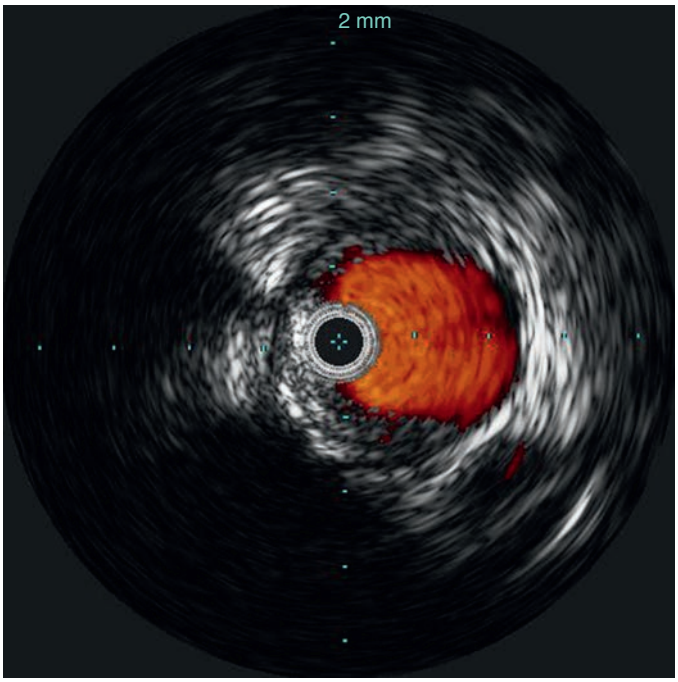

Figure 30.3 Color-flow intravascular ultrasound.

Virtual Histology Intravascular Ultrasound

Virtual histology (VH) IVUS utilizes the frequency of the returned signal as well as its amplitude to produce a color-coded map of a lesion based on the different frequencies at which various tissues reflect ultrasound. This allows histopathologic analysis of plaques based on their composition (Fig. 30.4). The Carotid Artery Plaque Virtual Histology Evaluation (CAPITAL) study, which compared 153 VH IVUS images with true histopathology sections from endarterectomies, found that VH IVUS was able to accurately diagnose 99.4% of thin-cap fibroatheromas, 96.1% of calcified thin-cap fibroatheromas, 85.9% of fibroatheromas, 85.5% of fibrocalcific plaques, 83.4% of pathologic intimal thickening, and 72.4% of calcified fibroatheromas.[24] A 2013 study analyzing 276 atherosclerotic plaques also found that VH IVUS had high sensitivities for various types of plaques (87% for noncalcified thin-cap fibroatheromas, 92% for calcified thin-cap fibroatheromas, 85% for noncalcified fibroatheromas, 89% for calcified fibroatheromas, and 79% for pathologic intimal thickening).[25] Although the accuracy of VH IVUS varies in identifying different types of plaque, it is overall able to provide insight into the morphology of

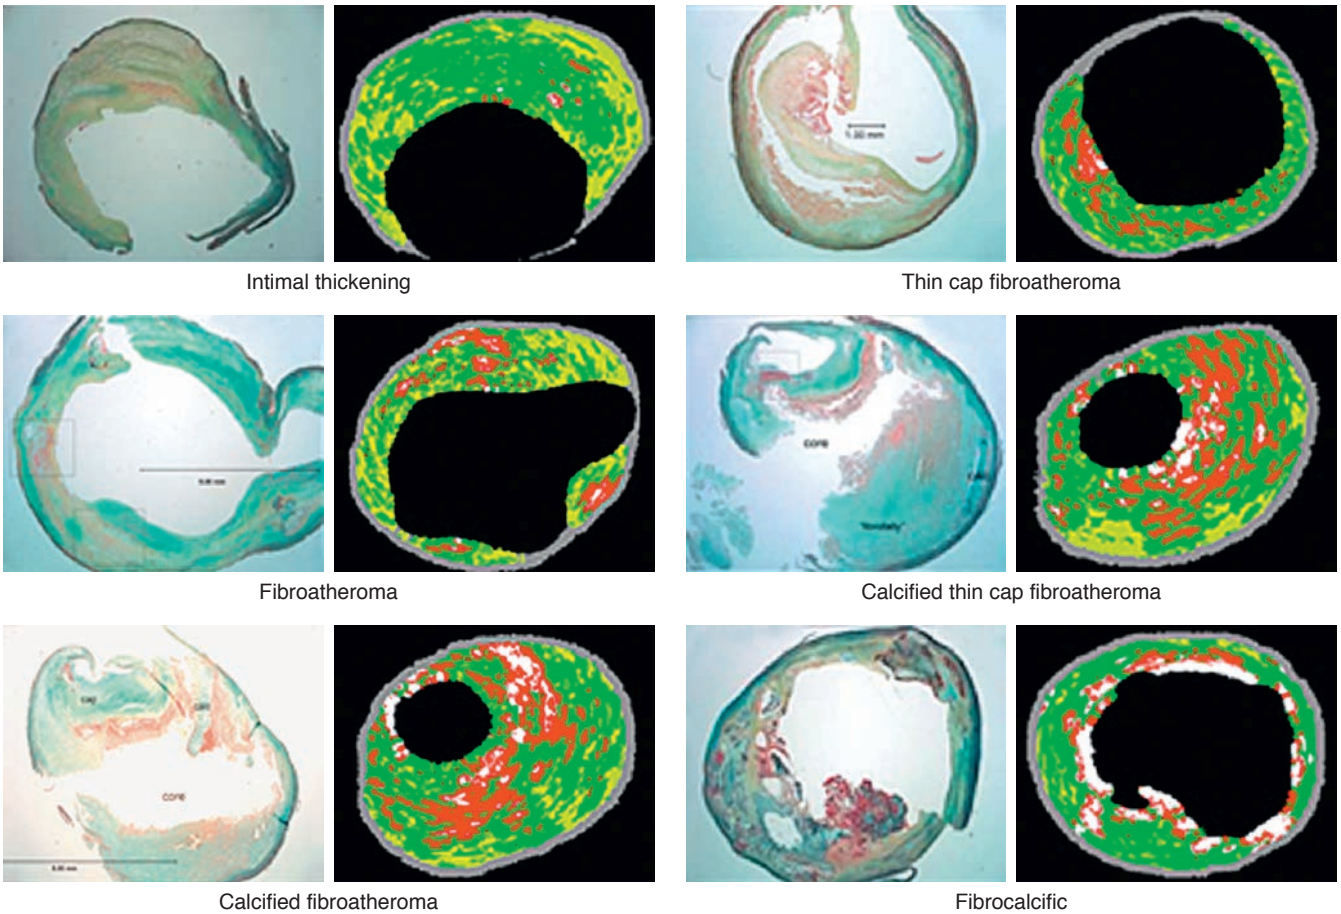

Figure 30.4 Virtual histology intravascular ultrasound software color codes images of atherosclerotic plaques based on their histologic components: dark green = fibrous, yellow/green = fibrofatty, white = calcified, red = necrotic lipid core.

lesions. The information about plaque composition offered by VH IVUS may improve outcomes by allowing physicians to predict plaque behavior in response to treatment, determining whether plaques may resist treatment or embolize when grafts or balloons are expanded.[26-31] Histopathologic analysis using IVUS is currently available only for smaller vessels, since the maximum fields of display are less than 20 mm, but future advances in VH IVUS technology may improve plaque characterization in larger vessels.

CLINICAL APPLICATIONS

Effectiveness of Intravascular Ultrasound

Cost Versus Benefits

As of 2009, IVUS systems were listed at between $100,000 and $200,000, while the disposable IVUS catheters cost between $600 and $1000 each.[32] These can represent significant added costs to procedures. However, the benefits of using IVUS suggest that it is cost-effective, because increased effectiveness of treatment can prevent reintervention and improve morbidity/mortality rates, especially in complex cases.[33] In a study examining the cost-effectiveness of IVUS in PCI, results demonstrated that use of IVUS was cost-effective, especially in patients at greater risk of restenosis, who benefit from more accurate stent implantation.[34] Improved long-term clinical outcomes can certainly decrease costs, and IVUS has been shown to improve clinical outcomes in many studies. Studies of aortoiliac artery stenting found that clinical outcomes were improved with IVUS guidance.[35,36] Studies investigating peripheral and branch vessel stenting found that IVUS was able to detect unsatisfactory deployment of stents, allowing further measures to be taken immediately and preventing later reintervention.[37] Similarly, IVUS-guided treatment of lower limb endovascular interventions was found to be predictive of lower postprocedural complications and significantly improved limb salvage rates.[38] Overall, the benefits of IVUS use tend to outweigh additional procedural costs.

General Benefits of Intravascular Ultrasound

IVUS is most often used because of its ability to provide additional diagnostic information to accurately assess vascular pathology, a benefit that has been well documented.[39] Intraoperatively, the dynamic imaging provided by IVUS allows for accurate deployment of grafts and assessment of successful therapy. The improved measurement ability of IVUS helps to determine proper stent graft sizing as well as in making last-minute adjustments based on intraoperative measurements.[40] Although measurements taken with IVUS have been found to be accurate overall, it is important to remember that because the catheter may not always be in the center of the lumen, it may provide a distorted oblique slice that does not reflect the true center-line diameter, especially in tortuous sections of the aorta.[41]

A significant benefit of IVUS is that it does not require the use of contrast. Because of this, patients with contrast allergies or renal impairment may benefit from preoperative imaging with IVUS instead of computed tomography angiography (CTA).[42,43] Intraoperatively, the use of IVUS is especially recommended as an alternative or adjunct to angiography because of its ability to decrease the volume of contrast injected as well as the radiation exposure.[44] It was shown in one comparison study that use of IVUS decreased fluoroscopy time from 39 to 19 minutes in comparable procedures.[45] In 2002, a study evaluating outcomes of endovascular aneurysm repair (EVAR) with IVUS as compared with angiography concluded that IVUS was accurate and reliable enough to be used for EVAR without additional angiographic assessment.[46] This ability to perform a procedure while eliminating or reducing contrast load and radiation exposure recommends the use of IVUS in patients with life-threatening contrast allergies or renal complications.[47] Because of its many benefits, IVUS has proven useful in a variety of vascular applications, including in the treatment of peripheral arterial disease, abdominal aortic aneurysm, thoracic aortic disease, dissection, and venous disease.

Arterial Applications: Carotid and Peripheral Arterial

Peripheral Arterial Disease

It has been shown that residual stenosis of greater than 60% after peripheral balloon angioplasty is associated with decreased patency rates.[48] Studies have also shown that more accurate sizing, especially with balloon-expandable stents, leads to better patency rates.[49] IVUS assessment of lumen diameter and degree of stenosis allows for accurate sizing of the vessel to be treated, thereby informing decisions regarding balloon and stent sizing.[50] One Japanese study found that 5-year overall patency rates were improved at 65% versus 35% when IVUS was used in the treatment of femoropopliteal lesions.[51] IVUS is also able to assess the initial results of balloon angioplasty and determine the need for further intervention, ensuring proper dilation of stents to improve apposition to vessel walls. In one study, 40% of patients had underexpanded stents after initial deployment and balloon expansion, but these were able to be further expanded with larger balloons because the lack of apposition was identified with IVUS.[52] Arteriography or angiography alone does not always visualize this type of problem, whereas IVUS is able to identify stent struts because of their echogenicity and assess the extent of stent expansion and apposition, allowing physicians to act to improve patency rates and overall success of treatment (Fig. 30.5).

In a study of popliteal aneurysms, researchers found that use of IVUS allowed accurate characterization of vessel morphology, including location and extent of thrombus burden. This improved outcomes in endovascular procedures because measurement of the diameter and location of desired landing zones allowed for appropriate sealing of the aneurysm proximally and distally.[53] In patients with drug-eluting stent placement for treatment of femoropopliteal lesions, IVUS guidance and postprocedural IVUS assessment was able to offer predictors of restenosis at 1 year.[54] In another study, IVUS use was associated with higher primary patency rates following nitinol stenting of TASC II

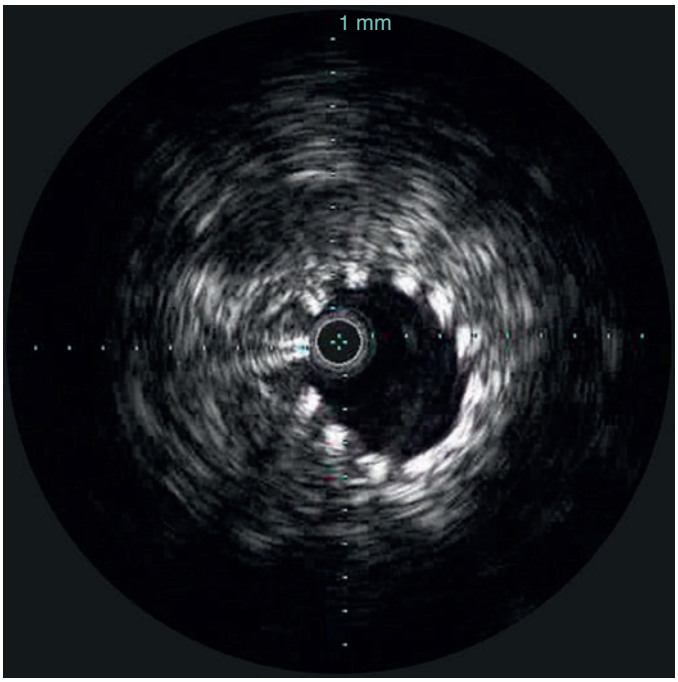

Figure 30.5 The echolucency of stent grafts allows for evaluation of graft apposition.

A-C lesions.[55] As these studies demonstrate, the information provided by IVUS has shown clear benefits in treatment of the peripheral vasculature.

Intravascular Ultrasound-Guided True Lumen Reentry

Endovascular revascularization to recanalize peripheral arteries is often unsuccessful because of a failure to reenter the true lumen after crossing an occlusion subintimally. Use of a device such as the Pioneer Plus,[56,57] which combines IVUS with reentry technology, can ensure true lumen reentry and improve outcomes, as shown in several studies. In one study of patients with chronic total occlusion of the iliac arteries, the use of the Pioneer device (a precursor to the Pioneer Plus) was able to decrease procedure time and improve precision of reentry, resulting in improved technical success of the recanalization procedure.[58] Another study found similarly positive outcomes in longitudinal follow-up of use of IVUS reentry devices for iliac and infrainguinal CTO.[59] Use of IVUS in conjunction with reentry devices ensures accurate needle placement and reentry.

Carotid Applications

IVUS can also be useful in the treatment of carotid arteries. A study of endarterectomy patients found that use of IVUS allowed correct identification of the distal ends of stenotic lesions, increasing the amount of information available to physicians that may not have been initially available with preoperative angiograms.[60] Similarly, a study of patients undergoing carotid angioplasty and stenting found that IVUS provided complementary information to allow more detailed characterization of lesions and thus to inform choice of type and size of stent.[61]

Endovascular Repair: Abdominal Aortic Aneurysms

Preoperative Intravascular Ultrasound

Abdominal aortic aneurysms (AAA) are increasingly being treated endovascularly.[62,63] Preoperative planning for such procedures requires high-quality imaging to characterize arterial morphology, particularly for accurate assessment of landing zones proximally and distally. Most of this planning is done using CTA. However, the use of IVUS preoperatively may be beneficial in several instances. It has been shown that IVUS provides accurate measurements of the length and diameter in landing zones, aiding in the proper selection and sizing of endografts.[64,65] In the case of patients with tortuous vessels, the combination of information from IVUS and CTA preoperatively can improve the ability to accurately assess and plan for cases that may be technically challenging.

Intraoperative Intravascular Ultrasound

For patients with abdominal aortic aneurysm, IVUS is most effectively used intraoperatively. Prior to stent graft deployment, IVUS can help to assess access anatomy in patients with questionable suitability for percutaneous endografting as seen on CTA. Prior to endograft delivery in patients with difficult access, IVUS can guide rotational atherectomy or balloon angioplasty or determine whether a conduit may be necessary. This assessment of access vessels can limit complications such as iliac dissection or rupture. During deployment, IVUS can visualize side branches for accurate placement of the graft. In the event that a bifurcated graft is being deployed, IVUS can also be used to ensure that the contralateral gate has been properly cannulated.

After Repair

After deployment of the stent-graft, IVUS can determine the completeness of treatment by assessing apposition to the vessel walls proximally and distally as well as apposition between overlapping stent-grafts. Potential endoleaks can thus be visualized and characterized. The use of IVUS for immediate intraoperative assessment of treatment can facilitate decision making about the necessity of further interventions such as ballooning, placement of proximal cuffs, or additional stent grafts, thus preventing the need for later reinterventions.

Endovascular Repair: Thoracic Aortic Disease

Endovascular thoracic aortic stent grafts are being used to treat a variety of thoracic aortic pathologies, including aneurysm, dissection, penetrating aortic ulcer (PAU), intramural hematoma (IMH), coarctation, and thoracic aortic injury secondary to trauma.[66-69] IVUS can clearly identify and characterize all those pathologies along with providing additional information that may not have been provided in CTA imaging. Unlike imaging for abdominal aortic pathologies, CTA imaging for thoracic disease often does not include abdominal and pelvic visualization. IVUS can therefore be used to provide information about access sites. Thoracic grafts often require larger sheath diameters,

thus increasing the risk for access-related complications and the need for accurate assessment to evaluate need for a conduit or additional treatment prior to delivering the main graft. IVUS can also provide information about arch vessel involvement that may not have been available on CTA, informing decisions about landing zones and any additional stenting that may be necessary.

Thoracic Aneurysms

The benefits of IVUS use in the treatment of thoracic aortic aneurysm are similar to the benefits provided in the treatment of abdominal aortic aneurysm, with the addition of the aforementioned benefits that are general to IVUS use in thoracic aortic disease. Before intervention, it can assess the access vessels, determine the amount of graph coverage necessary, guide graft sizing, and identify branch vessels and landing zones (Fig. 30.6 and Video 30.2). Of note, IVUS is especially beneficial in detecting any sources of potentially embolic material, such as calcific plaques or mobile atheroma in the aortic arch. This can allow physicians to limit ballooning in the arch so as to prevent embolic stroke.[70]

Blunt Traumatic Aortic Injury

Although CTA remains essential as a diagnostic tool for blunt traumatic aortic injuries (BTAIs), such as rupture, intimal tears, or transection, additional imaging is sometimes required. A study of BTAI patients with equivocal CTAs found that IVUS was more sensitive than angiography in these cases, with 3 out of 25 patients having had a negative angiogram, being diagnosed

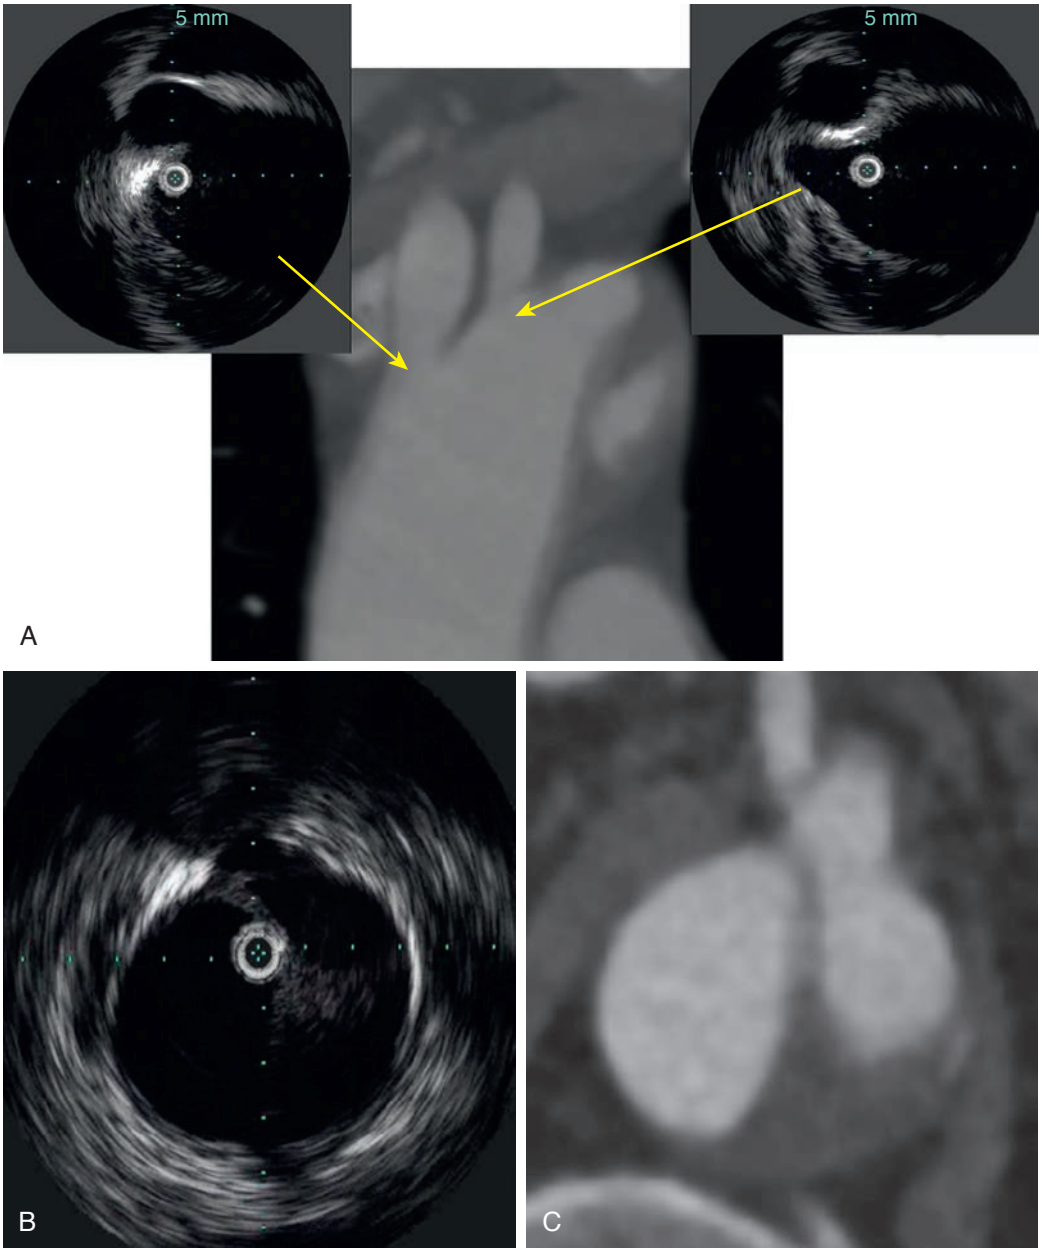

Figure 30.6 Branched vessels. On IVUS, it is possible to see the take-off of the great vessels (A, arrows indicate location of IVUS images captured at innominate and carotid arteries). IVUS image (B) and correlating CTA (C) show the celiac artery perfused by a partially thrombosed false lumen.

only by IVUS.[71] Additionally, the aortic diameter in patients with traumatic aortic injury often increases from the time of initial CTA to the time of repair due to hypovolemic shock and subsequent resuscitation, thus highlighting the need for intraoperative reassessment and real-time measurement to guide device sizing.[72] This accurate sizing of the true aortic luminal diameter can prevent graft infolding or bird-beak configuration and ensure proper apposition.[73] This is especially critical for BTAI patients, who are often younger, necessitating the anticipation of changes that come with aging and appropriate planning to promote longer-term durability of treatment.[74]

Coarctation

IVUS has emerged as an important imaging technique in endovascular repair of coarctation of the aorta. In a study examining balloon dilation for native and recurrent coarctation of the aorta, it was found that IVUS was more sensitive than angiography in providing detail regarding vascular wall changes, remodeling, and intimal tears.[75] Not only intraoperatively useful, it may also be beneficial in the diagnosis of arch anomalies or coarctation. In 2000, a total of 20 infants and children with arch anomalies were examined, and it was determined that it is possible to diagnose arch anomalies accurately using IVUS catheters from a transesophageal approach with three-dimensional image reconstruction.[76]

Dissection

Pre- and Intraoperative Intravascular Ultrasound

The benefit of IVUS in endovascular treatment of thoracic aortic dissections is most clearly seen in its ability to identify the true and false lumens (Fig. 30.7). Characterization of the dissection is

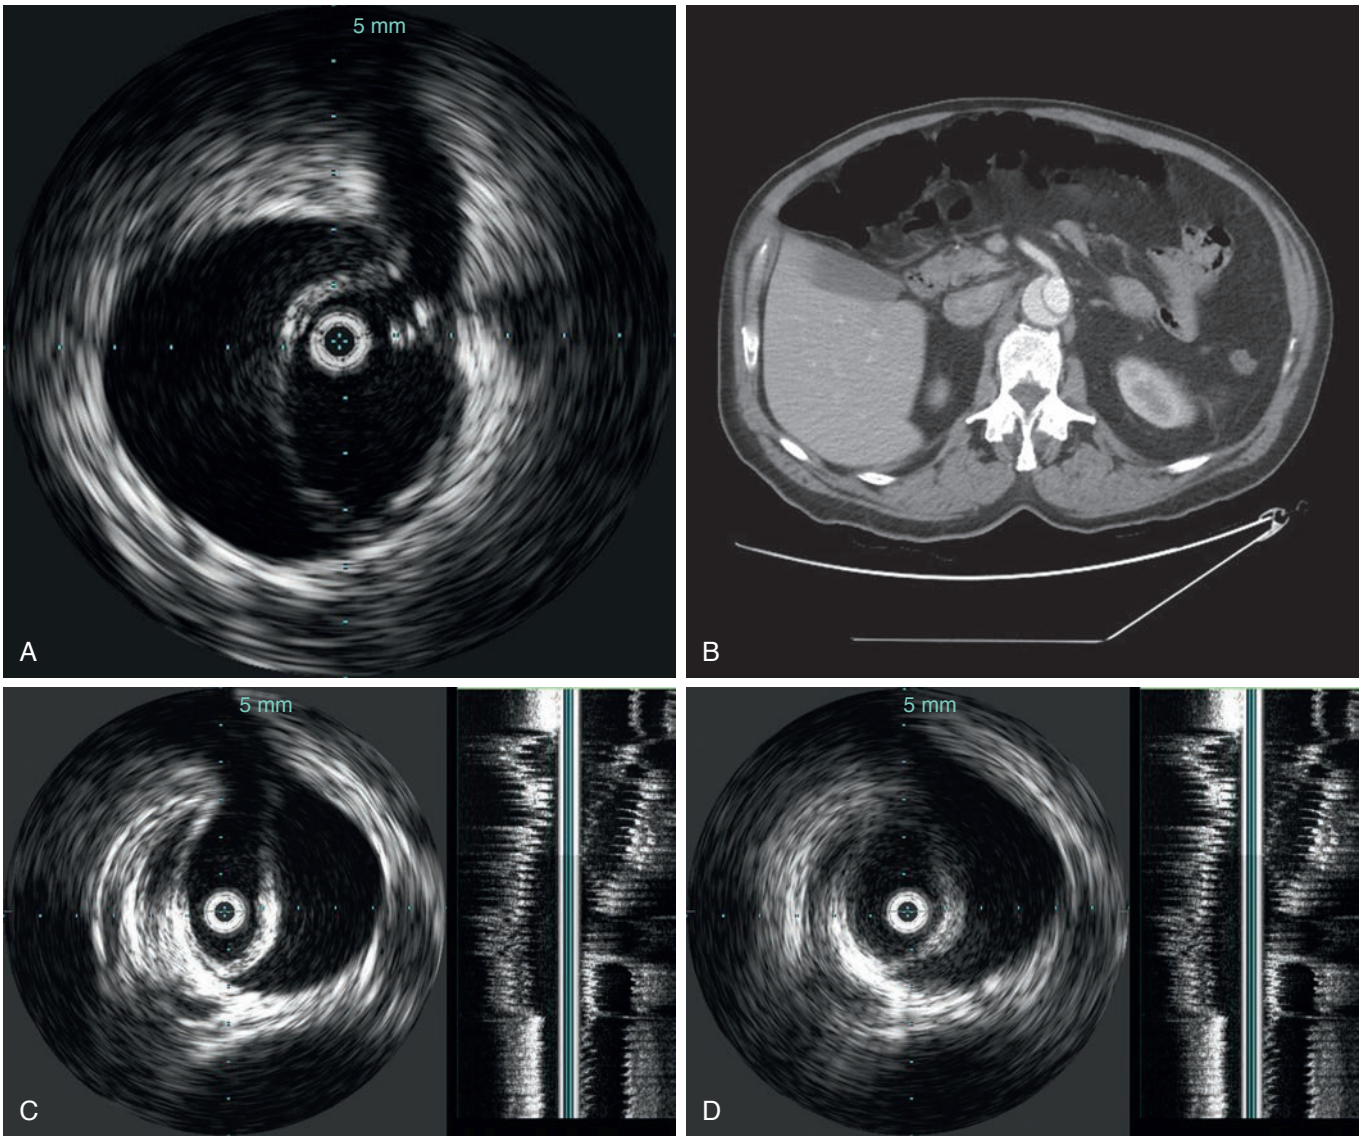

Figure 30.7 (A) It is possible to see the intima separating the true and false lumens and the superior mesenteric artery (SMA) coming off the true lumen. (B) Computed tomography angiography of dissection and SMA coming off true lumen. (C and D) Dynamic obstruction as seen on intravascular ultrasound with longitudinal reconstruction.

also possible, with the ability to identify the entry tear and other fenestrations between the true and false lumen. Movement and thickness of the dissection flap can be visualized, facilitating the diagnosis of dynamic obstruction due to flap motion (Videos 30.3 and 30.4). The benefit of IVUS in treating Stanford type B dissections, especially "complicated" type B dissections, is clear in its ability to identify visceral vessels.[77] Not only can dynamic obstruction be clearly seen, but it is also possible to assess through which lumen each artery is perfused, guiding further therapies if visceral stents are required (Fig. 30.8). Identification of the celiac artery with IVUS can also assist in placement of the graft, as the origin of this artery is sometimes difficult to identify solely with aortography.[78] Because it provides accurate measurements of vessel diameter and exact locations of branched vessels and fenestrations, the use of IVUS in treating dissections can facilitate the identification and characterization of proximal and distal landing zones, determining the amount of coverage required, and guiding selection of the appropriate size and length of the device to be used. As in other aortic pathologies, IVUS can also guide wires. This is especially important in the case of

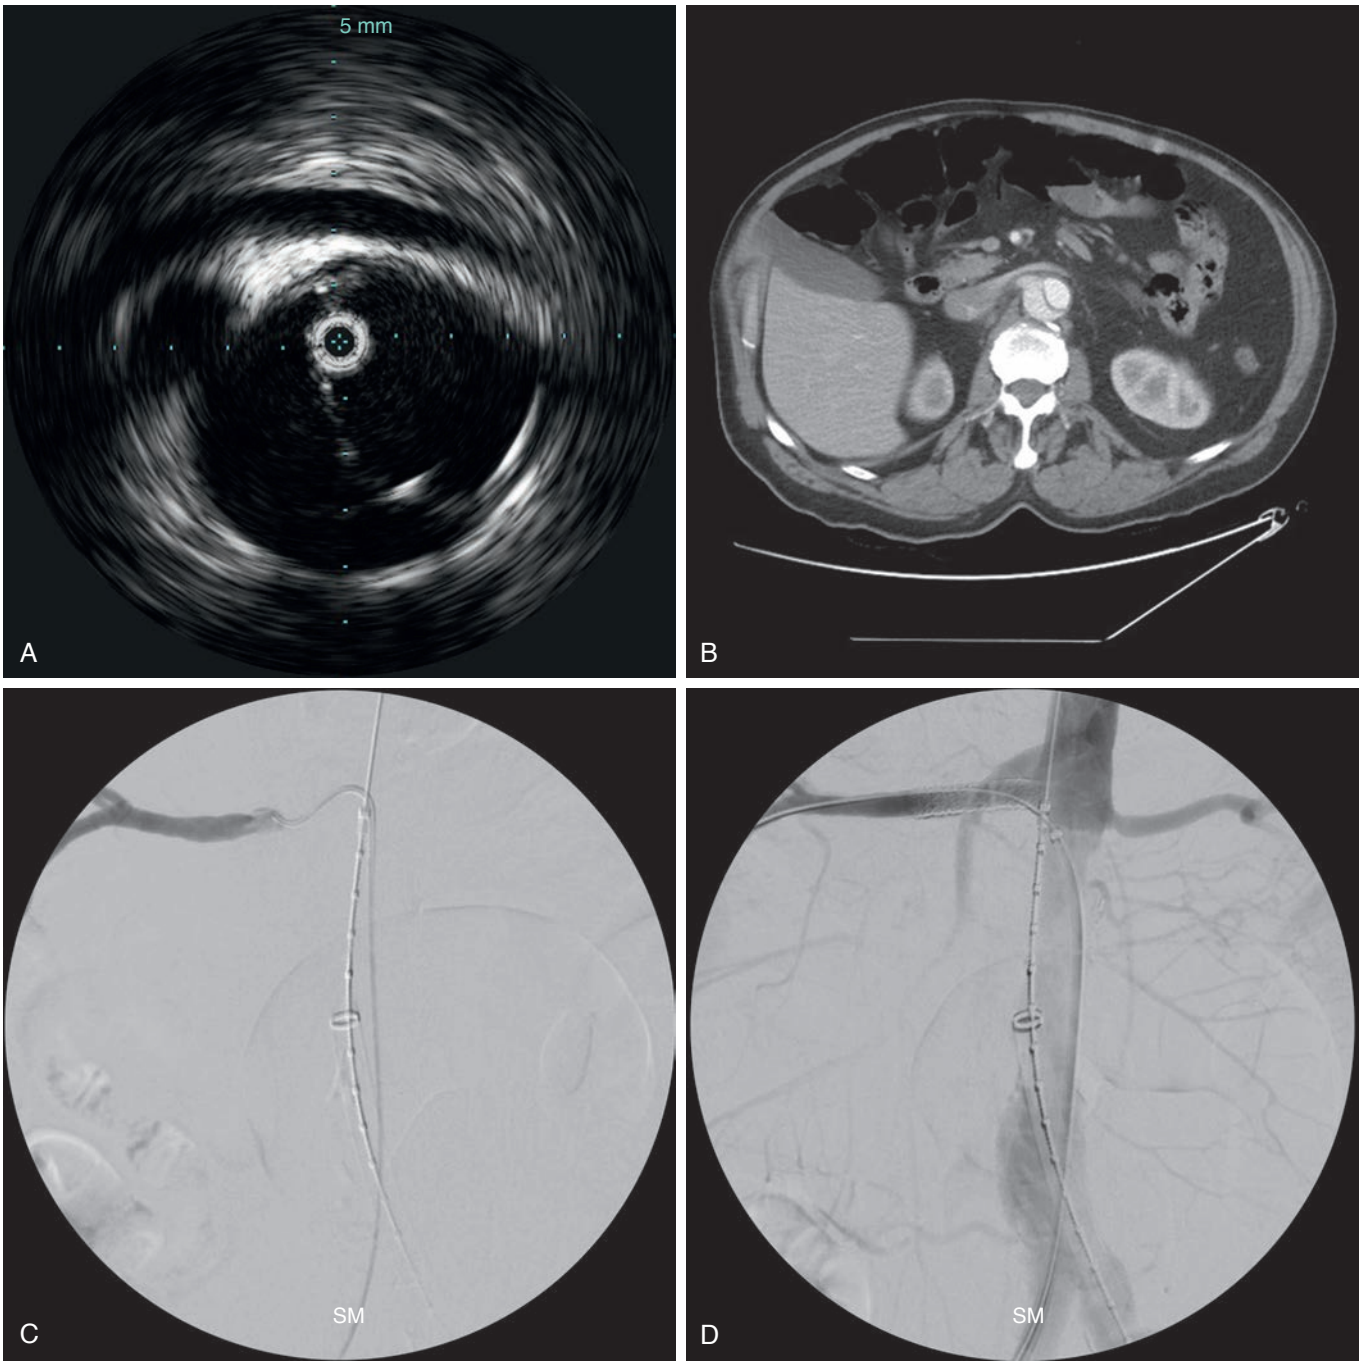

Figure 30.8 (A) The right renal artery coming off the false lumen. (B) Computed tomography angiography of dissection with the right renal artery coming off the false lumen. (C) Selective cannulation of the right renal artery. (D) Final placement of graft across the septum of the false lumen into the true lumen.

dissection, as it is difficult to determine by angiography alone whether a wire is in the true or false lumen. IVUS thus becomes especially useful in appropriately guiding wires into the arch, because it can confirm true lumen access. Where percutaneous fenestration of the intimal flap becomes necessary, IVUS may also guide this therapy.[79]

After Deployment

After deployment, IVUS can assess the completion and success of treatment. In Stanford type B dissections, IVUS can be used to examine the proximal deployment zone of the stent-graft and ensure that arch vessels are patent. It can also assess the ascending aorta for the presence of a retrograde dissection. IVUS can also be beneficial in the further evaluation of visceral vessels after the main stent-graft has been deployed, as it can identify continued malperfusion and guide further treatment. Postoperatively, expansion of the true lumen can be determined and the false lumen assessed for extent of thrombosis. In the case of type A dissections, IVUS has also been shown to be valuable in follow-up for patients with ascending arch replacement.[80]

Penetrating Aortic Ulcers and Intramural Hematoma

As with dissection, IVUS can be beneficial in the treatment of PAU and IMH.[81,82] The exact location and size of the ulcer can be visualized with IVUS, allowing appropriate proximal and distal landing zones to be determined. As in the treatment of other aortic pathologies, this information guides the choice of appropriate graft size and length. In the case of IMH, IVUS is especially useful in visualizing the arterial wall and distinguishing the intima and adventitia, allowing appropriate sizing to be obtained. After intervention, stent apposition can be clearly seen, ensuring that the ulcer is completely covered.

Venous Imaging and Applications

The ability of IVUS to characterize the extent and composition of lesions and provide information about vessel morphology is well documented in arterial and aortic pathology. However, IVUS is also well suited to the particular needs of venous imaging and has advantages over both single and multiplanar venography.[83,84] Although venography can characterize hemodynamics and visualize secondary veins, it does not allow for dynamic imaging, cannot accurately evaluate intraluminal pathologies, and does not provide accurate sizing information. IVUS can identify plaque morphology, trabeculae and intraluminal webs, neointimal hyperplasia, degree of thrombosis, immobile or inverted valves, and other deformities and abnormalities.[85] It can also provide measurements that may be difficult to obtain with venography. This is especially important in treatment of veins, since veins often have irregular circumferences and unusual contours, making the analysis of stenoses and vessel diameters difficult. By measuring cross-sectional areas and diameters of veins and evaluating the degree of disease or compression, IVUS can guide treatment and assist in the sizing of balloons or stents.

Venous Thromboembolism

In the case of deep venous thrombosis, IVUS can be useful in providing additional diagnostic imaging to identify lesions that may not be visualized by venography.[86,87] It has also been shown to be more sensitive than venography in detecting residual thrombus, thus recommending its routine use in thrombolytic regimens.[88] However, IVUS is more frequently utilized to treat venous thromboembolism in the inferior vena cava than in the peripheral vessels. Because IVUS can obtain accurate sizing measurements and identify branch vessels, it can guide the placement of filters.[89] Recent studies examining the use of IVUS instead of contrast venography for the placement of inferior vena caval (IVC) filters have found it to be a safe and effective technique.[90] Additionally, IVUS guidance in placing IVC filters can also eliminate the need to transport patients to an endovascular suite.[91] These benefits can be significant, especially for critically ill patients, as bedside IVC filter placement reduces the amount of contrast or fluoroscopy required while also eliminating the need for patient transfer.

Chronic Cerebrospinal Venous Insufficiency

As in other venous applications, IVUS aids in the diagnosis and treatment of chronic cerebrospinal venous insufficiency (CCSVI) because of its ability to assess and characterize vessel size and intraluminal abnormalities. The ability to evaluate valve abnormalities and endoluminal structures and constrictions is especially important in visualizing the jugular and azygos veins, as the nature of stenoses detected in major cerebrospinal veins is not always clearly seen in venography.[92] On IVUS, abnormal valves are easily seen because of the high echogenicity of thickened areas. One study assessing the accuracy of catheter venography as compared with IVUS and color Doppler (CD) sonography found that catheter venography was inferior to both IVUS and CD sonography in detecting jugular endoluminal malformations and that CD sonography underestimated the cross-sectional areas of internal jugular veins (IJV) as compared with IVUS.[93] Especially for the treatment of stenosis in an IJV, accurate sizing is difficult to obtain owing to the vessel's lack of a uniform circular shape. IVUS can therefore aid in proper balloon sizing, traditionally a challenge in treating IJV stenoses, and prevent complications secondary to improper sizing.

Venous Compression Syndromes

The use of IVUS in venous compression syndromes can allow for improved diagnosis and more effective treatment (Fig. 30.9). In studies of patients with May-Thurner syndrome, it was found that IVUS had a higher success rate than venography in identifying obstructions and in many cases was able to confirm diagnosis and influence endovascular management.[94,95] Similarly, a study evaluating IVUS and venography for patients with lower extremity venous stasis disease and for iliofemoral vein stenosis/obstruction found that IVUS was more sensitive and accurate than venography.[96] In the case of nutcracker syndrome, IVUS has been recommended to provide precise vessel sizing intraoperatively.[97] In 1994, a study examining the use of IVUS in

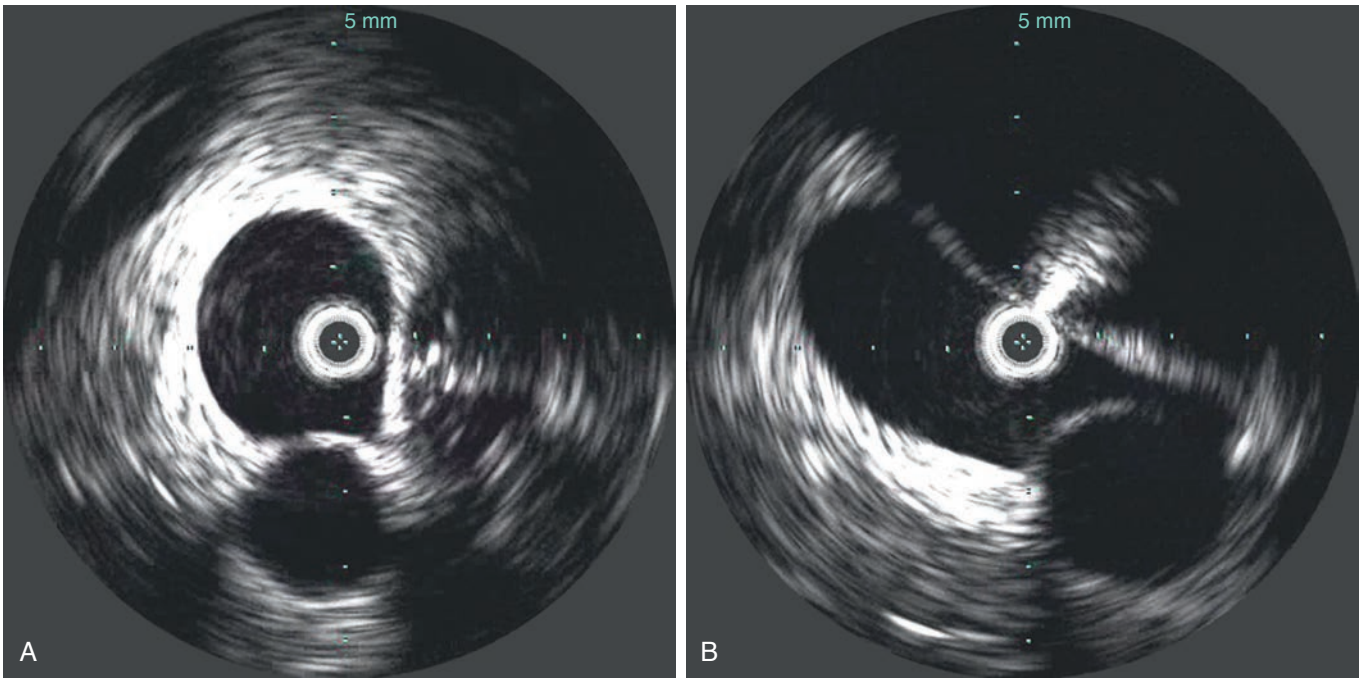

Figure 30.9 Intravascular ultrasound demonstrates an uncompressed vein (A) and a vein compressed by an artery (B) in venous compression syndrome.

the treatment of thoracic outlet syndrome found that IVUS was able to limit the extent of dissection necessary by providing real-time imaging of the release of extrinsic compression.[98] Several more recent studies of patients with thoracic outlet syndrome found that IVUS was able to provide a more detailed evaluation of the subclavian vein than venography, allowing for better identification of high-grade stenosis.[99,100] Overall, the precise imaging provided by IVUS recommends its use in venous compression syndromes.

LIMITATIONS AND RISKS

Comparison of Intravascular Ultrasound With Other Imaging Modalities

Intraoperative imaging options are limited. Although CTA and MRI provide high-quality imaging, they are not usable during a procedure. Imaging modalities besides IVUS that may be used intraoperatively include intravenous magnetic resonance imaging (IV MRI), optical coherence tomography (OCT), transesophageal echocardiography (TEE), near infrared spectroscopy (NIRS), angiography, and fractional flow reserve (FFR). Compared with other intraoperative imaging modalities, IVUS has clear benefits in some cases, while other modalities may be more suited for providing other types of information.[101]

Although angiography and venography are useful in that they provide details of blood flow and vessel contour, allowing visualization of collateral circulation and quality of flow, they are limited in that they do not allow characterization of wall disease and cannot accurately describe size or composition of lesions.[102] Similarly, FFR provides meaningful information about hemodynamic measures of lesion severity but cannot provide information about plaque composition.[103] It was found that in comparing IVUS with angiography for the evaluation and treatment of peripheral arterial disease, IVUS was superior in measuring diameter, areas of stenosis, plaque concentricity, plaque morphology, and calcification.[104] In terms of identifying plaque morphology, intravenous (IV) MRI is also able to characterize the composition of lesions and has been shown to be accurate in measuring vessel wall area.[105] However, although there have been significant improvements to decrease scan time and improve resolution, the associated cost, scan time, and presence of significant movement artifacts has thus far limited the effectiveness of IV MRI.[106,107] Many studies evaluating the efficacy of OCT have found that it is accurate and beneficial in characterizing plaque components in small arteries, such as coronary and infrapopliteal arteries, since it has significantly better spatial resolution than other intraoperative imaging modalities.[108] However, OCT's lack of penetrative depth, small field of view, use of contrast, and the fact that it requires blood removal from the vessel at the time of imaging diminish its usefulness with increased vessel size.[109-111] Overall, its ease of use and increased depth of penetration recommend IVUS for measurements and lesion identification in aortic and peripheral treatments.

Limitations and Risks of Intravascular Ultrasound

Although the risks associated with the use of IVUS are minimal, IVUS does require an invasive procedure and thus carries the risk of bleeding or clotting in the area of catheter insertion and possible damage to blood vessels. However, since IVUS is often performed in conjunction with other invasive procedures, its use adds little additional risk. Major complications are reported to occur in less than 0.5% of procedures and usually occur

during surgical intervention rather than diagnostic imaging.[112] Similarly, the use of IVUS does add additional cost to a procedure, with basic system implementation costing $70,000 to $120,000 and an additional cost per patient of around $600 for a disposable catheter tip.[113] However, studies of the long-term clinical outcomes of IVUS use suggest that the decreased number of postoperative complications and reduced need for reintervention may offset these costs.[114-116]

Another limitation of IVUS is the quality of imaging. A 2014 study of IVUS, OCT, and IV MRI compared the three imaging modalities and found a comparatively lower quality of imaging with IVUS, with low signal-to-noise ratios and significant artifacts and interference.[117] Normal ultrasound systems have frame rates between 50 and 750 frames per second, whereas current IVUS systems run at about 30 frames per second, accounting for the difference in image quality, a common complaint of vascular physicians using IVUS. The quality and utility of IVUS images is also user-dependent. Appropriate catheter and frequency selection is key, but other system settings such as gain, compression and rejection (specific to certain mechanical scanners), time-averaging and persistence, and gamma curves must also be adjusted properly to reduce image artifacts and decrease noise while ensuring that targets are not blurred or obscured and that inaccurate measurements are not introduced.[118] Physicians utilizing IVUS must recognize potential pitfalls in interpreting images, being aware of near-field and motion artifacts as well as artifacts created by transducer position, taking into account catheter obliquity and vessel curvature as well as angle-dependent artifacts that may be created by catheter eccentricity.[119,120] Technician support should be available and standards, protocols, and education should be established to ensure that IVUS use is as effective and efficient as possible.

FUTURE ADVANCES

In the future, technological advances may overcome some of the limitations of IVUS, allowing for improved imaging and ease of use. Currently, IVUS creates images with axial slices at 90 degrees to the probe, which limits its usefulness in guiding wires through chronic total occlusions. Recent advances in technology to overcome this limitation include the development of a single-chip forward-looking imaging system created by integrating capacitive micromachined ultrasonic transducer (CMUT) arrays with front-end electronics.[121-123] This type of array may also allow for IVUS use on guidewires, thus simplifying procedures by eliminating the need for separate catheters.[124,125]

Identification and characterization of plaques with IVUS may also be improving. The PROSPECT II trial is currently under way to evaluate the efficacy of a cardiac catheter combining IVUS with NIRS to help identify and characterize vulnerable lipid-rich coronary plaques.[126] NIRS has been shown to be more accurate than IVUS in characterizing soft plaques, so its combination with IVUS contributes to the accurate characterization of vulnerable plaques by providing precise information about lesion morphology.[127-129] Combination technologies, such as systems that integrate FFR or NIRS with IVUS, along with other types of technology that integrate IVUS with treatments such as angioplasty or ablation, may be the most promising developments for IVUS in the years ahead.[130]

BACKGROUND

Vascular surgery has pioneered the development of various novel, minimally invasive catheter-based endovascular procedures within the confines of the open surgical operating room (OR). Portable image-intensifier–based C-arm imaging systems were the original imaging platforms on which catheter-based therapies have evolved in the hands of vascular surgeons. Thus far, the portable C-arm imaging system has been the signature imaging tool in the OR that heralded the entry of open vascular surgeons into the endovascular interventional space. With the advent and rapid evolution of imaging technologies in the OR, vascular surgeons are now required to have an increased understanding of both basic and advanced imaging techniques.

As the complexity of endovascular interventions has evolved—with advancements in endovascular devices such as catheters, stents, and stent grafts—so imaging technologies have evolved in parallel. Image intensifiers in the portable C-arm imaging systems have been replaced with flat-panel–based digital image detector systems and provide better image quality, signal-to-noise ratio, and dynamic range with little to no geometric distortions.[1] However, the portable nature of these C-arm systems is still a limitation for having a more powerful x-ray tube with better cooling capabilities. Because of the advanced imaging demands for longer and more complex vascular procedures, fixed angiography imaging suites, traditionally the province of cardiologists and interventional radiologists, have become commonplace within the operating environment. Often referred to as *hybrid rooms*, they allow for both "open" surgical procedures and catheter-based endovascular interventions to be satisfactorily performed in the same operating suite. Although expensive, hybrid ORs, for the very first time, have paved way for intraoperative 3D imaging in the hybrid OR.[2-4] This has been followed by technologies like flexible endovascular robotics and integration of multimodal imaging modalities such as transesophageal echocardiographic imaging (TEE), intravascular ultrasound (IVUS), preoperative computed tomography (CT), and magnetic resonance imaging (MRI) within the hybrid OR. Indeed, the rapid evolution of imaging and endovascular devices is symbiotic and synergistic. Along with this evolution of

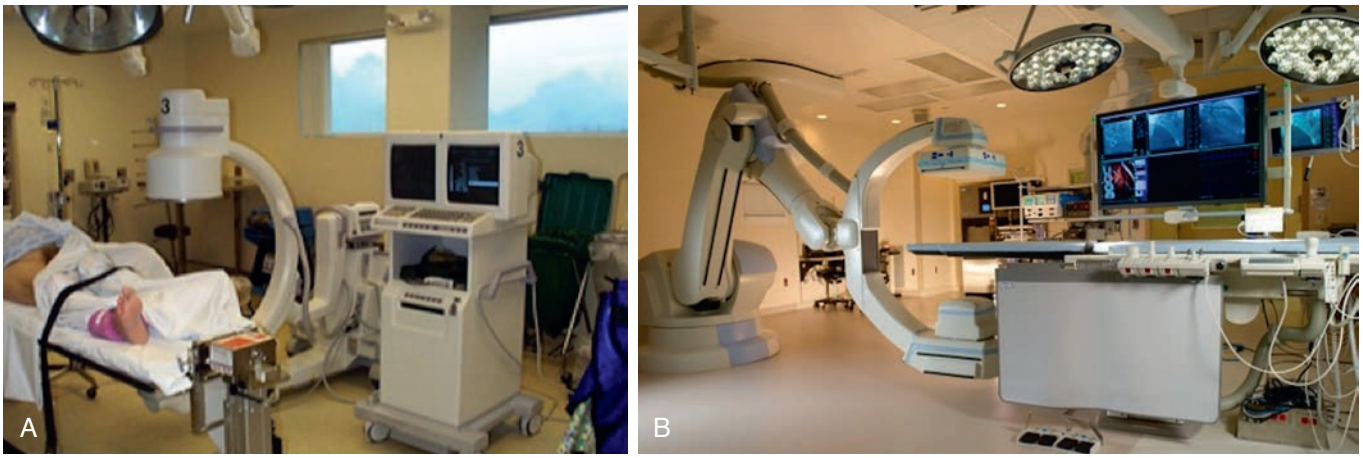

Figure 31.1 Figure illustrating the imaging (r)evolution in a vascular operating room from a portable C-arm with radiolucent patient table (A) to a robotic angiographic imaging suite with advanced intraoperative 3D imaging and image fusion capabilities (B).

intraoperative imaging, however, there is an increasing concern about the amount of radiation to which surgeons and interventionalists are being exposed. Consequently, new methods have been developed for monitoring radiation exposure and minimizing the amount of radiation employed during these procedures.

The goal of this chapter is to impart a broad overview of the recent evolution of advanced x-ray and multimodality imaging techniques for vascular surgery and to provide a glimpse into potential future imaging and catheter navigation technologies that could improve the safety and efficacy of minimally invasive endovascular procedures while minimizing the amount of radiation used in hybrid ORs.

X-RAY IMAGING AND HYBRID OPERATING ROOMS

Although alternate imaging modalities such as ultrasound and MRI are available and less invasive, diagnostic imaging for endovascular interventional and surgical procedures has primarily been superseded by multislice CT imaging and invasive 2D x-ray fluoroscopy and angiography. Despite lacking depth, the primary advantage of invasive x-ray angiography is better spatial resolution of around 0.2 mm in imaging smaller vessels with temporal resolution of ~20 ms after injecting iodinated contrast agent as a bolus into the vessel of interest.[5]

Portable C-Arm Imaging Systems

Although the portable image-intensifier–based C-arm imaging system has been the staple imaging modality for vascular surgery for many years, it has continued to evolve with technological advancements. For example, the image-intensifier–based x-ray detector system has been replaced by the flat-panel–based digital detectors; these have better sensitivity and lower noise levels, potentially offering better distortion-free image quality at a lower radiation dose.[1] In addition, newer x-ray tubes in mobile C-arms with higher power generators—in the order of 25 kW—and better cooling capabilities enable higher penetration power even in obese patients. Moreover, these allow uninterrupted imaging for longer endovascular procedures than was possible with fixed C-arm angiographic imaging systems.[6,7] Radiation exposure to both patients and the surgery team needs to be carefully considered during the usage of mobile C-arm imaging systems in the OR.[7,8] Perhaps the most revolutionary development is 3D imaging in upcoming mobile-C-arm imaging systems. Although there has been some preliminary work using this 3D imaging technique during spine and orthopedic procedures,[4,9,10] routine clinical use of this technology for vascular imaging is still in our future.

Recent advancements in mobile C-arm imaging systems, including image fusion and overlay capabilities, are very relevant. In most vascular surgery practices, the portable low-end mobile C-arm imaging system continues to be the primary imaging modality or a backup imaging option to the fixed hybrid OR. Moreover, portable-C-arm-imaging–based interventional suites have been increasingly used to set up office-based vascular practices (Fig. 31.1). With the technological gap between portable and fixed C-arm imaging systems narrowing, portable C-arms could represent a very practical and economical option for an outpatient interventional or endovascular suite, permitting both the technical and professional revenues to be captured in an office-based vascular surgery practice.

Fixed C-Arm Angiographic Imaging Systems

Typically the concept of a hybrid OR is one where high-resolution angiography can be performed in the same room—even concomitantly—as complex open surgical procedures. Over time, the concept of hybrid OR has been generalized, and not all hybrid ORs are equal. In this context, a modern, high-end hybrid OR often references one that is equipped with a fixed C-arm imaging system that can enable open, endovascular, or hybrid minimally invasive surgical procedures. A typical fixed C-arm angiographic imaging system can be floor- or ceiling-mounted

and is integrated to the OR table, with the option of surgical tables to improve the utilization of the hybrid suite across various surgical specialties.[11] In addition, fixed C-arm angiographic imaging systems mounted on a robotic arm offer versatility and the option of bringing the imaging system to the patient whenever needed during the surgical procedure (see Fig. 31.1).[12]

Concept of As Low As Reasonably Achievable and "Low"-Dose Radiation to the Patient

Monitoring radiation dose delivered to the patient and training and awareness of radiation safety for the entire OR team is critical but often overlooked. Adherence to ALARA (As Low As Reasonably Achievable) strategies should be a key part of training and must not be seen as a matter of convenience. However, in a recent anonymous survey of vascular surgery trainees, 45% had no formal training in radiation safety and 43% were unaware of annual maximum acceptable levels of radiation exposure.[13] In the same study, the vascular trainees also perceived themselves as practicing ALARA strategies, when they perceive that their attending physicians as regularly practicing ALARA strategies.[13,14] This further highlights the value and immediate need for improvement in radiation safety measures to optimize the radiation dose delivered to both patient and the operating team.[15-20]

Protection From Radiation Scatter

One of the challenges associated with radiation safety education is that the training is based on non-intuitive understanding of radiation scatter patterns in the OR. However, in certain scenarios, stepping away from the patient to respect inverse square law is not always feasible. The scenarios related to radiation safety must be redefined from an OR perspective. Recent studies have attempted to map radiation scatter patterns in the OR using personal wireless dosimeters,[21-23] which would pave a great step into the future of radiation safety training measures.

Designing a Hybrid Operating Suite

When designing a high-end hybrid OR, it is very important to consider the following factors: (1) type of procedures that will be performed in the room; (2) adequate area and ceiling height of the room; (3) location and proximity to other ORs or preexisting interventional suites and intensive care units; (4) recruiting experienced specialist architects, local hospital planning, and construction team; (5) involvement of all primary users and surgical and anesthesia departments throughout planning and execution process; (6) including strategic vendors; (7) determining appropriate staffing with dedicated OR managers, nurses, x-ray technologists, and a backup team; and more importantly, (8) adequate communication, education, and training of the entire OR team. Building a hybrid OR service typically take a few months to years from design to construction and being fully operational. It involves cohesive interaction between various clinical disciplines working together with specialist architects, imaging equipment vendors, OR equipment vendors, and hospital biomedical engineers. Therefore detailed planning that accounts for ergonomics, clinical workflow considerations, integration of imaging and informatics, and adequate risk management strategies is paramount. After all, these are some of the most expensive ORs built in the hospital and require careful planning and execution.[11,24,25]

Although installation of the imaging system may often seem like the most important decision, it is not the main challenge. Configuring and installing all the other OR accessories including overhead lights and booms, anesthesia equipment, imaging equipment, and cardiopulmonary bypass pumps all require careful planning and workflow considerations. Adequate staffing and training is another major often overlooked factor in the final functioning of a hybrid OR. Dedicated, highly trained interventional technologists and OR nurses familiar with both x-ray and multimodality 3D imaging are essential. It is also important to train some of the technologists to act as "special procedure" technologists and nurses to ensure adequate exposure and to maintain experience and skills training. In summary, tight integration of patient scheduling, audio, video, imaging, patient monitoring, and hospital informatics systems in a hybrid OR should enable seamless display and access to all the preoperative, intraoperative, and postoperative information during the surgical interventions.

Advanced 3D Imaging and Image Guidance Techniques

Preoperative Imaging and Why This Impacts Procedural Performance

Until recently, preoperative CT or MRI scans were used as tools for diagnosis and decision-making. However, for presurgical planning, a surgeon needs to review the images in multiplanar (Fig. 31.2), volume-rendered reconstructions (Fig. 31.3) and plan the endovascular or open surgical intervention. The evolution of endovascular stent grafting spurred parallel development of third-party, postprocessing software packages that facilitate advanced image visualization techniques, including multiplanar reconstructions, and now even provide advanced virtual stent graft planning software.

The latest generation of hybrid ORs has evolved with advanced imaging techniques such as acquiring three-dimensional cone-beam CT imaging, and advanced image fusion techniques such as 3D-3D image fusion and 2D-3D image fusion to incorporate preoperative imaging data. Consequently, the technique and quality of preoperative imaging is increasingly important not just for diagnosis but also for intraoperative use. This should be kept in mind during acquisition of preoperative images using CT and MRI protocols that generate high-resolution, thin-slice acquisitions that facilitate accurate 3D rendering and image fusion techniques. For example, during imaging for type-II endoleak evaluation, acquiring high-resolution 3D datasets encompassing both arterial and delayed phase enables the surgeon to understand and target the inflow and outflow patterns within the endoleak-feeding vessels. Once endovascular targets are defined on the preoperative CT images, these same targets can be overlaid onto the fluoroscopic image to guide interventions such as selective embolization.[26-28] In the long run, this will

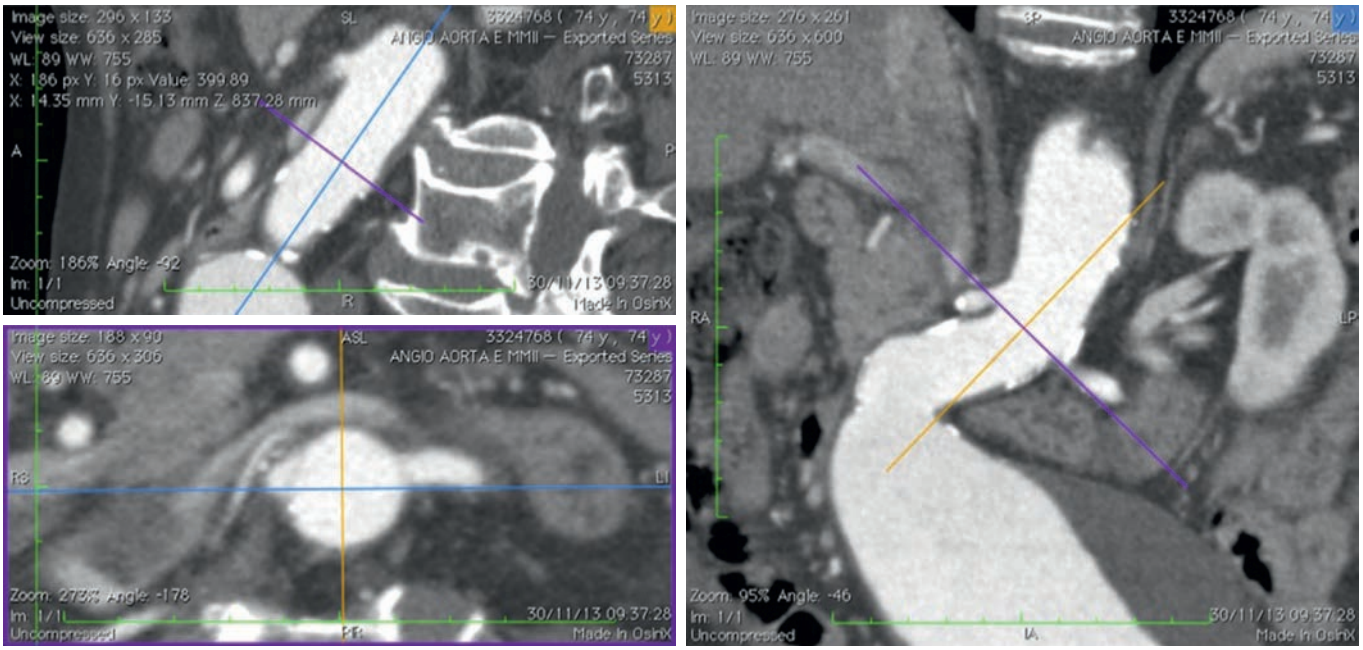

Figure 31.2 Standard multiplanar reconstruction (MPR) of three-dimensional CT dataset using commercially available software (OsirixMD). Angulation of aorta and other branches can be inferred accurately from such MPR rendering techniques and can be used to optimize the C-arm angulations during imaging and stent deployment.

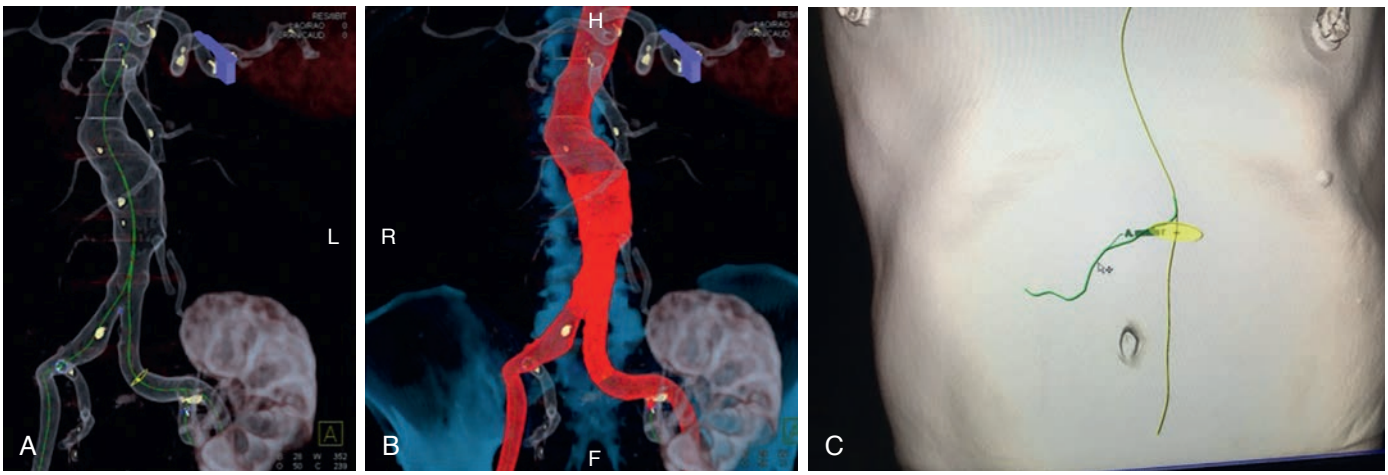

Figure 31.3 (A and B) Volume rendered reconstructions of CT datasets using a transparent visualization preset after segmentation of aortic centerlines using a prototype software (Siemens Healthcare GmbH). Transplanted kidney in the left iliac fossa can be seen, and the angulation for left internal iliac artery was defined using the CT datasets during the endovascular repair. (C) Surface rendering reconstruction of patient from the CT datasets overlaid with centerlines of aorta and right renal artery after image segmentation.

optimize judicious usage of radiation and contrast agents in patients during diagnosis and interventions.

Even when an open surgical procedure is planned, surface rendering of a CT scan will show the surface features of the patient such as prior surgical scars, nipples, and umbilicus (see Fig. 31.3C). This can be directly used for surgical incision planning after a surface-to-surface image co-registration process.[29] Understanding how to interact with the 3D imaging datasets can transform endovascular procedural planning and optimize incision planning and targeted approaches for minimally invasive open surgical procedures.

In summary, preoperative imaging and planning helps with achieving appropriate device sizing, avoiding parallax by selecting optimal C-arm angulation and providing a 3D roadmap during interventions after image fusion. Finally, the cardiovascular system is highly dynamic: the aorta varies in diameter and position with cardiac and respiratory cycle, the inferior vena cava (IVC) varies in diameter with respiration, and the aortic dissection septum moves extensively during systole and diastole. The emerging role of dynamic multimodality imaging such as CT and MRI in understanding the cardiovascular system is undisputable.[30,31] Increasingly, these dynamic images are being

incorporated into both diagnosis and interventional procedure guidance, such as endovascular stent grafting for complex aneurysms and dissections of aortic arch and ascending aorta.

C-Arm Cone-Beam Computed Tomography Imaging

In addition to 2D x-ray fluoroscopy and angiography, recent fixed C-arm angiographic imaging systems provide the additional capability of intraoperative 3D imaging by acquiring a series of 2D projections while the C-arm rotates around the patient for 200 degrees and reconstructing them as 3D cone-beam CT images. The development of high-contrast 3D angiographic imaging within the interventional neuro-radiology suites, and more recently, 3D cone-beam CT imaging capabilities, have revolutionized minimally invasive catheter-based interventions.[28,32-34] This cone-beam CT imaging technology and associated clinical applications have historically been well adopted and integrated in neuro-interventional and interventional radiology suites. To ensure consistency, the term CBCT will been used from here on to refer to intraoperative cone-beam CT imaging technique. Of course, different imaging vendors tend to use their own trademark terms—such as *syngo* DynaCT (Siemens Healthcare GmbH, Germany) or XperCT (Philips Medical Systems) or InnovaCT (General Electric Medical Systems)—adding to confusion surrounding individual room capabilities and adequate training. However, the penetration of these intraoperative 3D imaging and image fusion techniques into the ORs is rather recent and comes with its own challenges and opportunities. Evolution of such 3D imaging modalities in the OR could impact both the conduct of open surgical and endovascular procedures and could support the surgical community's further development of incremental technologies such as flexible-catheter robotics. Consequently, CBCT is a very versatile intraoperative imaging tool that can be considered the gateway for application of very sophisticated CT imaging applications in the future.[2,11,28,35,36] Along with this heavy dependence on x-ray imaging, however, there is an increasing concern about the amount of radiation exposure for surgeons and OR personnel.[19,37] Consequently, newer methods have been developed for monitoring radiation exposure and minimizing the amount of radiation delivered to the patient and surgical team during these procedures.[38,39] Nevertheless, the potential complementary role of other radiation-free tracking or imaging techniques, such as optical or electromagnetic device tracking and ultrasound and MRI, needs to be explored, especially for complex open and endovascular surgical procedures.

Image Fusion and Guidance Techniques

While having access to a fixed hybrid OR with its multiple advanced imaging capabilities is necessary for the conduct of complex endovascular procedures, the ability to perform a CT in the OR represents the next huge technological leap for vascular surgeons. It allows them to understand the intraoperative status of vasculature and stent grafts immediately after deployment to rule out potential endoleaks, kinking, and beaking of stents, thus potentially avoiding a future reintervention.

However, the core functionality of such an intraoperative imaging system is the ability to create a 3D DICOM dataset in the hybrid room. Until the real CT imaging capability in the OR is adopted into routine, image fusion of preoperative datasets can be performed using 2D3D and 3D3D image fusion techniques.[20,40,41] This minimizes additional radiation, avoids giving additional iodinated contrast usage, and allows the operator to use the entire prior computed tomographic angiography (CTA) dataset, which is often much more extensive than that which can be obtained using CBCT.

3D3D image fusion technique involves co-registration of a noncontrast CBCT dataset with a preoperative CT or MR dataset. After image fusion, the structures of interest electronically annotated in the preoperative dataset can be overlaid on the fluoroscopic image during intervention.[36,42,43] The significant advantage of this 3D3D image fusion is that relevant structures can be matched between two 3D datasets and no additional angiographic contrast is necessary during intervention. Additional nonradiation imaging such as IVUS or low-dose carbon-dioxide (CO_2) angiography can be used to verify and complement 3D3D fusion imaging. Furthermore, automated image segmentation algorithms can extract relevant vascular landmarks such as aortic centerlines, renal artery, and internal iliac artery ostia and overlay them onto fluoroscopy (see Fig. 31.3A and B). To demonstrate this image fusion process, we describe our workflow for endovascular abdominal aortic aneurysm repair (EVAR) using endografts. First, the patient is typically evaluated using outpatient thin-cut multislice CTA (MSCT). Next, after the patient arrives in the hybrid OR and is prepped and draped, a low-dose noncontrast CBCT is typically performed. A 3D postprocessing workstation was used to fuse noncontrast CBCT with the preoperative MSCT. An automated image segmentation algorithm then segments the vascular structures and relevant landmarks consisting of the aorta and its major branches. Then, after image fusion, all the relevant vascular structures segmented were immediately overlaid on the live fluoroscopy, even before the first injection of contrast agent during the procedure. Image fusion is typically achieved by aligning and fusing bony structures between CBCT and MSCT datasets. In theory, if the ribs, vertebrae, and pelvis are aligned, then the vascular structures should also be aligned. Bony structures are used to perform fusion because they are easily visible on noncontrast CBCT. However, there are a few limitations: if the patient is positioned differently during preoperative imaging and during the intervention, aligning bony landmarks may not achieve accurate alignment of vascular structures. Typically patients' arms are positioned abducted above their heads during preoperative CT imaging and are positioned adducted by their sides in the OR. Therefore dedicated context-specific image fusion techniques based upon vascular wall calcifications have been developed.[41,44,45] The vascular wall calcifications can be thought of as the bones of the blood vessels. This technique is possible and reliable because most of our elderly EVAR patients have extensive calcification easily visible on MSCT and CBCT. Based on our preliminary experience, we have found this to be a highly accurate method for fusing vascular structures.[44]

Another recently available image fusion technique can co-register preoperative images to fluoroscopy without the need for acquiring noncontrast CBCT imaging. This 2D3D image fusion technique works by acquiring two fluoroscopic images acquired at least 30 degrees apart and fusing them with digitally reconstructed radiographs derived from preoperative 3D images.[40,46] Although this 2D3D image fusion simplifies the image fusion workflow, the accuracy of this technique needs to be further validated.[47] In the future, it is likely that the image fusion technique will be chosen based upon the clinical context and accuracy necessary for conducting the procedure safely. For the time being, until robust automated workflow specific algorithms are routinely available, injection of dilute contrast agent or CO_2 angiography is typically performed to confirm image fusion accuracy before device deployment.

Needle Guidance

Not all procedures performed by vascular surgeons are endoluminal and permit target access via the peripheral vasculature. A typical example of a needle-based procedure is translumbar embolization of aneurysmal sac for treatment of type 2 endoleaks.[27,48,49] Conventionally this has been performed using bony landmarks, as seen on fluoroscopy, and carefully avoiding the puncture of the stent-graft.

Here the workflow for 3D needle guidance has been illustrated using CBCT imaging and dedicated needle guidance software (*syngo* needle guidance, Siemens Healthcare GmbH). The ability to perform intraoperative CBCT and fuse with a previously acquired MSCT or MRI in which the endoleak and feeding vessels are delineated is beneficial. Even with the patient placed prone on the hybrid OR table, the stent grafts from two datasets can be aligned to achieve accurate image fusion. The target endoleak site is typically electronically marked in the preoperative CT dataset (arterial or delayed phase). This virtual needle path electronically marked on the CT dataset is overlaid on 2D fluoroscopy during needle progression. In addition, the integrated laser crosshairs built in the detector helps with guidance of needle entry point in the skin to achieve ideal bull's-eye trajectory to reach the target endoleak site. Availability of virtual needle path overlay in all C-arm angulations helps with accurate 3D guidance and needle progression to the endoleak site (Fig. 31.4). Once the target is accessed by the needle, confirmation can be achieved by retrograde blood aspiration from endoleak site or by a repeat CBCT imaging. Then, a guidewire was placed and a sheath can be positioned to continue with the embolization procedure in standard fashion using embolization coils or liquid embolic agent.

Challenges and Next Steps

One of the current challenges associated with image fusion is that most solutions do not typically consider the vascular deformation caused by stiff wires, devices placed inside the lumen of the blood vessels. There are two approaches currently being evaluated to limit this problem: (1) acquiring an intraoperative 3D dataset (CBCT) after the device induced vessel deformation has occurred, and (2) deriving deformable registration of the preoperative dataset by acquiring biplane fluoroscopic images of device and reconstructing the 3D device followed by development of algorithms that automatically compensate for iliac straightening and can predict the final position of the internal iliac artery origin. In addition, patient-related movements need to be handled appropriately during image fusion.

A few more important practical challenges include optimization of appropriate preoperative imaging protocols, adequate training of the OR technologists and personnel in using these advanced imaging, and image fusion capabilities.

Optical and Electromagnetic Tracking for Image Fusion and Guidance

Although image fusion is currently performed by fusing two DICOM datasets using 3D3D fusion or using two fluoroscopic images using 2D3D fusion, there are other methodologies for fusing preoperative datasets in the OR. For example, non-radiation-based methods may be used: (1) electromagnetic tracking of sensors placed in the instruments and electromagnetic field generator placed in the surgical suite or (2) optical scanning of the patient's surface contours and fusing the surface to the surface-rendered from the CT datasets. Such non-radiation-based fusion techniques could be much more cost-effective than using a conventional hybrid room and could potentially be used in every OR for surgical procedure guidance. For example, the incisions for minimally invasive cardiac surgical procedures could be optimized, such as localizing the left internal mammary artery to left anterior descending coronary artery bypass graft prior to surgical incision for a minimally invasive MICS-CABG procedure.

ENDOVASCULAR NAVIGATION AND CATHETER ROBOTICS

The use of endovascular catheter robots represents yet another technological leap and could potentially transform endovascular navigation, providing a level of accuracy, maneuverability, and stability that cannot be achieved using manually controlled catheters. This endovascular robotic technology leverages a combination of minimally invasive remote catheter interventions with the ability to operate catheters from a distance (removing the need for the interventionist to be tableside) and to provide precise endovascular robotic control and navigation.[50-52]

Currently there are two endovascular catheter-based robotic systems (Fig. 31.5):

a. *CorPath precision vascular robotics system* (Corindus, Waltham, Massachusetts) is currently approved only for coronary interventions: Any off-the-shelf catheter mounted onto the robotic console is steered manually to the coronary arteries, and the robotic system enables the delivery of balloons and stents to the target vessel to facilitate therapeutic interventions.
b. *Magellan endovascular robotic system* (Hansen Medical Inc., Mountain View, California): Dedicated telescopic robotic catheter with four pull wires built into the catheter and sheath lumen enables precise robotic control and stability

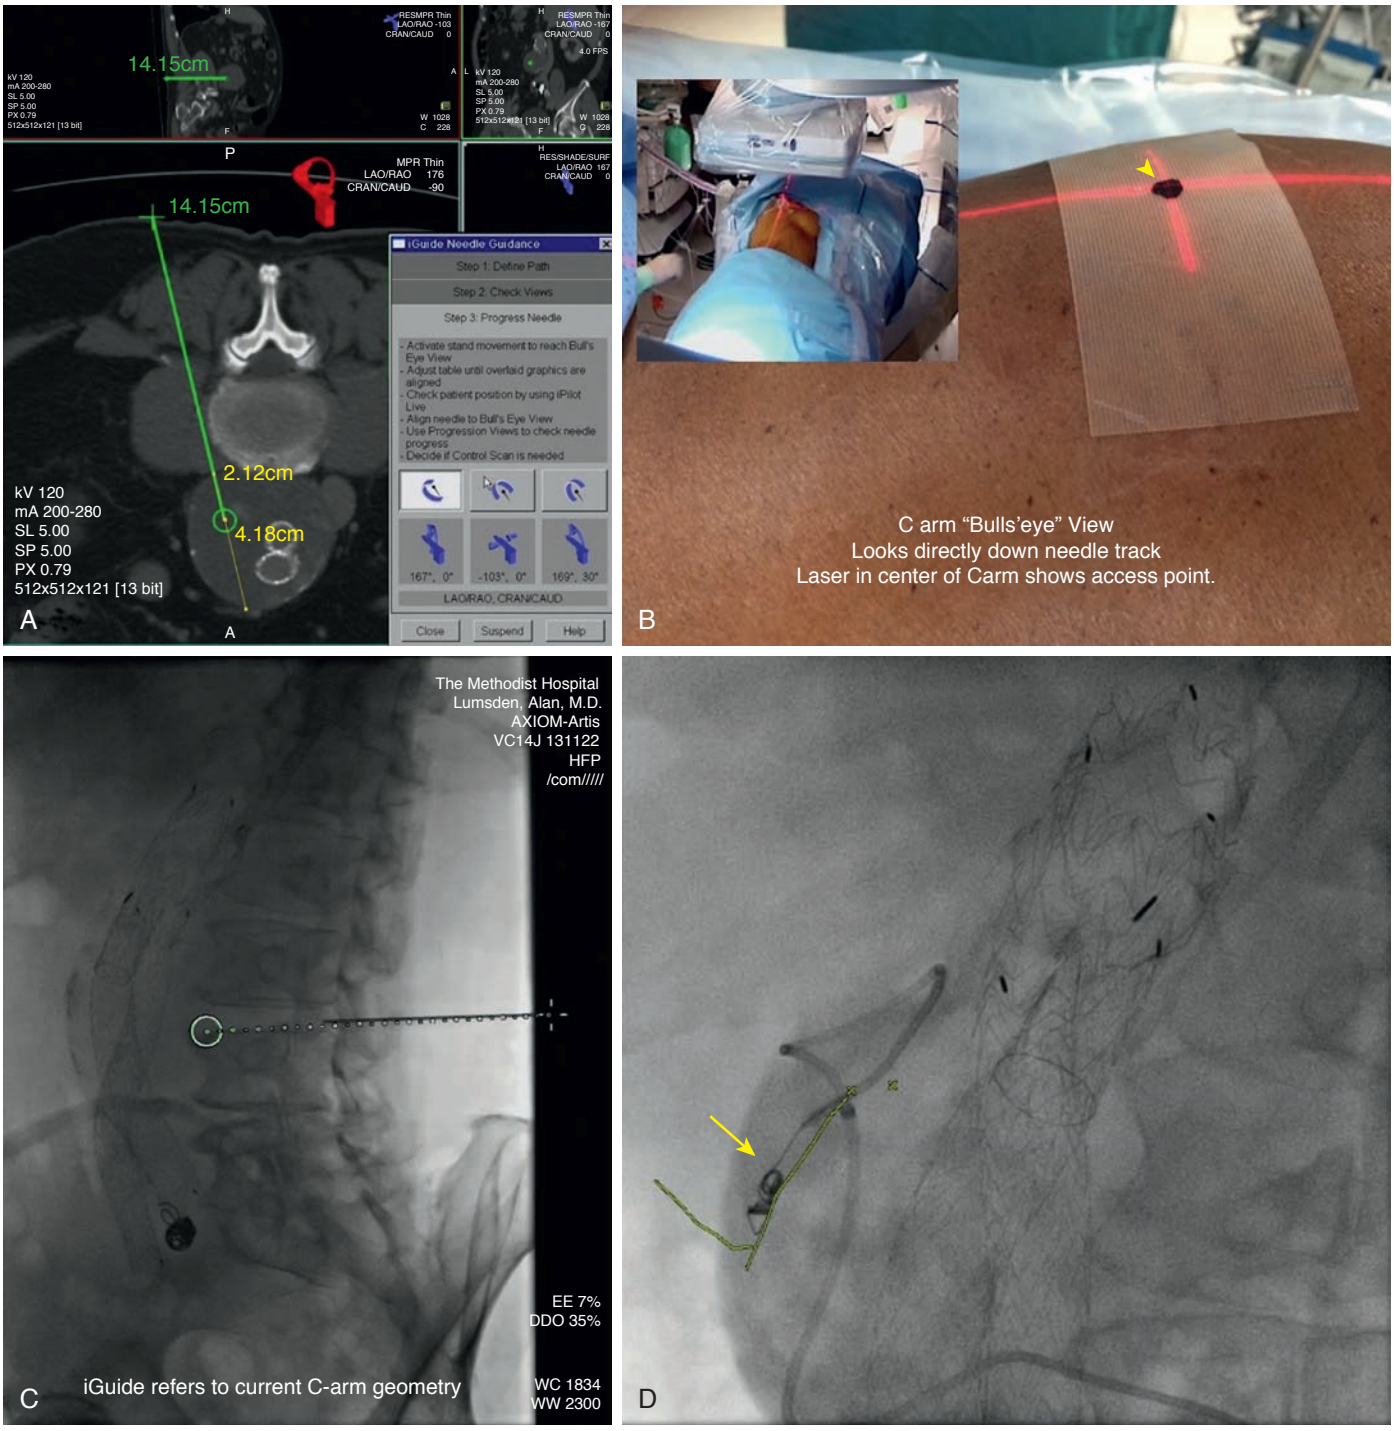

Figure 31.4 Workflow for 3D Needle Guidance for Type-2 Endoleak Embolization. of catheter, sheath, and guidewire steering, enabling target vessel cannulation.

Until recently, robotic catheters have not been integrated into the imaging system upon which all endovascular interventions are dependent. We are, however, beginning to see developments that allow path planning from 3D reconstruction models, followed by semiautonomous movement of the catheter to a target, termed as "assisted navigation." This, in our opinion, is the ultimate opportunity to integrate precise 3D navigation with high-resolution 3D imaging.[53] This novel "assisted" robotic navigation capability has recently been demonstrated by Schwein et al. in an ex-vivo aortic aneurysm model. Continuous electromagnetic tracking provides feedback on catheter localization, shape, and motion using EM sensors embedded within the robotic catheter. Such electromagnetic triangulation of an EM enhanced robotic system permits feedback on catheter motion, correction of catheter movement, and autonomous movement along a predetermined trajectory. Future endovascular navigation will be enhanced by non-radiation-based endovascular device localization, possibly facilitated by optical fiber based or electromagnetic-sensor–based tracking or other upcoming tracking technologies.

THE FUTURE HYBRID OPERATING SUITES

While the development of CBCT imaging capability fundamentally enhanced the functionality of the hybrid OR, performing the CBCT can be challenging at times and requires increased technical support. To bolster the intraoperative imaging capabilities, some future hybrid ORs are now increasingly being installed with integrated fully functional conventional multislice CT imaging systems. These CT imaging systems reside in the OR, mounted on the rails and slide over the patient whenever cross-sectional imaging is required. This could be a transformational technological development for minimally invasive image guided surgery that can impact patient care directly. For example, unstable patients with suspected pulmonary embolism may go straight to such a hybrid OR, where intensive care can be continued, a diagnosis can be confirmed or refuted, and therapy from lysis to open pulmonary thrombectomy can be immediately instituted. Such a room can transform trauma management, allowing immediate angiography, CT imaging, and appropriate therapy—either interventional or open surgical procedures instituted. However, these rooms also present some operational challenges in that cross-trained radiology technicians, knowledgeable in both angiography and CT scanning, and careful consideration of surgical workflows are necessary.

An additional imaging combination being explored is combined angiography suite and MRI imaging systems. An MRI must be kept in a magnetically isolated environment, separate from the main angiography suite or OR. Patients must be transported into the adjacent MRI imaging system using a dockable table transfer system whenever imaging is needed. Although having a dynamic imaging modality such as MRI is attractive, currently there are few uses for such a combination system in cardiovascular interventions; however, they are now being actively used in neurosurgery.

While the possibilities are endless, and "chance favors only the prepared mind," it may be prudent to say that the future of minimally invasive endovascular and open surgery is bright at the very cusp of upcoming "novel imaging and navigation" technologies on the horizon.

Nutrition 400
ETHICAL AND LEGAL CONCERNS/FRAILTY ASSESSMENT 401

Preoperative assessment and management of vascular patients are of utmost importance because patients with vascular disease have multisystem involvement, including cardiac, cerebrovascular, renal, and peripheral arterial disease, as well as multiple other comorbid conditions. Consequently, they are at high risk for complications after surgery. A focused preoperative evaluation should identify potential treatable risk factors so that complications can be minimized and optimal choices can be made for the timing of elective surgery.

GENERAL PREOPERATIVE RISK ASSESSMENT

Every patient undergoing elective vascular surgery should have a preoperative assessment that includes a thorough history and physical examination, blood analysis, and electrocardiogram (ECG). In addition, if there are patient-specific areas of concern, these should receive a more detailed, directed evaluation. A complete blood count should be obtained to screen for the presence of infection, to ensure an adequate red blood cell volume, and to rule out a serious hematologic abnormality. Serum electrolyte concentrations should be evaluated and corrected when abnormalities exist. Of special importance are serum potassium, calcium, and magnesium levels because if they are abnormal and not corrected, they can lead to deleterious cardiac effects. Furthermore, because renal disease is so prevalent in vascular patients and some vascular interventions may compromise renal function, a baseline creatinine level should be obtained. All patients should also have serum glucose concentration measured, and in diabetic patients, glucose levels should be controlled before, during, and after intervention. Measures of coagulation, such as the partial thromboplastin time and the prothrombin time (PT) and international normalized ratio (INR), should be determined to identify coagulation abnormalities, and in patients taking warfarin or other anticoagulants, an appropriate anticoagulation scheme should be decided on before surgery (Box 32.1). Chest radiography may be helpful in some patients if undiagnosed underlying disease is suspected based on the history and physical examination. Finally, overall assessment of health can be quantified by the American Society of Anesthesiologists (ASA) classification (Table 32.1).

Cardiac Evaluation

In addition to a thorough cardiac history, physical examination, and baseline ECG, advanced cardiac testing may be appropriate for selected patients undergoing elective vascular procedures. The American College of Cardiology (ACC) Foundation and the American Heart Association (AHA) have provided recommendations with regard to preoperative cardiac workup (Fig. 32.1).[1] Most major vascular procedures are classified as "high

Abstract

Preoperative assessment and management of vascular patients are of utmost importance because patients with vascular disease have multisystem involvement, including cardiac, cerebrovascular, renal, and peripheral arterial disease, as well as multiple other comorbid conditions. Consequently, these patients are at high risk for complications after surgery. A focused preoperative evaluation should identify potential treatable risk factors so that complications can be minimized and optimal choices can be made for the timing of elective surgery. Furthermore, a discussion regarding both the potential benefits and risks of any intervention viewed through the patient's current functional state allows both the surgeon and the patient to choose the optimal treatment strategy.

TABLE 32.1 American Society Anesthesiologists Classification

ASA I	Normal, healthy patient with good exercise tolerance
ASA II	Controlled medical conditions without significant systemic effects
ASA III	Medical conditions with systemic effects; functional compromise
ASA IV	Medical condition with significant dysfunction; potential threat to life
ASA V	Critical medical condition; little chance of survival with or without surgery
ASA VI	Brain death, anesthesia performed for organ donation

ASA, American Society Anesthesiology.

risk" except for carotid endarterectomy and endovascular aneurysm repair, which are classified as "intermediate risk." In patients with adequate functional capacity (>4 METs), further cardiac testing is not generally recommended. Furthermore, those who have undergone coronary revascularization within 5 years or have normal findings on coronary angiography or cardiac stress testing within 2 years may also undergo surgery without further cardiac evaluation provided there have been no significant functional changes since that time. Dipyridamole-thallium imaging or dipyridamole stress echocardiography may be indicated for patients at intermediate or high cardiac risk with poor or unknown functional capacity (<4 METs).

In patients with cardiac implantable electronic devices (CIEDs), pacemaker, or an implantable cardioverter-defibrillator (ICD), it should be determined if monopolar electrocautery is going to be used. If so, the device may require reprogramming or application of a magnet over the CIED to prevent the transient inhibition of pacing or the inappropriate triggering of shocks. Furthermore, the surgical team should be familiar with the type of CIED, its manufacturer, response of device following reprogramming or magnet application, and the patient's underlying rhythm. External defibrillation equipment with transcutaneous pacing ability should be readily available in the operating room for these patients.

PREOPERATIVE MEDICAL VERSUS INTERVENTIONAL THERAPY FOR CARDIAC DISEASE

An extended discussion on cardiac complications and the preventions of these is in Chapter 42. Perioperative use of beta blockers has long been the standard of care for most patients with cardiac disease undergoing vascular surgery. However, their use has engendered significant controversy during the past several years. The POISE (PeriOperative Ischemic Evaluation) trial confirmed a reduction in primary cardiac events with perioperative beta-blockade therapy.[2] Nearly 8000 patients undergoing noncardiac surgery were randomized to fixed higher-dose, extended-release metoprolol started the day of surgery or no treatment. Whereas patients receiving beta blockers experienced a reduction in cardiovascular death, MI, and cardiac arrest, this benefit was offset by an increased risk of stroke and total mortality. The results suggested that the administration of high-dose beta blockers in the absence of dose titration may be harmful in beta-blocker naive patients. In the Dutch Echocardiographic Cardiac Risk Evaluation Applying Stress Echocardiography trial (DECREASE-IV), patients were randomized to receive beta blockade only, statin only, beta blockade and statin, or neither medication before elective noncardiac surgery.[3] Beta-blocker use, initiated well before surgery and titrated for heart rate (50-70 beats/min), proved to be cardioprotective in intermediate-risk patients, without an increase in perioperative stroke or death. However, the results of both trials have been called into question.[4] In a separate systematic review, it was noted that the preoperative use of beta blockers was associated with a reduction of cardiac events, but support was lacking regarding the effectiveness of preoperative administration of beta blockers to reduce the risk of surgical death.[5] Furthermore, there is a clear association between beta-blocker administration and adverse outcomes, such as bradycardia and stroke. Thus the best recommendations for beta-blocker use are that they should be continued in patients who have been on them chronically. In patients with intermediate- or high-risk myocardial ischemia on preoperative risk stratification tests or having three or more Revised Cardiac Risk Index (RCRI) risk factors (e.g., diabetes mellitus, heart failure, coronary artery disease, renal insufficiency, cerebrovascular accident), it is reasonable to begin perioperative beta blockers. In these patients, beta blockers should be started long enough in advance to assess safety and tolerability. Beta-blocker therapy should generally not be started on the day of surgery.

Most other "home" medicines, including aspirin, statins, and antihypertensives, should be continued throughout the perioperative period.[1] There is evidence that statins reduce the risk of adverse cardiovascular events among high-risk patients through effects on endothelial function, reduction in vascular inflammation, and stabilization of atherosclerotic plaque.[6] In the absence of a specific contraindication, statins should be initiated prior to surgery and be continued throughout the perioperative period.

Although many surgeons prefer to discontinue clopidogrel or other $P2Y_{12}$ inhibitors due to a perceived risk of increased bleeding at the time of surgery, there are scant objective data

Moderate/good (4–10 METs)
No further testing (Class IIb)
Proceed to surgery
No further testing (Class III:NB)
Proceed to surgery
No or unknown
Poor OR unknown functional capacity (<4 METs): Will further testing impact decision making OR perioperative care? (Step 6)
Yes
Pharmacologic stress testing (Class IIa)
If normal
If abnormal
Coronary revascularization according to existing CPGs (Class I)
No
Proceed to surgery according to GDMT OR alternate strategies (noninvasive treatment, palliation) (Step 7)

Figure 32.1 Stepwise Approach to Perioperative Cardiac Assessment for CAD. Colors correspond to the Classes of Recommendations in Table 32.1. **Step 1:** In patients scheduled for surgery with risk factors for or known CAD, determine the urgency of surgery. If an emergency, then determine the clinical risk factors that may influence perioperative management and proceed to surgery with appropriate monitoring and management strategies based on the clinical assessment. **Step 2:** If the surgery is urgent or elective, determine if the patient has an ACS. If yes, then refer patient for cardiology evaluation and management according to GDMT according to the UA/NSTEMI and STEMI CPGs (18,20). **Step 3:** If the patient has risk factors for stable CAD, then estimate the perioperative risk of MACE on the basis of the combined clinical/surgical risk. This estimate can use the American College of Surgeons NSQIP risk calculator (http://www.surgicalriskcalculator.com) or incorporate the RCRI with an estimation of surgical risk. For example, a patient undergoing very low-risk surgery (e.g., ophthalmologic surgery), even with multiple risk factors, would have a low risk of MACE, whereas a patient undergoing major vascular surgery with few risk factors would have an elevated risk of MACE. **Step 4:** If the patient has a low risk of MACE (<1%), then no further testing is needed, and the patient may proceed to surgery. **Step 5:** If the patient is at elevated risk of MACE, then determine functional capacity with an objective measure or scale such as the DASI (133). If the patient has moderate, good, or excellent functional capacity (≥4 METs), then proceed to surgery without further evaluation. **Step 6:** If the patient has poor (<4 METs) or unknown functional capacity, then the clinician should consult with the patient and perioperative team to determine whether further testing will impact patient decision-making (e.g., decision to perform original surgery or willingness to undergo CABG or PCI, depending on the results of the test) or perioperative care. If yes, then pharmacologic stress testing is appropriate. In those patients with unknown functional capacity, exercise stress testing may be reasonable to perform. If the stress test is abnormal, consider coronary angiography and revascularization depending on the extent of the abnormal test. The patient can then proceed to surgery with GDMT or consider alternative strategies, such as noninvasive treatment of the indication for surgery (e.g., radiation therapy for cancer) or palliation. If the test is normal, proceed to surgery according to GDMT. **Step 7:** If testing will not impact decision making or care, then proceed to surgery according to GDMT or consider alternative strategies, such as noninvasive treatment of the indication for surgery (e.g., radiation therapy for cancer) or palliation. *ACS,* Acute coronary syndrome; *CABG*, coronary artery bypass graft; *CAD*, coronary artery disease; *CPG*, clinical practice guideline; *DASI*, Duke Activity Status Index; *GDMT*, guideline-directed medical therapy; *HF*, heart failure; *MACE*, major adverse cardiac event; *MET*, metabolic equivalent; *NB*, No Benefit; *NSQIP*, National Surgical Quality Improvement Program; *PGI*, percutaneous coronary intervention; *RCRI*, Revised Cardiac Risk Index; *STEMI*, ST-elevation myocardial infarction; *UA/NSTEMI*, unstable angina/non-ST-elevation myocardial infarction; *VHD*, valvular heart disease. (Reprinted with permission from Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol.* 2014;64:e77–e137.)

to support this practice. Furthermore, the role of dual antiplatelet therapy (DAPT) in the management of coronary artery disease continues to evolve. Current ACC/AHA guidelines[7] support the use of DAPT following percutaneous coronary intervention (PCI) with both bare metal stents (BMSs) and drug-eluting stents (DESs). The duration of DAPT is dependent on the indication (acute coronary syndrome vs. stable angina) and PCI technique (BMS vs. DES), balanced against the estimated risk of bleeding. If the risk of surgical bleeding is believed to be high, elective vascular procedures should generally be postponed until DAPT can be safely withheld.

For urgent vascular procedures, DAPT should be continued unless the risk of bleeding outweighs the risk of stent thrombosis, particularly during the first 4 to 6 weeks following BMS or DES implantation. Consultation with cardiology is appropriate prior to discontinuing DAPT. If the procedure is time sensitive or urgent, and coronary revascularization is absolutely necessary, coronary artery bypass grafting (CABG) combined with the surgery or preceding the surgery may be considered.

The role of coronary revascularization prior to vascular surgery is uncertain. The Coronary Artery Revascularization Prophylaxis (CARP) trial demonstrated that in patients with stable coronary artery disease, coronary artery revascularization (with either CABG or PCI) before elective major vascular surgery does not improve long-term cardiac outcomes or reduce short-term postoperative outcomes such as death, MI, or length of hospital stay.[8] In addition, preoperative coronary artery revascularization in vascular patients is associated with increased risk for procedure-related complications and may lead to delay in the intended vascular procedure. Furthermore, patients who have recently (<5 years) undergone CABG or PCI before vascular surgery do not have an obvious survival advantage over patients at high cardiac risk without previous coronary interventions. Only the subset of patients with unprotected left main disease (the left main trunk is defined as unprotected when there is a >50% stenosis and the absence of at least one patent bypass graft to the left circumflex [LCX] or left anterior descending [LAD] artery) showed a benefit from preoperative coronary artery revascularization. CABG showed improved outcomes versus PCI.[9]

Preoperative Management of Hypertension

Elective surgery should generally be delayed if systolic blood pressure is greater than 200 mm Hg or if diastolic blood pressure is greater than 120 mm Hg, and acute control within hours of surgery is inadvisable. Pain can elevate blood pressure; therefore, appropriate analgesia with nonsteroidal antiinflammatory drugs or opioids should be administered to alleviate pain. Agents with minimal hemodynamic effects should be considered, such as fentanyl rather than morphine. Before induction of anesthesia, patients should also be well hydrated because volume loading can minimize the drastic swings in blood pressure that are characteristic of hypertensive patients.

There is general consensus that "home" antihypertensive medications should be continued during the perioperative period, with the possible exception of angiotensin-converting enzyme inhibiters (ACEIs) and angiotensin receptor blockers (ARBs). The incidence of intraoperative hypotension appears to be increased in patients receiving ACEIs or ARBs on the day of surgery, and this has been reflected in an increased risk of all-cause death, stroke, and MI.[10]

Pulmonary Evaluation

Pulmonary complications are reported in 1% to 2% of minor surgeries and up to 20% in upper abdominal or thoracic operations (see Chapter 43).[11] As such, preoperative pulmonary

evaluation should be completed in all patients and should begin with a history and physical examination, which is the most sensitive evaluation to identify "at-risk" patients. Patient-related risk factors for postoperative pulmonary complications include chronic obstructive pulmonary disease, age older than 60 years, ASA class II or higher, functionally dependent, smoking, forced expiratory volume in 1 second (FEV1) <1 L, congestive heart failure, and obesity. Patients with a BMI ≥ 40 kgm^2 have a 30% chance of developing atelectasis and/or pneumonia. The surgeon should pay particular attention to any history of smoking, exercise intolerance, unexplained dyspnea, or coughing. On physical examination, decreased breath sounds, wheezes, crackles, or a prolonged expiratory phase should be noted. Procedure-related risks should likewise be assessed. The duration of surgery (surgical time greater than 3 hours), the need for emergent surgery, and the surgical site all influence the risk of perioperative pulmonary complications. Aortic aneurysm repair, thoracic surgery, abdominal surgery, upper abdominal surgery, and emergency surgery all increase the risk of pulmonary complications. Obstructive sleep apnea is present in up to 22% of the adult population undergoing surgical procedures, and a large number of patients are undiagnosed prior to the preoperative assessment.[12] The presence of obstructive sleep apnea increases the chances of postoperative hypoxemia and reintubation in the postoperative period.

In some situations the at-risk patient will require further pulmonary evaluation and risk stratification. Although clinicians frequently obtain chest radiographs as part of a routine preoperative evaluation, few show unexpected abnormalities or influence the management of the patient. Despite this, there is some evidence that chest radiographs may be helpful for patients with known cardiopulmonary disease and those older than 50 years who are undergoing upper abdominal, thoracic, and open abdominal aortic aneurysm surgery.[13]

The value of pulmonary function testing before lung resection surgery and in determining candidacy for coronary artery bypass is well documented. However, its value outside of these cases remains controversial. Currently the American College of Physicians recommends preoperative pulmonary function testing only in patients who are thought to have undiagnosed chronic obstructive pulmonary disease.[9] Low serum albumin (<35 g/L) is a powerful, independent marker of increased risk for postoperative pulmonary complications. Several indices incorporating multiple factors can be used to stratify pulmonary risk. These typically incorporate the type of surgery, age, functional status, weight loss/nutritional status, COPD, smoking, and whether the surgery is emergent. After a patient is identified as at risk for pulmonary complications, risk reduction strategies should be used. These include smoking cessation, respiratory physiotherapy, respiratory muscle training, optimization of nutritional status, intraoperative strategies, and postoperative lung expansion techniques when appropriate.

Patients who currently smoke have a twofold increased risk for postoperative complications, with the highest risk in patients who have smoked within the past 2 months. Smoking abstinence can reduce the rate of such complications. Patients who have quit smoking for more than 6 months have a risk similar to those who do not smoke, and the beneficial effects of smoking cessation, including improvement in ciliary function and a decrease in sputum production, occur gradually over a period of several weeks. Strategies to improve the quit rate for smoking include counseling, nicotine replacement therapy, bupropion, hypnosis therapy, and varenicline. Nicotine replacement therapy is available in several formulations, including transdermal patch, gum, nasal spray, inhaler, and lozenge. Bupropion is an atypical antidepressant, and varenicline is a partial agonist of the α4β2 nicotinic acetylcholine receptor. Second line agents are nortriptyline, a tricyclic antidepressant, and clonidine, an antihypertensive drug. All of the available treatments appear to be similarly effective, with the exception of varenicline, which has been shown to offer significant improvement in abstinence rates over antidepressants.

Patients with a history of bronchospasm and chronic obstructive pulmonary disease should also be optimized before surgery. International guidelines suggest the use of inhaled bronchodilators, β2 agonists, and anticholinergics as the mainstay of symptomatic therapy for patients with bronchial hyperreactivity. These interventions should begin at least 5 days before surgery. Systemic corticosteroids are recommended when the FEV1 is less than 80% of predicted. In addition, it has been demonstrated that the instances of bronchospasm during intubation in patients with bronchial hyperreactivity who were not previously receiving bronchodilators is reduced with the use of albuterol and steroids. The safety of perioperative corticosteroid use has been established, and it is not associated with death or serious infections. Lung expansion techniques, such as incentive spirometry, chest physical therapy, cough, postural drainage, ambulation, and continuous positive airway pressure, have been used to limit postoperative pulmonary complications. Available data suggest that for patients undergoing abdominal surgery, any type of lung expansion intervention is better than no prophylaxis at all, although no one modality is clearly superior and there is little benefit to combining modalities.[13] Despite the association of hypoalbuminemia with the development of postoperative pulmonary complications, the use of preoperative nutritional supplementation (either parenteral or enteral) has not been demonstrated to reduce postoperative pulmonary complications and should not be instituted solely for this purpose.

Renal Evaluation

Vascular patients are frequently found to have kidney dysfunction at initial evaluation because of the shared risk factors of diabetes, hypertension, atherosclerosis, obesity, alcohol, nicotine abuse, and hypercholesterolemia. One-third of all vascular surgery patients suffer from stage III or higher chronic kidney disease (CKD).[14,15] Therefore kidney function must be carefully evaluated preoperatively. The preoperative evaluation should include an assessment for the presence of renal failure symptoms such as fatigue, dry skin, muscle cramps, decreased urine output, recurrent urinary tract infections, edema, history of renal disease, and history of dialysis or transplantation. The examination should focus on signs of hyperkalemia, volume status, anemia, and bleeding.

In all patients a baseline creatinine level and glomerular filtration rate (GFR) should be obtained to identify problems with renal clearance preoperatively and to establish baseline renal function should renal compromise occur. Serum cystatin C level should be measured in patients with an estimated GFR of 45 to 59 mL/min for confirmation of CKD. In addition, as noted previously, laboratory tests should assess electrolyte status, the presence of anemia, and coagulation status; the chest radiograph should be examined carefully for signs of fluid overload. If the patient is being maintained with dialysis, careful examination of the vascular access site should be performed. If a dialysis catheter is present, it should be inspected for signs of infection, and functionality of the catheter should be verified. If an arteriovenous fistula or graft is present, the fistula or graft should be assessed for thrill and bruit, infection should be excluded, and the examiner should verify that there is adequate blood flow to the hand. The fistula or graft should also be protected before and during surgery, commonly by wrapping the site in loose gauze. The nursing and technical staff should also be advised to avoid drawing blood from the arm used for access.

Hyperkalemia is common in patients with chronic renal insufficiency or end-stage renal disease (ESRD). It is important to correct potassium levels before surgical intervention because hyperkalemia may cause cardiac instability. Treatment options include polystyrene binding resins, insulin in combination with intravenous dextrose, calcium carbonate for cardiac stabilization, intravenous bicarbonate, and dialysis. Polystyrene binding resins can be given orally or as retention enemas and, like dialysis, remove excess stores of potassium; although retention enemas should be used with care to prevent colonic necrosis. Patients maintained with dialysis should undergo dialysis the day before surgery. In addition to correction of electrolytes, acid-base balance should be achieved before surgery because acidosis can decrease the effectiveness of some local anesthetics.

A clinical history of prolonged bleeding and frequent bruising can suggest a potential coagulation abnormality. In the patient with renal dysfunction, uremia can be associated with platelet dysfunction, which may result in an increased incidence of perioperative bleeding. If confirmed, options to improve platelet function include dialysis, desmopressin, cryoprecipitate, conjugated estrogens, and transfusion of red blood cells or platelets (or both). Antiplatelet agents, including aspirin, clopidogrel, and dipyridamole, should be accounted for and recommendations made before surgery in patients with ESRD. In addition, drug-induced minor platelet effects may be exaggerated in ESRD patients, and drugs associated with such problems include diphenhydramine, nonsteroidal antiinflammatory drugs, chlordiazepoxide, and cimetidine.

Anemia is of particular concern in patients with ESRD because of decreased production of erythropoietin. If necessary, red blood cells can be transfused to correct the hematocrit before surgery. However, unnecessary transfusion should be avoided because antibody formation may result in higher rejection rates if the patient is a candidate for future renal transplantation. In addition, transfusion may result in red blood cell lysis and contribute to hyperkalemia. If surgery is elective, it should be delayed until erythropoietin can be administered and the hematocrit allowed to increase in response to the patient's own production of red blood cells.[16] Erythropoietin is also an important option for patients who refuse transfusion for religious reasons.

Contrast-induced nephropathy (CIN) is the third most common cause of hospital-acquired acute renal injury and the leading cause of iatrogenic renal failure. It is a significant problem as more patients are receiving iodinated contrast media for computed tomography, angiography, and endovascular therapies.[17] Strategies to reduce the risk of CIN include (1) avoidance of iodinated contrast completely by using alternative imaging techniques (e.g., MRA, ultrasound, or CO_2), (2) limit the volume of iodinated contrast agents and use only nonionic, low osmolar agents (e.g., iodixanol [Visipaque]), and (3) judicious periprocedural hydration with isotonic saline. Some authors recommend the use of oral N-acetylcysteine (Mucomyst) on the day before and the day of the procedure, although the evidence supporting this practice is conflicting. Recent evidence suggests that the use of sodium bicarbonate and N-acetylcysteine is of no addition value. There are insufficient data to recommend the use of ascorbic acid, statins, low-dose dopamine, or fenoldopam. The use of a gadolinium-based agent, such as those used in magnetic resonance imaging, should be avoided in the setting of compromised renal function. It has been associated with the development of nephrogenic systemic sclerosis, a rare but serious syndrome that involves fibrosis of the skin, joints, eyes, and internal organs. A detailed review of renal complications is presented in Chapter 44.

Diabetes

Surprisingly, the prevalence of undiagnosed diabetes in surgical patients is high despite the association of diabetes with multiple perioperative complications.

Preoperatively, the surgeon should elicit a complete diabetic history, including a history of metabolic control and diabetic complications such as heart disease, nephropathy, neuropathy, retinopathy, and previous episodes of diabetic ketoacidosis or hyperosmolar hyperglycemic nonketotic coma. In addition, evidence of diabetic autonomic neuropathy should be sought because this predisposes patients to perioperative hypotension, and gastroparesis increases a patient's risk for aspiration.

High glucose levels are associated with increased morbidity and mortality after surgery and in the intensive care unit. Independent of previous cardiac disease, diabetes, or other comorbid conditions, hyperglycemia at the time of carotid endarterectomy has been associated with an increased risk for perioperative stroke, MI, and death. In addition, poor perioperative glycemic control is associated with an unfavorable outcome after peripheral bypass surgery. Therefore it is imperative that blood glucose be controlled during and after vascular surgery. If necessary, every effort should also be made to ensure that glucose levels are controlled preoperatively. When possible, glucose control should be attained weeks before surgery; hemoglobin A1c (HbA1c) is a useful diagnostic test for assessing long-term glucose control. However, some patients will require

preoperative hospitalization and endocrine consultation to ensure diabetic control before surgery. When necessary, an insulin drip with hourly glucose monitoring can be used to stabilize blood glucose levels.

Several studies add additional perspective to perioperative diabetic management. Dronge et al. conducted a retrospective observational study of 490 diabetic patients using the Veterans Affairs National Surgical Quality Improvement Program (now VASQIP).[18] With primary outcomes of infectious complications, including pneumonia, wound infection, urinary tract infection, or sepsis, they observed that a preoperative HbA1c (within 180 days of surgery) of less than 7% was significantly associated with a decrease in infectious complications with an adjusted odds ratio of 2.13. Although this association was not observed in a subsequent larger study of more than 55,000 diabetic patients undergoing a variety of noncardiac operations, King et al. did report that higher rates of postoperative infection were associated with mean 24 hour postoperative serum glucose concentrations of 150 to 250 mg/dL (incidence rate ratio of 1.22) and greater than 250 mg/dL (incident rate ratio of 1.43).[19]

Glucose control should also be considered even in the nondiabetic patient. In a 2010 study, Frisch et al. studied morbidity and mortality in 3184 noncardiac surgery patients.[20] Using multivariate analysis, the risk of death increased in proportion to perioperative glucose levels; however, the relationship was only significant for patients without a history of diabetes. O'Sullivan and associates also found a link between poor preoperative glucose control in nondiabetics and perioperative mortality.[21] They studied preoperative HbA1c in 165 patients undergoing vascular surgery procedures; 43 had diabetes, and 122 did not. In diabetics, a HbA1c of greater than 7 was associated with a significantly higher incidence of 30-day mortality. In nondiabetics a suboptimal HbA1c (>6 to ≤7) was an independent predictor of 30-day morbidity.

Although there has been substantial observational evidence linking hyperglycemia in hospitalized patients with or without diabetes to worsening health outcomes, the optimal blood glucose range remains ill defined. Until recently, achievement of nearly normal glycemia was considered beneficial in the intensive care unit setting and during the postoperative period, predominantly on the basis of studies evaluating outcomes after cardiac surgery. Subsequent trials have not replicated the initial findings with tight glycemic control using intensive insulin therapy. The use of intensive insulin therapy has been demonstrated to have no effect on mortality, sepsis, or wound infection.[22] Similarly, the need for strict intraoperative glycemic control has not been demonstrated. There is insufficient evidence to provide definitive recommendations for glycemic targets for hospitalized patients. The American Diabetes Association,[23] the Canadian Diabetes Association,[24] and others have recommendations on inpatient glycemic control.[25] In the intensive care unit, the glucose goal should be maintained between 140 and 180 mg/dL. For general medical and surgical patients, a premeal glucose target less than 140 mg/dL and a random blood glucose concentration less than 180 mg/dL should be obtained.

Different regimens have been recommended for routine preoperative treatment of diabetic patients undergoing surgical procedures. Patients with type 2 diabetes who are being treated by diet alone are to abstain from oral intake overnight, and hydration may be maintained with intravenous solutions. Hyperglycemia is treated with supplemental short-acting insulin. In patients treated with oral agents, these medications are generally withheld the day of surgery, and hyperglycemia can be corrected with insulin. Metformin should be stopped 24 hours before surgery to prevent the possibility of lactic acidosis if the patient's renal function becomes compromised. For patients receiving insulin therapy and for the postoperative patient, recommendations are listed in Box 32.2. Specific sliding scale insulin regimens are typically standardized on the basis of hospital practices.

Adrenal Evaluation

Patients who have been chronically treated with steroids may not be able to mount a stress response and will thus be at risk for perioperative adrenal crisis. Therefore a careful history should be performed to screen for steroid use. Hypothalamic or pituitary dysfunction should be considered in patients with tumor, previous brain irradiation, or sarcoidosis. Furthermore, primary adrenal insufficiency may be present in patients with tuberculosis, acquired immunodeficiency syndrome, and autoimmune endocrine syndromes.

Following reports of adrenal suppression associated with chronic glucocorticoid pharmacotherapy in the 1950s, protocols for stress steroid coverage to prevent surgically induced adrenal insufficiency were initiated. However, studies through the late

BOX 32.2 Recommendations for Perioperative Glycemic Management With Insulin Therapy

Determine level of glycemic control.

Avoid alterations of long-acting basal insulin the day before surgery (unless hypoglycemia or on diet restrictions).

Reduce evening dose of intermediate-acting (NPH) insulin the day before surgery to 75%. The day of surgery, use 50%-75% of the morning dose.

Do not administer prandial insulin while the patient is fasting.

Maintain intraoperative glucose ranges between 100 and 180 mg/dL.

In nonintensive care unit settings

Preferable method for control is the use of subcutaneous basal-bolus-correctional insulin.

For noneating patients: use of basal insulin in combination with correctional insulin.

The use of sliding scale as monotherapy is inadequate and should be avoided.

Use standardized subcutaneous insulin protocols as clinically applicable.

Patients receiving intravenous insulin who are not insulin naïve, safely transition to subcutaneous insulin when appropriate. Use 60%-80% of total daily calculated insulin requirement based on the final 6 h of the infusion rate.

In patients receiving intravenous insulin who are previously insulin naive, the conversion can be more complex but is frequently based on 50% of the total daily need when instituted at glucose levels ≥140 mg/dL.

1990s began to suggest that stress steroid protocols might not be routinely necessary. In 2008 Marik and Varon published a review of the literature with the purpose of determining the requirement for perioperative supplemental stress doses of corticosteroids in patients receiving long-term corticosteroid therapy.[26] They identified nine studies, two randomized controlled trials (RCTs), and seven cohort studies. In the two RCTs, there was no advantage for those patients receiving stress doses of corticosteroids, and in five of the cohort studies there were no hemodynamic consequences in patients continuing to receive their daily dose of steroids without additional stress supplementation. In the remaining two studies, one patient in each (1% and 5% of the respective cohorts) had unexplained hypotension when steroids were discontinued before surgery. In each case the patients responded to steroid administration. The authors concluded that patients receiving therapeutic doses of corticosteroids do not require supplemental coverage if daily doses are continued. Patients receiving physiologic replacement doses because of hypothalamic-pituitary-adrenal axis dysfunction should receive supplemental steroids perioperatively. In these patients the authors recommend 50 mg of hydrocortisone intraoperatively, continued every 8 hours for 48 to 72 hours postoperatively.

There is significant individual variation in the dose and duration of steroid therapy that leads to suppression of the hypothalamic-pituitary axis. In evaluating the need for perioperative steroid coverage, the patient's steroid history and the complexity of surgery should both be considered. If patients are taking less than 5 mg of prednisone (4 mg of methylprednisolone, 0.5 mg of dexamethasone, 20 mg of hydrocortisone) in the morning, have been treated for less than 3 weeks, or are taking less than 10 mg of prednisone (or its equivalent) every other day, they should not require intraoperative steroid coverage. However, they should continue to receive their regular daily dose of steroids.[26a] Patients taking greater than 20 mg per day of prednisone (or equivalent) should receive supplemental perioperative steroid coverage. Recommendations for perioperative coverage vary. Marik and Voran[24] recommended 50 mg of hydrocortisone intraoperatively, continued every 8 hours for 48 to 72 hours for patients receiving physiologic replacement doses because of hypothalamic-pituitary-adrenal axis dysfunction. Other authors[27-29,29a] have based coverage on surgical complexity. Excessive steroid use may be associated with impaired wound healing, increased blood glucose concentration, or increased susceptibility to infection, and therefore steroids should be given based on the minimum requirement. Some have recommended that patients undergoing minor surgery (inguinal hernia equivalent) should receive 25 mg of hydrocortisone (or its equivalent) at the start of the procedure and then their usual replacement dose after the procedure. Others advocate no preoperative steroids for minor procedures. Patients undergoing moderately complex surgery (lower limb revascularization) should receive 50 to 75 mg of hydrocortisone on the day of surgery, tapered to the patient's usual replacement dose over 1 to 2 days. For major surgery (cardiothoracic surgery of its equivalent) patients should receive 100 to 150 mg of hydrocortisone on the day of surgery, which is tapered to the patient's usual dose over 2 to 3 days. As recommendations vary, it is best to coordinate planned steroid coverage with anesthesiology prior to any surgical procedure.

Patients taking 5 mg of prednisone a day or greater (or equivalent), less than 5 mg of prednisone (or equivalent), but in the evening, or patients who have discontinued glucocorticoids in the year prior to surgery should be evaluated for adrenal insufficiency by measuring a morning cortisol level or assessing the results of a corticotropin stimulation test. Corticotropin stimulation testing uses 250 μg of cosyntropin administered intravenously or intramuscularly and measures cortisol at baseline and then at 60 minutes. A plasma cortisol level greater than 20 μg/dL (552 nmol/L) at either time is diagnostic of adequate function. As an alternative, the low-dose stimulation test uses 1 μg cosyntropin intravenously and measures cortisol at baseline and 30 minutes. A plasma cortisol level greater than 18 μg/dL (497 nmol/L) is diagnostic of adequate function in the low-dose stimulation test.

Deep Venous Thrombosis Prophylaxis, Thrombotic Risk Factors, and Antithrombotic Therapy

The potential for deep venous thrombosis (DVT) in surgical patients can be stratified by risk factors and the type of operation. Prior to surgery, the surgeon should obtain a history of the patient's coagulation status and previous history of thrombotic events. A family history or a previous episode of DVT may indicate a genetic predisposition to abnormal clotting, such as factor V Leiden or prothrombin gene mutations. A pharmacologic history, including current and previous exposure to drugs that modify coagulation, such as aspirin, antiplatelet therapy, warfarin, unfractionated heparin (UFH), low-molecular-weight heparin (LMWH), and direct thrombin and factor Xa inhibitors, should also be obtained. Particular attention should be paid to adverse reactions, such as aspirin allergy or previous development of heparin-induced thrombocytopenia (HIT). In addition, physicians should be aware of the possibility of other procoagulant states, such as antithrombin III deficiency, protein C and S deficiency, antiphospholipid syndrome, disseminated intravascular coagulation, and abnormal platelet function, all of which may confound the underlying disease process responsible for the vascular insult (see Chapter 38).

Pharmacologic prophylaxis for venous thromboembolism includes UFH, LMWH, fondaparinux, warfarin, antiplatelet therapy, and direct thrombin or factor Xa inhibitors. Mechanical devices, such as graduated compression stockings, intermittent pneumatic compression, and venous foot pumps, are also effective modalities for prophylaxis of venous thromboembolism (see Chapter 146). Updated guidelines for DVT prophylaxis have been reported.[30] Recommendations specific to vascular surgery are limited because of the lack of large randomized trials evaluating outcomes in patients undergoing specific vascular procedures. Given this, recommendations for vascular surgery are pooled with recommendations for patients undergoing general, urologic, gynecologic, bariatric, and plastic or reconstructive surgeries (Table 32.2).

TABLE 32.2 Recommendations for Thromboprophylaxis in Various Risk Groups

Risk and Consequences of Major Bleeding Complications		
Risk of Symptomatic VTE	Average Risk (–1%)	High Risk (–2%) or Severe Consequences
Very low (<0.596)	No specific prophylaxis	
Low (~1.596)	Mechanical prophylaxis with IPC	
Moderate (~3.096)	LDUH, LMWH, or mechanical prophylaxis, preferably with IPC	Mechanical prophylaxis, preferably with IPC
High (~6.096)	LDUH or LWMH plus mechanical prophylaxis with ES or IPC	Mechanical prophylaxis, preferably with IPC, until risk of bleeding diminishes and pharmacologic prophylaxis can be added
High-risk cancer surgery	LDUH or LMWH plus mechanical prophylaxis with ES or IPC and extended-duration prophylaxis with LMWH postdischarge	Mechanical prophylaxis, preferably with IPC, until risk of bleeding diminishes and pharmacologic prophylaxis can be added
High risk, LDUH and LMWH contraindicated or not available	Fondaparinux or low-dose aspirin; mechanical prophylaxis, preferably with IPC; or both	Mechanical prophylaxis, preferably with IPC. until risk of bleeding diminishes and pharmacologic prophylaxis can be added

ES, Elastic stockings; *IPC*, intermittent pneumatic compression; *LDUH*, low-dose unfractionated heparin; *LMWH*, low-molecular-weight heparin; *VTE*, venous thromboembolism.

Prevention of VTE in nonorthopedic surgical patients: Antithrombotic therapy and prevention of thrombosis, 9th ed: American College of Chest Physicians evidence-based clinical practice guidelines. *Chest*. 2012;141(suppl):e2275–e2775.

With the increasing use of heparin and heparin-containing solutions in hospitalized patients, a history of HIT has become more common in the preoperative evaluation of patients. The reported incidence is variable, although HIT can occur in up to 5% of patients exposed to heparin.[31] Greinacher suggests an incidence of 1 in 5000 hospitalized patients. The risk is greatest after the use of UFH and can be seen in 1% to 3% of patients after coronary bypass. Thrombocytopenia is the result of autoantibodies to the heparin–platelet factor 4 complex (see Chapter 38).

The literature predominately addresses the significance of HIT relative to planned cardiac surgery and PCI. However, Warkentin et al. reviewed records over a 30-year period, identifying patients with a diagnosis of HIT who underwent vascular surgery while positive for heparin-dependent platelet activating antibodies using a serotonin release assay.[32] Most of the surgeries were necessitated by acute arterial thrombosis, and patients were divided into two groups, those receiving intraoperative anticoagulation with either UFH or an alternative non–heparin-based strategy. Limb amputation was the primary outcome. Fourteen patients were identified; 10 received intraoperative UFH, and four were managed with alternative strategies, including saline flushes, danaparoid, lepirudin, or argatroban. Two of the 10 receiving UFH underwent subsequent amputation, and three of four receiving alternative therapies had amputation. The review extended from 1981 to 2010, was observational, and included only a small number of patients. Patients were not randomized or matched. Nonetheless, the authors concluded that UFH administration to patients with SRA-positive HIT did not necessarily lead to adverse outcomes. Welsby et al. reported on the use of intraoperative plasmapheresis and heparin anticoagulation in cardiac surgical patients.[33] Three of 11 patients died of causes unrelated to HIT 3 months to 1 year after surgery. Only one patient developed foot ischemia, associated with cardiogenic shock and not thought to be HIT related. Current recommendations from the American College of Chest Physicians[34] are to use nonheparin anticoagulants, such as bivalirudin, lepirudin, or argatroban over heparin or LMWH in patients with a history of HIT who continue to have heparin antibodies present and who require cardiac surgery. In patients with a history of HIT but without heparin antibodies, heparin anticoagulants may be used.

Direct thrombin inhibitors, including argatroban, lepirudin, and bivalirudin, have been used during PCIs in patients with HIT.[35] The agents are valued because of their small molecular size, their ability to inhibit bound and unbound thrombin, and their lack of cross reactivity with HIT antibodies. Current recommendations from the American College of Chest Physicians suggest the use of bivalirudin (a grade 2B recommendation) or argatroban (a grade 2C recommendation) for percutaneous interventions.[34]

Previously perioperative management of anticoagulation has focused on the need to discontinue warfarin and the necessity to initiate bridge anticoagulation prior to and after surgery. Current consensus recommendations advocate the discontinuation of warfarin 5 days prior to surgery.[30] Patients should be assessed at least 7 days prior to surgery, should be provided with a calendar outlining the perioperative timing of warfarin discontinuation, and should undergo INR testing on the day before surgery. Warfarin can be resumed 12 to 24 hours after surgery.

Consensus recommendations support the use of bridging anticoagulation with therapeutic doses of LMWH in high-risk patients.[30] High-risk patients include those with any mitral valve prosthesis, any caged or tilting disc aortic prosthesis, or

recent (within 6 months) stroke or TIA. Patients with atrial fibrillation are at high risk if they have a $CHADS_2$ score of 5 or 6, have had a recent (within 3 months) stroke or TIA, or have a history of rheumatic valvular heart disease. Patients with a recent (within 3 months) history of venous thromboembolic disease or thrombophilia are also at high risk. The use of therapeutic dose, subcutaneous LMWH appears to have a lower incidence of arterial thromboembolic events. Protocols suggest that LMWH should be started 3 days prior to surgery and stopped the day of surgery. Bridging is resumed 12 to 24 hours after surgery depending on the risk of bleeding.[36]

When managing bridging anticoagulation, prior to the use of spinal or epidural anesthesia, prophylactic LMWH should be discontinued 10 to 12 hours prior to placement of the catheter and should be resumed 6 to 8 hours after catheter removal. When using therapeutic doses of LMWH, treatment should be discontinued 24 hours prior to catheter placement and restarted 24 hours after catheter removal.

The use of bridging anticoagulation in patients not at high risk is unclear, and individual risk factors for thromboembolic complications and perioperative bleeding need to be considered. Two recent studies have examined the value of periprocedural heparin bridging. Siegal et al. reported on a systematic review and meta-analysis, concluding that vitamin K antagonist (VKA)-treated patients receiving periprocedural heparin bridging appeared to be at increased risk of overall and major bleeding and at a similar risk of thromboembolic events.[37] The study did not define the risk of the patients reported. Furthermore, an accompanying commentary did caution that the study reflected a heterogeneous database because of a high variation in clinical practice and that uniform bridging protocols were not used.[38] A more recent randomized, double-blind placebo-controlled trial, in which patients with atrial fibrillation were assigned to receive LMWH bridging (100 IU of dalteparin per kilogram subcutaneously twice a day) or placebo after interruption of warfarin therapy, was reported by Douketis et al.[39] Bridging extended from 3 days before the procedure until 24 hours before the procedure. Patients with atrial fibrillation associated with valvular heart disease were excluded. The study showed that forgoing bridging anticoagulation was noninferior to perioperative bridging with LMWH with respect to the prevention of arterial thromboembolism and a decreased risk of bleeding.

With the advent of novel oral anticoagulants (NOACs) such as dabigatran, rivaroxaban, apixaban, and edoxaban, there are additional considerations. The newer agents are frequently not monitored; have dependable therapeutic profiles; and have more rapid onset and shorter half-lives, altering the time needed to clear the anticoagulant effect and the time needed to achieve clinical anticoagulation. Of the newer anticoagulants, dabigatran has been studied most extensively. Healey and others showed dabigatran facilitated shorter interruption of oral anticoagulants prior to surgery.[40] Depending on the renal function and risk of perioperative bleeding, dabigatran could be stopped 24 to 96 hours prior to surgery. Schulman et al. reported resuming dabigatran therapy on the day of the procedure in 40% of 541 cases studied.[41] Bridging was not used preoperatively but was used in nine patients (1.7%) postoperatively. Postoperative bridging was associated with bowel surgery and vascular surgery. For patients receiving neuraxial anesthesia, the American Society of Regional Anesthesia recommends stopping dabigatran 5 days prior to surgery.[42]

Management of the other non-VKA anticoagulants generally reflects the management protocols used for dabigatran. Discontinuation is dependent upon the risk of bleeding and renal function but generally can occur 2 to 4 days prior to surgery. Bridging anticoagulation has not been used preoperatively. Postoperatively, anticoagulants can be resumed, at preoperative dosages, once hemostasis has been ensured. Postoperative bridging may be necessary if the slow return of bowel function prevents oral intake in high-risk patients for arterial thromboembolism, stroke, or venous thromboembolic disease.

Infection

Patients with infection in the preoperative period should be identified because of their increased risk for surgical site infection. Common sources of infection, both preoperatively and postoperatively, include the urinary tract, the pulmonary system, and an ischemic extremity. If any prosthetic material has been implanted, it can also be a nidus for infection. A careful history should be performed to elicit signs of infection, such as recent fever, cough, sputum production, urinary symptoms, tenderness or erythema over a graft site, or purulence from an open wound or ischemic extremity. The physical examination should assess abnormal breath sounds, and careful inspection of the extremities and feet should identify any ulceration, tenderness, or erythema. Urinalysis, a chest radiograph, and a white blood cell count should be obtained to evaluate for specific sites of infection if indicated. If infection is identified, elective surgery should be delayed until the patient's health has been optimized. Choice of antibiotics should be tailored to the specific microbe and sensitivities identified from microbiology laboratory cultures. In the absence of an acute infection, perioperative prophylactic antibiotic administration is recommended in patients undergoing vascular surgery. Antibiotics should be administered within 1 hour before incision and should be discontinued within 24 hours postoperatively unless an underlying infection is being treated. Acceptable prophylactic antibiotics include cefazolin and cefuroxime. Vancomycin is an acceptable alternative in the setting of β-lactam allergy, methicillin-resistant *Staphylococcus aureus* (MRSA) colonization or infection, chronic wound care or dialysis, acute inpatient hospital extended care or nursing home care in the previous 12 months, or preoperative length of stay of 24 hours or longer.

Antibiotic resistance is a growing problem, in particular with MRSA, which has become a predominant cause of *S. aureus* infections in both healthcare and community settings, with up to 65% of healthcare–associated *S. aureus* infections due to MRSA. Unlike for traditional *S. aureus* infection, treatment options for MRSA infection are limited and less effective. MRSA is typically transmitted person to person, and colonization generally precedes infection. Colonization is frequently long lasting (months to years). Successful prevention of MRSA transmission is possible

through Centers for Disease Control and Prevention–recommended core and supplemental strategies. Core strategies target preventing transmission from colonized to uncolonized persons and preventing infection in colonized patients. Core preventive strategies include assessing hand hygiene practices, implementing contact precautions of MRSA-colonized/infected patients, recognizing previously colonized patients who have not met criteria allowing discontinuation of isolation, rapid laboratory reporting of MRSA identification, and providing MRSA education to healthcare providers. Supplemental strategies including active surveillance testing and decolonization have been recommended by many but met with controversy. Although several successful MRSA preventive collaboratives have used active surveillance testing, studies evaluating its utility have demonstrated mixed results. Active surveillance testing involves culture or polymerase chain reaction testing (frequently from the nares) done at the time of patient admission, typically focusing on high-risk patients such as those admitted to the intensive care unit. However, after it is identified, no data to date exist to support programs of pharmacologic decolonization.

Preoperative Anemia and Coagulation Assessment

Preoperative anemia increases the postoperative morbidity and mortality for patients undergoing noncardiac surgery. A history of chronic renal disease or anemia, such as sickle cell disease or thalassemia, should alert the physician to the potential for anemia, and a preoperative hematocrit level should always be obtained to provide information on the red blood cell status of the patient. Ideally, preoperative anemia should be identified and treated if possible. Bleeding from the upper and lower gastrointestinal tract or the genital-urinary tract should be considered and investigated. There are three types of iron-restricted erythropoiesis that should be considered: absolute iron deficiency, iron sequestration secondary to inflammation, and iron deficiency due to insufficient erythropoiesis stimulating agents.[43] Nutritional deficiencies also need consideration. These forms of anemia can be treated with pharmacologic interventions, including iron, vitamin and folate supplementation, or erythropoiesis-stimulating agents. Transfusion of blood preoperatively should be limited to patients who are symptomatic, bleeding with severe anemia, or poor physiologic reserve with insufficient time to correct the physiologic abnormality. However, because transfusion is not without side effects and blood is costly with limited availability, anemic patients should be carefully evaluated to determine whether transfusion is likely to be of benefit. In addition, the patient's cardiac status may influence the decision to transfuse inasmuch as anemia worsens outcomes in patients with coronary artery disease who undergo cardiac or noncardiac surgery. Although recommendations for transfusion have been debated, most current guidelines recommend adhering to a restrictive transfusion strategy when possible.[44] In adult and pediatric intensive care unit patients, transfusion should be considered at hemoglobin concentrations of 7 g/dL or less. In postoperative surgical patients, transfusion should be considered at a hemoglobin concentration of 8 g/dL or less or for symptoms including chest pain, orthostatic hypotension, and tachycardia unresponsive to fluid resuscitation.[45] For elective surgery, autologous transfusion or administration of erythropoietin should be considered to boost the patient's red blood cell volume from endogenous sources.

Due to the nature of most vascular surgical interventions and the fact that the majority of vascular patients are on antiplatelet agents or anticoagulants, coagulation studies are routinely checked. However, the medical history remains the most important tool for detecting inherited and acquired bleeding disorders that would increase the risk of perioperative bleeding. This includes a medication history, questions regarding a known coagulopathy, unexplained epistaxis, hematomas, prolonged bleeding following cuts or abrasions, or abnormal requirements for blood products after previous surgeries. Routine tests include an activated partial thromboplastin time (aPTT), a PT, which allows the generation of the standard INR, and a platelet concentration. Unfortunately, these values are poor predictors of perioperative bleeding and mortality, although an INR greater than 1.8 and a platelet count less than 50×10^3 have been associated with adverse outcomes and may delay surgery or prompt an intervention to correct the abnormality.[45]

Nutrition

Up to half of surgical patients have preoperative malnutrition that contributes to an increased risk for postoperative complications, such as impaired wound healing and infection, pulmonary complications, longer hospital stay, higher health cost, and overall increased morbidity and mortality. Vascular surgical patients are an elderly population with poor mobility and diet and multiple comorbidities that contribute to a higher prevalence of malnutrition, which may be exacerbated by specific vascular disease processes such as diabetes, chronic mesenteric ischemia, and renal failure. Lower preoperative nutritional indices are associated with more severe systemic inflammatory responses after major vascular surgery. Serum albumin is the standard laboratory assessment of nutritional status, and hypoalbuminemia (<3.5 g/dL) from malnutrition is an independent predictor of major adverse events and death after major open vascular surgery.[46] However, a similar relationship was not observed for endovascular procedures, suggesting that other preoperative factors (congestive heart failure, preoperative hematocrit level, and creatinine concentration) were more predictive of postoperative complications.

A nutritional assessment should be performed for all vascular surgical patients, including a history evaluating changes in weight and appetite as well as the patient's functional status (which may impair the ability to obtain or prepare food). Symptoms of nausea, vomiting, dysphagia, constipation, diarrhea, and related gastrointestinal complaints should be assessed, particularly in patients with suspected mesenteric ischemia. In general, weight loss of more than 5% in 1 month or 10% in 6 months can signify an increased risk for postoperative complications.[47] The physical examination should focus on body habitus and findings of general weakness, edema, pallor, decubitus ulcers, petechiae, ecchymoses, poor skin turgor, fissured tongue,

inflamed gums, ulceration of the oral mucosa, brittle hair, and nail abnormalities.

A number of laboratory values can be used to assess nutritional status, but serum albumin is the most appropriate. Albumin is the most abundant plasma protein and has a long half-life (18-21 days); it is a marker of chronic protein status and a better evaluation of nutritional status than anthropometric measurements. Serum prealbumin and transferrin levels have a shorter half-life and are more sensitive to the short-term response to nutritional support than are assessment tools for chronic malnutrition. The prognostic nutritional index, which relates operative risk to nutritional status, is determined on the basis of nutritional parameters including serum albumin, serum transferrin, triceps skinfold measurement, and skin test of delayed hypersensitivity.[48] It is seldom used in clinical practice.

Despite the nutritional assessment's ability to predict poor outcomes, there are no clear guidelines as to who would benefit from preoperative nutritional support, especially in patients undergoing vascular surgery. There is evidence that preoperative nutritional support can lower postoperative complication rates in patients undergoing intraabdominal surgery, particularly in those with severe malnutrition (albumin <2.1 g/dL). Up to 25 to 35 kcal/kg per day, based on adjusted body weight in obese patients, should be provided, incorporating 1.5 to 2 g/kg per day of protein. A Cochrane evaluation of preoperative nutritional support in patients undergoing gastrointestinal surgery demonstrated that the use of parenteral nutrition significantly reduced postoperative complications.[47] Similar results with oral supplementation or enteral nutrition were not observed, although most experts agree that enteral nutrition is preferred to parenteral because it is safer and more cost-effective. It is recommended that nutritional support be provided for 10 to 14 days before major surgery.[48] Interestingly, immune-enhancing nutritional supplementation can significantly reduce postoperative complications. Immune-enhancing formulas intend to bolster function of the immune system by providing immunonutrients, including arginine, glutamine, and ω-3 polyunsaturated long-chain fatty acids. However, the generalizability of these modalities to vascular surgical patients is unknown.

ETHICAL AND LEGAL CONCERNS/ FRAILTY ASSESSMENT

As part of the decision to proceed with surgery, both the physician and patient must consider ethical and legal matters. In the preoperative evaluation, situations pertaining to patient confidentiality, reporting of abuse, and informed consent may arise. Furthermore, should issues arise in the perioperative or postoperative period that ultimately result in legal action, a medical damages claim must establish three things to prove successful: it must be shown that (1) the provider had a duty to care for the patient, (2) the duty of care was breached in a deviation from the standard of care, and (3) this breach caused loss or damage to the patient. Therefore the preoperative setting is ideal for both the patient and the physician to come to a mutual understanding about the expectations of the physician-patient relationship and the treatment decided on to minimize the chance that legal action will be initiated.[49]

Patient confidentiality is an important topic since the passage of the Health Insurance Portability and Accountability Act (HIPAA) in the United States to address the privacy and release of health information. Physicians have a duty to maintain confidentiality with their patients, which means that they may not disclose any medical information discovered in connection with the treatment of a patient, thereby protecting the physician-patient relationship. Information contained in a patient's medical record may be released to third parties only if the patient provides consent. Breaches in confidentiality can lead to mistrust, lawsuits, or disciplinary action. Exceptions can be made if patients threaten bodily harm to themselves or to others. Federal and state laws vary on the reporting of suspected child, elder, or spousal abuse. It is the responsibility of the physician to be aware of these laws.

Informed consent must be obtained from all patients before surgical intervention and is a process of communication that results in the patient's agreement to undergo a medical intervention. To provide consent, the patient must have an understanding of the diagnosis, the purpose of a proposed procedure, the risks and benefits associated with the procedure, the alternative treatments, and the risks and benefits of not undergoing a procedure. This may seem straightforward, but it has been shown that surgeon characteristics influence how risks are presented to vascular patients.[50] Care must be taken while discussing the risks and benefits of the surgery so that patients do not think that they are being coerced into a specific decision. The informed consent, although not designed as such, is an instrument through which trust between physician and patient can be further enhanced.[48] Although informed consent is a process, for the purpose of protection from litigation it is important that this communication be documented. If the patient does not have decision-making capacity, a family member or someone with power of attorney will need to be designated to make decisions on behalf of the patient. A patient need not have the same level of awareness at all times to provide legally adequate informed consent. In these situations, consultation with the psychiatry and ethics teams can be helpful. Regardless, physicians should make themselves familiar with federal and state laws regarding confidentiality, reporting of abuse, and informed consent (Box 32.3).

The final step in risk assessment is brought about by the changing demographics of an aging population. Many of the classic risk stratification tools have failed to take into account

BOX 32.3 Key Components of Informed Consent

Date and time
Diagnosis explained
Risks and benefits of the proposed procedure explained
Alternative treatment options explained
Consent form must be read by the patient
Patient must be given the opportunity to ask questions
Patient must express understanding and wish to proceed

the physiologic reserve of elderly patients. This decreasing physiologic reserve, frailty, which is manifested in functional impairment and multiple comorbidities has been shown to indicate an inability to recover from major stresses and predict poor outcomes in several studies. The concept of frailty represents the increased vulnerability of a patient due to the loss of physical and mental function and the decline of several organ systems. The application of a frailty assessment preoperatively has the ability to engage the patient into a discussion on the risk of a procedure, and the potential outcomes from an intervention. Currently, research is attempting to identify what factors can guide decision-making in the frail and elderly patient. These considerations are necessary to take into consideration when evaluating and providing informed consent for patients.[51]

Douketis JD, Spyropoulos AC, Kaatz S, et al. Perioperative bridging anticoagulation in patients with atrial fibrillation. *N Engl J Med*. 2015;373:823–833.

This report describes a randomized, double-blind, placebo controlled trial in which patients with atrial fibrillation were assigned to receive bridging anticoagulation therapy or placebo following perioperative interruption of warfarin. The study concluded that foregoing bridging anticoagulation was noninferior to perioperative bridging with low-molecular-weight heparin for the prevention of arterial thromboembolism and risk of major bleeding.

Greinacher A. Heparin-induced thrombocytopenia. *N Engl J Med*. 2015;373:252–261.

This case vignette is used as a basis for a comprehensive discussion of the pathogenesis, clinical presentation, diagnosis, and treatment of heparin-induced thrombocytopenia.

Vascular patients are some of the most challenging to manage intraoperatively. These patients, even if known to the medical system, present with multiple comorbidities necessitating extensive preoperative evaluation and preparation. If new to the medical system, their surgical procedures can unmask unknown, often life-threatening medical conditions making their intraoperative management complex. Rarely do these patients present with an isolated vascular issue. Not infrequently, their procedures are complicated requiring long operative times, large incisions, and greater volume and blood loss compared to equally complex general surgery interventions. Frequently, these patients are elderly and lack the physiologic capability to rebound from homeostatic variations. Often only the slightest of insults can lead to their demise. The aim of this chapter is to review some of these intraoperative considerations the surgical team will face during vascular surgery.

ANESTHESIA

General Principles of Anesthesia

The term *anesthesia* refers to the practice of medicine that utilizes the three constituents of analgesia, amnesia, and relaxation. *Analgesia* refers to the absence of pain in the conscious or

TABLE 33.1 Continuum of Depth of Sedation: Levels of Sedation/Analgesia

	Minimal Sedation (Anxiolysis)	Moderate Sedation/Analgesia (Conscious Sedation)	Deep Sedation/Analgesia	General Anesthesia
Responsiveness	Normal response to verbal stimulation	Purposeful response to verbal or tactile stimulation	Purposeful response after repeated or painful stimulation	Unarousable, even with painful stimulation
Airway	Unaffected	No intervention required	Intervention may be required	Intervention often required
Spontaneous ventilation	Unaffected	Adequate	May be inadequate	Frequently inadequate
Cardiovascular function	Unaffected	Usually maintained	Usually maintained	May be impaired

unconscious state. The goal of *amnesia* is to block consciousness and memory formation. With *relaxation*, the aim is to block voluntary motor activity and suppress autonomic reflexes. Each of these components is addressed separately, often by specific agents or techniques in a balanced manner to achieve the level of anesthesia necessary for the planned procedure.

Proper anesthesia is tailored appropriately for the procedure and allows safe, comfortable, and humane conduct of interventions that the patient would otherwise not tolerate. Surgeons are well aware that the physiologic impact of our invasive therapies extends beyond the intraprocedural period into the following days and weeks. As such, the supportive treatments through the perioperative period form a continuum, and many therapeutic interventions initiated in the operating room may have ongoing or even greater importance in the postoperative period. Selection of an anesthetic approach for a particular patient must therefore integrate the preexisting status of the patient, the expected impact of the planned intervention, and the predicted needs of the patient during convalescence. A breakdown of the levels of anesthesia as described by the American Society of Anesthesiologists (ASA) is presented in Table 33.1.[1] Practitioners intending to produce a given level of sedation should be able to rescue patients whose level of sedation becomes deeper than initially intended.

A balanced approach is required as there is no single ideal anesthetic agent that can achieve each of the specific goals with complete safety in all patients. The spectrum of activity of every anesthetic agent can extend beyond the specific effect desired. Many agents induce disturbances in homeostasis that can impair autonomic responses and augment the detrimental impact of surgical trauma. The concept of balanced anesthesia is to administer a sequence of drugs with specific actions at safe dosing ranges without undesirable side effects of any particular agent (see Table 33.1).

Anesthesia Levels

Local/Regional Anesthesia

Local anesthetics produce their effects by interfering with nerve conduction through blockade of neuronal sodium channels.[2,3] The inward sodium current is an essential component for propagation of the action potential along nerve fibers. Most local anesthetics contain an aromatic ring, and are basic and lipid soluble. They are made soluble in an acid aqueous vehicle for administration. In tissue, neutral pH is required to promote neuronal interaction. This is the theoretical explanation for the diminished effect of local infiltration agents in the relatively acidic environment in regions of inflammation or infection.

A variety of agents are available for local anesthesia. These agents have structural homology but different functional properties (potency, onset, duration of action) that influence their selection for clinical applications (Table 33.2).[4] In clinical practice, most vascular surgeons use lidocaine or bupivacaine. Though less potent than lidocaine, bupivacaine has a longer duration of action that extends well into the postprocedural period and thus may enhance recovery comfort.

Systemic local anesthetic toxicity is the result of rapid drug absorption and uptake into the circulation. Beyond the occasional inadvertent intravenous administration, systemic toxicity may occur as a result of absorption from mucosal surfaces, peritoneal or pleural spaces, and muscle. Co-administration of a vasoconstrictor (epinephrine) will reduce these effects somewhat. A Bier block, in which a relatively high dose of local anesthetic is administered intravenously into an isolated limb, can deliver a dangerous systemic dose if the tourniquet is prematurely removed. Ester-containing local anesthetics are cleared by plasma cholinesterase rapidly, but amide-based local agents, including lidocaine and bupivacaine, require liver metabolism. Toxic central nervous system effects follow a dose-related progression from vertigo and tinnitus, to anxiety and fear, and subsequently to tremors, seizures, and coma.[5] Benzodiazepines may mask the early neurologic signs of local anesthetic toxicity, so particular care is needed in the setting of concomitant sedation. Direct cardiovascular toxicity is seen at levels exceeding the threshold for seizure and is manifested as arrhythmia and myocardial depression.

Moderate Sedation

The term *moderate sedation* (formerly referred to as "conscious sedation") describes a drug-induced depression of consciousness that facilitates intervention but does not depress the ability of patients to protect their airway. Moderate sedation does not impair independent respiration and normal cardiovascular function and may be administered by specifically trained individuals with appropriate credentialing. The Joint Commission has developed standards for healthcare facilities that conduct

TABLE 33.2 Clinical Features of Individual Local Anesthetic Drugs

	Drug	Main Use	Potency[a]	Onset	Duration[a]	Toxicity	Maximal Single Dose	Comments
Esters	Cocaine[a]	Topical	1	slow	30-60 min	Very high	150 mg	Addictive, vasoconstriction, "fight or flight response"
	Benzocaine	Topical	NA	slow	30-60 min	Low	200 mg	Topical only
	Procaine	Infiltration, nerve block	2	fast	30-60 min	Low	1000 mg	Allergic potential
	Chloroprocaine	Infiltration, nerve block	1	fast	30-60 min	Low	1000 mg	No longer available
	Tetracaine	Topical	4	slow	30-60 min	High	20 mg	No longer available
Amides	Lidocaine	Topical, infiltration, nerve block, epidural	1	fast	1-2 h	Medium	300-500 mg	Versatile agent
	Mepivacaine[a]	Infiltration, nerve block, epidural	1	fast	1-3 h	Medium	400-500 mg	No longer available
	Prilocaine	Infiltration, nerve block, epidural, intravenous regional	1	fast	1-3 h	Low	600 mg	Methemoglobinemia at >600 mg
	Ropivacaine	Infiltration, nerve block, epidural	4	slow	2-12 h	Medium	20 mg	Enantiomer of Bupivacaine
	Bupivacaine	Infiltration, nerve block, epidural	4	fast	2-12 h	Medium	225 mg	Ventricular arrhythmias, cardiovascular collapse at high doses
	Etidocaine	Infiltration, nerve block, epidural	2	fast	2-12 h	Medium	300-400 mg	No longer available

[a]Relative to lidocaine.

moderate sedation and the ASA has published detailed guidelines for the administration of moderate sedation.[1,5,6] The principal hazard of moderate sedation is induction of excessive sedation with a deeper than desired level of anesthesia and the potential for hypoventilation and hypoxia.

In preparation for moderate sedation, patients should be fasting. A careful history of allergies, adverse reactions, current medications, and conditions recognized to compromise cardiopulmonary function under sedation (e.g., sleep apnea) should be elicited. The facility should have devices and medications for rescue in the event of oversedation. Intraprocedural and postprocedural monitoring is critical to safety. The ASA strongly recommends monitoring the following: level of consciousness; oxygenation with pulse oximetry; arterial pressure with automated oscillometry every 5 minutes; respiration with an apnea monitor; and electrocardiogram in patients with cardiac disease or undergoing deep sedation. Table 33.3 lists basic information on several agents used in modern practice.[7,8] Reversal agents, naloxone for opiates and flumazenil for benzodiazepines, must be immediately available. These receptor antagonists may have durations of action shorter than the agents that they are used to block, and therefore continued careful observation of patients after any use of rescue agents is mandated as repeat dosing maybe required.

Dexmedetomidine is also being used with increasing frequency for procedural sedation. Dexmedetomidine is a centrally acting, alpha-2 adrenergic agonist that decreases anxiety while simultaneously providing pain relief and sedation. This agent induces sedation with limited respiratory depression and has a half-life of 2 to 3 hours. Dexmedetomidine has potential sympatholytic effects including hypotension, bradycardia, and decreased circulating norepinephrine. Patients receiving maintenance anesthetics (sevoflurane, isoflurane, propofol, and fentanyl) with dexmedetomidine, as opposed to those without, were found to have significantly lower heart rates, mean arterial blood pressures, less nausea and emesis, and decreased restlessness.[9] Patients given dexmedetomidine require close hemodynamic monitoring. Patients with hypovolemia and heart block should not receive dexmedetomidine. Atropine should be available to treat unwanted associated bradycardia. The sympatholytic effects have been shown to attenuate the stress response during emergence from general anesthesia specifically for vascular procedures.[10]

Ketamine, an N-methyl-D-aspartate (NMDA) receptor antagonist and dissociative anesthetic, may also be used for procedural sedation and to decrease the postoperative need for opioid analgesics. This agent increases cerebral blood flow and metabolism and has actions on both monoamine and opioid receptors. Ketamine can also increase systemic and pulmonary arterial pressure, heart rate, cardiac output, and myocardial oxygen requirements via stimulation of the central nervous system. Because of these actions, this agent should be avoided in patients with ischemic heart disease, congestive heart failure, cerebrovascular disease, increased intracranial or intraocular pressure, epilepsy, and psychotic illness. Therapeutic dosing is often reached after one dose. The initial dose is 0.5 mg/kg which can be repeated if the effect is inadequate after five minutes. Critically ill patients may experience negative cardiac inotropic effects with an unexpected drop in arterial pressure and heart rate if their sympathetic responses and endogenous catecholamines are exhausted.[11-13]

Regional Anesthesia

Regional anesthetic techniques include peripheral nerve blocks, cervical and brachial plexus blocks, spinal anesthesia, and epidural

TABLE 33.3 Properties of Drugs Commonly Used for Moderate Sedation

Drug	Pharmacologic Class	Pharmacologic Effects	Onset of Action	Duration of Action	Adverse Effects
Midazolam	Benzodiazepine	Sedation Amnesia Anxiolysis	1-5 min, peak in 3-5 min	1-3 h	Hypotension, hypoventilation, decreased tidal volume, increased respiratory rate, apnea, increased upper airway resistance
Diazepam	Benzodiazepine	Sedation Amnesia Anxiolysis	1-5 min	20-60 min	Hypotension, hypoventilation, respiratory depression
Meperidine	Opioid	Sedation Analgesia	5 min, peak in 10 min	2-4 h	Hypoventilation, hypotension, lower seizure threshold, respiratory depression, decreased tidal volume, nausea, vomiting
Propofol	Ultrashort-acting sedative, hypnotic	Sedation Hypnotic	30-60 s	3-10 min	Dose-dependent hypotension, hypoventilation, respiratory depression, pain at injection site
Droperidol	Neuroleptic	Neuroleptic Anxiolytic	30 min	1-4 h	Hypotension, tachycardia, hypoventilation, prolonged QT interval
Fentanyl	Opioid	Sedation Analgesia	<1 min, peak in 5-8 min	30-60 min	Hypoventilation, respiratory depression, decrease in tidal volume

anesthesia. Peripheral nerve blocks are frequently utilized for extremity and digital procedures with effects lasting well after the surgery is complete.

Spinal and Epidural Anesthesia

Spinal anesthesia refers to the injection of medications through the dura directly into the cerebrospinal fluid from lumbar levels. The specific agents chosen are based on time of onset, potency, and duration of action. Lidocaine and bupivacaine are often used for spinal anesthesia and have durations of action of 60 and 100 minutes, respectively. Patient positioning and solution density are also important factors that should be considered for successful spinal anesthesia. Spinal anesthesia is contraindicated when hemodynamic instability is expected since this technique often produces a variable degree of sympathetic blockade with some loss of arterial and venous tone and fluid sequestration. A decrease in systemic vascular resistance of >30% has been reported in older patients with known cardiac disease.[14] Hypotension associated with spinal anesthesia is treated with fluid resuscitation, Trendelenburg positioning, or inotropic or pressor agents if the patient has underlying heart failure. Severe coagulopathy, increased intracranial pressure, and infection at the injection site are other contraindications to spinal anesthesia.

Complications of spinal anesthesia include postdural puncture headache, nausea and emesis resulting from unopposed parasympathetic efferents, and respiratory depression particularly in patients with high punctures and chronic obstructive pulmonary disease. These patients rely on accessory muscles for respiration which can be compromised by a high spinal block. Other complications include direct neurologic injury, cauda equine syndrome, arachnoiditis, spinal hematoma, meningitis, and idiopathic cardiovascular collapse. Complications are rare with the exception of postdural puncture headache which may occur in 25% of patients undergoing spinal anesthesia. The headache may be associated with cranial nerve symptoms such as diplopia, tinnitus, and nausea and is classically relieved by the supine posture. Patients are treated with bed rest, caffeine, hydration, and analgesics.[15] This complication may be treated by the administration of an epidural blood patch which is thought to work by sealing the meningeal puncture site.[16,17]

Epidural anesthesia refers to the placement of a catheter into the epidural space around the distal thoracic or lumbar spine, frequently with the delivery of larger quantities of anesthetic required for absorption between the spinal ligament and dura (epidural space). Vascular specialists must be familiar with the advantages and limitations of these approaches, particularly as they affect postoperative management and analgesia. A major advantage of epidural anesthesia is the ability to continually deliver postprocedural analgesia via an indwelling catheter. Effective epidural postoperative analgesia obviates the need for systemically administered opioids and the accompanying risk for respiratory depression, excessive sedation, and gastrointestinal side effects. Epidural anesthetic infusions can be maintained in most patients safely for 3 to 4 days.

The technique of catheter placement is critical to properly enter the epidural space at the appropriate level without injury to the veins of Batson's plexus. Local anesthetic infused into the epidural space acts on the spinal nerve roots which are mixed nerves with somatosensory, somatomotor, and autonomic fibers. These component nerve fibers usually have different sensitivity to the blocking effect of anesthetic agents with the greatest effect on sympathetic autonomic fibers and the least effect on somatic motor nerves. Thus, the extent of autonomic, sensory, and motor blockade with a given epidural infusion may differ by several vertebral levels.

Contraindications to epidural catheter placement are similar to those for spinal block with the exception that recent anticoagulation is not an absolute contraindication. The American

TABLE 33.4 Recommended Time Interval Before and After Neuraxial Block or Catheter Removal

Drug	Time Before Neuraxial Manipulation	Time After Neuraxial Manipulation
Unfractionated heparin, subcutaneous prophylaxis	4 h	>60 min
Intraoperative therapeutic heparinization	2-4 h after the last heparin dose, check partial thromboplastin time	>60 min (Note intravenous anticoagulation should not be continued with neuraxial catheter in place)
Low molecular weight heparin	12 h for prophylactic doses 24 h for therapeutic doses	Prophylaxis should be delayed 24 h after neuraxial manipulation and should be limited to once a day dosing Delay prophylaxis until adequate hemostasis is achieved if blood is present during neuraxial manipulation Prophylaxis can be started 2 h after neuraxial catheter removal
Warfarin	When INR < 1.4	When INR < 1.4
Dabigatran	5 days	6 h
Apixaban	3 days	6 h
Rivaroxaban	3 days	6 h
Prasugrel	7-10 days	6 h
Ticagrelor	5-7 days	6 h
Aspirin, NSAIDs COX-2 inhibitors	Can be continued	Can be continued
Clopidogrel	7 days (if needed before, can perform P2Y12 assay to assess residual antiplatelet activity)	Should be held until after removal

Modified from Horlocker TT, Wedel DJ, Rowlingson JC, et al: Regional anesthesia in the patient receiving antithrombotic or thrombolytic therapy: American Society of Regional Anesthesia and Pain Medicine Evidence-Based Guidelines (3rd edition) *Reg Anesth Pain Med.* 2010;35:64-101.

Society of Regional Anesthesia and Pain Medicine recently released a consensus statement suggesting that epidural blocks may be performed four hours after the last subcutaneous dose of unfractionated heparin and 12 hours after the last subcutaneous dose of low-molecular-weight heparin (LMWH).[18] Treatment with nonsteroidal antiinflammatory drugs or aspirin is not considered a contraindication if placement is atraumatic. Clopidogrel should be discontinued 7 days before puncture. Systemic heparinization can be started one hour after catheter insertion. If a traumatic puncture occurs, elective vascular surgery should be delayed for 12 to 24 hours (Table 33.4).

Complications of epidural anesthesia are similar to those of spinal anesthesia. Accidental dural puncture can lead to postdural puncture headache, but this generally occurs less frequently with epidural anesthesia than with spinal techniques which naturally always involve dural puncture. With misplacement of epidural access, it is possible to inject agents into the subdural or the subarachnoid space, potentially resulting in total spinal anesthesia and even blockade of the brainstem, which can induce cardio-pulmonary reflexes, coma, and shock. This complication is extremely rare but special care must be exercised with high epidurals.

General Anesthesia

The term *general anesthesia* refers to a loss of consciousness with patients unarousable to painful stimuli. Patients under general anesthesia cannot protect their airway and in most cases require assisted ventilation. Patients receiving general anesthesia often have depressed cardiovascular function and require support by specially trained anesthetists. A complete discussion of the agents and techniques of general anesthesia are beyond the scope of this text; however, a few of the more commonly used agents are discussed below. A comprehensive review can be found in specialized work listed.[19] This text focuses on the aspects of general anesthesia of special interest to vascular surgeons and highlights the optimal anesthetic techniques to manage common vascular procedures.

Agents used in general anesthesia can induce peripheral vasodilation and inhibit sympathetic autonomic regulation, leaving the patient with the reduced ability to autoregulate circulation and tissue perfusion. Resulting hypotension is frequently noted between anesthesia induction and skin incision. The loss of vasoconstriction in the periphery leads to redistribution of blood flow to the skin, loss of thermoregulation, a decrease in core temperature. The patient can become dependent on therapeutic interventions with fluid and inotropes.

Succinylcholine is a depolarizing muscle relaxant with rapid onset and short action. Adverse effects of succinylcholine include malignant hyperthermia, sepsis, arrhythmias, elevated intracranial pressure, elevated intraocular pressure, elevated intragastric pressure, and transient increases in serum potassium. It should be avoided in patients with large-surface area burns, spinal cord injury, neuromuscular disease, cerebrovascular accident, and severe chronic debility, as the associated hyperkalemia can lead to cardiac arrest.

If malignant hyperthermia is suspected, the surgical procedure should be stopped as soon as possible. Intravenous dantrolene at 2.5 mg/kg can be given through a large bore IV. Doses can

be repeated until decreases in end-tidal CO_2, heart rate, and muscle rigidity are noted. Dantrolene dosing may need to be increased to 10 mg/kg if muscular contractions persist. The patient should be hyperventilated on 100% oxygen at greater than 10 L/min to lower end-tidal CO_2 and flush volatile anesthetics. Activated charcoal filters can be placed in the ventilator circuit and replaced frequently to remove inhaled anesthetic. The patient should be cooled if temperature is greater than 38°C. Metabolic acidosis should be corrected with bicarbonate. Calcium chloride 10 mg/kg or calcium gluconate 30 mg/kg, sodium bicarbonate 1 to 2 mEq/kg IV, 50% glucose 50 mL, and regular insulin 10 units IV can be used to treat hyperkalemia. Refractory hyperkalemia should be treated with albuterol, kayexalate, or dialysis. Avoid calcium channel blockers for treatment of arrhythmias.

Commonly used inhaled agents for general anesthesia in vascular surgery include nitrous oxide, desflurane, halothane, sevoflurane, and isoflurane. Nitrous oxide use has decreased with the availability of safe, more potent and short-acting agents. Significant cardiovascular depression with decreased myocardial contractility can occur when nitrous oxide is given with opioids. These actions can be exacerbated in patients with congestive heart failure. However, nitrous oxide as a component of balanced general anesthesia has no greater risk of death and cardiovascular complications in patients with known or suspected increased cardiac risk undergoing major noncardiac surgery. Absolute contraindications include respiratory compromise and patients with air-filled cavities including pneumothorax, pulmonary blebs, and bowel obstruction.

All halogenated inhalants can decrease mean arterial pressure. Halothane decreases myocardial contractility while desflurane, isoflurane, and sevoflurane decrease systemic vascular resistance. Small increases in desflurane dosing, however, can dramatically affect sympathetic nervous system activity and indirectly affect the cardiovascular responses. Therefore desflurane should not be used in patients in whom increased heart rate and blood pressure could be detrimental. Isoflurane does not have the same effect on the sympathetic nervous system at usual general anesthetic doses. Halothane and sevoflurane depress the sympathetic response. Halothane increases myocardium sensitivity to catecholamines and therefore should not be used in patients with prior history of arrhythmias. All halogenated inhalant agents cause respiratory depression, airway vasodilation, and irritation. These agents have different solubilities, metabolisms, and decrement times that allow for selection of the most appropriate agent for procedures of different lengths. All should be avoided in patients with a history of malignant hyperthermia.

Propofol is a rapidly acting intravenous sedative-hypnotic agent that decreases cerebral blood flow and metabolic oxygen requirements. It rapidly reaches an equilibrium between the plasma and brain but is not absorbed and metabolized in other tissues, explaining its rapid onset and sometimes prolonged effects. Propofol-associated hypotension occurs because of three separate mechanisms: inhibition of the sympathetic nervous system, impairment on the baroreflex regulatory mechanisms, and a dose-dependent decrease in potassium-induced tone in the veins and arteries.[20,21] Propofol is also frequently used for procedures requiring only moderate sedation; however, the ASA and the American Association of Nurse Anesthetists believe that only persons trained in the administration of general anesthesia, not concurrently involved with the procedure, should administer propofol to nonventilated patients.

Etomidate, another hypnotic agent frequently used upon induction, preserves hemodynamic stability and might be a better choice for some patients because it does not affect the sympathetic and autonomic reflexes as much as propofol. Etomidate can inhibit cortisol production by the adrenal glands in critically ill patients and therefore should be limited to induction of general anesthesia and not be used as a maintenance anesthetic in such patients.[22]

Vascular Anesthesia Technique and Outcomes

There is a great deal of interest in determining anesthetic approaches that minimize the physiologic impact of surgery, enhance vascular reconstruction durability, and improve patient survival. Some of the research efforts related to the anesthetic management for specific frequently performed vascular operations are considered here.

Elective Aortic Surgery

The use of epidural analgesia arose in the 1970s and 1980s as an attractive alternative to standard therapy with balanced general anesthesia and postoperative systemic opioid analgesia. Epidural techniques, generally supplemented with light general anesthesia during the procedure, were applied to high-risk vascular patients with apparent success. A fair number of trials were conducted in this period to compare the relative outcomes of these techniques in high-risk patients.[23-26] Unfortunately, these studies produced conflicting results. Three major randomized clinical trials have been published that directly address this question.

The first study is the Veterans Affairs (VA) Cooperative Study #345, reported by Park and associates in 2001.[27] This prospective randomized trial was conducted at 15 VA Medical Centers to compare outcomes in high-risk patients (ASA class III or IV) undergoing elective major abdominal surgery (gastric, biliary, colonic, and aortic). Patients were randomized to one of two anesthetic schemes: (1) balanced general anesthesia and postoperative pain management or (2) epidural combined with light general anesthesia and postoperative pain management with epidural supplemented with intravenous morphine as needed. The study was powered to detect a 50% reduction in relative risk of a projected 15% major complication rate. No differences were noted in the occurrence of any of the complications between the two anesthetic groups. Although epidural catheters were in use for only a mean of 55 hours, pains scores were significantly less in the epidural group. Of the 984 patients who entered the study, approximately 38% underwent major aortic surgery. A post hoc subgroup analysis of the aortic patients ($n = 374$) showed that occurrence of any complication was reduced significantly in patients managed with the epidural technique (22% vs. 37%, $P < .01$), mostly as a result of a reduction in the rate of new myocardial infarction, respiratory

failure, and stroke. The data suggest that the two anesthetic approaches are equivalent across the range of major abdominal surgery, but there could be advantages of epidural approaches in aortic surgery. The study suffers from the lack of blinding of the treating physicians, lack of proscribed guidelines for postoperative hemodynamic management, and less than optimal analgesic administration in the standard-therapy group.

A single-institution, prospective randomized double-blinded study performed at Johns Hopkins Hospital was reported in 2001.[28] The study was designed to evaluate intraoperative anesthesia technique and postoperative analgesic management in high-risk patients undergoing abdominal vascular surgery. Patients were randomly assigned to one of four groups: (1) general anesthesia with postoperative intravenous patient-controlled analgesia (PCA), (2) general anesthesia with postoperative epidural PCA, (3) epidural anesthesia and supplemental general anesthesia with postoperative intravenous PCA, and (4) epidural anesthesia and supplemental general anesthesia with postoperative epidural PCA. All randomized patients had an epidural catheter placed before surgery and the epidural was kept in place for at least 72 hours postoperatively. The primary endpoint was length of hospital stay, and the study was powered to detect a 20% reduction in an expected 12.7-day stay. There were detailed protocols for hemodynamic management, fluid administration, transfusion, and extubation. The study was closed prematurely when a preliminary conditional power analysis showed minimal likelihood of detecting a significant difference among the treatment groups. The data collected showed no differences in death, myocardial infarction, myocardial ischemia, reoperation, pneumonia, and renal failure between the treatments. Similarly, ICU length of stay, time to initiation of diet, time to independent ambulation, and pain scores were not different in the four groups. Epidural PCA was associated with a significantly shorter time to extubation. These data demonstrate that in a controlled setting with well-designed and managed treatment protocols there are no measurable differences in outcomes among these techniques.

The third study is the Multicentre Australian Study of Epidural Anesthesia (MASTER Anesthesia Trial), reported by Rigg and coauthors in 2002.[29] This multicenter, randomized controlled trial recruited 920 patients and was intended to confirm the benefit of epidural anesthesia noted in an earlier Australian trial while using more consistent anesthetic technique.[30] High-risk patients who were to undergo elective major abdominal surgery or esophagectomy were eligible for recruitment. Patients were randomized to either control, consisting of balanced general anesthesia with postoperative intravenous opioid analgesia, or epidural procedural anesthesia with postoperative epidural analgesia. Detailed protocols were included for the management of each aspect of care throughout the study period. There was no masking of treatment in this study. Primary outcomes were combined 30-day mortality and morbidity. Three quarters of patients were recruited in Australian centers and 18% of patients underwent major aortic surgery. The data showed no difference between the two treatments with regard to overall 30-day outcome. However, there were significant differences in pain score and respiratory failure that favored the epidural group. The MASTER Anesthesia Trial was limited by poor protocol compliance, specifically in the epidural group with only 225/447 patients fully completing the protocol. Further subgroup analysis of aortic surgery patients (n = 164) revealed no significant differences in cardiovascular complications between the two anesthetic techniques (4.5% vs. 4.7%, P = NS).

Since then, multiple reviews have attempted to compile the data from these trials and others to draw working conclusions. In 2012, a Cochrane Library meta-analysis was performed comparing the use of postoperative epidural or systemic analgesia in patients undergoing elective abdominal aortic surgery. The study included 15 randomized trials including 1297 patients receiving either postoperative epidural analgesia or postoperative systemic analgesia with opioids. Most patients receiving postoperative epidural analgesia also had the epidural in place during their surgical procedure. The epidural group had significantly lower postoperative pain scores, and the duration of postoperative intubation and mechanical ventilation was shortened by 48%. Rates of myocardial infarction, gastrointestinal complications, and renal complications were also significantly lower in the group treated with postoperative epidural.[31]

The benefits of epidural anesthesia in aortic surgery are observed with thoracic as opposed to lumbar epidurals. In the meta-analysis performed by Beattie in 2001, the superiority of thoracic epidural anesthesia was highlighted.[32] Thoracic regional anesthesia specifically reduces sympathetic activation and increases myocardial oxygen supply via coronary dilation.[33-35] The same effects are not seen with lumbar regional anesthesia which may actually result in a compensatory increase in sympathetic activity.[36] Thoracic epidural anesthesia also protects against splanchnic hypoperfusion during periods of ischemia and reperfusion resulting in decreased duration of postoperative ileus. Intestinal perfusion and bowel motility is not protected by lumbar epidural anesthesia.[37,38] Better pulmonary and diaphragmatic function with epidurals might also be explained by epidural anesthesia's ability to block inhibitory effects of abdominal surgery and general anesthesia on the phrenic nerve and diaphragm.[38,39]

Generally, the supplementation of general anesthesia with the epidural technique has advantages for the patient, especially in the postoperative phase with improved patient comfort and a reduction in cardiovascular, pulmonary, and other systemic complications.[31,40] The intraoperative use of epidural anesthesia in comparison with general anesthesia has not been proven to reduce mortality associated with aortic surgery and has not been shown to improve revascularization durability.

Ruptured Abdominal Aortic Aneurysms

The primary goal for anesthetists treating a patient with a ruptured abdominal aortic aneurysm is to maintain sufficient arterial pressure for vital organ perfusion. Careful resuscitation with intravenous fluids is paramount, because aggressive volume resuscitation to pressures higher than 100 mm Hg has been found to be associated with increased perioperative mortality.[41] As long as the patient is awake and exhibits mentation, permissive hypotension with systolic arterial pressure between 70 and 80 mm Hg should be tolerated. Transfusion of blood products

is also discouraged unless the patient is suffering from a concurrent myocardial infarction.[41] Pain control should be managed with small intravenous doses of narcotics until surgical arrangements are made.

Because the induction of anesthesia is associated with a reduction in sympathetic tone and myocardial depression, the anesthetist should be prepared for large volume resuscitation and transfusion. Furthermore, the relaxation of abdominal muscles may result in loss of the tamponade of the rupture and positive pressure ventilation will decrease venous return, either of which can further exacerbate hypotension. Systemic arterial pressure lability can be reduced with the use of a large volume endovascular balloon positioned proximal to the site of rupture prior to induction (Resuscitative Endovascular Balloon Occlusion of the Aorta, REBOA).[42] Such balloons can be inserted under local anesthesia from groin access. The patient should undergo sterile prep and draping prior to induction so that immediate incision is feasible once anesthetic is given. Once cross clamp control of the aorta is obtained, the anesthetic team should be allowed to catch up with blood losses.

No particular anesthetic technique has been shown to be superior for ruptured abdominal aortic aneurysms. Hemodynamically stable patients with contained ruptures should be evaluated for epidural placement as there are potential postsurgical advantages. Endovascular repair of ruptured abdominal aortic aneurysms can be initiated, if not always completed with local anesthetic and intravenous sedation.[43] Reasons cited for converting to general anesthesia included patient discomfort, loss of consciousness, and movement during the procedure. The technique of utilizing local anesthetic for ruptured abdominal aortic aneurysm repair might be a crucial factor for preventing large hemodynamic disturbances and improved patient survival.[44]

Infrainguinal Reconstructions

Anesthetic technique has also been studied in patients having infrainguinal vascular surgery, but the data are less extensive and few firm conclusions can be drawn.[45-49] Some evidence suggests that epidural anesthesia could impact early infrainguinal bypass graft patency. Christopherson and colleagues reported a prospective randomized study comparing general and epidural anesthesia in 100 patients undergoing elective lower extremity bypasses.[49] Although the data showed no evidence of an effect of anesthetic method on mortality or major morbidity, these authors found an unexpected dramatic reduction in postoperative graft thrombosis from a high rate of 43% with general anesthesia to 8% with the epidural technique over six-month follow-up. Additional investigators suggested that this may be due to an effect of epidural anesthesia on coagulation and fibrinolysis.[50,51] Epidural anesthesia does not affect fibrinogen or plasminogen activator inhibitor (PAI) levels, however PAI levels were significantly increased in the first 24 hours postoperatively in patients receiving general anesthesia for lower extremity bypass. These findings suggest an early prothrombotic effect of general anesthesia and that epidural anesthesia possibly promotes fibrinolysis.[52] This fibrinolytic effect was not found to be significant beyond 30 days after surgery.[53]

A large retrospective review of the National Surgical Quality Improvement Program database was recently performed comparing outcomes by the anesthetic technique used in patients who had infrainguinal arterial bypass. Not surprisingly, general anesthesia was the most common type of anesthesia, outnumbering both regional techniques, spinal and epidural, by more than three to one. When spinal anesthesia was compared to general anesthesia, early graft failure, early return to the operating room, cardiac morbidity, and pneumonia were significantly lower in the spinal anesthesia group. When spinal anesthesia was compared to epidural anesthesia, no statistically significant differences were noted in early graft failure or 30-day morbidity. No significant difference was noted in 30-day mortality among the three groups.[49]

Carotid Surgery

The optimal mode of anesthesia for carotid surgery has been a topic of interest for decades and numerous attempts have been made to determine whether general or local/regional anesthesia techniques are superior. A major benefit of performing carotid surgery under regional anesthesia is the ability to continuously monitor cerebral function in the conscious patient during carotid clamping. A Cochrane meta-analysis comparing patients undergoing carotid endarterectomies randomized to regional or general anesthesia demonstrated no significant differences in death, stroke, and other serious cardiopulmonary complications. However, nonrandomized patients undergoing the procedure with regional anesthesia did have a significant reduction in these serious complications.[54] The GALA (General Anesthesia versus Local Anesthesia) trial was designed to determine if this benefit persisted with a larger cohort of randomized patients. Over 3500 patients undergoing carotid endarterectomies were randomized to general versus local anesthesia over 8 years, but no difference in mortality and major morbidity was detected between the two groups at 30 days.[54] Critics of the study and proponents of regional anesthesia argue that successful regional anesthesia requires a dedicated team of surgeons, anesthesiologists, nurses, and support staff and the variability associated with randomizing does not allow for optimal patient care (see Chapter 91).[55,56]

INTRAOPERATIVE MONITORING

Continuous monitoring of the patient response to the surgical intervention is critical. This allows both the surgeon and the anesthesiologist to recognize deviations from the expected course and adapt to the changing condition of the patient.

Electrocardiography

Monitoring of the electrical activity of the heart should be applied throughout the perioperative period in almost all types of interventions. The rationale for electrocardiographic (ECG) monitoring is detection of arrhythmias and myocardial ischemia. Arrhythmias, common during vascular interventions, are related primarily to the choice of anesthetic agents, intraoperative variations in blood gases and serum electrolytes, direct autonomic

stimulation, activation of cardiovascular reflexes (endotracheal intubation, vagal stimulation, peritoneal traction, sinus nerve), or direct stimulation of the myocardium (central venous cannulation, cardiac retraction). Myocardial ischemia is usually the result of underlying coronary heart disease combined with increased myocardial work secondary to the neuroendocrine responses to surgical trauma and hemodynamic conditions that may reduce global myocardial perfusion (hypovolemia).

A five-electrode system with four limb leads and a single unipolar precordial lead (generally V_5) is standard for most vascular procedures. This configuration allows monitoring of any of the standard six bipolar limb leads, as well as the anterolateral chest wall lead in the distribution of the left anterior descending coronary artery. Leads II and V_5 are monitored continuously in most vascular cases. Some evidence suggests that V_3 or V_4 may have greater sensitivity for detection of myocardial ischemia in this setting.[57] Invasive leads (esophageal, endotracheal, or central venous) may have higher sensitivity for detection of arrhythmia and ischemia but are not used in routine clinical practice.[58,59]

Pulse Oximetry

Pulse oximetry is a noninvasive technique of monitoring oxygen saturation with probes placed peripherally, often on fingers, earlobes, and/or toes. It measures the absorption of different wavelengths of light that undergo preferential absorption by either oxyhemoglobin or deoxyhemoglobin. Monitoring with pulse oximetry is continuously performed throughout the perioperative period, but evidence to support its efficacy or impact on outcomes in patients undergoing general anesthesia is scant.[60,61] The potential benefit of intraoperative pulse oximetry is a continuous index of tissue perfusion. Pulse oximetry is prone to a number of artifacts and may be particularly misleading in patients with vascular disease.[62] Risk factors for discordant pulse oximetry include ASA physical status III, IV, or V; orthopedic, vascular, or cardiac surgery; and intraoperative hypothermia, hypotension, or hypertension. Furthermore, pulse oximetry cannot detect changes in PaO_2 above 100 mm Hg and thus is insensitive to potentially clinically relevant changes in gas exchange in the lungs.

When vascular surgery patients have compromised extremities that are not easily monitored with standard pulse oximetry, reflectance cerebral oximetry can be used. The reflectance monitor uses an emitter and light detector that measures the backscatter of light. Such probes can be placed on the forehead, which receives blood flow from the internal carotid and ophthalmic artery rather than peripheral arteries. Standard pulse oximetry probes and reflectance probes readings were compared and found to be comparable in patients undergoing vascular surgery.[63]

Capnography

Continuous monitoring of the end-tidal CO_2 using infrared absorption spectroscopy is the standard of care for the assessment of ventilation during general anesthesia. This information is displayed most commonly as a continuous plot of the partial pressure of CO_2 versus time (time capnogram). Exhaled gases can be sampled either by a sensor placed directly within the respiratory circuit or by a sensor placed remotely with gases aspirated. It is important to bear in mind that the gradient between end-tidal CO_2 and $PaCO_2$ (normally about 5 mm Hg) may be affected by disease states and that the measurement of end-tidal CO_2 using capnography is subject to artifacts. The clinical applications of capnography have been reviewed recently.[64,65] In 2011, the ASA updated its statement on Standards for Basic Anesthetic Monitoring to recommend the addition of continuous monitoring of end-tidal CO_2 during both moderate and deep sedation.[66,67]

Arterial Pressure

Noninvasive Methods

The high incidence of cardiac disease in vascular patients and the dramatic effects of vascular procedures on afterload and blood volume make monitoring arterial pressure especially important in vascular interventions. All patients should have periodic measurement of arterial pressure with noninvasive techniques throughout the perioperative period. This is accomplished with automated oscillometric devices with a single cuff that measure the amplitude of oscillations as the cuff is slowly deflated. The pressure at which oscillations are maximal is the mean arterial pressure, and systolic and diastolic pressures are calculated by various proprietary algorithms.[68] Such devices correlate well with invasive arterial pressure measurements, although the decreased arterial compliance in the elderly and in diabetics may lead to overestimation of systolic pressure and underestimation of diastolic pressure.[69] Automated oscillometry may be less useful in the setting of atrial fibrillation, bradycardia, and in patients with severe vasoconstriction.

Invasive Methods

Real-time measurement of arterial pressure is extremely useful, particularly in the case of vascular surgery procedures with aortic clamping and release resulting in sudden changes of afterload, intentional pharmacologic manipulation of arterial pressure (hypotension during the thoracic endograft procedure, hypertension in occasional carotid cases), and manipulation of critical cardiovascular reflex arcs (with carotid angioplasty, endarterectomy, or both). In clinical practice today, intraarterial pressure is usually measured with a fluid-filled catheter, tubing, and an electromechanical pressure transducer system. The accuracy of these systems is limited by the length and compliance of the tubing and the presence of small air bubbles in the tubing. The fluid-filled systems have the added benefit of being able to repeatedly sample arterial blood.

The arterial cannula is commonly inserted into the radial artery. Stenosis, thrombosis, and occlusion of the radial artery are possible complications of cannulation and ischemia of the hand can result.[70] The ulnar artery is the dominant supply of arterial perfusion to the hand in approximately 90% of people.[71] Assessment of the adequacy of collateralization through the ulnar artery by way of the Allen test is a critical step before safe use of the radial artery for monitoring pressure. Alternatively,

monitoring catheters can be placed in the brachial, axillary, and femoral arteries. Femoral lines can be placed at the time of arterial exposure or cannulation for diagnostic or adjunctive arteriography and can be discontinued at the end of the procedure. Brachial catheters should be avoided because of the poor collateralization around the elbow in the event of thrombosis, and axillary lines may be complicated by axillary sheath hematoma which can produce devastating neurologic consequences if not promptly identified and treated.

Insertion should be assisted with either a separate or integral guidewire using Seldinger technique.[72] Ultrasound imaging provides the proceduralist with the advantage of real-time assessment showing needle location in relationship to the vessel. Ultrasound imaging can also show vessel patency and atherosclerotic disease helping to determine if the vessel is appropriate for catheter placement. The use of ultrasound for the placement of arterial catheters has been shown to improve the likelihood of successful cannulation.[73,68]

Advanced Hemodynamic Monitoring

Systemic arterial pressure is a derived variable and is a physiologic result of the interaction of cardiac output and peripheral arterial resistance. Cardiac output is the product of heart rate and stroke volume and is determined by myocardial contractility and left ventricular end-diastolic volume (LVEDV). Central venous and pulmonary artery (PA) catheterization have been performed historically to measure pressures that may have a useful relationship to left ventricular filling and thus to cardiac output. It is important to understand the function of these devices. However, the development of less invasive monitoring technology has reduced the role of real-time monitoring of hemodynamic parameters by these methods.

Central Venous Catheterization

Central venous catheterization can be used to measure central venous pressure (CVP) and to theoretically provide a real-time estimate of intravascular volume and venous return. Unfortunately, CVP is affected by a large number of confounding variables which limits its value. CVP correlates well with left ventricular filling pressure only in patients with normal cardiac and pulmonary function. The correlations are further weakened with the use of positive pressure ventilation during surgery and by patient positioning. Absolute values of CVP have little meaning but changes in the parameter with intervention are valuable. The ASA has recently published comprehensive practice guidelines to enhance the safety of central venous catheterization.[69] The use of central venous catheterization to regularly measure CVP intraoperatively and estimate intravascular volume for moderate to high-risk surgery has largely been replaced by other techniques including transesophageal echocardiography and minimally invasive hemodynamic monitoring.

Pulmonary Artery Catheterization

Some of the shortcomings of CVP monitoring were overcome by the development of PA catheters. Basic flow-directed balloon-tipped PA catheters can be used to measure both pulmonary artery diastolic pressure (PADP) and pulmonary capillary wedge pressure (PCWP). PA catheters also allow estimation of cardiac output by several different methods and permit sampling of mixed venous blood, which enables calculation of total body oxygen delivery (Do_2) and total body oxygen consumption (Vo_2).

The PA catheter was developed to optimize cardiac function in critically ill patients and was used extensively in the ICU during the perioperative period in high-risk patients. This practice was the result of an observation by Shoemaker and others that the metrics of systemic perfusion and oxygen delivery (cardiac output and Do_2) were closer correlates of survival than were more traditional cardiovascular parameters, such as heart rate, arterial pressure, and CVP.[74-77] The PA catheter was an essential tool for implementing the strategy of hemodynamic optimization before elective major vascular surgery.[77]

However, several large prospective studies have suggested that the use of PA catheters in critically ill patients may offer little objective benefit and this conclusion has been further supported by meta-analysis.[78-89] In brief, the evidence is insufficient to recommend preoperative hemodynamic optimization for high-risk surgical patients and there is no evidence of benefit for the routine use of PA catheters during high-risk general or vascular surgery. Guidelines from both the American College of Cardiology/American Heart Association (ACC/AHA) and the ASA reflect these data and advise against the routine use of PA catheters in vascular surgery but suggest that these devices may be of some benefit in high-risk subsets.[90,91]

Minimally Invasive Hemodynamic Monitoring

Minimally invasive hemodynamic monitoring refers to a number of devices that can provide real-time assessment of cardiac output without the need of inserting a PA catheter. Some of the more commonly used devices evaluate the arterial pressure tracing and percent changes in pulse pressure to calculate stroke volume and systemic vascular resistance. The underlying principle of these devices is that stroke volume is proportional to arterial pressure. When an algorithm was developed to determine aortic compliance, the ability to calculate stroke volume based on the area under the systolic phase of the arterial curve became possible.[92]

There are a variety of devices that use the pulse pressure analysis method to extrapolate cardiac output, some of which are "autocalibrated" and some of which are externally calibrated. Autocalibrated minimally invasive devices use an indwelling arterial monitor and include the FloTrac sensor (Edwards Lifesciences, Irvine, California), ProAQT sensor with Pulsioflex monitor (Pulsion Medical Systems, Munich, Germany), and LidCO rapid system (LidCO Ltd., Cambridge, UK).[93]

Calibrated minimally invasive devices include those using thermodilution similar to PA catheters and lithium dilution. Transpulmonary thermodilution utilizes an injection of cold fluid into the superior vena cava via a central venous catheter. A thermistor in a main (femoral, axillary, or brachial) arterial branch subsequently measures temperature change over time and CO is extrapolated.[94] The two commercially available devices using this technique are the PiCCO plus monitor (Pulsion Medical Systems, Munich, Germany) and

EV1000/VolumeView monitor (Edwards Lifesciences, Irvine, California). Lithium dilution is performed with small volume lithium chloride injections via a peripheral or central venous catheter. Lithium concentration is measured by aspirating arterial blood. A lithium-sensitive electrode at the tip of the catheter generates a voltage corresponding with a change in lithium concentration.[95] Lithium dilution hemodynamic monitoring is not accurate in patients treated with lithium or muscle relaxants. Muscle relaxants can incorporate a positively charged quaternary ammonia ion that can trigger the lithium electrode and cause an overestimation of CO. Commercially available lithium dilution hemodynamic monitors include the LidCOplus (LidCO Ltd., Cambridge, UK).

Minimally invasive hemodynamic monitoring to calculate CO correlates well with the gold standard of PA catheters in patients with a regular cardiac rhythm, stable respiratory patterns, and without abrupt hemodynamic changes. The minimally invasive monitors are not as accurate calculating continuous CO in patients with abrupt hemodynamic changes, specifically including those treated with norepinephrine or those having off-pump coronary artery bypass surgery or open abdominal aortic aneurysm repair. However, newer generation software with upgraded algorithms is improving the correlation between the two techniques and research is on-going.[96-98]

Transesophageal Echocardiography

Transesophageal echocardiography (TEE) has become a mainstay of the intraoperative management for patients undergoing surgery on the heart and thoracic aorta.[99,100] In this application, TEE allows not only monitoring of cardiac function in real time but also can provide information that may modify the conduct or extent of surgery. TEE provides two-dimensional gray-scale images of the cardiac chambers in a wide spectrum of projections. In addition, pulsed, continuous wave, and color-flow Doppler capabilities allow physiologic measurement of flow and global cardiac dynamics. In particular, TEE can provide direct information on ventricular systolic function. The contribution of asymptomatic LV dysfunction to mortality in vascular surgery highlights the value of direct observation with TEE.[101] Some data indicate that TEE-derived LVEDP correlates better with cardiac output than do PA catheter-derived data (PCWP).[102] Myocardial contractility is best assessed with the ejection fraction calculated from two-dimensional data by standard formulas. Diastolic function (left ventricular relaxation) is assessed by pulsed Doppler examination of flow through the mitral value. Intraoperative TEE allows appropriate diagnosis of hemodynamic changes (e.g., hypovolemia vs. reduced ejection fraction in hypotension) and provides prompt feedback on therapeutic interventions. Myocardial ischemia may be detected by early diastolic dysfunction and regional wall motion abnormalities.

No published reports to date demonstrate an outcome-based improvement with TEE.[103-108] This may be related to the generally poor correlation between TEE findings of myocardial ischemia, ECG data, and eventual cardiac outcome. The ACC/AHA 2007 Guidelines on Perioperative Cardiovascular Evaluation and Care for Noncardiac Surgery suggest that intraoperative or perioperative TEE is reasonable for investigating acute, life-threatening hemodynamic disturbances.

NEUROLOGIC MONITORING

Central Nervous System

Monitoring of central nervous system function is critical to optimize neurologic outcome with carotid interventions. Regardless of the anesthetic technique or the use of an intracarotid shunt during clamping, these procedures can be completed safely only with a clear understanding of cerebral perfusion. Placement of an intracarotid shunt does not guarantee that the shunt is functioning or that perfusion of the brain is satisfactory. The adequacy of cerebral perfusion has been assessed by a wide range of approaches including conscious monitoring of the neurologic responses of the patient, continuous electroencephalography, and transcranial Doppler measurements of flow in the middle cerebral artery (see Chapter 91).

Spinal Nervous System

Monitoring of spinal nerve function is useful in procedures that involve possible disruption of perfusion to the spinal cord, most commonly through temporary clamping of thoracic aortic segments or ligation or exclusion of intercostal arteries giving rise to the great radicular artery. Such monitoring is generally accomplished with sensory- and/or motor-evoked potentials to test the integrity of the spinal segments (see Chapter 77).

INFECTION CONTROL AND MAINTENANCE OF HOMEOSTASIS

Perioperative Antibiotics

Surgical Site Infection (SSI) has been estimated to account for at least 25% of all nosocomial infections in hospitals and has been associated with increase mortality, length of hospital stay, and cost.[109-111] Kirkland et al. found that patients with SSI experienced twice the mortality (7.8% vs. 3.5%), a greater likelihood of requiring ICU care (29% vs. 18%), and a higher incidence of readmission (41% vs. 7%) than matched controls.[112-116]

The tenets of SSI prophylaxis were established in the 1960s and have been noted in numerous reviews.[117-121] The fundamental requirement for effective SSI prophylaxis is maintenance of an effective concentration of an antibiotic suitable for the probable organisms in tissue at the site and time of inoculation (wounding). The critical role of timing of antibiotic administration is illustrated in the report by Classen.[121] When compared with the group who received antibiotics within 2 hours of incision (0.6% incidence of SSI), those who were treated early (>2 hours before incision), perioperatively (within 3 hours after incision), and late (3 to 24 hours after incision) had relative risks for SSI of 6.7, 2.4, and 5.8, respectively.

The Centers for Disease Control and Prevention (CDC) published formal guidelines in 1999, and in 2002, the Centers

for Medicare and Medicaid Services (CMS) and the CDC implemented the national Surgical Infection Project (SIP).[114,122,123] The strategy was to reduce the incidence of SSI by monitoring three specific performance measures: (1) the number of patients receiving parenteral SSI prophylaxis within 1 hour of incision, (2) the proportion of patients receiving SSI prophylaxis with an agent consistent with published guidelines, and (3) the proportion of patients whose prophylactic antimicrobial therapy is discontinued within 24 hours of completion of surgery.[124] In 2004, the SIP was incorporated into a more comprehensive surgical quality initiative, the Surgical Care Improvement Project (SCIP). According to the SCIP guidelines, the approved antibiotic agent for SSI prophylaxis during vascular procedures was cefazolin. Vancomycin and clindamycin were appropriate substitutes in the event of β-lactam allergy. Additional recommendations included preoperative dosing 60 minutes before surgical incision, dosing adjustments for body weight, intraoperative redosing to ensure adequate serum and tissue concentrations, shortened postoperative course of antimicrobials to a single dose or for continuation less than 24 hours.[123,124] Despite the retirement of the SCIP in December 2015, these recommendations continue.

Risk factors for postoperative surgical site infections in patients undergoing vascular procedures include lower extremity surgical sites, delayed procedures after hospitalization, diabetes mellitus, and history of prior coronary or vascular bypass.[125,126] Richet et al. prospectively evaluated 561 vascular surgery patients undergoing a revascularization procedure with prosthetic and found a surgical site infection rate of 4.1% and Ross et al. found a similar rate of surgical site infections (3.85%) in over 200 patients undergoing peripheral arterial revascularization.[126,127]

The appropriateness of prophylactic antibiotics in endovascular interventions has not been determined by prospective randomized controlled trials. The Society of Interventional Radiology (SIR) Standards of Practice Committee has developed recommendations for the use of antibiotic prophylaxis during percutaneous vascular interventions.[128] Prophylactic antibiotics for the placement of stent grafts is recommended not because of high stent graft infection rate but rather the mortality associated if an infection occurs. Recommendations are extended for thoracic, abdominal, and extremity stent grafts.[127,129-131] Prophylactic antibiotics are not recommended for angiograms, angioplasty, placement of bare metal stents, venous procedures, thrombolysis, and closure devices.[127,129,132-136] In cases of endovascular re-intervention defined as within 7 days, interventions in the presence of hematoma, procedures lasting more than two hours, immunosuppressed patients, and interventions in the presence of another intravascular implant, prophylactic antibiotics should be considered.[137-141]

Adrenergic Agents

A great deal of research has been performed on the potential role of cardiotonic drugs in reducing the cardiac risk associated with major general and vascular surgery.[142] Administration of beta-blockers through the perioperative period has the theoretical benefit of reducing myocardial work through control of heart rate and anti-inotropic actions. The 2014 ACC/AHA Guideline Update for Perioperative Cardiovascular Evaluation for Noncardiac Surgery recommended beta-blocker therapy be continued throughout the perioperative period if patients have been taking it longitudinally and it is well tolerated (see Chapters 32 and 42).[143-150]

Recommendations for patients undergoing vascular surgery with intermediate or high risk for myocardial ischemia as determined preoperatively can be started on beta blockade therapy, especially if at risk for stroke.[151-154] Such intermediate and high-risk patients with uncompensated heart failure should not be started on beta blockade therapy without heart failure optimization. Therapy should be started at least 2 to 7 days prior to surgery to titrate dosing and should not be started on the day of surgery.[155-158] There is no proven benefit to starting beta blockade therapy greater than 30 days prior to surgery. For patients with three or more revised cardiac risk index risk factors (diabetes mellitus, heart failure, coronary artery disease, renal insufficiency, and prior cerebrovascular accident), the safety and efficacy of starting beta blockade in the preoperative setting is less clear.[144,150,159]

Beta-blockers are contraindicated in patients with asthma, sick sinus syndrome, and second- and third-degree heart block. Potential adverse intraoperative effects include augmented intraoperative hypotension and bradycardia, which may be significant in vascular patients with impaired cardiac reserve. In such cases, there is evidence that a similar reduction in periprocedural cardiac morbidity may be obtained with α_2-adrenergic agonists.[160]

Maintenance of Normothermia

The combination of anesthesia and surgery leads to major increases in convective heat loss in patients. The loss of peripheral vasoconstriction resulting from anesthesia diverts perfusion from the visceral organs to the extremities and the skin where heat is lost to the environment through thermal radiation. Similar heat loss occurs in large open surgical wounds, especially those of the chest or abdominal cavity where heat loss is augmented by evaporative cooling. For clinical purposes, normothermia is a core temperature higher than 36°C and lower than 38°C. Mild hypothermia refers to core temperatures between 34°C and 36°C. The physiologic responses of awake humans to mild hypothermia include peripheral sympathetic activation with increased circulating norepinephrine, shivering with increased metabolic rate, oxygen consumption, and mean arterial pressure.[161] In patients undergoing anesthesia with sympathetic blockade, these normal responses to hypothermia are blunted.

Hypothermia is associated with a number of potentially serious complications in surgical patients including wound infection, immune dysfunction, coagulopathy, increased blood loss, increased transfusion requirements, major adverse cardiac events, and death.[162-170] The most significant concern in patients with coronary heart disease is an increased risk for perioperative myocardial ischemia.[171] Frank and associates assessed myocardial ischemia in the first postoperative day in 100 patients undergoing lower extremity bypass surgery and divided the population into

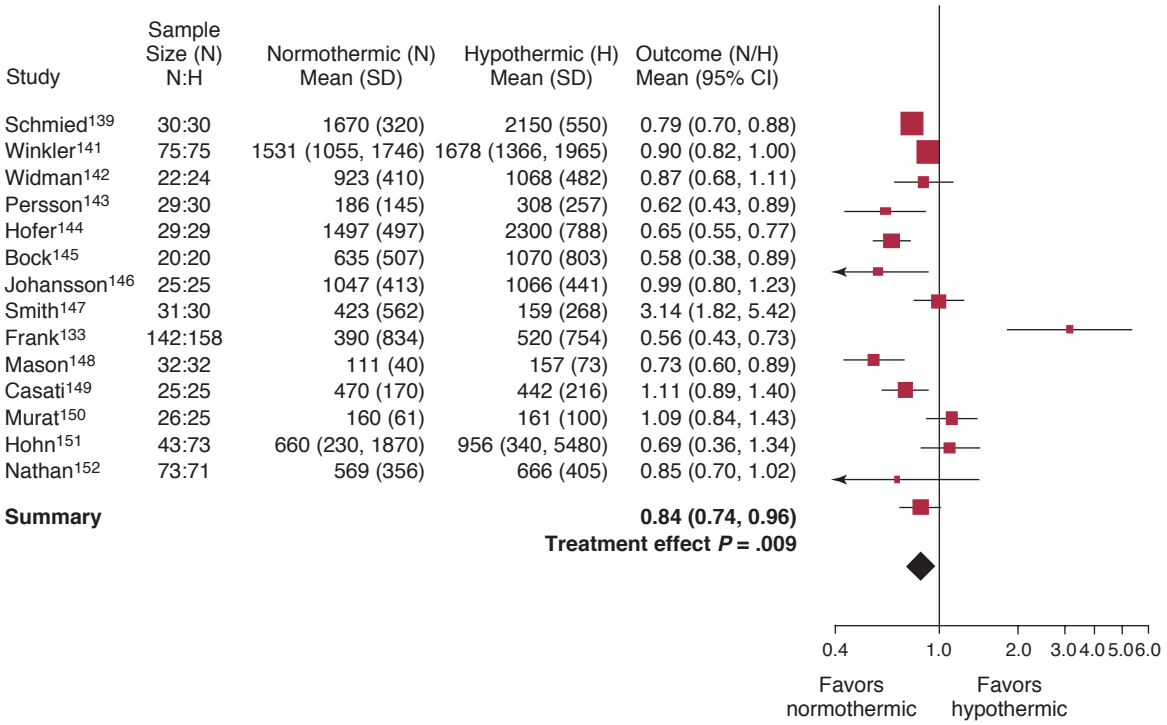

Figure 33.1 Total Blood Loss: Meta-Analysis and Forest Plot. Treatment effect is expressed as the ratio of geometric means of blood loss for normothermic *(N)* versus hypothermic *(H)* patients. Results indicate an estimated 16% (95% confidence interval *[CI]*, 4% to 26%) lower average blood loss in normothermic than in hypothermic patients, P = .009. *SD*, Standard deviation.

hypothermic (<35°C) and normothermic (≥35°C) groups on the basis of immediate postoperative body temperature.[171] ECG changes indicative of myocardial ischemia were three times more likely to occur in the hypothermic group (36% vs. 13%), and multivariate analysis showed that temperature was an independent risk factor for myocardial ischemia. A subsequent prospective RCT of supplemental warming of at-risk cardiac patients undergoing vascular, abdominal, and thoracic surgery by these investigators confirmed that hypothermia is an independent predictor of morbid cardiac events with a relative risk of 2.2.[162] This and other studies have shown a clear relationship between postoperative hypothermia and ventricular tachycardia and atrial fibrillation.[172]

Hypothermia also has a significant effect on coagulation. Many coagulation factors are temperature-sensitive proteases whose activity is reduced by hypothermia. Measurement of this effect in vivo is complicated by the fact that the common clinical assays of coagulation (prothrombin time and partial thromboplastin time) are performed at 37°C and thus results do not reflect the impact of actual body temperature at the site of bleeding.[173] Generally, in the absence of major hemorrhage or consumptive coagulopathy, the functional impact of mild hypothermia on coagulation is relatively mild.[174] There is also clear evidence of platelet dysfunction with hypothermia.[175] Platelet margination occurs with dropping temperature because hypothermia concentrates blood cell volume, induces a change in platelet shape, decreases rate of blood flow, and increases expression of adhesion molecules such as thromboxane A2. The drop in platelet count can be reversed with restoration of normal body temperature.[176-178]

The clinical impact of mild hypothermia on perioperative bleeding was determined in the report of Schmied estimating that mild hypothermia (1°C) may increase blood loss by 16% and the increase relative risk for transfusion by 22% (Fig. 33.1).[162,168,179-190]

Hypothermia is also a major risk factor for SSI. This effect is mediated by a combination of vasoconstriction at the site of wounding (inoculation) and a generalized effect on immune function. Local vasoconstriction affects the delivery of antibiotics to the wound and may produce relative hypoxia.[165] The impact on immune function involves mitogen-induced responses of lymphocytes, and alterations of cytokine production, neutrophil phagocytosis and oxidative killing.[191-193] Kurz and colleagues studied the clinical effect of core temperature on SSI in a prospective randomized trial of 200 patients undergoing colorectal surgery.[194] SSI occurred in 6% of normothermic patients (36.6°C ± 0.5°C) and 19% of hypothermic patients (34.7°C ± 0.6°C). Furthermore, sutures were removed 1 day earlier in normothermic patients and normothermic patients had a shorter hospital stay (2.6 days, about 20% less).

Other undesirable effects of hypothermia include variable and drug-specific effects on the distribution and metabolism of both muscle relaxants and anesthetic agents, enhanced cardiotoxicity of bupivacaine, mild hypokalemia, and thermal discomfort. Despite these data, there may be a protective role for mild hypothermia in certain specific clinical situations that

involve tissue ischemia.[195] Skepticism may, however, be warranted based on the inability of recently released systematic reviews to show any clear benefit of hypothermia as a preventive strategy for brain injury associated with head trauma, stroke, cerebral aneurysm surgery, and cardiac surgery.[196-199] Passive hypothermia is often used as an empirical component of visceral and spinal cord protection during repair of thoracoabdominal aneurysms. This topic is covered in Chapter 77.

Intraoperative normothermia is maintained thorough a comprehensive strategy to reduce radiant heat loss and provide active warming. Components of this approach include prewarming to reduce the core-to-periphery thermal gradient, passive insulation, active heating (circulating water, forced air, radiant heat), fluid warmers, and airway heating and humidification. The ambient temperature in the operating room is an important factor in reducing radiant heat loss. The recommended temperature range for the operating room is between 68°F and 75°F.[200,201] Maintenance of normothermia has been recognized as a quality metric.

Glycemic Control

Although the potential benefit of close glycemic control on the incidence of long-term complications of diabetes has been known for some time, it has become increasingly clear that acute hyperglycemia can have short-term detrimental effects on surgical and critically ill patients. Krinsley et al. performed a retrospective review of the impact of glycemia on outcomes in a mixed medical/surgical ICU at a university-affiliated community hospital between 1999 and 2002.[197] Among 1826 consecutive patients studied, hospital mortality was directly related to the mean glucose value and nearly doubled between those with a mean glucose level of 80 to 99 and 140 to 159 mg/dL (9.6% vs. 18.8%).[202]

Hyperglycemia can be a problem in nondiabetic surgical patients because the normal hormonal response to even uncomplicated surgery involves glycogenolysis, gluconeogenesis, and relative insulin resistance. Furthermore, as many as 6% of cardiothoracic surgical patients with no history of diabetes are found to have diabetes, and an additional significant proportion of such patients will have abnormally elevated hemoglobin A_{1c} values.[203,204] There is a clear relationship between hyperglycemia and SSI. Latham and associates showed a history of diabetes and postoperative hyperglycemia (defined as glucose >200 mg/dL) were independent risk factors for SSI (OR = 2.76 and 2.02, respectively). In theory, this association is related to the impact of hyperglycemia on immune function. Specific effects of hyperglycemia may include impaired vasodilatory responses in the wound; changes in expression of adhesion molecules, cytokines, and chemokines; enhanced responses of complement; and depressed neutrophil chemotaxis, phagocytosis, and release of reactive oxygen species. The basic and clinical data supporting these effects have been reviewed recently.[205,206] In a study of 995 general and vascular surgery patients, Ramos et al. discovered postoperative hyperglycemia increased the risk of postoperative infections by 30% with every 40-point increase from normoglycemia (<110 mg/dL).[207]

There is substantial evidence that aggressive therapy to maintain normoglycemia can have a beneficial effect on mortality in surgical patients. Van der Berghe and colleagues compared either routine glycemic management or intensive glycemic control.[208] The intensive-treatment group was managed with insulin infusion to maintain blood glucose between 80 and 110 mg/dL. Overall ICU mortality was 8% with conventional care and 4.6% with intensive management ($P < .04$). The greatest difference in mortality was seen in patients who required more than 5 days of ICU care (10.6 vs. 20.2%, $P < .005$). Similar substantial differences were noted in the rates of in-hospital mortality, bloodstream infection, and acute renal failure. Others have reported similar findings.[209,210]

Recent studies have shown that there is an increased incidence of hypoglycemia among intensive care patients undergoing strict glycemic control with an increased mortality rate. The Normoglycemia in Intensive Care Evaluation-Survival Using Glucose Algorithm Regulation (NICE-SUGAR) trial randomized 6104 patients within 24 hours of admission to ICU to see if strict glucose control defined as blood glucose of 81 to 108 mg/dL and 3050 patients assigned to undergo conventional glucose control defined as 180 mg/dL or less. There was a significantly higher mortality rate in the strict glucose control group (27.5%, 829 patients) versus the conventional group (24.9%, 751 patients).

No specific performance measures have been issued regarding postoperative glycemic control for general or vascular surgical patients to date and there are to date no randomized controlled trials specifically addressing the monitoring and treatment of hyperglycemia during major vascular surgery. Recommendations are based on studies evaluating comparable groups. The current guidelines for the perioperative care of patients with peripheral arterial disease is to maintain a blood glucose level of <200 mg/dL.[211]

ANTICOAGULATION/ANTIPLATELET THERAPY

All vascular interventions involve interruption of blood flow and some disruption of the vascular wall, risking local and distant arterial thrombosis. Although the use of systemic anticoagulation and antiplatelet therapy during and after vascular interventions seems logical, the efficacy of this strategy has not been tested rigorously. There is evidence that systemic anticoagulation is not necessary to prevent local thrombotic complications with aortic aneurysm surgery, although most vascular surgeons treat such patients with anticoagulants. The need for anticoagulation probably varies inversely with the diameter of the arteries and the rate of blood flow.[212] Newer anticoagulants with more favorable therapeutic ratios and enhanced safety profiles are now available (see Chapter 39).[213,214]

Anticoagulation

Anticoagulation is generally initiated at the time of arterial clamping by bolus administration of unfractionated heparin

via either an empirical, fixed-dose regimen (3000 to 5000 units is the common fixed-dose range seen in practice) or a weight-based dosing scheme (100 to 150 units/kg). The half-life of unfractionated heparin is dose-dependent since clearance has both a rapid saturable phase due to binding to endothelial cells and blood elements and a slower first-order elimination phase. The effective half-life in most individuals is 30 to 90 minutes so repeat dosing (500 to 1000 units, or 50 units/kg) every 45 to 60 minutes is required to maintain effect.[215,216] There is considerable variability in the anticoagulation responses to unfractionated heparin, and several studies support monitoring the level of anticoagulation during certain procedures, which is typically accomplished with the activated clotting time (ACT) at the point of care.[217,218]

Although the degree of anticoagulation seen with fixed-dose regimens will vary among patients, the clinical impact of such variation is small. Poisik and colleagues measured ACT values during 140 carotid endarterectomies receiving a fixed-dose regimen (5000 units).[219] This regimen in effect delivered weight-based heparin doses of 44 to 116 units/kg and produced ACTs of 175 to 425 seconds with no measurable differences in neurologic outcome or wound hematoma. An ACT longer than 350 seconds appears to be associated with the least risk for ischemic events during percutaneous coronary intervention, and similar values may be appropriate for small-artery interventions in the legs or carotid angioplasty.[220] Intraprocedural anticoagulation may also have benefits beyond avoidance of thrombosis in the treated arteries. Some data show a reduction in both fatal and nonfatal periprocedural myocardial infarction after abdominal aneurysm repair when unfractionated heparin was administered systemically at the time of aortic clamping.[212]

There is controversy regarding the benefit of anticoagulation reversal in vascular procedures. Reversal is generally used in shorter duration procedures to speed closure or after intra-cavitary operations, where the risk of unrecognized hemorrhage can be substantial. Administration of protamine has some risk with anaphylaxis reported in up to 3% of patients. The risks associated with protamine administration have been reviewed recently.[221] Protamine does not counteract the anticoagulant effect of LMWH. Guidelines from the Seventh American College of Chest Physicians (ACCP) Conference on Antithrombotic and Thrombolytic Therapy support the use of unfractionated heparin during vascular interventions but state that the benefit of reversal has not yet been demonstrated.[222] The 9th edition of the American College of Chest Physicians (ACCP) does not address this question.[223] Some suggest that a single measurement of ACT with reversal for high values (>400 seconds) may be a reasonable approach.[219]

For patients with anti-heparin antibodies or heparin-induced thrombocytopenia, several direct thrombin inhibitors are marketed, including hirudin derivatives and argatroban. These agents may not be immediately available in all hospitals. As recommended in the literature describing its use with percutaneous coronary interventions, anticoagulation with argatroban can start with a bolus of 350 μg/kg administered over 3 to 5 minutes followed by an infusion of 25 μg/kg per minute. For a subtherapeutic ACT, an additional 150 μg/kg/bolus can be given and the infusion rate can be increased to 30 μg/kg per minute. An ACT should be rechecked in 5 to 10 minutes. For supratherapeutic ACT (>450 seconds), the infusion rate should be decreased to 15 μg/kg per minute. Initial doses in the patient with hepatic impairment should be 0.5 μg/kg per minute.[224] Effective means of argatroban reversal have not been established. Bivalirudin initial bolus dosing is 0.75 mg/kg followed by and immediate infusion of 1.75 mg/kg/hour. ACT should be checked in 3 to 5 minutes and if subtherapeutic, an additional bolus of 0.3 mg/kg should be given if required.[225] Bivalirudin reversal can be accomplished with recombinant factor VIIa and can be eliminated with hemodialysis.

Table 33.5 reviews some of the target-specific anticoagulants and their nonspecific and specific reversal options. Prothrombin complex concentrate (PCC) is a nonspecific reversal agent derived from plasma composed of vitamin K-dependent coagulation factors II, VII, IX, and X with variable amounts of protein C and S. PCC is approved by the FDA to be used for the reversal of vitamin K antagonists (warfarin) associated bleeding. Activated prothrombin complex concentrate (aPCC) was developed to treat hemophilia patients and contains activated forms of the coagulation factors II, VII, IX, and X. It is important to note that none of the nonspecific reversal agents are Food and Drug Administration (FDA) approved to reverse target specific anticoagulants with the exception of Praxbind. Activated charcoal can be used if ingestion of an oral agent occurred within two hours. Hemodialysis is generally only effective for clearance of dabigatran.[226-228]

Antiplatelet Therapy

The overwhelming majority of arterial interventions are performed to treat advanced atherosclerosis. Accordingly, virtually every patient undergoing a vascular procedure should be treated with an effective antiplatelet agent to reduce the greater incidence of myocardial infarction and ischemic stroke.[229] The general recommendation in at-risk patients is low-dose aspirin (81 mg) daily. Although clopidogrel is often added empirically as a second antiplatelet agent in many patients, there is little evidence to support the benefit of this agent in low-risk patients who can tolerate aspirin.[230] On the other hand, clopidogrel has an important role together with aspirin in enhancing the patency of percutaneous coronary interventions. In general, dual platelet therapy is recommended for a minimum of 1 month after coronary angioplasty with a bare-metal stent and for a minimum of 12 months after the use of a drug-eluting stent.[92] These recommendations are based on the theoretical time required for endothelialization of the stent. The significant risk for stent thrombosis and fatal myocardial infarction with premature discontinuance of dual platelet therapy has prompted the publication of the ACC/AHA 2007 Guidelines on Perioperative Cardiovascular Evaluation and Care for Noncardiac Surgery and the Joint Advisory on Prevention of Premature Discontinuation of Dual Antiplatelet Therapy in Patients with Coronary Artery Stents.[231-233] These guidelines suggest (1) delay of elective surgical procedures associated with significant risk for periprocedural bleeding until the appropriate course of dual platelet

TABLE 33.5 Target-Specific Anticoagulants

Agent	Mechanism	Half Life	Metabolism	Coagulation Assay	Nonspecific Reversal	Specific Reversal Agents
Dabigatran **Pradaxa**	Direct thrombin inhibitor Blocks fibrinogen →fibrin	12-17 h	85% renal excretion	• Prolonged thrombin time (TT) • Prolonged ecarin clotting time (ECT) • Range of effect on activated partial thromboplastin time (aPTT)	• Hemodialysis is effective • Activated charcoal • Prothrombin complex concentrates (PCC, KCentra) not effective—Erenberg ES, et al. 2011 • Recombinant factor VIIa (rFVIIa, Novoseven) effective—Marlu R, et al. 2012 • Activated prothrombin complex contrite (aPCC, FEIBA) effective—Khoo TL, et al. 2013	• **Anti-Dabi-Fab** (Idarucizumab/ Praxbind)—Humanized monoclonal antibody fragment • 5 g IV • **FDA approved** • **PER977** (Aripazine/ Ciraparantag)—binds Xa and IIa • Phase 2 clinical trials
Rivaroxaban **Xarelto**	Factor Xa inhibitor Blocks prothrombin → thrombin	5-9 h	66% renal excretion 33% hepatic excretion	• Anti-factor Xa activity assay • May elevate prothrombin time (PT) • Prolonged aPTT	• Hemodialysis is not effective • Activated charcoal • 4 factor PCC (KCentra) is effective, 50 units/kg (max 5000 units)—Erenberg ES, et al. 2011, Marlu R, et al. 2012, Dinkelaar J, et al. 2013 • aPCC (FEIBA) effective, 8-25 units/kg	• **PRT064445** (Andexanet Alfa/ AndexXa)—binds to Xa inhibitor site • Phase 3 clinical trials • **PER977** (Aripazine/ Ciraparantag)—binds Xa and IIa • Phase 2 clinical trials
Apixaban **Eliquis**	Factor Xa inhibitor Blocks prothrombin → thrombin	7-14 h	66% hepatic excretion 33% renal excretion	• Anti-factor Xa activity assay • Prolonged aPTT	• Hemodialysis is not effective • Activated charcoal • 4 factor PCC (KCentra) is effective, 50 units/kg (max 5000 units) • aPCC (FEIBA) effective, 8-25 units/kg	• **PRT064445** (Andexanet Alfa/ AndexXa)—binds to Xa inhibitor site • Phase 3 clinical trials • **PER977** (Aripazine/ Ciraparantag)—binds Xa and IIa • Phase 2 clinical trials
Fondaparinux **Arixtra**	Binds to antithrombin III and causes neutralization of Factor Xa	17-21 h	renal	• Anti-factor Xa activity assay	• Hemodialysis is not effective • rFVIIa, Novoseven, 90 µg/kg • aPCC (FEIBA) effective, 8-25 units/kg	• None

Modified from Hu TY, Vaidya VR, Asirvatham SJ. Reversing anticoagulant effects of novel oral anticoagulants: role of ciraparantag, andexanet alfa and idarucizumab. *Vasc Health Risk Manag*. 2016;12:35-44.

therapy has been completed and (2) continuation of aspirin throughout the perioperative period in any cases requiring major intervention for which clopidogrel must be discontinued. Naturally, these considerations play a large part in decision making regarding the role of coronary intervention as a risk reduction strategy for high-risk cardiac patients needing urgent vascular interventions.

The risk of bleeding complications with vascular procedures performed on patients treated with aspirin is measurable but small.[234] Neilipovitz and associates estimated that continuation of aspirin through the perioperative period would reduce periprocedural mortality from 2.78% to 2.05% with an associated 2.46% increase in bleeding complications.[235,236] The 2012 ACCP guidelines on Perioperative Management of Antithrombotic Therapy recommend continuing aspirin in the perioperative period for patients at high cardiovascular risk.[223] Bleeding during surgery in patients treated with both aspirin and clopidogrel can be a significant problem.

Periprocedural clopidogrel has been reported to increase the risk of intraoperative bleeding, as well as the risk of reoperation (OR = 5.1 and 6.9, respectively).[237-239] Like aspirin, clopidogrel must be discontinued for 5 to 7 days for complete resolution of its effect.[240] Most vascular surgeons discontinue clopidogrel in preparation for major open operations. If significant diffuse, punctate platelet-type bleeding occurs intraoperatively, platelet transfusion is often administered. However, there are no real clinical data to support the efficacy of platelet transfusion in this setting.[239,241]

Desmopressin (DDAVP) is a V2 receptor agonist analogue of arginine vasopressin that may enhance platelet function through the stimulated release of von Willebrand factor from endothelial cells, although the precise mechanism of its action

is not known.[242] This agent has been used for many years to control platelet-related bleeding in patients with end-stage renal disease and after cardiac surgery.[243] The true impact of this agent on surgical bleeding is not known because of conflicting reports and an inconclusive meta-analysis by the Cochrane group.[244] DDAVP has been associated with a 2.4-fold increase in postprocedural myocardial infarction in cardiac surgical patients.[245] Similarly, recombinant factor VIIa is an approved drug to treat bleeding in patients with hemophilia and acquired hemophilia. This agent also enhances thrombin generation by platelets and may control bleeding in the setting of thrombocytopenia or platelet dysfunction. Anecdotal reports of the administration of recombinant factor VIIa in cases of refractory surgical bleeding or trauma suggest that it could also have a role in these difficult situations. However, reports indicate that this agent carries an increased risk for thromboembolic complications, and its availability is restricted in many centers.[246,247]

Intraoperative Fibrinolysis

Although intraoperative fibrinolysis as an adjunct to mechanical thrombectomy in patients with acute limb ischemia was originally reported in the 1980s and has been widely adopted, there are no systematic data to support the optimal dose ranges for specific agents in this application.[248-253] Consensus recommendations for intraoperative dosing from the Working Party on Thrombolysis in the Management of Limb Ischemia are available.[254,248,255-263] Although surgical bleeding may not be an issue, the risk for potentially fatal intracranial hemorrhage is real, and rates ranged from 1.2% to 2.1% in the STILE and TOPAS trials.[264,265] Intracranial hemorrhage may be difficult to detect intraoperatively and special caution is thus warranted. Recombinant tissue plasminogen activator (rt-PA) is the most commonly used agent and is typically administered as a catheter-directed bolus into the thrombus often followed by a continuous transcatheter infusion at rates of 0.05 to 0.1 mg/kg per hour until lysis of the thrombus is confirmed. Generally, rt-PA infusions are only continued 12 to 48 hours until the presence of the thrombus can be re-evaluated angiographically (see Chapter 41).

CONTROL OF BLOOD LOSS/TRANSFUSION

Compensatory Responses to Anemia and Blood Loss

Allogenic transfusion of blood components is performed to restore specific functions that are lost by either failure of synthesis of blood components or increased losses. These functions fall into two broad categories: oxygen transport and coagulation. The initial physiologic responses to anemia are an increased stroke volume as a result of decreased impedance to ventricular ejection secondary to reduced blood viscosity and increased venous return because of reduced peripheral vascular resistance. Activation of aortic and carotid chemoreceptors will initiate reflex autonomic hemodynamic compensatory mechanisms to maintain oxygen delivery in the presence of decreased oxygen content of the blood. These autonomic reflexes further increase cardiac output through increases in myocardial contractility and heart rate. The capacity for compensation is substantial in normal healthy subjects with normal blood volume. Data from humans undergoing clinical hemodilution for surgery and from studies of anemic patients who were not transfused for religious reasons suggest that healthy individuals can survive blood loss that reduces the hemoglobin concentration to 5 to 6 g/dL (50 to 60 g/L).[265-270] However, these mechanisms depend on maintenance of adequate resuscitation in the setting of active bleeding and result in increases in myocardial work and oxygen demand that may be poorly tolerated by vascular patients with significant coronary heart disease.

Risks Associated With Allogeneic Transfusion

Allogeneic transfusion exposes the recipient to a myriad of cellular, lipid, and protein antigens that can evoke a wide range of immune-mediated adverse events, including anaphylaxis, transfusion-related acute lung injury (TRALI), transfusion-associated circulatory overload (TACO), and both acute and delayed hemolytic reactions. The leading causes of transfusion-related mortality are TRALI, fatal hemolytic transfusion reactions, and transfusion associated sepsis (TAS).[271]

TRALI is an acute respiratory distress syndrome characterized by noncardiogenic pulmonary edema and hypoxia occurring within six hours of transfusion.[271-273] It is defined as acute hypoxemia with a ratio of partial pressure of arterial oxygen to fractional inspired oxygen concentration (PaO_2/FiO_2) of <40 kPa (300 mm Hg) with bilateral infiltrates on chest radiograph without pulmonary vascular overload. The risk of TRALI is highest after the infusion of plasma and platelets, but due to the shear number of units transfused, the majority of TRALI cases occur after the transfusion of red cells. The estimated incidence is 1.12% per unit transfused and in at-risk populations, the incidence may be as high as 8%. The mortality rate ranges from 5% to 45%.[274] The etiology of TRALI has not been defined, but there are two main theories.[273] The first postulates that donor antibodies to recipient leukocyte antigens result in leukocyte activation and lung injury. The other involves a two-hit concept consisting of sensitization of the recipient's pulmonary endothelium by stimuli such as sepsis, trauma, cardiopulmonary bypass, and ischemia-reperfusion with resultant pulmonary sequestration of neutrophils, followed by exposure to donor antibodies or inflammatory lipid mediators, or both. Treatment is supportive with cessation of transfusion and respiratory support with lung protective mechanical ventilation if indicated (see Chapter 43).

TACO is a common transfusion reaction in patients typically receiving a large volume of blood products. However, patients receiving less than a unit of blood have been reported to have developed TACO suggesting its etiology is more complex than simple volume overload.[275] TACO complicates 1% to 8% of transfusions. Cardiopulmonary dysfunction with TACO is characterized by hydrostatic pulmonary edema in the presence

of increased pulmonary artery and left atrial pressures and it often occurs in patients with a history of left ventricular failure. This syndrome is also diagnosed within six hours of transfusion. Clinical symptoms include acute respiratory distress, tachycardia, increased blood pressure, acute or worsening pulmonary edema, jugular venous distention, or any other signs of positive fluid balance. The chest radiograph will also reveal bilateral infiltrates. Elevated brain natriuretic peptide has a positive predictive value of up to 78%.[276] Treatment includes providing telemetry monitoring, supplemental oxygen, elevating the head of the bed, noninvasive positive pressure ventilation, diuresis, vasodilation with nitrates to reduce preload especially if hypertensive, and renal replacement therapy if indicated.

The greatest risk for transfusion-associated transmission of disease arises from bacterial contamination of platelets.[277] Platelet packs are an ideal culture medium for small inocula of bacteria because the protein-rich plasma may be stored for up to 5 days at 20°C to 24°C. The frequency of bacterial contamination of platelets may be as high as 1 in 1000 or 2000. Bacterial contamination of RBC units is much lower with an estimated rate of less than 1 in 1,000,000. The most common organism in RBC bacterial contamination is *Yersinia enterocolitica*, which carries a mortality rate of 60% and is often fatal in less than 24 hours.[278] The combination of donor screening programs and nucleic acid testing has progressively lowered the rate of transmission of lipid-encapsulated viruses such as human immunodeficiency virus and hepatitis C to less than 1 in 1,000,000, rates similar to those of major acute hemolytic transfusion reactions.[279] Transmission rates of hepatitis B virus are somewhat higher at about 1 in 50,000 to 150,000.[277] Other infectious agents can also be transmitted through blood products, but rates of transmission in the United States are extremely low. Included in this category are hepatitis D, hepatitis A, hepatitis E, syphilis, leishmaniasis, Lyme disease, brucellosis, parvovirus B19, tick-borne encephalitis virus, Colorado tick fever virus, West Nile virus, and human herpesviruses, as well as parasitic diseases (e.g., malaria, babesiosis, toxoplasmosis, and Chagas disease). Certain diseases are transmitted by transfused leukocytes, including Epstein-Barr virus, human T-lymphotropic virus type I, and cytomegalovirus.

Fatal hemolytic transfusion reactions caused by the infusion of ABO-incompatible blood occur at an estimated incidence of 1 in 1,000,000 and are most commonly due to preventable human error.[280] Acute hemolytic transfusion reactions may be difficult to identify intraoperatively and should be suspected in the event of circulatory decompensation or acute coagulopathy. Management of anaphylaxis intraoperatively involves maintenance of the airway and oxygenation, aggressive fluid resuscitation, and administration of pressors (epinephrine and vasopressin).[281]

Infusion of allogeneic leukocytes may cause a number of immunologic effects, including alloimmunization-related febrile nonhemolytic transfusion reaction (FNHTR), graft-versus-host disease, and immunomodulation. FNHTR frequency is unknown with a great deal of variability in the rates reported; however, the risk associated is increased with platelet transfusion (with some groups reporting over 20%) as compared to RBC transfusion. The median rates for FNHTR are 4.6% for platelets and 0.33% for RBCs.[282] These immunologic reactions have been attributed to leukocytes either directly via infusion of intact immunologically competent allogeneic leukocytes or indirectly as a result of infusion of biologically active substances released from leukocytes during storage. These latter substances include histamine, eosinophil cationic protein, myeloperoxidase, plasminogen activator inhibitor-1, and a host of proinflammatory cytokines and chemokines, including interleukin-1, tumor necrosis factor, and interleukin-6. The downregulation of immune system responses after transfusion has been referred to as transfusion-related immunomodulation (TRIM). Immunotolerance has long been recognized in the setting of renal transplantation with increased transplant survival in recipients who had received multiple previous allogeneic transfusions.[283,284] TRIM has been invoked as the cause of several other deleterious conditions associated with allogeneic transfusion, including an increased rate of recurrence of solid tumors, increased nosocomial infections, and increased mortality.[285-287] These and other possible detrimental effects of TRIM have been the subject of an extensive body of basic and clinical research.[285,286]

Leukocyte reduction has been shown to decrease the incidence of these immunologic complications of allogenic blood transfusion, as well as reduce transmission of cytomegalovirus in populations at high risk.[288,289] Based on the data available, several countries have adopted universal leukocyte reduction programs for all blood transfusions, and data suggest that such an approach can decrease fever, mortality, and antibiotic use in at-risk patients.[290] There is evidence that the use of leukocyte-depleted blood transfusion may have particular benefit in surgical patients, such as a decrease in the risk for multiple organ system failure and shorter length of stay.[277,290-292] The impact of leukocyte depletion on the incidence of postoperative infection is less clear and remains controversial.[293,294] Leukocyte reduction may also have a beneficial impact on a number of changes that affect RBCs during storage, collectively referred to as the "RBC storage lesion."[295-297] Such changes include a decrease in RBC survival, morphologic alterations, increased osmotic fragility, loss of deformability, conversion of hemoglobin to methemoglobin, and depletion of 2,3-diphosphoglycerate with a resultant decrease in oxygen-carrying capacity and an increase in oxygen affinity.[298,299] There has been a great deal of controversy regarding the potential detrimental effect of RBC storage lesions on the value of RBC transfusion and on the outcomes of patients receiving transfusion. Several small observational studies in patients after trauma or with sepsis have suggested that transfusion of "old blood" (stored between 17 and 25 days) is associated with a greater risk for complications than is transfusion of "fresh blood."[300-303] Koch and coauthors reported a retrospective series of patients who underwent cardiac surgery receiving "newer blood" (stored 14 days or less) and "older blood" (stored longer than 14 days).[304] Patients receiving older blood had higher in-hospital mortality (2.8% vs. 1.7%) and higher rates of prolonged intubation, renal failure, and sepsis. Large prospective studies will be required to determine the accuracy of these retrospective observations, which if true, clearly have profound implications for the current

practice of blood banking and maintenance of the blood supply.

Transfusion Triggers

Although the benefit of replenishment of RBC volume through transfusion in ill anemic patients seems intuitive, the data regarding the impact of RBC transfusion on morbidity and mortality in surgical patients are mixed. There is a lack of clarified threshold for transfusion of RBCs in either critically ill or postsurgical patients.[305-308] The data from patients who refused transfusion would indicate that most patients can tolerate a postoperative hemoglobin concentration of 7.1 to 8.0 g/dL without mortality.[265-270] In contrast, Carson and coworkers demonstrated a clear relationship between mortality and the degree of anemia in the postoperative period, with a 2.5-fold increase in the odds of death for each gram decrease in hemoglobin below 8.0 g/dL.[309] Separate investigators found no evident increase in perioperative mortality in elderly patients undergoing surgical repair of hip fracture who received RBC transfusion based on a trigger of 8.0 to 10 g/dL versus those transfused at a trigger value of 10 g/dL or greater.[310]

Reports of the Transfusion Requirements in Critical Care (TRICC) investigators support the safety of lower transfusion triggers. This multicenter study compared the effects of a "liberal" transfusion strategy (transfusion trigger of 10 g/dL) and a "restrictive" transfusion strategy (transfusion trigger of 7 g/dL) on outcomes of critically ill, euvolemic patients.[311] The in-hospital mortality rate was somewhat lower in the restrictive-strategy group (22.2% vs. 28.1% for liberal), but 30-day mortality in the two groups was not different (18.7% for restrictive vs. 23.3% for liberal). Analysis of participants with cardiovascular disease was published separately, and similar results were reported with no differences in 30-day, 60-day, or in-hospital mortality between the two transfusion strategies.[312] There was a suggestion (not statistically significant) that the liberal transfusion strategy led to slightly better survival in the subgroup with severe ischemic heart disease (257 patients). A comprehensive meta-analysis of data available in 1999 and a recent practice guideline from the American Association of Blood Banks generally support restrictive transfusion triggers in patients without cardiac disease but highlighted the need for additional data in higher risk groups.[310]

On the other hand, there is clear evidence of silent and evident perioperative myocardial ischemia in patients with anemia, particularly those with coronary heart disease and intraoperative or postoperative tachycardia.[313,314] A retrospective report of observational data from the VA National Surgical Quality Improvement Program (NSQIP) indicated a 1.6% increase in 30-day postoperative mortality with each percent decrease in hematocrit below 39%, although any conclusions from this data set must be tempered by the nature of the data.[315] The best evidence and analysis suggest that the hemoglobin concentration must be assessed in light of the overall condition of the patient and, in particular, the adequacy of circulating blood volume and perioperative resuscitation.[316] The recommendations of a number of authoritative bodies indicate consensus that transfusion is required frequently in patients with a low hemoglobin concentration (<6 to 8 g/dL) and rarely in those with a hemoglobin concentration greater than 10 g/dL and point to the important role of physiologic assessment of the patient as a major determinant for transfusion in the intermediate range (7.0 to 10 g/dL).[280,285,291,296,317-320] Hebert and colleagues have suggested a reasonable set of transfusion triggers based on current evidence (Table 33.6).[308]

TABLE 33.6 Transfusion Recommendations

Variables	TRANSFUSION TRIGGERS[a]		GOAL	
	g/L	g/dL	g/L	g/dL
General critically ill (no acute bleeding)	70	7	70-90	7-9
Critically ill with septic shock (>6 hr)	70	7	70-90	7-9
Critically ill with septic shock (<6 h)	80-100	8-10	100	10
Critically ill with chronic cardiac disease	70	7	70-90	7-9
Critically ill with acute cardiac disease	80-100	8-10	100	10

[a]Administer 1 unit of red blood cells at a time and re-measure hemoglobin concentrations.

From Hebert PC, Tinmouth A, Corwin HL. Controversies in RBC transfusion in the critically ill. *Chest*. 2007;131:1583.

Bursi et al. performed a retrospective review of 359 consecutive patients undergoing major elective vascular surgery (carotid endarterectomy, aortic surgery, and infra-inguinal surgery) to assess for an association between postoperative transfusion and early mortality and myocardial infarction, and demonstrated an increased hazard ratio for early death and myocardial infarction in patients receiving transfusion that were not anemic even after adjustment for surgical risk and postoperative bleeding. The study also did not show that anemic patients receiving postoperative transfusions experienced less myocardial infarctions or early deaths as compared to those anemic patients not receiving a transfusion.[321] Currently, there is a Danish prospective clinical trial appropriately named *The Transfusion Triggers in Vascular Surgery Trial* to determine the appropriate transfusion triggers for vascular surgery patients.[321a,b]

TRANSFUSION STRATEGIES

Given the considerable risks associated with allogenic blood transfusion (ABT), a number of proactive strategies have been developed to reduce or replace the need for transfusion. Key components common to all approaches focus on limiting blood loss and include selection of the proper procedure, meticulous surgical hemostasis, limited phlebotomy, maintenance of normothermia, aggressive management of coagulopathy, and careful resuscitation.[322,323]

The first option is to accept a lower transfusion trigger, carefully resuscitate, monitor cardiac status, and accelerate innate

RBC synthesis and replenishment. Wallis and coworkers studied 30 patients after hip arthroplasty and demonstrated evidence of increased erythropoiesis (increased reticulocytes and erythropoietin) 7 days postoperatively and recovery of about two thirds of the drop in hemoglobin concentration by 28 days postoperatively.[324] Appropriate attention to replenishment of iron stores is important.[325] Preoperative treatment with erythropoietin may be helpful in anemic patients, as has been demonstrated in elective orthopedic surgery.[326-329] These approaches can reduce but not absolutely eliminate the need for ABT.

The other strategies involve autogenous transfusion via a number of different techniques. Interest in these approaches arose in the 1980s, primarily because of heightened concern regarding viral transmission by transfusion. There are three main methods: preoperative autologous blood donation (PAD), acute normovolemic hemodilution (ANH), and intraoperative autologous blood recovery and transfusion (IAT). The basic concept of PAD is that the patient can donate sufficient RBC units to meet the expected perioperative need preoperatively and reconstitute the lost RBC mass before the planned surgery. In practice, the time interval between collection and surgery has rarely been sufficient, and the effect is chronic hemodilution with the potential for an increased incidence of transfusion (both autogeneic and allogeneic).[330] The use of PAD increased rapidly in the late 1980s and early 1990s but has subsequently declined.[331-335] PAD has limited utility in vascular surgery because of the relatively high incidence of anemia and the urgent nature of many interventions.

ANH involves removal of whole blood from the patient immediately before surgery with maintenance of normovolemia by infusion of crystalloid or colloid solutions. This technique has several clear benefits. Any intraoperative blood loss entails a lesser loss of RBC mass because of the lower hematocrit. The blood thus collected requires no testing, has a low risk for bacterial contamination, requires no storage cost, contains clotting factors and platelets, and has virtually eliminated the chance of misadministration. Studies in urologic and orthopedic patients suggested similar reductions in the need for periprocedural ABT with PAD and ANH, but a more recent meta-analysis of available data questions the overall benefit of this approach.[336-339] ANH increases the demands on the anesthesia team intra-operatively and is not well suited to many vascular patients with baseline anemia and significant fixed coronary heart disease. However, there is evidence of clear benefit of ANH combined with IAT in several reports of patients treated for AAA.[340,341]

IAT uses one of several commercially available devices to collect, wash, and concentrate RBCs shed during surgery. The in vivo survival of recovered RBCs is similar to that of allogeneic RBCs.[342] The washing process does not completely remove malignant cells, bacteria, or potentially toxic substances such as antibiotics, cytokines, or vasoactive substances, so malignancy, gross infection, and ascites may limit use of this technique. There are reports indicating that IAT can reduce the need for ABT in cardiac, orthopedic, and vascular surgery and recent meta-analyses of available data support this conclusion, at least with regard to orthopedic and possibly cardiac surgery.[343,344] Several studies have evaluated the role of IAT in aortic surgery. RCTs have shown variable benefits with four studies demonstrating a reduction in the frequency and amount of ABT with the use of IAT in patients undergoing aortic surgery. Two recent meta-analyses support the conclusion that IAT reduces ABT in the periprocedural period in patients undergoing AAA repair, although a previous meta-analysis suggested no clear benefit.[345-348] A number of cost analyses have been reported with varying methodology and rigor.[349-355] Huber and coauthors reported a decision tree assessment of the cost versus benefit (quality-adjusted life years) of IAT and concluded that routine use of IAT was not justified in surgery for AAA unless the expected blood loss was 5 or more units.[355,356] More recent studies have suggested a decrease in perioperative morbidity and reduced length of stay with IAT for AAA surgery, and the impact of these considerations will need to be incorporated into any future economic analysis.[357,356] Nevertheless, use of IAT is common practice for infrarenal AAA repair and routine for thoracoabdominal aortic surgery in most centers today.

VENOUS THROMBOEMBOLIC PROPHYLAXIS

Surgery is a major risk factor for venous thromboembolism (VTE). Moreover, vascular surgery patients often have other well-recognized VTE risk factors including advanced age, decreased mobility, cardiac disease, obesity, and smoking. Vascular surgery in many ways reduces the risk for VTE. Most vascular patients are treated with antiplatelet agents and virtually all receive full therapeutic anticoagulation during intervention. Postoperatively, some are treated with systemic anticoagulation. VTE prophylaxis has been the subject of call to action by the Surgeon General and was a major component of the Surgical Care Improvement Project (SCIP) and is included in several schemes of value-based reimbursement.[358]

INTRAOPERATIVE SAFETY

The operating room is a hazardous environment in which anesthetized patients are subjected to potentially lethal medications and treatments with well-recognized safety concerns. As physicians, protecting our patients from harm is our responsibility. The magnitude of the challenge became evident in the well-publicized report of the Institute of Medicine (IOM): To Err Is Human.[359] This report estimated that at least 44,000 people die in US hospitals each year as a result of preventable medical errors and injuries. The report emphasized that most errors are not intentional or malicious, but rather are the result of "faulty systems, processes and conditions" that either lead to mistakes or fail to safeguard against them.

The idea that safety is primarily a "systems" or "process" problem has led to research designed to modernize healthcare using models taken from other fields. Viewing a medical procedure as a "process" rather than an assemblage of interacting independent practitioners has profound implications on the

mode of practice in the operating room. Attention has been focused on two main ideas: (1) team development and shared management of patient care and (2) policies/procedures/protocols to reduce error.

Our current concept of the surgical team is based on management concepts developed in the military.[360,361] Crew Resource Management (CRM) describes a model of high-performance team interaction that has evolved out of the findings of a joint National Aeronautics and Space Administration (NASA)/industry conference to address human issues associated with airline disasters.[362] The basic concept is that "error is an inevitable result of the natural limitations of human performance and the function of complex systems."[363] Essential components of CRM implementation include a nonpunitive approach to error, team education on sources of error, and accurate error reporting. CRM team training focuses on empowerment of all team members. It also focuses clear protocols, flattening of hierarchical structures, education on effective communication techniques, and mandatory status reporting. The essential components of this approach are standard operating polices and guidelines, briefings, and checklists.[322] CRM concepts have been applied as well to the care of the surgical patient. This approach expands the duties, responsibilities, and competencies required of the team leader (i.e., the surgeon), and also has important implications for surgical education, credentialing, and maintenance of competency.[363-370]

In the decade leading up to the IOM report and since, a large number of healthcare organizations have issued suggested guidelines to improve the surgical patient safety. In the United States, the National Patient Safety Goals and the Core Measures of the Joint Commission are standards that must be met for accreditation of healthcare facilities. The partnership between the Center for Disease Control (CDC) and Centers for Medicare and Medicaid Services (CMS) led to the comprehensive quality initiative, the Surgical Care Improvement Project (SCIP).[371] Many of these measures are followed currently as best practices and included as standards for hospital accreditation today. More information and tools provided by the Joint Commission to avoid wrong site surgery and surgical infections can be obtained at: http://www.ihi.org/resources/Pages/Tools/WHOSurgicalSafetyChecklistGettingStartedKit.aspx.

The World Health Organization (WHO) and the Harvard School of Public Health in collaboration with more than 200 national and international societies implemented the "The Safe Surgery Saves Lives Initiative" proving checklists utilized in the surgical setting can dramatically reduce complication and mortality associated with surgical procedures.[372] The checklist focuses on three phases of the surgical setting: preanesthesia, preincision, and postprocedural. The developed checklist reinforces safety practices and fosters better communication and leads to teamwork between clinicians caring for surgical patients. The World Health Organization (WHO) Surgical Safety Checklist and additional information can be found at http://www.ihi.org/resources/Pages/Tools/WHOSurgicalSafetyChecklistGettingStartedKit.aspx.

Keywords

postoperative care
ICU
monitoring
complications

Vascular surgery patients remain at high risk for the development of complications in the postoperative period because of the complexity of their surgical procedures and their preoperative comorbidities. This chapter addresses management issues in the postoperative period with an emphasis on issues in the intensive care unit (ICU) and specially monitored high-dependency step-down units.

POSTOPERATIVE TRIAGE

An important aspect of postoperative medical care involves identifying patients at highest risk for postoperative complications and triaging them to the appropriate care environment. The safest postoperative environment for patients undergoing vascular surgical procedures is determined by their preoperative medical comorbid conditions (see Chapters 9, 33, 37, 47, 43, and 44), the inherent risks of the type of operation performed, and the ability to maintain the patient's intraoperative and postoperative homeostasis. Emergency operations, such as those for a ruptured abdominal aortic aneurysm (AAA), have an increased risk for mortality.[1]

Admission to the Intensive Care Unit and High-Dependency Step-Down Unit

The need for invasive hemodynamic monitoring and observation remains the most common criterion for the admission of selected patients to an ICU or step-down unit. The main distinction between these two environments in most institutions is the severity of critical illness and need for invasive positive-pressure ventilation. These environments can provide patients with the following: decreased myocardial oxygen demand through expeditious rewarming, effective fluid resuscitation, effective analgesia, meticulous control of hemodynamics, and careful monitoring and appropriate nursing care to aid in the early diagnosis and treatment of complications. In a cohort study of patients after elective aortic surgery, Lawlor et al.[2] demonstrated that care in an ICU decreased mortality in patients with preoperative severe coronary artery disease, defined as an ejection fraction of less than 40%, congestive heart failure, or New York Heart Association class III or IV angina. Consideration of direct admission to the ICU should also be given to patients with significant chronic obstructive pulmonary disease (COPD, defined as forced expiratory volume in 1 second of less than 1 L) and those who are dialysis-dependent or have a need for continuous renal replacement therapy. Hemodynamically unstable patients (systolic blood pressure <90 mm Hg or inotropic support at the end of the operation), intubated patients with an ongoing need for ventilatory support, those with clinically significant perioperative cardiac ischemia, patients with pulmonary artery catheters, patients with spinal drains, patients with hypothermia (temperature <35°C), and those who required massive transfusion of blood products (>3 L) during the procedure should be admitted to the ICU.

Selective use of high-dependency step-down units and rationing of ICU resources can be safe and cost-effective with appropriate patient risk stratification.[3,4] Each patient must be individualized according to preoperative comorbid diseases, perioperative hemodynamic stability, and the surgical procedure performed. Patients undergoing less invasive vascular procedures associated with fewer fluid shifts and lower surgical morbidity can safely be managed in a step-down unit. This is the case with patients undergoing peripheral arterial bypass, elective repair of infrarenal AAAs, and carotid endarterectomy. Several scoring models predicting risk in vascular patients have been studied and validated as predictors of high-risk patients undergoing vascular surgery.[5]

Organizational Structure of the Intensive Care Unit

The organizational structure of the ICU, independent of a patient's medical factors, has a direct impact on outcomes.[6-11] In looking at outcomes after abdominal aortic surgery, Pronovost et al.[7,12] showed a relationship between increased in-hospital mortality and the absence of a full-time ICU director, less than 50% of ICU attending physicians certified in critical care, no daily rounds by an ICU physician, and decreased ICU nurse-patient ratio in the evening (<1:2). In patients undergoing abdominal aortic surgery, intensivists not making routine ICU rounds is associated with an increase in hospital mortality (odds ratio [OR], 3.0; 95% confidence interval [CI], 1.9-4.9), cardiac arrest (OR, 2.9; 95% CI, 1.2-7.0), acute renal failure (OR, 2.2; 95% CI, 1.3-3.9), septicemia (OR, 1.8; 95% CI, 1.2-2.6), platelet transfusion (OR, 6.4; 95% CI, 3.2-12.4), and reintubation (OR, 2.0; 95% CI, 1.0-4.1). Dang et al.[6] also demonstrated that ICUs with decreased nurse staffing had increased rates of cardiac and respiratory complications after abdominal aortic surgery.

HEMODYNAMICS AND PRESSURE MONITORING

Monitoring is required to intervene in abnormal physiology with the goal of improving outcomes. However, even patients with normal hemodynamic parameters may have inadequate organ perfusion.[13] Distributive hypoxia is a state that results from inadequate oxygen delivery to tissues; it is exacerbated by increased metabolic demands, with resultant multiorgan dysfunction.[14] Indicators of organ perfusion to guide resuscitation[15] include blood pressure, heart rate, central venous pressure (CVP), pulmonary capillary wedge pressure, cardiac output,[16] urine output, blood lactate concentration, tissue carbon dioxide levels, base deficit, mixed venous oxygen levels, and mixed venous carbon dioxide levels.[15,17] The key to interpreting and managing these indicators appropriately is to follow trends over time rather than individual measurements.

Central Venous Catheters and Central Venous Pressure

Central venous catheters are used primarily to infuse fluids, administer vasoactive drugs, and assess intravascular volume.

The most common sites for the placement of central venous catheters are the internal jugular veins, subclavian veins, and femoral veins. To measure CVP, internal jugular or subclavian central venous catheters must be positioned with the catheter tip in the distal segment of the superior vena cava. More distal placement in the right atrium is associated with a potential risk for erosion, perforation, and cardiac tamponade. CVP measures right atrial pressure, providing an estimation of preload. This measurement, however, is inaccurate in patients with COPD or in those with valvular heart disease. Femoral lines are good for resuscitation but not for CVP measurements because of the effect of intra-abdominal pressure (IAP) on measurements.

The transducer must be zeroed at the level of the midaxillary line, and normal values of CVP are between 6 and 12 mm Hg. In patients being managed with positive pressure ventilation, CVP should be measured at end-expiration, when pleural pressure in the chest is approximately zero.[18] The addition of positive end-expiratory pressure (PEEP) in a ventilated patient is another important consideration in measuring pressure in the chest. In normal lungs and with low levels of PEEP (between 5 and 8 cm H_2O), intrapleural pressure, which affects CVP, is only slightly affected.[18] The effect on CVP of high levels of PEEP (>12 to 15 cm H_2O) when the lungs are probably not compliant is unclear.[19] High levels of PEEP prevent the backflow of fluid outside the chest to the heart, thus decreasing venous return. If sudden changes in CVP occur, a cardiorespiratory cause such as pneumothorax or cardiac tamponade should be considered. Further discussion of CVP monitoring can be found in Chapter 33

Peripheral Arterial Lines

Peripheral arterial catheters are the "gold standard" for direct assessment of blood pressure and allow direct vascular access for blood sampling. Complications include bleeding, hematoma, line-related infection, thrombosis, and, rarely, limb ischemia.[20] These complications occur to varying degrees, depending on the cannulation site. The most common site for cannulation is the radial artery, followed by the femoral artery, axillary artery, brachial artery, and, less commonly, dorsalis pedis and ulnar arteries. The radial and the femoral arteries have similar cannulation complication rates[22]; some prefer the femoral artery as the primary cannulation site because of ease of insertion. The most common complication of radial artery cannulation is temporary arterial occlusion, which occurs approximately 20% (1.5%-35%) of the time; however, the occlusion is temporary in most cases and rarely causes acute ischemia.[20] In contrast to the radial artery, cannulation of the femoral artery is associated with a higher risk of bleeding (1.58% vs. 0.53%) and pseudoaneurysm (0.3% vs. 0.09%) but a lower risk of thromboembolism.[20] Cannulation of the axillary artery has a complication rate similar to that at other sites, and it may be the only site available for arterial access in some patients. In the ICU, however, it is not commonly used because of lack of familiarity with the approach and the potential, albeit unproven, risk for carotid embolization.[20] In the hands of experienced operators, the brachial artery also has a low reported complication rate. Yet because it requires meticulous attention to technique and anatomy, it is not commonly used.[21] The level of the transducer relative to the pressure being measured will determine the measured value of the arterial pressure, thus making its position critical for obtaining an accurate measurement. The standard level is the midpoint of the right atrium, approximately 5 cm below the sternal angle in the midaxillary line. This is the area where the preload pressure of the heart is determined.[23]

The distance of the measuring catheter from the heart, the length and compliance of the tubing, and the presence of air bubbles affect systolic and diastolic measurements in the system. These variables affect systolic and diastolic pressure proportionately in opposite directions and have no net effect on the measurement of mean arterial pressure (MAP). For this reason, measurement of MAP is a more accurate reflection of mean aortic pressure. MAP is manually calculated with the formula MAP = 1/3 ([2 × diastolic blood pressure] + systolic blood pressure). Electronic monitoring systems, however, measure MAP as the area under the pulse wave, often averaged over three or more cycles.

Pulmonary Artery Catheters

Pulmonary artery catheters provide central hemodynamic measurements, waveform tracings, and specific blood gas calculations such as mixed venous oxygen and carbon dioxide saturation (also see discussion of pulmonary artery catheter use in Chapter 33). Pulmonary artery catheters were initially used to assess and treat patients with acute myocardial infarction (MI); however, their use has declined significantly because several randomized trials have failed to demonstrate a reduction in mortality.[24-26] Pulmonary artery catheters are typically inserted in the ICU in situations where the clinician believes that measuring cardiac output, cardiac pressure, and mixed venous oxygen saturation will aid in guiding therapy and for direct assessment of the effect of and response to various treatments, such as the administration of fluids and vasopressors.[27] Included in this category are patients in cardiogenic or refractory shock and those in whom right ventricular dysfunction, such as infarction, is suspected.[18,28] Pulmonary artery catheters may induce arrhythmias, which are usually transient and not life-threatening.[29] Left bundle branch block is a relative contraindication to the use of pulmonary artery catheterization because it can induce a temporary right bundle branch block and the potential for subsequent complete heart block.[29] Other catheter-related complications include catheter knotting, pulmonary artery rupture, catheter fragmentation, and cardiac rupture secondary to forceful insertion. Long-term placement, more than 72 to 96 hours, can also lead to thrombosis and infection.

Echocardiography

Echocardiography is used to assess cardiac function by measuring ventricular contractility, chamber size, valve function, and flow.[30,31] Global assessment of ventricular function with transthoracic echocardiography can be helpful in guiding hemodynamic management because one can easily differentiate between

left and right ventricular dysfunction and adjust treatment appropriately.[32] For instance, a patient with a poorly functioning left ventricle may benefit from an inotropic agent, whereas the presence of a hyperdynamic left ventricle and evidence of tissue hypoxia may indicate the need for fluid challenge and vasopressors.[30] Echocardiography is helpful in the case of normotensive shock in a patient who has been adequately fluid resuscitated and who may require afterload-reducing agents such as nitroglycerin.[33] Calculation of ejection fraction, pulmonary artery pressure, and cardiac output is also possible, but specific expertise is required and such measurements may not be reliable in ICU settings.[32]

Transesophageal Doppler ultrasound is a noninvasive modality for measuring cardiac output.[34] Cardiac output is calculated by using the diameter of the descending aorta, the distribution of flow to the descending aorta, and the measured flow velocity of blood.[15] The accuracy of the calculated cardiac output may be affected by the position of the ultrasound probe, which is inserted blindly in the esophagus. Poor positioning of the probe most commonly results in underestimation of the cardiac output.[15]

Intra-Abdominal Pressure

Abdominal compartment syndrome is defined as clinically relevant organ dysfunction caused by intra-abdominal hypertension. IAP is the steady-state pressure concealed within the abdominal cavity. For most critically ill patients, an IAP of 5 to 7 mm Hg is considered normal.[35] Morbidly obese and pregnant individuals may have chronically elevated IAP without adverse consequences. Intra-abdominal hypertension is defined as IAP in excess of 12 to 20 mm Hg.[36,37] Abdominal perfusion pressure is calculated as MAP minus IAP. Elevated IAP may reduce blood flow to the abdominal viscera. Abdominal compartment syndrome is diagnosed by the combination of intra-abdominal hypertension and evidence of organ malperfusion. Specifically, it is a constellation of symptoms consisting of new attributable organ dysfunction, such as cardiovascular (decreased cardiac output), respiratory (high peak airway pressure), and renal (oliguria) malperfusion in the context of a sustained IAP of 20 mm Hg or higher.[36] Patients at increased risk for abdominal compartment syndrome are those who received large volumes of fluid for resuscitation (>10 L of crystalloid, >5 L of colloid) or transfusion of more than 10 units of packed red blood cells (PRBCs) during a 24-hour period.[37]

IAP is most commonly measured by the intravesicular technique.[38] An indwelling bladder catheter is connected to a pressure transducer. A defined volume of fluid (25-50 mL of normal saline) is instilled into the catheter and used to distend the bladder and eliminate bladder wall coaptation.[37] Volumes greater than 50 mL falsely elevate IAP values. IAP is then measured at end-expiration with the patient in the supine position and the manometer or other pressure measuring system at the level of the symphysis pubis. Another technique of IAP measurement uses a nasogastric or orogastric tube.[39] This technique involves a lower risk for sepsis secondary to iatrogenic urinary tract infection as a result of catheter manipulation, but it is a more cumbersome method and rarely used. The timing and frequency of IAP monitoring are not standardized, but the highest risk for the development of abdominal compartment syndrome is during and shortly after resuscitation. The main reason for monitoring IAP is that the early recognition and treatment of abdominal compartment syndrome appears to improve survival.[37]

CARDIOVASCULAR COMPLICATIONS

Hypertension

Hypertension is common after surgery and may be caused by hypoxia, hypercapnia, hypervolemia, hypothermia, gastric or bladder distention, agitation, and pain. Furthermore, a common cause of postoperative hypertension is simply neglecting to restart preoperative antihypertensive medications. Sedation, analgesia, and rewarming often resolve most cases of mildly elevated blood pressure. However, hypertension increases myocardial oxygen consumption and can potentially cause myocardial ischemia. In addition, in the immediate postoperative period, it may contribute to increased bleeding from raw surfaces or through vascular anastomoses. After all possible causes have been evaluated and addressed, drug treatment may be considered. In general, blood pressure treatment targets should center on systolic blood pressure values 20 mm Hg above or below preoperative pressure.[40] Deviations in MAP greater than 20% from preoperative values should also be treated.[41,42] Several agents may be used; the surgeon should become familiar with a few for an effective and safe approach to hypertensive patients in the postoperative period. Nitrates, beta blockers, angiotensin-converting enzyme inhibitors, calcium channel blockers, and vasodilators are the most common classes of drugs used (see Chapter 14).[43]

Hypertensive crisis causes acute damage to end organs (heart, brain, retina, and kidney); it is associated with a systolic blood pressure higher than 179 mm Hg or diastolic blood pressure higher than 109 mm Hg. In the absence of evidence of end-organ damage, these elevations in blood pressure constitute hypertensive emergencies.[44] When such an emergency is diagnosed, short-acting intravenous antihypertensive agents should be used; the reduction in blood pressure should occur within 1 hour in hypertensive crisis and within 24 hours in a hypertensive emergency.[9] The goal is to reduce the patient's diastolic blood pressure to less than 110 mm Hg within 30 to 60 minutes.[45] Hypertensive patients in these circumstances will manifest natriuresis, which causes intravascular fluid depletion requiring the administration of fluid along with antihypertensive medications. Several agents can be used in hypertensive emergencies; one of the most common and effective is labetalol because it is a combined α_1-adrenergic and nonselective β-adrenergic receptor blocker.[46]

Hypotension

Hypotension is dangerous and is associated with an increased risk for end-organ dysfunction (MI, cerebrovascular events, and

renal failure) and possibly bypass graft thrombosis. Common causes of hypotension after surgery are hypovolemia, cardiac dysfunction, and a diffuse vasodilatory state with or without sepsis. The management strategy for the correction of hypotension involves the administration of fluids and vasoactive agents. A fluid challenge should be the first line of treatment of postoperative hypotension. Surgical bleeding should be excluded as a cause to prevent delays in returning the patient to the operating room.[47]

In administering fluids for resuscitation, one must first determine whether the patient is on the ascending portion of the Frank-Starling curve and will benefit from a fluid challenge. If the patient is on the flat portion of the curve, fluid loading will only increase tissue edema and worsen tissue dysoxia, with little effect on cardiac output.[15] A large pulse pressure–stroke volume ratio (>10%:15%) is indicative of hypovolemia and predictive of volume responsiveness.[15] A fluid challenge in these circumstances will increase preload and subsequently increase stroke volume.[48] Similarly, in patients with a pulse pressure variation greater than 12%, a fluid challenge is likely to have a positive effect on cardiac output.[49] If the hypotension does not respond to fluid resuscitation, cardiac output must be optimized by pharmacologic means. Short-acting peripheral vasoconstrictors, such as phenylephrine and dopamine, are readily available on crash carts and can be given peripherally and titrated to effect. Once adequate central intravenous access has been established, the patient should be switched from dopamine to more definably titratable vasopressors.

In cardiogenic shock, peripheral vasoconstrictors may increase myocardial workload and dysfunction. In this setting, inotropic agents may be necessary to increase cardiac output. Patients in cardiogenic shock secondary to acute MI have mortality rates higher than 50%.[50] In these situations, volume must be optimized, rhythm must be controlled, and beta agonists should be administered to enhance contractility.[51] Finally, intra-aortic balloon pump counterpulsation may be necessary to aid the heart in generating cardiac output when pharmacologic agents fail. Beta blockers and calcium channel blockers have a negative inotropic effect and are relatively contraindicated in this setting.

Arrhythmias

Patients with preexisting structural heart disease are at highest risk for postoperative arrhythmias.[52] Common triggers for postoperative arrhythmias are hypoxia, hypercapnia, acid-base imbalances, electrolyte abnormalities, and myocardial ischemia. Treatment must focus on predisposing factors, and the goal should be hemodynamic stabilization, control of the ventricular response, and restoration of rhythm.[52]

Tachyarrhythmias

The most common tachyarrhythmias are sinus tachycardia, atrial fibrillation (AF), ectopic atrial tachycardia, junctional tachycardia, multifocal atrial tachycardia, atrioventricular (AV) nodal reentry tachycardia, ventricular tachycardia (VT), and ventricular fibrillation. Tachyarrhythmias that traverse the AV node can often be controlled pharmacologically by altering conduction through the AV node.[52] Tachyarrhythmias that are conducted by accessory pathways and ventricular tachyarrhythmias are more difficult to control pharmacologically than those that transverse the AV node. Supraventricular tachyarrhythmias are common after surgery, with an incidence of approximately 4% to 13%,[52] and after AAA repair, with an incidence of 3.2%.[53] Short bursts of atrial tachycardia do not require treatment. It is important, however, to correct any underlying causes, such as electrolyte imbalances. For sustained atrial tachyarrhythmia in a hemodynamically stable patient, the rate may be slowed with beta blockers or calcium channel blockers. Caution should be exercised with these agents, however, when they are used in patients with poor left ventricular function or congestive heart failure. Alternatively, in monitored settings, treatment can be switched to intravenous amiodarone. In stable patients with nodal reentrant rhythms, adenosine (6-12 mg intravenously) can also be used instead of beta blockers or calcium channel blockers. If patients are hemodynamically unstable, they should be electrically cardioverted regardless of the type of atrial tachyarrhythmia.

Ventricular tachyarrhythmias are also managed according to their duration and hemodynamic consequences. In the presence of coronary artery disease, these rhythms are ominous. Furthermore, the presence or absence of structural heart disease has prognostic significance[52]; it is important when the treatment of runs of premature ventricular contractions and nonsustained VT is being considered. Prompt evaluation and treatment of predisposing factors—such as hypokalemia, hypomagnesemia, hypoxia, and myocardial ischemia—are important to prevent sudden death. In addition, unstable VT is an indication for immediate electrical defibrillation. In contrast, hemodynamically stable monomorphic VT should be treated with antiarrhythmics such as intravenous amiodarone, followed by prompt cardiac evaluation.

Polymorphic VT and ventricular fibrillation occur most commonly in the setting of acute MI and can rapidly lead to hemodynamic instability. These arrhythmias are also treated with urgent defibrillation and intravenous antiarrhythmics. Polymorphic VT with prolonged QT intervals is called torsades de pointes. The most common cause of this rhythm is drug-related or QT prolongation secondary to electrolyte abnormalities. Intravenous magnesium should be given empirically for suspected torsades de pointes. Positive chronotropic agents such as isoproterenol or temporary overdrive pacing to shorten the QT interval can also be used.

Atrial Fibrillation

AF is the most common arrhythmia encountered in the postoperative period; it affects 10% of patients undergoing major noncardiothoracic operations.[54,55] Onset is often within the first few days after the operation, and AF is associated with increased 30-day postoperative mortality, increased ICU stay, and increased overall hospital length of stay. Common risk factors for the development of AF include advanced age, male gender, valvular heart disease, and previous history of AF.[54] AF can be precipitated by hypokalemia, hypomagnesemia, volume overload, withdrawal of beta blockers or angiotensin-converting enzyme inhibitors,

COPD, obesity and obstructive sleep apnea, and infections, especially pulmonary infections.[54,56,57] A rapid heart rate limits ventricular filling, and loss of the atrial component of the cardiac cycle—the so-called atrial kick—decreases left ventricular stroke volume by 20% to 35%.[58] This is especially important in patients with diastolic dysfunction and dilated left ventricles, whose cardiac output is volume-dependent.[59]

Treatment focuses on controlling the heart rate, restoring normal sinus rhythm, and preventing thromboembolic complications.[59] Patients who are hemodynamically unstable, have pulmonary edema, or have ongoing chest pain should undergo urgent electrical cardioversion. Hemodynamically stable patients should have their heart rates pharmacologically controlled with beta blockers, amiodarone, digitalis, or calcium channel blockers. Chemical cardioversion can also be used in hemodynamically stable patients, and one-third of patients will convert to normal sinus rhythm with amiodarone loading alone.[60]

Before electrical cardioversion, one must consider the patient's risk for thromboembolic complications. If the patient has been in AF for longer than 48 hours or for an unknown period, intracardiac thrombus must be excluded.[61] This is obviously not feasible in the event of acute hemodynamic instability, in which case one should proceed with electrical cardioversion to stabilize the patient and subsequently monitor for thromboembolic complications. If an intracardiac thrombus cannot be excluded and the patient is hemodynamically stable, the safest course is anticoagulation with unfractionated heparin before cardioversion.[54]

Bradyarrhythmias

Bradyarrhythmias are not generally a diagnostic challenge and treatment options are straightforward. Those associated with sinus node dysfunction are sinus bradycardia, sinus pause, sinoatrial block, and sinus arrest.[62] Postoperatively, these rhythms are most often due to increased vagal tone and myocardial ischemia. If the bradyarrhythmia is transient and not associated with hemodynamic instability, it does not require treatment. Treatment of sustained bradyarrhythmias and hemodynamic compromise is with antimuscarinic agents such as atropine. If there is no response with continued bolus doses of atropine, the patient must be paced either externally or with a temporary transvenous pacer.

Postoperative Myocardial Infarction

Diagnosis

MI is the most common cause of cardiac complications and mortality in patients with peripheral vascular disease.[47,63-66] The three modes of detecting clinically meaningful postoperative cardiac ischemia are symptoms, the electrocardiogram (ECG), and evaluation of myocardial enzymes. Symptoms elicited from the patient, often in the form of anginal chest pain, are not a frequent manifestation of postoperative myocardial ischemia but are more commonly found in those with acute coronary syndrome.[67] In the postoperative period, these symptoms are also difficult to distinguish from distracting postoperative pain and are influenced by the concomitant use of analgesia and anesthetics. The presence of ST-segment changes on the ECG may indicate an MI. However, after major vascular surgery, approximately one-third of patients will have ST changes on the ECG in the absence of clinically significant myocardial ischemia.[68] Regardless, the presence of such changes correlates with an approximately 9- to 16-fold increased risk for MI and death.[68] The third method of diagnosing postoperative MI is through the detection of myocardial proteins released into the circulation as a result of myocardial cellular injury. The most common enzymes evaluated are the MB isoenzyme of creatine kinase (CK-MB) and the myocardial-specific cardiac protein troponin I.[69] In vascular surgery patients, increased cardiac troponin I levels in the absence of clinical symptoms have also been demonstrated to be useful in the risk stratification of postoperative patients for cardiac morbidity.[69] Elevated levels after major vascular surgery are associated with an increased risk for perioperative MI and increased risk for mortality at 6 months.

ST-Segment Elevation Myocardial Infarction

ST-segment elevation MI (STEMI) is most commonly caused by acute rupture of atherosclerotic plaque and thrombosis of the involved coronary arteries. For this diagnosis to be made, the ECG must show ST-segment elevation of at least 0.1 mV (1 mm) in two consecutive leads.[70] In patients with preexisting left bundle branch block, diagnosis of STEMI is difficult. Biochemically, CK-MB levels are elevated 3 to 12 hours after infarction, peak at 24 hours, and can be elevated for 3 days. Cardiac troponin levels can be detected 4 to 12 hours after infarction, peak at 12 to 48 hours, and can remain elevated for 1 week.

Treatment involves rapid resuscitation with administration of supplemental oxygen, afterload-reducing agents, antiplatelet therapy, anticoagulation with unfractionated heparin (if at low risk for bleeding), and urgent reperfusion therapy with either fibrinolysis or primary percutaneous coronary intervention (PCI). Postoperatively, fibrinolysis may be relatively contraindicated, but this decision must be individualized to the patient according to the extent of surgery and time after the operation. For clinically significant ischemia and patients in cardiogenic shock in the postoperative period, urgent PCI and revascularization are indicated. Primary PCI is associated with primary patency rates of greater than 90%. Emergency coronary artery bypass surgery is reserved for patients who have failed to respond to PCI or fibrinolysis or who have a complication that requires surgery, such as ventricular septal rupture, cardiac rupture, or severe mitral valve insufficiency.[71] Beta blockers should also be started unless patients are hypotensive or bradycardic, are in congestive heart failure, have advanced AV block, or have reactive airway disease. In addition, an angiotensin-converting enzyme inhibitor should be started in the first 24 hours after infarction. In the long term, patients also benefit from treatment with statins.

Non–ST-Segment Elevation Myocardial Infarction

Non–ST-segment elevation MI (non-STEMI) is characterized by the presence of biomarkers indicative of myocardial injury in the absence of ST elevation on the ECG. The key difference

from STEMI is myocardial ischemia in the absence of significant coronary obstruction, such as occurs with acute plaque rupture. The myocardial ischemia in this setting is due to a transient reduction in coronary blood flow that causes an imbalance in myocardial oxygen supply and demand, often with shortness of breath and decompensated heart failure. The ECG can demonstrate nonspecific T-wave inversion or ST depression, and the key to diagnosis is the presence of circulating biomarkers (CK-MB, troponin I, troponin T) indicative of myocardial cellular necrosis.[72] Mortality risk is directly proportional to troponin levels.[73]

Treatment is medical and centered on optimizing myocardial oxygen delivery and demand and preventing reinfarction and death.[72] Supplemental oxygen should be administered, and pharmacologic agents to decrease preload and cardiac afterload should be given. Treatment can be thought of as the ABCs (acetylsalicylic acid, angiotensin-converting enzyme inhibitor, beta blockers, and cholesterol lowering). Administration of unfractionated heparin is also associated with a mortality benefit,[72] but its use must be balanced with the risk of bleeding. Statin therapy should also be instituted and treatment continued in the long term. In the setting of ongoing chest pain, the most recent American College of Cardiology/American Heart Association guidelines recommend the use of sublingual nitroglycerin if the systolic blood pressure is higher than 90 mm Hg and the heart rate is not less than 50 beats per minute or more than 100 beats per minute. If further analgesia is needed after nitroglycerin is given, morphine sulfate or meperidine can be used.[74]

PULMONARY MANAGEMENT

Respiratory insufficiency can be divided into either oxygenation failure or ventilation failure. Oxygenation failure is typically associated with hypoxia and ventilation failure with hypercapnia. Management of patients with acute respiratory failure and acute respiratory distress syndrome is discussed extensively in Chapter 40. The following comments focus on pulmonary support provided for the mechanically ventilated patient.

Ventilatory Support

Mechanical Ventilation

Mechanical ventilators affect oxygenation by controlling airway pressure and fraction of inspired oxygen and affect ventilation by controlling tidal volume and respiratory rate. Patients are ventilated primarily in two modes: controlled and supported. In controlled ventilation, the ventilator initiates and delivers a set amount of tidal volume; in supported mode, the breath is initiated by the patient and supported by the ventilator. Ventilators may deliver either a fixed tidal volume with variable pressure (volume control) or a variable tidal volume at a fixed pressure (pressure control). The combination of these two general modes of ventilation (controlled versus spontaneous) with either of these two settings (volume control versus pressure control) accounts for the majority of modes with which patients are ventilated. Patients with hemodynamic instability or in severe respiratory distress should be placed on a controlled mode of ventilation to limit the work of breathing. Either volume control or pressure control ventilation will be adequate, and practitioners should select the mode with which they are most familiar. Pressure support mode is generally used in patients who are more stable. It is also used as a weaning mode (discussed in the next section).

It is important to ventilate patients with use of a lung protective strategy to reduce ventilator-induced lung injury, which can occur through two main mechanisms. The first is referred to as volutrauma, which causes overdistention of alveoli due to high tidal volume and high alveolar pressure and can lead to barotrauma (pneumothorax, pneumomediastinum). The second main mechanism is caused by shear forces on alveolar endothelium.[75] These shear stresses are created in alveoli by cyclic opening and closing, and the resultant injury is called atelectatic trauma.[76] PEEP applied throughout the ventilatory cycle serves to stent alveoli open, which prevents atelectatic trauma and facilitates gas exchange. The ideal level of PEEP is unknown, but an accepted range, depending on the clinical situation, is 5 to 15 cm H_2O.

In ventilating patients at increased risk for volutrauma, such as those with acute respiratory distress syndrome, a lung protective strategy using pressure control ventilation to reduce peak airway pressure is most appropriate (Fig. 34.1). In this mode, inspiratory time can also be lengthened to allow increased alveolar recruitment, and alveolar distending plateau pressure and transpulmonary pressure are to be kept below 30 cm H_2O by use of tidal volumes that should not exceed 6 to 8 mL/kg ideal body weight.[77] However, low tidal volume ventilation causes decreased clearance of carbon dioxide, with associated respiratory acidosis. However, this "permissive hypercapnia" and acidosis are well tolerated if the patient's pH is above 7.2.[78] One caveat is that permissive hypercapnia is contraindicated in patients with cerebral edema.

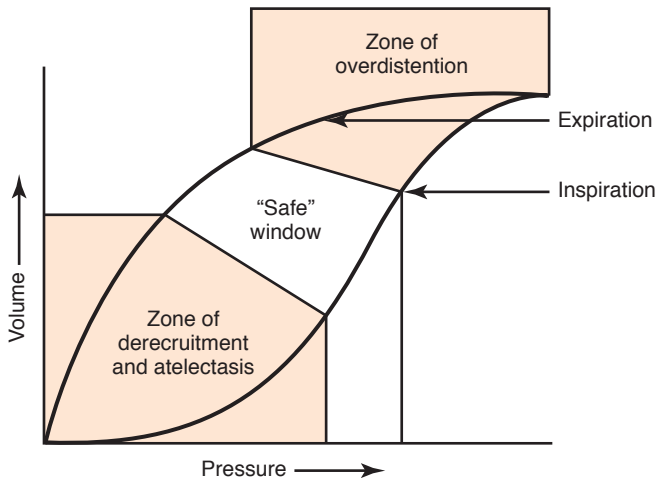

Figure 34.1 Protective Ventilation. Ventilation of a patient with parameters on the left side of the pressure-volume curve places the patient at risk for atelectatic trauma, and ventilation of a patient with parameters on the right side of the curve places the patient at risk for barotrauma. (Redrawn from Froese AB. High-frequency oscillatory ventilation for adult respiratory distress syndrome: let's get it right this time. *Crit Care Med.* 1997;25:906–908.)

Weaning

There are two main considerations in the weaning process. The first is weaning the support provided by the ventilator, and the second is removing the endotracheal tube (liberation from the ventilator). Patients should be assessed daily for readiness to be weaned, which can be done only after interruption of sedation.[79] This method has been called "wake up and breathe." Several randomized trials have revealed that weaning method influences the duration of ventilation.[80,81] The traditional approach to weaning has been a progressive reduction in ventilatory support over time according to a protocol.[82] A second technique is the use of spontaneous breathing trials without progressive withdrawal of ventilatory support, which may be associated with earlier extubation.[83] With the traditional approach to weaning, patients are switched from a controlled to a spontaneous mode of ventilation, such as pressure support ventilation. The amount of ventilatory support and PEEP is then decreased according to oxygen saturation, respiratory rate, and tidal volume. If the patient is not ready for weaning, a decrease in tidal volume and an increase in respiratory rate will be noted.[84] When a spontaneous breathing trial is used, patients are allowed to breathe spontaneously with little or no assistance. Most often, patients will be placed on minimal support (pressure support at 5-8 cm H_2O, PEEP at 5 cm H_2O) for 30 minutes to 2 hours. In a successful trial, the patient does not demonstrate respiratory distress (respiratory rate >35 for >5 minutes), desaturation (SaO_2 <90% for >30 seconds), increase or decrease in heart rate (±20% for >5 minutes), systolic blood pressure higher than 180 mm Hg or lower than 90 mm Hg, or other signs of agitation and distress (paradoxical breathing, use of accessory muscles, diaphoresis).[85]

Indications for Extubation

Once patients are weaned from the ventilator and have successfully spent a prolonged time with minimal PEEP and on minimal pressure support, they can be assessed for the potential for extubation. If any indication for intubation exists, it is a contraindication to extubation. Contraindications to extubation are sedation, inability to protect the airway, presence of copious secretions, and lack of a cough reflex. Consideration must also be given to how difficult it would be to reestablish the airway if needed. Failure of extubation is associated with increased mortality and a need for long-term ventilation.[86] The harm of reintubation must be balanced by the harm created by prolonged mechanical ventilation. Reintubation rates of 10% to 15% are within the normal range in most ICUs.[87]

Tracheostomy

Tracheostomy relieves the patient of the portion of the work of breathing required to overcome the resistance of the endotracheal tube and the upper airway. It also allows better oral hygiene and secretion management and improves patient comfort. The major disadvantages of a tracheostomy are procedure-related complications, stomal complications, formation of a tracheoinnominate fistula, and formation of a tracheoesophageal fistula. Early tracheostomy within the first week in patients who are thought to require ventilation for more than 10 days facilitates weaning and is associated with a shorter length of stay in the hospital.[87] Jubran et al.[80] found that in patients who required prolonged mechanical ventilation, unassisted breathing through a tracheostomy resulted in shorter median weaning time compared with pressure support. However, in a retrospective observational study after abdominal and thoracoabdominal repair, Diedrich et al.[88] found that, overall, tracheostomy correlated with worse outcomes but that patients with preexisting COPD who received a tracheostomy had improved survival.

Tracheostomy can be done either by an open surgical procedure or percutaneously. Percutaneous tracheostomy is as safe as open surgical tracheostomy, with the advantage that the patient does not require transport to the operating room; operating room resources are thus conserved.[89] Furthermore, no difference in long-term outcomes between percutaneous and open surgical tracheostomy has been shown.[89] However, percutaneous tracheostomy is relatively contraindicated in patients who are hypoxic and have high PEEP requirements, those who are obese with short necks, those who are coagulopathic, and those with recent (<10 days) anterior cervical spine fixation.[90]

BLEEDING

Evaluation of Bleeding Patients

Patients with greater than expected fluid requirements postoperatively must be urgently evaluated for bleeding.[47] The physiologic response to hypovolemia includes tachycardia, hypotension, low CVP, decreased urine output, and signs of peripheral vasoconstriction.[91]

Surgical Bleeding

Surgical bleeding can worsen coagulopathy and render it resistant to medical correction. A thorough patient examination is necessary to evaluate for possible sources of bleeding. Coagulopathy is generally assessed with a hemoglobin level, platelet count, prothrombin time (usually expressed as the international normalized ratio [INR]), activated partial thromboplastin time (aPTT), and fibrinogen assay. A blood sample for typing and screening should also be drawn to ensure that blood is available for transfusion if needed. Hemoglobin level may not show an initial drop when the patient is bleeding acutely. The role of imaging is dependent on the stability of an acutely bleeding postoperative patient. If the patient is stable and the bleeding source is not clear, computed tomography, ultrasonography, and angiography may be helpful.

Coagulopathy

For a summary of coagulopathy, see Table 34.1. Early in the postoperative period, coagulopathy is often dilutional or caused by incomplete reversal of the heparin administered during surgery (or both). Assessment of the coagulation system by measurement of the aPTT, prothrombin time (expressed as the INR), platelet count, and fibrinogen should be done immediately to guide

TABLE 34.1 Postoperative Coagulopathy

	Possible Problems	Treatment
Prolonged aPTT and normal INR	Heparin Hemophilia A Hemophilia B Hemophilia C	Protamine Factor VIII Factor IX Factor XI
Normal aPTT and increased INR	Warfarin Vitamin K deficiency Drugs	FFP or vitamin K or prothrombin complex concentrates Vitamin K
Normal aPTT and normal INR	Platelet dysfunction Thrombocytopenia	Platelet transfusion Platelet transfusion
	Hypothermia	Warm patient
Prolonged aPTT and increased INR	Primary fibrinolysis Disseminated intravascular coagulation	Treat underlying cause Cryoprecipitate if fibrinogen <100 mg/dL (<150 to 200 mg/dL in severe bleeding) Tranexamic acid FFP if factors <25% of normal Keep platelets >50 × 10^9

therapy. The etiology, diagnosis, and management of specific coagulopathies are discussed in Chapter 37. Included here is a practical approach to the management of coagulopathic patients in the postoperative period.

Prolonged Activated Partial Thromboplastin Time and Normal International Normalized Ratio

If the patient has a prolonged aPTT and a normal INR, potential residual heparin effect may be reversed with protamine sulfate, which should be administered slowly to avoid inducing hypotension.[92] However, the heparin effect may not be reduced by the administration of fresh frozen plasma (FFP) because it may increase the level of antithrombin III, and most of the effect of heparin is mediated through activation of this factor. A normal INR and a prolonged aPTT may also be found in factor VIII deficiency (hemophilia A) or von Willebrand disease. This may be treated with administration of the specific factor and, in mild cases, desmopressin (DDAVP). An increased aPTT with an often normal INR may also be found in patients with hemophilia. Diagnosis of the three types of hemophilia is made through specific factor analysis. Type A involves a deficiency of factor VIII, type B involves a deficiency of factor IX, and type C involves a deficiency of factor XI.[91] In these patients, transfusion of the missing factors may be necessary. For further discussion of hemophilia, see Chapter 37.

Increased International Normalized Ratio and Normal Activated Partial Thromboplastin Time

An increased INR with a normal aPTT may be caused by warfarin administration or by vitamin K deficiency secondary to chronic illness or malnutrition or as a side effect from treatment with broad-spectrum antibiotics. The coagulopathy in this setting is due to a reduction in vitamin K–dependent coagulation factors (factors II, VII, IX, and X), and FFP; vitamin K may be necessary to reverse this coagulopathy. In situations where rapid reversal is required within 6 hours, FFP or prothrombin complex concentrates may be required.

Normal International Normalized Ratio and Activated Partial Thromboplastin Time

In patients with a normal INR and aPTT, the bleeding diathesis may be caused by platelet dysfunction. This, in turn, may be due to lack of a sufficient number of platelets or, in the presence of a normal number, to a defect in their function. Other less common causes of coagulopathy associated with a normal INR and aPTT are factor XIII deficiency and hyperfibrinolysis. Causes of thrombocytopenia include bacterial infection, drugs (other than heparin), and bone marrow disease. Platelet dysfunction can also result from hypothermia. The level at which platelets should be transfused is controversial in an actively bleeding patient, but general guidelines for platelet transfusion are discussed later (and also in Chapter 37). Platelet dysfunction may be caused by platelet inhibitors or uremia. Platelet transfusion and DDAVP may be helpful in these settings. In the immediate postoperative period, patients need to be rewarmed expeditiously because platelet function is enhanced at normothermic body temperatures.[47]

Increased International Normalized Ratio and Increased Activated Partial Thromboplastin Time

Primary fibrinolysis and disseminated intravascular coagulation (DIC) rarely occur in the postoperative period. DIC is usually associated with an increased INR and aPTT as well as thrombocytopenia. The hallmark of this condition is excessive stimulation of the coagulation system with an imbalance between thrombosis and fibrinolysis. The severity of the coagulopathy is dependent on the level of fibrinogen. Microthrombi are formed and induce the body's natural mechanism of fibrinolysis. This, in turn, causes bleeding, and bleeding results in the release of tissue factors, including activation of factor VII, which increases coagulation. This scenario creates a vicious circle leading to depletion of stores of coagulation factors and subsequent consumptive coagulopathy. DIC can result from shock liver secondary to massive hypotensive episodes in the postoperative period, especially in the setting of chronic liver failure. Other common causes in postoperative patients are massive occult hemorrhage and sepsis. DIC has also been rarely associated with the administration of different blood products, including factor VII, in a dose-dependent manner.[93]

DIC is a clinical diagnosis, and laboratory tests are confirmatory.[94] They show low fibrinogen levels, increased fibrin degradation products, and thrombocytopenia. The principles of management include treating the underlying cause, such as debridement of devitalized tissue and source control for sepsis or disseminated bacterial infection. Replacement of blood products is reserved for patients actively bleeding or at high risk for bleeding, not in response to laboratory abnormalities.

It may be appropriate to administer cryoprecipitate when fibrinogen levels are less than 100 mg/dL (<150 to 200 mg/dL in severe bleeding), to transfuse FFP when other factor levels are below 25% of normal or the INR is abnormal, to transfuse platelets to increase counts to greater than 50,000/mm^3, and to replace blood volume as needed.[91,94]

FLUIDS

Infusion of Fluids

Fluid administration in the postoperative period must be tailored to the individual patient. A balance must be reached between adequate tissue perfusion by replacing fluid loss at surgery and avoidance of fluid overloading. Hypervolemia is as detrimental to the patient as hypovolemia because it causes unwanted tissue edema and impedes tissue oxygenation. If large volumes of crystalloid solution are administered for resuscitation, it is recommended that a balanced salt solution such as lactated Ringer's solution be given instead of normal saline to reduce the development of iatrogenic hyperchloremic metabolic acidosis. Restricted fluid regimens based on physiologic response versus standard fluid administration based on fluid algorithms and fixed rates have been associated with improved outcomes and decreased lengths of hospital stay after major gastrointestinal surgery and decreased pulmonary morbidity after thoracic surgery.[95,96] We favor the administration of intravenous fluids in the postoperative period at low maintenance rates of 75 to 100 mL/h and small boluses of crystalloid (500-1000 mL) as needed, with titration to low blood pressure, increased heart rate, or low urine output (Fig. 34.2). Colloids are commonly used for fluid resuscitation because they have the theoretical benefit of expanding intravascular volume and their osmotic activity reduces third spacing. However, there appears to be no survival benefit when albumin is used in severely ill patients and no difference among the different types of colloid used.[97]

Electrolyte Management

In the immediate postoperative period, it may be dangerous to add routine electrolytes, such as potassium, to maintenance fluids because of perioperative fluid shifts. Routine testing of sodium, potassium, magnesium, calcium, and phosphate should be performed. Electrolytes should then be replaced individually as needed, and this can safely be done by protocol. Magnesium and potassium levels must be maintained in the normal range to avoid cardiac arrhythmias. Maintenance of calcium and phosphate levels is also important for cardiac function as well as for several cellular functions. The serum sodium level is a reflection of total body water. Both hyponatremia and hypernatremia require assessment of the patient's volume status and careful treatment to avoid adverse neurologic complications.

Transfusion of Blood Products

For a summary of blood product transfusion, see Table 34.2. The evidence for guiding transfusion practices is sparse with respect to the timing and volume of product administration and the ideal ratio of red blood cells (RBCs), platelets, and FFP. It is accepted that giving a disproportionate amount of one product over another can exacerbate dilutional coagulopathy. In addition, relying on laboratory tests to guide transfusion may be misleading because of the delay in obtaining results and the fact that normal levels do not equate to normal function. Additional discussion of the following topics can be found in Chapter 33.

TABLE 34.2 Transfusion of Blood Products

	Clinical Scenario	Transfusion Threshold
Red blood cells	Stable patient, absence of CAD	Hb <7.0 g/dL (<70 g/L)
	Stable patient with CAD	Hb 8.0-9.0 g/dL (80-90 g/L)
Platelets	Major cardiac surgery and unexplained bleeding	$<100 \times 10^9$
	Coagulopathy and active bleeding	$<50 \times 10^9$
	No active bleeding, febrile, with coagulopathy	$<20 \times 10^9$
	No active bleeding, low risk for hemorrhage, no fever	$>10 \times 10^9$
Fresh frozen plasma	Active bleeding and INR >1.5	INR >1.5
Cryoprecipitate (factor VIII, factor XIII, vWF)	Active bleeding and fibrinogen <100 mg/dL (<2.9 µmol/L)	<100 mg/dL

CAD, Coronary artery disease; *Hb,* hemoglobin; *INR,* international normalized ratio; *vWF,* von Willebrand factor.

Red Blood Cells

The transfusion threshold for RBCs has decreased for all patients on the basis of a randomized nonblinded study in critically ill euvolemic patients in the intensive care setting by Hébert et al.[64] They compared 418 patients treated with a restricted transfusion strategy to maintain the hemoglobin concentration between 7.0 and 9.0 g/dL (70 and 90 g/L), in whom PRBCs were transfused when the hemoglobin level was lower than 7.0 g/dL (70 g/L), with 420 patients in whom the hemoglobin target was 10.0 to 12.0 g/dL (100-120 g/L), who were administered PRBCs when the hemoglobin level fell below 10.0 g/dL (100 g/L). The restrictive strategy resulted in a 54% reduction in the number of units of PRBCs transfused. Overall, 30-day mortality and organ dysfunction were similar in the two groups. Mortality at 60 days was significantly less in the restrictive group ($P = .05$). Furthermore, subgroup analysis suggested improved 30-day mortality in patients with an Acute Physiology and Chronic Health Evaluation (APACHE) score of less than 20 and age younger than 55 years for the restricted group ($P = .02$). No difference was found in patients with a primary or secondary diagnosis of cardiac disease. Thus, for clinically stable patients not at risk for coronary artery disease, transfusion of RBCs is likely to be beneficial when the hemoglobin level is less than 6.0 g/dL (60 g/L) but not when it is greater than 7.0 g/dL (70 g/L) as long as normal blood volume is maintained and the patient is carefully monitored.

In contrast to critically ill patients, guidelines state that for those at risk for coronary artery disease, transfusion may be indicated when hemoglobin is less than 8.0 to 9.0 g/dL (80-90 g/L). In acute blood loss, the lower limit of tolerance has not been established, but oxygen delivery will probably be adequate with a hemoglobin level of 6.0 to 8.0 g/dL (60-80 g/L). With ongoing blood loss, however, the measured hemoglobin concentration may be misleading, because by the time that the hemoglobin value is reported, the actual oxygen-carrying capacity may have changed. In these circumstances, the decision to administer RBC transfusions should be determined by evaluating the rate of ongoing blood loss, evidence of end-organ dysfunction, and risk for or presence of coronary artery disease.[91]

Platelets

The definition of a threshold for platelet transfusion would be relatively easy if there were consistent, well-defined relationships between platelet count, platelet function, and bleeding manifestations. However, 10 review articles and 12 guidelines for platelet transfusion therapy were published between 1966 and 1999, thus suggesting that such a relationship is less than clear. One unit of platelets from whole blood contains 5.5 to 10×10^{10} platelets, whereas 1 unit from platelet pheresis contains 40×10^{10} platelets and is equivalent to 6 units from whole blood.

In nonsurgical patients, spontaneous bleeding is uncommon with platelet counts greater than 20×10^9/L. In contrast, the platelet count at which surgical patients are likely to experience increased bleeding is unknown. Regardless, in 1994, the College of American Pathologists recommended platelet transfusion for patients with platelet counts less than 50×10^9/L.[98] For major surgery with life-threatening bleeding, this guideline also concluded that transfusions might be indicated at higher platelet counts to maintain a concentration greater than 50×10^9/L. In addition, it indicated that some experts recommend platelet transfusion after cardiopulmonary bypass in patients with normal coagulation values and platelet counts below 100×10^9/L when major unexplained bleeding occurs because platelets are dysfunctional. Similarly, the American Society of Anesthesiologists Task Force concluded that bleeding risk in surgical patients is defined by the type and extent of surgery, ability to control the bleeding, consequences of uncontrolled bleeding, actual and anticipated rate of bleeding, and presence of factors that adversely affect platelet function (e.g., extracorporeal circulation, renal failure, medications). Moreover, in the absence of contradictory evidence, the opinion of the task force is that platelet transfusion is justified at higher platelet counts in bleeding patients than in nonbleeding patients because of the increased risk for complications from bleeding in surgical patients. Similarly, massively transfused patients with microvascular bleeding that is suspected to be secondary to platelet deficiency may benefit from empiric platelet therapy. However, the task force indicates that surgical patients with microvascular bleeding will usually require platelet transfusion if the platelet count is less than 50×10^9/L but rarely require therapy if the count is greater than 100×10^9/L. With intermediate platelet counts (50-100 $\times 10^9$/L), the decision to transfuse platelets should be based on the patient's risk for more significant bleeding.

In summary, for patients who are actively bleeding after major surgery, platelet counts should be maintained at a level greater than 50,000/mm^3. In nonbleeding patients and those in whom the risk for hemorrhage is low, platelet counts can be maintained above 10,000/mm^3. However, if patients have a fever or are coagulopathic, the target should be a level greater than 20,000/mm^3.

Fresh Frozen Plasma

According to the American Society of Anesthesiologists, after major transfusion, defined as transfusion of more than 10 units of RBCs, or after major surgery with active bleeding, FFP should be given to reduce the INR to a level below 1.5, because pathologic microvascular bleeding does not tend to occur until coagulation test results are greater than 1.5 times normal. In massive resuscitation, as for trauma, it has also been suggested that FFP be given in a 1 : 1 ratio with RBCs to reduce the risk of dilutional coagulopathy, although definitive evidence supporting this practice is lacking. FFP is also indicated for warfarin overdose, but it will not correct the anticoagulant effect of heparins because it contains antithrombin, which is augmented by both unfractionated heparin and low-molecular-weight heparin.

Cryoprecipitate

Cryoprecipitate consists of fibrinogen, factor VIII, factor XIII, and von Willebrand factor. The majority of acquired hypofibrinogenemias are due to consumptive coagulopathy and fibrinolysis. With postoperative bleeding, administration of cryoprecipitate should be reserved for patients with fibrinogen

levels less than 100 mg/dL (2.9 μmol/L). Each unit of cryoprecipitate contains approximately 150 mg of fibrinogen and is compatible only with normal saline. The volume needed to raise fibrinogen concentration 0.5 to 1.0 g/L can be estimated as 1 unit of cryoprecipitate per 5 to 10 kg of body weight.[99]

Summary of the Transfusion of Blood Products

For clinically stable patients not at risk for complications of coronary artery disease, transfusion of PRBCs is likely to be beneficial when the hemoglobin level is less than 7.0 g/dL (70 g/L) as long as normal blood volume is maintained and the patient is carefully monitored. Critically ill patients and those at risk for coronary artery disease will probably benefit from maintenance of hemoglobin in the range of 8 to 9 g/dL (80-90 g/L). In acute blood loss, the lower limit of tolerance has not been established, but oxygen delivery will probably be adequate with a hemoglobin level between 6 and 8 g/dL (60 and 80 g/L). With ongoing blood loss, however, the measured hemoglobin concentration may be misleading; by the time the hemoglobin value is reported, the actual oxygen-carrying capacity may have changed. In this circumstance, the decision to administer RBC transfusions should be determined by evaluating the rate of ongoing blood loss, evidence of end-organ dysfunction, and risk for or presence of coronary artery disease. FFP should be administered in the context of massive transfusions if there is microvascular bleeding associated with a significant (>1.5 times the normal value) increase in INR or aPTT. If these tests are not readily available, however, plasma may be transfused in an attempt to stop diffuse nonsurgical bleeding. Cryoprecipitate should be given when the fibrinogen level is less than 100 mg/dL (2.9 μmol/L) or possibly when time or the intravascular volume does not allow transfusion of FFP. Platelets should be transfused to patients who are bleeding from nonsurgical causes and have a platelet count of 50×10^9/L or less. Clinical circumstances may also require transfusion of platelets at a higher threshold.

Adjuncts in Hemostasis

Several adjuncts may be used with the aim of improving hemostasis. Recombinant activated factor VII (VIIa) has been used to control bleeding in patients with hemophilia types A and B. Recombinant factor VIIa also generates thrombin at the site of vessel injury and induces coagulation.[100] It has been used in the treatment of patients with hemorrhage from blunt trauma, thrombocytopenia, warfarin overdose, obstetric bleeding, and intracranial bleeding.[100,101] It is no longer recommended for off-label use in patients without hemophilia because of increased thromboembolic arterial events and lack of mortality benefit.[102]

Antifibrinolytic agents such as tranexamic acid and aminocaproic acid have been successfully used to treat postoperative hemorrhage.[103] These synthetic lysine analogues inhibit plasminogen and plasmin-mediated fibrinolysis.[92] Similarly, serine proteases such as aprotinin—which neutralize trypsin, plasmin, and kallikrein—have been used when fibrinolysis contributes to bleeding.[104] These agents have been shown to decrease transfusion of blood products in cardiac, hepatic, and orthopedic surgery.[104] Aprotinin has also been used prophylactically in coronary artery bypass surgery, but there has been concern because of an increased incidence of renal failure and increased risk for MI in these patients; this led to its temporary removal from the market.[100] Finally, DDAVP, a synthetic vasopressin analogue that stimulates endothelial release of factor VIII and von Willebrand factor, has been used to enhance platelet aggregation.[105] It is used mainly in patients with hemophilia and those with both congenital and acquired platelet disorders, but its value in surgical hemostasis is unproven. Thus its use in postoperative patients who do not have bleeding disorders is not recommended.[100]

Complications of Massive Transfusion

The definition of massive transfusion is replacement of 50% of a patient's blood volume in 3 hours or one blood volume in 24 hours.[106] The major complication of massive transfusion is the development of coagulopathy from multiple causes, including hemodilution, hypothermia, acidosis secondary to tissue hypoxia, and DIC.[106] Hemodynamically unstable patients are initially resuscitated with crystalloids, which are acellular and dilute the blood components, thereby aggravating the coagulopathy. Hypothermia associated with the infusion of large volumes of cold solution also inhibits the enzymatic coagulation cascade, synthesis of coagulation factors, and platelet function.[107] Administration of large volumes of fractionated blood products also causes coagulopathy by complex mechanisms, some known and some unknown: dilution of coagulation factors (particularly factors V and VIII:C, which have a limited shelf life), hypocalcemia because of the citrate used as an anticoagulant, and platelet dysfunction as a result of aging and metabolic alterations caused by storage.[91] Furthermore, when RBCs are stored, their extracellular potassium levels increase over time, so patients receiving large volumes of RBCs are at risk for hyperkalemia.

One of the most common sequelae of massive transfusion is acute lung injury secondary to congestion caused by overload, alveolar inflammation, and increased permeability.[108] Passive transfer of leukocyte antibodies in donated blood resulting in immune-mediated transfusion-associated lung injury can also occur.[109] Finally, massive transfusion has been described as an immunosuppressant leading to sepsis and sepsis-induced lung injury.[108] (See Chapter 33 for further discussion of transfusion-associated lung injury.)

RENAL FAILURE

A detailed discussion of renal failure can be found in Chapter 44. Therefore this discussion focuses on issues related primarily to the care of patients with postoperative renal failure. Briefly, patients with preoperative renal insufficiency are at the highest risk for postoperative renal failure. After vascular surgery, the major cause of postoperative renal failure is perioperative hypotension and ischemic injury leading to acute tubular necrosis.[47] Unfortunately postoperative renal failure is a marker for increased mortality, with rates of 60% to 80% after major

vascular surgery.[47] Physiologically patients are found to have oliguria or anuria and rising creatinine concentration despite volume resuscitation.

Few strategies have proven effective in reducing the incidence of this complication in the postoperative period. Diuretics may improve diuresis but they have no demonstrated effect on the prevention of renal failure. Low-dose dopamine has also been used, but without a reduction in morbidity or mortality.[110] In small studies, the use of fenoldopam (a renal vasodilator with natriuretic effect) given intraoperatively and postoperatively has been associated with some beneficial effect in patients with preexisting renal insufficiency.[111,112]

Early management of postoperative renal dysfunction should focus on reperfusion of the kidneys, which is most often achieved by fluid resuscitation. Forced diuresis has also been used in addition to fluid loading, but diuresis can be detrimental because it increases oxygen demand in the kidney and exacerbates ischemic injury.[113] Loop diuretics are the drugs of choice when forced diuresis is used because they offer the theoretical benefit of decreased oxygen consumption by the kidney by inhibiting adenosine triphosphatase in the medullary thick ascending limb.[114] In patients with renal dysfunction, doses of many drugs used in intensive care (particularly antibiotics excreted through the kidneys) should be adjusted according to creatinine clearance.

GENERAL ISSUES

Gastrointestinal Ischemia

Postoperative gastrointestinal ischemia is a rare but potentially lethal postoperative complication. Colonic ischemia occurs in 2% of patients after elective AAA repair and carries an overall mortality of 40% to 60% if it is transmural.[115] The incidence of ischemic colitis in patients undergoing repair of a ruptured AAA is reported to be 15% to 65%.[116] A high index of suspicion for colonic ischemia is necessary after aortic repair in patients with persistent acidosis and shock with no other obvious cause, greater than expected fluid requirements, new onset of gastrointestinal bleeding, or simply bloody bowel movements. Laboratory investigations often demonstrate anion gap acidosis and leukocytosis. In advanced cases, a plain abdominal radiograph may demonstrate free air in the peritoneal cavity or in the portal venous system. Abdominal computed tomography may demonstrate evidence of pneumatosis intestinalis. Bedside flexible sigmoidoscopy or colonoscopy can be diagnostic of colon ischemia. Stable patients with colonoscopic results suggesting ischemia limited to the mucosa may be treated conservatively with hydration and broad-spectrum intravenous antibiotics. However, immediate exploration is warranted in such patients if the condition worsens or hemodynamic instability ensues. Unstable patients with evidence of bowel ischemia should undergo urgent surgical exploration to reduce mortality. In selected cases of colon ischemia that has not progressed to gangrene, reimplantation of the inferior mesenteric artery can be considered. In the setting of frank gangrene, the colon should be resected and a colostomy created.

Nutrition

The nutritional state of critically ill patients has a direct effect on outcome. This is due to the catabolic stress that critical illness creates. Malnutrition in this patient population is associated with increased morbidity and mortality as well as increased length of stay in the hospital. In the general medical and surgical ICU population, it has been shown that commencing enteral nutrition within 24 to 48 hours of ICU admission is associated with improved outcomes.[117] It has been associated with reduced infections, increased protection against stress ulceration as well as intestinal ischemia, maintenance of gut flora, decreased catabolism, and decreased mortality.[118] Nutritional support in the ICU has had the goals of maintaining lean body mass to preserve immune function and avert metabolic complications.[119] This includes delivery of both micronutrients and macronutrients and meticulous glycemic control.[119] Early enteral nutrition has been shown to be safe in patients admitted to the ICU after major abdominal surgery.[120]

Several studies have also shown that patients undergoing major vascular surgery have a significant incidence of preoperative and postoperative malnutrition.[121] Patients undergoing surgery for AAAs have higher nutritional depletion and increased rates of postoperative infection compared with those having carotid or peripheral vascular surgery.[122] Interestingly, after AAA surgery, it has also been demonstrated that small bowel function returns to normal by 18 hours and starting enteral nutrition within 3 hours of surgery can promote activity in the small intestine, that fasting would not. This suggests that enteral nutrition may in fact aid the return of normal bowel function.[123] As suggested by others, it is our practice to initiate oral or enteral feeding within the first 48 hours after AAA surgery even in the absence of traditional clinical markers for readiness to feed (presence of bowel sounds, flatus, bowel movement, or volume of gastric aspirate).[124] Most ICUs use enteral nutrition protocols and guidelines for critically ill patients for this reason.[118] Although there are few studies of the applicability of these protocols specifically to vascular patients, both our vascular surgeons and intensivists think that these guidelines are safe and beneficial in this patient population.[125]

There are several newly updated North American and European guidelines available to help guide the assessment of nutrition and support therapy in critically ill adult patients.[118,119] These patients represent a heterogeneous population, and their nutritional needs should be individualized. These guidelines are intended for patients who are expected to require more than 2 or 3 days of ICU care and who have had significant metabolic or surgical stress. They are not intended for those patients who require only temporary monitoring or who have had minimal surgical stress. Some of the general highlights of the guidelines are reviewed here.

Nutrition in the ICU can be subdivided between dosing and route of administration. Several predictive equations exist that are used to estimate calorie requirements for patients in the ICU. However, these predictive equations are often less accurate than indirect calorimetry. These predictive equations are also more problematic in making accurate assessments of

nutritional goals for obese patients. Once goal calories are determined, patients should be given 50% to 65% of goal calories in their first week of ICU admission, thereafter increasing to goal rate. In obese patients (body mass index >30) with critical illness, permissive underfeeding or hypocaloric feeding with enteral nutrition is recommended. The target in obese patients should remain at 60% to 70% of ideal weight.

The two main routes of administering nutrition in critically ill patients are the enteral route and the parenteral route. As a general rule, the enteral route has the most benefit for the patient. In patients who are unable to eat, enteral nutrition is preferred to parenteral. As mentioned before, feeding should be started within the first 24 to 48 hours of admission to the ICU and advanced toward goal during the next 48 to 72 hours. Enteral feeding can be started through either a gastric tube or small bowel tube in the absence of traditional markers of bowel function (bowel sounds, flatus, or passage of stool). Patients are often challenged with trickle feeding at 10 mL/h to ensure tolerance before increasing rapidly toward goal.

It is recommended that either parenteral or enteral nutrition be provided to critically ill patients who are unable to voluntarily maintain their nutritional needs. In general, enteral feeding is preferred to parenteral feeding because of its superior nutritional efficacy and better safety profile. Enteral feeding through a nasogastric tube or small bowel feeding tube should be started within the first 24 to 48 hours after admission to the ICU and continued until adequate oral intake is firmly established. Placement of a feeding tube in the proximal small bowel should be considered in patients with inadequate gastric emptying as evidenced by residual gastric volumes in excess of 500 mL. If early enteral feeding is not feasible, parenteral nutrition should be considered if the anticipated duration of nutritional support will exceed 7 days. Shorter periods of parenteral nutrition (e.g., <5 to 7 days) expose the patient to a variety of vascular access, metabolic, and infectious risks without proven benefit. Even in patients stabilized on parenteral nutrition, periodic efforts should be made to start enteral feeding. Parenteral nutrition should not be stopped until enteral nutrition is providing at least 60% of target requirements. Recommended nutrition doses based on guidelines are up to 20 to 25 kcal/kg actual body weight per day in the acute phase of critical illness (72-96 hours) and 25 to 30 kcal/kg body weight per day in the recovery phase.[118]

Pain Management

Effective postoperative analgesia is important and may be associated with a reduction in the incidence of myocardial ischemia after surgery.[63] This reduction in incidence of MI does not appear to be related to changes in heart rate, blood pressure, or requirement for postoperative vasoactive agents compared with patients with inadequate pain control.[63] In nonintubated patients who are able, patient-controlled analgesia is preferred to intermittent on-demand narcotic dosing because patients can be in a significant amount of pain while waiting for the next narcotic dose. Epidural analgesia can also be effective in the postoperative period, and it offers the potential benefit of reducing the dose of opiates, which improves gastric emptying and ileus and increases patient mobility.[126] Patients who are mobilized earlier can benefit from reduced thrombotic events and pulmonary complications. However, care must be taken to prevent significant hypotension, which can be caused by the administration of epidural anesthesia. The balance between analgesia and sedation is discussed in the earlier section on sedation and delirium in the ICU.

Deep Venous Thrombosis Prophylaxis

The etiology, treatment, and prophylaxis of deep venous thrombosis (DVT) are reviewed in depth in Chapter 147. Thus only issues relevant to the prophylaxis and treatment of DVT after vascular surgical procedures are discussed here. Because most vascular surgery involves the intraoperative administration of heparin, it has been suggested that these patients do not carry the same postoperative risk for DVT as other surgical patients do. However, the incidence of DVT after aortic surgery has been reported to be between 2% and 18%[127]; therefore, all patients undergoing vascular surgical procedures should receive postoperative DVT prophylaxis.

General measures in postoperative care—such as elevation of the lower extremities, early ambulation, and leg exercises—may reduce the incidence of DVT.[128] Graduated compression stockings, intermittent pneumatic compression, and venous foot pumps have also been shown to decrease the incidence of DVT, but they have not been proved to prevent fatal pulmonary embolism when used as monotherapy.[128] It is also generally accepted that aspirin is not effective in the prevention of DVT.[129] In contrast, treatment with either low doses of subcutaneous unfractionated heparin (5000 units subcutaneously two or three times per day) or subcutaneous low-molecular-weight heparin at prophylactic doses is effective and safe in the prevention of postoperative DVT.[128] The potential benefit of prophylaxis with low-molecular-weight heparin is a reduced rate of heparin-induced thrombocytopenia. Prophylaxis is generally given until patients become ambulatory and mobile. This topic is extensively reviewed in Chapter 147.

Bridging Postoperative Oral Anticoagulation

Patients taking oral anticoagulants in the preoperative period require specific considerations. The most common strategy is to interrupt the oral anticoagulation and use either subcutaneous low-molecular-weight heparin or intravenous unfractionated heparin.[130]

The American College of Chest Physicians has published guidelines with regard to patient risk for thromboembolic events.[131] Patients are categorized as being at low, moderate, or high risk. Bridging with full-dose anticoagulation is recommended only for patients at high risk. Such patients include those with mechanical mitral valves or old-model mechanical aortic valves. However, in patients at low risk for stroke and thromboembolism, such as those with atrial fibrillation (AF) and no other risk factors for stroke such as rheumatic valve disease, bridging may be unnecessary and potentially harmful.[132]

In these patients, oral anticoagulation can be stopped several days before the procedure and restarted several days after it. Although limited data regarding benefit are available, a prophylactic dose heparin may be used for such patients.

In patients taking oral anticoagulants who are at high risk for perioperative stroke, such as those with mechanical mitral valves or old-model mechanical aortic valves, oral anticoagulants should be stopped 4 days before and heparin started 2 days before surgery, when the oral agent is assumed to become subtherapeutic.[130] In the absence of postoperative bleeding, bridging doses of heparin can be restarted 12 to 24 hours after the surgical procedure. If unfractionated heparin is used, it should be restarted without a bolus dose. However, the risk of bleeding caused by restarting anticoagulation after major vascular surgery must be carefully considered. If anticoagulation is delayed because the risk of bleeding is deemed too high, prophylactic doses of heparin may be given.[130] After minor surgical procedures, oral anticoagulation can be restarted on the evening after surgery. In any case, clinicians must decide on a strategy that balances stroke risk with bleeding risk in each individual.

Alcohol Withdrawal Syndrome

Alcohol is the most abused drug worldwide.[133] Autonomic hyperactivity—including tremulousness, sweating, nausea, vomiting, anxiety, and agitation—appears within the first 24 to 48 hours after withdrawal in patients who abuse alcohol.[133] Symptoms can peak between the third and fifth postoperative days. Serious complications that may develop are delirium tremens and grand mal epileptiform seizures. Delirium tremens, which occurs in less than 5% of patients abusing alcohol, is associated with an increase in postoperative mortality[134] and characterized by fever, tachycardia, hypertension, tremors, diaphoresis, hallucinations, disorientation, agitation, and urinary incontinence. Physicians must exclude other life-threatening causes of confusion, such as myocardial ischemia, congestive heart failure, hypotension, pulmonary embolism, bleeding, stroke, metabolic and electrolyte disorders, and sepsis. Before sedation is initiated for presumed alcohol withdrawal, hypoxia must be ruled out, because hypoxia is the most common cause of confusion and agitation in the postoperative period.

Patients can be identified preoperatively to be at risk by the quantity and frequency of their alcohol consumption. Preoperative detoxification or abstinence before elective surgery may prevent adverse postoperative complications, but data in this regard are lacking. Patients known to be at risk should be administered prophylactic doses of benzodiazepines throughout the entire perioperative period to prevent the development of alcohol withdrawal syndrome.[134] Patients who regularly consume alcohol at dependency levels (determined by how alcohol consumption affects relationships, jobs, educational goals, and family life and not by the specific quantity consumed) have been shown to have increased postoperative morbidity and mortality.[135]

The first-line treatment for patients with alcohol withdrawal syndrome is benzodiazepines.[136] They mimic the central nervous system effects of alcohol on γ-aminobutyric acid receptors and suppress the withdrawal response.[137] Alcohol replacement therapy with oral or intravenous alcohol is still used but is controversial and has not been shown to be superior to benzodiazepine treatment.[138] Treatment of severe acute alcohol withdrawal may require intubation and admission to the ICU. Beta blockers may also be used to reduce sympathetic overactivity and cardiac complications. Seizures should be treated with intravenous benzodiazepines. All patients should also be given daily thiamine and multivitamins to prevent Wernicke-Korsakoff syndrome.

Sedation and Delirium in the Intensive Care Unit

Emphasis on sedation and analgesia in critically ill patients has recently come to the forefront of patient care in the ICU. The primary goal is to achieve adequate pain control and anxiolysis with appropriate sedation and analgesia. Unfortunately, in critically ill patients on mechanical ventilation, this is very challenging and can lead to oversedation, delirium, and harm to the patient.[139] It is very important to titrate the medications used for analgesia and sedation in a goal-directed manner so as to safely provide comfort without impeding recovery, affecting weaning from the ventilator, and prolonging length of stay. Several sedation monitoring systems have been developed in the ICU, such as the Sedation Agitation Scale, the Motor Activity Assessment Scale, and the Richmond Agitation-Sedation Scale (RASS).[139] A multidisciplinary team at Virginia Commonwealth University in Richmond has developed the RASS; it is a validated method used to avoid oversedation in the ICU. It is unique in that it separates verbal from physical stimulation in generating the score, thereby assessing the patient's arousal with varying potency of stimulus.[140] The RASS assesses consciousness by the use of a 10-point scale from −5 to +4 (−5, unarousable, to 0, alert and calm, to +4, combative), with three defined steps that incorporate the duration of eye contact to determine arousal and content of thought.[141] The entire assessment takes approximately 20 seconds.[139] The first step is simply to observe the patient; if he or she is alert, restless, or agitated, a score of 0 to +4 is given accordingly. If such a patient is not spontaneously alert, he or she is asked to look at the rater, with duration of eye contact rated (more or less than 10 seconds) and scored from −1 to −3 accordingly. If the patient does not respond to verbal stimulation, a physical stimulus is given and a score of −4 or −5 assigned accordingly.[141] However, if the patient is calm but not alert before verbal and physical stimulation, a score from −1 to −5 is given even if he or she becomes agitated on stimulation.

Ely et al.[139] compared the RASS with the Glasgow Coma Scale, which is a trauma-specific consciousness assessment tool; they demonstrated excellent correlation and discrimination between the scores in assessing levels of consciousness. They also compared RASS with cumulative lorazepam, propofol, fentanyl, and morphine doses of the prior 8-hour and 24-hour periods before RASS assessment. Interestingly, they found significantly different correlations with RASS between opiates (analgesics) and benzodiazepines (sedatives), with a higher likelihood of reintubation with deeper sedation measured by RASS. There

was further agreement in this study that RASS provided a consensus target for goal-directed sedation and improved team communication regarding sedation management.

Consciousness is considered a combination of level of arousal plus the content of that consciousness, such as delirium.[142] Unaddressed pain and anxiety in critically ill patients has been shown to lead to increased morbidity and mortality as well as posttraumatic stress disorder over the long term.[143] RASS is used to assess the level of arousal, but another key to patient outcome is delirium, a key feature of which is the presence or absence of inattention. Because the RASS incorporates eye contact as part of its assessment, it also correlates with the onset of inattention and delirium. The Confusion Assessment Method for the Intensive Care Unit (CAM-ICU) is a delirium-monitoring tool that complements the RASS and is used to assess acute brain dysfunction.[144] Whereas RASS measures the level of consciousness, CAM-ICU determines the content of that consciousness and the presence or absence of delirium. Delirium is a common but underdiagnosed form of organ dysfunction in the ICU. It was once thought to be a normal part of the process as patients arose from coma to consciousness, but it also occurs in the absence of this process or preexisting coma. Critically ill patients at risk for the development of delirium are those with preexisting cognitive impairment, advanced age, use of psychoactive drugs, mechanical ventilation, untreated pain, and sleep deprivation.[144]

Three subtypes of delirium are described: hyperactive, hypoactive, and mixed. Hyperactive delirium is represented by the patient who is agitated and attempting to pull out lines and tubes; patients with hypoactive delirium typically are characterized by a flat or withdrawn affect; and those who fluctuate between the two have mixed delirium. ICU physicians have concentrated on treating multiorgan dysfunction, often dismissing delirium as an unavoidable, often iatrogenic consequence of critical illness with little long-standing ill effect. However, the development of delirium has been shown to be an independent predictor of higher 6-month mortality and longer hospital stay in mechanically ventilated patients.[145] In this study, the investigators demonstrated that the development of delirium and the number of days spent in a delirious state were associated with a threefold increase in mortality in mechanically ventilated patients compared with those who did not develop delirium. Current guidelines suggest, in fact, that critically ill patients should be monitored daily for delirium.[146]

The assessment for delirium combines the RASS score with inattention and either disorganized thinking or an altered level of consciousness.[144] If patients respond to verbal stimulation (RASS score of −3 to +4) and have a positive CAM-ICU assessment, they are found to be delirious. Monitoring delirium with the CAM-ICU daily takes approximately 1 to 2 minutes, and nurses can easily be trained to perform it along with their routine assessments.[145] One important aspect in daily assessment for delirium is identifying patients with the hypoactive delirium subtype. As mentioned before, this subtype is characterized by a flat affect present in a calm, seemingly alert patient.[147] These patients have normal or nearly normal arousal compared with the agitated patients with delirium, which is likely why they are underdiagnosed and may have a worse outcome. Outcomes can be improved by reducing the unnecessary use of sedatives and analgesics.

Treatment of delirium can be divided between the use of nonpharmacologic and pharmacologic agents. Nonpharmacologic methods concentrate on minimizing risk factors with repeated reorientation of patients, early mobilization and activity, nonpharmacologic sleep protocol, and timely removal of catheters and lines; unnecessary noise and stimuli are minimized, and patients are given their normal aids, such as glasses and hearing aids. Pharmacologic strategies first involve the reduction or removal of unnecessary sedatives and analgesics. Many drugs, such as benzodiazepines, used to treat confusion often exacerbate it; lorazepam is a well-recognized offender. Pharmacologic agents with a procognitive advantage, such as haloperidol, have also been recommended for the treatment of delirium, although this is based on sparse data in the ICU population.[146] Other antipsychotic and neuroleptic agents—such as risperidone, quetiapine, and olanzapine—are often used in both hyperactive and hypoactive delirium, but patients receiving these agents must be closely monitored for adverse cardiac and extrapyramidal events. An important resource for physicians is available at www.icudelirium.org. Fig. 34.3 gives an overall approach to balancing both pharmacologic and nonpharmacologic approaches in critically ill patients. It attempts to improve patient outcomes

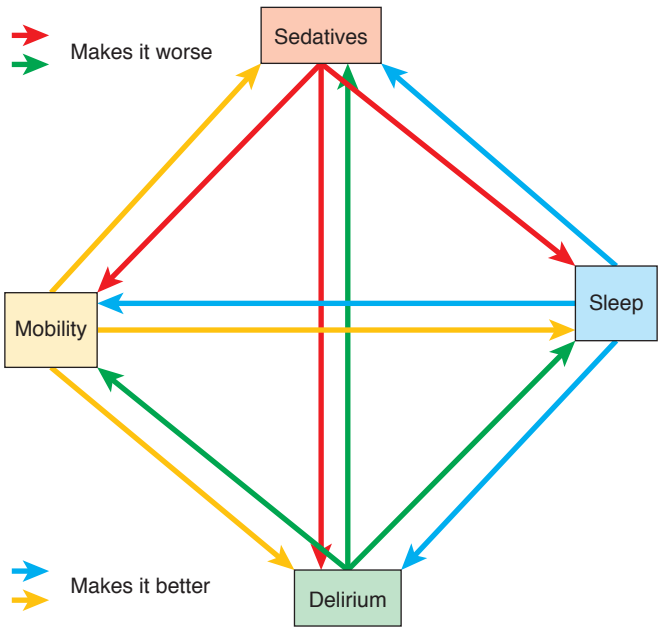

Figure 34.3 Sedation, Mobility, Sleep, Delirium Harm-Reduction Model. This diagram demonstrates the interrelationship between unrecognized delirium, oversedation, immobility, and lack of sleep. The red and green denote pathways that make this problem worse, whereas the blue and yellow pathways make this problem better. For example, the overuse of sedation decreases the likelihood of mobility, increases delirium risk, and decreases restorative sleep. Alternatively, mobilizing patients can make apparent a decreased need for sedation, improve sleep, and help to clear delirium. (From Clemmer T. *Rethinking critical care: reducing patient harm from sedation, immobility, and delirium*. 2001; Institute for Healthcare Improvement.)

by addressing oversedation, immobilization, and delirium simultaneously in high-risk critically ill patients.

Outside the ICU, postoperative delirium requires a hypoxic, metabolic, and septic workup. Medications and medication interactions must be ruled out. Older patients, such as vascular patients, suffer from multisensory deprivation, which makes them particularly vulnerable to extreme confusion at night.

INTRODUCTION

The United States spends over $3 trillion annually on healthcare, or over 17% of the nation's Gross Domestic Product (GDP) (Fig. 35.1).[1] This is projected to reach nearly 20% of GDP by 2024.[2] This unsustainable spending has driven a keen interest in cost containment and the concept of increasing value in healthcare.[3] An area that has come under increasing focus in recent years is the issue of unplanned readmission. Readmission is a common occurrence that results in increased costs both to the patients and to the healthcare system as a whole. It has been estimated that potentially preventable readmissions cost Medicare approximately $12 billion annually.[4] Under the assumption that at least a fraction of these readmissions are related to breakdown in care and poor transition from the inpatient to the outpatient setting, readmissions have become a marker of quality of care, and reducing readmissions has become a focus of healthcare reform and the Affordable Care Act (ACA).[5] This focus on readmissions, specifically 30-day readmissions, as well as the financial penalties that are now tagged to this metric, have driven physicians, hospitals, and healthcare organizations to devote substantial time and effort to minimizing readmission. While on its face avoiding expensive hospitalizations is a good thing, emphasizing 30-day readmission as a primary quality metric—and tagging to it what can be steep financial penalties for hospitals—obscures what could be a holistic view to patient care and moves focus from clinical outcomes to what many have deemed a somewhat arbitrary measure.

Particularly for surgeons, how to best quantify and report quality has been a challenge. As stated by Lord Kelvin, the 19th century mathematical physicist who calculated the point of absolute zero on the thermodynamic temperature scale, "when you cannot measure it, when you cannot express it in numbers, your knowledge is of a meagre and unsatisfactory kind."[6]

HISTORY

The Centers for Medicare and Medicaid Services (CMS) uses a diagnosis-related group (DRG) payment scheme for hospital reimbursement. DRGs were introduced by CMS in 1983 as an alternative to the initial payment model for CMS, which had no incentive to control cost.[7] The DRG system has been revised multiple times and, in its current incarnation, attempts to capture patient illness severity, comorbidities, risk of mortality, interventions, and likely resource use.[8] Payments are calculated by multiplying the fees by the DRG code plus modifiers for hospital factors, including teaching institutions, low-volume

Abstract

Thirty-day readmissions after vascular surgery is a blunt metric for capturing quality in patients with complex medical comorbidities. Avoiding this penalty may lead to unintended practices. Better quality metrics may lead to more meaningful incentives and outcomes.

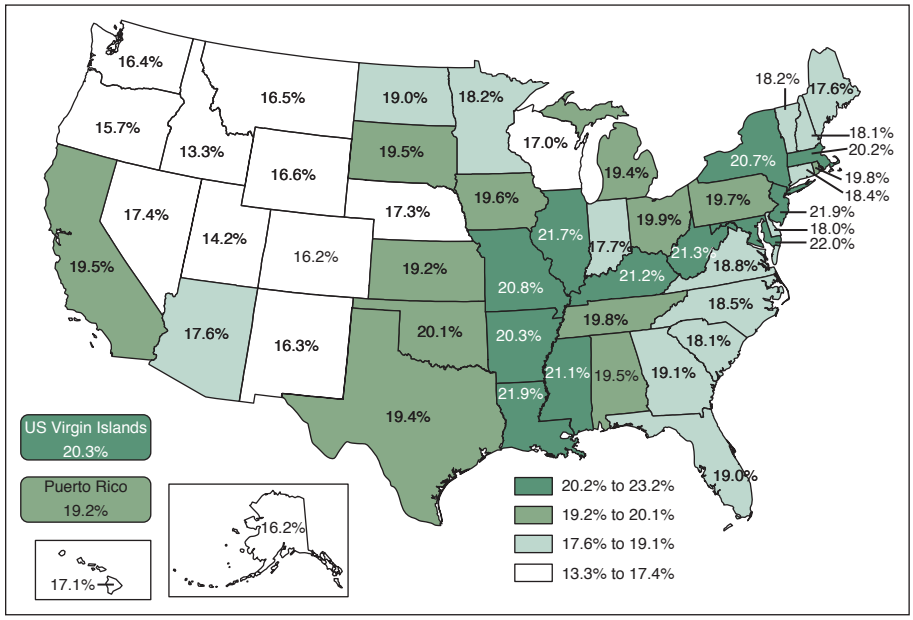

Figure 35.2 Rates of re-hospitalization within 30 days after hospital discharge. The rates include all patients in fee-for-service Medicare programs who were discharged between October 1, 2003, and September 30, 2004. The rate for Washington, DC, which does not appear on the map, was 23.2%. (From Jencks SF, Williams MV, Coleman EA. Rehospitalizations among patients in the Medicare fee-for-service program. *N Engl J Med*. 2009; 360(14):1418-1428.)

hospitals, transfers, and outliers. While unlike direct billing, DRGs attempt to control costs by limiting payments to adjusted but set amounts, and they continue to incentivize hospitals to operate at or near capacity in order to bill for patients treated. In addition to the many changes that came with the ACA, a focus of cost control was also implemented, and one aspect of that was a focus on 30-day readmissions under the Hospital Readmissions Reduction Program (HRRP).[9] To capture this, CMS calculated anticipated readmission rates based on performance over the prior 3 years and then instituted penalties for institutions that were above that calculated benchmark. The readmission period is defined as 30 days from discharge rather than from procedure date, an important nuance particularly in surgical specialties, and captures readmission to any part of the hospital, to either surgical or nonsurgical specialties. In 2012, readmission measures began with acute myocardial infarction (AMI), heart failure (HF), and pneumonia. Also pertinent to surgeons, in 2014 CMS began to adjust for planned readmissions. Beginning in 2015, chronic obstructive pulmonary disease (COPD) became a tracked condition, as well as elective total hip arthroplasty (THA) and total knee arthroplasty (TKA). Coronary artery bypass graft (CABG) was added in 2017. Once expected risk-adjusted readmissions are calculated, the excess readmission ratio is calculated, and reimbursement for each targeted DRG is then discounted by that ratio to a maximum penalty of now 3% of the hospital's annual DRG payments.[9]

READMISSION IN VASCULAR PATIENTS

Work by Jencks et al.[4] provides much of the basis of our current understanding of the issue of 30-day readmissions (Fig. 35.2). While the average estimated readmission rate for Medicare patients for all-comers is as high as 18% of patients, readmission rates vary by geographic area and by specialty, with an average 11.1% of surgical patients readmitted within

30 days of discharge.[4] Within surgical specialties, readmission rates also vary. In a recent study within the VA population, 16% of vascular patients were readmitted within 30 days of discharge compared to only 9.6% of orthopedic patients.[10] Indeed, unplanned readmission rates for vascular surgery patients are high, and range from 9.3%[11] to 24%[4] (Table 35.1). Surgery for peripheral vascular disease had the third highest rate of 30-day readmission behind only congestive HF and psychosis.[4] Ninety-day readmission rates climb significantly higher, to an average 17.9% for vascular patients tracked in the American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP).[12] This can be as high as 48% following outpatient upper extremity hemodialysis access creation.[13] Readmissions were often associated with surgical site infections, treated deep vein thrombosis (DVT), cerebrovascular or cardiovascular events, and increased direct hospital costs 61% over the index hospitalization.[12]

TABLE 35.1 Readmission Rates for Vascular Procedures by Procedure Type

Procedure	30-Day Unplanned Readmission Rates	References
Carotid endarterectomy	6.5%-9.6%	48,49
Endovascular aortic repair	7.6%-13.3%	26,48
Open AAA repair	8%-12.8%	26,48
Open aortoiliac bypass	12.3%	50
Endovascular infrainguinal procedures	13.1%	50
Infrainguinal bypass graft	15.7%-30%	48,51-53
AV fistula	26%	13

AAA, Abdominal aortic aneurysm; *AV*, arteriovenous.

A number of factors have been identified that increase 30-day unplanned readmissions in the vascular population. Estimates of 30-day unplanned readmission following carotid endarterectomy were approximately 6.5%, with cardiac issues being the most frequent reason for readmission (followed by headache, bleeding complications, and stroke). Medical complications other than cardiac, both possibly related to the surgery or unrelated, were also among the most frequent reasons for unplanned readmission following carotid endarterectomy (CEA) (Fig. 35.3).[14]

Capturing this information is further complicated by the fact that patients are often readmitted to hospitals that did not perform their index procedure. Using a statewide database, following complex thoracic and thoracoabdominal aortic aneurysm repair, 79% of readmitted patients were readmitted to a hospital different from that at which their index procedure occurred.[15] Readmissions at the index hospital were more likely to be related to their aneurysm repair, as opposed to readmission to other hospitals, which were more likely to be related to medical morbidities.[15] Costs associated with readmissions were lower at nonindex hospitals, although this was possibly related to the increased likelihood of these readmissions being for medical complications. Indeed, in a single institution study, Orr et al.[16] found that readmissions potentially requiring repeat intervention, including endoleaks and graft occlusion, were associated with significantly higher median costs than complications that could potentially be managed nonoperatively including surgical site infections, which, while more common, had a median cost of only $4500 rather than $23,000 for endoleaks and $17,700 for graft occlusion. Interestingly, no difference has been seen between readmissions for open compared to endovascular procedures on average. In a single institution trial, among 605 open procedures and 421 endovascular procedures there was no significant difference between the two groups in terms of index hospitalization institutional cost ($27,653 vs. $23,999),

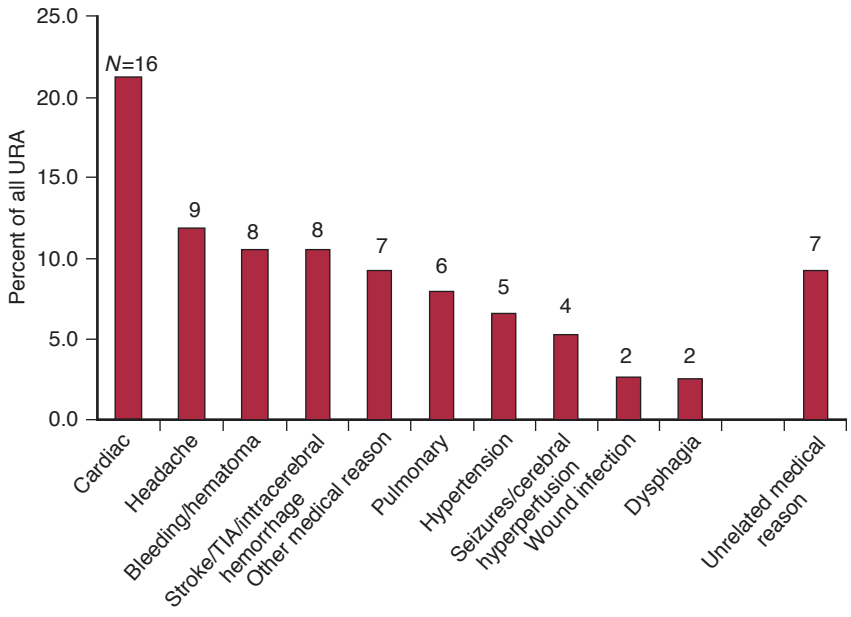

Figure 35.3 Reason for 30-day readmission following carotid endarterectomy (CEA). Frequency of reasons for unplanned readmission (URA) after CEA. *TIA*, Transient ischemic attack. (From Ho KJ, Madenci AL, Semel ME, et al. Predictors and consequences of unplanned hospital readmission within 30 days of carotid endarterectomy. *J Vasc Surg*. 2014;60(1):77-84.)

unplanned readmission rates (16.9% vs. 17.8%), or cost of readmission ($19,117 vs. $17,887).[17]

Risk Factors for Readmission

Primary preoperative predictors of readmission include American Society of Anesthesiologists (ASA) operative class, preoperative open wound, inpatient operation, dialysis dependence, and a history of diabetes mellitus. However, as with many surgical patients, the strongest predictors of readmission remain postoperative factors, meaning that they cannot be used to improve patient selection prior to the operating room.[11,18,19] Among vascular patients, postoperative complications are the most significant predictor of readmission and the complications with this best predictive ability were postdischarge deep space infection, superficial surgical site infections, pneumonia, myocardial infarction (MI), and sepsis.[18] Given that these complications often require hospitalization for management, it is not surprising that they predicted readmission.

INTERVENTIONS TO DECREASE READMISSIONS IN VASCULAR SURGERY

Brooke et al.[20] reported a framework to address the issue of readmissions in vascular surgery across various phases of care from patient selection to postprocedure follow-up, and point out the various opportunities for complications in patient care as well as research at each phase (Fig. 35.4).

Within patient selection, multiple patient level factors exist that have been associated with increased risk of readmission, including diabetes and advanced age. Preoperative health optimization programs are becoming increasingly popular and focus on increased activity, smoking cessation, weight loss, and sleep training among other factors.[21]

At the provider level, while the decreased rates of death and stroke following carotid endarterectomy is a classic example of the impact of surgeon volume on patient outcomes, the link between surgeon volume and readmission remains tenuous.[22] Among pancreatic surgeons, there does appear to be a link between the increasing volume of procedures performed and the decreased rates of readmission, ranging from 23% for low volume surgeons to 12% for those with higher operative volumes.[23] However, the vast majority of variation in readmission appears to be due to patient-related factors, with surgeon-level factors explaining only approximately 3% of variability.[24] At the hospital level, following surgical procedures, higher volume institutions do appear to have lower rates of readmissions: 16.8% for lower volume hospitals compared to 12.7% for higher volume hospitals.[5]

Patient discharge is also a transition point that influences the rates of readmission. Within the state of Maryland, in a study of hospital discharges across multiple services including surgical subspecialties, discharge summaries that were greater than 3 days delayed in completion were associated with an increased risk of readmission and each additional 3-day delay in discharge summary completion was associated with an increase in the adjusted odds of readmission of 1%.[25]

Postoperative care also has a predictably significant impact on readmission rates. Among individuals undergoing open and endovascular abdominal aortic aneurysm (AAA) repairs, the odds of readmission more than doubled for those individuals with a postoperative wound infection and were significantly higher if patients required discharge to a skilled nursing facility rather than their own home.[26] What is perhaps most disconcerting was that readmission was also associated with a significant increase in 1 year mortality rates, going from 4.5% to 23.4%.[26]

There has been concern that a move toward enhanced recovery pathways and earlier discharge may drive increases in readmission rates. However, in both cases, this has not been seen.[27,28] In fact, it appears that standardizing care likely leads to better coordination and fewer deviations from care pathways and that stronger adherence to pathways are associated with better outcomes and decreased readmissions.[29]

LIMITATIONS OF 30-DAY READMISSIONS

Focusing on 30-day readmissions appears to have at least, in part, had a positive impact on readmission rates. While readmission rates decreased across the board between 2012 and 2015, the rates for targeted conditions appeared to decline more than nontargeted conditions.[30] Furthermore, this occurred without a corresponding increase in observation admissions, which is a potential loop-hole to readmission penalties.[30]

Despite this improvement, 30-day readmission remains a proxy measure for larger issues and the impact of readmission reduction programs on quality of care is less clear. Looking at six major procedures, including CABG, pulmonary lobectomy, colectomy, hip replacement, endovascular aneurysm repair (EVAR), and open AAA repair, an association was seen between 30-day readmission rates and other commonly accepted measures that are felt to correlate with a higher quality of surgical care, including higher surgical volume and lower operative mortality.[5] However, adherence to surgical process measures as measured by Hospital Quality Alliance (HQA) score was not significantly associated with better outcomes.[5]

Specific to vascular surgery, an additional weakness of readmission as a quality indicator for hospitals is the fact that there is little year-to-year reliability in the readmission rank for hospitals. Looking at readmissions following open and endovascular AAA repair and lower extremity bypass within Medicare for 63% of hospitals, the change in their year-to-year rank moved across quintiles, with the previous 2 years' readmission rank explaining only 32% of the variation.[31] The magnitude of this variation is much larger than one would expect, based on the quality of the hospital alone and suggests that a substantial degree of year-to-year variability may be random.[31]

Measuring readmissions also has the potential to penalize hospitals when, in reality, it is often community-level factors that influence readmission.[32] Among safety-net hospitals, 30-day

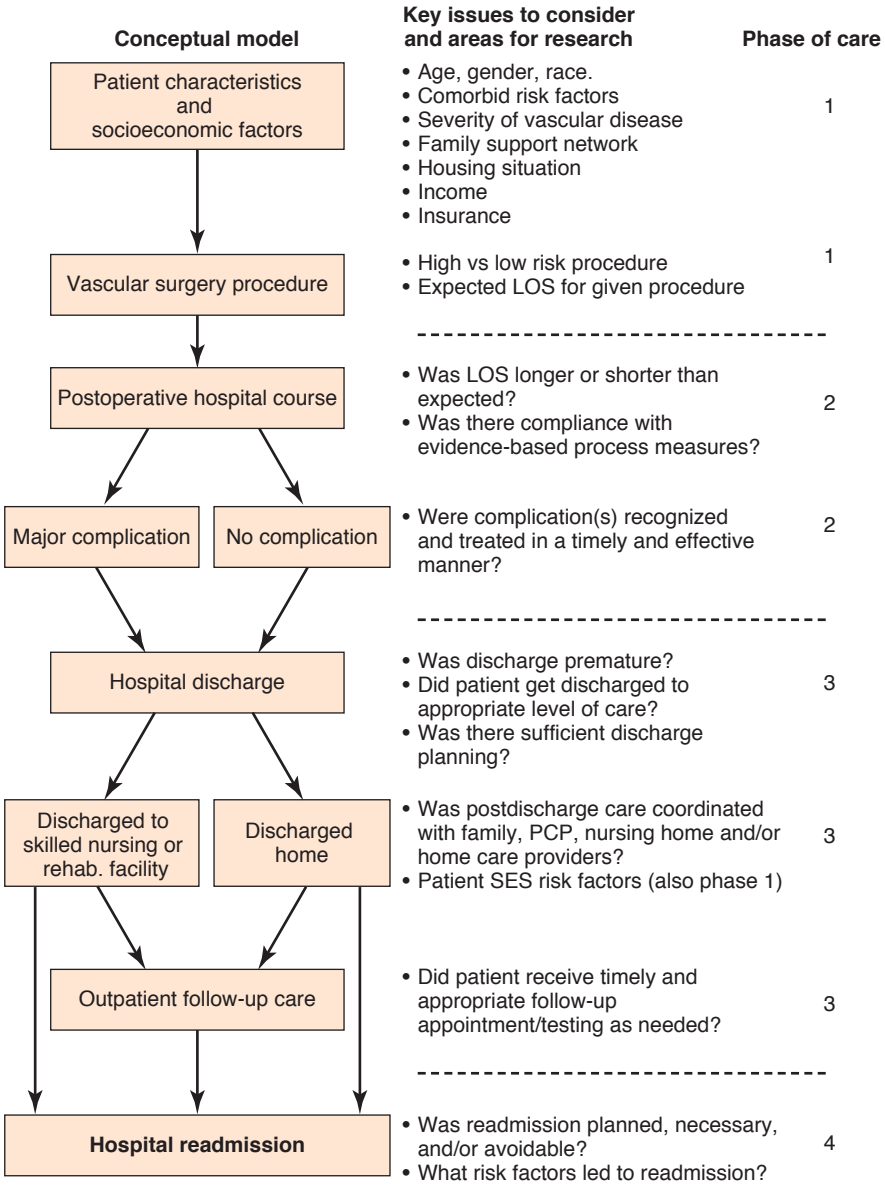

Figure 35.4 Conceptual model of readmission in vascular surgery. Conceptual model of prevental readmission in vascular surgery. There are multiple risk factors and key issues to consider at four separate phases of care for a patient readmitted following a vascular surgery procedure. These represent points where variability in clinical pathways and decision making may be associated with increased risk for readmission, and where future research may be targeted. *LOS*, Length of stay; *PCP*, primary care provider; *SES*, socioeconomic status. (From Brooke BS, De Martino RR, Girotti M, Dimick JB, Goodney PP. Developing strategies for predicting and preventing readmissions in vascular surgery. *J Vasc Surg*. 2012;56(2):556-562.)

readmission following discharge from a general surgical service only appeared to be linked to the index hospitalization in a minority of cases, with the vast majority of the readmissions being related to patient and disposition issues, and only 9.2% of all readmissions being related to the initial injury or condition.[32] In one study, the most frequent reasons for readmission included new soft tissue infections, either related to intravenous drug use (16.8%) or de novo (13.3%), or to disposition support issues (14.5%).[32] Furthermore, the degree to which readmissions are preventable—even those that are related to the index hospitalization or hospital-level factors—has also been raised as a concern. Some estimates report that less than one-third of all readmissions are actually preventable.[33,34]

Safety-net hospitals are also disproportionally burdened by the 30-day readmission penalty given the severity of the disease faced by many of the patients for which they care. While safety-net hospitals have been able to respond to readmission penalties by reducing readmission rates,[35] the CMS has acknowledged this issue with proposed adjustment to penalties based on the socioeconomic demographics of a hospital's patient mix.[35]

An additional concern regarding readmission as a measure of quality is that often factors leading to patient readmission are tied to perioperative complications. If wound complications are captured during the index hospitalization, leading to quality penalties, and then lead to a later readmission, clinicians are potentially being doubly penalized.

This is further complicated by the fact that readmission data vary widely by their source. In analyzing the extent to which readmissions are preventable, the data varied from 59% for reports based on administrative data to only 12% for those studies that relied on clinical data.[33,34] In another study, when based on administrative claims, readmission diagnosis varied from clinical diagnosis 30% of the time and miscategorized a

significant proportion of planned readmissions as unplanned.[36] This raises significant concerns regarding the achievability and appropriateness of lowering 30-day readmissions as a quality metric. Furthermore, where Medicare defines readmission as 30 days from discharge, the ACS-NSQIP starts the 30-day clock on the day of surgery. This creates what has been described as an immortal time bias, in that individuals with prolonged postoperative admissions are not at risk for readmission.[37] This leads to a systematic underreporting of 30-day readmissions when compared to Medicare data, and this is exacerbated by longer hospitalizations.[37]

Both longer and shorter timeframes for readmission penalties have been suggested, with those arguing for a longer duration of surveillance pointing out that 30 days likely fails to capture the entirety of postdischarge complications. Shorter timeframes, often 3 to 7 days, have also been suggested as being more directly linked to factors that hospitals have the potential to control.[34] In hierarchical modeling, the impact of hospital-level quality factors on readmission rate nadirs at 7 days postdischarge.[38] It has also been suggested that clinicians feel more personal responsibility for early readmissions and, therefore, are committed to improving care transitions.[34,39]

Existing Interventions to Reduce 30-Day Postprocedure Readmissions and Alternative Metrics

While the body of literature surrounding the issue of hospital readmissions has grown exponentially, interventions designed to reduce 30-day readmission, particularly following surgical procedures, are lacking, and those that are reported are often quite limited in their generalizability.[40] The vast majority focus on improving transitional care.

Rather than focus on readmissions as a quality metric, some groups have begun to propose alternative means of measuring quality and value in healthcare.[41] Financial incentives, bundled payments, risk sharing, accountable care organizations, and a focus on the concept of value in care have all come to the forefront. Particularly pertinent to procedural care, bundled, or episode-based payments create a single payment for the complete episode of care.[42] Rather than penalizing hospitals for unplanned readmissions, it is thought that bundles create a financial incentive to minimize low value care or expensive complications. Bundles are mandatory for joint replacement within Medicare and Medicaid, and capture the index hospitalization, procedure, plus 90 days following discharge. Voluntary oncology care bundles, as well as four variations of bundled payment models that address 48 different conditions and procedures and attempt to capture both in-hospital and postacute care costs, are also being piloted.[42] In addition to their impact on costs, in early data these bundles appear to be associated with a decreased length of stay and 30-day readmissions.[42]

It is important to note that—as with readmission penalties and other novel reimbursement strategies—safety-net hospitals, which carry a larger burden of patients with more advanced disease, face disproportionate financial losses in the bundling environment. Patients managed at safety-net hospitals for diabetic foot wounds are more likely to require an amputation and more complex disease, meaning that safety-net hospitals would face significantly higher penalties for their care compared to other institutions.[43]

Patient-centered outcomes have also become increasingly prevalent, particularly as patient satisfaction begins to play a greater role in the perception of quality care.[44] Within vascular surgery, while graft patency and amputation-free survival are widely accepted outcomes, patient quality of life, independence, and ambulatory status capture a more nuanced picture of the patient experience, and help to allow patients and providers to speak a similar language around expected outcomes and benefits for procedures.[45]

Multidisciplinary care centered around conditions rather than the current specialty-centric silos that exist within clinical medicine has been proposed as a means of decreasing costs and increasing value to patients and the healthcare system.[3] It has been proposed that this would decrease the duplication of effort that plagues the current system.[3] Many areas of vascular surgery lend themselves well to this approach. Within orthopedic surgery, setting a common goal and mobilizing a multidisciplinary team was associated with increased early mobilization, discharge home, and decreasing costs.[46] A multidisciplinary approach to care for patients with critical limb ischemia was associated with a twofold increase in amputation-free survival.[47]

CONCLUSIONS

The issue of cost containment in healthcare has led to a focus on the issue of unexpected readmissions as a potential area of intervention. While a great deal of work has been done in this area, 30-day readmissions remain an imprecise metric in measuring quality. It is undeniable that unplanned readmissions are costly and can be the result of complications during the index hospitalization, but the degree to which they are a stable measure of quality, or are within the ability of physicians or institutions to improve, seems less clear. A number of alternatives to readmission penalties have been proposed that each attempt to incentivize improved value in care. As the healthcare system continues to evolve, it is likely that readmissions will remain a factor in assessing quality of care. However, as our understanding of this process further develops, the interventions to improve transitions of care will become more prevalent and the quality metrics more refined.

INTRODUCTION

Vascular endothelial cells, blood, and extravascular tissue maintain blood flow fluidity or produce an integrated response to attenuate blood leakage by localized clotting at the site of vascular injury. The processes of blood coagulation and fibrinolysis are the primary defense systems of the vasculature. The opposing forces of fibrin clot formation and dissolution maintain hemostasis and preserve vascular function and integrity. Procoagulant events that culminate in the generation of thrombin and the formation of a fibrin clot protect the vasculature from perforating injury and excessive blood loss. Fibrinolysis removes the clot and initiates mechanisms involved in tissue repair and regeneration. Therefore, hemostasis refers to multiple discrete processes that center on

Abstract

The blood coagulation process is essential to maintaining hemostasis and preventing hemorrhage. Excessive or aberrant activation of the coagulation process can lead to unwanted thrombosis. It is necessary to closely monitor patients to minimize the risks of hemorrhage and thrombosis in a surgical setting.

thrombin generation, fibrin clot formation, and fibrin clot dissolution.

Hemostasis is not a passive state, but instead it is actively maintained by the vascular system. Specific cellular and protein interactions are required to maintain a state of equilibrium. When the system is perturbed, an integrated series of processes are required to initiate procoagulant events and to promote fibrinolysis and tissue repair. Each individual process that contributes to hemostasis must operate properly or the entire system is compromised. A balance among procoagulant, anticoagulant, and fibrinolytic factors is required to prevent uncontrolled bleeding or, conversely, excessive clot formation.[1]

PROCOAGULANT, ANTICOAGULANT, AND FIBRINOLYTIC PROTEINS, INHIBITORS, AND RECEPTORS

History and Nomenclature

Current knowledge of the components involved in the complex process of blood coagulation (Fig. 36.1) is the result of observations that date back to the second century.[2] Many hypotheses were envisioned about the transformation of fluid blood to a gel-like mass as it escaped the body,[3] but the realization that clots stem blood loss did not occur until the beginning of the 18th century,[3,4] and it was not until the 19th century that the existence of thrombin, the key enzyme in blood coagulation, was recognized.[3,5] Four clotting factors were initially identified[6]: factor I, fibrinogen; factor II, prothrombin; factor III, thromboplastin; and factor IV, calcium ions (or Ca^{2+}). As more coagulation factors were identified, initially by bleeding pathology and subsequently by laboratory clotting tests,[7,8] they were assigned consecutive Roman numerals, with activated forms distinguished by an *a* after the Roman numeral designation.

To describe the multiple simultaneous processes involved in generation of a hemostatic response, we identify an inventory of the procoagulant, anticoagulant, and fibrinolytic participants in blood coagulation. Subsequently, we describe the connections between these components and the dynamics of this process.

Vitamin-K-Dependent Proteins (See Chapter 39: Anticoagulant Drugs)

The vitamin-K–dependent proteins, synthesized in the liver, play central roles in both the procoagulant or anticoagulant pathways. The family includes the procoagulant factors VII, IX, X, and prothrombin and the anticoagulants protein C, protein S, and protein Z (Fig. 36.2 and Tables 36.1 and 36.2). Except for proteins S and Z, these proteins in their active forms are serine proteases. The cleavage of specific peptide bonds converts the vitamin-K-dependent zymogens to their active serine protease forms. All share noncatalytic domains, each of which is characterized by highly conserved regions that provide

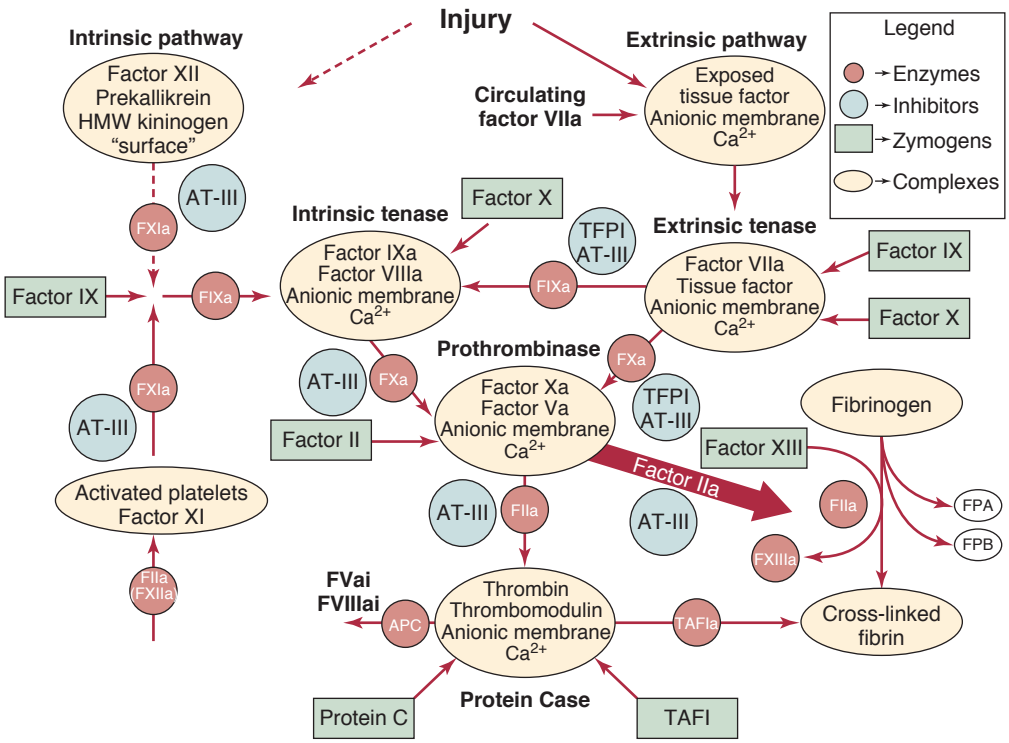

Figure 36.1 Overview of hemostasis. Two pathways can be used to initiate coagulation: the primary extrinsic pathway (shown on the right) and the intrinsic pathway (shown on the left). *AT,* Antithrombin; *HWM,* high-molecular-weight; *TAFI,* thrombin-activatable fibrinolysis inhibitor; *TFPI,* tissue factor pathway inhibitor. (Modified from Brummel-Ziedins K, et al. In: Lee GR, et al, eds. *Wintrobe's Clinical Hematology*. 11th ed. Philadelphia: Lippincott Williams & Wilkins; 2003: Chapter 21.)

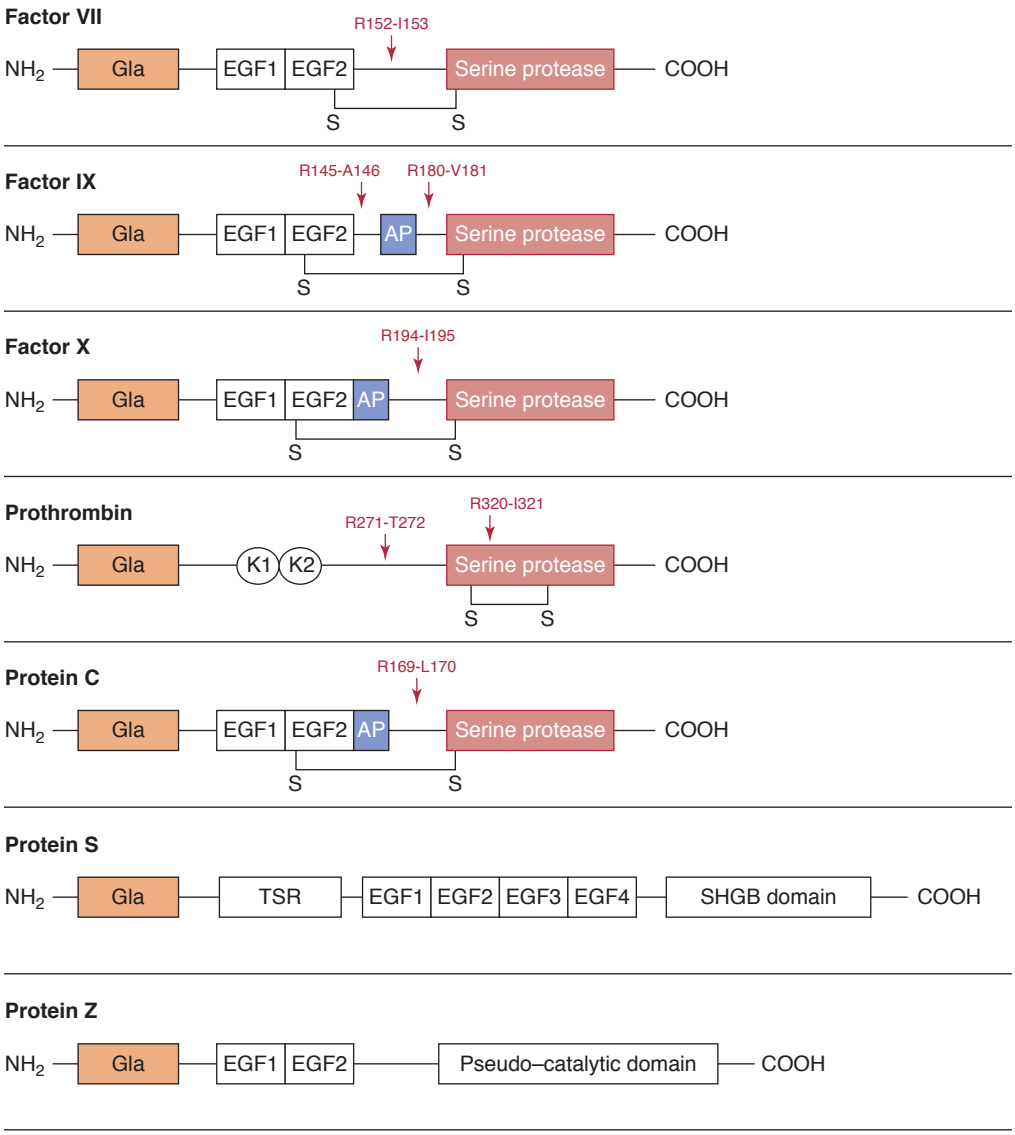

Figure 36.2 Schematic representation of the vitamin-K-dependent proteins. The building blocks for these proteins include an NH_2-terminal Gla domain with 9 to 13 γ-carboxyglutamate residues followed by either an epidermal growth factor *(EGF)*-like domain in factor VII, factor IX, factor X, protein C, protein S, and protein Z or kringle *(K)* domains in prothrombin. Activation cleavage sites, disulfide bonds (–S–S–), and activation peptides *(AP)* are illustrated. The sex hormone-binding globulin *(SHBG)* and thrombin-sensitive regions *(TSR)* are also represented in proteins.

specific binding characteristics essential for their function. The domain organizations of the vitamin-K-dependent proteins are illustrated in Fig. 36.2.[9-13]

Vitamin K is essential for the biosynthesis of these clotting factors by participating in a cyclic oxidation and reduction process that converts 9 to 13 amino-terminal glutamate residues into γ-carboxyglutamate (Gla) residues.[12,14,15] This posttranslational modification enables the vitamin-K-dependent proteins to interact with Ca^{2+} (or calcium ions) and appropriate membranes.[16-18] Inhibition of the Gla residue modification is the basis for "blood-thinning" anticoagulant therapy with coumarin derivatives (e.g., warfarin) that interfere with the redox cycle. The level of anticoagulation achieved with vitamin K antagonist therapy in individuals taking the same dose regimen is variable.[19,20] For instance, altered sensitivity to warfarin has been identified in patients when it is prescribed after surgery.[21] Factors affecting the efficacy of treatment include liver function in the synthesis of clotting factors, the influence of other medications, and the dietary intake/absorption of vitamin K[22]; therefore, monitoring of warfarin therapy is essential.[19,20]

NH_2-terminal Gla domains are followed by either a Kringle domain or an epidermal growth factor-like domain (see Fig. 36.2). Protein S is not a serine protease precursor but instead contains a thrombin-sensitive region before the epidermal growth factor domain and a sex hormone-binding globulin-like domain in the COOH terminus.[23] Protein Z contains a

TABLE 36.1 Procoagulant Proteins

Protein	Molecular Weight (kD)	Plasma Concentration (nmol/L)	Plasma Concentration (μg/mL)	Plasma $t_{1/2}$ (Days)	Clinical Phenotype Associated With Deficiency	Functional Classification

TABLE 36.2 Anticoagulant Proteins, Inhibitors, and Receptors

Protein	M_r (kD)	Plasma Concentration (nmol/L)	Plasma Concentration (μg/mL)	Plasma $t_{1/2}$ (Days)	Clinical Phenotype Associated With Deficiency	Functional Classification
Protein C	62	65	4	0.33	Thrombotic	Proteinase zymogen
Protein S	69	300	20	1.75	Thrombotic	Inhibitory cofactor
Protein Z	62	47	2.9	2.5	Sometimes thrombotic	Inhibitory cofactor
Thrombomodulin	100	N/A	N/A	N/A		Cofactor/modulator
Tissue factor pathway inhibitor	40	1-4	0.1	minutes		Proteinase inhibitor
Antithrombin	58	2400	140	2.5-3	Thrombotic	Proteinase inhibitor
Heparin cofactor II	66	500-1400	33-90	2.5	Often thrombotic	Proteinase inhibitor
α_2-Macroglobulin	735	2700-4000	2-3000	<1 h		Proteinase inhibitor
α_1-Proteinase inhibitor	53	28,000-65,000	1500-3500	6		Proteinase inhibitor
Endothelial protein C receptor						Receptor

"pseudo-catalytic domain" in the COOH terminus and is not a zymogen.[24]

Cofactor Proteins

Cofactor proteins (Fig. 36.3A, B) either circulate in plasma (factor V and factor VIII) or are the cell-bound tissue factor (TF) and thrombomodulin (TM).

Soluble Plasma Procofactors

Factor V

Factor V (see Fig. 36.3A and Table 36.1) is a large single-chain glycoprotein[25-28] found in plasma or platelet alpha granules (18%-25% of the total factor V pool)[29] and is secreted upon platelet activation. It is proteolytically activated by thrombin to form the cofactor factor Va (Fig. 36.3A).[30] Factor Va functions

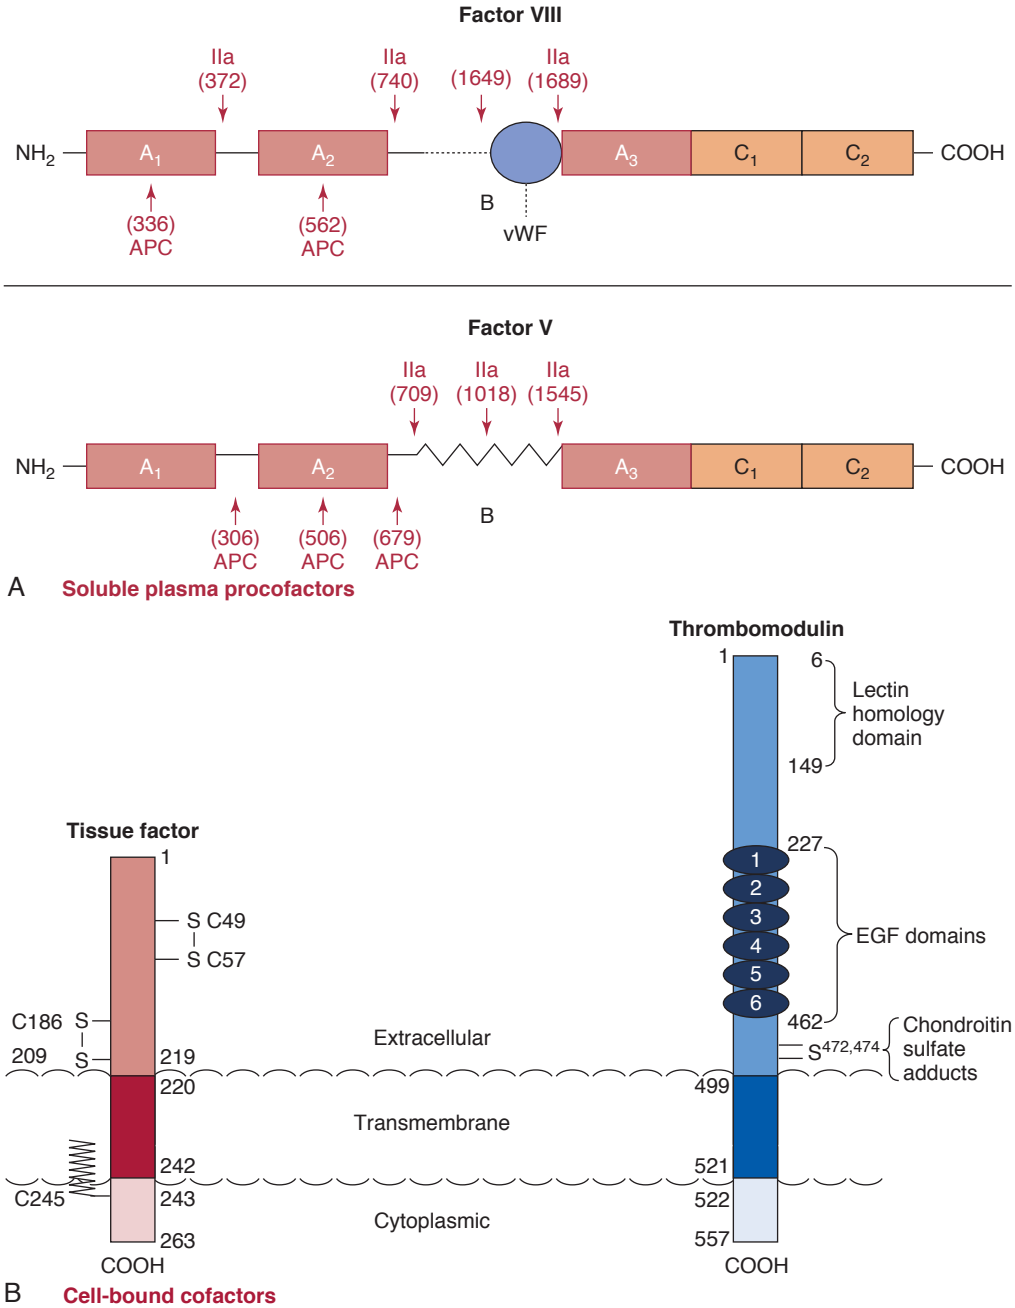

Figure 36.3 Cofactors. **(A)** Plasma procofactors factor VIII and factor V. The linear domain structures (A_1-A_2-A_3-C_1-C_2) are represented. *APC,* Activated protein C; *vWF,* von Willebrand factor. **(B)** Cell-bound cofactors tissue factor and thrombomodulin. Epidermal growth factor (EGF), transmembrane, and cytoplasmic domains are illustrated.

as positive modulator of factor Xa's catalytic potential in the prothrombinase complex in the presence of Ca^{2+} and an appropriate membrane surface.[31] It is proteolytically inactivated by activated protein C (APC) (see Fig. 36.3A).[32,33] Cleavage at Arg^{506} by APC reduces factor Va activity, while the slower cleavage at Arg^{306} eliminates activity. The importance of this regulatory mechanism is illustrated by the factor V Leiden, characterized by an $Arg^{506}Gln$ mutation.[34] Therefore, despite normal activity in the prothrombinase complex, factor Va Leiden is more slowly inactivated resulting in a prothrombotic phenotype.

Factor VIII

The procofactor factor VIII circulates in plasma in complex with the large multimeric protein von Willebrand factor (vWF; see Fig. 36.3A). It is homologous (40% identity) with factor V,[35,36] but circulates in plasma as a two-chain molecule.[37] Factor VIII is activated by thrombin cleavage at three sites to generate the heterotrimeric cofactor factor VIIIa that lacks a vWF binding site.[38] Factor VIIIa enhances the enzymatic activity of the factor IXa in the presence of Ca^{2+} and an appropriate membrane surface, forming intrinsic tenase complex. Its function is downregulated

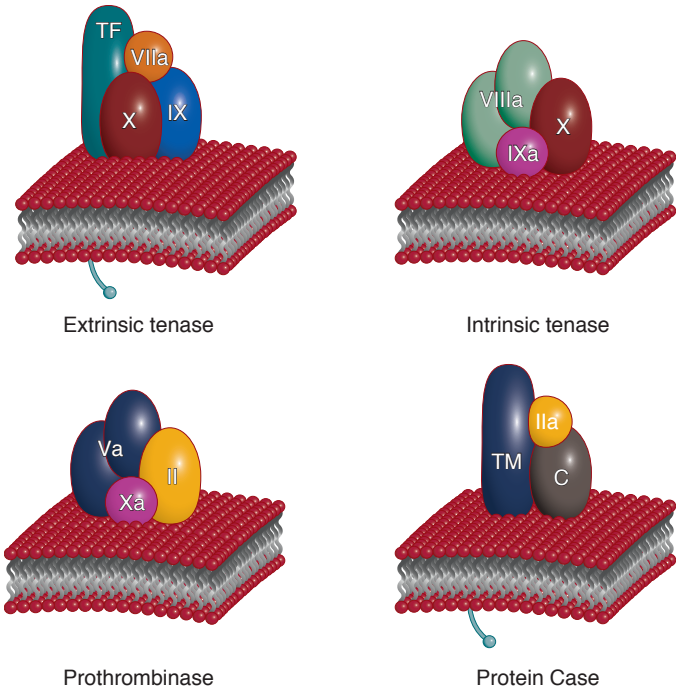

Figure 36.4 Vitamin-K-dependent complexes. Three procoagulant complexes (extrinsic tenase, intrinsic tenase, and prothrombinase) and one anticoagulant complex (protein Case) are illustrated. Each serine protease is shown in association with the appropriate cofactor protein and zymogen substrate or substrates on the membrane surface. Calcium ion is not shown. *TF,* Tissue factor; *TM,* thrombomodulin. (Redrawn from Mann KG. *Coagulation explosion,* Vermont Business Graphics; 1997.)

by the rapid and spontaneous dissociation of the noncovalently bound A_2 subunit or proteolysis of the factor VIIIa light chain by APC. Deficiency of factor VIII (hemophilia A) is a well-characterized bleeding disorder linked to the X chromosome.[39]

Cell-Bound Cofactors

Tissue Factor

TF is a transmembrane protein that functions as a nonenzymatic cofactor with factor VIIa in the extrinsic tenase complex that activates both factors IX and X (Fig. 36.4).[40] TF is not expressed in blood in the absence of injury or inflammatory stimulus, and its presentation triggers the extrinsic pathway for hemorrhage control (see Fig. 36.1).[41-43] Functional TF is presented following vascular damage that exposes the subendothelium or cytokine stimulation of monocytes.[44-46] There are no known deficiencies of human TF, and the absence of TF in mice is lethal during embryonic development.[47]

Thrombomodulin

TM is a high-affinity receptor for α-thrombin and acts as a cofactor for the activation of protein C (see Fig. 36.3B).[48] The endothelial cell protein C receptor provides cell-specific binding sites for both protein C and APC.[49,50] Once thrombin is bound to TM, its procoagulant activities are neutralized and the rate of inactivation of α-thrombin by antithrombin (AT) is increased.[51-53] Protein C activation by the thrombin-TM complex (protein Case) leads to inactivation of the cofactors factor Va and factor VIIIa, suppressing thrombin formation (see Fig. 36.2).[54] The protein Case complex also has an antifibrinolytic role through activation of thrombin-activatable fibrinolysis inhibitor (TAFI).[55-57] TM activity on the surface of endothelial cells is decreased by inflammatory cytokines[58]; this decrease may contribute to hypercoagulation in inflammatory states.

Complexes

Vitamin-K-dependent protein complexes are essential for establishing hemostatic balance (see Fig. 36.4). Each complex is composed of a serine protease (factor VIIa, factor IXa, factor Xa, or thrombin [factor IIa]), a cofactor that functions as a receptor/enhancer for the enzyme (factor VIIIa, factor Va, TF, TM), Ca^{2+}, and an appropriate anionic phospholipid membrane of cellular origin. There are four vitamin-K-dependent enzyme complexes (see Fig. 34.4): the extrinsic tenase complex (factor VIIa–TF), the intrinsic tenase complex (factor IXa–factor VIIIa), the prothrombinase complex (factor Xa–factor Va), and the anticoagulant protein Case complex (thrombin-TM). These membrane-bound complexes serve to localize enzymatic activity to the appropriate regional site for their required enzymatic functions and result in the only biologically relevant enzymatic activity for factor VIIa, factor IXa, and factor Xa—10^4-fold to 10^9-fold faster reaction rates than the enzyme in solution.[59]

Intrinsic (Accessory) Pathway Proteins

Deficiencies of proteins associated with the intrinsic pathway (factor XII, prekallikrein, and high-molecular-weight kininogen [HMWK]) are not associated with abnormal bleeding, even after surgical challenge.[60-62] In contrast, deficiencies of the protein components of the extrinsic or primary pathway (prothrombin and factors V, VII, VIII, IX, and X) can lead to severe bleeding diatheses.[63-67] The physiologic significance of the intrinsic pathway is still debated, but mounting evidence suggests that it serves as the link between inflammation and innate immunity.[68]

Factor XI represents an intersection point for the two pathways. Individuals with factor XI deficiency (hemophilia C) express variable bleeding with surgical challenge,[69,70] thus establishing a role for factor XI in hemostasis. During the hemostatic process, formation of factor XIa appears to be catalyzed by thrombin as part of a positive feedback loop.[71] Factor XIa then functions in the propagation phase of thrombin generation in association with the primary pathway by activation of factor IX.[72]

Three proteins, factor XII, prekallikrein, and HMWK, are required for activity of the intrinsic pathway. Factor XII and prekallikrein are zymogens that are activated to generate serine proteases, and HMWK is a nonenzymatic procofactor (Fig. 36.5). Activation of this pathway in vitro is accomplished when factor XII autoactivates to factor XIIa with exposure to a foreign surface (e.g., glass, kaolin, dextran sulfate, sulfatides).[73-75] The substrates for factor XIIa, prekallikrein and factor XI, exist in a noncovalent complex with HMWK and become activated to kallikrein and factor XIa, respectively.[76] This pathway is positively and negatively regulated via cleavage of HMWK by

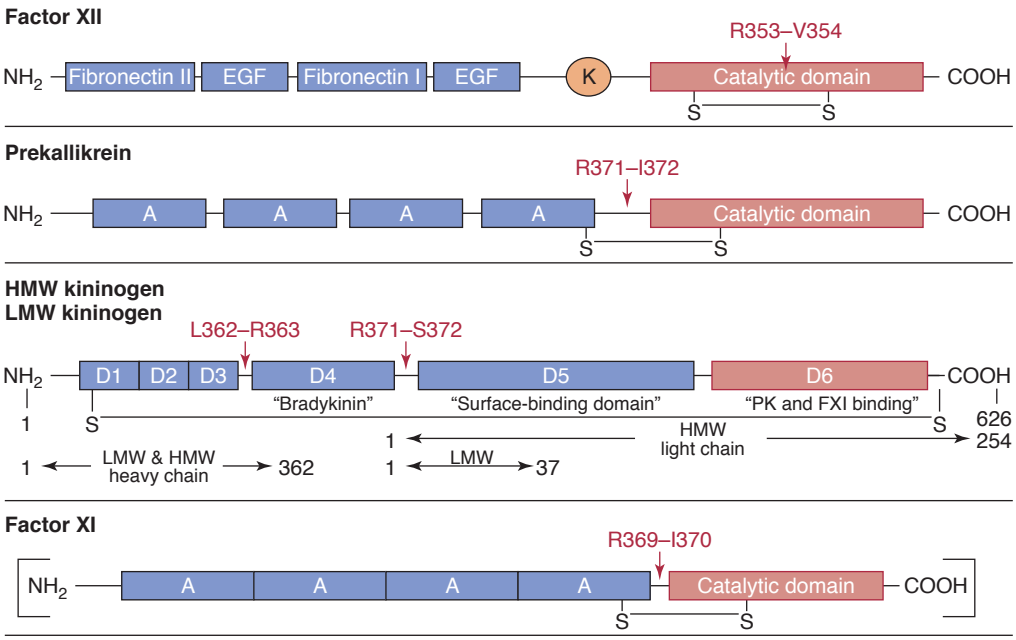

Figure 36.5 Schematic representation of the intrinsic pathway proteins. Factor XII, prekallikrein *(PK)*, high-molecular-weight kininogen *(HMWK)*, low-molecular-weight kininogen *(LMWK)*, and factor XI *(FXI)* are shown with their various domains depicted. *A,* Apple domain; *EGF,* epidermal growth factor domain; *K,* kringle domain. Cleavage sites and key interchain disulfide bonds (S–S) are shown. For the kininogens, *horizontal arrows* indicate the amino acid residues defining heavy- and light-chain regions of the activated forms of the cofactors. The factor XI molecule is a dimer of the illustrated monomer. Factor XI is a disulfide-linked homodimer with each subunit containing four apple domains, which provide binding sites for high-molecular-weight kininogen, thrombin, factor XIIa, platelets, and heparin. Activation of factor XI (by thrombin or factor XIIa) results in a conformational change that permits factor IX binding to the apple 3 domain.

kallikrein and FXIa, respectively.[77,78] It has also been reported that the intrinsic pathway is activated by inorganic polyphosphates[79,80] or the assembly of these proteins on endothelial cell membranes.[81,82] Activation of the intrinsic pathway is important in cardiopulmonary bypass because of contact between blood components and synthetic surfaces.[83]

Stoichiometric Inhibitors

An array of inhibitors is present in blood with both specific and broad-spectrum actions. Inhibitors of clot formation are AT, tissue factor pathway inhibitor (TFPI), heparin cofactor II, and protein C inhibitor (Fig. 36.6).

Antithrombin

AT is a member of the serpin proteinase family and circulates in blood as a single-chain glycoprotein (see Fig. 36.6).[84,85] Congenital AT deficiency exhibits an autosomal dominant pattern of inheritance, with an incidence of 1 in 2000 to 5000.[86] Individuals with this deficiency have partial expression of AT and are prone to thromboembolic disease.[87] The complete absence of AT is lethal. AT is a broad-spectrum anticoagulant, interacting with most proteases participating in the coagulation cascade (see Fig. 36.1), including thrombin, factor Xa, factor IXa, factor VIIa–TF, factor XIa, factor XIIa, plasma kallikrein, and HMWK.[88-90] Heparins and heparan sulfates potentiate these reactions and are used in the treatment of thrombosis. When AT is complexed with heparin, its rate of inhibition of several coagulation proteases is accelerated by up to 10,000-fold as heparin induces structural changes that expose its reactive center loop. Antithrombin also displays antiproliferative and anti-inflammatory properties that primarily derive from its ability to inhibit thrombin. In addition, latent or cleaved forms of AT have antiangiogenic activity.[91]

Tissue Factor Pathway Inhibitor

TFPI (also called extrinsic pathway inhibitor or lipoprotein-associated coagulation inhibitor) is a multivalent, Kunitz-type inhibitor that circulates in plasma as a heterogeneous collection of partially proteolyzed forms (see Fig. 36.6).[92-95] Ninety percent of circulating TFPI is found associated with lipoproteins.[94,96,97] Circulating TFPI is cleared principally by the liver and has an unusually short half-life compared with other proteinase inhibitors.[98]

Complete deficiency of TFPI is incompatible with birth and survival in transgenic mice;[18] however, this lethality can be rescued by heterozygous or homozygous factor VII deficiency.[99] Mice bred to have a combined heterozygous TFPI deficiency and homozygous apolipoprotein E deficiency exhibit an increased atherosclerotic burden, suggesting a role for TFPI in protection from atherosclerosis and as a regulator of thrombosis.[100]

TFPI is the principal stoichiometric inhibitor of the extrinsic tenase complex (factor VIIa–TF).[101] Effective TFPI inhibition

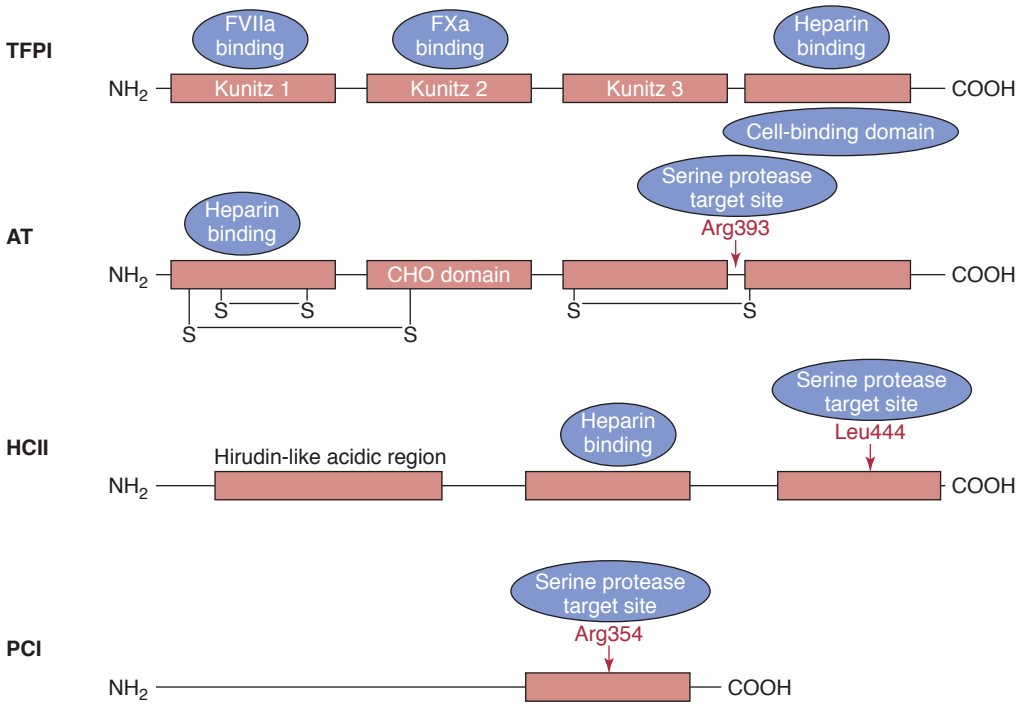

Figure 36.6 Stoichiometric inhibitors. Tissue factor pathway inhibitor *(TFPI)* has three Kunitz domains. The Kunitz 1 domain binds factor VIIa, the Kunitz 2 domain binds factor Xa, and the Kunitz 3 domain has been reported to bind protein S. The COOH terminus of TFPI contains a basic region, the cell-binding domain that also binds to heparin and some forms of factor Va. Antithrombin *(AT)* has two intrachain disulfide bonds (-S-S-) at its NH_2 terminus and one in its COOH terminus with a carbohydrate-rich domain (CHO) in between. The region of interaction between the active sites of target proteases and AT is called the reactive center loop, R393-S394. Heparin binding occurs in the NH_2 terminus. Heparin cofactor II *(HCII)* contains an NH_2-terminal hirudin-like region, a heparin- or dermatan sulfate-binding region, and a reactive center loop. The reactive site is Leu444.

of the factor VIIa–TF complex depends on the presence of factor Xa; thus, inhibition of the extrinsic factor tenase by TFPI occurs only after significant generation of factor Xa. The TFPIα splice variant can also bind to some forms of factor Va formed early in the coagulation process and inhibit the prothrombinase complex.[102] This interaction is the basis of the east Texas bleeding disorder, which is associated with life-threatening bleeding after trauma or surgery due to the production of a factor V splice variant that binds tightly to TFPIα.[103,104]

Heparin Cofactor II

Heparin cofactor II is a member of the serpin family (see Fig. 36.6). Like AT, heparin cofactor II inhibits thrombin in a reaction that is accelerated more than 1000-fold by heparin.[105] However, unlike AT, thrombin is the only coagulation enzyme inhibited by heparin cofactor II.[106] Heparin cofactor II and dermatan sulfate levels increase during pregnancy,[107-109] and decreased heparin cofactor II is associated with preeclampsia.[110,111]

Endothelium and Platelets (See Chapter 40: Antiplatelet Agents)

Blood cells and the vasculature are crucial to normal hemostasis, in part because they supply appropriate anionic surfaces to support the coagulation process. Additionally, interactions between the vessel wall, the circulating platelets, and the plasma protein moieties are essential for maintaining blood fluidity (Fig. 36.7AB). The biologic elements contributing to the phospholipid requirement of the coagulation process include damaged vascular tissue, activated platelets, and inflammatory cells.[101,112,113] Mechanically damaged cells can provide the anionic membrane required to support general procoagulant complex formation, but more subtle cellular activation events also generate selective complex-forming sites on intact cells, as is the case with platelets.[114,115] Therefore, pathologic hemorrhage is associated with thrombocytopenia, and is also seen in Scott's syndrome in which there is improper presentation of these platelet-binding sites.[116]

Endothelium

The endothelium plays key roles because of its strategic interface with organs, tissues, and circulating blood, and varies considerably in morphology and physiologic function in different parts of the vasculature. This complex cellular network not only provides a structural barrier to contain flowing blood, but also actively regulates blood pressure, vascular tone, permeability, and processes involving other cells. It also has roles in inflammation, immune responses, and angiogenesis.[117] Therefore, defects in vascular endothelial function have profound physiologic implications. Excessive bleeding can result from structural

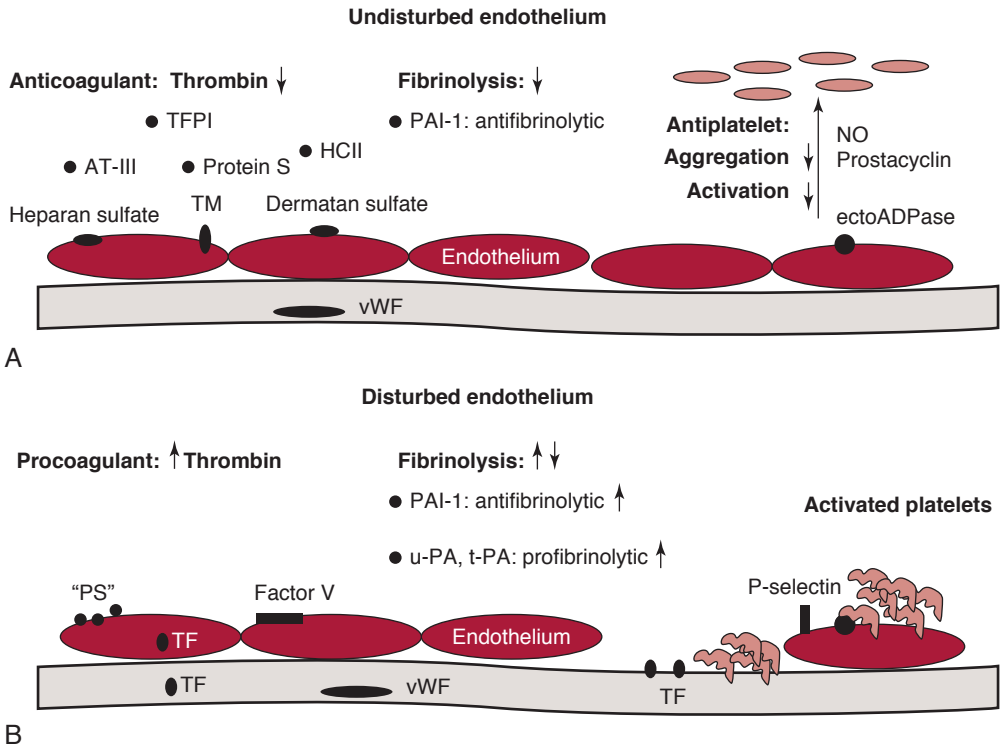

Figure 36.7 The endothelium in hemostasis. **(A)** Under normal conditions and in the absence of injury or chemical stimulus, the undisturbed endothelium actively downregulates thrombin generation through production of tissue factor pathway inhibitor *(TFPI)*, antithrombin *(AT)*, protein S, heparin cofactor II *(HCII)*, heparan sulfate, thrombomodulin *(TM)*, and dermatan sulfate. The undisturbed endothelium is also antifibrinolytic and secretes plasminogen activator inhibitor-1 *(PAI-1)*. In the absence of stimulus, the endothelium is likewise antiplatelet and prevents platelet adhesion activation, secretion, and aggregation through production of nitric oxide *(NO)*, prostacyclin, and the membrane-associated protein ectoADPase. **(B)** When the endothelium is disturbed, the endothelium becomes procoagulant and accelerates thrombin formation by exposing or expressing anionic phospholipid *("PS")*, limited tissue factor *(TF)*, and factor V. The fibrinolytic response is modulated by the release of both antifibrinolytic and profibrinolytic molecules. Urokinase (urinary plasminogen activator, *u-PA*) and tissue plasminogen activator *(t-PA)* are profibrinolytic and serve to activate plasminogen, whereas PAI-1 inhibits both enzymes and is antifibrinolytic. Platelet activation, secretion, and aggregation are also promoted under conditions in which the endothelium is disrupted. Exposure of von Willebrand factor *(vWF)* in the subendothelial matrix allows platelets to attach to the surface of the vessel. P-selectin likewise promotes platelet attachment.

abnormalities of the endothelial cell layer or supporting matrix. For example, impaired plasminogen activator inhibitor-1 (PAI-1) expression and/or secretion by the endothelium promotes bleeding through increased fibrinolytic activity.[118]

Platelets

Platelets are vital to procoagulant events and contribute to the fibrinolytic process as well. Like the endothelium, the undisturbed platelet presents a nonthrombogenic surface. Important components of platelet physiology are surface adhesion protein complexes and platelet secretory granules: alpha granules, lysosomes, and dense granules. The contents of alpha granules include procoagulant, adhesive, fibrinolytic, and antifbrinolytic proteins, among others.[29,119-127] In the unstimulated platelet, the granule contents remain internalized, and anionic phospholipids are sequestered in the inner leaflet of the plasma membrane.

When the vascular system is perturbed, platelet plug formation occurs in stages. Initially, platelets adhere and are activated by exposure to collagen, vWF, and other matrix components (Fig. 36.8). However, thrombin is the most potent activator of platelets; it is able to overcome most pharmacologic and cytokine inhibitors that depress platelet function.[128] During platelet activation, the cytoskeleton spreads, platelet-fibrinogen aggregates are formed, and the contents of the granules are secreted.[129-131] The activated platelets adhere to each other, and to endothelial cells, leukocytes, and components of the subendothelial matrix.[132] The phosphatidylserine-rich internal face of cell membranes is exposed and presents a highly procoagulant surface to the circulation. In addition, activated platelets express specific receptors and/or binding sites for assembly of both the prothrombinase and intrinsic tenase complexes.[114,133-137]

During the extension phase of platelet plug formation, activated platelets accumulate on top of the initial monolayer of platelets bound to collagen. The presence of receptors on the platelet surface allows agonists, such as thrombin, adenosine diphosphate, and thromboxane A_2 to further recruit circulating platelets into the growing hemostatic plug. During this phase

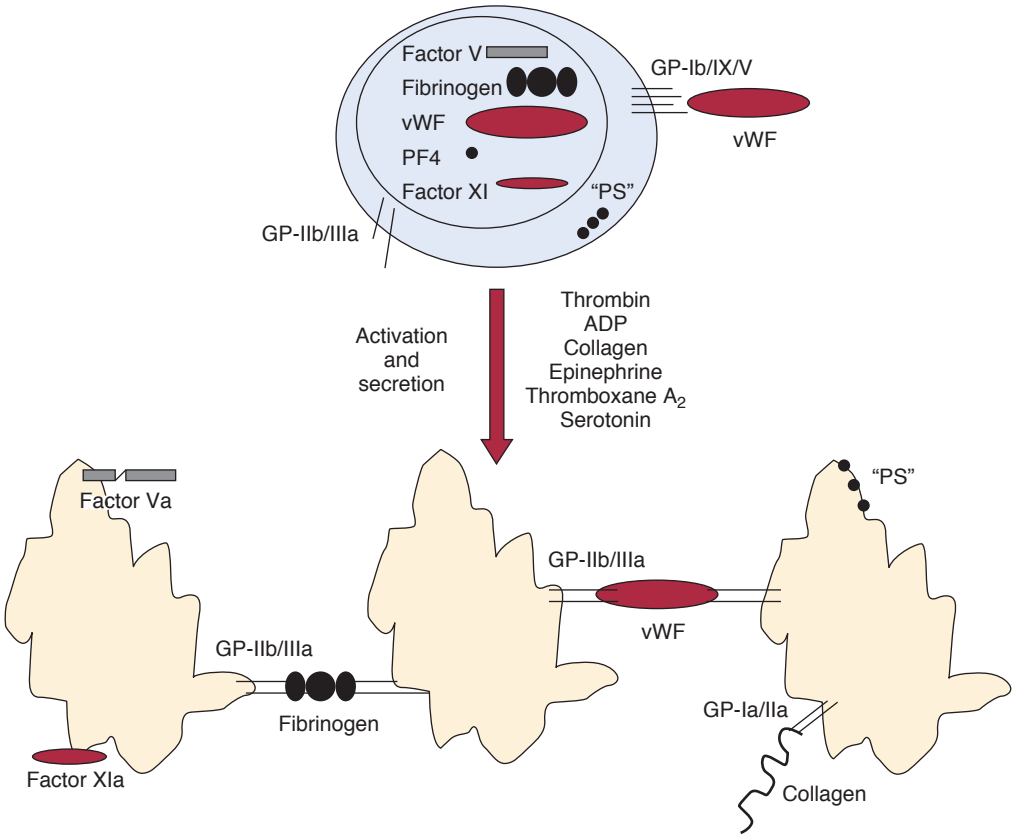

Figure 36.8 Activation, secretion, and aggregation of platelets. Platelets have multiple functions in hemostasis. They serve as reservoirs of factor V, fibrinogen, von Willebrand factor *(vWF)*, platelet factor 4 *(PF4)*, and factor XI. Platelets also contribute a significant portion of the anionic phospholipid *("PS")* necessary for membrane-dependent complex formation and function. In the unstimulated state, proteins and other molecules are sequestered in the platelet granules. Anionic phospholipid is found only in the inner leaflet of the platelet membrane and is not exposed to flowing blood. The glycoprotein Ib/IX/V *(GP-Ib/IX/V)* complex that recognizes vWF is an active receptor, whereas the GP-IIb/IIIa receptor that recognizes a variety of molecules, including fibrinogen and vWF, is not active. The GP-Ib/IX/V receptor probably allows unstimulated platelets to attach to exposed subendothelial vWF and promotes procoagulant events before platelet activation. On activation by a variety of agonists, platelets secrete granule contents, activate and bind factor V/Va and factor XI/XIa, and expose anionic phospholipid. The GP-IIb/IIIa receptor serves to link platelets to each other and the vessel wall. Collagen receptors, such as GP-Ia/IIa, promote both platelet activation and aggregation.

of clot growth, close contact between platelets that stimulates growth and stabilization of the hemostatic plug, in part through contact-dependent signaling mechanisms.[128,138]

Clot Proteins

The primary proteins of the clot are fibrin and the transglutaminase factor XIIIa. A central event in blood coagulation is the conversion of soluble fibrinogen to insoluble fibrin (see Fig. 36.1).[139,140] Fibrinogen serves as a molecular bridge to support interplatelet aggregation, and is the precursor of fibrin, the protein scaffolding component of the hemostatic plug (Fig. 36.9). Platelet aggregation critically depends on fibrinogen binding to activated the platelets, and depends on fibrin adhesion. Fibrinogen/fibrin also regulates thrombin activity by sequestering thrombin via an exosite mediated interactions.[141,142] Although it is primarily recognized for its role in hemostasis, fibrinogen is also associated with inflammation. Fibrinogen is an acute-phase reactant, with levels increasing during inflammation where it functions as a bridging molecule in cell-cell interactions.[143]

The fibrin clot is stabilized by the transglutaminase factor XIIIa,[144-146] whose function is to cross-link fibrin and other adhesive proteins, including integrin receptors, thereby providing a stable network (Fig. 36.10). The protransglutaminase factor XIII circulates in plasma as a tetramer and is also present as a dimer in platelets. Activation of the protein by thrombin cleavage and Ca^{2+} binding yields the transglutaminase factor XIIIa that cross-links fibrin by forming exopeptide bonds between the ε-amino group of lysine and the γ-carboxamide group of glutamine residues.[147,148] The resulting stable fibrin clot creates an insoluble network that, along with the primary platelet plug, seals the perforation in the blood vessel with a temporary scaffold, stopping further blood loss.

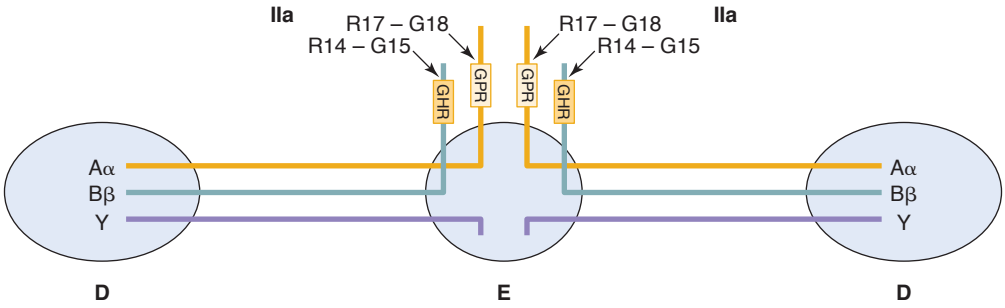

Figure 36.9 A schematic representation of human fibrinogen. Fibrinogen is composed of six polypeptide chains (two Aα, two Bβ, and two γ). These are organized into two identical half-molecules. All six NH_2 termini are linked by disulfide bonds in the central or E domain. The three chains extend out from this domain through coiled coils in either direction, terminating in the globular D domains. Thrombin *(IIa)* cleavage sites at the N termini of the Aα and Bβ *(arrows)* are indicated, with the new N termini *(box)* that associate with "holes" in the D domains to form fibrin.

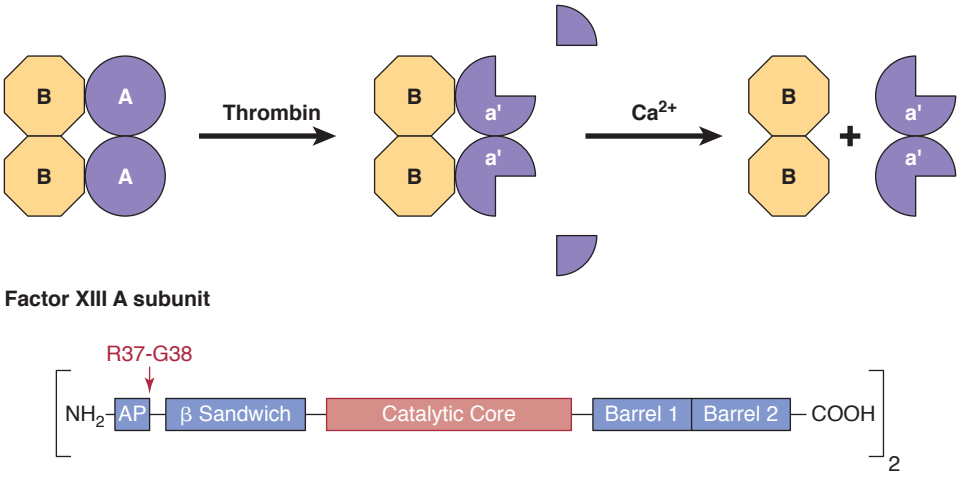

Figure 36.10 Plasma factor XIII. Thrombin-catalyzed activation of plasma factor XIII (A_2B_2; 320,000 Da) occurs in two steps. First, thrombin cleaves the R37-G38 bond. This releases the activation peptides (residues 1-37) from the A chains, producing the inactive intermediate a'_2B_2. In the second Ca^{2+}-dependent step, the B chains dissociate from the a'_2B_2 intermediate, exposing the active site cysteine, Cys314, of the a′ subunits. The enzyme a'_2 catalyzes the formation of isopeptide bonds between glutamine residues and lysine residues of adjoining polypeptide chains.

Fibrinolysis Proteins (See Chapter 41: Thrombolytic Agents)

Clot formation is integrated with clot dissolution. The mechanisms of clot dissolution center on fibrin-specific reactions. The key proteins involved are plasminogen; the plasminogen activators tissue plasminogen activator (t-PA) and urokinase plasminogen activator (u-PA); thrombin; and the inhibitors PAI-1, α_2-antiplasmin, and TAFIa (Fig. 36.11 and Table 36.3).

Fibrinolysis Activators

Plasminogen/Plasmin

Plasminogen is the inactive precursor of the enzyme plasmin, the primary catalyst of fibrin degradation.[149] Hereditary plasminogen deficiency is described either as a deficiency of plasminogen antigen and activity (type I) or as a normal antigen level but reduced activity (type II, dysplasminogenemia).[150] Plasminogen is also an acute phase reactant protein.[151,152] Homozygous plasminogen-deficient mice are viable, but exhibit severe thrombosis with systemic fibrin deposition and die prematurely.[153] The zymogen is converted to the serine protease plasmin following cleavage at Arg^{561}, primarily by t-PA and u-PA in vivo although pharmacologic agents can also exogenously activate plasminogen. Plasminogen activation is primarily inhibited by PAI-1, which targets u-PA and t-PA.[154] Congenital deficiency of PAI-1 is rare, with homozygous individuals displaying abnormal bleeding in response to trauma.[155] Once formed, plasmin cleaves after basic amino acid residues. The lysine analogues ε-aminocaproic acid and tranexamic acid can compete with lysyl residues in proteins for binding to plasminogen and hence are inhibitors of fibrinolysis.[156,157] Inhibition of plasmin by α_2-antiplasmin is the primary route for the regulation of plasmin's hemostatic function in vivo; suppression of plasmin activity beyond the locale of fibrin deposition is imperative if systemic fibrinogenolysis is to be prevented; therefore, plasmin bound through its lysine binding sites to fibrin reacts more slowly with α_2-antiplasmin than when it is free in solution.

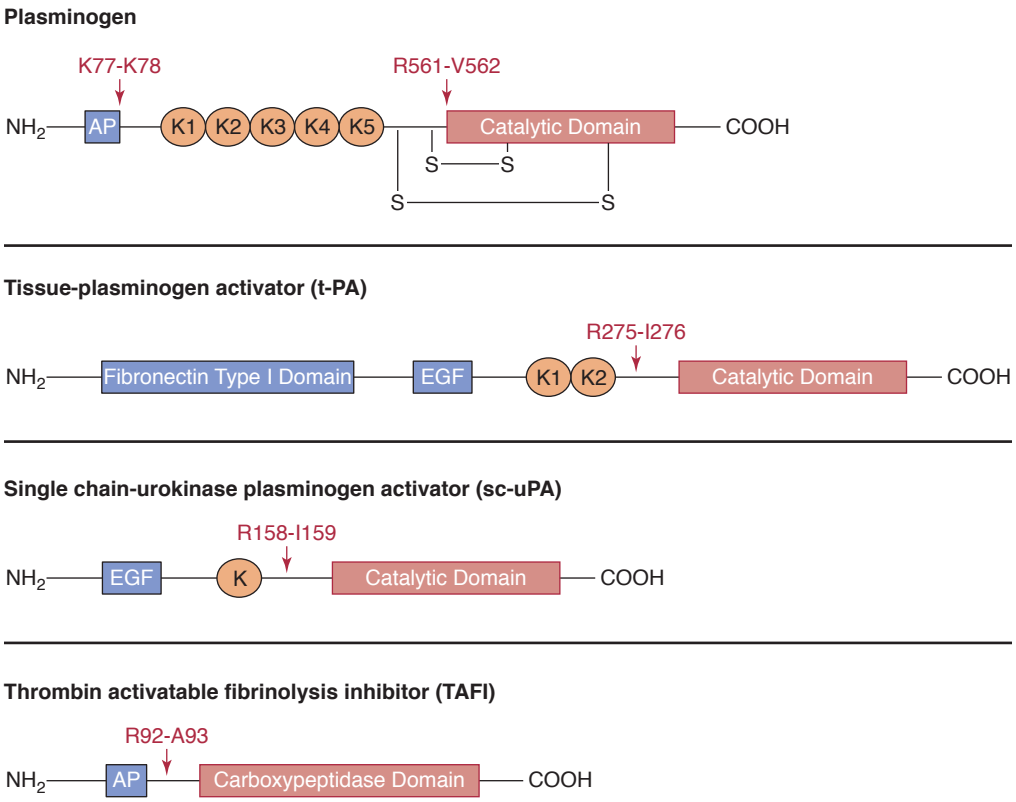

Figure 36.11 A schematic representation of proteins of the fibrinolytic system. Plasminogen, tissue-type plasminogen activator, urokinase plasminogen activator, and thrombin-activatable fibrinolysis inhibitor are shown with their various domains depicted. Cleavage sites with the specific amino acid residues are shown. *AP,* Activation peptide; *K,* kringle domain; *EGF,* epidermal growth factor.

Tissue Plasminogen Activator

t-PA manifests its full fibrinolytic potential only when it is bound to fibrin.[158-160] This binding interaction aligns t-PA and plasminogen on the fibrin surface so that the catalytic efficiency of t-PA is enhanced several-hundred-fold. This is vital to the localization of plasmin generation at the site of fibrin deposition. Release of t-PA from the vessel wall is another important regulator of fibrinolysis.[161,162] The rate at which clots lyse depends on how rapidly t-PA is secreted by the relevant cells in the vicinity of an injury.[163,164] For example, activated platelets secrete serotonin, which can induce endothelial cells to release t-PA; they also release PAI-1 from their alpha granules. Although only a fraction of this PAI-1 is in the active form, it functions to downregulate plasminogen activation.[165,166] No cases of congenital deficiency of t-PA have been reported.

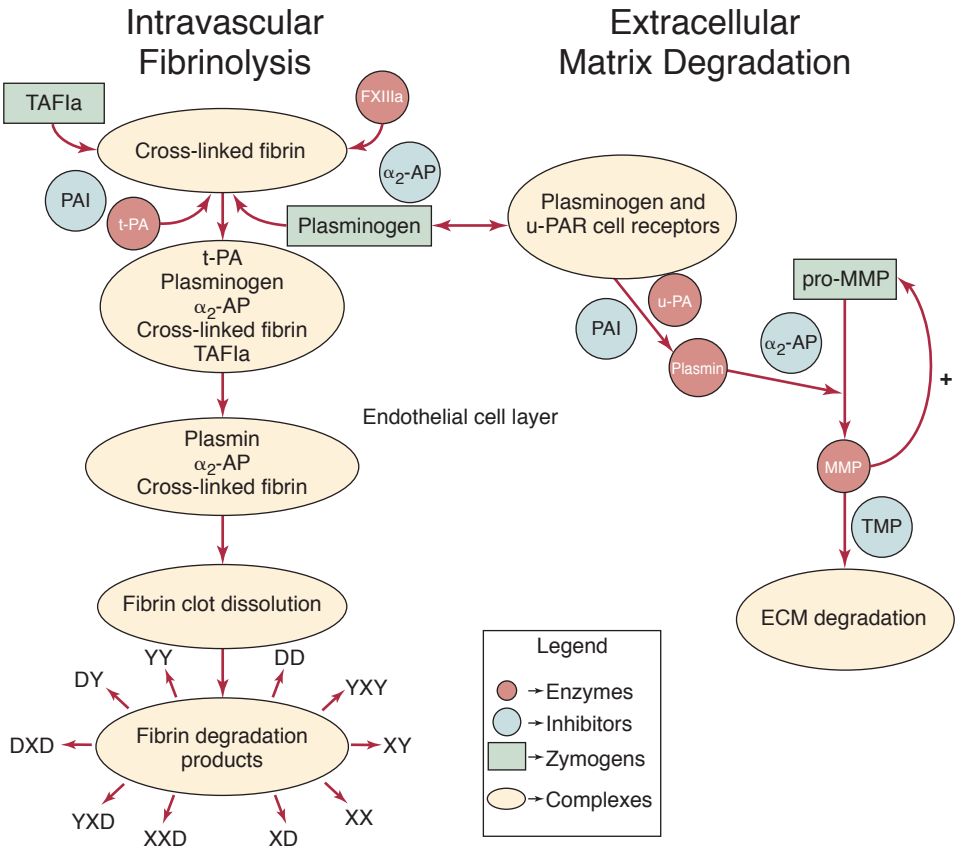

Figure 36.12 Schematic of the dynamic interaction between the proteins and inhibitors of intravascular fibrinolysis and extracellular matrix degradation. Cross-linked fibrin formation *(left)* is integrated with fibrin clot dissolution and degradation of its products. Two pathways are shown: intravascular fibrinolysis and extracellular matrix degradation, separated by an endothelial cell layer. The enzymes, inhibitors, zymogens, and complexes are illustrated in simplified form to show this multicomponent process. Degradation of fibrin occurs by cleavage of plasmin at the D-E-D domains of fibrin polymers to yield a variety of polymers, as illustrated. Plasminogen can cross the endothelial cell layer and become converted to plasmin by urokinase (urinary plasminogen activator; u-PA) *(right)*. Plasmin can convert latent matrix metalloproteinases (pro-MMP) to their active form (MMP). MMPs themselves can act in a positive feedback mechanism to convert pro-MMP to more MMP and ultimately degrade the extracellular matrix. Plasmin-mediated effects are inhibited by plasminogen activator inhibitor (PAI) and α_2-antiplasmin. MMP-mediated effects are inhibited by tissue inhibitors (TMP). *α_2-AP,* α_2-Antitrypsin; *ECM,* extracellular matrix; *t-PA,* tissue plasminogen activator; *TAFI,* thrombin-activatable fibrinolysis inhibitor; *u-PAR,* u-PA receptor.

Urokinase Plasminogen Activator

The main site of urokinase-driven plasminogen activation appears to be extravascular, where it has an important role in promoting degradation of the extracellular matrix by triggering the activation of plasminogen and, possibly, matrix metalloproteinases. The regulation of urokinase is important for normal and pathologic processes, including embryogenesis, wound healing, tumor cell invasion, and metastasis.[167-169] Inhibitors of urokinase have been shown to suppress the growth of primary tumors and to interfere with metastasis of tumor cells.[170-177] t-PA appears to be the primary plasminogen activator in the vasculature, with u-PA amplifying rather than initiating plasmin formation.[178,179] Transgenic mice lacking a functional t-PA gene develop normally and display a normal basal hemostatic phenotype.[180] Mice in which both the t-PA and u-PA genes are disabled have shortened life spans and experience severe spontaneous thrombotic episodes.[180,181]

Fibrinolysis Inhibitors

Plasminogen Activator Inhibitor-1

PAI-1, the primary physiologic inhibitor of plasminogen activation in blood, targets u-PA and t-PA (Fig. 36.12). Congenital deficiency of PAI-1 is rare, with homozygous individuals displaying abnormal bleeding in response to trauma.[182-186] In the normal population, plasma PAI-1 concentrations vary over a 15-fold range (6-80 ng/mL; mean, 10 ng/mL [0.2 nmol/L])[187,188] and exhibit circadian variations.[189] Some of this variability stems from polymorphisms in the PAI-1 gene; however, a larger fraction of the variability appears to derive from the responsiveness of PAI-1 gene expression to a wide variety of physiologic effectors and conditions as well as pharmacologic agents.[190] Higher levels of plasma PAI-1 delay fibrin removal by shortening the functional lifetime of plasminogen activators, delaying fibrinolysis.[191]

α_2-Antiplasmin

α_2-Antiplasmin (or α_2-plasmin inhibitor) is the primary plasmin inhibitor[192-195] and thus is an important regulator of fibrinolysis (see Fig. 36.12). Congenital deficiency of α_2-antiplasmin is rare, with homozygous individuals displaying a moderate to severe bleeding disorder.[196] The primary site of synthesis is the liver, although the kidney may be another contributing source;[197] its in vivo half-life is 2.6 days.[198,199]

Thrombin-Activatable Fibrinolysis Inhibitor

TAFI is a plasma procarboxypeptidase B synthesized in the liver and is thought to circulate in blood in complex with plasminogen.[200] Activation of TAFI yields an exopeptidase (TAFIa) that catalyzes the removal of basic amino acids (arginines, lysines) from the COOH termini of polypeptides. Its primary physiologic activator appears to be the thrombin-TM complex.[201] The COOH-terminal lysyl residues of peptides produced during fibrin degradation are the primary substrates for TAFIa. In the initial phase of plasmin proteolysis of fibrin, peptides are produced that amplify activation of plasminogen by t-PA. These fibrin degradation products contribute to a positive feedback process that accelerates clot lysis. Removal of these terminal lysine residues by TAFIa reduces the number of plasminogen binding sites, thus downregulating the rate of plasmin generation and, thereby, the rate of clot lysis.

CONNECTIVITY AND DYNAMICS OF BLOOD COAGULATION

In the healthy state, the three-compartment system consisting of vascular endothelium, blood, and extravascular tissue functions to maintain fluidity or to produce an integrated response to attenuate leakage of blood by localized activation at the site of vascular injury. When the endothelium is disrupted, the extravascular compartment and blood interact to rapidly produce a vigorous local coagulation response that attenuates blood loss and initiates the vascular repair process in four phases: initiation, propagation, termination, and elimination/fibrinolysis, which overlap.

Initiation

Exposure of subendothelial TF activates blood coagulation by binding to circulating plasma factor VIIa.[40,202] Before binding to TF, the plasma serine protease factor VIIa is essentially inert from the catalytic perspective and is, therefore, impervious to the abundant protease inhibitors in plasma.[203] Factor VII competes with factor VIIa for TF binding, thus serving as a negative regulator, buffering the overall reaction. The TF VIIa-factor Xa product complex is under tight supervision by TFPI.[204,205] If the initiating procoagulant stimulus is sufficient to overcome the level of this anticoagulation, a threshold is exceeded and the downstream complexes can form and lead to an explosive burst of thrombin generation. The small amounts of factor Xa produced that escape inhibition by TFPI and AT can activate small amounts of prothrombin to thrombin on an activated membrane surface.[206] Although this process is inefficient, this initial thrombin is essential to the acceleration of the process by serving as the activator for platelets, the procofactors factor V and factor VIII, and factor XI.[72] The initial thrombin also begins activating factor XIII to factor XIIIa[207] while converting some fibrinogen to fibrin,[142] and at this point clot formation is observed.

Propagation

Once the factor VIIIa is formed, it combines on activated platelets with IXa generated by the factor VIIa–TF complex to form the intrinsic tenase complex. This complex is the major activator of factor X; it is 50 times more efficient than factor VIIa–TF in catalyzing the activation of factor X[208,209] and is not under the control of TFPI.[210,211] In the absence of factor VIII or factor IX, the intrinsic tenase complex cannot be assembled; therefore, no amplification of factor Xa generation occurs. This is the principal defect observed in hemophilia A and hemophilia B.[212,213]

Factor Xa combines with factor Va on the activated platelet membrane and other surfaces at specific receptor sites[114,214,215] to form the prothrombinase complex, the principal generator of thrombin. This process serves as a major amplification loop of blood coagulation. Factors Xa and IXa, of the prothrombinase and intrinsic tenase complexes, respectively, are protected from inhibition by AT and other plasma inhibitors in their complexed form.[216] Furthermore, these membrane-bound enzyme complexes execute the propagation phase of the reaction, during which massive amounts of thrombin are produced efficiently and continuously, as long as more blood enters the wound site to resupply the procoagulant catalytic process.[217,218]

Termination

Once flow has ceased because of the formation of a fibrin-platelet "dam," the velocity of thrombin formation diminishes and the overwhelming concentration of inhibitors present in blood can "catch up" and inhibit the various proteases as they dissociate from their respective complexes. In the intact vasculature surrounding the growing thrombus, procoagulant enzymes and cofactors escaping the wound site are quenched rapidly under normal circumstances by the stoichiometric and dynamic inhibitory systems of blood in cooperation with elements of the vascular endothelium. Any thrombin escaping from the wound site may bind resident TM constitutively present on vascular endothelial cells. When it is TM bound, thrombin is converted from a procoagulant enzyme to an anticoagulant enzyme as part of the protein Case complex. Activation of protein C downregulates the intrinsic tenase and prothrombinase complexes by cleaving factors VIIIa and Va, whereas TAFI activations act to prolong clot lysis[53,219] When it is operating properly, this system of attenuation of blood leakage displays the appropriate level of procoagulant required to obstruct blood loss, but it is precluded from systemic activation of the coagulation system.

Elimination/Fibrinolysis

The thrombus restricting blood flow is structurally composed of aggregated platelets and cross-linked fibrin. Other plasma proteins and blood cells are also trapped within the clot. Clot formation is integrated with clot dissolution by plasmin to maintain hemostatic balance. The lytic system has two roles: t-PA generates plasmin at the fibrin surface and governs fibrin homeostasis, whereas u-PA binds to a cellular u-PA receptor and generates pericellular plasmin, which plays an important role in tissue remodeling and cellular migration. The latter function is, to a great extent, mediated by plasmin activation of matrix metalloproteinases, which degrade the extracellular matrix. t-PA and u-PA are secreted by vascular endothelial cells and regulated by cellular cytokines and components produced during the clotting cascade, including thrombin.

The elimination phase begins the process of tissue repair by dissolving the fibrin-platelet clot generated in the earlier phases of hemostasis. The damaged vascular tissue requires plasmin not only to clear the fibrin clot but also to initiate removal of damaged tissue so that cells can migrate into the injured area.[220,221] Plasmin activates a variety of matrix metalloproteinases that degrade subendothelial matrix components and extricate the damaged tissue.[222,223] These processes mark the beginning of the final stages of the hemostatic response: repair and regeneration.

The importance of tight regulation of these processes is perhaps best illustrated by malfunctions of the hemostatic response. An inappropriate response can lead to one of two opposing but equally undesirable outcomes. Failure to form a sufficient hemostatic plug to arrest blood flow subsequent to vascular injury can result in pathologic hemorrhage. Excessive clot formation or failure to efficiently lyse a clot may result in thrombosis with consequent vascular obstruction. Under normal circumstances, the vascular endothelium together with the aforementioned positive and negative feedback loops within the procoagulant pathways prevents these negative outcomes by actively controlling the coagulation process until a triggering stimulus of sufficient magnitude threatens vascular integrity. Initiation of the procoagulant response also initiates the fibrinolytic response simultaneously with the repair and regeneration processes.

BLOOD COAGULATION MONITORING

Most clinical assays use fibrin clot formation as a means to assess hemostasis (e.g., the prothrombin time (PT), activated partial thromboplastin time (aPTT) and thrombin time (TT) assays). These clinical clot-based assays were designed to be rapid; where the formation of a visible clot occurs during the initiation phase of coagulation at only 3% to 5% of the total amount of thrombin produced.[217,224] These clot end point assays have advanced our detection of clinical risk by being able to quickly distinguish certain protein defects in either the intrinsic or extrinsic pathways (Fig. 36.13); however, the majority of thrombin (>95%) is generated after clot formation during the propagation phase,[217] during which most hemostatic and thrombotic physiology is occurring, and is not captured by the fibrin clotting endpoint assays. The development of assays that capture the propagation phase dynamics are

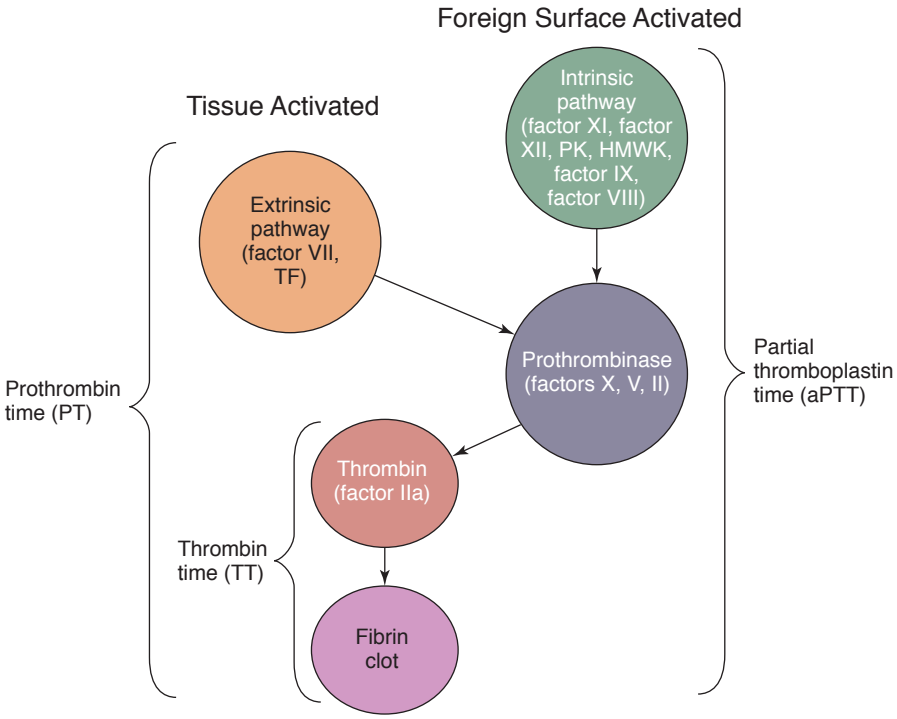

Figure 36.13 Schematic of plasma coagulation tests. The prothrombin time evaluates the tissue factor *(TF)* or extrinsic activated pathway of blood coagulation. This test uses thromboplastin as an initiator of blood coagulation. The plasma test for evaluation of the intrinsic (contact or accessory) pathway is referred to as the partial thromboplastin time. This test uses a foreign surface (e.g., kaolin or silica) as the activator of blood coagulation. The thrombin time, also known as the thrombin clotting time, specifically evaluates conversion of fibrinogen to fibrin through the action of thrombin. *HMWK,* High-molecular-weight kininogen; *PK,* prekallikrein.

leading to a more holistic view of each individual's clinical risk profile.

Plasma Clotting Tests

Fig. 36.13 represents a simplified continuity diagram for the coagulation system and interrogation of that system by common plasma assays, including the PT, aPTT, and TT. These tests are conducted with citrated plasma.

Prothrombin Time

The three main uses of the PT assay are the monitoring of warfarin therapy, the assessment of liver function in patients with severe liver disease, and the screening for deficiencies in the extrinsic and common pathways. This assay depends on the infusion of Ca^{2+} and exogenous TF-lipid preparation (thromboplastin, recombinant, or prepared from human placenta or rabbit brain) to citrated plasma. The intrinsic pathway contributions to coagulation in the PT assay are negligible because of the large amount of TF-lipid used. PT results are standardized by the international normalized ratio (INR).[225] This assay is most sensitive to factor II, factor V, factor VII, factor X, and fibrinogen; however, mild deficiencies in any of these factors can go undetected with the PT assay.

Activated Partial Thromboplastin Time

The continuity of the intrinsic pathway of coagulation is assessed by the aPTT, which involves adding phospholipid, Ca^{2+}, and a foreign "surface" (e.g., kaolin or silica) to citrated plasma in the absence of TF.[8] This test evaluates the ability of the intrinsic pathway catalysts (i.e., factor XII, prekallikrein, HMWK, factor XI, factor VIII, and factor IX) and components of the common pathway (i.e., fibrinogen, prothrombin, factor V, and factor X) to produce a clot. The primary utility of the aPTT is that it provides identification of the congenital hemostatic defects associated with hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency). The aPTT is also used to monitor therapy with unfractionated heparin and to detect the lupus anticoagulant.

Thrombin Time

The TT test detects direct inhibitors of thrombin or fibrin polymerization. It is particularly sensitive to heparin, fibrin degradation products, and hypofibrinogenemia or dysfibrinogenemia. Thus, this screening test is useful in evaluating a prolonged PT or aPTT by discriminating between a problem in thrombin generation and the inhibition of thrombin activity.

Thrombin Generation Assays

Aberrations in thrombin generation can affect the critical balance of many hemostatic processes that ultimately can result in bleeding and/or clotting. An integrated view of the ability of recalcified platelet-rich or platelet-poor plasma samples to generate thrombin on stimulation with either contact pathway activator or TF has more recently come into use. In the thrombin generation assay (TGA), thrombin, once produced, hydrolyzes a specific substrate to give a fluorescent signal that is continuously recorded and to provide an evaluation of the phases of thrombin generation.[226-228]

This assay has recently been adapted for use in whole blood,[228] and continued adaptations of TGA will ultimately lead to improved correlation between the diagnostic value of these tests and clinical outcome.[229,230]

Platelet Function Tests

Platelet function tests are used to aid diagnosis (e.g., impaired platelet function or thrombocytopenia), predict risk (e.g., hemorrhage or thrombosis), and monitor antiplatelet therapy. If platelets are not functioning normally or a thrombocytopenia is present, a patient is at an increased risk of excessive bleeding. A platelet count continues to be utilized as a first-line test, but the overall function of the platelet is more difficult to measure. Platelets are sensitive to manipulation and are prone to spontaneous activation in vitro. Assays to test platelet function include platelet aggregometry, platelet function analyzers, flow cytometry, and molecular biology techniques.[231-233]

Platelet Aggregometry

Platelet aggregometry allows the laboratory to test how particular stimulators (agonists) affect platelets in the milieu of plasma or whole blood. This test is used to diagnose inherited and acquired platelet function disorders. It is affected by aspirin and a variety of other drugs that alter platelet function. Platelet aggregometry does not mimic the physiologic processes of platelet adhesion, activation, and aggregation that occur during hemostasis in vivo. Other tests have been developed to simulate the in vivo processes that occur during vessel wall damage.

Instruments That Simulate Platelet Function in Vitro

The Plate Function Analyzer-100 (PFA-100) is the mainstay for platelet function screening in hospitals and screens platelet adhesion and aggregation under high shear conditions in response to defined agonists.[234,235] This test is sensitive to both platelet count as well as hematocrit. Although abnormal results are indicative of platelet dysfunction, they are not specific for any disorder. Furthermore, it has not been shown to be able to predict the likelihood that a patient will bleed excessively during surgery, and its full clinical utility is still being established.

Other platelet function tests have been developed to address existing gaps in our ability to analyze platelet function:[235] the Clot Signature Analyzer (CSA) can detect abnormalities in both global hemostasis and platelet function under high shear conditions,[236,237] while the Thrombotic Status Analyzer (TSA) measures both thrombotic and thrombolytic activities within nonanticoagulated blood[238] and is capable of detecting defective or excessive platelet function, and monitoring both antiplatelet and thrombolytic therapy. The VerifyNow system was developed to address the need for monitoring platelet receptor blockade in order to ensure optimal dosing of anti-GPIIb/IIIa therapy.[239] Finally, thromboelastography (described below) also tests platelet function in the context of the coagulation process.

Whole-Blood Assays

There is renewed interest in "global coagulation testing" with methods enabling on-site measurements of coagulation that provide rapid and continuous information on coagulation. The use of whole blood gives a better picture of the situation in vivo because all the blood components are allowed to interact during the test. The whole-blood, on-site assays in common use in surgery and cardiovascular percutaneous interventions are the activated clotting time (ACT) and thromboelastography.

Activated Clotting Time

The ACT, introduced by Hattersley in 1966,[240] is an adjusted aPTT test for samples of citrated whole blood. The ACT assay can evaluate the influence of coagulation inhibitors, such as heparin and the direct thrombin inhibitors.[241,242] It is one of the most frequently performed coagulation assays and has shown utility as a point-of-care evaluation of the hemostatic response in surgical and interventional suites to control treatment with intravenous unfractionated heparin during vascular procedures.[243]

Thromboelastography

Thromboelastography uses technology that has existed for more than 40 years.[244,245] The modern iterations of the thromboelastograph are computerized, user-friendly devices that provide on-site evaluations of clotting performance and the potency of in situ fibrinolysis. These devices are viscometers that measure the increasing viscosity of blood during the coagulation process, producing a time-based record. Viscoelastic measurements are currently being performed on one of two instruments using their proprietary reagents: rotational thromboelastography (ROTEM) and thromboelastometry (TEG). The thromboelastogram arises through movement of the cup (TEG) or the pin (ROTEM). As fibrin forms, this movement is impeded and transformed to a trace (Fig. 36.14) reflecting different phases of the clotting process from which different semiquantitative parameters that evaluate the quality and timing of clot formation and lysis are measured, including clot time (R), clot build-up and cross-linking (K and α), and overall strength of the fibrin clot (maximum amplitude, MA). Protracted evaluations yield parameters associated with clot lysis. To describe these viscoelastic changes, both systems have their own terminology. The viscoelastic measurement of a patient's blood sample is increasingly being used in clinical settings.[246] These settings include cardiac surgery,[247-250] liver transplantations,[251] sepsis trauma,[252-259] obstetrics,[260] anticoagulant activity,[261,262] and treatment with fibrinolytic agents.[263-267] Modifications of thromboelastography to measure platelet aggregation are also being utilized more in the clinical setting.[268,269]

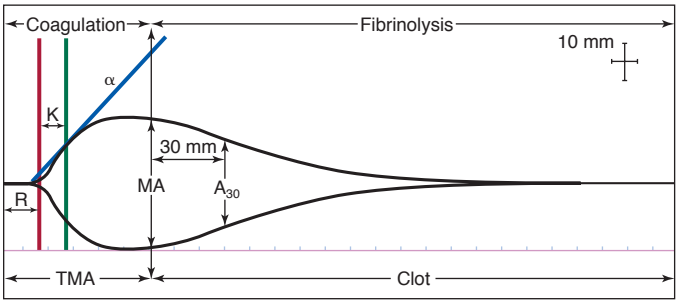

Figure 36.14 Representation of a thromboelastographic tracing. Evaluation of the quality and timing of clot formation and lysis is illustrated in terms of semiquantitative parameters: *R*, the reaction time, estimates the time to initial clot formation; *K* and α estimate the rate of fibrin formation and cross-linking; *MA* estimates the maximum amplitude of the fibrin clot and its strength; *TMA* calculates the time to MA. A_{30} is the amplitude at 30 minutes.

Future Coagulation Assays

Advancing technology will permit the translation of our ever-expanding understanding of blood coagulation physiology into even more refined and informative clinical assays. The advent of new, direct-acting procoagulants and anticoagulants is leading to the push for the development of new plasma-based and on-site whole-blood assays that will improve the reporting of the quality of an anticoagulant response, its monitoring, and its reversal.

Abstract

Coagulation is a physiologic defense mechanism aimed at maintaining the integrity of the circulatory system in the setting of vascular injury. There is a critical balance between coagulation and fibrinolysis aimed at preventing both pathologic hemorrhage and thrombosis. The surgeon is thus tasked with preventing adverse events by achieving adequate hemostasis without effecting extensive thrombosis. In this chapter, we review the pathophysiology of the coagulopathies that may lead to perioperative hemorrhage and highlight options for both diagnosis and treatment.

POSTOPERATIVE BLEEDING 479

Understanding the complex biology of coagulopathy and hemorrhage is imperative in the perioperative management of surgical patients. "Coagulopathy" is a term employed loosely in the literature and in the clinical setting. It is applied to patients without identifiable coagulation abnormality but with clinical bleeding or recurrent thrombosis as often as to patients with disseminated intravascular coagulopathy and significantly abnormal coagulation parameters, or those with specific inherited factor deficiencies. The *Gale Encyclopedia of Medicine* defines coagulopathy as a disorder in which blood is either too quick or too slow to coagulate (clot).[1] Coagulation is a physiologic defense mechanism aimed at maintaining the integrity of the circulatory system in the setting of vascular injury. There is a critical balance between coagulation and fibrinolysis aimed at preventing pathologic hemorrhage and thrombosis. The vascular surgeon is thus tasked with preventing adverse events by achieving adequate hemostasis without effecting extensive thrombosis, and an understanding of normal hemostasis is necessary to assimilate the pathophysiology of the coagulopathies and necessary treatments (see Chapter 36).

DIAGNOSIS AND PREOPERATIVE SCREENING FOR BLEEDING DISORDERS

Identifying patients preoperatively who are at risk for bleeding allows the surgeon to initiate corrective treatment before performing a surgical procedure and to plan for optimal perioperative management.

History and Examination

The key to minimizing perioperative hemorrhage is to identify patients at significant risk for hemorrhage or coagulopathy by means of a thorough history and physical examination. A detailed history should elicit any previous episodes of bleeding with prior surgery, dental extractions, or trauma as well as any easy bruising or epistaxis. A patient with a family history of significant hemorrhagic complications should be evaluated for increased bleeding risk. Complete drug and medication histories (including homeopathic or herbal remedies) are important to evaluate for agents that affect the clotting cascade. A history suggestive of hematuria or melena requires further investigation. Physical examination should identify any evidence of petechiae or excessive bruising.

Laboratory Testing

With the abundance of laboratory tests available for the evaluation of hemostasis, performing all of them is neither cost-effective nor necessary. One must adopt a systematic approach to selecting which, if any, laboratory studies a particular patient requires.

Risk Stratification

Rapaport devised the following four-level stratification scheme to determine the need for preoperative laboratory testing according to the patient's clinical status and bleeding history, and the planned operation[2]:

Level I

Patients who have no bleeding history and will undergo minor procedures, such as lipoma excision. No further hematologic evaluation is required because the cost of testing outweighs the probability of finding an abnormality and the risk of bleeding, even if one exists.

Level II

Patients who have no previous bleeding history but will undergo a major operation. Normal activated partial thromboplastin time (aPTT) and platelet count should effectively eliminate the risk of life-threatening bleeding.

Level III

Patients whose bleeding history raises concern for defective hemostasis and those whose procedure might impair hemostasis (e.g., cardiac or neurosurgical interventions). In these patients, preoperative evaluation of the following factors is appropriate:

1. Adequacy of hemostatic plug formation—bleeding time and platelet count
2. Adequacy of coagulation reactions—prothrombin time (PT) and aPTT
3. Size and stability of the fibrin clot—factor XIII deficiency and fibrinolysis screening

Level IV

A history or physical findings highly suggestive of abnormal hemostasis, and the surgical procedure is not a factor. In addition to performing the tests indicated for level III patients, the following should be considered (especially if the results of level III testing are normal):

1. Bleeding time after the administration of 600 mg of aspirin—to uncover von Willebrand disease (vWD) or a qualitative platelet disorder[3]
2. Factor VIII and factor IX levels
3. Thrombin time (TT)—to detect dysfibrinogenemia

Proper Blood Drawing

A properly drawn blood sample is paramount to interpreting the results of clotting tests; the specific methodology is beyond the scope of this chapter.[4] Whole blood is collected into an evacuated sample tube containing a fixed amount of citrate as an anticoagulant. The ratio of whole blood to citrate solution should be 9:1. An adult sample tube should be filled to at least 60% to 80% of its full collection volume to avoid excessive anticoagulation (a pediatric sample tube needs to be filled to 90% of its volume).[4] The anticoagulated blood should be mixed gently by being inverted three to four times. Testing should be done within 2 hours if the sample is kept at room temperature and within 4 hours if kept at 4°C. The screening tests used to determine the cause of coagulopathy are summarized on Table 37.1.

Specific Laboratory Tests (See Chapter 36)

Prothrombin Time

PT is used to assess the extrinsic pathway of clotting (factors II, V, VII, IX, and X and fibrinogen). The end point is the time required (in seconds) for a fibrin clot to form. Argatroban therapy and very high doses of heparin can also cause an elevated PT value secondary to thrombin (IIa) inhibition.[5]

Activated Partial Thromboplastin Time

The aPTT is used to assess the intrinsic pathway (factors VIII, IX, XI, and XII) and final common pathway (factors II, V, and X and fibrinogen) of clotting. Primary uses of aPTT include monitoring heparin therapy and detecting lupus anticoagulant, hemophilia A, and hemophilia B.

Thrombin Time

TT measures the conversion of fibrinogen to fibrin, which is the final step in the clotting pathway. Prolongation of TT is attributable to direct thrombin inhibitor (DTI) therapy, heparin, lytic administration, and dysfibrinogenemia.

Activated Blood Clotting Time

The activated clotting time (ACT) test is performed by addition of a coagulant-accelerating matrix (e.g., diatomaceous earth) to a sample of whole blood and measurement of the time required for clot formation. This method is generally used to monitor adequacy of heparinization in the operating room or interventional suite.

Bleeding Time

The bleeding time, or the time needed for a superficial wound to clot, is used to assess primary hemostasis. One measures bleeding time by making a controlled wound in the forearm or earlobe and subsequently measuring the time for clotting to occur.[6] Clotting that takes longer than 5 minutes is considered abnormal. Bleeding time is mainly affected by the number and function of platelets, although vasoconstriction or vasodilatation may affect the bleeding time as well. Other factors that prolong the bleeding time include heparin therapy (as a result of platelet inhibition), vWD, thrombocytopenia, aspirin or other antiplatelet therapy, and uremia.

Thromboelastography and Rotational Thromboelastometry

Thromboelastography (TEG) and rotational thromboelastometry (ROTEM) are point of care tests which measure real-time clot

TABLE 37.1 Tests of Coagulation and Clinical Uses

Test	Measured Variable	Causes of Abnormalities	Clinical Use
Prothrombin time (PT)	Factors II, V, VII, IX, and X; proteins C and S; tissue factor; fibrinogen	Consumptive coagulopathy, warfarin therapy, vitamin K deficiency, liver disease	Identify coagulopathy, monitor warfarin therapy
Activated partial thromboplastin time (aPTT)	All coagulation factors except factor VII	Consumptive coagulopathy, heparin therapy, lupus anticoagulants	Identify coagulopathy, monitor heparin therapy
Thrombin time (TT)	Fibrinogen (functional)	Consumptive coagulopathy, fibrinolysis, dysfibrinogenemia	Monitor fibrinolysis
Activated clotting time (ACT)	Global clotting function	Heparin use	Monitor intraoperative heparin therapy
Bleeding time (BT)	Platelet number and function	Abnormal platelet function, antiplatelet therapy, thrombocytopenia, uremia, von Willebrand disease	Evaluate platelet function
Thromboelastography (TEG)	Clotting kinetics	Anticoagulants, platelet deficiency/dysfunction, fibrinolytics	Liver transplantation, monitoring during/after cardiopulmonary bypass
Fibrin degradation products (FDPs)	Fibrinolysis	Consumptive coagulopathy	Identify coagulopathy
Euglobulin lysis time (ELT)	Fibrinolysis	DIC, primary fibrinolysis	Monitor fibrinolysis, adjunct to diagnosing DIC or primary fibrinolysis

DIC, Disseminated intravascular coagulation.

characteristics, including formation and dissolution kinetics, as well as in situ fibrinolysis.[7] Due to rapid turnaround time for these tests, they are useful for intraoperative monitoring of anticoagulation (e.g., cardiac surgery) as well as in goal-directed hemostatic therapy in a bleeding patient after trauma, surgery, or post-partum hemorrhage.[7-8] There is emerging data to support the use of TEG/ROTEM to guide blood product administration in patients on extracorporeal membrane oxygenation (ECMO).[9] Future studies may establish the utility of TEG/ROTEM for guiding anticoagulation on ECMO, especially in the pediatric population.[10-11]

Fibrin Degradation Products

Fibrin degradation products (FDPs) occur as the result of primary or secondary fibrinolysis. Elevations of their levels are seen in disseminated intravascular coagulation (DIC), cirrhosis, eclampsia, and trauma, and following lytic therapy. The FDP assay has few specific clinical applications except in the attempt to identify primary fibrinolysis.

Euglobulin Lysis Time

The euglobulin lysis time (ELT) is an assay used to assess global function of the plasma fibrinolytic system. It measures the time required for a clot to lyse in a test tube (the normal value is 90-240 minutes). For this test to be useful, a patient must have adequate clot formation. This test is used as part of a panel to help differentiate a primary fibrinolytic state from DIC. A shortened ELT in patients without thrombocytopenia or schistocytosis is diagnostic of primary fibrinolysis, whereas a shortened ELT with thrombocytopenia or schistocytosis probably indicates DIC. Reports imply that ELT can also be used to determine the presence of excessive tissue plasminogen activator (t-PA) and deficiency of plasminogen activator inhibitor.[12] A drawback of this assay is its significant reported interlaboratory variability.[13]

INHERITED COAGULOPATHIES

Platelet Disorders

Inherited platelet disorders are rare conditions with varying degrees of phenotypic severity. These disorders affect multiple aspects of platelet function, namely aggregation, secretion, adhesion, and procoagulant activity. There are a large number of rare conditions, the most common of which are described in the following sections.

von Willebrand Disease

von Willebrand factor (vWF) plays an important role in primary hemostasis by binding to both platelets and endothelial components, effecting formation of an adhesive bridge between them. vWF also contributes to clot formation by acting as a carrier protein for factor VIII.[14]

von Willebrand disease (vWD) is the most common inherited bleeding disorder. Although it affects about 1% of the population, only 5% of affected patients are symptomatic.[15] Clinical manifestations range from nil to severe bleeding, depending on the level of functional, circulating vWF. Easily identifiable but nonspecific symptoms include easy bruising, mucous membrane bleeding, prolonged epistaxis, postoperative bleeding, gastrointestinal bleeding, and heavy menstrual bleeding.[16,17] Previously undiagnosed patients sometimes have the first manifestation of the disease after taking antiplatelet agents such as nonsteroidal anti-inflammatory drugs (NSAIDs) and aspirin.

vWD is classified into three major types on the basis of clinical laboratory test results and genetic mutations, as delineated in Table 37.2. Type 2 comprises at least four subtypes with variable inheritance patterns. Patients with type 2A vWD (≈15% of all with vWD) have decreased platelet-dependent functions owing to loss of high-molecular-weight multimers. Those with type 2B disease (≈5% of all with vWD) have vWF with increased affinity for platelet glycoprotein Ib (GP-Ib). Type 2M is less common and results in reduced binding of vWF to platelet GP-Ib despite the presence of large vWF multimers. Patients with type 2N disease have mutations that alter the vWF binding site for factor VIII. Impaired binding effects rapid clearance of factor VIII.[15]

If vWD is suspected, the initial screening tests are (1) bleeding time, (2) closure time (vWF-dependent platelet function), (3) platelet count, and (4) aPTT. If results of these studies are positive or suspicious, more specific testing is pursued (Table 37.3).[14,18-20]

Treatment decisions are based on severity of symptoms and type of vWD. Symptomatic patients should avoid NSAIDSs. Desmopressin (DDAVP) is effective in patients with type I vWD perioperatively and in those with mild to moderate bleeding episodes. Patients with type 3 and severe forms of type 2A, 2B, and 2M disease usually require replacement therapy with vWF, factor VIII–vWF concentrates, or cryoprecipitate. In general, the goal of treatment in these patients is to maintain

TABLE 37.2 Types of von Willebrand Disease

Type	Transmission	Percentage of Cases of vWD (%)	Defect	Phenotype
1	AD	75	Quantitative deficiency of vWF	Mild-moderate bleeding
2	Autosomal but varied	20%	Multiple qualitative defects (2A,2B, 2M, 2N)	Variable
3	AR	5	Absence/severe decrease in vWF	Severe bleeding

AD, Autosomal dominant; *AR,* autosomal recessive; *vWD,* von Willebrand disease; *vWF,* von Willebrand factor.

TABLE 37.3 Tests for von Willebrand Disease

Test	Evaluates	Type in Which Abnormality Seen
Plasma vWF antigen	Quantitative defects (presence)	1,3
Ristocetin cofactor activity	Agglutination requires largest vWF multimers	2A, 2M
Factor VIII coagulant activity	Factor VIII half-life and secretion depend on vWF	1,3
Ristocetin-induced platelet aggregation (RIPA)	vWF concentration and affinity for GP-Ib	2A, 2M, 3
vWF multimer distribution	Presence of high-molecular-weight multimers	2A, 2B
vWF: factor VIII binding assays	Affinity of factor VIII: vWF binding	2N (vs. hemophilia A)

the activity of factor VIII and vWF between 50% and 100% for 3 to 10 days to address episodes of serious bleeding or for major surgery.[16]

Giant Platelet Disorders

Giant platelet disorders are a group of rare disorders characterized by thrombocytopenia, large platelets, and variable bleeding symptoms. They are generally subcategorized into four groups: those with a structural defect (e.g., Bernard-Soulier syndrome with glycoprotein abnormalities), those with abnormal neutrophil inclusions (e.g., May-Hegglin anomaly), those with systemic manifestations (e.g., hereditary macrothrombocytopenia with hearing loss), and those with no specific abnormalities (e.g., Mediterranean macrothrombocytopenia).[21]

Bernard-Soulier syndrome, the most common of these platelet disorders, is characterized by thrombocytopenia, large platelets, and bleeding. It is attributed to dysfunction or absence of the GP-Ib/IX/V complex, which is a primary adhesion receptor of platelets.[21] The disorder manifests early in life as bleeding symptoms, most frequently epistaxis or gingival or cutaneous bleeding. Frequently, a severe hemorrhagic episode is noted after surgery (e.g., circumcision). Laboratory findings include thrombocytopenia ranging from less than 30 to $200 \times 10^3/\mu L$ (normal) and a prolonged bleeding time with normal clot retraction.[21,22] Management of patients with this syndrome usually entails education and avoidance of minor trauma. In the event of significant hemorrhage, platelet transfusion is generally indicated.[23]

Glanzmann's Thrombasthenia

Glanzmann's thrombasthenia is an autosomal recessive disease with a large number of reported mutations. A defect in GP-IIb/IIIa renders platelets unable to aggregate.[24,25] Normal GP-IIb/IIIa allows platelets to bind soluble proteins and vWF. In Glanzmann's thrombasthenia, platelets can attach to exposed endothelium but cannot form aggregates. A wide spectrum of phenotypic severity is reported, but mucocutaneous bleeding and the absence of platelet aggregation are classic findings.[26] Significant bleeding episodes typically require platelet transfusion.[21,24,27]

Storage Pool Disorders

Storage pool disorders result from platelet granule deficiencies. The granules are usually divided into two groups: alpha granules (which contain vWF, thrombospondin, fibrinogen, and platelet-derived growth factor) and dense granules (which release adenosine diphosphate [ADP] and serotonin). Gray platelet syndrome is an example of an alpha-granule storage disorder.[28] This autosomal recessive disorder results in granules deficient in secretory proteins. Manifestations are typically limited to mucosal bleeding, but trauma-associated hemorrhage can occur. Laboratory analysis reveals moderate thrombocytopenia and a prolonged bleeding time. Preprocedural DDAVP and platelet transfusions form the basis for treatment.

Dense-granule deficiencies include Chédiak-Higashi syndrome, Wiskott-Aldrich syndrome, and thrombocytopenia-absent radius syndrome.[29] Wiskott-Aldrich syndrome is an X chromosome-linked immunodeficiency manifested as thrombocytopenia with platelets of reduced size and function as well as eczema.[30] A defect in glycoprotein L115 (a leukocyte/platelet surface molecule) yields platelets that are unable to form aggregates.[30,31] Patients with the syndrome are typically diagnosed in early childhood with the constellation of thrombocytopenia, atopic dermatitis, and frequent infections. The only curative therapy is bone marrow transplantation. If platelet transfusion is required prior to transplantation, HLA-selected platelets should be used and all blood products should be irradiated.[31]

Hemophilia

The hemophilias are inherited bleeding disorders caused by low concentrations of specific coagulation factors.

Pathogenesis

The most common hemophilias are X-linked deficiencies of factor VIII (hemophilia A) and factor IX (hemophilia B).[32] Factor XI deficiency (hemophilia C) is a less common autosomally transmitted disorder. Factor VIII is a complex plasma glycoprotein produced by liver sinusoidal endothelial cells and by vascular endothelial cells.[33] It has a half-life of 12 hours in adults and is protected from premature degradation by vWF. Factor IX is a vitamin-K-dependent protein synthesized by the liver with a plasma concentration approximately 50 times that of factor VIII and a half-life of 24 hours.[34] Bleeding in hemophilia results from a failure of secondary hemostasis. Although a normal platelet plug forms, stabilization of the plug by fibrin is defective owing to inadequate amounts of thrombin.

Diagnosis

Hemophilias A and B are clinically indistinguishable. A diagnosis of hemophilia is confirmed by an assay for the specific factor. However, factor VIII deficiency secondary to hemophilia A

requires distinction from vWD by assays for vWF. Depending on the concentration of the factor, the bleeding tendency is classified as mild, moderate, or severe.[35] Mild disease has a factor VIIIc or IXc concentration between 0.05 and 0.40 IU/mL (5%-40% of normal) with bleeding manifestations after surgery, dental intervention, or trauma. Spontaneous bleeding is not seen. Moderate disease translates to a factor VIIIc or IXc concentration of 0.01 to 0.05 IU/mL (1%-5% of normal). This concentration can result in bleeding into muscles and joints following minor injury. Major surgical or dental intervention effects severe hemorrhage.[34] Severe disease is seen with a concentration of factor VIIIc or IXc of less than 0.01 IU/ml (<1% of normal).

Though most cases of hemophilia are identified via family history, some appear as de novo mutations. Whereas severe disease is typically diagnosed by 2 years of age, mild or moderate disease may not be recognized until adulthood. The hallmark of severe hemophilia is spontaneous bleeding into joints and muscles.

Management

The primary goal of treatment is to sufficiently increase the concentration of the missing factor to stop or prevent spontaneous, traumatic, or surgical hemorrhage. A critical aim is to aggressively treat and prevent joint bleeding, which otherwise can lead to crippling arthropathy and joint deformity.[36] Primary prophylaxis (prior to any episode of joint hemorrhage) to prevent this devastating complication is now recommended, with most centers recommending initiation prior to 3 years of age.

Although DDAVP can sufficiently raise factor VIII levels in patients with mild hemophilia A, factor concentrations are typically required for more significant disease. Multiple factor VIII and IX concentrations are available as either recombinant or plasma-derived products. For prophylaxis of a nonbleeding patient, a factor VIII concentration of 3% is considered adequate. A level of 30% is required for minor bleeding, and 50% for major bleeding. Prior to elective surgery, a factor VIII level greater than 80% is recommended, with a goal of 30% to 50% to be maintained in the first 2 postoperative weeks. The goals for hemophilia B include a factor IX level of 30% for minor bleeding and greater than 50% for major bleeding.[37]

In some patients who undergo long-term replacement therapy, antibodies against factors VIII and IX develop. For these patients, recombinant factor VIIa (rFVIIa) or activated prothrombin complex concentrates might be necessary to achieve hemostasis. These agents act by bypassing the need for factors VIII and IX to achieve coagulation. The long-term goal for patients with high antibody titers is immune tolerance induction therapy, which results in a gradual reduction of antibody titers and increased tolerance of factor replacement therapy.

ACQUIRED COAGULOPATHIES

Platelet Disorders

Acquired platelet dysfunction has myriad causes, including uremia, liver dysfunction, cardiopulmonary bypass, hypersplenism, hematologic malignancy, thrombotic thrombocytopenic purpura, and immune thrombocytopenic purpura. These processes can result in quantitative or qualitative platelet deficiencies and should be considered in any investigation of abnormal bleeding, especially that accompanied by thrombocytopenia.

Liver disease evokes thrombocytopenia via portal hypertension with splenic sequestration as well as by decreased thrombopoietin production. Cardiopulmonary bypass and mechanical assist devices place platelets in contact with nonphysiologic machine surfaces, which result in pathologic alterations in surface glycoprotein expression. Activation of these glycoproteins results in granule release as well as decreased endothelial adhesion and aggregate formation.

Uremia

Although bleeding diatheses secondary to uremia are not completely understood, it is clear that platelet dysfunction plays a critical role. Uremia results in both intrinsic platelet defects and alteration of platelet-endothelial interaction.[33] Changes have been described in GP-IIb/IIIa, in ADP release from alpha granules, and in the arachidonic acid pathway.[38]

Uremic patients can exhibit easy bruising and mucosal bleeding. Laboratory evaluations demonstrate a prolonged bleeding time in the setting of normal values for PT, aPTT, and platelet count. Directed treatment is typically reserved for major surgery or active bleeding, including correcting anemia to a hematocrit of 25% to 30% (to improve platelet aggregation and adhesion) and the administration of DDAVP (to enhance release of vWF) and/or conjugated estrogen (unknown mechanism).[39] Dialysis is the most effective treatment for uremic complications.

Vitamin-K-Related Disorders

Factors II, VII, IX, and X as well as proteins C and S require vitamin K for activation. Functional impairment of these factors is due to failure of vitamin-K-dependent carboxylation. The cause is typically lack of vitamin K (malnutrition or malabsorption due to biliary obstruction or gut bacterial overgrowth) or pharmacologic blockade of vitamin K (warfarin).

Treatment entails either functional factor replacement (FFP) or vitamin K (allowing carboxylation of patient's factors) to address active bleeding or in anticipation of surgical intervention. FFP acts quickly as a direct replacement without the need for enzymatic reactions; it has an immediate effect that lasts about 6 hours. Vitamin K takes at least 6 hours to take effect but exerts a more durable reversal.

Disseminated Intravascular Coagulation

DIC is systemic activation of the coagulation cascade that induces both thrombosis and hemorrhage.

Pathogenesis

DIC is primarily caused by uncontrolled production of thrombin, which leads to systemic intravascular deposition of fibrin. The inciting factor is generally vascular injury or intravascular exposure to a procoagulant, which results in initiation of normal

TABLE 37.4 Mechanisms for Common Causes of Disseminated Intravascular Coagulation

	Mechanism
Sepsis	Extrinsic pathway Thrombin generation Suppression of protein C/thrombomodulin system[36,37,126]
Major tissue injury	Direct endothelial injury Release of phospholipids and enzymes to circulation
Malignancy	Expression of tissue factor by circulating tumor cells Procoagulant: calcium-dependent cysteine protease[38] Directly activates factor X

hemostasis. Normally, thrombin generation is tightly regulated by a combination of intravascular and endothelial factors. In DIC, these inhibitory mechanisms become dysfunctional or overwhelmed, leading to the production of excess thrombin. The increased circulating levels of thrombin provoke greater fibrin production with microvascular deposition. Thrombosis of the microvasculature causes the end-organ damage seen in severe DIC. The systemic thrombosis activates t-PA, which causes thrombolysis, consumptive coagulopathy, and bleeding diathesis.

Etiology

The most common precipitants of DIC are sepsis, extensive traumatic tissue injury, cancer, amniotic fluid embolism, and placental abruption. The final common pathway for all of these entities is systemic activation of the coagulation cascade. Proposed specific mechanisms are delineated in Table 37.4.[40-43]

Clinical Phases

Even though DIC is a continuously progressing cascade of events, it can be described as three major clinical phases.[44] They are described here, and their typical laboratory findings are delineated in the Table 37.5.

Management

The overriding goal in the management of DIC is correction of the precipitating disease. Supportive therapy generally necessitates replacement of clotting factors and platelets while the inciting process is addressed. In patients with active bleeding, very aggressive replacement is pursued. Goals of resuscitation include a fibrinogen level over 100 mg/dL. Management also requires achieving and maintaining normothermia and adequate tissue perfusion. There is little evidence to support heparin therapy in acute DIC. During the supportive phase, emphasis should be put on correcting the underlying pathologic process, the achievement of which will, in turn, stop the activation of the cascade. For instance, in septic patients, broad-spectrum antibiotics, abscess drainage, and debridement of infected or necrotic tissues is critical.

TABLE 37.5 Coagulation Parameters in Disseminated Intravascular Coagulation

	Phases of DIC[a]		
	Phase I	Phase II	Phase III
Prothrombin time	Normal	↑	↑↑
Activated partial thromboplastin time	Normal	↑	↑↑
Platelet count	Normal	↓	↓↓
Thrombin time	Normal	Normal/↑	↑↑
Thombin-antithrombin complex (TAT)	↑	↑	↑
Prothrombin fragment F_{1+2}	↑	↑	↑
Fibrinogen	Normal	↓	↓↓
Fibrin degradation products	Normal	↑	↑↑

[a]Phases of DIC are defined as follows:
Phase I: Compensated activation of the hemostatic system. Patients are asymptomatic.
Phase II: Decompensated activation of the hemostatic system. Hemorrhage from injuries and venipuncture sites becomes evident. Renal, hepatic, and pulmonary function are impaired. Frequent laboratory analyses are indicated during this phase due to rapid ongoing changes.
Phase III: Complete DIC. Patients have numerous ecchymoses and multi-organ failure. Laboratory tests demonstrate consumption.

DIC, Disseminated intravascular coagulation; ↑, increased (no. of arrows indicates extent of increase); ↓, decreased (no. of arrows indicates extent of decrease).

Primary Fibrinolysis

Fibrinolytic system derangements can result in either excessive bleeding or thrombosis. It is essential to differentiate primary fibrinolysis from secondary fibrinolysis (DIC) because of their differing management strategies.

Fibrinolytic System (See Chapter 36)

Plasminogen circulates as an inactive zymogen. Activation of plasminogen by t-PA or urinary-type plasminogen activator (u-PA) results in its conversion to plasmin, a serine protease that degrades fibrin. Inhibitors of plasmin include plasminogen activator inhibitor (inhibits tissue and u-PA) and α2-antiplasmin (hepatic production). Thrombin-activatable fibrinolysis inhibitor (TAFI; a procarboxypeptidase activated by thrombin-antithrombin complex [TAT]) also constrains fibrinolysis by cleaving the C-terminal lysine residue of fibrin fragments. This disruption prevents recruitment of plasminogen to a partially digested clot, thereby inhibiting fibrinolysis.

Pathogenesis

In this complex plasmin-plasminogen activator system, excessive bleeding can result from hyperactivity of plasminogen activators

or deficient activity of fibrinolysis inhibitors. In primary fibrinolysis, there is pathologic direct activation of plasminogen. Excess circulating plasmin saturates plasminogen activator inhibitor-1 and α2-antiplasmin and cleaves fibrin and clotting factors, including factors V and VIII. Plasmin generated on the surfaces of platelets and endothelium inappropriately lyses hemostatic plugs. To counter the excess plasmin and fibrinolysis, excess thrombin is generated, resulting in microvascular thrombosis.

Etiology/Diagnosis

A primary hyperfibrinolytic state can develop in multiple clinical settings, including malignancy, liver failure, trauma, and congenital deficiency of fibrinolysis inhibitors.[45,46] Differentiating primary fibrinolysis from a secondary process, such as DIC, can be exceedingly difficult. The simplest laboratory findings to diagnose primary fibrinolysis are a short euglobulin lysis time in the absence of thrombocytopenia and the presence of schistocytes. Though challenging, the distinction between these two entities is critical as they require quite dissimilar treatments.

Management

The crux of treatment is the inhibition of fibrinolysis using lysine analogues. The lysine analogues, aminocaproic acid and tranexamic acid, act as competitive inhibitors of the conversion of plasminogen to plasmin.[42] Often, factor replacement is also required, typically factors V and VIII. Prior to its removal from the market, aprotinin was also used as a therapy for this disorder.[43]

DRUG-INDUCED COAGULOPATHIES

Heparins

Heparin is a naturally occurring, highly sulfated glycosaminoglycan. Heparin prevents clot formation and propagation by binding to and activating antithrombin. The resulting conformational change in antithrombin accelerates its ability to inactivate factors II (thrombin), Xa, and IXa.[47] Heparin can be monitored via ACT or aPTT, both of which demonstrate prolongation. Heparin is available for subcutaneous (half-life 8 hours) or intravenous (half-life 1.5 hours) administration. Intravenous heparin is frequently used for intraprocedural anticoagulation because of its short half-life, point-of-care monitoring, and ease of reversal (protamine at 1 mg per 100 U intravenous heparin).[48]

Enzymatic depolymerization of unfractionated heparin results in fragments that are approximately a third the size of heparin. These are marketed as low-molecular-weight heparins (LMWHs; such as enoxaparin and fondaparinux). Administered subcutaneously, these agents offer a longer half-life and greater bioavailability than heparin.[48] Benefits of LMWHs include ability to be given once or twice daily and decreased need for laboratory monitoring for therapeutic use. The risk of bleeding with LMWH prophylaxis is low and is comparable to that seen with prophylactic subcutaneous heparin. Withholding fully therapeutic LMWH for 24 hours prior to major surgical intervention is recommended. There is no described benefit in protamine for reversal of LMWHs.[49] The use of either type of heparin risks heparin-induced thrombocytopenia. Briefly, patients with this disorder form antibodies to the complex of heparin and platelet factor IV on platelet surfaces. The presence of the antibodies leads to uncontrolled platelet activation and pathologic thrombosis.

Thrombin Inhibitors

Intravenous DTIs include hirudin, lepirudin (recombinant hirudin), argatroban, and bivalirudin. The most common indication to use any of these agents is for the treatment of patients with heparin-induced thrombocytopenia. In contradistinction to heparins, these agents can bind to and inactivate clot-bound thrombin (a strong thrombogenic stimulus).[50] Furthermore, in comparison with heparins, DTIs have a more predictable response and are not impacted by acquired or inherent antithrombin deficiency. A brief review of these agents is shown in Table 37.6.

Oral Anticoagulants

Warfarin

Warfarin is an orally administered vitamin K antagonist (VKA). It acts by preventing vitamin-K-dependent carboxylation of factors II, VII, IX, and X and of proteins C and S. The liver synthesizes nonfunctional forms of these proteins, which require carboxylation to become active. Following initiation, warfarin typically requires 2 or 3 days to take effect. Owing to the relatively shorter half-lives of proteins C and S in comparison with the clotting factors, a heparin bridge is sometimes required at the initiation of warfarin therapy to prevent sequelae of a paradoxically hypercoagulable state. The earlier loss of the anticoagulant effect of protein C or S (more commonly problematic in patients with protein C or S deficiency) can result

TABLE 37.6 Intravenous Direct Thrombin Inhibitors

	Half-Life (min)	Monitoring Test	Disadvantages
Hirudin	40-50	aPTT	Expensive Narrow therapeutic window No antidote Problematic in renal dysfunction
Lepirudin	60-100	aPTT	Expensive Problematic in renal dysfunction Antigenic
Bivalirudin	25	aPTT Activated clotting time	Expensive
Argatroban	45	aPTT	Problematic in hepatic dysfunction Expensive

aPTT, Activated partial thromboplastin time.

in small vessel thrombosis, which manifests as warfarin-induced skin necrosis. This entity, if encountered, is treated with the cessation of warfarin and the initiation of therapeutic heparin.[51]

Direct Oral Anticoagulants

The impetus to find alternative agents included the need for frequent monitoring due to multiple food and drug interactions and a less predictable anticoagulant effect based on weight, requiring multiple adjustments. Two new classes of oral anticoagulants were developed with the goal of improving monitoring and safety: factor Xa inhibitors (rivaroxiban, apixaban, edoxaban) and DTIs (dabigatran and ximelagatran). The advantages of these agents, which have been termed direct oral anticoagulants (DOACs), include significant reductions in the need for laboratory monitoring, and shorter half-lives, which may aid in preoperative planning. The safety and efficacy of DOACs has been confirmed in randomized trials for multiple indications. These include perioperative prevention of venous thromboembolism (VTE), prevention of embolic events in atrial fibrillation, treatment of venous thromboembolism, thrombo-prophylaxis in major orthopedic surgery, and acute coronary syndrome.[50,52,53,54] However, further research is necessary to evaluate the efficacy of DOACs for the treatment of VTE associated with cancer or antiphospholipid syndrome, where the recurrence risk is high.[54] While the benefit of oral anticoagulation without frequent monitoring is obvious for the pediatric population, most trials to date have been in adults. No DOACs are currently approved for children, although several trials are currently ongoing.[55]

The disadvantages of DOACs compared with VKAs include the lack of a known effective reversal protocol with known antidotes and lack of a simple laboratory test to evaluate efficacy.[50] Since plasma and cryoprecipitate do not reverse the anticoagulation effect of DOACs, local management plans including mechanical compression, blood transfusion, and surgical and radiologic intervention must be developed. Life-threatening bleeding may require off-label use of hemostatic agents such as prothrombin concentration complex (PCC) and recombinant factor VIIa. Specific antidotes for DOACs are being developed, including the human monoclonal antibody idarucizumab specific for dabigatran, which has completed phase III clinical trials.[56] With increased attention to the need for reversal of the anticoagulant effects of DOACs, other promising antidotes are in clinical safety trials or drug development.[57]

Also, since many DOACs have yet to be compared in head-to-head trials, choosing a specific DOAC for an individual patient can be challenging.[58] Furthermore, dosing adjustments for renal impairment differ from agent to agent, requiring a high level of clinical knowledge and experience to prevent dosing errors. There has also been some controversy over the description of a possible increase in myocardial infarction rate in patients treated with dabigatran.[52]

Antiplatelet Agents (See Chapter 40)

Antiplatelet agents, such as aspirin, thienopyridines, clopidogrel, and ticlopidine, are most often used in patients who have had previous cerebrovascular events, recent acute coronary syndrome, or peripheral vascular disease, or who have undergone peripheral or coronary interventions. Aspirin irreversibly inactivates platelet cyclooxygenase with the resulting inhibition of platelet production of thromboxane A_2. Clopidogrel and ticlopidine block platelet ADP receptors, effecting decreased GPIIb/IIIa expression. The duration of effect of all of these agents is 5 to 7 days because reversal requires the synthesis of new platelets.

Decisions regarding perioperative cessation of antiplatelet agents are frequent areas of debate. Most later reports favor continuation of these agents when possible throughout the perioperative period. Ultimately, the determination depends on the indication for antiplatelet therapy as well as the extent of planned surgery and its attendant bleeding risk. Studies suggest that withdrawal of aspirin therapy in anticipation of coronary artery bypass grafting is associated with an elevated in-hospital mortality risk.[53,59] This finding was echoed in the analyses of the peripheral bypass population.[60]

Recommendations for patients with coronary stents who are taking clopidogrel are well-delineated. In this population, elective surgery should be postponed for at least 6 months for bare metal stents and 1 year for patients with drug-eluting stents in order to avoid interruption in therapy.[61] When therapy can safely be interrupted, cessation of clopidogrel or ticlopidine should occur 5 days prior to elective operation.

Abciximab and eptifibatide are antiplatelet agents that act via inhibition of GP-IIb/IIIa. Abciximab, frequently used during coronary procedures, is synthesized from Fab fragments of anti-GPIIb/IIIa immunoglobulins.[62] The result is inhibition of platelet aggregation. Platelet aggregation typically returns to normal 24 to 48 hours after cessation of therapy because of the agent's short half-life. Platelet transfusion can be used for emergency reversal because abciximab remains strongly bound to native platelets. Eptifibatide also decreases platelet aggregation and prolongs bleeding time.[63] It binds reversibly to GP-IIb/IIIa with a half-life of 2.5 hours. Platelet transfusion is not effective to reverse this agent.

A newer class of antiplatelet agents targets the platelet $P2Y_{12}$ receptor for ADP (collectively called $P2Y_{12}$ inhibitors). Agents are available for intravenous (elinogrel, cangrelor) or oral (ticagrelor, elinogrel) administration. These drugs are direct-acting inhibitors of the receptor. This alternative mechanism of action is important because about 30% of patients show inadequate platelet inhibition with clopidogrel therapy. The $P2Y_{12}$ inhibitors also have rapid onset and offset of platelet inhibitory action. This feature allows them to serve as a bridge therapy (when clopidogrel needs to be stopped in anticipation of an invasive intervention) as well as an alternative when clopidogrel fails. Although the efficacy of these agents is at least comparable to that of clopidogrel, there is some suggestion of higher bleeding complication rates with elinogrel.[64-66]

Therapeutic Thrombolysis

Thrombolytic agents are all plasminogen activators that directly or indirectly convert plasminogen to plasmin. Plasmin then

degrades fibrin and fibrinogen as well as additional factors, such as prothrombin and V and VII. The most commonly used agents are urokinase, tenecteplase, reteplase, and alteplase (t-PA). Thrombolytics are thoroughly discussed in Chapter 41. These agents can be used systemically or in a more directed fashion.

HYPOTHERMIA

Because coagulation factors are enzymes, their activity is substantially impaired by extremes of temperature or pH. Hypothermia in vascular surgery can result from insufficient ambient temperature, prolonged operative time, excessive blood loss, and the administration of cold fluid and blood products.[67] Results of laboratory studies can be falsely reassuring as the studies are routinely performed after sample warming to 37°C, which does not reflect the current patient condition.[68]

Maintenance of normothermia is critical during vascular procedures. Measures that should be undertaken to prevent heat loss include ambient temperature control, the use of warming blankets to cover the body except for the surgical field, and the use of warm, humidified air in the ventilator circuit. Intravenous fluids and blood products can also be warmed with countercurrent warming systems. Warming of inspired air can contribute significantly to maintenance of normothermia, increasing patient temperature as much as 3.5°C in 20 minutes.[69] Efforts to minimize the duration of the procedure and the extent of blood loss are also effective. Generally, active rewarming approaches, such as body cavity lavage, cardiopulmonary bypass, and continuous arteriovenous rewarming, are reserved for severe hypothermia related to trauma or submersion injuries.[70]

ACIDOSIS

It is well recognized that acidosis impairs normal coagulation. Later studies have suggested that its major inhibitory effect is on thrombin generation in the propagation phase of clotting, although the exact mechanism has yet to be fully elucidated. As in hypothermia, prolonged bleeding times in acidosis are believed to be related to the slowing of enzymatic reactions. For example, a pH decrease from 7.4 to 7.0 results in a reduction in factor VIIa activity by more than 90% and in factor VIIa–tissue factor complex by more than 60%.[70,71] Acidosis is often seen in surgical settings related to bacteremia, in septic or cardiogenic circulatory compromise, and in other hypoperfusing states. In vascular surgery, it is often seen following reperfusion of large ischemic areas.

The most effective treatment of coagulopathy related to acidosis is to identify and address the underlying cause of the acidotic state. In sepsis, this process generally involves broad-spectrum antibiotics and aggressive drainage and/or débridement of infected tissue. If hypoperfusion is the cause of acidosis, volume repletion and inotropic support may be required. If reperfusion injury is anticipated, preemptive induction of respiratory and metabolic alkalosis prior to arterial clamp removal can reduce resulting acidosis.

DILUTION

Coagulopathy secondary to dilution is common and is frequently overlooked. Large-volume resuscitation in the form of red blood cells (RBCs) or crystalloid or colloid fluids result in decreased plasma concentrations of coagulation factors and platelets. This relative depletion can lead to coagulopathy, especially in the setting of active bleeding. Some reports also suggest that hydroxyethyl starches, gelatins, and dextran solutions impair platelet function and interfere with fibrin polymerization. Hypertonic saline is also recognized to have anticoagulant and antiplatelet effects.[70] Literature from the military has emphasized dilutional coagulopathy in the setting of massive transfusion. Studies have also demonstrated the importance of high ratios of FFP to packed RBCs (PRBCs) and, to a lesser extent, of platelets to PRBCs to prevent this problem in trauma resuscitations.[72,73]

TREATMENT

Treatment of clinically significant bleeding prioritizes therapies tailored to the etiology of bleeding and the maintenance of adequate perfusion. The surgeon should emphasize the determination of the cause of bleeding to appropriately tailor therapy. The currently available resuscitation and product replacement factors are summarized in Table 37.7.

Packed Red Blood Cells

PRBCs are the most commonly transfused blood component. They are typically used to replace intraoperative or traumatic losses and to restore oxygen-carrying capacity. After blood donation, RBCs are separated out to create a concentrated product with 42.5 to 80 g of hemoglobin. The idea of a threshold hematocrit to trigger transfusion is debated. There is a move toward administering transfusion only in the presence of symptomatic anemia or ongoing or expected significant blood loss. The reasons for this paradigm shift are multifold. Studies have demonstrated that transfusing RBCs to a target hemoglobin of 7 g/dL rather than 10 g/dL did not adversely affect patient outcome.[74,75] In addition to concerns regarding infection transmission and transfusion reactions, data have been published describing problematic storage lesions in banked blood that may actually worsen patient oxygenation rather than improve it with transfusion.[76] There are also studies demonstrating significantly worse outcomes with a liberal compared to a conservative transfusion strategy. These outcomes include increases in postoperative infections, in-hospital mortality, lengths of stay in hospital and intensive care unit, and the duration of mechanical ventilation.[75,77-81] The American Society of Anesthesiologists Task Force on Perioperative Blood Transfusion and Adjuvant Therapies recommends that in otherwise healthy patients, hemoglobin levels be maintained at 6 g/dL (60 g/L) or above.[82] The adequacy of oxygen delivery must be assessed in individual patients, particularly those with limited cardiac reserve or significant atherosclerotic vascular disease. The initiation of transfusion should be based on developing signs of

TABLE 37.7 Blood/Coagulation Factor Replacements for Achieving Hemostasis

Resource	Dose and Effects	Product Content	Use
Packed red blood cells	1 unit (350 mL) increases hemoglobin level by 1 g/dL (10 g/L)	Red blood cells	Symptomatic anemia (guideline hemoglobin level <6 g/dL if healthy), massive hemorrhage, decreased oxygen-carrying capacity
Platelets	1 unit (250 mL) increases the platelet count by 30,000-60,000/μL	Platelets, clotting factors	Thrombocytopenia, massive hemorrhage, platelet function deficit
Fresh frozen plasma	1 unit (250 mL)	All coagulation factors, especially factors II, VII, IX, and X, proteins C and S, and antithrombin III	Bleeding from warfarin therapy, massive transfusion, thrombotic thrombocytopenic purpura, coagulation factor deficiencies, antithrombin III deficiency
Cryoprecipitate	20 mL contains 200 mg fibrinogen, 70-80 units of factor VIII	Fibrinogen, factors V, VIII, and XIII, and von Willebrand factor	Hypofibrinogenemia, massive hemorrhage
Desmopressin	0.3-0.4 μg/kg	Stimulates release of von Willebrand factor	Uremic platelet dysfunction, some von Willebrand disease cases with bleeding
Vitamin K	10 mg intramuscularly, intravenously, or subcutaneously	Restores the function of factors II, VII, IX, X, protein C, and protein S	Liver dysfunction, bleeding from warfarin therapy
Protamine sulfate	1 mg neutralizes 100 units of heparin	Heparin antagonist	Reversal of heparin therapy
Factor VII	50 μg/kg (20-90 μg/kg)	Recombinant factor VIIa	Hemophilia, massive hemorrhage
Aminocaproic acid	0.1 g/kg loading dose, 1 g/h	Plasminogen inhibitor	Primary fibrinolysis

organ ischemia, the magnitude and rate of bleeding, and the patient's intravascular volume status.

Platelets

Standard platelet transfusion doses are prepared by pooling concentrated platelets from whole blood donated by four to six patients. A unit of platelets approximately comprises 250 mL and 3.5 to 4×10^{11} platelets. Such a dose is expected to increase the platelet count by 30,000 to 60,000/μL^3.[83] Single-donor apheresis platelets are also available. Potential advantages of these products include decreased risk of infectious transmissions and reduced alloimmunization. With the improvements in infection screening and leukoreduction techniques, these are likely no longer actual benefits and the use of the products simply increases the cost of platelet transfusion.[84] Generally accepted indications for platelet transfusion include prophylactic use in a patient with a platelet count less than 10,000/mm^3, and planned surgery or active bleeding in a patient with a platelet count less than 50,000/mm^3.[85] Early administration of platelets in massive transfusion treatment of major hemorrhage is also now recommended. Although not always possible, platelet transfusions should be avoided in patients with thrombotic thrombocytopenic purpura or autoimmune thrombocytopenias.

Fresh Frozen Plasma

Plasma consists of the acellular portion of blood, which is separated and frozen after donation. FFP contains all coagulation factors. Accepted indications for its use are severe bleeding or a planned operation in a patient requiring replacement of multiple factors (as seen in liver disease or DIC); as part of a massive transfusion to treat or prevent dilutional coagulopathy; bleeding or the need for quick invasive intervention in a patient taking warfarin; and specific coagulation factor deficit for which no factor concentration or directed therapy is available. ABO compatibility is required.[86]

Cryoprecipitate

Cryoprecipitate contains concentrated levels of fibrinogen, factor VIII, vWF, factor XIII, and fibronectin as well as platelet microparticles.[87] In the current era of factor concentrates, the primary indication for cryoprecipitate treatment is for hypofibrinogenemia (often due to consumptive coagulopathy, primary fibrinolysis, or therapeutic thrombolysis).[86] A single unit of cryoprecipitate provides 150 to 250 mg of fibrinogen and 80 units of factor VIII.[86,87]

Desmopressin

DDAVP is an arginine vasopressin analogue that stimulates release of vWF from the vascular endothelium.[88] Its initial uses focused on decreasing bleeding in patients with mild hemophilia A and vWD who required invasive interventions. Although the finding that DDAVP administration raises plasma levels of vWF and factor VIII seems to support this practice, extension of the practice to general use has not resulted in improved hemostasis.[89] A 2008 *Database Systematic* update found no evidence that DDAVP decreased perioperative transfusion requirements or any other clinically relative outcomes in patients without congenital bleeding disorders. It is still possible that patients with specific

congenital or acquired platelet disorders may benefit from this agent.[89]

Vitamin K

Patients requiring operative intervention are not infrequently undergoing long-term oral VKA (warfarin) therapy (mechanism previously described). Whether vitamin K administration will offer adequate reversal of the effect depends on the urgency of the planned intervention. In a study of patients taking warfarin (international normalized ratio [INR] 1.4-1.9) administered 1 mg of oral vitamin K 1 day prior to surgery, 77% had INR values lower than 1.2 on the day of surgery.[90] However, vitamin K treatment by any route does not allow the immediate reversal required for more urgent or emergency interventions. These patients generally require FFP. The most rapid and effective reversal of VKAs may be provided by administration of either prothrombin complex concentrate, recombinant factor VIIa, or both.[91,92]

Protamine Sulfate

Protamine sulfate is a small arginine-rich protein derived from salmon sperm nuclei. In order to reverse heparin effects, one administers 1 mg of protamine per 100 units of heparin administered in the last 6 hours. The use of this agent is plagued by a multitude of adverse reactions ranging from mild rash to life-threatening cardiovascular collapse. Previous exposure to protamine in this form or as neutral protamine Hagedorn (NPH) insulin predisposes patients to adverse reactions.[93] Vasectomy may also raise the risk of protamine-related events owing to the formation of antisperm antibodies via the exposure of blood to sperm (normally immunologically isolated in the testes). In a study of 243 patients undergoing cardiac surgery who received protamine sulfate, 26 had immediate protamine reactions; of these, 21 had previous protamine exposure (cardiac catheterization or surgery).[94] The precise mechanism of adverse protamine reactions is not well elucidated, but is believed to involve mast cell activation, complement activation, and antiprotamine antibodies. The most severe reactions are attributed to immunoglobulin G or E antibodies to protamine.[93]

Factor VIIa

Recombinant factor VIIa (rFVIIa) (NovoSeven; Novo Nordisk A/S, Bagsvaerd, Denmark) was developed and is approved by the US Food and Drug Administration (FDA) for uses related to hemophiliac patients in whom antibody development limits the use of standard factor replacement therapies. Since its introduction, off-label uses of rFVIIa have steadily increased. Common off-label uses include cardiac surgery, trauma, and intracranial hemorrhage.[95] Although some reports suggest a decrease in transfusion requirement with its use, current evidence does not demonstrate reduction in mortality or other commonly measured outcomes in the off-label use of this agent. There also persists a concern regarding increased thromboembolic events associated with the administration of rFVIIa. Additionally, the cost associated with the use of this agent is not negligible; it is approximately $7000 (USD) for a single 90 μg/kg dose.[96] Combat situations in which blood product supplies are limited may offer a reasonable off-label indication for rFVIIa.

Antifibrinolytic Agents

Aminocaproic Acid and Tranexamic Acid

Lysine analogues such as aminocaproic acid (Amicar) and tranexamic acid prevent the conversion of plasminogen to active plasmin. A 2011 *Cochrane-Database review* confirmed the role of lysine analogues in reducing perioperative blood loss and the need for allogeneic transfusion. The evidence analyzed in the review suggested greater efficacy for tranexamic acid than for aminocaproic acid.[97] These agents are reported to have good safety profiles and cost-benefit analyses when used for surgical patients with a high bleeding risk.[98,99]

Aprotinin

Aprotinin is a serine protease inhibitor with antifibrinolytic effects. It was withdrawn from the U.S. market following the BART (Blood Conservation using Antifibrinolytics in a Randomized Trial), in which a significant increase in renal failure and mortality was associated with the use of this agent.[100]

INTRAOPERATIVE BLEEDING

Intraoperative and traumatic bleeding should be immediately managed with manual pressure. Mechanical pressure allows temporary control while the surgeon rationally evaluates the type and extent of vascular injury, gains adequate exposure, and assembles the equipment required for definitive control. In the case of arterial bleeding, achieving proximal and distal control is a critical initial step allowing fastidious vascular repair. If there is a discrete source of bleeding, the need for pronged clamping of an artery, and no coagulopathy, systemic heparin can be administered.

The approach to venous bleeding is quite different because of the fragile, thin wall of the vessel and the more frequent extensive tributaries and branches. The risk of tearing or otherwise injuring veins is higher than for arteries and results in significant bleeding that can be quite difficult to control. Most small venous injuries can be adequately controlled with pressure, packing, or topical hemostatics. Extensive collateralization of the venous system often allows more liberal ligation of these structures without significant clinical consequence in comparison with arteries. The following sections describe tools used for intraoperative hemostasis.

Mechanical Tools

Electrosurgery

William T. Bovie is the pioneer of electrosurgery (often inappropriately referred to as electrocautery, which would imply heating of a probe rather than heating of tissue).[100] He invented the prototype of the electrosurgical unit that was first used by

neurosurgeon Harvey Cushing in October of 1926. The basis of electrosurgery is the finding that high-frequency current passes through the body, producing heat rather than evoking neuromuscular stimulation. Ohm's law (Eq. 3.1) and Joule's law (Eq. 3.2) are essential to the understanding of electrosurgery. Recall that in a circuit, voltage is proportional to applied current and resistance. Furthermore, the heat generated is a function of the applied current density (squared), tissue resistance, and time (Eq. 3.2).[101]

$$\text{Voltage} = \text{Current} \times \text{Resistance} \quad \textbf{(Equation 3.1)}$$

$$\text{Energy} = (\text{Current/Cross} - \text{Sectional Area})^2 \times \text{Resistance} \times \text{Time} \quad \textbf{(Equation 3.2)}$$

$$\text{Power} = \text{Voltage} \times \text{Current} \quad \textbf{(Equation 3.3)}$$

Energy application in electrosurgery can be monopolar or bipolar. For monopolar electrosurgery, the current passes from the probe, through the tissue, to a grounding pad that returns it to the generator (completing the circuit). In bipolar electrosurgery, no return electrode is necessary because both electrodes are incorporated in the forceps between which the target tissue is held.

Electrosurgical unit settings include cutting and coagulation modes. The differences between these modes are in current continuity and voltage. The surgeon adjusts the mode (cut vs. coagulate) and power settings on the unit but cannot directly manipulate the current or voltage. For a given power setting, cutting mode minimizes the voltage but functions continuously, yielding a high current density that heats tissue very rapidly, resulting in vaporization. In contrast, the coagulate mode maximizes the voltage and applies the current in an interrupted fashion. This results in deeper tissue penetration with lower current density. The intermittent nature of the application generates less heat and produces a coagulum.

For monopolar electrosurgery, adequate sealing of the grounding pad is mandatory to prevent pad site burns resulting from increased current density over the reduced surface area caused by an insufficient seal. Alternatively, with very poor grounding pad application, the current can be directed to another site, such as electrocardiogram electrodes, resulting in burn injuries remote from the surgical field. A related caveat is that monopolar surgery should be avoided in locations with a limited cross-sectional area over which to spread the current (e.g., penis or finger). Monopolar electrodes are preferred, however, when deeper tissue heating is necessary.

When using bipolar devices, the surgeon grasps the target tissue between the tines of the forceps, allowing alternating current to flow from one tine to the other. This maneuver limits the production of heat to the small area of tissue grasped and effects the selective application of heat, avoiding injury to adjacent structures. Less power is required than for monopolar devices because the distance between the electrodes is significantly reduced. Bipolar devices are also effective in saline solution because of the smaller area of application. The LigaSure (Covidien AG, Boulder, Colorado) is a sealing device that combines bipolar electrocautery with pressure application designed to fuse collagen and elastin in vessel walls, producing a hemostatic seal.

Argon Beam Coagulator

Monopolar devices can be enhanced by the addition of a stream of argon gas.[101,102] The column of argon gas passes over the tip of the electrode in a line with it. This arrangement adds several functions. First, the fully ionized gas beam disperses pooled blood from the target area, allowing the electrical energy to have an effect where it otherwise would not. As a noble gas, argon also allows arcing of the current from the electrode along the gas beam to the target tissue, making possible diffuse coagulation of surfaces along the line of the argon column.[101] It is of particular use over raw bleeding surfaces, such as the liver or spleen.

Radiofrequency Devices

The TissueLink device (Salient Surgical Technologies, Inc., Boston, Massachusetts) combines radiofrequency with continuous saline irrigation. It is designed to hemostatically seal cut bone and soft tissue.[103] The continuous and simultaneous application of saline is intended to decrease the temperature of the treated tissue, favoring mechanical sealing of the vessels rather than the coagulation and associated burning and charring seen with conventional electrosurgery.[104] The saline keeps the tissue temperature below 100°C (compared with up to 300°C seen with conventional devices). Luminal narrowing of target vessels is ascribed to collagen shrinking caused by the device.

The device is available in monopolar or bipolar forms for either spot application or painting of large raw surface areas. A disadvantage is the potential for "steam popping," which can occur if the temperature of the subsurface tissue exceeds the desired 100°C despite a surface temperature of 100°C.[105] This complication may result in steam formation and tissue disruption. Constant moving of the probe over the target surface rather than continuous static application over a small area can prevent this complication.

Topical Hemostatic Agents

Pusateri et al.[106] described the ideal topical hemostatic as (1) able to stop large vessel arterial and venous bleeding within 2 minutes of application to a wound even in a pool of blood, (2) ready to use without the need for special preparation or mixing, (3) simple to apply with minimal training, (4) lightweight and durable, (5) stable and functional for 2 years at room temperature and for several weeks at extreme ambient temperatures, (6) safe to use without the risk of injury to tissue or the transmission of infection, and (7) inexpensive. Though we are yet to develop a single agent fulfilling all of these criteria, many advances have been made.[107,108]

Mechanical Agents

Gelatin

Gelatin foam provides a physical matrix for clotting initiation and is available as Gelfilm and Gelfoam (both produced by

Pfizer Inc., New York) in film, sponge, and powder forms. The powder is mixed with a sterile saline solution and applied as paste to sites of bleeding. Because Gelfoam paste is associated with less infection and inhibition of bone healing, it is a good alternative to bone wax for stopping bleeding from bony surfaces, such as a sternotomy incision.[109] It is important to note that Gelfoam swells more than collagen or cellulose products and can double its volume. Although this feature can enhance mechanical hemostatic action, swelling can also cause compressive complications, especially when the product is used near nerves or in confined spaces. Gelatin foam is absorbed within 4 to 6 weeks and is largely nonantigenic despite its origin from animal products. Unlike oxidized cellulose, the pH of gelatin foam is neutral; therefore, it can be used in conjunction with thrombin or other pH-neutral biologics to enhance hemostatic action.

Oxidized Cellulose

Oxidized regenerated cellulose is branded as Surgicel Fibrillar and Surgicel Nu-Knit (both produced by Ethicon, Inc., Somerville, New Jersey). The material offers handling characteristics superior to those of gelatin foam, and the knitted fabric can be trimmed to fit any size. It does not stick to instruments and can easily be held firmly against bleeding tissue until hemostasis is achieved. Surgicel Fibrillar resembles cotton in consistency and remains pliable when laid into a wound. These products should not be moistened before use because greater hemostatic effect is exerted when they are applied dry.

Oxidized cellulose products result in a decreased local pH. There are theoretical advantages to this effect, including antimicrobial effects and hemostatic effects. Disadvantages of acidity include inactivation of other topical agents, such as thrombin (which should not be used together with cellulose) and potential increases in inflammation resulting in delayed wound healing.[110]

The observed discoloration of cellulose products following blood contact are attributable to low pH resulting in RBC lysis and hematin generation. Only the minimal necessary amount of product should be applied, with any excess agent removed after hemostasis is achieved.

Collagen

Microfibrillar collagen (MFC) is derived from bovine corium and available in several forms:

- A powder form, which is a fluffy, white-appearing dry material that conforms well to irregular surfaces: Avitene Flour (C.R. Bard, Inc., Murray Hill, New Jersey), Helitene (Integra LifeSciences Corporation, Plainsboro, New Jersey), and Instat (Ethicon, Inc.)
- A nonwoven sheet: Avitene and EndoAvitene (both C.R. Bard, Inc.)
- A sponge: Avitene Ultrafoam and Avitene UltraWrap (both C.R. Bard) and Helistat (Integra LifeSciences Corporation)
- A pad: Instat (Ethicon, Inc.)

Platelets adhere to the fibrils on the collagen's surface, resulting in activation and granule release. This results in platelet aggregation and thrombus formation with expected hemostasis in 2 to 5 minutes. Because this mechanism depends on functional platelets, its utility is limited in severe thrombocytopenia but retained in the setting of heparinization.

MFC should be applied with dry instruments because it adheres to gloves. It does not swell significantly, though adherence to neural structures should be avoided. Excess material should be removed after adequate hemostasis is attained. Blood from areas where this product is used should not be returned to the patient because the material may pass through the filters of blood-scavenging systems.

Polysaccharide Spheres

The synthetic agents known as polysaccharide spheres—Arista (Medafor, Inc., Minneapolis, Minnesota) and Trauma Dex—are designed to absorb plasma or blood and to concentrate clotting factors and platelets on their surfaces, forming a matrix that promotes clot formation. They require no preparation or delay for use. Disadvantages of these agents include a tendency to swell as well as a high sugar content, which limit use in closed spaces and in diabetic patients, respectively.

Active Hemostatic Agents

Thrombin: Liquid/Gel Products

Thrombin promotes the conversion of fibrinogen to fibrin and forms the basis of a fibrin clot. The original thrombin products used medically were of bovine origin; however, despite their reported efficacy, they demonstrated a tendency to result in antibody formation, which negatively affected outcomes in cardiac surgery as well as hemodialysis access (mostly involving coagulopathy and bleeding issues).[111-114] Recombinant human (Recothrom, The Medicines Company, Parsippany, New Jersey) and human plasma-derived (Evithrom, Ethicon, Inc.) thrombins were developed in response to these issues. In a phase II, randomized, double-blinded, comparative trial of topical recombinant human thrombin with bovine thrombin in surgical hemostasis, recombinant human thrombin was found to have comparable efficacy, a similar safety profile, and significantly less immunologic response in comparison with bovine thrombin.[115]

Thrombin: Solid Products

TachoComb (NYCOMED Austria GmbH, Linz, Austria) is a collagen (equine) sheet coated on one side with human fibrinogen, bovine thrombin, and bovine aprotinin. The three components are distributed in layers that dissolve on contact with blood, allowing the formation of fibrin, which seals the wound by binding the collagen sheet to it.[116]

TachoSil (Takeda Pharmaceuticals International GmbH, Zurich) was developed in response to the realization that topical products containing aprotinin can have potential adverse effects, including anaphylaxis and renal injury. Therefore, TachoSil is made without aprotinin and with human rather than bovine-derived thrombin. This product is found to have equivalent hemostatic effects too, but has a lower risk of side effects than TachoComb.[117]

Sealants

FloSeal, Tisseel, Evicel

Fibrin sealants consist of two primary components that are mixed on application. Tisseel (Baxter International Inc., Deerfield, Illinois) combines human fibrinogen, human thrombin, and calcium chloride. Its mechanical strength is determined by the fibrin concentration. Thrombin concentration determines the speed of clot formation and tensile strength. This product does contain small amounts of aprotinin, which may carry the aforementioned risks of this agent. Evicel (Ethicon, Inc.) is a similar, later-developed product composed of fibrinogen and human-derived thrombin that lacks aprotinin.

FloSeal (Baxter International, Inc.) comprises a gelatin matrix of bovine collagen and microgranules cross-linked with glutaraldehyde and human thrombin.[118,119] The cross-linked gelatin granules swell on contact with blood, offering an additive tamponade effect. FloSeal was found to be superior to Gelfoam-thrombin in cardiac surgery and was shown to successfully reduce bleeding when used for open and laparoscopic nephrectomy.[118,120]

Dry Fibrin Sealant Dressings

A dry fibrin sealant dressing consists of gauze embedded with lyophilized fibrinogen and thrombin. It is a solid-phase delivery mode for the clotting factors to promote and support clot formation. Its advantages include a long shelf-life and a lack of requirement for pre-mixing. Its use is limited in some forums by the brittle nature of the material.

Tissue Glue

Several unique characteristics render tissue glues potential vehicles for drug delivery. They have a predictable pattern of biodegradability, can be applied in a site-specific manner, and are biocompatible.[58] BioGlue (CryoLife Inc., Kennesaw, Georgia) contains glutaraldehyde and bovine serum in addition to the tissue glue component. A scaffold is created by cross-linking of albumin to wound proteins.

Newer Agents

Chitins

The modified Rapid Deployment Hemostat (mRDH, Marine Polymer Technologies, Inc., Danvers, MA) bandage is a lyophilized matrix of acetylated, poly-N-acetyl glucosamine-containing nanofibers. The bandage rapidly binds and absorbs plasma proteins from blood. The nanofibers interact with receptors on platelets to stimulate activation and coagulation as well as agglutinating and activating RBCs. These interactions with platelets and RBCs result in the generation of thrombin and the deposition of a fibrin mesh. In addition to the formation of this hemostatic plug, thromboxane (from the activated platelets) and endothelin-1 (from endothelial contact with the bandage) effect vasoconstriction.[121] Case series from military use support the efficacy of this agent for at least temporary control of hemorrhage.[117,122]

Chitosans

Chitosans are a deacetylated form of chitin. The gauze base of agents such as HemCon (HemCon Medical Technologies, Inc., Portland, OR) and TraumaStat (Ore-Medix, Salem, OR) contains silica and polyethylene, which interact with wound blood and coagulation factors to promote rapid hemostatic plug formation in a manner similar to that displayed by chitins.[123]

Mineral Zeolite

Mineral zeolite agents such as QuikClot (Z-Medica, Wallingford, Connecticut) function by absorbing water, an action that concentrates platelets and clotting factors to accelerate hemostasis. They may also activate factor XII. Multiple studies have demonstrated this to be a very rapid and effective manner to achieve hemostasis.[124,125] However, this mechanism is realized via an exothermic reaction that has been demonstrated to cause nontrivial parenchymal thermal injuries in the region of application. A newer version, QuikClot Advanced Clotting Sponge, is intended to create a less exothermic reaction.[123]

Lysine Analogues

The topical application of lysine analogues has been best studied in cardiac and orthopedic procedures. These antifibrinolytic agents act by preventing the binding of plasminogen to fibrin (thus countering the action of t-PA released from endothelial cells in response to surgical trauma). Of the four randomized, controlled, blinded studies of tranexamic acid in cardiac surgery, all showed less postoperative bleeding than with placebo; only one demonstrated a reduction in the perioperative transfusion requirement. In orthopedic surgery, topical or intra-articular tranexamic acid similarly reduced blood loss. A sole study evaluated the use of aminocaproic acid in cardiac surgery. It demonstrated decreased blood loss in the first 24 postoperative hours (although accumulated loss prior to chest tube removal was not significantly different in the aminocaproic acid and the placebo arms) and a lower transfusion requirement in patients receiving aminocaproic acid. None of the studies evaluating topical lysine analogue use has been considered adequately tailored or powered to determine thrombotic or other potential risks (Table 37.8).[108]

POSTOPERATIVE BLEEDING

When patients demonstrate signs or symptoms of bleeding in the immediate postoperative period, a critical decision point is to determine whether it represents medical or surgical bleeding. Thus, while instituting aggressive, goal-directed resuscitation, the surgeon should be assessing the nature of the bleeding. Adjuncts in this process include coagulation parameters such as PT and aPTT, as well as the platelet count. If there is a suspicion or suggestion of consumptive coagulopathy, additional useful tests include fibrinogen, FDPs, and TT.

Management of postoperative bleeding hinges on its etiology. Surgical bleeding should be initially managed with manual pressure while the patient is transported back to the operating

TABLE 37.8 Intraoperative Hemostatic Tools: Advantages and Disadvantages

Hemostatic Agent	Products	Mechanism of Action	Specific Advantages	Specific Disadvantages
		Mechanical Agents		
Gelatin	Gelfoam Gelfilm Surgifoam (Ethicon, Inc.)	Matrix for clot formation Mechanical barrier to bleeding	Immediately available for use; stored at RT Can be used with thrombin/saline Conforms to wounds	Not for use in infected fields or near neural elements due to swelling risk Intravascular use should be avoided
Oxidized cellulose	Surgicel Surgicel NuKnit Surgicel Fibrillar BloodSTOP (LifeScience PLUS, Inc., Mountain View, CA)	Matrix for clot formation	Immediately available for use; stored at RT Small pieces easy to manipulate into small spaces	Not for use in closed spaces due to swelling risk Cannot be combined with thrombin
Microfibrillar collagen	Avitene Helitene Instat	Matrix for clot formation/strengthening Enhances platelet activity	Immediately available for use; stored at RT	Not for use in closed spaces Cannot be combined with saline/thrombin
Polysaccharide spheres	Arista	Hydrophilic effect dehydrates blood Concentrates solid components, resulting in barrier	Immediately available for use; flexible storage temperature	Not for use in closed spaces due to swelling risk Not for ophthalmologic, neurologic, or urologic procedures Limitations in diabetes due to sugar content of spheres
	TraumaDex (microporous polysaccharide hemospheres)	Absorbs plasma-concentrating coagulation factors and platelets, forming gel matrix for clot formation	No preparation	With sterilization, no risk of infection
		Active Hemostatic Agents		
Synthetic or plasma-derived	Recothrom (recombinant human)	Actively converts fibrinogen to fibrin	Stored at RT and reconstituted with saline	Cannot be used in patients hypersensitive to hamster/snake proteins
	Evithrom (plasma-derived)	Actively converts fibrinogen to fibrin		Frozen liquid form (takes at least 1 h to prepare) Contraindicated in patients with human blood product allergies
	TachoSil (equine collagen patch with human fibrinogen and thrombin)	Human thrombin converts fibrinogen to fibrin and polymerization yields coagulation effect; mechanical collagen effect	Stored at RT Patch placed directly on bleeding Modification of TachoComb (aprotinin should be avoided)	Human plasma-derived Infection risks Cannot be used in neurologic or urologic procedures
	TachoComb (sponge)	Collagen sheet, one side coated with human fibrinogen and bovine thrombin and aprotinin		Aprotinin content risks anaphylactic reactions and renal injury
		Sealants		
Polyethylene glycol	Coseal	Polyethylene glycol matrices cross-link in and with wound	Fast-acting Not exothermic	Not for use in closed spaces due to significant swelling

TABLE 37.8 Intraoperative Hemostatic Tools: Advantages and Disadvantages—cont'd

Hemostatic Agent	Products	Mechanism of Action	Specific Advantages	Specific Disadvantages
Fibrin sealants	Tisseel	Fibrinogen source	Does not need active bleeding to polymerize (prophylactic)	Frozen: 5-105 min to thaw
	Evicel	Fibrinogen source	No mixing required Does not need active bleeding to polymerize (prophylactic)	Frozen: at least 10 min to thaw Should be avoided in patients with known severe reactions to human blood products
Thrombin sealants	FloSeal (gelatin thrombin suspension)	Human and bovine thrombin formulation resulting in mechanical and active hemostasis contributions	3-min reconstitution Stored at RT	Should be avoided in ophthalmologic procedures
	Dry Fibrin Sealant Dressings (gauze embedded with lyophilized fibrinogen and thrombin)	Provides fibrinogen and thrombin	Has longer shelf-life than other sealants and does not require mixing	Brittle material causes handling and packaging issues
Bovine-derived factors	BioGlue (glutaraldehyde and bovine serum; glue)	Glutaraldehyde cross-links bovine albumin to wound proteins to make scaffold	Fast-acting Flexible use environment (temperature, moist)	Hypersensitivity reactions Theoretic mutagenic potential
		Newer Agents		
Chitin	mRDH (Modified Rapid Deployment Hemostat) (gauze)	Mobilizes clotting factors, platelets, RBCs Mechanical sealant Vasoconstrictive	Very portable	No known significant adverse effects Gauze backing and small size[101] Varied results with severe injuries
Chitosan (deacetylated form of chitin)	HemCon, TraumaStat (granules) Chitogauze (HemCon Technologies), Celox (MedTrade Products Ltd., Crewe, United Kingdom), Hemogrip (Remedium Technologies, Inc., College Park, MD)(gauze)	Hemostatic plug forms on thrombin and fibrin mesh formed on gauze by receptor-based contact with RBCs and platelets	Antimicrobial properties Immediately available for use, stored at RT	No known adverse effects Cannot be used in patients with shellfish allergy Very user dependent
Mineral zeolite	QuikClot (combat gauze, granules, mesh bags)	Absorbs water from blood, thus concentrating platelets and clotting factors and promoting rapid local hemostasis Activates factor XII	Stored at RT, immediately available for use	Exothermic (burn) Foreign body reaction
Lysine analogues[102]	Tranexamic acid Aminocaproic acid	Antifibrinolytics block the binding of plasminogen to fibrin

room. Here, small discrete bleeding may require a topical hemostatic, sutures, or a simple electrosurgery application. Large raw surfaces with venous oozing may be best managed with argon beam therapy or conventional electrosurgery application rather than a topical agent. Arterial bleeding is best addressed by rapid attainment of proximal and distal control followed by suture repair with or without the addition of topical agents.

Nonsurgical/medical bleeding is generally due to an isolated inherited or acquired coagulopathy or a diffuse coagulopathy related to surgery, sepsis, or massive resuscitation. Specific factor or blood element deficiencies can be treated with replacement. Drug-induced coagulopathies can sometimes be directly reversed. Homeostasis-related or diffuse coagulopathies require the correction of all involved factors, normothermia, and the correction of acidosis and dilution. Coagulopathy-related bleeding events are generally not best served by a return to the operating room. Fig. 37.1 summarizes the causes of and treatment strategies for perioperative bleeding.

EVALUATION OF THE PATIENT WITH SUSPECTED THROMBOPHILIA 494

Thromboembolism is an enormous problem across the spectrum of medicine. Approximately 10 million individuals in the United States have symptomatic peripheral artery disease, and approximately 100,000 arterial reconstructive procedures are performed annually.[1] In the United States and Europe, more than 600,000 people will experience a venous thromboembolism (VTE), and nearly 20% will die as a result.[2] The incidence of arterial embolism and VTE is highly age dependent, contributing significant morbidity and mortality to an aging population.[3-5]

More than 150 years ago, the great German pathologist, Rudolf Virchow, proposed the concept known as *Virchow's triad.* He observed that thrombosis occurred when the following three situations were present; vascular wall (endothelial) injury, stasis of blood, and changes in the consistency of blood that enhances coagulation (hypercoagulability). An understanding of the latter, now termed the hypercoagulable state, was least apparent and could not be further characterized until there was a greater understanding of the normal mechanisms of hemostatic regulation (see Chapter 36). In the last 40 years, a number of inherited

and acquired hemostatic disorders have been characterized that are associated with an increased risk of venous and/or arterial thrombosis. In most circumstances, the relationship between specific hemostatic defect and the hypercoagulable state is readily apparent by the respective role in normal hemostasis. However, the mechanism(s) by which other well-documented hypercoagulable defects (e.g., the antiphospholipid syndrome or elevated homocysteine) contribute to an increased risk of venous and arterial thrombosis remain poorly understood. The interactions of these hypercoagulable defects, alone or in combination, or when combined with other transient factors, such as vascular injury from surgery or trauma, can result in a significant increased risk of thrombosis. The interaction between inherited hypercoagulable defects and acquired additional factors, such as age or acute illness, can result in what has been termed an increased "thrombosis potential," which, upon reaching a "thrombosis threshold," can result in symptomatic thromboembolism.[6]

PATHOPHYSIOLOGY

Hemostasis is a highly organized series of reactions involving platelet adhesion and activation to form the platelet plug, followed by activation of coagulation proteins in a series of controlled enzymatic reactions to generate thrombin. Thrombin potentiates platelet aggregation and activation, and acts on fibrinogen to generate the insoluble fibrin clot. Under normal conditions, these reactions occur on the endothelial surface only at sites of endothelial injury. This limits the size of the clot and allows blood to remain liquid and flowing. When this balance is altered, excess thrombin is generated, and abnormal thrombosis may occur. Therefore, thrombosis can result from defects in normal hemostasis that either increase the procoagulant activity or decrease the naturally occurring anticoagulants. These hypercoagulable defects have been termed thrombophilic syndromes and have been further classified as either congenital or acquired thrombophilias.[6,7]

In addition, there is a group of other disorders whose prothrombotic mechanisms are poorly understood. These include elevations of homocysteine (hyperhomocysteinemia) and lipoprotein(a) (Lp[a]). The management of patients with thrombosis with these disorders remains controversial.[8-13]

Arterial thrombosis, unlike VTE, is associated with conditions that primarily affect the vascular wall and endothelium. Endothelial disruption, which occurs with atherosclerosis, vasculitis (vascular inflammation), infection, trauma, or surgery, is most often associated with an arterial thrombotic event. In well-controlled population studies, the majority of congenital hypercoagulable defects associated with venous thrombosis are not associated with a statistical increased risk of arterial thromboembolism.[14-17] The few congenital hypercoagulable defects that may be associated with an increased risk of both venous and arterial thrombosis, such as hyperhomocysteinemia or increased Lp(a), are also associated with an increased risk of arterial atherosclerosis.[8,9,18-20] Other defects associated with an increased risk of arterial thromboembolism, such as those observed with increased levels of fibrinogen and von Willebrand factor, are known to enhance platelet function.[21,22]

CONGENITAL HYPERCOAGULABILITY

Although the thrombosis potential or risk of thrombosis for inherited prothrombotic defects have been well characterized in a number of prospective and retrospective population studies, it is important to understand that thrombosis is a multigenetic and multifactor disorder. The thrombosis potential for specific congenital thrombophilic abnormalities is classically defined as a relative risk of thrombosis compared with a patient population without these abnormalities.[6,7,14-16] In most circumstances, patients who inherit more than one abnormality have a significantly higher risk of thrombosis potential or a relative risk of thrombosis.[6,7,14-16,23] However, patients may have additional risk factors, such as aging, oral contraceptive (OC) use, hormone replacement therapy (HRT), pregnancy, cancer, infection, trauma, or surgery. In these circumstances, a patient's individual risk also can be increased by a factor that is more than the sum of each individual risk factor.[23]

Classification

Crowther and Kelton[7] proposed a simple classification system that divides the congenital hypercoagulable (thrombophilic) states associated with VTE into two broad groups (Table 38.1). The first group constitutes defects associated with the reduced levels of the natural anticoagulants, such as antithrombin, protein C, and protein S.[7] The defects in this "loss of inhibition" group are much less common, but are associated with a significantly higher risk of thrombosis.[7] The second group is associated with defects that result in a "gain in procoagulant function" due to increased levels or function of coagulation factors.[7] These include factor V Leiden (activated protein C resistance [APCR]) and prothrombin G20210 mutations, increases in coagulation factors VIII, IX, and XI, and the dysfibrinogenemias. Although these defects have a lower thrombosis potential, they are more frequently found in the general population, and therefore, are more commonly associated with clinical thrombosis. The understanding that certain defects alone or in combination can be associated with a significantly higher risk of thrombosis may be important in determining the physician's approach to antithrombotic prophylaxis, the duration of anticoagulation after venous thrombosis, and family screening for patients with these defects.

Group 1 Thrombophilia

Group 1 includes deficiencies of the naturally occurring anticoagulant factors antithrombin, protein C, and protein S. All are rare, representing less than 1% of the population.[7] However, they are highly prothrombotic, with 30% to 50% of carriers (heterozygote) having a symptomatic thrombotic event before they reach 60 years of age.[7] A significant number of carriers will have had a spontaneous thromboembolic event before the age of 40 years. Frequently, there is a strong family history of venous thrombosis. Although the risk of thrombosis is high, routine prophylactic anticoagulation in ambulatory healthy individuals has not been demonstrated to be of benefit and

TABLE 38.1 Venous Thromboembolism and Inherited Thrombophilias

Abnormality	Frequency in General Population (%)	Frequency in Patients With VTE (%)	Relative Risk	Reference
Antithrombin	0.02	4-7.5	8.1-21	14-16, 23, 26-29
Protein C	0.2	2.5-6	7.3-11	15, 16, 23, 28, 29, 44, 45
Protein S	Unknown	1.3-5	8.5-32	15, 16, 23, 45
Factor V Leiden (APCR) heterozygote	2-7	10-19	2.5-7	6, 16, 17, 23, 67-73
Factor V Leiden homozygote	0.015	1.5	80	16, 70, 75
PT G20210A heterozygote	1-4	5-10	1.7-3	6, 86-90, 94
PT G20210A homozygote	Unknown	Unknown	Unknown	
Factor VIII	11	25	4.8	6, 99
Homocysteine	5-10	10	2-4	6, 118-122

APCR, Activated protein C resistance; *PT*, prothrombin; *VTE*, venous thromboembolism.
The Factor V Leiden and Prothrombin G20210A mutations are predominantly in populations of European descent.

should be reserved for high-risk situations, such as surgery, sepsis, pregnancy, and immobilization.[7] Because of the high risk of recurrence, with group 1 deficiencies and patients homozygous for certain group 2 abnormalities, lifelong anticoagulation may be recommended after a spontaneous thrombotic event.[7,24]

Antithrombin Deficiency

Pathogenesis and Incidence

Physiologically, antithrombin is the most important inhibitor of thrombin and other activated clotting factors (e.g., factors Xa, IXa, and VIIa). Antithrombin physiologic activity is enhanced 1000-fold by the binding of naturally occurring or administered heparin or heparin sulfates.[25] Antithrombin deficiency is rare, reportedly occurring in an estimated 0.02% of the general population in a study that screened samples from healthy blood donors.[26,27] It has been reported in 4% to 7.5% of patients with VTE.[14-16,28,29] Antithrombin inheritance is autosomal dominant.[30] More than 250 mutations within the molecule have been described.[31] Homozygosity, particularly for antithrombin deficiency types I and II, is extremely rare and appears to be incompatible with life. Homozygosity for antithrombin deficiency results in a severe thrombophilic phenotype.[32]

Types

There are three general subtypes of antithrombin deficiency.[31] Type I is characterized by decreased antithrombin functional activity and antigen. Type II defects are antithrombin mutations that have reduced functional activity, but normal antigen levels resulting from a mutation in the active inhibitory site on the protein. Type III antithrombin mutations are characterized by moderate decreased activity due to impaired interaction with heparin. Screening for antithrombin deficiency should always be undertaken using a functional assay, because screening with an antigen assay may fail to diagnose type II and III defects. In the presence of low antithrombin activity, further characterization can be made with an antigen assay.

Patients with antithrombin deficiencies are at a significantly higher risk of thrombosis than patients with other congenital deficiencies. Approximately 60% of carriers of type I and II deficiencies will have a thrombotic event by the age of 60 years. The risk for type III deficiency may be lower.[33,34] A strong family history of thrombosis is usually present. A Spanish Multi-Center study reported the relative risk of thrombosis in these thrombophilic families as 21-fold.[29] A multicenter, multinational European Prospective Cohort on Thrombophilia (EPCOT) study reported an adjusted relative thrombotic risk of 17.5 (95% confidence interval [CI], 9.1 to 33.8).[23] After the diagnosis of antithrombin deficiency is made in an individual with thrombosis, screening of family members is recommended.

Clinical Presentation and Management

The clinical presentation of antithrombin deficiency is predominantly lower extremity thrombosis with or without pulmonary embolism.[30,33,35] Recurrent events are common, and atypical thrombotic events involving the portal, mesenteric, and hepatic venous system, or cerebral veins have been reported.[29,36,37] Arterial events are rare, and patients are not at increased risk more than the unaffected adult population.[14-16,23] Pregnancy is a particularly high-risk situation, and prophylaxis with heparin is indicated throughout pregnancy and in the immediate postpartum period.[35,38] Patients with breakthrough events can receive antithrombin concentrates.[39] An acquired form of antithrombin deficiency has been reported in pregnant women with the fatty liver syndrome with disseminated intravascular coagulation (DIC).[40] Treatment with plasma or antithrombin concentrates rapidly reverses the coagulopathy.[40]

Protein C Deficiency

Pathogenesis and Incidence

Protein C is a vitamin K-dependent anticoagulation protein that is activated by thrombin to activated protein C (APC).[41] When thrombin levels are high, thrombin binds to the endothelial protein receptor, thrombomodulin (TM), which changes

the specificity of thrombin from cleaving fibrinogen or activating platelets to activating protein C. Protein C binds to its specific endothelial receptor, termed the endothelial protein C receptor, which enhances its activation. APC is a potent serine protease anticoagulant that cleaves the coagulant cofactors VIIIa and Va, thus modulating thrombin generation and subsequent clot formation.[41,42] Deficiency of protein C is found in 0.2% of the general population, and in 2.5% to 6% of patients with VTE.[28,29,43,44]

Types

Similar to antithrombin deficiency, multiple mutations resulting in protein C deficiency have been reported. These mutations have been classified into two general subtypes: type I mutations have reduced functional and antigenic protein levels; and type II mutations have reduced functional levels but preserved antigen levels of the protein.[45] Adult heterozygous patients with protein C deficiency usually have activity levels of less than 60%.

Clinical Presentation and Management

Patients who have VTE usually present in the lower extremities. Unusual sites of thrombosis have been reported and are similar to those seen with antithrombin deficiency.[41,42,44,45] Although rare arterial events have been reported, large cohort studies do not support an increased risk of arterial events.[46] In protein C deficient patients from thrombophilic families who present with an unprovoked (idiopathic) thrombosis, recurrent thrombotic events are frequent. Life-long anticoagulation should be considered in these patients, particularly those who present before the age of 40 years.

Homozygosity for protein C deficiency, with absent protein C activity, may present at birth as a neonatal disorder termed purpura fulminans.[47] This disorder is characterized by diffuse microvascular thrombosis of the skin and systemic organs. Immediate treatment with heparin, plasma, or protein C concentrates can be lifesaving.[47] The majority of homozygous neonates with protein C deficiency will have functional levels less than 20% of normal.[47]

A similar severe disseminated thrombotic disorder, characterized by skin necrosis, can occur in heterozygous patients with protein C deficiency treated with higher doses of warfarin, usually without concomitant anticoagulation with heparin.[48,49] The syndrome, termed warfarin necrosis, results from the disproportional decrease in protein C in comparison to other procoagulant vitamin K-dependent coagulation factors. Patients presenting with this disorder should be treated with fresh frozen plasma, vitamin K, and heparin.[48,49] The syndrome can be prevented by initiating oral anticoagulation with lower doses of warfarin and concomitant use of heparin.

Protein S Deficiency

Pathogenesis and Incidence

Protein S is the vitamin K-dependent cofactor necessary for the inactivation of factors Va and VIIIa by APC. A deficiency in protein S is phenotypically similar to protein C deficiency. Protein S exists in two forms: the functionally active free form that usually constitutes 20% to 40% of the total protein, and the remaining 60% to 80% that is active and bound to complement binding protein C4b.[50,51] Most patients with protein S deficiency will have activity levels between 50% and 75% of normal.[50-52]

Types

Similar to the other natural anticoagulant proteins, protein S deficiency can be classified into 3 subtypes: type I is characterized by reduced functional and antigen protein levels; type II has reduced functional activity, but normal antigen levels; and type III has normal antigen levels, but reduced free active protein S due to enhanced C4b binding.[53] Type I and type III protein S deficiencies are the most common forms of the deficiency encountered, and do not appear to differ in their risk of venous thrombosis.[54]

The measurement of protein S activity and antigen can be confounded by a number of physiologic and clinical conditions. In pregnancy, protein S levels fall in the second and third trimesters.[55,56] Reduced protein S levels have also been reported in patients with active cancer, lupus erythematosus, antiphospholipid antibody syndrome (APLAS), sepsis, chronic inflammatory disorders (e.g., inflammatory bowel disease) and in advanced HIV disease.[57-69]

Clinical Presentation and Management

Protein S deficiency is clinically characterized by venous thrombosis and has been frequently reported in association with venous thrombosis in atypical sites.[50-52,60,61] These reports may be confounded by other comorbidities in these patients that can be associated with acquired protein S deficiency. In addition, several reports have suggested a relationship between low protein S levels and arterial thrombosis, including a reported association between low free protein S and cardiolipin antibodies in stroke patients.[62]

Like protein C deficiency, homozygous deficiency can be associated with neonatal purpura fulminans. Approach to management is similar to that of homozygous protein C deficiency.[63] Warfarin necrosis can also develop in heterozygote protein S patients.[63]

Group 2 Thrombophilia

Although associated with a lower thrombosis potential than Group 1 thrombophilia, Group 2 hypercoagulable disorders are more frequently found in the general population and are found in a greater proportion of patients with VTE. They represent gain of function mutations resulting in increased thrombin generation. They are typified by either increased synthesis of specific coagulation factors or as observed with factor V Leiden, resistance to the inactivation of this cofactor by APC.

Factor V Leiden (Activated Protein C Resistance)

Pathogenesis and Incidence

Factor V is a cofactor that accelerates the conversion of factor II (prothrombin) to thrombin by factor Xa. Under normal

circumstances, factor V is degraded by the serine protease, APC, which cleaves the protein at two sites. Factor V Leiden has a mutation in the 506 position that results in a substitution of glycine for arginine. This renders one of the factor V cleavage sites resistant to the action of APC, which, like all coagulation serine proteases, cleaves arginine bonds.[64-66] This results in a slowing of the inactivation of the cofactor, which leads to increased thrombin generation.

Factor V Leiden is a common mutation, occurring in approximately 2% to 7% of individuals of European ancestry.[66-68] It can be found in nearly 10% of people with VTE and in 30% to 50% of individuals being evaluated for thrombophilia.[66-69] The mutation is very rare in native Asians and Africans.[68,69] The mutation is also rare in African Americans (0.6%) and has not been reported in Native Americans.[68,69] Compared with patients with group 1 thrombophilia, patients with factor V Leiden have a lower relative risk of thrombosis, estimated between 2.5- and 7-fold.[16,17,23,70-73] A cross-sectional study from Italy found that only 6% of carriers of the mutation developed a thromboembolic event by the age of 65 years.[74] Homozygotes are at much higher risk than heterozygotes, with an estimated relative risk of 80-fold.[16,70,75] However, heterozygotes with combined defects have a significantly increased risk of VTE.[16,23,74] A second, very rare, mutation of the second factor Va cleavage site (Arg306Thr) has also been reported to be associated with increased risk of thrombosis, whereas other studies have failed to find a relationship of this mutation with the development of VTE.[76]

Clinical Presentation and Management

The clinical presentation of thrombosis with factor V Leiden is overwhelmingly venous. Rare, unusual thrombosis sites, such as the cerebral vein and the retinal vein, have been reported.[77,78] The onset of thrombosis is frequently at an older age than seen in patients with type 1 thrombophilia.[17] In the Physicians Health Study, the risk of VTE in men with the factor V Leiden mutation did not become statistically significant until after the age of 50 years.[17] The study also found no association with the factor V Leiden and an increased risk of stroke or myocardial infarction.[17] Thrombosis is frequently triggered by transient risk factors, such as a prolonged plane flight, OC use, or pregnancy.[79-82] In women carriers of the mutation, the reported thrombosis risk associated with the use of second-generation OCs varies widely, ranging from 6- to 50-fold.[79-82] The wide variation reported in the thrombotic risk of OCs may be explained, in part, by a higher risk of thrombosis in women more than 30 years old who are taking OCs and some variation in the specific OCs used in the European studies, some of which contain prothrombotic progesterone substitutes.[82]

There is no excess mortality in carriers of the factor V Leiden mutation. No prophylaxis is recommended for carriers except what is recommended by guidelines for surgical interventions. Antepartum prophylaxis is not recommended for women who have not had a previous thrombotic event or a history of recurrent fetal loss.[83] The risk of recurrent VTE after cessation of oral anticoagulation is not greater than that observed in other patients with unprovoked VTE.[84]

Prothrombin Gene Mutation G20210A

Pathogenesis and Incidence

The prothrombin G20210A mutation is an abnormality located at the untranslated 3′ end of the prothrombin gene that results in increased plasma levels of prothrombin. The mutation affects the 5′ end cleavage signal, leading to increased prothrombin mRNA stability.[85] The thrombotic risk is relatively low.[86-88] The gene frequency in the European population is about 1% to 4%, with the greatest frequency in southern Europe and Spain.[89,90] It is present in 5% to 10% of patients with VTE, and 15% of patients with thrombophilia.[86-90] Similar to factor V Leiden, the prothrombin G20210A mutation is very rare in Native Asians, Native Africans, African Americans, and Native Americans.[91] Many carriers with a history of VTE have coinheritance of the factor V Leiden mutation.[23,92] The relative risk of thrombosis is low in carriers of the prothrombin mutation, ranging from two- to threefold higher in carriers compared with noncarriers of the mutation.[93,94]

Clinical Presentation and Management

The clinical presentation is predominantly venous thrombosis of the lower extremities, and unusual sites are rare.[86-88,93,94] Some controversy exists as to whether the prothrombin mutation is associated with an increased risk of arterial thrombosis.[94-96] In carriers of the mutation who develop thrombosis, studies to date have shown either no increase in risk or only a slight increased risk of recurrent VTE after discontinuation of anticoagulation.[94,97]

The risk of VTE in women on OCs has been reported to be significantly increased, similar to that reported for factor V Leiden.[93] Women who are carriers of both the prothrombin G20210A mutation and the factor V Leiden mutation have a markedly high risk of VTE.[93] An association between the development of cerebral venous thrombosis in women carriers of the prothrombin mutation taking OCs has been reported, in which 20% of patients carried the mutation versus only 3% of controls.[98]

Elevated Factors VII, XI, and IX

Pathogenesis and Incidence

Koster et al.[99] first reported an increased risk of VTE in patients with an elevated factor VIII coagulant protein of more than the 90th percentile (>150%). Factor VIII activity levels more than 150% were associated with an adjusted relative risk of 4.8% compared with factor VIII levels 100% or less.[99] These elevations appear to be independent of ABO blood type and were measured in patients without evidence of inflammation confirmed by a normal erythrocyte sedimentation rate (ESR) and C-reactive protein.[100,101]

Subsequent studies have supported this observation and found both a family and racial clustering suggestive of an inherited propensity for increased factor VIII levels.[100,102] A study of African American women found a statistically higher level of factor VIII compared with the white and Asian population in the United States.[103] Unlike female carriers of the factor V Leiden

and prothrombin mutations, the use of OCs did not appear to significantly increase the risk of VTE.[104] Elevations of factor VIII activity have also been associated with an increased risk of recurrent VTE.[105]

The measurement of factor VIII activity is confounded by the fact that factor VIII, along with its carrier protein, von Willebrand factor, is an acute phase reactant and increases with bleeding and inflammation.[100,101] Therefore, measurement of factor VIII activity should be performed with a simultaneous acute phase marker, such as the ESR or C-reactive protein. The assay should also be repeated at least twice at distant time intervals.[99-101] Each laboratory must define the 90th percentile range for its own population to determine the patient population at risk.

Clinical Presentation and Management

The clinical presentation of patients with elevations in factor VIII activity is predominantly VTE of the lower extremities.[99] Because factor VIII levels increase with inflammation, the elevation of this coagulation protein is an important cofactor in the development of thrombosis associated with infection, inflammatory bowel disease, and cancer. There is controversy as to whether increased levels of factor VIII are associated with arterial thrombosis, because elevations in factor VIII activity are associated with increases in von Willebrand factor. Increased levels of von Willebrand factor have been shown in population-based studies to be associated with an increased risk of arterial thrombosis.[106]

Increased levels of factors IX and XI have been associated with a twofold increase in the risk of VTE.[107,108] These are relatively weak risk factors for thrombosis, but if combined with other defects, they may become significant. To date, no molecular markers have been reported to characterize these elevations in factors VIII, IX, and XI.[109]

Other

Hyperhomocysteinemia

An association was made between markedly elevated levels of homocysteine and arterial vascular disease in individuals with homocysteinuria.[110,111] Additional studies confirmed this association and found additional evidence that individuals with homocysteinuria also experience an increased incidence of VTE.[110] Subsequent studies found an association between elevations of plasma homocysteine and an increased risk of atherosclerosis and arterial thrombosis in apparently healthy individuals.[112-120] Additional studies that focused on risk factors for venous thrombosis reported a similar association.[120-123]

Homocysteine metabolism involves two enzymatic pathways that require essential vitamin cofactors: folate, vitamin B_{12}, and vitamin B_6 (pyridoxine).[124] The vitamine B_6-dependent pathway involves the enzymatic conversion of homocysteine to cystathionine by the enzyme cystathionine-β-synthase (CBS).[111,124] The second pathway involves remethylation of homocysteine back to methionine requiring folate, vitamin B_{12}, and the two enzymes 5,10-methylenetetrahydrofolatate reductase (MTHFR) and methionine synthetase.[124] The primary mutations responsible for homocysteinuria are in the CBS gene.[111] However, in the general population, independent of deficiencies in the vitamin cofactors, a common mutation in the MTHFR gene at position 677 is most frequently associated with elevations in homocysteine.[124] This C to T mutation results in a 50% reduction in the enzymatic activity of the gene.[124] However, even in MTFR C677T homozygotes, folate supplementation or a diet intrinsically rich in folate can reduce homocysteine levels into the normal range.[124,125]

The reported mechanisms by which homocysteine increases the risk of both arterial and venous thrombosis include (1) a direct toxic effect on endothelium; (2) enhanced platelet activation; (3) oxidation of low-density lipoprotein cholesterol; (4) an inflammatory decrease in endothelial TM; and (5) an increase in von Willebrand factor and factor VIII.[124] However, no single reported effect of homocysteine adequately explains its prothrombotic effect in both the arterial and venous vasculature.

A number of cohort studies and some prospective studies have found a statistically significant association between elevated homocysteine and an increased risk for myocardial infarction and stroke with estimated risks of 2- to 7.8-fold for individuals in the highest quartile.[112-114] However, several prospective studies have failed to confirm this association.[115-117] Data from the Physicians' Health Study,[117] the Atherosclerosis Risk in Communities Study,[118] and the Women's Health Study[115,116] suggest a gender-defined risk for elevated homocysteine in which the risk is most significant in women. Elevations of homocysteine have also been found in case-controlled studies to be a weak risk factor for VTE, with a relative risk of only 2 to 4.[117-123] Meta-analyses further confirmed an increased risk in patients with homocysteine levels more than the 95th percentile.[123]

Complicating the issue of elevated homocysteine as a risk factor for both arterial and VTE disease is the lack of response, in randomized controlled trials, to lowering homocysteine in reducing the risk of recurrent arterial[10-12] and VTE[13] disease in patients treated with vitamin therapy.

The measurement of homocysteine in patients can be complicated by comorbid conditions, such as vitamin deficiency, renal insufficiency, and improper plasma collection and handling. Measurements are best performed using freshly collected plasma, preferentially with patients in the fasting state. It is reasonable to repeat the assay on at least two separate occasions. Studies to date do not support an advantage for determination of the MTHFR genotype over direct measurement of homocysteine.[125]

Lipoprotein(a)

Lp(a) is a serum lipoprotein composed of a low-density lipid particle with a disulfide link to a long polypeptide chain, apolipoprotein(a).[20,126] The protein has "kringle-like" domains that compete with tissue plasminogen activator, plasminogen, and plasmin for binding to fibrin and endothelial annexin II, thereby inhibiting fibrinolysis.[126,127] The plasma levels of Lp(a) vary greatly within and between different racial populations, with African Americans having higher levels.[128] Also, Lp(a) may increase as an acute phase reactant[129,130] and has been reported to be elevated in certain inflammatory rheumatologic disorders.[131]

Early retrospective studies suggested a relationship between elevated levels of Lp(a) and the risk of premature atherosclerosis and arterial thrombosis.[132-134] However, prospective studies have been less supportive and at the most suggest only a small increase in risk for individuals with elevated plasma Lp(a).[135-141] Additional reports have suggested a role for elevated Lp(a) as an independent risk factor for VTE,[142,143] although a failure to find an association has been reported by other investigators.[144]

Sticky Platelet Syndrome

Sticky platelet syndrome (SPS) is an inherited, autosomal dominant disorder associated with early-onset myocardial infarction and peripheral vascular disease.[145-147] Although most often associated with arterial vasculopathy, VTE has been reported.[145-147] A causal relationship to early miscarriage has also been reported. Patients usually present with a history of myocardial infarction or thromboembolism as young adults. The events often are precipitated by stress.[145-147] The defect appears to be common in patients with unexplained thromboembolic events. In an analysis of 200 patients and family members identified with SPS, 21% had arterial thromboembolic events and 13.2% had VTE events.[146] SPS platelets demonstrate hyperreactivity to epinephrine and adenosine diphosphate (ADP) even with dilution, but have normal responses to thrombin, collagen, and arachadonic acid.[145-147] Three types of platelet responses have been noted: type I is hyperreactive to both ADP and epinephrine; type II is hyperreactive to epinephrine only; and type III is hyperreactive to ADP only. Increased arterial events may be mediated through polymorphisms of glycoprotein IIIa allele PLA-A2.[148] Although other investigators have reported similar hyperreactivity of platelets in patients with ischemic stroke,[149] there remains controversy as to whether SPS represents a true congenital prothrombotic syndrome. In patients with documented platelet reactivity and thrombosis, low-dose acetylsalicylic acid (81 mg) appears to be effective in inhibiting platelet hyperreactivity.[147]

Idiopathic (Unprovoked) Venous Thrombosis

Unprovoked or idiopathic venous thrombosis is defined as the development of deep vein thrombosis and/or pulmonary embolism in the absence of known genetic prothrombotic mutations, permanent factors, or acquired risk factors. Patients who develop VTE provoked by surgery, trauma, immobilization, pregnancy, or female hormone intake are at low risk of recurrent thrombosis.[150,151] Patients with unprovoked VTE have a recurrence risk of 5% to 10% per year, with nearly 50% developing a recurrent event by 10 years.[150,151] A recent prospective clinical trial evaluated whether D-dimer screening 4 weeks after completion of 6 months of warfarin for unprovoked VTE could predict risk of recurrence off anticoagulation.[152] The study found males, even with low D-dimer levels continue to have a greater than 7% annual risk of recurrent VTE.[152] Women with low D-dimer levels and women with estrogen associated VTE have a significantly lower risk of recurrent VTE. A prospective study that screened 66 patients with idiopathic venous thrombosis found abnormalities in 26 (39.3%) patients when they were screened for thrombophilia (antithrombin, protein C, protein S, factor V Leiden, prothrombin G20210A, antiphospholipid antibodies).[153] Therefore, 60% of patients with unprovoked VTE have no underlying known major inherited or acquired thrombophilia and still remain at high risk of recurrent VTE. It has been proposed that an underlying inflammatory state may be responsible for the increased risk of VTE in patients with unprovoked events.[154,155] Laboratory assessment of patients with idiopathic VTE have demonstrated higher levels of interleukin (IL)-6 and IL-8 with low levels of IL-10 compared with age- and sex-matched controls.[156] It is notable that the same inflammatory markers are linked to an increased risk of atherothrombotic disease.[154-157]

ACQUIRED HYPERCOAGULABILITY

An increased risk of thrombosis can be associated with a variety of acquired abnormalities. Disorders such as the APLAS and cancer are significant prothrombotic syndromes.[158,159] Common clinical situations such as cancer, pregnancy, infection, and estrogen use are transient causes of hypercoagulability.[160-162] Surgery is a well-documented transient cause of hypercoagulability in which the risk of thrombosis is related to a number of factors, such as the type of surgery, the duration of surgery, the age of the patient, and other patient comorbidities.[162] A significant iatrogenic thrombotic disorder is heparin-induced thrombocytopenia (HIT), in which early diagnosis and treatment may be lifesaving.[163] Chronic inflammatory and autoimmune disorders, such as inflammatory bowel disease, Behcet's syndrome, or lupus erythematosus, with and without antiphospholipid antibodies, are also associated with a significant risk of thrombosis.[164-167]

Acquired elevations in factor VIII levels or depressions in protein S may be important contributing factors to a number of prothrombotic disorders, including cancer, pregnancy, infection, and chronic inflammatory disorders. In patients with cancer, the expression of tissue factor by the malignant cell further increases the thrombotic risk.[168,169] Paroxysmal nocturnal hemoglobinuria, a rare hemolytic disorder in which nearly half of the patients develop symptomatic thrombosis, has been shown to be associated with both increased platelet activation and increased leukocyte tissue factor expression.[170,171] Thrombosis in patients with myeloproliferative syndromes frequently involves unusual sites, such as the portal and hepatic veins, and is more often associated with syndromes associated with the Janus kinase-2 (JAK-2) mutation.[172-175] The presence of JAK-2 mutation has also been shown to be associated with thrombosis in the splanchnic, portal, and hepatic veins, even in the presence of normal blood counts.[175]

Antiphospholipid Antibody Syndrome

The APLAS is one of the more common causes of acquired hypercoagulability.[158,159] The syndrome is associated with an increased risk of both arterial and venous thrombosis.[158,159] Although the APLAS can occur with systemic lupus erythematosus (SLE), 50% of the patients do not fulfill criteria for lupus

or other autoimmune disorders.[176] The syndrome is characterized by the presence of antibodies that inhibit in vitro coagulation reactions, the lupus anticoagulant (LA), and antibodies that bind to anticardiolipin and β_2-glycoprotein.[158,159] Clinical criteria include a history of either thrombosis and/or pregnancy complications with fetal loss.[177]

Pathogenesis and Incidence

There is strong epidemiologic evidence to support a relationship between the presence of these antiphospholipid antibodies and thrombosis.[158,148,178] There appears to be a differential risk with the highest risk of thrombosis associated with the presence of an LA and high titer immunoglobulin-G (IgG) anticardiolipin antibody.[158,178] The Leiden Thrombophilia Study, a large population-based, case-control study of unselected patients with a first episode of venous thrombosis, found a 3.6-fold increased risk for deep venous thrombosis for individuals positive for LA (odds ratio [OR], 3.6; 95% CI, 1.2 to 10.9).[178] However, patients who were positive for both the LA and either antiprothrombin or anti-β_2-glycoprotein-1 antibodies had an estimated 10-fold increased risk of VTE (OR, 10.1; 95% CI, 1.3 to 79.8).

The syndrome is something of a paradox in that this thrombotic disorder is characterized by antibodies that prolong in vitro coagulation tests, most commonly, the activated partial thromboplastin time (aPTT). The mechanism(s) by which these antibodies result in thrombosis remains unclear.[179] Activation of monocytes, platelets, and endothelial cells by antibody/β_2-glycoprotein-1 complexes has been implicated in the etiology of thrombotic events.[180-183] Antibodies to annexin II on endothelial cells, tissue plasminogen activator, and plasmin have been proposed as additional antigenic targets.[182] Complement (C5a)-mediated inflammation has been demonstrated to be associated with increased thrombogenicity and recurrent fetal loss.[179,183]

Diagnosis

Laboratory diagnosis of the APLAS should include screening for LA with two different assay systems.[177] Assessment of anticardiolipin antibodies should include screening for both IgG and IgM antibodies.[177] Anti-β_2-glycoprotein-1 screening can provide further confirmatory evidence for the diagnosis.[177] Positive tests should be confirmed 12 weeks after the initial screen, because transiently positive values may be seen during infections, during autoimmune hemolytic anemia, and with malignancy.[177]

Clinical Presentation and Management

APLAS has been associated with both arterial and VTE.[158,159,176] No laboratory test can distinguish patients at risk for either an arterial or venous event. However, recurrent events most often recur in the vascular sites of previous thrombosis.[184] Thrombosis at unusual sites is well described with the APLAS, including multiple arterial emboli due to nonbacterial thrombotic endocarditis.[184] Retrospective studies have reported a risk of recurrence as high as 50%.[185,186] However, recent prospective treatment trials have estimated the risk to be somewhat lower, but still significant, with a relative risk of recurrence after stopping oral anticoagulants of 4- to 7.7-fold.[187-189] This has led to consensus recommendations to consider extended or indefinite anticoagulation for patients with the APLAS and thromboembolism.[24]

Two prospective randomized trials in patients with APLAS associated thrombosis compared moderate- to high-intensity warfarin (prothrombin time [PT] international normalized ratio [INR] 2.0 to 3.0 vs. 3.0 to 4.0) for secondary antithrombotic prophylaxis. Both trials demonstrated that moderate-intensity warfarin was equivalent to high-intensity treatment with a lower risk of bleeding complications.[188,189] Assessing adequate anticoagulation with the PT INR may, at times, be difficult in the rare patient with an LA that affects the PT test.

A catastrophic form of APLAS designated as CAPS is a life-threatening variant of the disorder characterized by diffuse macro- and microvascular thrombosis with multiple organ involvement.[190] Prompt recognition and treatment with corticosteroids and heparin, and in refractory cases, plasmapheresis, can be lifesaving.[190]

Cancer

Pathogenesis and Incidence

The etiology of thrombosis in patients with cancer is complex, including expression of tissue factor by tumor cells and malignancy-induced inflammation resulting in prothrombotic hemostatic changes in blood, such as increases in fibrinogen, factor VIII, and platelet count.[160,191,192] Additional prothrombotic risk factors frequently encountered by the cancer patient include compression and invasion of vessels by tumors, surgical procedures, indwelling catheters, and systemic chemotherapy.[161,191-193]

The association of cancer with an increased propensity for thrombosis has been recognized since 1861, when Armand Trousseau made his seminal presentation.[194] According to various studies, the incidence of clinically significant VTE ranges from 1% to 43% among cancer patients, depending on the type and stage of the tumor, the modality of cancer treatment, contributing risk factors, and comorbidities.[160,195-198] Cancer patients receiving chemotherapy are at a significantly higher risk of VTE.[160,194,195] In comparison to patients without cancer, cancer patients have an approximately 7-fold increased risk of VTE, and with metastatic disease, the risk may be as high as 20-fold.[161] Furthermore, the identification of unsuspected pulmonary emboli among cancer patients at autopsy and by highly sensitive computed tomography scanning, which is now used for routine staging, suggests that VTE remains an underdiagnosed phenomenon.[198,199]

Clinical Presentation and Management

Venous

Cancer patients with VTE have a threefold higher incidence of recurrent thrombosis and a higher risk of treatment-related bleeding than patients without cancer.[200,201] In a prospective study comparing patients with and without cancer who were newly diagnosed with VTE and treated with unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH) followed by oral warfarin, the 12-month cumulative incidence

of recurrent VTE among the cancer patients was 20.7% versus 6.8% among patients without cancer, although the degree of anticoagulation achieved was superior among the cancer patients.[201] Recurrences were more likely in patients with more extensive disease. The 1-year cumulative incidence of major bleeding was 12.4% in cancer patients, as opposed to 4.9% in patients without cancer, with no difference in the number of patients who had levels of anticoagulation above the therapeutic range.[201] The results of these retrospective studies resulted in a reassessment in the use of warfarin for secondary antithrombotic prophylaxis in cancer patients with VTE. Subsequent clinical trials[202,203] and resulting guidelines[204,205] now recommend against the use of warfarin in favor of long-term LMWH for the management of cancer-associated VTE.

Arterial

Arterial thromboembolic events account for 10% to 30% of the thrombotic complications in cancer patients.[160] Cancer patients, who, in general, represent an older age population, have the same risk factors for arterial thrombotic events, such as stroke or myocardial infarction, as older patients without cancer. However, the impression emerges of a greater risk imposed by the presence of a malignancy. As with VTE, systemic therapy of cancer may increase the risk of arterial thrombosis. In a meta-analysis of five completed cancer trials using chemotherapy plus the antiangiogenic agent, bevacizumab, the incidence of arterial thromboembolic events was 3.8%, twice that seen in patients who received chemotherapy alone.[205] The mortality associated with these events was 0.8%, again twice that seen with chemotherapy alone.

Cerebral emboli resulting in infarction may result from underlying nonbacterial thrombotic endocarditis (NBTE). NBTE may be the most common cause of stroke in patients with solid tumors.[206,207] NBTE is the cardiac manifestation of systemic hemostatic activation in the cancer patient, resulting in the formation of platelet and fibrin vegetations on cardiac valves. In one study, atherosclerosis accounted for 14.5% of symptomatic cerebral infarcts compared with 18.5% of thrombotic events associated with NBTE.[208] Of patients with NBTE, 30% to 70% have laboratory evidence of overt DIC.[206,207,209] Although NBTE is more frequently diagnosed with advanced malignancy, patients with localized or occult malignancy have been reported.[206,207] In autopsy series, NBTE has been detected in 0.9% to 1.3% of patients dying of cancer.[208-210] Antemortem diagnosis of NBTE with transesophageal echocardiography (TEE) has the greatest diagnostic yield.[207] However, a negative TEE cannot completely exclude the diagnosis of NBTE in cancer patients with new-onset stroke or other arterial thrombotic event. Hemostatic studies to look for DIC should be performed before NBTE is ruled out.[207-209]

Pregnancy and Oral Contraceptives

Pregnancy

Pathogenesis and Incidence

Pregnancy induces an acquired prothrombic state due to hormone-related elevations of fibrinogen, factor VIII, reduced protein S, and depressed fibrinolysis.[55,56] Therefore, it is not surprising that the incidence of VTE significantly increases for patients who have underlying inherited thrombophilia.[211] Patients with congenital deficiencies of AT-III and proteins C or S are eight times more likely to have thromboembolic complications during pregnancy compared with controls, and are more likely to have antepartum thromboembolism.[35,80,83,211] Heligren et al.[80] reported, in a noncontrolled study of northern European pregnant patients with VTE, that 60% had the factor V Leiden mutation. In a case-controlled study of 119 women with a history of VTE during pregnancy and postpartum, the prevalence of factor V Leiden was 43.7% compared with 7.7% among normal women.[212] The prothrombin G20210A mutation was detected in 16.9% of women with VTE compared with only 1.3% in the nonpregnant controls.[212] In an Italian case-controlled study, 39% of women presenting with their first venous thrombotic event during a pregnancy had a thrombophilic defect.[213] Factor V Leiden was the most commonly associated thrombophilia.[214]

The risk of VTE associated with pregnancy is increased four- to sixfold compared with comparable age-matched nonpregnant patients.[211-213,215,216] The overall incidence of VTE, as estimated by the Rochester Epidemiology Project (Olmsted County, Minnesota) from 1966 to 1995, was 199.7 per 100,000 woman-years.[211] Greer[215] estimated the acute antepartum risk of deep venous thrombosis to be 0.6 per 1000 in women younger than 35 years and 1.2 per 1000 in women older than 35 years. VTE is a leading cause of maternal mortality in the United States, representing 11% of maternal deaths.[216] Thromboembolism can develop any time during pregnancy; the lowest risk occurs in the first trimester, but the risk does not increase during the last 20 weeks of gestation.[212] The postpartum period accounts for greater than 50% of pregnancy-related VTEs.[212,216-218] The incidence is higher after cesarean section than vaginal delivery.[217] The left leg is affected in 90% of cases, which is felt to be due to a compressive effect on the left iliac vein by the right iliac artery where the two blood vessels cross.[219-221,214]

Clinical Presentation and Management

Women with a history of pregnancy-associated thrombosis without documented thrombophilia can have antepartum prophylactic anticoagulation withheld, but should be followed closely and receive prophylaxis in the immediate postpartum period.[83] Patients with congenital deficiencies, such as antithrombin, protein C, protein S, and antiphospholipid syndrome, should be considered for both ante- and postpartum prophylaxis, even if they have not had a previous thromboembolic event. Patients with the factor V Leiden mutation should receive prophylaxis in the peri- and postpartum periods (6 weeks), unless they have had an antepartum thrombosis with a previous pregnancy. Pregnant patients with active thrombosis should receive a full dose of LMWH.

Oral Contraceptives

Pathogenesis and Incidence

Estrogen alone as HRT or when used in combination with progestin in OCs is a well-documented risk factor for venous

thrombosis.[222-225] A reduction in the estrogen content of OCs from 150 μg to the present preparations containing 15 to 20 μg resulted in a reduction of arterial thrombotic events in American studies, but not European studies.[226-229] The progestagen component of OCs was changed from the second-generation compounds (levonorgestrel, norgestrione, norgestrel) to the third-generation agents (desgestrel, gestodene) in the hope of lower androgenic effects and beneficial effects on high-density lipoprotein cholesterol levels. However, these third-generation progestagen compounds were associated with a doubling of the risk of VTE compared with second-generation agents.[230-232]

The first-generation OCs were associated with a 10-fold increased risk of VTE that decreased to a 4-fold risk with the second-generation OCs.[232-234] The third-generation OCs containing the newer progestagen compounds have a two- to threefold increased risk of VTE over second-generation OCs.[232-234] A meta-analysis including case-controlled studies and cohorts performed before October 1995 estimated the overall adjusted ORs for third- versus second-generation OCs to be 1.7 (95% CI, 1.4 to 2.0).[234] The role of OCs in the development of venous thrombosis in unusual sites remains controversial. A meta-analysis of studies on risk factors associated with cerebral venous thrombosis estimated a sixfold increased risk for users of OCs,[235] whereas a study of risk factors for the development of portal vein thrombosis failed to document an increased risk for users of OCs.[236] Retrospective studies have demonstrated that the combination of OC use and inherited thrombophilia has a multiplicative effect on the risk of VTE.[81,82,93,237-239]

Case-controlled studies[240,241] and randomized clinical trials[242-244] of HRT in postmenopausal women demonstrated a two- to threefold increased risk of VTE without demonstrable benefit in the reduction of cardiovascular disease. The risk appeared to be the highest in the first year and significantly higher in women with thrombophilia.[245,246] A recent case-controlled study suggested that transdermal estrogen replacement might be associated with a lower risk of VTE, even in women with inherited thrombophilia.[247,248]

Heparin-Induced Thrombocytopenia

Heparin use in cardiac and vascular surgery patients is ubiquitous. Therefore, the differential diagnosis of thrombocytopenia in these patients must include consideration of HIT. HIT is the most significant adverse event associated with heparin use. It is an immunopathologic disorder that places patients at a significant higher risk of developing venous and arterial thrombotic complications and is associated with a substantial mortality.[163,249-255] Although HIT is associated with thrombocytopenia, it is not a bleeding disorder.

Pathogenesis and Incidence

HIT is an immunologic disorder in which there is a polyclonal antibody response against neoantigens expressed on platelet factor 4 (PF4) upon binding to heparin.[256,257] Platelet activation is mediated solely by IgG antibodies directed against the heparin-PF4 complex.[258,257,259] The larger heparin molecules contained in UFH induce larger PF4 bundles, resulting in greater antibody binding. This may explain the greater incidence of HIT observed with UFH as opposed to LMWH or fondaparinux.

Upon binding to the heparin-PF4 complex, the Fc domain of the HIT IgG antibodies activate platelets through the platelet Fc receptors.[260,261] Upon activation, platelets release significant membrane microparticles,[262] which express P-selectin capable of activating monocytes and inducing tissue factor expression, the initiator of the coagulation cascade.[263] However, heparin-PF4/HIT IgG complexes have also been reported to independently induce tissue factor expression and cytokine release from monocytes and macrophages.[264] The resulting activation of coagulation leads to significant thrombin generation, which, in turn, results in further platelet activation and thrombocytopenia. In many ways, clinical HIT can be viewed as similar to DIC because both syndromes are mediated by excessive thrombin generation.[265] Although venous thrombosis predominates over arterial thrombotic events at a rate of 4:1, the targeting of specific thrombotic events in patients with HIT can be explained, in part, by the clinical circumstances associated with the development of HIT.[251] Patients who develop HIT during the treatment of venous thrombosis are most likely to develop new or progressive VTE. Antecedent arterial events may precipitate additional arterial thromboses. If HIT is not diagnosed promptly and appropriately treated, thrombotic events at multiple sites can occur, as seen in patients with DIC.[266] The incidence of HIT varies depending upon the patient population, the duration and type of heparin utilized, and the medical or surgical procedure.[249-253,267,268-272]

Diagnosis and Management

The diagnosis of HIT is based upon clinical findings, including the development of thrombocytopenia and/or thrombosis during or immediately following heparin use.[163,250,251,256,267] Rapid-onset HIT can occur as early as 24 hours of heparin treatment in patients who have been exposed to heparin within the previous 100 days and have developed HIT antibodies.[273] Although the development of thrombocytopenia or an unexplained decrease in the platelet count (>50% of pretreatment baseline) during heparin exposure is the clinical hallmark of this disorder, thrombotic sequelae can develop in 30% to 70% of HIT patients, and this accounts for much of the morbidity associated with this diagnosis.[252,253,256,267] The thrombotic death rates in these retrospective studies are between 4% and 5%.[252,253,256,267] Thrombotic complications may occur even when the platelet count nadir remains greater than 150×10^9/L.[256] Severe thrombocytopenia (platelet count <20 K) is rare with HIT. In large clinical studies of HIT, the median platelet count nadir has been in the range of 50 to 60×10^9/L.[252,253,267] The development of new thrombosis or progression of an existing venous or arterial thrombosis in a patient receiving heparin, particularly if accompanied by a drop in the platelet count, is highly suggestive of HIT.

Appropriate platelet monitoring is essential to the early diagnosis of HIT. In heparin-naive patients, the platelet count should be monitored every other day, beginning 5 days after starting heparin. In patients with previous heparin exposure, the platelets should be monitored with the start of heparin use.

A 50% or greater decrease in platelet count from the pretreatment platelet count should alert the clinician to the development of HIT.[163,250,274] The development of platelet activating, noncomplement fixing IgG antibodies directed against the complex of heparin and PF4 is the hallmark of this immunopathic disorder.[273,259,258,274] Therefore, confirmation of a clinical suspicion of HIT requires serologic screening for HIT-associated heparin/PF4 antibodies.[273,259,257] Prospective studies of heparin/PF4 antibody formation indicate that clinical HIT occurs in a minority of patients who form antibodies.[275] Antibody detection can be performed by either the use of functional assays that detect antibodies capable of inducing platelet activation (serotonin release assay), or by a PF4/heparin immunoassay (enzyme-linked immunosorbent assay [ELISA]). The more readily available heparin/PF4 ELISA has significant sensitivity (>90% to 95%) and specificity (80% to 90%).[274] Therefore, a negative ELISA has a strong negative predictive value of more than 95%, suggesting an alternate diagnosis for thrombocytopenia. A strongly positive ELISA is also more likely to be associated with a positive functional assay as determined by either a washed platelet C^{14}-serotonin-release assay (SRA) or heparin-induced washed platelet aggregation assay.[274] A positive platelet SRA or platelet aggregation assay has a reported sensitivity of greater than 90% and specificity for clinical HIT of greater than 95%.[274] The combined use of both the PF4/heparin ELISA and a functional assay provide a diagnostic sensitivity approaching 100% for clinical HIT.[274]

Prompt recognition of the disorder, immediate cessation of all forms of heparin and rapid initiation of a direct thrombin inhibitor, such as argatroban, lepirudin, or bivalrudin, is essential in preserving life and limb (see Chapter 39). Approximately 50% of patients with HIT characterized by thrombocytopenia alone will develop thrombosis if managed with only the discontinuation of heparin.[251] The use of warfarin alone in these patients is not protective, and warfarin loading after a diagnosis of HIT can result in severe thrombotic complications, such as ischemic limb gangrene.[251,276] Other thrombotic complications reported in patients with HIT include overt DIC with hypofibrinogenemia, adrenal necrosis, and cutaneous necrosis at the sites of heparin injections.[163,256] HIT appears to be a unique event in many patients, without recurrence. However, patients within 100 days of diagnosis should not receive any form of heparin therapy.[273,277] Patients beyond 100 days may receive heparin if indicated, but they should have daily platelet counts monitored. Antibody testing should be closely followed to make sure the patient does not have a recurrence.

Obesity

Obesity, as defined by a body mass index (BMI) greater than 25 kg/m^2, has been shown to be a comorbidity and an independent risk for VTE. In a prospective study of risk factors, the Copenhagen City Heart Study, a BMI of more than 35 kg/m^2 was found to be associated with a hazard ratio of 2.1 versus patients with a BMI less than 20 kg/m^2.[278] In the Tromsø study, the combination of tall stature and obesity (BMI >30 kg/m^2) was associated with an increased risk of VTE in both men and women.[279] Tall, obese men had a fivefold increase in VTE (hazard ratio 5.16) and tall, obese women had a threefold increase (hazard ratio 2.89). Moreover, in an analysis of patients with idiopathic VTE, the presence of the "metabolic syndrome," defined as abdominal obesity, impaired glucose metabolism, arterial hypertension, and dyslipidemia, was detected in 23.5% of patients with idiopathic VTE (P =< .001; OR, 2.99).[280]

In association with other risk factors, such as family history, OCs, and surgery, the risk for VTE in obese patients increases significantly independent of age and sex.[281] Data stratified by age, regardless of race and family history of VTE showed obesity to be a statistically significant risk factor for VTE (age 18 to 44 years: OR, 3.5; 95% CI, 1.6 to 7.6; age 45 to 54 years: OR, 2.6; 95% CI, 1.3 to 5.0; age ≥55 years: OR, 2.6; 95% CI, 1.3 to 5.2). Further, when the association between family history and VTE was examined, among men and women, regardless of race, a family history of VTE was a statistically significant risk factor for VTE among both men and women who were obese (OR, 3.5; 95% CI, 1.8 to 6.6 vs. OR, 2.2; 95% CI, 1.3 to 3.7, respectively).[281] However, among obese patients, a family history of VTE in a relative before age 50 years was a statistically significant risk factor for VTE only among men (OR, 6.9; 95% CI, 2.2 to 21.6), although the OR was elevated among women (OR, 1.8; 95% CI, 0.86 to 3.6), but the P-value for interaction was not significant.[281]

EVALUATION OF THE PATIENT WITH SUSPECTED THROMBOPHILIA

The purpose for testing for thrombophilia in patients with venous thrombosis is to determine the risk of recurrent thrombosis, and, therefore, the duration of anticoagulation. Figs. 38.1 and 38.2 provide a suggested outline for hypercoagulable testing. Patients with significant prothrombotic defects alone or in combination can be at a significantly higher risk of recurrent VTE; therefore, extended or lifelong anticoagulation may be recommended. In patients in whom significant prothrombotic defects are detected, further testing of family members, who have not had a VTE, should be performed. This will allow asymptomatic carriers to be counseled regarding high-risk situations of increased hemostatic stress, such as surgery, pregnancy, OC pills, HRT, or prolonged travel. Patients with VTE who should be tested include those younger than 50 years with unprovoked (idiopathic) VTE, patients with unprovoked recurrent VTE, and patients who develop thrombosis, including those associated with a transient risk factor, if there is a strong family history of VTE.

In the younger patient (<50 years of age) without a history of diabetes, who has experienced an unprovoked arterial thrombotic event, a screening evaluation can lead to the identification of prothrombotic risk factors. This allows for effective treatment strategies to reduce the risk of a recurrent arterial event. Table 38.2 lists the recommended studies for the evaluation of patients with VTE and patients with arterial thrombotic events.

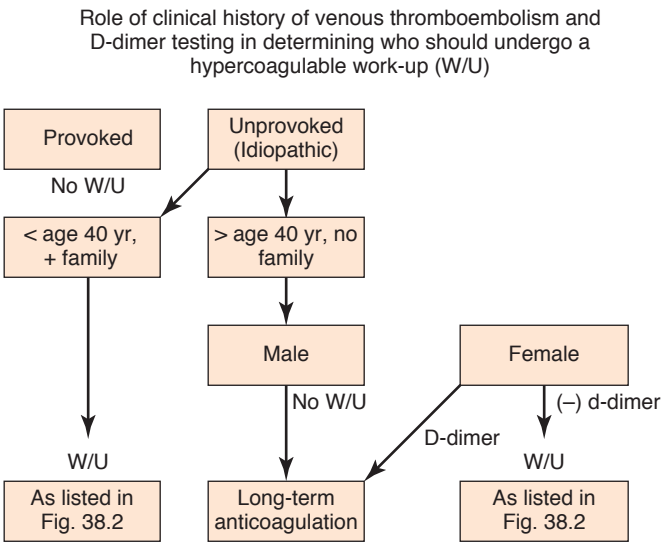

Figure 38.1 The role of clinical history and D-dimer screening before undertaking a hypercoagulable work-up. Based on the findings, a work-up as outlined in Fig. 38.2 may be indicated.

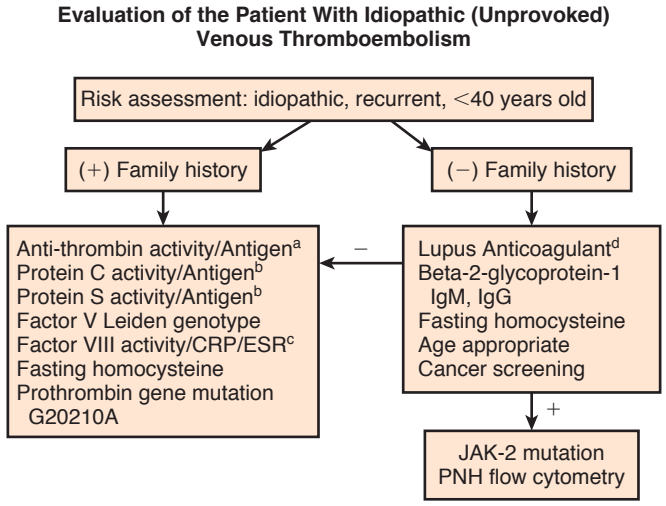

[a] Should not be tested in the setting of acute clot or heparin therapy
[b] Should not be tested in the setting of acute clot or warfarin therapy
[c] Should not be tested in the setting of acute clot
[d] Cannot be tested on unfractionated heparin therapy

Figure 38.2 Evaluation and laboratory testing for hypercoagulability in patients with venous thromboembolism. *CRP*, C-reactive protein; *ESR*, erythrocyte sedimentation rate; *Ig*, immunoglobulin; *JAK-2*, Janus kinase-2; *PNH*, paroxysmal nocturnal hemoglobinuria.

TABLE 38.2 Recommended Tests for Evaluation of Congenital and Acquired Prothrombotic Defects in Patients With Venous and Arterial Thrombosis

Thrombophilic Defect	Type of Test Available
Venous Thrombosis	
Factor V Leiden	Polymerase chain reaction
Prothrombin G20210A	Polymerase chain reaction
Antithrombin	Functional, then antigenic assay[a]
Protein C deficiency	Functional, then antigenic assay[a]
Protein S deficiency	Functional, then antigenic assay[a]
Elevated factor VIII, IX, and XI levels	Functional assay
Dysfibrinogenemia	Functional assay
Hyperhomocysteinemia	HPLC
Lupus anticoagulant	Coagulation-based assays[b]
Cardiolipin antibodies	Enzyme-linked immunoassay
β_2-Glycoprotein-1 antibodies	Enzyme-linked immunoassay
Arterial Thrombosis	
Lupus anticoagulant	Coagulation-based assays[b]
Cardiolipin antibodies	Enzyme-linked immunoassay
B2-glycoprotein 1 antibodies	Enzyme-linked immunoassay
Lipoprotein (a)	Enzyme-linked immunoassay[c]
Sticky platelet syndrome	Platelet aggregation studies

[a] Abnormal functional assays should be performed first, followed by antigen assays to subtype the defect.
[b] Two different coagulation-based assays should be performed in screening for a lupus anticoagulant.
[c] Screening for elevated lipoprotein (a) should be performed in conjunction with a full cholesterol and lipid panel.
HPLC, High-performance liquid chromatography.

INTRODUCTION

Arterial thrombi are rich in platelets because of the high shear in the injured arteries. In contrast, venous thrombi, which form under low shear conditions, contain relatively few platelets and are predominantly composed of fibrin and trapped red cells.[1] Because of the predominance of platelets, arterial thrombi appear white, whereas venous thrombi are red in color, reflecting the trapped red cells. Antithrombotic drugs are used for prevention and treatment of thrombosis. Targeting the components of thrombi, these agents include (1) antiplatelet drugs, which inhibit platelets; (2) anticoagulants, which attenuate coagulation; and (3) thrombolytic agents, which induce fibrin degradation. With the predominance of platelets in arterial thrombi, strategies to inhibit or treat arterial thrombosis focus mainly on antiplatelet agents (see Chapter 40), although, in the acute setting, they often include anticoagulants and thrombolytic agents. Anticoagulants are the mainstay of the prevention and treatment of venous thromboembolism (VTE) because fibrin is the predominant component of venous thrombi. Antiplatelet drugs are less effective than anticoagulants in this setting because of the limited platelet content of venous thrombi.

Anticoagulants are the focus of this chapter and are available in parenteral and oral forms. Parenteral anticoagulants include unfractionated heparin, low-molecular-weight heparin (LMWH), fondaparinux, a synthetic pentasaccharide, and parenteral direct thrombin inhibitors (bivalirudin, hirudin analogs, and argatroban). Oral anticoagulants include vitamin K antagonists (VKAs),

such as warfarin, and the direct oral anticoagulants (DOACs); dabigatran etexilate, which inhibits thrombin, and rivaroxaban, apixaban, and edoxaban, which inhibit factor Xa.

Parenteral Anticoagulants: Indirect Inhibitors

Heparin

A sulfated polysaccharide, heparin is isolated from mammalian tissues rich in mast cells. Most commercial heparin is derived from porcine intestinal mucosa and is a polymer of alternating D-glucuronic acid and *N*-acetyl-D-glucosamine residues.[2]

Mechanism of Action

Heparin acts as an anticoagulant by activating antithrombin (previously known as antithrombin III) and accelerating the rate at which antithrombin inhibits clotting enzymes, particularly thrombin and factor Xa.[3] Antithrombin, the obligatory plasma cofactor for heparin,[3] is a member of the serine protease inhibitor superfamily. Synthesized in the liver and circulating in plasma at a concentration of 2.6 ± 0.4 μM, antithrombin acts as a suicide substrate for its target enzymes.

To activate antithrombin, heparin binds to the serine protease inhibitor via a unique pentasaccharide sequence that is found on one third of the chains of commercial heparin (Fig. 39.1). The remainder of the heparin chains that lack this pentasaccharide sequence have little or no anticoagulant activity.[4] Once bound to antithrombin, heparin induces a conformational change in the reactive center loop of antithrombin that renders it more readily accessible to its target proteases. This conformational change enhances the rate at which antithrombin inhibits factor Xa by at least two orders of magnitude but has little effect on the rate of thrombin inhibition by antithrombin.[5] To catalyze thrombin inhibition, heparin serves as a template that binds antithrombin and thrombin simultaneously.[6] Formation of this ternary complex brings the enzyme in close apposition to the inhibitor, thereby promoting the formation of a stable covalent thrombin-antithrombin complex.[6,7] Only pentasaccharide-containing heparin chains composed of at least 18 saccharide units (which corresponds to a molecular weight of 5400) are of sufficient length to bridge thrombin and antithrombin together.[8] With a mean molecular weight of 15,000 and a range of 5000 to 30,000, almost all of the chains of unfractionated heparin are long enough to effect this bridging function.[9] Consequently, by definition, heparin has equal capacity to promote the inhibition of thrombin and factor Xa by antithrombin and is assigned a 1:1 ratio of anti–factor Xa to anti–factor IIa (thrombin) activity.[3]

Heparin induces the release of tissue factor pathway inhibitor, a factor Xa–dependent inhibitor of tissue factor–bound factor VIIa, from the endothelium.[9-11] Tissue factor pathway inhibitor may contribute to the antithrombotic activity of heparin. Longer heparin chains induce the release of more tissue factor pathway inhibitor than shorter chains.[10,11]

Pharmacology

Heparin must be given parenterally. It is usually administered subcutaneously when given for prophylaxis and by continuous intravenous infusion when used for therapeutic purposes. If heparin is given subcutaneously for treatment of thrombosis, the dose of heparin must be high enough to overcome the limited bioavailability associated with this method of delivery.[3]

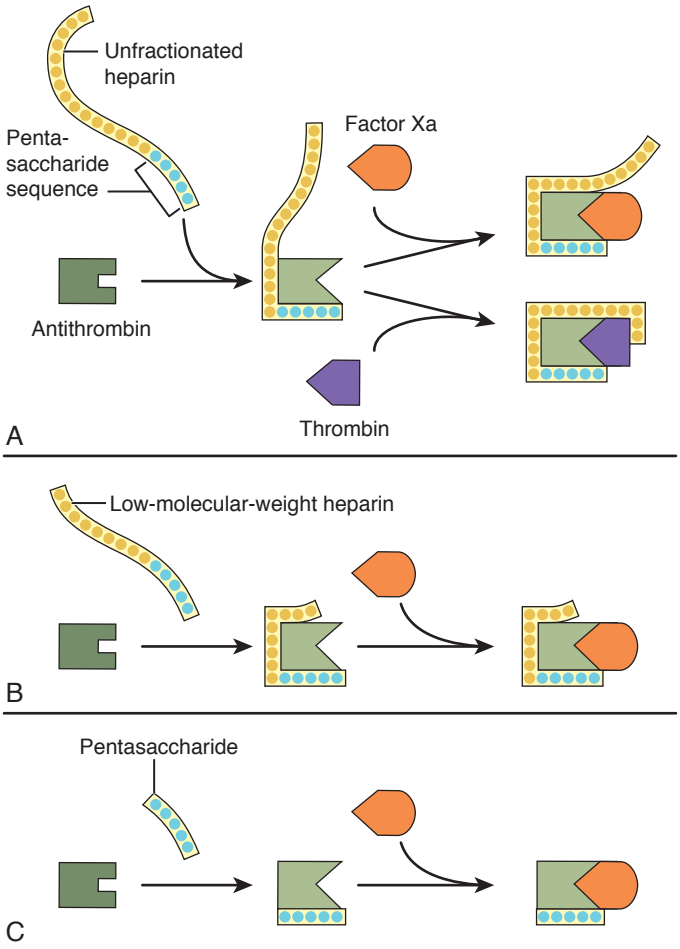

Figure 39.1 Mechanism of action of heparin, low-molecular-weight heparin (LMWH), and fondaparinux, a synthetic pentasaccharide. (A) Heparin binds to antithrombin via its pentasaccharide sequence and induces a conformational change in the reactive center loop of antithrombin that accelerates its interaction with factor Xa. To potentiate thrombin inhibition, heparin must simultaneously bind to antithrombin and thrombin. (B) LMWH has greater capacity to potentiate factor Xa inhibition by antithrombin than thrombin because at least half of the LMWH chains are too short to bridge antithrombin to thrombin. (C) Fondaparinux only accelerates factor Xa inhibition by antithrombin because it is too short to bridge antithrombin to thrombin.

In the circulation, heparin binds to the endothelium, and this explains its dose-dependent clearance. At low doses, the half-life of heparin is short because it rapidly binds to the endothelium.[3] With higher doses of heparin, the endothelium is saturated and the half-life is longer.[3] Because of this phenomenon, the plasma half-life of heparin ranges from 30 to 60 minutes with bolus intravenous doses of 25 and 100 U/kg, respectively.[3] Clearance of heparin is mainly extrarenal; heparin binds to macrophages, which internalize and depolymerize the long heparin chains and secrete shorter chains back into the circulation.

Once the endothelium is saturated, heparin enters the circulation, where it binds plasma proteins other than antithrombin,

a phenomenon that reduces the anticoagulant activity of heparin.[12] Some of the heparin-binding proteins in plasma are acute-phase reactants whose levels are elevated in ill patients.[12,13] Others, such as high-molecular-weight multimers of von Willebrand factor (vWF), are released from activated platelets or endothelial cells.[14,15] Activated platelets also release platelet factor 4 (PF4), a highly cationic protein that binds heparin with high affinity.[16] The large amounts of PF4 found in the vicinity of platelet-rich arterial thrombi can neutralize the anticoagulant activity of heparin.[17] This phenomenon may attenuate heparin's capacity to suppress thrombus growth.

Because the levels of heparin-binding proteins in plasma vary from person to person, the anticoagulant response to fixed or weight-adjusted doses of heparin is unpredictable. Consequently coagulation monitoring is essential to ensure that a therapeutic response is obtained. This is particularly important when heparin is administered for treatment of established thrombosis, because a subtherapeutic anticoagulant response renders patients at risk for recurrent thrombosis,[18,19] whereas excessive anticoagulation increases the risk of bleeding.[20,21]

The interaction of heparin with plasma proteins also contributes to the phenomenon of heparin rebound. Defined as the reappearance of anticoagulant activity after adequate neutralization of heparin with protamine, heparin rebound may contribute to excessive bleeding after cardiac surgery. This phenomenon likely reflects the slow release of protein-bound heparin after circulating heparin is neutralized by protamine. Heparin rebound can be managed by administration of additional protamine by intravenous bolus or as a low-dose continuous infusion.[22]

Monitoring

Heparin therapy can be monitored using the activated clotting time (ACT), activated partial thromboplastin time (aPTT), or anti–factor Xa level. The ACT, which is less sensitive than the aPTT and can be measured at the bedside, is used to monitor the high doses of heparin given during catheter-based or open cardiovascular surgical procedures. The aPTT is the test most often used to monitor therapeutic doses of heparin. aPTT reagents vary in their sensitivity to heparin, and the type of coagulometer used for testing can influence the results.[23] Consequently laboratories must establish a therapeutic aPTT range with each reagent-coagulometer combination by measuring the aPTT and anti–factor Xa level in plasma samples collected from heparin-treated patients. For most of the aPTT reagents and coagulometers in current use, therapeutic heparin levels are achieved with a two- to threefold prolongation of the aPTT.[24] Anti–factor Xa levels can also be used to monitor heparin therapy. With this test, therapeutic heparin levels range from 0.3 to 0.7 U/mL. Although this test is gaining in popularity, anti–factor Xa results can vary between laboratories.

Up to 25% of heparin-treated patients with VTE require more than 35,000 U/day to achieve a therapeutic aPTT. These patients are considered heparin resistant.[25] It is useful to measure anti–factor Xa levels in heparin-resistant patients because many will have a therapeutic anti–factor Xa level despite a subtherapeutic aPTT. This dissociation in test results occurs because elevated plasma levels of fibrinogen and factor VIII, both of which are acute-phase proteins, shorten the aPTT but have no effect on anti–factor Xa levels.[26] Heparin therapy in patients who exhibit this phenomenon is best monitored using anti–factor Xa levels instead of the aPTT.[25] Patients with congenital or acquired antithrombin deficiency and those with elevated levels of heparin-binding proteins may need higher doses of heparin to achieve a therapeutic aPTT or anti–factor Xa level. If there is good correlation between the aPTT and the anti–factor Xa levels, either test can be used to monitor heparin therapy.

Dosing

For prophylaxis, heparin is usually given in fixed doses of 5000 units subcutaneously two or three times daily. With these low doses, coagulation monitoring is unnecessary.[27] In contrast, monitoring is essential when the drug is given in therapeutic doses. Fixed-dose or weight-based heparin nomograms are used to standardize heparin dosing and to shorten the time required to achieve a therapeutic anticoagulant response. At least two heparin nomograms have been validated in patients with VTE; these reduce the time required to achieve a therapeutic aPTT.[28,29] Weight-adjusted heparin nomograms have also been evaluated in patients with acute coronary syndromes. After an intravenous heparin bolus of 5000 units or 70 U/kg, a heparin infusion rate of 12 to 15 U/kg per hour usually is administered.[29,30] In contrast, weight-adjusted heparin nomograms for patients with VTE use an initial bolus of 5000 units or 80 U/kg followed by an infusion of 18 U/kg per hour.[28] Thus patients with VTE appear to require higher doses of heparin to achieve a therapeutic aPTT than do patients with acute coronary syndromes. This may reflect differences in the thrombus burden. Heparin binds to fibrin, and the fibrin content of large deep venous thrombi is greater than that of small coronary thrombi. For interventions, heparin is usually given as a fixed intravenous bolus of 5000 to 10,000 units or as a weight-adjusted dose of 70 to 100 U/kg.[31,32]

Limitations

Heparin has pharmacokinetic and biophysical limitations (Table 39.1). The pharmacokinetic limitations reflect heparin's propensity to bind in a pentasaccharide-independent fashion to cells and plasma proteins. Heparin binding to endothelial cells explains its dose-dependent clearance, whereas binding to plasma proteins results in a variable anticoagulant response and can lead to heparin resistance.

The biophysical limitations of heparin reflect the inability of the heparin-antithrombin complex to (1) inhibit factor Xa when it is incorporated into the prothrombinase complex,[33,34] the complex that converts prothrombin to thrombin, and (2) to inhibit thrombin bound to fibrin.[35,36] Consequently factor Xa bound to activated platelets within platelet-rich thrombi has the potential to generate thrombin, even in the face of heparin.[37] Once this thrombin binds to fibrin, it too is protected from inhibition by the heparin-antithrombin complex.[38,39] Clot-associated thrombin can then trigger thrombus growth by locally activating platelets and amplifying its own generation through feedback activation of factors V, VIII, and XI.[38-40]

TABLE 39.1 Pharmacokinetic and Biophysical Limitations of Heparin

Limitations	Mechanism
Poor bioavailability at low doses	Limited absorption of long heparin chains
Dose-dependent clearance	Binds to endothelial cells
Variable anticoagulant response	Binds to plasma proteins whose levels vary from patient to patient
Reduced activity in the vicinity of platelet-rich thrombi	Neutralized by platelet factor 4 released from activated platelets
Limited activity against factor Xa incorporated in the prothrombinase complex and thrombin bound to fibrin	Reduced capacity of heparin-antithrombin complex to inhibit factor Xa bound to activated platelets and thrombin bound to fibrin

Further compounding the problem is the potential for heparin neutralization by the high concentrations of PF4 released from activated platelets within the platelet-rich thrombus.[18]

Side Effects

Bleeding. The most common side effect of heparin is bleeding. The risk of heparin-induced bleeding increases with higher heparin doses. Concomitant administration of drugs that affect hemostasis, such as antiplatelet or fibrinolytic agents, increases the risk of bleeding, as does recent surgery or trauma.[41] Heparin-treated patients with serious bleeding can be given protamine sulfate to neutralize the heparin. Protamine sulfate, a mixture of basic polypeptides isolated from salmon sperm, binds heparin with high affinity, and the resultant protamine-heparin complexes are then cleared. Typically, 1 mg of protamine sulfate neutralizes 100 units of heparin. Protamine sulfate is given intravenously. Anaphylactoid reactions to protamine sulfate[42] can occur, and drug administration by slow intravenous infusion is recommended to reduce the risk of these problems.[42,43]

Thrombocytopenia. Heparin-induced thrombocytopenia (HIT) is an antibody-mediated process triggered by antibodies directed against neoantigens on PF4 that are exposed when heparin binds to this protein.[44] These antibodies, which usually are of the IgG subtype, bind simultaneously to the heparin-PF4 complex and to platelet Fc receptors. Such binding activates the platelets and generates platelet microparticles. Circulating microparticles are prothrombotic because they express anionic phospholipids on their surface and can bind clotting factors, thereby promoting thrombin generation.[45]

The clinical features of HIT are illustrated in Table 39.2. Typically HIT occurs 5 to 14 days after initiation of heparin therapy, but it can manifest earlier if the patient has received heparin within the past 3 months.[46] Even a 50% decrease in the platelet count from the pretreatment value should raise the suspicion of HIT in those receiving heparin.[44] HIT is more common in surgical patients than in medical patients and, like many autoimmune disorders, it occurs more frequently in females than in males.

TABLE 39.2 Features of Heparin-Induced Thrombocytopenia

Features	Details
Thrombocytopenia	Platelet count of 100,000/μL or less or a decrease in platelet count of 50% or more
Timing	Platelet count falls 5-10 days after starting heparin
Type of heparin	More common with unfractionated heparin than low-molecular-weight heparin; almost never occurs with fondaparinux
Type of patient	More common in surgical patients than medical patients; more common in women than men
Thrombosis	Venous thrombosis more common than arterial thrombosis

TABLE 39.3 Management of Heparin-Induced Thrombocytopenia

Stop all heparin
Give an alternative anticoagulant, such as lepirudin, argatroban, bivalirudin, danaparoid, fondaparinux, or rivaroxaban
Do not give platelet transfusions
Do not give warfarin until the platelet count returns to its baseline level. If warfarin was administered, give vitamin K to restore the international normalized ratio to normal
Evaluate for thrombosis, particularly deep venous thrombosis

HIT can be associated with thrombosis, either arterial or venous. Venous thrombosis, which manifests as deep venous thrombosis and/or pulmonary embolism, is more common than arterial thrombosis. Arterial thrombosis can manifest as ischemic stroke or acute myocardial infarction (MI). Rarely, platelet-rich thrombi in the distal aorta or iliac arteries can cause critical limb ischemia.[44]

The diagnosis of HIT is established using enzyme-linked assays to detect antibodies against heparin-PF4 complexes or with platelet activation assays. Enzyme-linked assays are sensitive but can be positive in the absence of any clinical evidence of HIT.[44] The most specific diagnostic test is the serotonin release assay. This test is performed by quantifying serotonin release when washed platelets loaded with labeled serotonin are exposed to the patient's serum in the absence or presence of varying concentrations of heparin. If the patient's serum contains the HIT antibody, the addition of heparin induces platelet activation and subsequent serotonin release.[44]

Management of HIT is outlined in Table 39.3. Heparin should be stopped in patients with suspected or documented HIT, and an alternative anticoagulant should be administered to prevent or treat thrombosis.[47] The agents most often used for this indication are parenteral direct thrombin inhibitors (such as lepirudin, argatroban, or bivalirudin) or parenteral or oral factor Xa inhibitors (such as fondaparinux, danaparoid, or

rivaroxaban).[48] The alternative anticoagulant should be continued until the platelet count is normal or the diagnosis of HIT is excluded. Warfarin should be avoided in HIT patients because it can trigger skin necrosis and thrombosis. These complications occur because warfarin lowers the levels of protein C, and many HIT patients already have low levels of this anticoagulant protein as a consequence of increased thrombin generation.

Osteoporosis. Treatment with therapeutic doses of heparin for over a month can cause a reduction in bone density. This complication has been reported in up to 30% of patients given long-term heparin therapy,[48-51] and symptomatic vertebral fractures occur in 2% to 3% of these individuals.

Studies in vitro[52] and in laboratory animals[53-55] have provided insights into the pathogenesis of heparin-induced osteoporosis. These investigations suggest that heparin causes bone resorption both by decreasing bone formation and by enhancing bone resorption.[52-55] Thus heparin affects the activity of both osteoblasts and osteoclasts.

Elevated Transaminases. Therapeutic doses of heparin frequently cause modest elevation in the serum levels of hepatic transaminases, without a concomitant increase in the level of bilirubin.[56,57] The levels of transaminases rapidly return to normal when the drug is stopped. The mechanism responsible for this phenomenon is unknown.

Perioperative Management

When given subcutaneously for thromboprophylaxis, the last dose of heparin should be administered at least 2 hours before surgery. Full-dose intravenous heparin should be stopped 4 to 6 hours before surgery.[58] Low-dose heparin can be restarted 12 to 24 hours after surgery. Resumption of full-dose heparin should be delayed until hemostasis is secure. Often in this setting, heparin is started as an infusion without a loading dose.

Low-Molecular-Weight Heparin

Consisting of smaller fragments of heparin, LMWH is prepared from unfractionated heparin by controlled enzymatic or chemical depolymerization. The mean molecular weight of LMWH is 5000, one third the mean molecular weight of unfractionated heparin.[59] LMWH has advantages over heparin (Table 39.4) and has replaced heparin for most indications.

Mechanism of Action

Like heparin, LMWH exerts its anticoagulant activity by activating antithrombin. With a mean molecular weight of 5000, which corresponds to about 17 saccharide units, at least half of the pentasaccharide-containing chains of LMWH are too short to bridge thrombin to antithrombin (see Fig. 39.1). However, these chains retain the capacity to accelerate factor Xa inhibition by antithrombin because this activity is largely the result of the conformational changes in antithrombin evoked by pentasaccharide binding. Consequently LMWH catalyzes factor Xa inhibition more than thrombin inhibition.[59] Depending on their molecular weight distribution, the anti–factor Xa to anti–factor IIa ratios of the various LMWH preparations range from 2:1 to 4:1.

TABLE 39.4 Advantages of Low-Molecular-Weight Heparin Over Heparin

Advantage	Consequence
Better bioavailability and longer half-life after subcutaneous injection	Can be given subcutaneously once or twice daily for both prophylaxis and treatment
Dose-independent clearance	Simplified dosing
Predictable anticoagulant response	Coagulation monitoring is unnecessary in most patients
Lower risk of heparin-induced thrombocytopenia	Safer than heparin for short- or long-term administration
Lower risk of osteoporosis	Safer than heparin for extended administration

Pharmacology

Although usually given subcutaneously, LMWH can also be administered intravenously if a rapid anticoagulant response is needed. LMWH has pharmacokinetic advantages over heparin,[59,60] since shorter heparin chains bind less avidly to endothelial cells, macrophages, and heparin-binding plasma proteins.[61-63] Reduced binding to endothelial cells and macrophages eliminates the rapid, dose-dependent, and saturable mechanism of clearance characteristic of unfractionated heparin. Instead, the clearance of LMWH is dose independent and its plasma half-life is longer.[60] Based on measurement of anti–factor Xa levels, LMWH has a plasma half-life of about 4 to 6 hours. LMWH is cleared almost exclusively by the kidneys, and the drug can accumulate in patients with renal insufficiency.[59,60]

LMWH exhibits about 90% bioavailability after subcutaneous injection.[59,60] Because LMWH binds less avidly to heparin-binding proteins in plasma than heparin, LMWH produces a more predictable dose response, and resistance to LMWH is rare. With a longer half-life and more predictable anticoagulant response, LMWH can be given subcutaneously once or twice daily without coagulation monitoring.[59] These properties render LMWH more convenient to use than unfractionated heparin. Studies in patients with VTE have shown that home treatment with LMWH is as effective and safe as in-hospital treatment with continuous intravenous infusions of heparin.[64-66] Outpatient treatment with LMWH streamlines care, reduces healthcare costs, and increases patient satisfaction.

Monitoring

In the majority of patients, LMWH does not require coagulation monitoring. If monitoring is necessary, anti–factor Xa levels must be measured, because LMWH has little effect on the aPTT. Therapeutic anti–factor Xa levels with LMWH range from 0.5 to 1.2 U/mL when measured 3 to 4 hours after drug administration. When LMWH is given in prophylactic doses, peak anti–factor Xa levels of 0.2 to 0.5 U/mL are desirable.[67]

Potential indications for LMWH monitoring include renal insufficiency, obesity, and pregnancy. LMWH monitoring in patients with a creatinine clearance of 50 mL/min or less is prudent to ensure that there is no drug accumulation. Although

weight-adjusted LMWH dosing appears to produce therapeutic anti–factor Xa levels in patients who are overweight, this approach has not been extensively evaluated in those with morbid obesity. It may also be advisable to monitor the anticoagulant activity of LMWH during pregnancy because dose requirements can change, particularly in the third trimester.[67] Monitoring should also be considered in high-risk settings, such as in patients with mechanical heart valves who are given LMWH for the prevention of valve thrombosis.

Dosing

The doses of LMWH recommended for prophylaxis or treatment vary depending on the LMWH preparation. For prophylaxis, once-daily subcutaneous doses of 4000 to 5000 units are often used, whereas doses of 2500 to 3000 units are given when the drug is administered twice daily. For treatment of VTE, a dose of 150 to 200 U/kg is given if the drug is administered once daily. If a twice-daily regimen is employed, a dose of 100 U/kg is given. In patients with unstable angina, LMWH is given subcutaneously on a twice-daily basis at a dose of 100 to 120 U/kg.[59]

Side Effects

Bleeding. The major complication of LMWH administration is bleeding. Meta-analyses have suggested that the risk of major bleeding may be lower with LMWH than with unfractionated heparin.[68,69] HIT and osteoporosis are also less common with LMWH than with unfractionated heparin.[59] As with heparin, bleeding with LMWH is more common in patients receiving concomitant therapy with antiplatelet or fibrinolytic drugs. Recent surgery, trauma, or underlying hemostatic defects also increase the risk of bleeding with LMWH.[41]

Although protamine sulfate can be used as an antidote for LMWH, it incompletely neutralizes the anticoagulant activity of LMWH because protamine sulfate binds only the longer chains of LMWH.[70] Since longer chains are responsible for catalysis of thrombin inhibition by antithrombin, protamine sulfate completely reverses the anti–factor IIa activity of LMWH. In contrast, protamine sulfate only partially reverses the anti–factor Xa activity of LMWH because the shorter pentasaccharide-containing chains of LMWH do not bind to protamine sulfate.[71] Consequently patients at high risk for bleeding may be more safely treated with continuous intravenous unfractionated heparin than with subcutaneous LMWH.

Thrombocytopenia. The risk for HIT is about fivefold lower with LMWH than with heparin.[72,73] LMWH binds less avidly to platelets and causes less PF4 release. Furthermore, with lower affinity for PF4 than heparin, LMWH is less likely to induce the conformational changes in PF4 that trigger the formation of HIT antibodies.

LMWH should not be used to treat HIT patients[47] because most HIT antibodies exhibit cross-reactivity with LMWH.[74,75] This in vitro cross-reactivity is not simply a laboratory phenomenon; cases of worsening thrombocytopenia and thrombosis have been reported when HIT patients are treated with LMWH.

Osteoporosis. The risk for osteoporosis is lower with long-term LMWH than with heparin.[76] For extended treatment, therefore, LMWH is a better choice than heparin because of the lower risk for osteoporosis and HIT.

TABLE 39.5 Comparison of Features of Heparin, Low-Molecular-Weight Heparin, and Fondaparinux

Features	Heparin	LMWH	Fondaparinux
Source	Biologic	Biologic	Synthetic
Molecular weight	15,000	5000	1500
Target	Xa and IIa	Xa and IIa	Xa
Bioavailability (%)	30	90	100
Half-life (hr)	1	4	17
Renal excretion	No	Yes	Yes
Antidote	Complete	Partial	No
HIT	<5%	<1%	Never

Perioperative Management

When used in prophylactic doses, the last dose of LMWH should be given at least 12 hours before surgery. With treatment doses of LMWH, the drug should be held for 24 hours before surgery. Thromboprophylaxis with LMWH can be started 12 to 24 hours after surgery; if started 12 hours after major surgery, a half dose can be given provided that hemostasis has been secured. Resumption of full-dose LMWH should be delayed for 2 to 3 days.

Fondaparinux

A synthetic analog of the antithrombin-binding pentasaccharide sequence, fondaparinux differs from LMWH in several ways (Table 39.5). Fondaparinux is licensed for thromboprophylaxis in general surgical and high-risk orthopedic patients and as an alternative to heparin or LMWH for the initial treatment of patients with established VTE. Although approved as an alternative to heparin or LMWH in patients with acute coronary syndrome in Europe and Canada, fondaparinux is not licensed for this indication in the United States.

Mechanism of Action

As a synthetic analog of the antithrombin-binding pentasaccharide sequence found in heparin and LMWH, fondaparinux has a molecular weight of 1728. Fondaparinux binds only to antithrombin (see Fig. 39.1) and is too short to bridge thrombin to antithrombin. Consequently fondaparinux catalyzes factor Xa inhibition by antithrombin and does not enhance the rate of thrombin inhibition.[77]

Pharmacology

Fondaparinux exhibits complete bioavailability after subcutaneous injection. With no binding to endothelial cells or plasma proteins, the clearance of fondaparinux is dose independent and its plasma half-life is 17 hours.[78] The drug is given subcutaneously once

daily. Because fondaparinux is cleared unchanged via the kidneys, it is contraindicated in patients with a creatinine clearance less than 30 mL/min, and it should be used with caution in those with a creatinine clearance less than 50 mL/min.[77,78]

Fondaparinux produces a predictable anticoagulant response after administration in fixed doses because it does not bind to plasma proteins. The drug is given at a dose of 2.5 mg once daily for prevention of VTE. For initial treatment of established VTE, fondaparinux is given at a dose of 7.5 mg once daily. The dose can be reduced to 5 mg once daily for those weighing less than 50 kg and increased to 10 mg once daily for those over 100 kg. When given in these doses, fondaparinux is as effective as heparin or LMWH for the initial treatment of patients with deep venous thrombosis or pulmonary embolism and produces similar rates of bleeding.[79,80]

Fondaparinux is used at a dose of 2.5 mg once daily in patients with acute coronary syndrome. When this prophylactic dose of fondaparinux was compared with treatment doses of enoxaparin in patients with non–ST-segment elevation acute coronary syndromes, no difference was seen in the rate of cardiovascular death, MI, or stroke at 9 days.[81] However, the rate of major bleeding was 50% lower with fondaparinux than with enoxaparin, a difference that likely reflects the fact that the dose of fondaparinux was lower than that of enoxaparin. In patients with acute coronary syndrome who require percutaneous coronary intervention (PCI), there is a risk for catheter thrombosis with fondaparinux unless adjunctive heparin is given.[82]

Side Effects

Although fondaparinux can induce the formation of HIT antibodies, HIT is rare with fondaparinux. In contrast to LMWH, there is no cross-reactivity of fondaparinux with HIT antibodies. Consequently fondaparinux appears to be effective for the treatment of HIT patients,[83] although large clinical trials supporting its use are lacking.

The major side effect of fondaparinux is bleeding. There is no antidote for fondaparinux. Protamine sulfate has no effect on the anticoagulant activity of fondaparinux because it fails to bind to the drug. Recombinant activated factor VII reverses the anticoagulant effects of fondaparinux in volunteers,[84] but it is unknown whether this agent controls fondaparinux-induced bleeding.

Perioperative Management

When used in prophylactic or treatment doses, the last dose of fondaparinux should be given at least 36 hours before major surgery.

Parenteral Direct Thrombin Inhibitors

Heparin and LMWH are indirect inhibitors of thrombin because their activity is mediated by antithrombin. In contrast, direct thrombin inhibitors do not require a plasma cofactor; instead, these agents bind directly to thrombin and block its interaction with its substrates. Approved parenteral direct thrombin inhibitors include lepirudin and desirudin—recombinant forms of hirudin—as well as argatroban, and bivalirudin (Table 39.6). Lepirudin and argatroban are licensed for treatment of patients with HIT with or without associated thrombosis, desirudin is licensed for thrombophylaxis after elective hip arthroplasty, and bivalirudin is approved as an alternative to heparin in patients undergoing PCI, including those with HIT.[85]

TABLE 39.6 Comparison of the Properties of Hirudin, Bivalirudin, and Argatroban

	Hirudin	Bivalirudin	Argatroban
Molecular mass (Da)	7000	1980	527
Site(s) of interaction with thrombin	Active site and exosite 1	Active site and exosite 1	Active site
Renal clearance	Yes	No	No
Hepatic metabolism	No	No	Yes
Plasma half-life (min)	60	25	45

Lepirudin and Desirudin

Lepirudin and desirudin are bivalent direct thrombin inhibitors that interact with both the active site and exosite 1, the substrate binding site, on thrombin.[85] For rapid anticoagulation, lepirudin is given by continuous intravenous infusion, but the drug can be given subcutaneously for thromboprophylaxis. Lepirudin has a plasma half-life of 60 minutes after intravenous infusion and is cleared by the kidneys. Consequently lepirudin accumulates in patients with renal insufficiency.[86] A high proportion of lepirudin-treated patients develop antibodies against the drug.[87] Although these antibodies rarely cause problems, in a small subset of patients they can delay lepirudin clearance and enhance its anticoagulant activity. Serious bleeding has been reported in some of these patients.[87]

Desirudin is given subcutaneously at a dose of 15 mg twice daily. The dose is reduced in patients with a creatinine clearance less than 60 mL/min. In contrast to lepirudin, antibody formation is rare with desirudin, possibly because the drug is only administered subcutaneously.

Desirudin does not usually require anticoagulation monitoring. Lepirudin is monitored using the aPTT, and the dose is adjusted to maintain an aPTT that is 1.5 to 2.5 times the control. The aPTT is not an ideal test for monitoring lepirudin therapy because the aPTT plateaus with higher drug concentrations. Although the ecarin clotting time provides a better index of lepirudin dose than the aPTT does, the ecarin clotting time is not widely available.

Argatroban

A univalent inhibitor that targets the active site of thrombin, argatroban is metabolized in the liver.[85] Consequently, this drug must be used with caution in patients with hepatic insufficiency. Argatroban is not cleared via the kidneys, so this drug is safer than lepirudin for HIT patients with renal insufficiency.

Argatroban is administered by continuous intravenous infusion and has a plasma half-life of about 45 minutes. The aPTT is used to monitor its anticoagulant effect, and the dose is adjusted to achieve an aPTT 1.5 to 3 times the baseline value but not to exceed 100 seconds. Argatroban also prolongs the international normalized ratio (INR), a feature that can complicate the transitioning of patients to warfarin.[88] This issue can be circumvented by using the levels of factor X to monitor warfarin in place of the INR. Alternatively, argatroban can be stopped for 2 to 3 hours before INR determination.

Bivalirudin

A synthetic 20–amino acid analog of hirudin, bivalirudin is a divalent thrombin inhibitor.[89] Thus the NH2-terminal portion of bivalirudin interacts with the active site of thrombin, whereas its COOH-terminal tail binds to exosite 1, the substrate-binding domain on thrombin. Bivalirudin has a plasma half-life of 25 minutes, the shortest half-life of all the parenteral direct thrombin inhibitors.[85] Bivalirudin is degraded by peptidases and is partially excreted via the kidneys. When bivalirudin is given in high doses in the cardiac catheterization laboratory, its anticoagulant activity is monitored using the ACT. With lower doses, its activity can be assessed using the aPTT.

Studies comparing bivalirudin with heparin suggest that bivalirudin produces less bleeding.[90,91] This feature plus its short half-life make bivalirudin an attractive alternative to heparin in patients undergoing PCI.[92] Bivalirudin has also been used successfully in HIT patients who require PCI or cardiac surgery.[89]

Oral Anticoagulants

Current oral anticoagulant practice dates back almost 60 years to when the VKAs, such as warfarin, were discovered as a result of investigations into the cause of hemorrhagic disease in cattle. Over the past decade, however, a new class of oral anticoagulants has been licensed. Known as the non–vitamin K antagonist oral anticoagulants (NOACs) or DOACs, this class includes dabigatran, which inhibits thrombin, and rivaroxaban, apixaban, and edoxaban, which inhibit factor Xa. The NOACs are now replacing warfarin for many indications.

Warfarin

A water-soluble VKA initially developed as a rodenticide, warfarin is the coumarin derivative most often prescribed in North America. Like other VKAs, warfarin interferes with the synthesis of the vitamin K–dependent clotting proteins, which include prothrombin (factor II) and factors VII, IX, and X. VKAs also reduce the synthesis of the vitamin K–dependent anticoagulant proteins, proteins C, S, and Z.

Mechanism of Action

All of the vitamin K–dependent clotting factors possess glutamic acid residues at their N-termini. A posttranslational modification adds a carboxyl group to the γ-carbon of these residues to generate γ-carboxyglutamic acid.[93] This modification is essential for expression of the activity of these clotting factors because it permits their calcium-dependent binding to negatively charged phospholipid surfaces.[94,95] The γ-carboxylation process is catalyzed by a vitamin K–dependent carboxylase. Thus vitamin K from the diet is reduced to vitamin K hydroquinone by vitamin K reductase (Fig. 39.2). Vitamin K hydroquinone serves as a cofactor for the carboxylase enzyme, which, in the presence of carbon dioxide, replaces the hydrogen on the γ-carbon of glutamic acid residues with a carboxyl group. During this process, vitamin K hydroquinone is oxidized to vitamin K epoxide, which is then reduced to vitamin K by vitamin K epoxide reductase (VKOR).[96]

Warfarin inhibits VKOR, thereby blocking the γ-carboxylation process.[96,97] This results in the synthesis of vitamin K–dependent clotting proteins that are only partially γ-carboxylated.[98] Warfarin acts as an anticoagulant because these partially γ-carboxylated proteins have reduced or absent biologic activity. The onset of action of warfarin is delayed until the newly synthesized clotting factors with reduced activity gradually replace their fully active counterparts.

The antithrombotic effect of warfarin depends on a reduction in the functional levels of factor X and prothrombin, clotting factors that have half-lives of 24 and 72 hours, respectively.[99] Because of the delay in achieving an antithrombotic effect, initial treatment with warfarin is supplemented by concomitant administration of a rapidly acting parenteral anticoagulant, such as heparin, LMWH, or fondaparinux, in patients with established thrombosis or those who are at high risk for thrombosis.[99]

Pharmacology

Warfarin is a racemic mixture of *R*- and *S*-isomers. Warfarin is rapidly and almost completely absorbed from the gastrointestinal tract. Levels of warfarin in the blood peak about 90 minutes after drug administration.[99] Racemic warfarin has a plasma half-life of 36 to 42 hours, and more than 97% of circulating warfarin is bound to albumin. Only the small fraction of unbound warfarin is biologically active.[99]

Warfarin accumulates in the liver, where the two isomers are metabolized via distinct pathways. Oxidative metabolism of the more active *S*-isomer is mediated by CYP2C9 (see Fig. 39.2). Two relatively common variants, CYP2C9*2 and CYP2C9*3, have reduced activity. Patients with these variants require lower maintenance doses of warfarin. Polymorphisms in the C1 subunit of vitamin K reductase (VKORC1) can also influence the anticoagulant response to warfarin.[100,101] These findings have prompted the recommendation that patients starting on warfarin should be tested for these polymorphisms and that this information should be incorporated into their warfarin-dosing algorithms. However, whether warfarin-dosing algorithms that incorporate pharmacogenetics data improve clinical outcomes remains uncertain.

In addition to genetic factors, the anticoagulant effect of warfarin is influenced by diet, drugs, and various disease states. Fluctuations in dietary vitamin K intake affect the activity of warfarin. A wide variety of drugs can alter the absorption, clearance, or metabolism of warfarin.[99] Because of the variability in the anticoagulant response to warfarin, coagulation monitoring is essential to ensure that a therapeutic response is obtained.

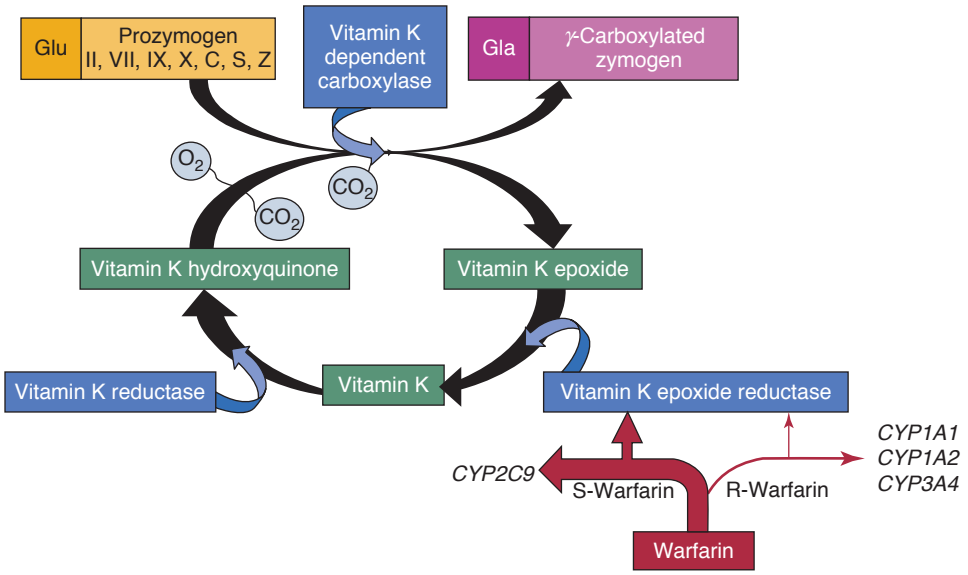

Figure 39.2 The vitamin K cycle and its inhibition by warfarin. Dietary vitamin K is reduced by vitamin K reductase to generate vitamin K hydroquinone. Vitamin K hydroquinone serves as a cofactor for the vitamin K–dependent carboxylase, which converts glutamic acid residues at the N-termini of the vitamin K–dependent precursors to γ-carboxyglutamic acid residues, thereby creating the so-called Gla-domain. By binding calcium, the Gla-domain is critical for the interaction of the vitamin K–dependent clotting factors with negatively charged phospholipid membranes. During vitamin K–dependent carboxylation, vitamin K is oxidized to vitamin K epoxide. Vitamin K epoxide is then converted to vitamin K by vitamin K epoxide reductase. Vitamin K antagonists, such as warfarin, interfere with this cycle by inhibiting vitamin K epoxide reductase. Supplemental vitamin K overcomes the inhibitory effects of vitamin K antagonists by providing more substrate for vitamin K reductase.

Monitoring

Warfarin therapy is most often monitored using the prothrombin time, a test that is sensitive to reductions in the levels of prothrombin, factor VII and factor X. The test is performed by adding thromboplastin—a reagent that contains tissue factor, phospholipid, and calcium—to citrated plasma and determining the time to clot formation. Thromboplastins vary in their sensitivity to reductions in the levels of the vitamin K–dependent clotting factors. Consequently less sensitive thromboplastins will trigger the administration of higher doses of warfarin to achieve a target prothrombin time. This is problematic because higher doses of warfarin increase the risk of bleeding.

The INR was developed to circumvent many of the problems associated with the prothrombin time. To calculate the INR, the patient's prothrombin time is divided by the mean normal prothrombin time, and this ratio is then multiplied by the international sensitivity index (ISI), an index of the sensitivity of the thromboplastin used for prothrombin time determination to reductions in the levels of the vitamin K–dependent clotting factors. Highly sensitive thromboplastins have an ISI of 1.0. Most current thromboplastins have ISI values that range from 0.9 to 1.4.

Although the INR has helped to standardize anticoagulant practice, problems persist. The precision of INR determination varies, depending on reagent-coagulometer combinations. This leads to variability in the INR results. Also complicating INR determination is unreliable reporting of the ISI by thromboplastin manufacturers.[99] Furthermore, every laboratory must establish the mean normal prothrombin time with each new batch of thromboplastin reagent. To accomplish this, the prothrombin time must be measured in fresh plasma samples from at least 20 healthy volunteers using the same coagulometer that is used for patient samples.[99]

For most indications, warfarin is administered in doses that produce a target INR of 2.0 to 3.0. An exception is patients with mechanical heart valves in the mitral position, in which case a target INR of 2.5 to 3.5 is recommended.[99] Studies in atrial fibrillation demonstrate an increased risk for cardioembolic stroke when the INR falls below 1.7 and an increase in intracranial bleeding with INR values over 4.5.[102] These findings highlight the fact that VKAs have a narrow therapeutic window. In support of this concept, a study in patients receiving long-term warfarin therapy for unprovoked VTE demonstrated a higher rate of recurrent VTE with a target INR of 1.5 to 1.9 compared with a target INR of 2.0 to 3.0.[103]

Dosing

Warfarin is usually started at a dose of 5 to 10 mg. The dose is then titrated to achieve the desired target INR. Because of its delayed onset of action, patients with established thrombosis or those at high risk for thrombosis are given concomitant treatment with a rapidly acting parenteral anticoagulant, such as heparin, LMWH, or fondaparinux. Initial prolongation of the INR reflects reduction in the functional levels of factor VII. Consequently concomitant treatment with the parenteral anticoagulant should be continued until the INR has been

therapeutic for at least 2 consecutive days. A minimum 5-day course of parenteral anticoagulation is recommended to ensure that the levels of prothrombin have been reduced into the therapeutic range with warfarin.[99]

Because warfarin has a narrow therapeutic window, frequent coagulation monitoring is essential to ensure that a therapeutic anticoagulant response is obtained. Even patients with stable warfarin dose requirements should have their INR determined every 2 to 4 weeks. More frequent monitoring is necessary when new medications are introduced because so many drugs enhance or reduce the anticoagulant effects of warfarin.

Side Effects

Bleeding. As with all anticoagulants, the major side effect of warfarin is bleeding. At least half of the bleeding complications with warfarin occur when the INR exceeds the therapeutic range. Bleeding complications may be mild, such as epistaxis or hematuria, or more severe, such as retroperitoneal or gastrointestinal bleeding. Life-threatening intracranial bleeding can also occur.[41]

To minimize the risk of bleeding, the INR should be maintained in the therapeutic range. In asymptomatic patients whose INR is between 4.5 and 9, warfarin should be withheld until the INR returns to the therapeutic range. If the INR is higher than 9, a therapeutic INR can be achieved more rapidly by administering low doses of sublingual vitamin K.[104,105] A vitamin K dose of 2 to 5 mg is usually adequate, but higher doses can be administered if more rapid reversal of the INR is required or if the INR is excessively high.

Patients with serious bleeding need more aggressive treatment. These patients should be given vitamin K to reverse the warfarin and prothrombin complex concentrate to replenish the missing clotting factors. Vitamin K should be administered by slow intravenous infusion at a dose of 10 mg; additional vitamin K should be given until the INR is in the normal range. Derived from pooled human plasma, three- and four-factor prothrombin complex concentrates are available. These differ in their content of factor VII; three-factor concentrate contains little or no factor VII, whereas four-factor prothrombin concentrate contains a full complement of factor VII as well as the other three vitamin K–dependent coagulation factors (factors II, IX, and X). Four-factor prothrombin complex concentrate is preferred over three-factor concentrate for warfarin reversal, but the three-factor form should be used if four-factor prothrombin concentrate is unavailable.[106] Prothrombin complex concentrate reverses the INR more rapidly than fresh frozen plasma and is associated with a lower risk of heart failure and transfusion-related lung injury because the required volume is much less. Recombinant factor VIIa should not be used for warfarin reversal because it supplements only one of the missing factors. In support of this concept, factor VIIa failed to attenuate warfarin-induced bleeding from punch biopsy sites in volunteers even though it normalized the INR.[107]

Warfarin-treated patients who experience bleeding when their INR is in the therapeutic range require investigation into the cause of the bleeding. Those with gastrointestinal bleeding often have underlying peptic ulcer disease or a tumor. Similarly, investigation of hematuria or uterine bleeding in patients with a therapeutic INR may unmask a tumor of the genitourinary system.

Skin Necrosis. A rare complication of warfarin, skin necrosis usually is seen 2 to 5 days after initiation of therapy. Well-demarcated erythematous lesions form on the thighs, buttocks, breasts, or toes. Typically, the center of the lesion becomes progressively necrotic. Examination of skin biopsies taken from the border of these lesions reveals thrombi in the microvasculature.

Warfarin-induced skin necrosis is seen in patients with congenital or acquired deficiencies of protein C or protein S.[108,109] Initiation of warfarin therapy in these patients produces a precipitous fall in plasma levels of proteins C or S, thereby eliminating this important anticoagulant pathway before warfarin exerts an antithrombotic effect by lowering of the functional levels of factor X and prothrombin. The resultant procoagulant state triggers thrombosis. Why the thrombosis is localized to the microvasculature of fatty tissues is unclear.

Treatment involves discontinuation of warfarin and, if needed, reversal with vitamin K. An alternative anticoagulant, such as heparin or LMWH, should be given to patients with thrombosis. Protein C concentrates can be given to protein C–deficient patients to accelerate healing of the skin lesions; fresh frozen plasma may be of value for those with protein S deficiency. Occasionally, when there is extensive skin loss, grafting is necessary.

Because of the potential for skin necrosis, patients with known protein C or protein S deficiency require overlapping treatment with a parenteral anticoagulant when warfarin therapy is being initiated. Warfarin should be started in low doses in these patients, and the parenteral anticoagulant should be continued until the INR is therapeutic for at least 2 to 3 consecutive days. Alternatively, a DOAC could be used in place of warfarin, but data with these agents in patients with protein C or protein S deficiency are lacking.

Pregnancy. Warfarin crosses the placenta and can cause fetal abnormalities or bleeding. The fetal abnormalities include a characteristic embryopathy, which consists of nasal hypoplasia and stippled epiphyses. The risk of embryopathy is highest if warfarin is given in the first trimester of pregnancy.[110] Central nervous system abnormalities can also occur with exposure to coumarin drugs at any time during pregnancy. Finally, maternal administration of warfarin produces an anticoagulant effect in the fetus, which can cause bleeding. This is of particular concern at delivery, when trauma to the head during passage through the birth canal can lead to intracranial bleeding. Because of these potential problems, warfarin is contraindicated in pregnancy, particularly in the first and third trimesters. Instead, heparin, LMWH, or fondaparinux can be given during pregnancy for the prevention or treatment of thrombosis. Warfarin does not pass into the breast milk. Consequently warfarin can safely be given to nursing mothers.

Special Problems

Patients being treated with a lupus anticoagulant or those who need urgent or elective surgery present special challenges.

Although observational studies have suggested that patients with thrombosis complicating antiphospholipid syndrome require higher-intensity warfarin regimens to prevent recurrent thromboembolic events, two randomized trials have demonstrated that the targeting of an INR of 2.0 to 3.0 is as effective as higher-intensity treatment and produces less bleeding.[111,112] Monitoring warfarin therapy can be problematic in patients with antiphospholipid syndrome if the lupus anticoagulant prolongs the baseline INR; factor X levels can be used in place of the INR to dose warfarin in such patients.

Periprocedural Management

Warfarin should be stopped 5 days before surgery or invasive procedures to allow the INR to return to normal levels. The INR should be determined before surgery to ensure that it is less than 1.5. Recent studies indicate that bridging with LMWH before and soon after surgery does not reduce the risk of thrombotic complications in patients with atrial fibrillation and increases the risk of bleeding after surgery.[113] However, few patients with atrial fibrillation and a prior history of stroke were included and patients with mechanical heart valves were excluded. Therefore bridging remains indicated in such patients. Bridging can be done with intravenous heparin or once- or twice-daily subcutaneous injections of LMWH when the INR falls below 2.0. Intravenous heparin should be stopped 4 to 6 hours before surgery, whereas the last dose of LMWH should be given 24 hours before surgery. Warfarin can be restarted 12 to 24 hours after surgery, and patients should receive prophylactic doses of heparin or LMWH after surgery until the INR is at least over 1.8.

In the case of urgent surgery, warfarin can be rapidly reversed with four-factor prothrombin complex concentrate and intravenous vitamin K. Prothrombin complex concentrate rapidly normalizes the INR; therefore patients can undergo surgery as soon as it is given.

Direct Oral Anticoagulants

The DOACs include dabigatran, which inhibits thrombin, and rivaroxaban, apixaban, and edoxaban, which inhibit factor Xa. All of these drugs have a rapid onset and offset of action and have half-lives that permit once- or twice-daily administration. Designed to produce a predictable level of anticoagulation, the DOACs are more convenient to administer than warfarin because they are given in fixed doses without routine coagulation monitoring.

Mechanism of Action

The DOACs are small molecules that bind reversibly to the active site of their target enzyme. Table 39.7 summarizes the pharmacologic properties of these agents.

Indications

The DOACs were compared with warfarin for stroke prevention in patients with nonvalvular atrial fibrillation in four randomized trials that enrolled 71,683 patients.[114-118] Compared with warfarin, the higher doses of the DOACs significantly reduced stroke or systemic embolism by 19% ($P = .001$), primarily driven by a 51% reduction in hemorrhagic stroke ($P < .0001$); they were associated with a 10% reduction in mortality ($P < .0001$).[119] The DOACs reduced intracranial hemorrhage by 52% compared with warfarin ($P < .0001$) but increased gastrointestinal bleeding by about 24% ($P = .04$).[119] Overall, therefore, the DOACs demonstrate a favorable benefit-to-risk profile compared with warfarin, and their relative efficacy and safety are maintained across a wide spectrum of patients with atrial fibrillation, including those over the age of 75 years and those with a prior history of stroke.[120] Based on these findings, DOACs are licensed as alternatives to warfarin for stroke prevention in nonvalvular atrial fibrillation, which is defined as atrial fibrillation that occurs in patients without mechanical heart valves or severe rheumatic valvular disease, particularly mitral stenosis and/or regurgitation.

The DOACs were compared with conventional anticoagulation therapy in 27,023 patients with acute VTE.[121-126] The primary efficacy endpoint in these trials was recurrent VTE, while the primary safety outcome was either major bleeding or the composite of major and clinically relevant nonmajor bleeding. In a pooled analysis of these trials, recurrent fatal and nonfatal VTE occurred in 2.0% of those given DOACs compared with 2.2% of those given VKAs (relative risk [RR]: 0.90, 95% confidence interval [CI]: 0.77–1.06).[127] Compared with VKAs, DOACs were associated with a 39% reduction in the risk of major bleeding (RR: 0.61, 95% CI: 0.45–0.83), a 63% reduction in intracranial bleeding (RR: 0.37, 95% CI: 0.21–0.68) and a 64% reduction in fatal bleeding (RR: 0.36; 95% CI: 0.15–0.84).[127] In addition, clinically relevant nonmajor bleeding was reduced by 27% with the DOACs compared with VKAs (RR: 0.73; 95% CI: 0.58–0.93).[127] Therefore the DOACs are noninferior to well-managed therapy with VKAs for the treatment of VTE but are associated with significantly less bleeding.

TABLE 39.7 Comparison of the Features of the Direct Oral Anticoagulants

Target	Dabigatran *Thrombin (IIa)*	Rivaroxaban *Factor Xa*	Apixaban *Factor Xa*	Edoxaban *Factor Xa*
Active drug	No	Yes	Yes	Yes
Onset time (h)	0.5-2	2-4	3-4	1-3
Half life (h)	12-17	5-13	~12	9-11
Renal excretion (%)	80	33	27	50

Whereas dabigatran and edoxaban were started after a minimum of a 5-day course of parenteral anticoagulant therapy, rivaroxaban and apixaban were administered in all-oral regimens starting with a higher dose for 21 days and 7 days, respectively. When used in this all-oral fashion, both agents were noninferior to conventional therapy and were associated with significantly less major bleeding. Therefore rivaroxaban and apixaban simplify treatment and facilitate out-of-hospital management of most patients with deep venous thrombosis and many with pulmonary embolism, thereby reducing healthcare costs. With these advantages, recent clinical guidelines now endorse the DOACs for first-line treatment of VTE in patients without active cancer. For those with active cancer, LMWH remains the preferred therapy.

Dabigatran, rivaroxaban, and apixaban have also been compared with enoxaparin for thromboprophylaxis after elective hip or knee arthroplasty, and although all three are licensed for this indication, dabigatran is rarely used.

Dosing

For stroke prevention in patients with nonvalvular atrial fibrillation, dabigatran is given at a dose of 150 mg twice daily with a dose reduction to 75 mg twice daily in those with a creatinine clearance of 15 to 30 mL/min; rivaroxaban is given at a dose of 20 mg once daily with a dose reduction to 15 mg once daily in patients with a creatinine clearance of 15 to 49 mL/min; apixaban is given at a dose of 5 mg twice daily with a dose reduction to 2.5 mg twice daily for patients with at least two of the following criteria; age of 80 years or more, body weight of 60 kg or less, and serum creatinine >1.5 g/dL; edoxaban is given at a dose of 60 mg once daily with a dose reduction to 30 mg once daily for patients with a creatinine clearance of 15 to 50 mL/min, body weight of 60 kg or less, or receiving potent P-glycoprotein inhibitors such as amiodarone or verapamil.

For the treatment of VTE, dabigatran is given at a dose of 150 mg twice daily after a minimum of a 5-day course of heparin or LMWH; rivaroxaban is started at a dose of 15 mg twice daily for 21 days and the dose is then reduced to 20 mg once daily thereafter; apixaban is started at a dose of 10 mg twice daily for 7 days and the dose is then reduced to 5 mg twice daily for the following 6 months, after which the dose can be further reduced to 2.5 mg twice daily; and edoxaban is given at a dose of 60 mg once daily after a minimum of a 5-day course of heparin or LMWH, with the dose reduced to 30 mg once daily for patients with a creatinine clearance of 15 to 50 mL/min, body weight of 60 kg or less, or receiving potent P-glycoprotein inhibitors.

For thromboprophylaxis after elective hip or knee replacement surgery, rivaroxaban is given at a dose of 10 mg once daily, whereas apixaban is given at a dose of 2.5 mg twice daily. These drugs are usually given for 14 days after knee arthroplasty and for 35 days after hip arthroplasty.

Monitoring

Although the DOACs are designed to be administered without routine monitoring, there are situations where determination of their anticoagulant activity can be helpful. These include assessment of adherence, detection of accumulation or overdose, identification of bleeding mechanisms, and determination of activity prior to surgery or intervention. For the qualitative assessment of anticoagulant activity, the prothrombin time can be used for factor Xa inhibitors and the aPTT for dabigatran.[128] Rivaroxaban and edoxaban prolong the prothrombin time more than apixaban. In fact, because apixaban has such a limited effect on the prothrombin time, anti–factor Xa assays are needed to assess its activity. The effect of the drugs on tests of coagulation varies depending on the time that the blood is drawn relative to the timing of the last dose of the drug and the reagents used to perform the tests. Chromogenic anti–factor Xa assays and a diluted thrombin clotting time with appropriate calibrators provide quantitative assays to measure the plasma levels of the factor Xa inhibitors and dabigatran, respectively.[129]

Side Effects

As with all anticoagulants, bleeding is the most common side effect of the DOACs. The DOACs are associated with less intracranial bleeding than warfarin. The increased risk of intracranial bleeding with warfarin likely reflects the reduction in functional levels of factor VII, which precludes efficient thrombin generation at sites of microvascular bleeding in the brain. Because the DOACs target downstream coagulation enzymes, they produce less impairment of hemostatic plug formation at sites of vascular injury.

A downside of the DOACs is the increased risk of gastrointestinal bleeding. This likely occurs because unabsorbed active drug in the gut exacerbates bleeding from lesions. Although dabigatran etexilate is a prodrug, only 7% is absorbed and the remainder passes through the gut, where at least two-thirds is metabolically activated to dabigatran by gut esterases.[130]

Dyspepsia occurs in up to 10% of patients treated with dabigatran; this problem improves with time and can be minimized by administering the drug with food. Dyspepsia is rare with rivaroxaban, apixaban, and edoxaban.

Periprocedural Management

Like warfarin, the DOACs must be stopped before procedures associated with a moderate or high risk of bleeding. The drugs should be held for 1 to 2 days or if renal function is impaired for longer. Assessment of residual anticoagulant activity before procedures associated with a high bleeding risk is prudent.

Management of Bleeding

The management of bleeding with DOACs is dependent upon the severity of bleeding and the drug that has been taken (Fig. 39.3). With minor bleeding, holding one or two doses of drug is usually sufficient. The approach to serious bleeding is similar to that with warfarin except that vitamin K administration is of no benefit. Thus, anticoagulant and antiplatelet drugs should be held, the patient should be resuscitated with fluids and blood products as necessary, and, if possible, the bleeding site should be identified and managed. Coagulation testing will determine the extent of anticoagulation, and renal

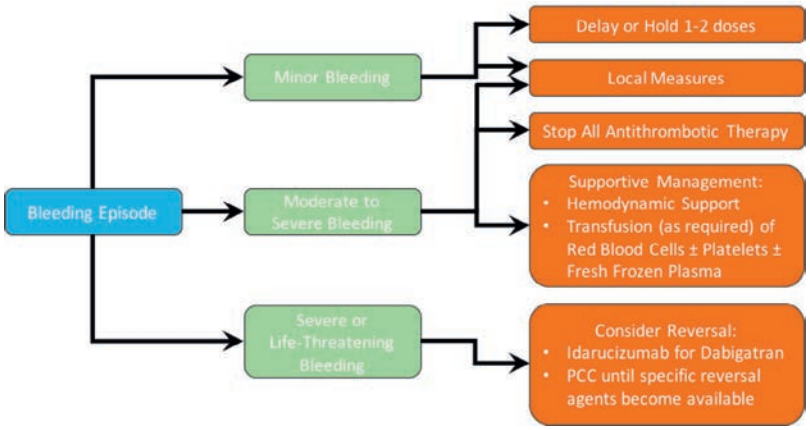

Figure 39.3 Flow diagram for the management of bleeding in patients taking DOACs.

function should be assessed so that the half-life of the drug can be calculated. Timing of the last dose of anticoagulant is important; administration of oral activated charcoal may help to prevent absorption of drug administered in the preceding 2 to 4 hours.

Anticoagulant reversal should be considered in patients with life-threatening bleeding, such as intracranial bleeding, bleeding that continues despite supportive measures, or if patients require urgent surgery. Idarucizumab is a specific reversal agent for dabigatran. A monoclonal antibody fragment, idarucizumab binds dabigatran with high affinity to form a 1 : 1 complex that is then cleared by the kidneys.[131] Idarucizumab is given as an intravenous bolus of 5 g.

Andexanet alfa and ciraparantag are under development for reversal of rivaroxaban, apixaban, and edoxaban, but neither is approved.[132] Until these reversal agents are available, intravenous prothrombin complex concentrate (25 to 50 U/kg) should be considered for reversal of the oral factor Xa inhibitors in patients with life-threatening or ongoing bleeding.

Special Considerations

In a phase II dose-finding study comparing dabigatran with warfarin in patients with mechanical heart valves, there was a trend for more ischemic strokes and more bleeding with dabigatran than with warfarin.[133] Consequently dabigatran and the other DOACs are contraindicated in patients with mechanical heart valves; such patients should receive warfarin. All DOACs pass through the placenta and should not be used in pregnancy. They should also be avoided in nursing mothers because it is uncertain whether they are excreted in breast milk. There is limited information about DOAC dosing in children.

INTRODUCTION

Platelets are the smallest blood cells in the human body, normally numbering 150–350 × 109/L, and play a central role in the normal homeostatic process of hemostasis and thrombosis. As first described in the 18th century,[1] platelets are involved in nearly all aspects of vascular occlusive disease. This includes the disruption of platelet- and fibrin-rich atherosclerotic plaques which lead to further platelet aggregation and deposition causing thrombus formation and, possibly, clinically relevant thrombotic events.[2] Antiplatelet agents modulate the role of platelets in these delicate processes. Thus a detailed understanding of platelet function and antiplatelet pharmacology is essential for the practicing vascular specialist.

NORMAL PLATELET FUNCTION AND PLATELET ACTIVATION

Normally platelets circulate without interacting with the blood vessel wall. This delicate balance is modulated by the interaction of platelets with the endothelium. The endothelium releases nitric oxide and prostacyclin to prevent platelet aggregation. In addition, endothelial cells express ADPase, which degrades adenosine diphosphate (ADP) released from activated platelets, further inhibiting platelet aggregation. A platelet life span ranges from 8 to 10 days.

Platelets are the essential components of primary hemostasis. Primary hemostasis is defined as the early stages of hemostasis to prevent blood loss. When vessel injury occurs, the subendothelium is exposed. Exposed tissue factor, subendothelial collagen, von Willebrand factor, and fibronectin interact with molecules expressed on the platelet surface *($\alpha_2\beta_1$, glycoprotein Ib/IX,* and *$\alpha_5\beta_1$)*. These interactions induce a conformational change in platelet morphology and stimulate platelet granule release of ADP and thromboxane A_2. Exposure of ADP receptors on activated platelets induces platelet aggregation by cross-linking ADP molecules. Thromboxane A2 induces vasoconstriction and further recruitment of platelets to the site of injury. Platelet activation also results in the expression of glycoprotein IIb/IIIa *(GP-IIB/IIIA)* on the platelet surface. *GP-IIB/IIIA* ligates divalent fibrinogen to bridge platelets, thus promoting aggregation. The platelet aggregates are woven into a fibrin mesh formed by the cleavage of fibrinogen by thrombin. This platelet plug forms the basis for the later stages of hemostasis. Antiplatelet agents modulate various steps in these intricate processes (Fig. 40.1).[3-5]

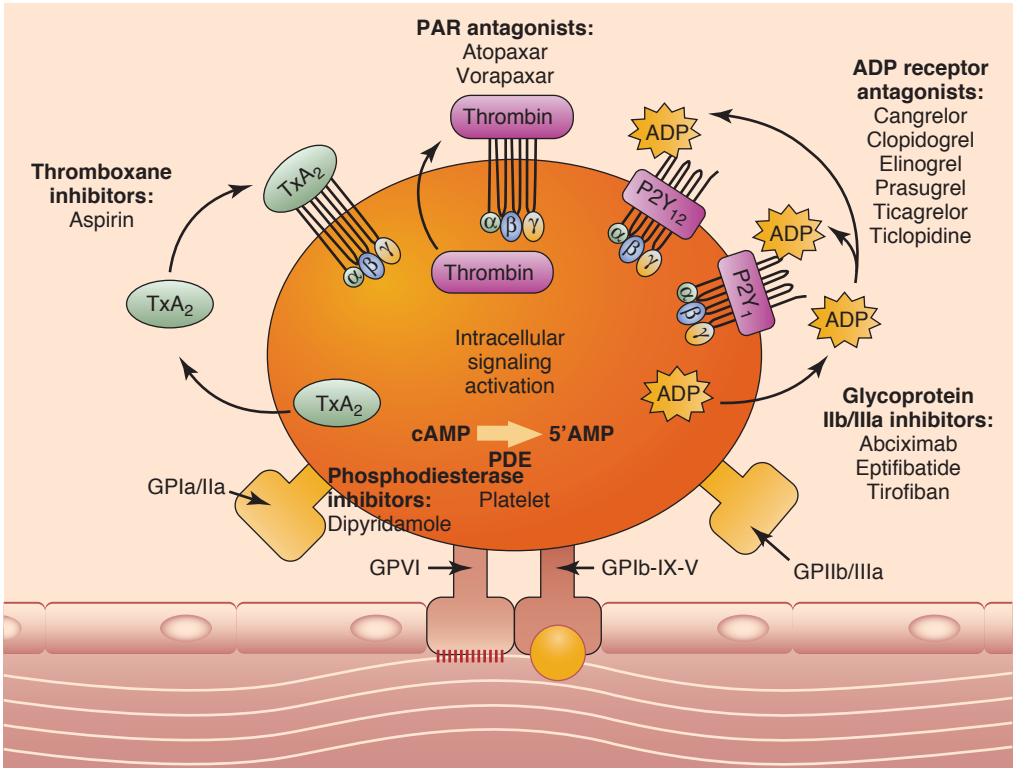

Figure 40.1 Platelet function and molecular targets of antiplatelet agents.[5] *ADP*, Adenosine diphosphate; *cAMP*, cyclic adenosine monophosphate; *TxA2*, thromboxane A2; *PAR*, protease-activated receptor.

Antiplatelet Agents

Thromboxane Inhibitors

Aspirin

Mechanism of Action. Aspirin is the most commonly used antiplatelet agent. It is a nonselective, irreversible cyclooxygenase enzyme *(COX)* inhibitor. It irreversibly acetylates *COX-1,* interrupting the production of prostaglandin H2 and the production of thromboxane A2 (TXA_2) to prevent platelet aggregation.[6,7] At higher doses, *COX-2* is also inhibited, promoting the antiinflammatory effect of aspirin.[8]

Indications and Dose. Aspirin is indicated for the prevention of cardiovascular events in patients with established coronary disease, peripheral arterial occlusive disease, or cerebrovascular occlusive disease.[9] More recently, the use of aspirin for primary prevention in patients without an established cardiovascular risk profile has been scrutinized.[10] Currently, there is no consensus recommendation regarding aspirin use for primary prevention of adverse cardiovascular events.[11,12]

Aspirin doses range from 75 to 325 mg/daily. Non–enteric-coated aspirin can achieve platelet inhibition approximately 1 hour after ingestion. Enteric-coated aspirin may achieve platelet inhibition at 3 to 4 hours after ingestion.[13] Chewing aspirin can result in inhibition as rapidly as 20 minutes after ingestion and is independent of the enteric coating of the pill.[14]

Side-Effect Profile. The most common side effects involve the gastrointestinal (GI) tract and range from dyspepsia to gastritis and ulcers, which may lead to bleeding and/or perforation. *Helicobacter pylori* infection may predispose to a higher risk of GI bleed. The risk of bleeding is estimated to be between 1% and 3% per year and increases with the addition of other antiplatelet agents (e.g., clopidogrel) or anticoagulants (e.g., warfarin).[13]

Allergy to aspirin is a rare phenomenon (~0.3% of patients). Bronchospasm can occur in patients allergic to aspirin, and this stands as a contraindication to aspirin administration. Allergy to aspirin may be more common in patients with asthma, urticaria, nasal polyps, or chronic rhinitis and thus administration should be undertaken with caution.[15]

Perioperative Management. Aspirin is generally discontinued 7 to 10 days before surgery in those at moderate to high risk for bleeding and a low estimated risk for cardiovascular events while off the medication. Otherwise, aspirin can be continued perioperatively in patients undergoing diagnostic or therapeutic interventions at low risk for bleeding. In patients undergoing vascular surgery, aspirin can be safely continued in the perioperative period.[16,17]

Thienopyridines (Adenosine Diphosphate Receptor Antagonists)

Clopidogrel

Mechanism of Action. Clopidogrel is a prodrug that is activated by the hepatic cytochrome-450 *(CYP450)* enzyme system (mainly *CYP2C19*). It irreversibly inhibits $P2Y_{12}$ (a key

ADP receptor) on the platelet surface.[18] Because it requires activation, the onset to therapeutic inhibition can be variable and can be influenced by genetic polymorphisms of the *CYP450* system.[19]

Indications and Dose. Clopidogrel is indicated for use in patients with unstable angina/non–ST-elevated myocardial infarction (UA/NSTEMI), ST-segment myocardial infarction (STEMI), recent myocardial infarction, recent cerebrovascular accident (CVA), or established peripheral arterial occlusive disease. Off-label use includes adjunctive therapy after percutaneous coronary intervention (PCI), coronary artery bypass graft (CABG) surgery, or peripheral artery percutaneous transluminal angioplasty. For patients with symptomatic carotid artery stenosis or with aspirin intolerance, clopidogrel is frequently used.

The usual daily dose of clopidogrel is 75 mg.[20] The time to platelet inhibition (the onset of action) is dose-dependent and may take to the second day of therapy to detect activity at the usual daily dose. During periods that require more rapid therapeutic levels (e.g., coronary stenting), a bolus dose between 300 and 600 mg of clopidogrel may be administered. This provides a more rapid onset of platelet inhibition (typically about 2 hours).[21,22]

Side-Effect Profile. The main side effect of clopidogrel is bleeding, and this can occur at any site. The incidence of severe GI hemorrhage is estimated to be 2%.[23] Other, less common side effects include pruritus and epistaxis.[23]

Perioperative Management. Clopidogrel should be discontinued 7 to 10 days prior to surgery (minimum of 5 days) before elective surgery, except in patients with coronary stents who have not completed a full course of dual antiplatelet therapy.

Drug-Drug Interactions. Clopidogrel's antiplatelet effect may be influenced by other drugs metabolized via the *CYP450* enzyme system.[24] Specifically, proton-pump inhibitors, which are inhibitors of *CYP2C19,* may lessen the ability of clopidogrel to inhibit platelet aggregation. This interaction may not be clinically relevant for most patients; however, current recommendations are to avoid the administration of *CYP2C19* inhibitors concomitantly with clopidogrel, whenever possible.[25]

Clopidogrel Resistance. The most important *CYP450* isoenzyme involved in clopidogrel metabolism (and thus activation) is *CYP2C19*. Patients with certain variant *CYP2C19* alleles *(CYP2C19*2 or CYP2C19*3)* may have reduced conversion of clopidogrel to the active metabolite compared with wild-type alleles *(CYP2C19*1),* which may result in reduced platelet inhibition,[26,27] This may result in a higher rate of adverse cardiovascular events.[28] Additional polymorphisms in *ABCB1* (a gene encoding the P-glycoprotein pump responsible for transporting molecules across intracellular and extracellular membranes) and *CYP3A4* can also reduce the effectiveness of clopidogrel and have been linked to adverse events.[29] However, there is insufficient evidence to recommend routine genetic testing. Tests are available to determine the *CYP2C19* genotype and may be used to determine therapeutic strategy (i.e., alternative treatment may be considered if the patient is identified as a poor metabolizer). Functional testing (e.g., the VerifyNow *P2Y12* assay) can be done after the initiation of treatment to determine a patient's clinical responsiveness to clopidogrel (i.e., assess for a nonresponder) and to further optimize antiplatelet strategy.[30,31] The GRAVITAS trial, however, did not show any benefit in individualizing the dose of clopidogrel in patients based on functional testing results.[32]

Ticlopidine

Ticlopidine is metabolized to an active metabolite that irreversibly blocks the *P2Y12* component of ADP receptors, reducing platelet aggregation. Like clopidogrel, it is metabolized via the *CYP450* system (mostly via *CYP3A4*).

Ticlopidine was previously approved for the prevention of ischemic stroke and for patients with recent coronary intervention. However, due to the incidence of severe neutropenia, aplastic anemia, and thrombotic thrombocytopenic purpura (TTP) associated with the drug, it is no longer available in the United States.

Ticagrelor

Mechanism of Action. Ticagrelor reversibly and noncompetitively binds the ADP *P2Y12* receptor reducing platelet aggregation. Due to the reversible nature of the receptor binding, the levels of platelet inhibition may fluctuate due to serum concentration of drug. It is metabolized via the cytochrome P450 enzyme system (the major isoenzyme is *CYP3A4*).[33]

Indications and Dose. Ticagrelor is indicated for acute coronary syndrome (ACS) to reduce the rate of cardiovascular death, myocardial infarction (MI), and stroke. Ticagrelor reduces the rate of in-stent thrombosis in patients stented during treatment of ACS. Off-label indications include use in patients with UA/NSTEMI and an allergy to or intolerance of aspirin.

Ticagrelor is initiated with a loading dose of 180 mg followed by a maintenance dose of 60–90 mg twice daily ($t_{1/2}$ = 7 to 9 hours).[34] Time to maximal inhibition of platelet aggregation is approximately 2 hours.

Side-Effect Profile. Side effects are similar to clopidogrel. Unique side effects specific to ticagrelor include elevated serum uric acid levels and transient dyspnea. Ticagrelor should, therefore, be used with caution in patients with a history of gouty arthritis or baseline hyperuricemia.[35,36] Dyspnea is typically self-limited and resolves within 1 week. It does not require any specific intervention nor does it warrant cessation of therapy unless the patient is intolerant to the medication-associated dyspnea.[37]

Perioperative Management. As with clopidogrel, ticagrelor should be discontinued 7 to 10 days prior to elective surgery (at least 5 days prior to procedure).

Drug-Drug Interactions. Strong inducers of the cytochrome P450 enzyme system (specifically inducers of *CYP3A4*) may decrease serum drug concentrations and reduce platelet inhibitory activity. Some examples of commonly used *CYP3A4* inducers include barbiturates, anticonvulsants (e.g., phenytoin), and glucocorticoids. Caution should be exercised when combining these classes of medications.

Prasugrel

Mechanism of Action. Prasugrel is a prodrug that is activated by the *CYP450* enzyme system. Its active metabolite irreversibly blocks the $P2Y_{12}$ component of ADP receptors on the platelet surface, reducing platelet activation and aggregation.[38]

Indications and Dose. Prasugrel is indicated for ACS managed with PCI or as an alternative for those patients intolerant to aspirin. It is contraindicated for use in patients with a history of transient ischemic attacks (TIAs) or stroke.[38]

Patients are usually started with a loading dose of 60 mg followed by a maintenance dose of 10 mg daily. For patients weighing less than 60 kg, the daily dose is typically 5 mg/day. Prasugrel administration is not recommended for patients above 75 years of age, though its use may be considered in high-risk situations.[38]

Side-Effect Profile. As with other thienopyridines, the major adverse side effect is bleeding. Other specific side effects include hypertension, hyperlipidemia, and thrombotic TTP.[39]

Perioperative Management. Similar to clopidogrel and ticagrelor, prasugrel should be discontinued 7 to 10 days prior to elective surgery (minimum 5 days prior).

Cangrelor

Mechanism of Action. Cangrelor reversibly binds to the *P2Y12* receptor to block ADP-induced platelet activation and aggregation.

Indications and Dose. It is used during coronary intervention to reduce the risk of periprocedural myocardial infarction, and stent thrombosis in patients who were not previously taking another *P2Y12* inhibitors.

The drug is administered with an intravenous 30 μg/kg bolus prior to PCI followed immediately by an infusion of 4 μg/kg per minute continued for at least 2 hours or for the duration of the procedure. The patient is then transitioned to an oral agent (clopidogrel, prasugrel, or ticagrelor) after the infusion is complete.

Side-Effect Profile. The major side effect of cangrelor is bleeding; however, in the Champion Phoenix study, the incidence of bleeding was no different from that seen in patients on clopidogrel. Dyspnea or breathlessness was the other adverse effect associated with cangrelor use and occurred in 1.2% of patients compared with 0.3% of patients on clopidogrel ($P < .001$).[40]

Perioperative Management. Cangrelor is approved for use in the periprocedural period only. After a bolus, platelet inhibition is almost immediate (<2 minutes). The half-life of cangrelor is 3 to 6 minutes, and platelet activity returns to normal within 60 minutes of cessation of the infusion.[41]

Glycoprotein IIB/IIIA (GPIIB/IIIA) Inhibitors

Mechanism of Action. Three intravenous *GPIIB/IIIAs* are available for clinical use: abciximab, eptifibatide, and tirofiban. Abciximab is a monoclonal antibody against the *GPIIB/IIIA* receptor, preventing activation and, thus platelet aggregation. Eptifibatide and tirofiban, on the other hand, are peptide antagonists of the *GPIIB/IIIA* receptor, which accomplish a similar effect in platelet inhibition.[42,43]

Indications and Dose. Abciximab is indicated for the prevention of ischemic complications in patients undergoing PCI and patients with UA or non–ST-elevation MI scheduled to undergo PCI. It is administered intravenously as a loading dose of 0.25 mg/kg given prior to starting PCI followed by an infusion of 0.125 μg/kg per minute.[43,44]

Eptifibatide is indicated for patients with ACS who are to be managed medically or those undergoing PCI. It is administered intravenously with a bolus of 180 μg/kg followed by a continuous infusion of 2 μg/kg per minute.[43,44]

Tirofiban is indicated for patients with UA/non–ST-elevation MI to decrease the rate of adverse cardiovascular events. It is administered intravenously as a loading dose of 25 μg/kg followed by a continuous infusion dose of 0.15 μg/kg per minute.[43,44]

Side-Effect Profile. The main adverse effect associated with all the *GPIIB/IIIA* modulators is bleeding, especially when these drugs are combined with other antiplatelet agents or anticoagulants. Other side effects associated with abciximab use include nausea, hypotension, and chest pain. Eptifibatide is associated with hypotension and tirofiban has been associated with coronary artery dissection. All the *GPIIB/IIIA* modulators are associated with thrombocytopenia. With abciximab, thrombocytopenia occurs in up to 5% of patients. Thrombocytopenia is less common with the two other agents (1% of patients).[45]

Perioperative Management. Abciximab provides inhibition of platelet aggregation greater than 80% at 10 minutes after administration. It has a plasma half-life ($t_{1/2}$) of 30 minutes; however, the dissociation half-life from the *GPIIB/IIIA* receptor can take up to 4 hours. Consequently, the infusion should be stopped at least 12 hours prior to surgery.[46,47]

Eptifibatide achieves more than 80% inhibition of platelet aggregation within 5 minutes after bolus dose and has a half-life of 2.5 hours. It should be stopped 2 to 4 hours prior to elective surgery.[47]

Tirofiban achieves inhibition of platelet aggregation greater than 90% within 10 minutes and has a half-life of 2 hours. It should also be stopped 2 to 4 hours prior to elective surgery.[47]

Phosphodiesterase Inhibitors

Dipyridamole

Mechanism of Action. Dipyridamole inhibits the activity of adenosine deaminase and phosphodiesterase to increase the concentration of adenosine and cyclic adenosine monophosphate *(cAMP),* which promotes vasodilation and inhibits platelet aggregation. At baseline, dipyridamole alone is a relatively weak antiplatelet agent. A combination medication of dipyridamole and aspirin (Aggrenox) has been used for prophylaxis against stroke.[48,49]

Indications and Dose. Dipyridamole is indicated as a pharmacologic agent for cardiac stress testing. The combination drug, Aggrenox, is indicated for stroke prevention.[50-52]

Dipyridamole alone can be administered orally or intravenously. Oral doses are typically between 50 and 100 mg three to four times daily. The intravenous dosing for cardiac stress testing is usually 0.14 mg/kg per minute for 4 minutes with a maximum dose of 60 mg. Aggrenox contains 200 mg of dipyridamole and 25 mg of aspirin, and is administered twice daily.[48]

Side-Effect Profile. Oral administration has been associated with headache most commonly, but also dizziness, skin rash, and GI upset. Intravenous administration is associated with worsening chest pain, dizziness, or headache.[48] The vasodilatory effect of dipyridamole may adversely affect cardiac perfusion; therefore caution should be exercised when using this medication

in patients with established coronary disease. Contraindications to dipyridamole for cardiac stress testing include bronchospastic lung disease with ongoing wheezing or significant reactive airway disease, hypotension (SBP < 90 mm Hg) or uncontrolled hypertension (SBP > 200 mm Hg), ingestion of caffeine within 12 hours of the procedure, or UA, ACS, or recent acute MI (PMID: 26914678).

Perioperative Management. The half-life of dipyridamole is 10 to 12 hours. Perioperative management of Aggrenox is dictated by the aspirin component, which produces irreversible *COX-1* inhibition to reduce platelet aggregation. This may be stopped 7 to 10 days in advance of surgery, if necessary.

Protease-Activated Receptor-1 Inhibitors

Vorapaxar

Mechanism of Action. Vorapaxar is a reversible antagonist of the protease-activated receptor-1 *(PAR-1)* to inhibit thrombin-induced and thrombin receptor agonist peptide *(TRAP)*–induced platelet aggregation.[53,54]

It achieves 80% or greater inhibition of TRAP-induced platelet aggregation within 1 week of starting therapy and has a half-life of 3 to 4 days.[54]

Indications and Dose. Vorapaxar is indicated to reduce adverse cardiovascular events in patients with a history of MI or with peripheral arterial disease (PAD).[55,56]

The approved dose of vorapaxar is 2.5 mg (vorapaxar sulfate) orally once daily in combination with aspirin and/or clopidogrel.[56]

Side-Effect Profile. Bleeding is the major adverse effect associated with vorapaxar use. In the Thrombin Receptor Antagonist in Secondary Prevention of Atherothrombotic Ischemic Events (TRA 2P) study, any degree of bleeding was found in 25% of patients. Clinically significant bleeding (any bleeding requiring medical attention, including intracranial hemorrhage [ICH] or overt signs of bleeding with a drop in hemoglobin of ≥3 g/dL), occurred in 13.4% of patients.[56] Also, patients with a history of ischemic stroke had higher rates of ICH on vorapaxar compared with placebo. Consequently vorapaxar is contraindicated in patients with a history of stroke, TIA, or ICH.[56] Other, less common side effects include anemia, depression, and rash.[57]

Atopaxar

Similar to vorapaxar, atopaxar is a selective *PAR-1* antagonist that blocks thrombin-mediated platelet activation. It is currently in clinical trial and is not FDA approved.

CLINICAL USE OF ANTIPLATELET AGENTS IN VASCULAR DISEASE

Cardiovascular Death, Stroke, or Myocardial Infarction

The primary prevention of cardiovascular disease using antiplatelet agents is controversial. The most recent CHEST guidelines from 2012 recommend the use of low-dose aspirin (75 to 100 mg) over no aspirin in patients aged 50 years or older without symptomatic cardiovascular disease. This recommendation was based on the 2009 Antithrombotic Trialists collaboration study demonstrating a reduction in nonfatal MI (low-risk patients had 6 fewer MIs per 1000 patients treated, moderate-risk patients had 19 fewer nonfatal MIs per 1000 treated, and high-risk patients had 31 fewer nonfatal MIs per 1000 treated) and improved total mortality (six fewer deaths per 1000 treated in low-risk and moderate- to high-risk groups) in patients taking aspirin based on a 10-year risk estimate using the Framingham risk score. There was, however, an increase in major bleeding in all groups taking aspirin compared with those not taking aspirin.[12,58] In a more recent meta-analysis, aspirin reduced the incidence of cardiovascular events by 10%, driven mostly by a significant reduction in nonfatal MI. Cardiovascular death was not improved with intake of aspirin, and the incidence of bleeding was significantly higher in those patients. Consequently, the authors were not able to make a recommendation for aspirin use in the primary prevention of cardiovascular disease.[59]

Secondary prevention of adverse cardiovascular events in patients who have survived an occlusive episode is well validated.[9,60] Antiplatelet therapy reduced subsequent vascular events by 25% in patients with previous MI, by 30% in patients with an acute MI, by 22% in patients with previous CVA/TIA, and by 11% in patients with acute CVA (Fig. 40.2). The positive effects were independent of the aspirin dose used.[9,61]

The CAPRIE trial compared clopidogrel to aspirin in 19,185 patients with recent stroke, MI, or symptomatic PAD. The study found that patients treated with clopidogrel had an annual 5.32% risk of stroke, MI, or death compared with 5.83% in patients treated with aspirin (8.7% relative risk reduction favoring clopidogrel).[23]

It should be noted that there is some evidence that the sudden discontinuation of aspirin therapy may be associated with an increased risk of thrombotic events, especially within the first 5 to 7 days. These include ACSs, stent-associated thrombosis, acute MI, ischemic stroke, and limb ischemia. Although further study is needed, it appears that aspirin withdrawal may be associated with a prothrombotic state.[62]

Peripheral Artery Disease

Relative to the amount of evidence regarding cardiovascular death, stroke, and MI in patients taking antiplatelet agents, the literature on the impact of antiplatelet agents on the natural history of PAD is not as clear or robust.[63,64]

The recent TRA 2P trial assessing vorapaxar for the secondary prevention of ischemic events enrolled patients with stable atherosclerotic disease, including recent MI, CVA, and symptomatic PAD (claudication with an ABI ≤0.85 or previous revascularization for ischemia).[56] The patients with symptomatic PAD were studied separately regarding specific limb efficacy endpoints including acute limb ischemia (ALI), the need for peripheral revascularization (urgent and elective), or hospitalization for any vascular cause of an ischemic nature. Vorapaxar, in combination with other antiplatelet agents, reduced the risk

Category of Trial	No of Trials with Data	NO (%) OF VASCULAR EVENTS: Allocated Antiplatelet	Adjusted Control	Observed-Expected	Variance	% Odds Reduction (SE)
Previous myocardial infarction	12	1,345/9,984 (13.5)	1,708/10,022 (17.0)	−159.8	567.6	25 (4)
Acute myocardial infarction	15	1,007/9,658 (10.4)	1,370/9,644 (14.2)	−181.5	519.2	30 (4)
Previous stroke/transient ischaemic attack	21	2,045/11,493 (17.8)	2,464/11,527 (21.4)	−152.1	625.8	22 (4)
Acute stroke	7	1,670/20,418 (8.2)	1,858/20,403 (9.1)	−94.6	795.3	11 (3)
Other high risk	140	1,638/20,359 (8.0)	2,102/20,543 (10.2)	−222.3	737.0	26 (3)
Subtotal: all except acute stroke	188	6,035/51,494 (11.7)	7,644/51,736 (14.8)	−715.7	2,449.6	25 (2)
All trials	**195**	**7,705/71,912 (10.7)**	**9,502/72,139 (13.2)**	**−810.3**	**3,244.9**	**22 (2)**

Heterogeneity of odds reductions between:
Five categories of trial: $\chi^2 = 21.4$, $df = 4$; $P = 0.0003$
Acute stroke *v* other: $\chi^2 = 18.0$, $df = 1$; $P = 0.00002$

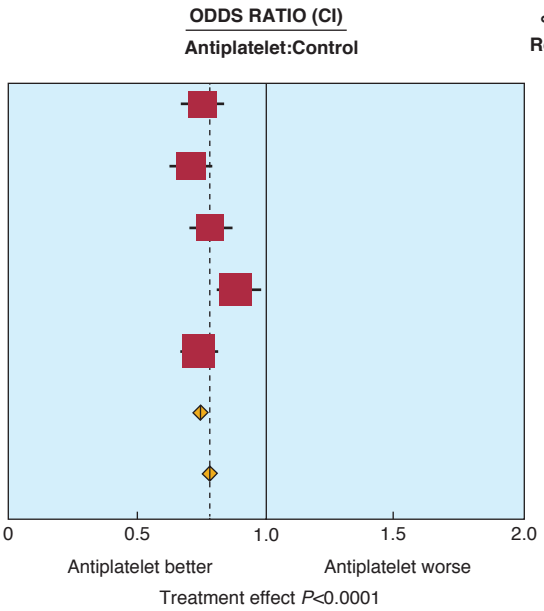

Figure 40.2 Proportional effects of antiplatelet therapy on vascular events.[9]

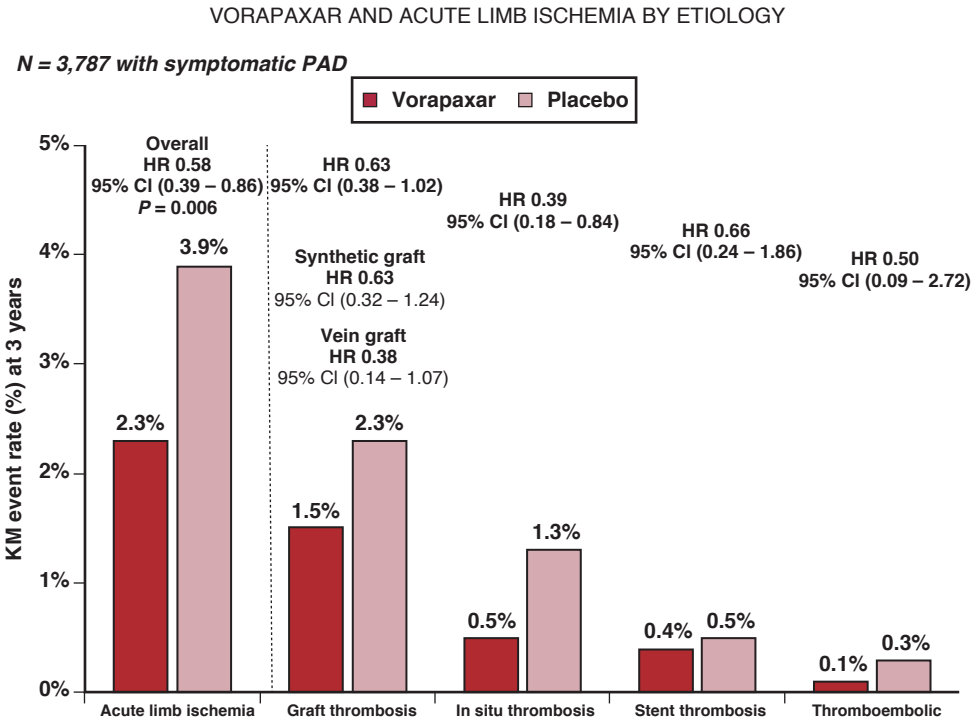

Figure 40.3 Vorapaxar and acute limb ischemia by etiology.[65] *PAD*, Peripheral arterial disease.

of hospitalization for ALI (2.3% vs. 3.9%) and the need for peripheral revascularization (18.4% vs. 22.2%) compared with placebo, respectively.[55] A follow-up study on ALI in this patient cohort showed that vorapaxar reduced the risk of a first ALI event by 42% and reduced total ALI events by 41% compared with the placebo arm. This reduction was evident for all etiologies of ALI (graft thrombosis, in situ thrombosis, stent thrombosis, or thromboembolism; Fig. 40.3).[65]

Given the paucity of data regarding antiplatelet agent use specifically for peripheral artery disease, the main indication for the use of antiplatelet agents in peripheral artery disease is to reduce the risk of cardiovascular death, stroke, and MI.

Perioperative Management of Dual Antiplatelet Therapy

Dual antiplatelet therapy (DAPT) generally refers to a combination of aspirin and a $P2Y_{12}$ inhibitor (a thienopyridine), such as clopidogrel. Patients with a coronary artery disease (CAD) and history of MI are at an increased risk of recurrent infarctions

as a result, in part, of enhanced platelet activation. Aspirin alone suppresses only one pathway of platelet activation. DAPT suppresses more than aspirin alone and has been shown to improve cardiovascular endpoints in patients with CAD. Coronary artery stenting is done with either bare-metal stents or drug-eluting stents (DESs). The 2014 American Heart Association/American College of Cardiology (AHA/ACC) guidelines recommended DAPT in all patients with bare-metal coronary stents for at least 30 days after implantation. Discontinuing DAPT before 30 days is associated with an increased risk of stent thrombosis, adverse cardiovascular events, and mortality.[62] Thus the timing of procedures should take this risk into account. Elective procedures should be delayed until after the first 30 days after bare-metal stent implantation. For urgent, emergent, or nonelective operations, DAPT should generally be continued within the first 30 days after stent implantation unless the bleeding risk associated with the procedure is thought to be higher than the risk of stent thrombosis or adverse cardiovascular events. In these cases, aspirin alone should be continued.[66]

First-generation DESs were sirolimus- or paclitaxel-eluting stents. The newer DESs use everolimus or zotarolimus. The 2014 AHA/ACC guidelines for patients with DES recommended therapy for 12 months.[66] This recommendation was formed from the evidence of stent thrombosis within the first 3 to 6 months in the first-generation of DESs.[67-69] More recent studies on the newer generation of DESs have shown that they are associated with a lower risk of stent thrombosis.[70,71] A 2016 update to the AHA/ACC guidelines recommends that elective surgery be delayed for 3 months in patients treated with newer-generation DESs (Fig. 40.4).[71] For patients treated with greater than 3 months of therapy, DAPT may be discontinued for the procedure, if necessary, however with a slightly increased risk of thrombosis within the 3- to 6-month time frame. After 6 months, DAPT is safe to discontinue for procedures. In all cases, aspirin should be continued throughout the perioperative period, if possible. DAPT should be resumed as soon as the perioperative bleeding risk is considered low.[72]

For patients who require urgent or emergent surgery before the recommended minimum duration of DAPT, the risk of

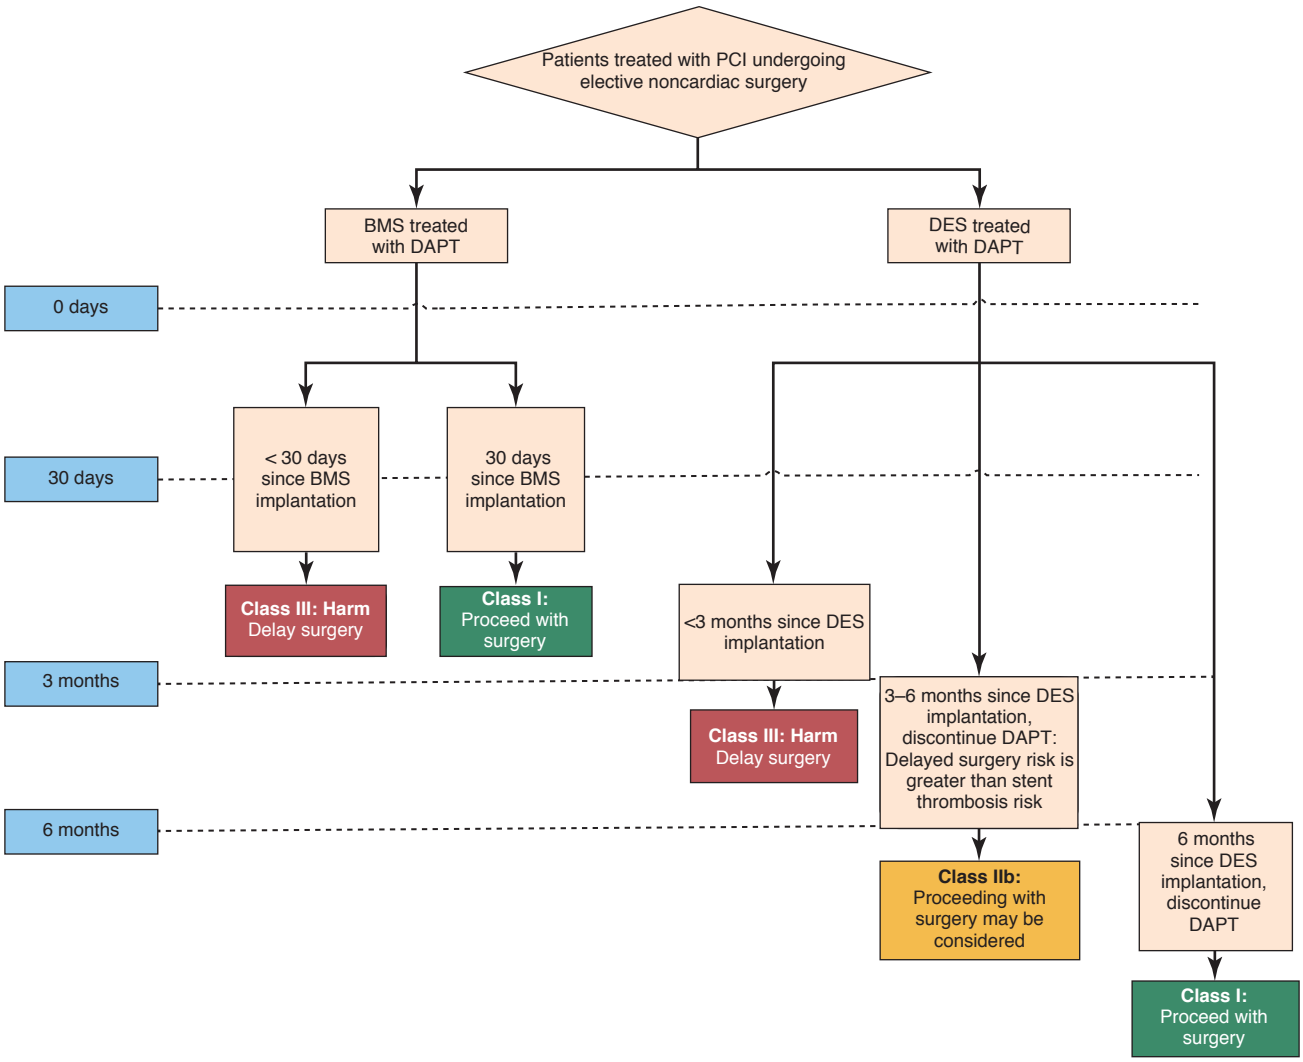

Figure 40.4 2016 ACC/AHA Guidelines for Perioperative Management of Dual Anti-Platelet Agents in patients undergoing noncardiac surgery. *DAPT*, Dual antiplatelet therapy; *DES*, drug-eluting stents; *PCI*, percutaneous coronary intervention.

discontinuing the DAPT should be weighed against the risk to the patient of not undergoing the procedure. Strategies to limit the risk of adverse cardiovascular events or perioperative bleeding include perioperative platelet transfusion and "bridging" with an intravenous platelet inhibitor. Platelet transfusion may be used to stem the risk of bleeding in patients with DAPT; however, no studies have been performed to develop an optimal management strategy. Perioperative intravenous antiplatelet bridging has been studied. It has not been proven to eliminate the risk of stent thrombosis and may, in fact, be associated with a higher incidence of bleeding complications.[73,74]

The long-term duration of DAPT has been a focus of more recent studies. The Dual Antiplatelet Study (DAPT study) assessed 12 months versus 30 months of DAPT after coronary stenting. It showed a significant reduction of late coronary stent thrombosis and less major adverse coronary or cerebrovascular events in patients treated with DAPT compared with aspirin alone. The Dual Anti-Platelet Score (http://www.daptstudy.org/for-clinicians/score_calculator.htm) was developed from this study and is a useful tool for assessing the benefit for continued DAPT in these patients.[71] In patients with bleeding complications, or with a relatively increased risk of bleeding (e.g., history of TIA or stroke, age ≥75 years, recent trauma or surgery, recent or recurrent GI bleeding, active peptic ulcer disease, severe hepatic impairment, body weight <60 kg, or use of oral anticoagulants), consideration can be given for treatment for less than 12 months with DAPT.[71,75]

Embolic and thrombotic events in the arterial and venous systems lead to end-organ malperfusion and dysfunction. In the past, open surgical procedures were used to restore vessel patency and organ function; however, with the advent of thrombolytic agents and endovascular techniques, intravenous thrombolysis (IVT) and catheter-directed thrombolysis (CDT) have become essential components in the contemporary management of acute arterial and venous thrombotic conditions.

Thrombolytic agents have evolved with time, and many of the original agents (streptokinase [SK] and urokinase [UK]) are no longer manufactured in the United States, although they still hold Food and Drug Administration (FDA) labels for use. In current practice, alteplase (recombinant tissue plasminogen activator [rt-PA]) is the agent most commonly used. Current FDA indications for thrombolysis include acute myocardial infarction (AMI),[1-4] pulmonary embolism (PE),[1,2,5] acute ischemic stroke (AIS),[2] arterial thrombosis and embolization,[1] deep venous thrombosis (DVT),[1] and central venous catheter occlusion (Table 41.1).[2]

HISTORY

Early theories on the process of clot lysis arose from observations that postmortem blood existed in both liquid and coagulated forms. In 1769, Morgagni noted this phenomenon occurred after traumatic death,[6] and in 1906, Morawitz found that postmortem liquid blood contained no fibrinogen and could liquefy coagulated blood.[7] It was postulated that an "inactive component" of blood, controlled by a "regulator," could be converted into a "fibrin-degrading agent."

The "inactive component" was first described by Milstone in 1941 as "lytic factor" and is now known as plasminogen.[8] Subsequently, Kaplan and Christensen separately identified the "fibrin-degrading agent" as plasmin.[9-11] The "regulator," or tissue plasminogen activator (t-PA), was the last to be isolated in 1957 by Albrechtsen.[12]

The discovery of the first thrombolytic agent, SK, came by chance at Johns Hopkins University in 1933 by Tillett. He observed that streptococcus in human plasma would

Abstract

Intravenous thrombolysis and catheter-directed thrombolysis (CDT) have become essential components in the contemporary management of acute arterial and venous thrombotic conditions. There has been significant growth in the area of CDT devices and thrombolytic agents, allowing for expansion in clinical applications and safety profile

TABLE 41.1 Thrombolytic Agents and Indications Approved by the US Food and Drug Administration as of 2012

Generic Name	Trade Name	Manufacturer	FDA Indication
Streptokinase[a]	Streptase Kabikinase	CSL Behring (King of Prussia, Pennsylvania) Pharmacia & Upjohn AB	AMI, PE, DVT, peripheral arterial thrombosis or embolism
Urokinase[a]	Kinlytic	Microbix Biosystems (Ontario, Canada)	PE
Alteplase	Activase CathFlo Activase	Genetech (South San Francisco, California) Genetech	AMI, PE, stroke Central venous catheter occlusion
Reteplase	Retavase	Cornerstone Therapeutics (Cary, North Carolina)	AMI
Tenecteplase	TNKase	Genetech	AMI

[a]Though still FDA approved, no longer available in the United States.
AMI, Acute myocardial infarction; *DVT*, deep venous thrombosis; *FDA*, US Food and Drug Administration; *PE*, pulmonary embolism.

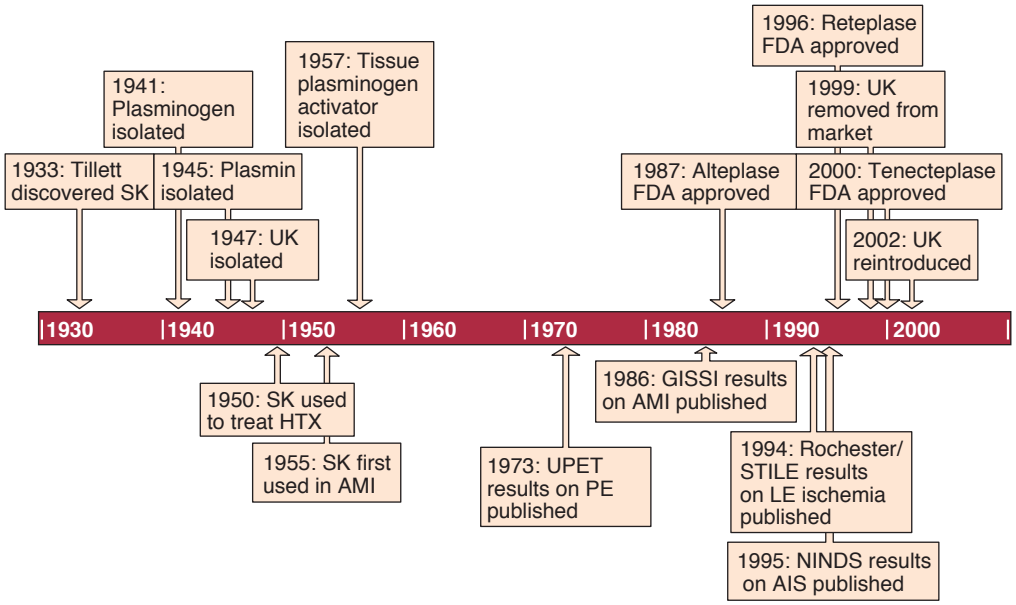

Figure 41.1 Timeline of key moments in thrombolytic history. *AMI*, Acute myocardial infarction; *AIS*, Acute ischemic stroke; *FDA*, US Food and Drug Administration; GISSI, Gruppo Italiano per lo Studio della Streptochinasi nell'Infarto Miocardico; *HTX*, hemothorax; *LE*, lower extremity; *NINDS*, National Institute of Neurological Disorders and Stroke; *PE*, pulmonary embolism; *SK*, streptokinase; *STILE*, surgery or thrombolysis for the ischemic lower extremity; *UK*, urokinase; *UPET*, Urokinase Pulmonary Embolism Trial.

agglutinate, whereas streptococcus in human serum did not. He hypothesized that fibrinogen, present in plasma but not in serum, bound to the bacteria and caused agglutination. To test the hypothesis, he compared human plasma in test tubes as a control to human plasma in which streptococci were added. After addition of calcium, both tubes demonstrated clot formation. However, after the test tubes sat overnight, he noted the clot had liquefied in the streptococcal-containing tube. He attributed this finding to the production of "fibrinolysin" by streptococci.[13,14] A year later he isolated "fibrinolysin," which is now known as SK.[15]

In 1949, Tillett and Sherry reported the first clinical uses of SK in the thoracic cavity to treat empyema and retained hemothorax.[16,17] They reported the first human intravascular experience with SK in 1954.[18,19] Urokinase was the second thrombolytic agent discovered in 1946, and put into clinical use in 1961.[20] As experience with these two early agents grew and additional agents developed, large clinical trials encompassing many vascular applications soon followed, including two of the earliest, AMI and PE (Fig. 41.1).

THROMBOLYTIC DRUG ADMINISTRATION

Systemic/Intravenous Thrombolysis

When thrombolysis was first introduced, systemic delivery via a peripheral intravenous catheter was the only method of administration. Although this was effective in certain clinical scenarios, it required large doses of thrombolytic agent with an increased risk of hemorrhagic complications. The development of CDT has allowed a more targeted delivery of thrombolytic agents in smaller doses. However, IVT still remains a common

mode of delivery in applications in which preservation of end organ function requires rapid delivery (AMI, AIS).

Catheter-Directed Thrombolysis

CDT provides direct delivery of the thrombolytic agent into existing thrombus.[21,22] It is the preferred method of delivery for acute limb ischemia,[23,24] DVT,[25] and arteriovenous graft (AVG) occlusion.[26] The endovascular techniques used for CDT also permit concomitant percutaneous treatment of the underlying culprit lesions responsible for vessel or graft occlusion.[3]

CDT requires traversal of the occluded arterial or venous thrombosis with a guide wire, followed by placement of a multiple side-hole infusion catheter. An initial bolus is delivered via pulse spray technique. Depending on the particular vessel and end organ being treated, a continuous infusion for a specified period of time follows. To maximize the effectiveness and minimize systemic delivery of the thrombolytic, the infusion catheter side holes should be placed within the thrombus. Heparin is used as an ancillary drug during CDT and commonly infused through the indwelling arterial sheath. Administration of heparin is crucial to prevent propagation of thrombus around the indwelling catheter.[23,24,27] Full anticoagulation with heparin with an activated partial thromboplastin time (aPTT) of 60 to 80 seconds should be achieved before thrombolysis, but once CDT has begun, the heparin dose should be decreased to 500 to 1000 U/h. The heparin drip should be adjusted to maintain an aPTT no more than 1.5 times control. Full anticoagulation with larger doses of heparin during CDT has not improved outcomes, and evidence suggests that excessive anticoagulation can potentiate bleeding complications.[28]

Catheter-Directed Thrombolysis With Mechanical Thrombectomy

Percutaneous mechanical thrombectomy is a catheter-based therapy that disrupts the thrombus and allows better penetration of the clot by the thrombolytic agent. Its putative advantages include decreased thrombolytic dosing and shortened therapy time. Most mechanical devices were originally used for the treatment of AVG thrombosis,[29] but their use has been extended to the peripheral vasculature (discussed in greater detail in Chapters 101, 161, and 162).[30] A number of methodologies and devices exist for mechanical thrombectomy, each with advantages and disadvantages:

1. Hydrodynamic: Saline is infused and aspirated to create a local reduction in pressure (the Venturi effect).
2. Rotational recirculation: Rotating blades or propellers macerate the thrombus.
3. Mixing: Devices with a double-balloon catheter system confine the thrombolytic agent within a vessel, whereas a rotating, sinusoidal wire disrupts the clot.
4. Ultrasound: High-frequency, low-power ultrasound energy is delivered to loosen and separate fibrin strands to permit better penetration of the thrombolytic agent.
5. Aspiration: Aspiration of thrombus by a large suction catheter and syringe.

Monitoring

No existing laboratory test directly monitors the degree and effectiveness of thrombolysis. D-dimer and fibrin degradation products are elevated by thrombolysis, but levels do not correlate with the degree of thrombolysis. Thrombolytic therapy creates a dynamic fibrinolytic state consisting of both thrombus dissolution and thrombus formation. Formation occurs in an attempt to replace lysed clot, and coagulation factors and fibrinogen are consumed in the process. If fibrinogen drops below 100 mg/dL (2.9 mcmol/L) or the aPTT increases above 100 seconds, excessive consumption of coagulation factors is present and an increased risk of hemorrhagic complications exists. In these situations, it is prudent to reduce or temporarily stop the lytic infusion until fibrinogen increases or the aPTT decreases, or both.[31]

Other laboratory tests for indirect monitoring of the thrombolytic state include hemoglobin, platelet count, and creatinine. Patients treated by thrombolysis should be monitored in the intensive care unit or intermediate unit, where laboratory tests can be drawn at 4- to 6-hour intervals and patients assessed on an hourly basis.[1-5,31]

With CDT, serial angiography is performed through the indwelling catheter to assess the results of thrombolysis at 6- to 12-hour intervals over a 24- to 48-hour period. Restored pulse or Doppler signal or improved symptoms can be used as surrogates for successful treatment. CDT should be discontinued once organ perfusion has been adequately restored, and transition to full anticoagulation with heparin instituted.[23,24,27] Thrombolysis beyond the 48-hour window increases the risk of complications with little to no additional benefit.

Complications

Complications of thrombolytic therapy can be classified as hemorrhagic, antigenicity-related, catheter-related, or embolic.

Hemorrhagic

Bleeding is always a risk when thrombolysis is used. Major versus minor bleeding depends on the degree of bleeding and clinical consequence, but in general, major bleeding includes intracerebral, retroperitoneal, or gastrointestinal hemorrhage. Minor bleeding is usually at the puncture site for CDT and managed with local measures.[31,32] Puncture-site bleeding can become major if a large hematoma develops or if blood tracks into potential spaces such as the retroperitoneum. Ultrasound guidance can minimize multiple needle passes for vascular access and thus minimize this bleeding risk.

The risk of remote-site bleeding increases as more thrombolytic drug is administered and clotting factors and fibrinogen are depleted. In general, patients treated for pathologies that require longer infusions have a higher bleeding risk. Acute limb ischemia, PE, and DVT use more total thrombolytic when compared with AMI and AIS. AVG and catheter occlusion use the smallest doses.[33]

Intracerebral hemorrhage (ICH) is the most dreaded complication. AIS is associated with the greatest incidence of ICH (6.4%

to 8.8%). Thrombolysis provides reperfusion of a stunned penumbra, but it also lyses hemostatic plugs, leading to hemorrhagic reperfusion.[34] For other conditions, incidence of ICH varies depending on the thrombotic process: PE (0% to 4.5%), AMI (0.3% to 1.8%), and peripheral artery occlusion (1% to 2%).[32,33] The true incidence of other remote bleeding complications is difficult to determine, given inconsistent definitions and reporting. When major bleeding is defined as that causing permanent disability, increased hospital stay, or a requirement for blood transfusion, rates as high as 27% have been noted.[32,33] Major bleeding after thrombolysis is seen in 10% to 27% of patients with acute limb ischemia, 5% to 21% with PE, 0.3% to 5.9% with AMI, and 4% to 11% with DVT.

Antigenicity Related

This complication is mainly related to SK. Minor allergic reactions have been reported in 1% to 10% of cases, and life-threatening allergic reactions in less than 0.01%.[1] Pretreatment with 100 to 250 mg of methylprednisolone, antihistamines, or acetaminophen (or any combination of these drugs) can reduce the allergic response.[1] Other thrombolytics, such as UK and rt-PA, are naturally found in vivo, and allergic reactions are rare.[2,5]

Catheter Related

Catheter insertion for CDT poses the same risks associated with any endovascular procedure, including but not limited to dissection of the artery, pseudoaneurysm, dislodgment of thrombus during wire or catheter manipulation, and bleeding around the introducer sheath.[35]

Embolic

As a thrombus is lysed, fragments may embolize. Embolization is most often seen in patients with acute limb ischemia. Typically, after initial clinical improvement with restoration of a pedal pulse or Doppler signal, sudden clinical deterioration due to embolism occurs. In randomized clinical trials of patients with acute limb ischemia, embolic events occurred in 9% to 13% of patients. In most cases, advancing the catheter distally and continuing the thrombolytic infusion can effectively treat the embolic malperfusion.[35-37]

Embolic events occur less often in other applications. Clinically significant PE has been seen after thrombolytic treatment of DVT (0% to 10%), and though it is a hypothetical risk in catheter and AVG occlusion, PE has been rarely reported (<1%).[33]

Contraindications

Absolute contraindications to thrombolytic treatment include conditions that are likely to be associated with existing or very recent hemorrhage: (1) active internal bleeding; (2) recent (within 2 months) cerebrovascular accident, trauma, or intracranial or intraspinal surgery; (3) known intracranial neoplasm; (4) severe uncontrollable hypertension; (5) uncontrollable clotting disorders; (6) previous severe allergic reactions to the thrombolytic agent.

Relative contraindications include (1) recent (within 10 days) operative or obstetric procedures, biopsy, or procedure in a location that is not compressible, gastrointestinal bleeding, or trauma, including cardiopulmonary resuscitation; (2) left heart thrombus; (3) subacute bacterial endocarditis; (4) severe liver or kidney disease; (5) diabetic hemorrhagic retinopathy; (6) acute pancreatitis; (7) pregnancy; (8) any other condition in which bleeding constitutes a significant hazard or would be particularly difficult to manage because of its anatomic location.[1,2,5,27]

THROMBOLYTIC AGENTS

Currently, the most commonly used thrombolytic agents are the recombinant plasminogen activators and genetically modified variants (see Table 41.1). Characteristics of commercially available thrombolytic agents are listed in Table 41.2. A number of other investigational thrombolytic agents are being studied. Thrombolytic agents can be classified as follows:

TABLE 41.2 Pharmacology of US Food and Drug Administration—Approved Thrombolytic Agents

Name	Molecular Weight (kD)	Half-Life (Min)	Fibrin Specificity	Mechanism of Action	Cost ($US)[a]
Streptokinase	47	20	0	Plasminogen activator	NA
Urokinase	33	13	++	Plasminogen activator	NA
Alteplase	70	5	+++	Recombinant human tissue plasminogen activator	$40/mg
Reteplase	39	15	++	Same as alteplase but has extended half-life because of lack of carbohydrate side chains, finger domain, epidermal growth factor, and kringle 1 domain	$150/U
Tenecteplase	65	22	++++	Same as alteplase but has three single–amino acid and a tetra-alanine substitution, which extends its half-life	$70/mg

[a]Costs for thrombolytic agents vary depending on location and individual pricing agreements. These costs are from a tertiary hospital based in the Los Angeles, California, region.

NA, No longer manufactured in the United States.

1. Plasminogen activators: The mechanism of action for thrombolysis is indirect. These agents convert intrinsic plasminogen to active plasmin that cleaves linked fibrin. There are two types:
   a. Biologic, naturally occurring, such as SK and UK
   b. Recombinant and genetically modified variants
2. Direct-acting agents: The mechanism of action is direct cleavage of fibrin linked strands.

Biologic, Naturally Occurring Plasminogen Activators

Streptokinase

SK is FDA approved for use in most clinical applications: AMI, PE, DVT, peripheral arterial thrombosis, or embolism (see Table 41.1). It has been marketed under different names—Kabikinase (Pharmacia & Upjohn, Somerset County, New Jersey) and Streptase (CSL Behring, King of Prussia, Pennsylvania)—but in 2004, CSL Behring (the only manufacturer of SK in the United States) discontinued production. Despite its multiple FDA indications, it is rarely used in the United States because of its side effects. In developing countries, SK is still used because of its low cost. There are now recombinant technologies to produce SK via *Escherichia coli*, but these products can have variable lytic activity.[38-40]

SK is a 414–amino acid, single-chain protein with a molecular weight of 47 kD. Produced by β-hemolytic streptococci, it is present in the broth of cultured bacteria and can be purified and then isolated. After multiple strains of streptococci were tested, the Lancefield group C *Streptococcus equisimilis* was chosen for pharmaceutical production because it lacks production of the erythrogenic toxin and has fastidious growth requirements.[41]

SK has three main structural domains: α, β, and γ. The β domain is involved in forming the SK-plasminogen complex, and the γ domain assists in making the plasminogen within this complex active.[42] The SK-plasminogen complex has a half-life of 20 minutes and does not dissociate.[1,43] It can be inactivated by systemic plasmin inhibitors (α_2-antiplasmin and α_2-macroglobulin), but when administered as a therapeutic agent, concentrations are increased such that the SK-plasminogen complex overwhelms this inhibition.[44]

Because SK is derived from streptococci, previous bacterial infection or exposure to SK can cause antibody formation, which makes any SK administered in the future inactive. Neutralizing antibodies to SK last for a minimum of 4 days and can persist for up to 4 years in 50% of patients.[45,46] Minor hypersensitivity reactions to SK are uncommon, 4.4% in one study,[47] but cases of life-threatening anaphylaxis and serum sickness have been documented.[48,49] Readministration of SK can be attempted up to 4 days after the initial dose; however, repeat dosing after 5 days to a year is not recommended because of inactivation by an increased amount of antistreptococcal antibodies.[1]

Urokinase

Unlike SK, UK lacks antigenicity because it is normally present at low levels in human plasma (10 μg/L).[50] It is called urine plasminogen activator (u-PA) when found in vivo and is normally involved in intracellular signaling pathways and cell proliferation, adhesion, and migration.[51,52] Produced predominantly by kidney cells, commercially used UK was originally isolated from urine.

Native, or naturally occurring, UK exists in a number of forms in both plasma and urine. The precursor to all forms is prourokinase, a 55-kD, 411–amino acid single-chain protein also called single-chain urokinase plasminogen activator (scu-PA). It has little enzymatic activity, but in the presence of fibrin it is cleaved by plasmin into active forms.[53,54] The resultant high-molecular-weight urokinase is the predominant form of UK found in urine and is also called a two-chain urokinase plasminogen activator. It weighs 55 kD and is composed of a 22-kD light chain and a 33-kD heavy chain linked by a single disulfide bond.[55] The final form is the 33-kD, low-molecular-weight urokinase, which is an enzymatically degraded form of high-molecular-weight UK.[56]

Despite the poor fibrin/fibrinogen affinity of naturally occurring UK, it was once the only alternative to SK. UK was marketed as Abbokinase (Abbott, Abbott Park, Illinois). It is rapidly cleared by the liver, and its half-life is 6.4 to 18.8 minutes, with a volume of distribution of 11.5 L.[5] Current methods of production use donated human kidney cells from neonates who have died from noninfectious causes. The neonatal kidney cells can be cultured to secrete large quantities of UK.[5,57]

The trade name Abbokinase was stigmatized after the FDA halted its production in 1999 due to manufacturing issues and viral validation.[58] The FDA intervention created a relative shortage of UK and led to investigational development of other thrombolytic agents such as modified SK, rt-PA, and staphylokinase. In 2002, Abbokinase was reintroduced by Abbott Laboratories. In 2006, Abbokinase was sold to ImaRx, and a year later its trade name was changed to Kinlytic. Two years later, in September 2008, Microbix Biosystems (Ontario, Canada) acquired all the rights related to UK from ImaRx.[59] Of note, the only licensed indication for UK is PE (see Table 41.1), but before being taken off the market in 1999, UK was FDA approved for PE, AMI, and catheter occlusion.

Recombinant Plasminogen Activators

Recombinant Urokinase

To improve the yield of manufactured UK, investigators have produced recombinant UK from genetically engineered mouse hybridoma cells. Recombinant UK, or urokinase alfa, is a 48-kD, two-chain UK once marketed as Open-Cath-R (ImaRx). Despite successful clinical trials in treating catheter occlusion, it is not currently available in the United States.[60,61]

Alteplase

Currently alteplase, or rt-PA, is the most commonly used thrombolytic agent in clinical practice. It is identical to the naturally occurring t-PA, which is normally produced by endothelial cells. After sequencing of the native t-PA protein, recombinant technology now produces rt-PA from Chinese hamster ovary cells.[2]

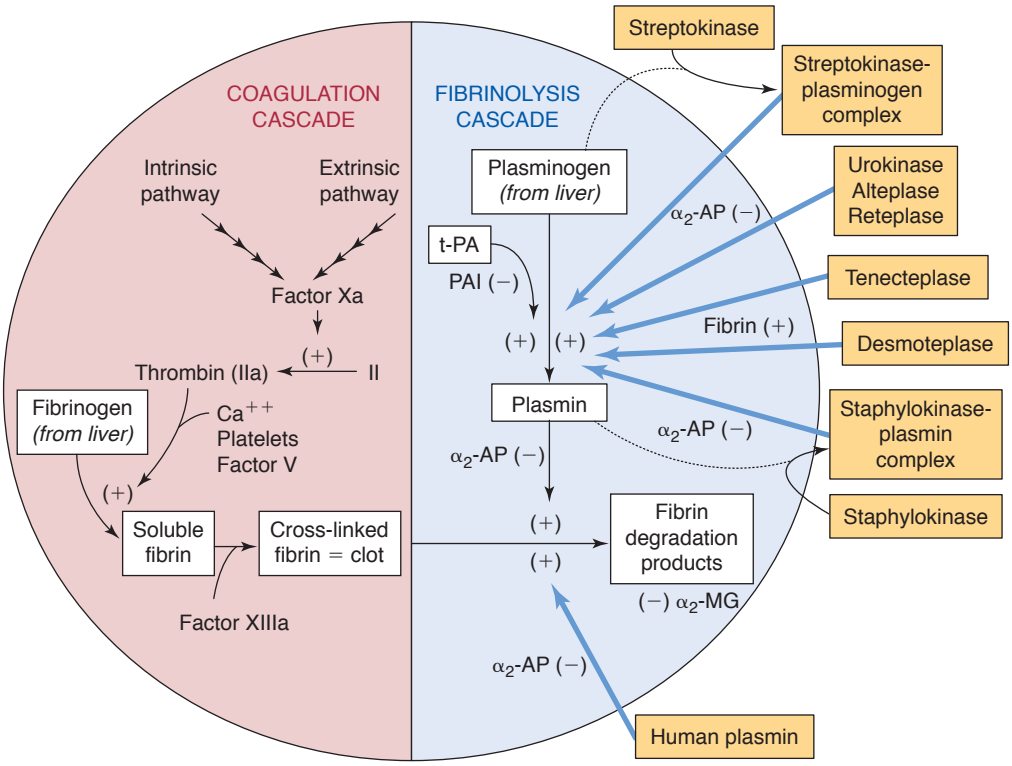

Figure 41.2 Coagulation and fibrinolytic pathway in relation to thrombolytic agents and the mechanism of action. α_2-*MG*, α_2-Macroglobulin; α_2-*AP*, α_2-antiplasmin; *PAI*, plasminogen activator inhibitor; *t-PA*, tissue plasminogen activator.

rt-PA and t-PA have the same molecular structure and characteristics (Fig. 41.2). Both are 70-kD molecules and contain five distinct functional domains. The carboxyl-terminal protease domain cleaves the plasminogen peptide bond, arginine 560–valine 561, which converts plasminogen to plasmin.[62] The fibronectin finger domain and the two kringle domains assist in binding to fibrin. Kringle domains are triple-looped, disulfide-bonded structures of about 80 amino acid residues that contain lysine-binding sites with different affinities for various molecules and receptors.[63] The epidermal growth factor (EGF) domain assists in liver binding and clearance and gives rt-PA a short half-life of 5 minutes and a terminal half-life of 72 minutes.[2] Because rt-PA is the same protein as native t-PA, it should lack antigenicity, but rare cases of hypersensitivity and allergic reactions have been reported.[64,65]

Alteplase was developed jointly by Genentech in the United States and Boehringer Ingelheim in Germany. Alteplase is marketed in the United States as Activase and Cathflo (Genentech, Inc., South San Francisco, California) and in Europe as Actilyse (Boehringer Ingelheim, Ingelheim, Germany). Activase has FDA approval for use in patients with AMI, PE, and AIS, whereas Cathflo (which is alteplase packaged into 2-mg vials) is approved for occluded central venous catheters (see Table 41.1).

Reteplase

Removal of the finger, EGF, and kringle K1 domains of rt-PA results in a protein called reteplase (see Figs. 41.2 and 41.3, and Table 41.2). This 355–amino acid protein also lacks carbohydrate side chains because it is produced from *E. coli* rather than from mammalian cells.[66] The changes remove the less desirable characteristics of native t-PA. Lack of the EGF and carbohydrate side chains decreases liver clearance and thus prolongs its half-life to 15 minutes and terminal half-life to 1.6 hours. This allows bolus dosing of reteplase, usually in two separate 10-unit intravenous doses 30 minutes apart.[67,68] Reteplase is cleared by both the renal and hepatic systems. Although reteplase lacks the EGF and K1 domains, retention of the K2 domain still gives it some fibrin/fibrinogen specificity.

Reteplase was originally developed by Boehringer Ingelheim, which merged with Roche. Abroad, reteplase was marketed as Rapilysin (Roche, Basel, Switzerland), but in the United States it was marketed as Retavase (EKR Therapeutics, Cedar Knolls, New Jersey). The rights to Retavase in the United States have gone from Roche to Centocor (Horsham, Pennsylvania), to PDL, Inc. (Redwood City, California), in 2006, to EKR Therapeutics in 2008, and since June 2012 to Cornerstone Therapeutics (Cary, North Carolina). It is FDA-approved for AMI (see Table 41.1).

Tenecteplase

Tenecteplase is another genetically modified rt-PA produced in Chinese hamster ovary cells. It differs from native t-PA in three ways. Threonine 103 is replaced by asparagine, asparagine 117 is replaced by glutamine (both within the K1 domain), and the amino acid sequence from positions 296 to 299 within the carboxyl-protease domain is replaced by four alanines.[4] The

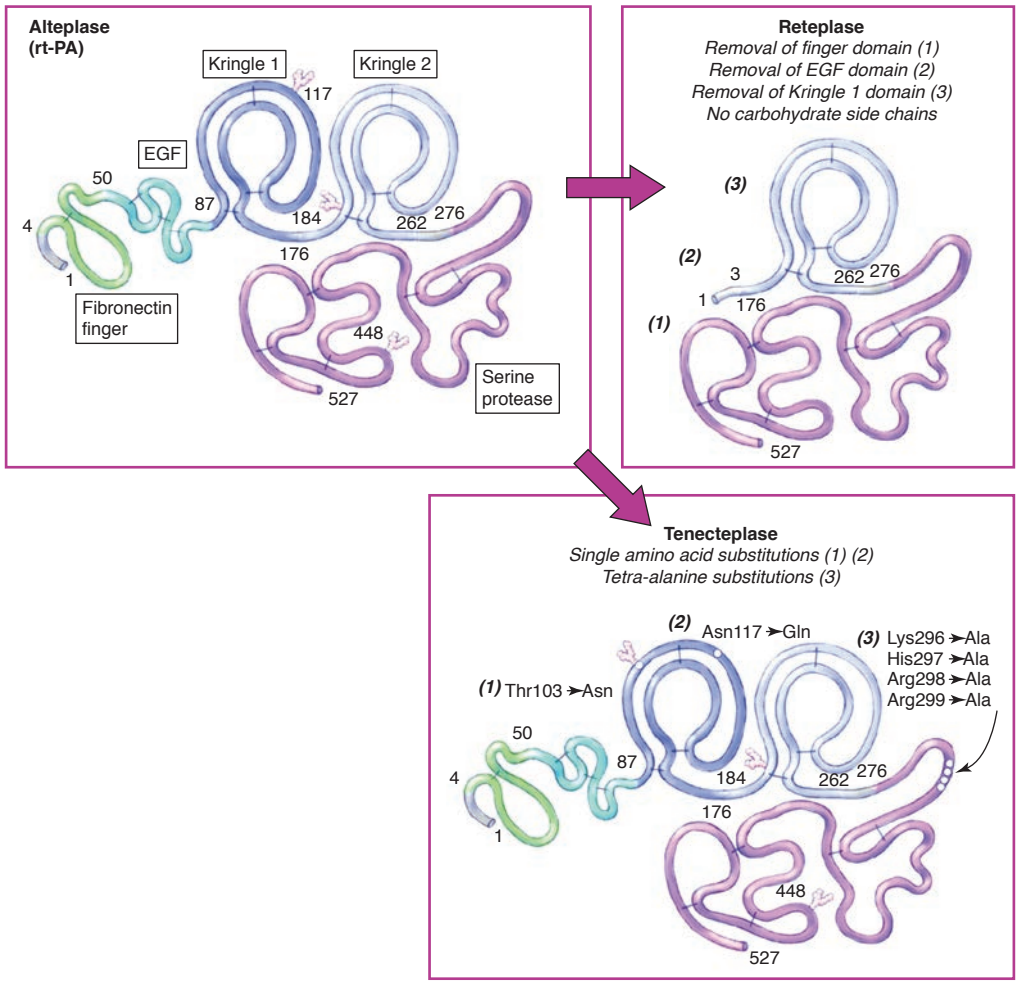

Figure 41.3 Molecular structure of the recombinant plasminogen activators. *EGF*, Epidermal growth factor. (Image modified with permission from Fig. 41.2 in Llevadot J, Giugliano RP, Antman E. Bolus fibrinolytic therapy in acute myocardial infarction. *JAMA*. 2001;286:442–449. Copyright © 2001, American Medical Association. All rights reserved.)

tetra-alanine substitution creates increased fibrin specificity. The substitution at position 103 allows decreased clearance, and the final position 117 exchange is needed to retain the thrombolytic effect of the entire protein (see Fig. 41.2 and Table 41.2).[68,69]

These modifications give tenecteplase a longer half-life than rt-PA, while retaining fibrin affinity. In vivo models demonstrate an 80-fold higher resistance to plasminogen activator inhibitor-1 (PAI-1) and 14-fold enhanced fibrin specificity when compared with rt-PA.[69] Tenecteplase half-life is 20 to 24 minutes, with a terminal-phase half-life of 90 to 130 minutes. Hepatic metabolism is the main method of clearance. Dose is based on weight and administered as a single bolus.[4] In 2000, tenecteplase was approved by the FDA for AMI and marketed as TNKase (Genentech). Abroad, tenecteplase is known as Metalyse (Boehringer Ingelheim; see Table 41.1).

Direct-Acting Agents

All the thrombolytic agents described to this point are plasminogen activators that convert intrinsic plasminogen to active plasmin, which cleaves linked fibrin. This "indirect" method of achieving thrombolysis results in a varied thrombolytic response. Direct-acting thrombolytic agents could theoretically eliminate this variability, since they act directly on the fibrin polymer. However, these "plasmin"-like compounds are inhibited by circulating inactivators and therefore cannot be delivered systemically. Thus catheter-directed administration of these agents to the offending thrombus is required for therapeutic effect.

Plasmin

The only direct-acting thrombolytic currently under investigation is plasmin. As early as 1960, research was conducted to investigate using human plasmin to treat thrombotic occlusion, but the initial clinical results were poor because of inactivation of systemically administered plasmin by α_2-antiplasmin.[70,71] Later animal studies demonstrated that plasmin directly delivered to the thrombus provides more rapid and effective thrombolysis than currently available plasminogen activators.[72]

Talecris (Barcelona, Spain), purchased by Grifols in 2011, is investigating two forms of plasmin: The first form is γ-Plasmin

(TAL-6003), a recombinant plasmin that is still in preclinical development. It is a simplified form of human plasmin, in which the K1 domain is directly attached to the serine protease domain. This modified plasmin can potentially be more active and fibrin specific.[73]

The other form is human plasmin. It is obtained from donors who are screened to rule out blood-borne pathogens. Phase I and II clinical trials in the Plasmin Revascularization by Intrathrombus Infusion for the Ischemic Lower Extremity (PRIORITY) study tested a total dose of plasmin from 25 to 175 mg, in 25-mg increments. Using CDT and pulse-spray delivery, 27% was given as a bolus; then 30 minutes later another 13% of the total dose was given as a second bolus, and the last 60% was infused over a period of 4.5 hours. Thrombus resolution (≥50%) occurred in 79% of subjects receiving 125 to 175 mg of plasmin, as compared with 50% who received 25 to 100 mg, with no trend toward more bleeding at higher dosages of plasmin. Major bleeding occurred in 4.8%, and minor bleeding in 15.7%.[74]

Phase II randomized trials comparing plasmin with placebo and rt-PA in peripheral artery obstruction are in different stages of development.[75] Phase I/II trials of CDT using plasmin (doses of 20, 40, 80 mg) in AIS within a 9-hour window are also being considered.[76]

CLINICAL APPLICATIONS

Each thrombolytic agent has been studied in a number of well-performed multicenter, randomized clinical trials, and although the FDA-licensed indications are limited for most agents, off-label use is common. The choice of agent is often based on the treating physician's experience and the availability in the hospital. In most facilities, rt-PA is the most readily available, followed by reteplase and tenecteplase.

Acute Myocardial Infarction

In most centers, emergency cardiac catheterization has replaced thrombolytic treatment of AMI, but in institutions without this capability, IVT still has a role. Furthermore, the development and dosing of almost every new thrombolytic agent has been tested in patients with AMI. The first trial to establish IVT as a useful treatment of AMI was reported in 1986 (see Fig. 41.1). The Gruppo Italiano per lo Studio della Streptochinasi nell'Infarto Miocardico (GISSI) study randomized 11,806 patients seen within 12 hours of the onset of symptoms to receive intravenous SK or placebo. At 21 days, overall hospital mortality was 10.7% in SK recipients versus 13% in controls ($P = .0002$).[77] The International Study of Infarct Survival (ISIS) 2 not only confirmed the benefits of SK versus placebo in patients with AMI but also proved combination therapy with aspirin to be beneficial.[47]

Similarly, the use of rt-PA for AMI has been extensively studied. The results of the Anglo-Scandinavian Study of Early Thrombosis (ASSET) demonstrated the superiority of rt-PA over placebo in 5011 randomized patients with AMI.[78] In comparing rt-PA with SK, several trials have demonstrated superiority of rt-PA over SK in respect to coronary arterial flow[79] and relative risk of 30-day mortality.[79,80,81] Furthermore, reteplase and tenecteplase have been studied in a number of trials that ultimately established a licensed indication for AMI (Table 41.3).[82-88]

TABLE 41.3 Dosing of Currently Available Thrombolytic Agents for Acute Myocardial Infarction

Agent	Dose
Alteplase	100 mg in accelerated or 3-h infusion: Accelerated infusion: Give 15-mg bolus, then 50 mg over next 30-min period, then 35 mg over next 60-min period 3-h infusion: Give 60 mg during first hour (of which 6-10 mg is administered as a bolus), then 20 mg during second hour, then 20 mg during the third hour
Reteplase	10 U + 10 U double-bolus injection, each 10 U over 2-min period, 30 min apart
Tenecteplase	Weight-based dosing, single bolus (30-50 mg) over 5-s period, not to exceed 50 mg

Dosages are for adult use (≈70 kg) and intravenous injection.

Pulmonary Embolism

Multiple trials with different thrombolytic agents in various dosages have been undertaken for PE. Unlike AMI, IVT for the management of PE has not consistently demonstrated mortality benefits. Success thus far has been based on improved pulmonary angiography, lung scans, or pulmonary pressure (or any combination of these endpoints).[89-96]

In 2012, the Ninth American College of Chest Physicians (ACCP) Conference on Antithrombotic and Thrombolytic Therapy did not support the routine use of IVT for PE unless the patient was hemodynamically unstable or becoming unstable despite anticoagulation (grade 2C). IVT with the shortest infusion times are still recommended over CDT. However, whereas previously the ACCP recommended against CDT all together, they now weakly recommend CDT (in combination with mechanical thrombectomy) in patients with an acute PE, which is associated with hypotension and either contraindications to thrombolysis, failed thrombolysis, or shock that is likely to cause death before IVT can take effect.[25]

These ACCP recommendations are supported by evidence demonstrating that mechanical device assisted thrombolysis improves thrombus removal with a smaller dose of thrombolytic agent.[97,98] One such device, the Ekosonic Endovascular System (EKOS, Bothell, Washington), when used to assist thrombolysis has demonstrated the capacity to rapidly clear thrombus in patients with large pulmonary thrombi.[98,99] The ULTrasound Accelerated Thrombolysis of PulMonAry Embolism (ULTIMA) trial was one of the first randomized controlled trials comparing EKOS assisted CDT to anticoagulation alone. This trial included 59 patients with intermediate risk PEs and concluded that EKOS was superior to anticoagulation alone in reversing RV dilation at 24 hours.[100] Results from this trial led to the FDA

approval of EKOS for the treatment of PE in 2014. In 2015, the results of a single-arm multicenter prospective clinical trial (SEATLE II) concerning the safety and efficacy of EKOS assisted CDT in the treatment of acute massive and submassive PEs were published. The authors concluded that EKOS decreased RV dilation, reduced pulmonary hypertension, decreased thrombus burden, and minimized intracranial hemorrhage.[101] A systematic review and proportional meta-analysis done by Mostafa evaluated the use of EKOS in patients with acute PE. The main finding was that major bleeding rates were 2.3% with EKOS assisted CDT, in contrast to 10% seen in IVT. They also concluded that EKOS improved postprocedural RV/LV ratio, as compared with preprocedural values.[102] The PERFECT trial, published in 2015, also supported the above findings for CDT when used for treatment of massive and sub massive PE showing an improvement in mean pulmonary artery pressures from 51.17 ± 14 mm Hg to 37.23 ± 15.8 mmHg ($P < .0001$). There were no major bleeding or procedure-related complications, or hemorrhagic strokes.[103] Finally, EKOS Corporation, now owned by United Kingdom based company BTG, is currently sponsoring a clinical trial called OPTALYSE PE, which is recruiting participants to determine the optimum duration of EKOS CDT in acute sub massive PE.

Acute Ischemic Stroke

Well-controlled randomized clinical trials have established the benefits of IVT in patients with AIS.[109, 110, 112-114] The 2012 ACCP guidelines recommend administration in less than 3 hours (grade 1A), but have extended the window to 4.5 hours (grade 2C) based on new data.[25] Of note, the only FDA-approved agent is rt-PA, although a number of thrombolytic agents, either no longer commercially available or discontinued, have been used in case reports and even clinical trials.[104-107] Results of phase II clinical trials comparing alteplase to tenecteplase for the treatment of ischemic stroke suggest neurologic and radiologic outcomes do not differ.[108] A more recent randomized controlled trial compared low-dose (0.6 mg per kg of body weight) versus standard-dose (0.9 mg per kg of body weight) intravenous alteplase in AIS. The study showed low-dose alteplase to be noninferior to standard dose alteplase for the treatment of acute stroke. Low-dose alteplase had a lower incidence of symptomatic intracranial hemorrhage, and lower incidence of early fatal events.[109]

IVT with rt-PA administered within 3 hours of AIS in combination with CDT, or CDT plus EKOS for distal thrombus was studied in 81 patients in a phase II trial Interventional Management of Stroke (IMS)-II.[110] Compared with historic data from the National Institute of Neurological Disorders and Stroke, the 3-month mortality was lower (16%), but symptomatic ICH was higher (9.9%).[110] In the phase 3 trial (IMS-III), patients who received IVT with rt-PA within 3 hours after stroke symptom onset were randomly assigned to receive either additional IVT or CDT with rt-PA.[111] After randomizing 665 patients, the study was terminated, because no difference was demonstrated in stroke outcome between the two therapies. A concurrent study from the SYNTHESIS Expansion investigators also demonstrated no benefit to CDT with rt-PA when compared with IVT alone.[110,112] This is consistent with an earlier phase I study, the Emergency Management of Stroke (EMS) trial, which studied CDT alone against CDT plus IVT in 35 patients and found no difference in clinical outcomes or rates of symptomatic ICH.[113] However, a prospective observational study of 2650 patients with ischemic stroke showed that percutaneous mechanical thrombectomy plus CDT or IVT showed improved functional outcome (common odds ratio, 1.84; 95% confidence interval, 1.32 to 2.57) and decreased mortality (15% vs. 33%, $P < .0001$) when compared with IVT alone.[114]

The 2012 ACCP guidelines recommend intraarterial rt-PA in patients with AIS due to proximal cerebral artery occlusions who do not meet eligibility criteria for treatment with IV rt-PA (past the 3- to 4.5-hour window) but are still within 6 hours of symptom onset. They recommended against combined IVT and intraarterial rt-PA or mechanical thrombectomy, except in carefully selected patients willing to accept an increased risk with uncertain benefit. It should be noted that these recommendations were all grade 2C, weak with low quality of evidence (Table 41.4).[115]

TABLE 41.4 Dosing of Currently Available Thrombolytic Agents for Pulmonary Embolism

Agent	Dose
Alteplase	100 mg over 2-h period
Reteplase[a]	10 U + 10 U double-bolus injection, each 10 U over 2-min period, 30 min apart

[a]These dosing guidelines are based on case reports and series. Additional dosing schedules (not reported here) have been used. Given the lack of clinical trials, caution should be used if thrombolytic agents are administered at these doses. Dosages are for adult use (≈70 kg) and intravenous injection.

Acute Limb Ischemia

Initial evidence that thrombolysis could effectively treat acute arterial occlusions of the extremity and delay or replace surgical interventions came from several nonrandomized case series.[116,117] Preliminary studies proved CDT to be safer and more efficacious than IVT for all the reasons discussed previously.[21,22] Three randomized, prospective clinical trials provided definitive evidence that in patients with acute limb ischemia of less than 14 days of duration, CDT was of clinical benefit.

The Rochester Trial randomized 114 patients with less than 7 days of limb-threatening ischemia to either open surgery or CDT with UK. The 12-month limb salvage rates (82%) were similar, but thrombolysis provided improved 12-month survival (84% with CDT vs. 58% with surgery, $P = .01$).[35]

The Surgery Versus Thrombolysis for the Ischemic Lower Extremity (STILE) trial included patients with up to 6 months of ischemic symptoms. It compared open surgical therapy with CDT using either rt-PA or UK. The study was stopped after 393 patients, due to adverse primary outcomes in the CDT group when compared with the surgical group. However, a subgroup analysis of patients with less than 14 days of ischemia

TABLE 41.5 Dosing of Currently Available Thrombolytic Agents for Acute Ischemic Stroke

Agent	Dose
Alteplase	Systemic: 0.9 mg/kg total dose (not to exceed 90 mg): Load 10% as a bolus over 1-min period and infuse remainder over 60-min period Catheter directed: 2 mg bolus (over 2 min) distal to thrombus, then 2 mg bolus (over 2 min) into the thrombus; then infusion 9 mg/h for up to 2 h—not to exceed 120 min (based on the IMS study[112])

Dosages are for adult use (≈70 kg).

showed a lower amputation rate at 6 months when treated with CDT than when treated surgically (CDT 11% vs. surgery 30%, $P = .02$).[36]

The Thrombolysis or Peripheral Arterial Surgery (TOPAS) trial randomized 544 patients with acute (<14 days) arterial or bypass graft occlusion to open surgery versus CDT with UK. At 12 months, rates were similar for amputation-free survival (CDT 65% vs. surgery 75%) and mortality (CDT 20% vs. surgery 17%). However, CDT allowed 40% of patients to avoid a surgical intervention with the tradeoff being an increased rate of major bleeding (CDT 12.5% vs. surgery 5.5%, $P = .005$).[37]

Current recommendations support CDT in patients with Rutherford class I to class IIa limb ischemia of less than 14 days of duration.[23,24] In selected circumstances, treatment may also be of value in patients with Rutherford class IIb. The enthusiasm for this recommendation is tempered by the time required for successful CDT and the associated bleeding complications with currently available thrombolytic agents.[23,24] Contemporary dosing for CDT has evolved to a low-dose extended infusion (Table 41.5). A Cochrane review in 2009 found that although high-dose and forced-infusion techniques achieved vessel patency in less time than low-dose infusion; bleeding complications were more common, and at 30 days no improvement in patency rates or limb salvage was documented.[118]

CDT with EKOS may allow for even lower doses of thrombolytic agents to be used with equal efficacy and improved safety. A Dutch randomized trial (DUET) comparing CDT with EKOS assisted CDT for thromboembolic infrainguinal disease showed significantly reduced thrombolysis time for EKOS assisted CDT (17.7 ± 2.0 hours) compared with CDT alone (29.5 ± 3.2 hours, $P = .009$).[119]

A recent retrospective review analyzed 154 patients with acute limb ischemia who were treated with CDT or pharmacomechanical thrombolysis (PMT), with other adjunctive endovascular and surgical interventions. Technical success was achieved in 84% with a 30-day mortality rate of 5.2% and an overall rate of major amputation of 15%. CDT and PMT had equal benefit. Additional revascularization procedures, mostly endovascular (69%), were required in 89% of patients. End stage renal failure and poor pedal outflow were predictors of limb loss.[120] Early experimental studies looking at contrast-enhanced ultrasound to accelerate the thrombolytic effects of low-dose CDT in arterial occlusions have shown results in porcine models sufficient to warrant clinical studies.[121]

Deep Venous Thrombosis

Until recently, most data on thrombolysis in the management of DVT had been predicated on small randomized clinical trials or venous registries. In 1984, Goldhaber pooled data from six small, randomized studies (N = 185) of IVT with SK versus heparin for the management of DVT. Venous patency was achieved 3.7 times more often in patients treated with SK versus heparin, but bleeding was 2.9 times greater with SK.

A 2005 review by Janssen identified 18 randomized controlled trials of IVT for DVT. Twelve studies compared SK with heparin in 468 patients, two trials compared UK with heparin in 117 patients, and four trials compared rt-PA with heparin in 150 patients. Only one trial compared CDT with standard anticoagulation, and no trials compared PMT with conventional anticoagulation.[122] The conclusion, similar to that of Goldhaber, was that IVT can improve venous patency but with an increased risk of bleeding. A later Cochrane review of 17 randomized controlled trials involving 1103 patients demonstrated that when compared to anticoagulation alone, IVT was associated with lower risk of post thrombotic syndrome, and leg ulceration; but with a higher bleeding risk (RR: 2.23; 95% CI: 1.4 to 3.5, $P = .0006$).[123] To examine whether CDT could decrease the bleeding risk, Mewissen established a venous registry that included 63 institutions and 287 patients. A higher frequency of venous patency was reported for CDT than for anticoagulation, but major bleeding complications still occurred in 11% of the patients.[124]

Before 2012 only one randomized trial had compared CDT with anticoagulation. In 2002, Elsharawy randomized 35 patients with acute iliofemoral DVT and found that those treated with CDT as opposed to anticoagulation had an improved 6-month patency (72% vs. 12%, $P = .0001$) and less venous reflux (11% vs. 41%, $P = .04$).[125] In 2012, the Catheter-Directed Thrombolysis Versus Standard Treatment for Acute (<21 days) Iliofemoral Deep Vein Thrombosis (the CaVenT study) trial randomized 209 patients to CDT versus anticoagulation alone. After 6 months, iliofemoral vein patency was higher in the CDT group (66%) versus the anticoagulation group (47%, $P = .012$), and at 24 months, rates of postthrombotic syndrome were lower in the CDT group (41.1%) compared with the anticoagulation group (55.6%, $P = .047$). However, 20 bleeding complications related to CDT occurred, including three major bleeding complications.[126]

Engelberger performed a prospective single center study in 87 patients with iliofemoral DVT using EKOS assisted CDT. Primary and secondary patency rates at 1 year were 87% and 96%, respectively. PTS at 1 year was 6%, and the incidence of major bleeding was 1%.[127] They subsequently in a later open-label randomized controlled study of 48 patients compared EKOS assisted CDT with CDT alone and found that there was no difference in long-term outcomes.[128]

Debate continues on whether the DVT clearance and immediate patency achieved by thrombolysis translates into

TABLE 41.6 Dosing of Currently Available Thrombolytic Agents for Acute Limb Ischemia

Agent	Dose
Alteplase	Catheter directed: Low-dose (extended infusions >12 h): 0.5-2.5 mg/h High-dose: 0.05 mg/kg per hour up to 12 h (or until maximum of 100 mg administered)
Reteplase[a]	Catheter directed: 2-U bolus, then infuse 0.5-1 U/h (should not exceed a total administered dose of 20 U)
Tenecteplase[a]	Catheter directed: 0.25-0.5 mg/h; infusion stopped if no improvements on serial arteriograms

[a]These dosing guidelines are based on case reports and series. Additional dosing schedules (not reported here) have been used. Given the lack of clinical trials, caution should be used if thrombolytic agents are administered at these doses. Dosages are for adult use (≈70 kg).

TABLE 41.7 Dosing of Currently Available Thrombolytic Agents for Venous Thrombosis

Agent	Dose
Alteplase[a]	Catheter directed: 0.25-2 mg/h
Reteplase[a,b]	Catheter directed: 0.75 U/h
Tenecteplase[a,b]	Catheter directed: 0.25-0.5 mg/h

[a]Infusions are stopped once no improvement is seen on serial venograms performed every 8 to 12 hours.
[b]These dosing guidelines are based on case reports and series. Additional dosing schedules (not reported here) have been used. Given the lack of clinical trials, caution should be used if thrombolytic agents are administered at these doses. Dosages are for adult use (≈70 kg).

TABLE 41.8 Dosing of Currently Available Thrombolytic Agents for Arteriovenous Graft Occlusion

Agent	Dose
Alteplase[a,b]	Catheter directed: 2 mg
Reteplase[a,b]	Catheter directed: 1 U
Tenecteplase[a,b]	Catheter directed: 1 mg

[a]These dosing guidelines are based on case reports and series. Additional dosing schedules (not reported here) have been used. Given the lack of clinical trials, caution should be used if thrombolytic agents are administered at these doses.
[b]The listed dosages are administered under fluoroscopic guidance. Dosing can be repeated if arteriovenous graft patency is not restored.
Dosages are for adult use (≈70 kg).

superior long-term outcomes. The current guidelines favor anticoagulation over CDT (grade 2C) for an acute proximal DVT. ACCP stipulates that CDT (with or without PMT) or IVT can be considered if patients attach a high value to the prevention of postthrombotic syndrome and a lower value to the initial complexity, cost, and risk of bleeding (Table 41.6).[25] DUTCH CAVA (NCT 00970619) and ATTRACT (NCT 0070035) trials are ongoing randomized controlled trials that will hopefully provide further clarification as to the use of CDT for DVT.

Arteriovenous Graft Occlusion

The use of thrombolysis in patients with AVG thrombosis was reported as early as 1983, when Rodkin used SK to successfully lyse eight of nine thrombosed AVGs.[129] Over the years, a number of techniques have been developed that have made thrombolysis quite efficient and clinically effective. The cross-catheter method uses two overlapping catheters placed at separate locations within the AVG, with their tips just past the arterial inlet and venous outlet.[26,130] The "lyse and wait" technique is a method in which the thrombolytic agent is infused into the graft while the arterial and venous ends are manually occluded. With the advent of PMT devices, thrombolytic agents are being used as more of an adjunct following thrombus extraction.[131,132] Although no FDA-approved thrombolytic agents are available for the treatment of AVG occlusion, case reports and series exist for almost every agent.[133-135] Thrombolytic doses of 2 mg of rt-PA, 1 mg of tenecteplase, and 1 unit of reteplase have all been used with success and minimal to no bleeding complications (Table 41.7).

Central Catheter Occlusion

The only FDA-approved thrombolytic for central catheter occlusion is rt-PA marketed in 2 mg vials as Cathflo. It was studied in 1064 patients in the Cardiovascular Thrombolytic to Open Occluded Lines (COOL) trial. Increased catheter patency was seen after 2 hours with one 2 mg dose of rt-PA (74%) versus placebo (17%, $P = .0001$).[136] Efficacy rates were similar among catheter types (single-, double-, and triple-lumen catheters and ports), and 30-day adverse events were rare: ICH (0.0%), embolic events (0.0%), gastrointestinal bleeding (0.3%), thrombosis (0.3%), and sepsis (0.4%).[137]

In children, rt-PA has also been found to be safe and effective through the Cathflo Activase Pediatric Study (CAPS). Patients weighing less than 30 kg received instillations of rt-PA (1 mg/1 mL) equal to 110% of the estimated internal lumen volume of the dysfunctional central venous catheter, not to exceed 2 mL.[26]

Hemodialysis catheters were excluded from all clinical trials on Cathflo; therefore hemodialysis catheters are not included in the FDA indication for catheter occlusion. However, the successful use of rt-PA (2 mg), reteplase (0.4 U) has been reported (Tables 41.8 and 41.9).[138-140]

Miscellaneous Uses

Intraoperative thrombolytic therapy used as an adjunct to open arterial thrombectomy or thromboembolectomy has been described and shown to be safe and effective in breaking down distal thrombus.[141] However, in patients with extensive distal clot burden, thrombolytic boluses given intraoperatively may not be enough. In these circumstances, isolated limb perfusion with high-dose thrombolysis has been described with or without a pump oxygenator. Another purported advantage of this

TABLE 41.9 Dosing of Currently Available Thrombolytic Agents for Catheter Occlusion

Agent	Dose
Alteplase[a]	≥30 kg: 2 mg in 2 mL; may repeat after 120 min if catheter still occluded <30 kg: 110% of the internal lumen volume (not to exceed 2 mg in 2 mL); may repeat above after 120 min if catheter still occluded
Reteplase[a,b]	0.4 U in 2 mL; may repeat after 30-60 min if catheter still occluded

[a]The volume instilled is not to exceed the internal lumen volume. Clamp the catheter and try to aspirate its contents in 30 minutes. If no result, a second dose can be attempted (see individual agents for timing).
[b]These dosing guidelines are based on case reports and series. Additional dosing schedules (not reported here) have been used. Given the lack of clinical trials, caution should be used if thrombolytic agents are administered at these doses. Dosages are for adult use (≈70 kg).

treatment is the mitigation of the systemic effects of reperfusion injury.[142] Although combining open surgical procedures with thrombolysis is infrequently employed, there may be selected patients in which knowledge of these techniques can be limb and/or life sparing.

Abstract

Vascular surgery patients as a groups are the patients with the largest prevalence of cardiac disease among all non-cardiac surgery patients. As such, they are also at high risk of developing perioperative cardiac morbidity and mortality. This chapter will focus on understanding the pathophysiology of perioperative cardiac events in vascular surgery patients, on the methods to accurately define and diagnose preoperative cardiac pathologies and cardiac risks and on the possible measures that can be taken to improve perioperative cardiac risk.

EPIDEMIOLOGY

Prevalence of Coronary Disease

Coronary artery disease (CAD) is highly prevalent in vascular surgical patients. Hertzer and colleagues drew attention to this by showing the small percentage of vascular surgery patients (8%) who were free of CAD.[1] In a study from the Cleveland Clinic from more than 30 years ago, 5% of patients had left main CAD and 11% had significant three-vessel disease. In fact, 15% of these patients had severe, yet unsuspected CAD. Since then, significant changes in both the primary and secondary prevention of coronary disease have occurred, including smoking cessation and the adoption of aggressive lipid lowering therapies. Subsequently, the incidence of myocardial infarction (MI) and cardiac death in nonsurgical populations decreased by 30%.[2] Conversely, patients presenting for vascular surgery in 2013 are on average a decade older, with more comorbidities, and the incidence of major coronary pathology in vascular patients may be even higher. Thus, despite clear advances in the treatment of CAD, it is conceivable that many patients presenting for vascular surgery have silent yet significant CAD. In the intervening years, our ability to identify patients with significant coronary disease has apparently been imperfect. This was demonstrated by Monaco and colleagues, where screening patients using the American Heart Association/American College of Cardiology (AHA/ACC) guidelines identified fewer patients with three-vessel or left main coronary disease than a randomized cohort having routine preoperative coronary angiograms.[3] In this chapter we will outline and define the pathology and document the incidence, the diagnostic criteria, risk stratification, and treatment options designed to limit the effect of postoperative cardiac adverse events.

Definition of Adverse Postoperative Cardiac Events

These can be classified using the following terms:

- Acute coronary syndromes (i.e., unstable angina pectoris [UAP], acute MI, or sudden cardiac death)
- Congestive heart failure (CHF)
- Myocardial injury
- Life-threatening arrhythmias

Myocardial Infarction

MI is one of the leading causes of death after surgical procedures. Since the introduction of cardiac troponin assays in the 1990s and the recognition of their high sensitivity, specificity, and prognostic value, the diagnosis of MI is based mainly on serum troponin elevations. The most recent universal definition of MI[4] endorsed by all major cardiology organizations defines MI as a rise and fall in cardiac troponin above the 99th percentile of the upper reference limit (for the specific troponin assay), in association with signs or symptoms of myocardial ischemia—that is, at least one of the following: (1) symptoms of myocardial ischemia (i.e., typical chest pain); (2) electrocardiographic evidence of acute ischemia, ST-T wave changes, or left bundle branch block; (3) development of new pathologic Q waves; (4) imaging showing loss of viable myocardium or a new abnormal left ventricular (LV) wall motion. The universal definition of MI identifies two main types of MI.[4]

Type-1 Myocardial Infarction

This is a sudden, spontaneous coronary event typically occurring in an unstable or "vulnerable" coronary plaque that has a large and highly inflammatory lipid core with a thin, weakened fibrous cap that suddenly undergoes acute disruption, leading to acute coronary thrombosis. Acute plaque rupture and coronary thrombosis that occur in a major coronary artery, supplying an area that was not significantly stenosed prior to the acute occlusion and lacks sufficient collaterals, typically results in ST-elevation-type MI (STEMI). STEMI, as a rule, is a medical emergency. It typically causes severe chest pain, dyspnea, and sweating, and requires an emergency intervention to reopen the occluded coronary artery, preferably by percutaneous coronary intervention (PCI). Even with the urgent coronary intervention, STEMI is associated with up to 10% early mortality. Other patients may have similar symptoms but no ST-segment elevations or, rather, ST-depression on electrocardiogram (ECG/EKG). These infarctions are defined as non-ST-elevation infarctions or NSTEMI. Pathologically, these are plaque ruptures and coronary thromboses in coronary arteries supplying smaller myocardial territories or territories supplied also by collaterals, or thromboses causing partial coronary occlusions. Patients with NSTEMI usually do not benefit from urgent coronary interventions, unless hemodynamic instability or progression of symptoms occurs. In the past, the proportions of STEMI and NSTEMI, in the general nonsurgical Western populations were approximately 50% each. Currently, with the older age of the population, with primary and secondary prevention strategies available, and with the better detection of MI by the high-sensitivity troponin assays, the absolute incidence of STEMI in the Western world is declining while the incidence of NSTEMI is increasing. Hence the current proportion of STEMIs of all infarctions is 30% or less.

Type-2 Myocardial Infarction

In contrast, type-2 MI often occurs in patients with severe yet stable CAD, usually due to extracardiac causes leading to a prolonged imbalance between myocardial oxygen supply and demand. The most common triggers for type-2 MI are prolonged tachycardia, hypotension or hypertension, anemia, and emotional or physical stress causing coronary vasospasm.[5] Type-2 MI is almost uniformly associated with ST-depression or non-ST-elevation type ischemia and is therefore indistinguishable from type-1 NSTEMI. The clinical circumstances (i.e., spontaneous, primary event in type-1 versus stress-induced, secondary event in type-2) can help distinguish between the two types of MI (Fig. 42.1).

Postoperative MI occurs in up to 24% of vascular surgery patients if MI is defined only based on troponin elevation and the low cutoff level of troponin elevations is used to define MI.[6] Postoperative ST elevation MI (STEMI) is usually less than 1% of all postoperative MIs.[7] Many more patients sustain

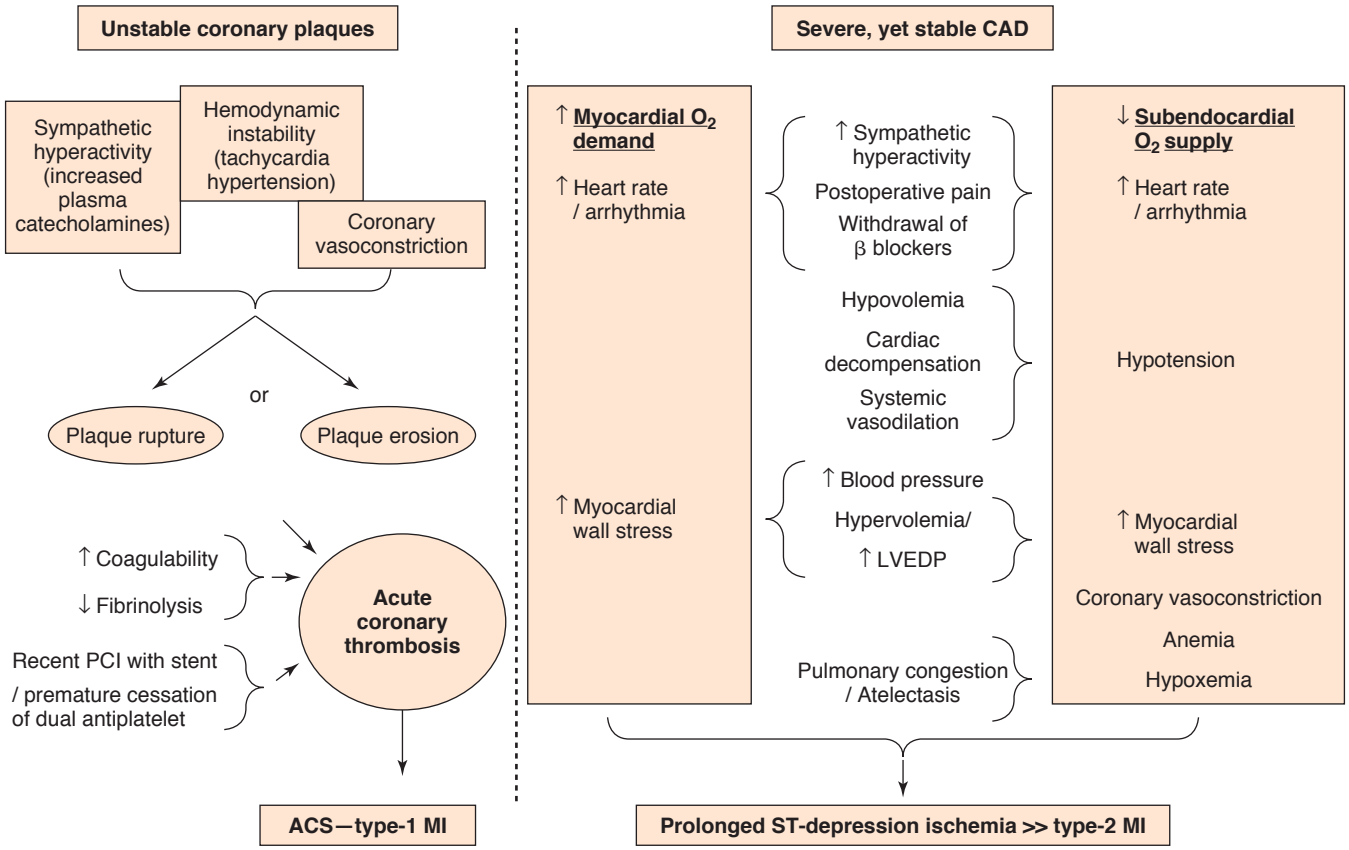

Figure 42.1 The two distinct mechanisms of PMI. *CAD*, Coronary artery disease; *MI*, myocardial infarction; *PCI*, percutaneous coronary intervention.

a biomarker rise with ST-segment depression or without any transient ST-T changes, which is analogous to a non-ST elevation myocardial infarction (NSTEMI) or myocardial injury.

Unstable Angina Pectoris

UAP occurs when a patient has recurrent or new onset typical chest pain, especially during rest, yet with no evidence of serum troponin elevations, since the presence of serum troponins elevation already makes the diagnosis of MI.

Congestive Heart Failure

Heart failure is the inability of the heart to provide adequate cardiac output to meet the normal metabolic requirements of all peripheral organs. Acute heart failure often leads to a drop in blood pressure and shock. Chronic, compensated heart failure is a situation in which the periphery adapts itself to the lower capacity of the heart to supply adequate cardiac output. Currently heart failure is divided into two main subtypes: (1) heart failure with reduced ejection fraction (HFrEF) or systolic heart failure (these are usually patients with dilated hearts due either to MIs or dilated cardiomyopathy and reduced systolic function), or (2) heart failure with normal or preserved ejection fraction (HFnEF) or diastolic heart failure (these are often patients with prolonged severe hypertension, left ventricular hypertrophy [LVH] and are more likely in female than males). Another type of heart failure is right ventricular failure, which is most commonly either secondary to LV failure, such as in the presence of severe mitral valve disease, or secondary to severe lung disease (i.e., cor pulmonale). In the perioperative setting, congestive failure is often ill defined and is frequently the result of fluid overload or transfusion-associated cardiac overload (TACO). The inability to handle excess fluids is a sign of a failing left ventricle. Postoperative CHF should be more thoroughly investigated with biomarkers (B-type naturetic peptide [BNP], N-terminal pro-B-type naturetic peptide [NT-proBNP]), chest x-ray, cardiac imaging, and particularly with echocardiography.

Life-Threatening Arrhythmia

Most life-threatening arrhythmias (ventricular tachycardia, ventricular fibrillation, high-degree A-V block) occur in the setting of acute myocardial ischemia and infarction, or in the presence of structural myocardial disease such as severely dilated cardiomyopathy. Fortunately, these LTAs are rare in the perioperative period, and if they do occur, it is mostly in patients with known predisposing factors such as severe CAD or cardiomyopathy. The more common arrhythmia in the perioperative setting is new onset or recurrent atrial fibrillation, and the most common causes of postoperative AF in patients with no known myocardial or valvular disease are severe diastolic dysfunction and chronic lung disease or pulmonary hypertension. Patients with new onset postoperative atrial fibrillation obviously have the worse prognosis.

Cardiac Death

Cardiac death has also been defined in the universal definition statement. Type-3 MI is death or cardiac arrest that is sudden and unexpected, with symptoms suggestive of myocardial ischemia, occurring before cardiac biomarkers could be obtained or before they appear in the blood.[4]

THE PATHOPHYSIOLOGY OF PERIOPERATIVE MYOCARDIAL INFARCTION

The high prevalence of CAD in vascular surgery patients and the strong perioperative physiologic and emotional stresses, including catecholamine surge, hemodynamic instability, vasospasm, reduced fibrinolytic activity, platelet activation, and hypercoagulability, predispose the vascular patients to a high incidence of postoperative cardiac complications. Interestingly, however, numerous studies showed that postoperative STEMI is disproportionately rare compared with the common occurrence of NSTEMI and that tachycardia is a frequent cause of postoperative myocardial ischemia.[6,8-10] Studies using continuous perioperative 12-lead ECG monitoring with online ST-segment analysis showed that prolonged, reversible episodes of ST-segment depression, indicative of subendocardial myocardial ischemia, occur in up to 41% of vascular surgery patients and precede the occurrence of troponin elevation.[11] These ST-depression-type ischemic events peak early after surgery and troponin elevations are maximal within the first 2 days.[12-14] In contrast, postoperative ST-elevation type ischemia is rare.[6-10] The data suggest, therefore, that perioperative MI is most commonly type-2 MI, caused by a prolonged ST-depression-type ischemia that is the result of an imbalance between myocardial oxygen supply and demand,[15] usually as a result of tachycardia and increase in myocardial load. Anemia, hypoxemia, increased myocardial oxygen demand, ventricular overload or underload, systolic or diastolic dysfunction, and neuroendocrine responses to the stresses of surgery all contribute to the decreased ischemic threshold early after surgery and with the increase in heart rate may lead to prolonged ischemia and infarction.[15] Although small pathologic studies showed that plaque disruption or hemorrhage can be found in postmortem analyses in up to half of patients who died after postoperative MI,[16,17] it is now well recognized that vulnerable plaques are ubiquitous in patients with CAD and most of them are not related to MIs.

Perioperative Myocardial Injury and Mortality

Studies that used routine postoperative troponin measurements showed that most patients with postoperative troponin elevations do not fulfill the additional diagnostic criteria necessary for the diagnosis of postoperative MI and that postoperative troponin elevation is predominately clinically silent. Landesberg and colleagues[8] first showed that almost 24% of all 447 patients who underwent major vascular surgery had at least minor postoperative troponin elevations (troponin-T > 0.03 ng/mL), yet only 30% of these patients with troponin elevations exhibited myocardial ischemia on continuous 12-lead EKG monitoring with ST-segment analysis and 82% of them had no symptoms related to MI (Tables 42.1 and 42.2). When a higher cutoff level of troponin elevation (troponin-T > 0.1 ng/mL) was selected, 8.7% of the patients had such troponin elevation yet 56% of these patients were still asymptomatic. Regardless if patients were symptomatic or not, even minor troponin elevation in the first 3 days after vascular surgery was associated with increased 5-year mortality, and higher postoperative troponin elevation was associated with worse long-term survival (Fig. 42.2). LeManach and colleagues studied more than 1100 patients undergoing open abdominal aortic aneurysmectomy.[14] Fourteen percent of these patients had troponin elevations, and in their study, too, minor troponin elevation was associated with greater 30-day postoperative mortality.[4] Van Waes and colleagues found similar results.[9,10] Similarly, the VISION prospective multicenter study that included more than 15,000 patients and the single center retrospective study that included more than 10,000 have confirmed that troponin elevations on the first 3 days after surgery predict early (30-day) mortality in a dose-dependent manner.[13,18,19]

The reasons for this lack of symptomatology in most patients with postoperative troponin elevations remain elusive. Elderly, diabetic, and vascular patients in particular are known to have a high incidence of silent ischemia. The concomitant use of narcotics and other competing somatic postoperative sensations may contribute to masking cardiac symptoms. The ECG, which is central for the diagnosis of MI, is less specific and sensitive in the presence of preexisting changes such as left or right bundle branch block, pacemaker rhythms, or baseline ST-T wave changes.[20,21] Moreover, the ischemic EKG changes may

TABLE 42.1 Universal Classification of Myocardial Infarction

Type 1: Spontaneous Myocardial Infarction

Spontaneous myocardial infarction related to atherosclerotic plaque rupture, ulceration, assuring, erosion, or dissection, with resulting intraluminal thrombus in one or more of the coronary arteries leading to decreased myocardial blood flow or distal platelet emboli with ensuing myocyte necrosis. The patient may have underlying severe CAD but on occasion nonobstructive or no CAD.

Type 2: Myocardial Infarction Secondary to an Ischemic Imbalance

In instances of myocardial injury with necrosis where a condition other than CAD contributes to an imbalance between myocardial oxygen supply and/or demand, e.g. coronary endothelial dysfunction, coronary artery spasm, coronary embolism, tachy-/brady-arrhythmias, anemia, respiratory failure, hypotension, and hypertension with or without LVH.

CAD, Coronary artery disease; *LVH*, left ventricular hypertrophy.

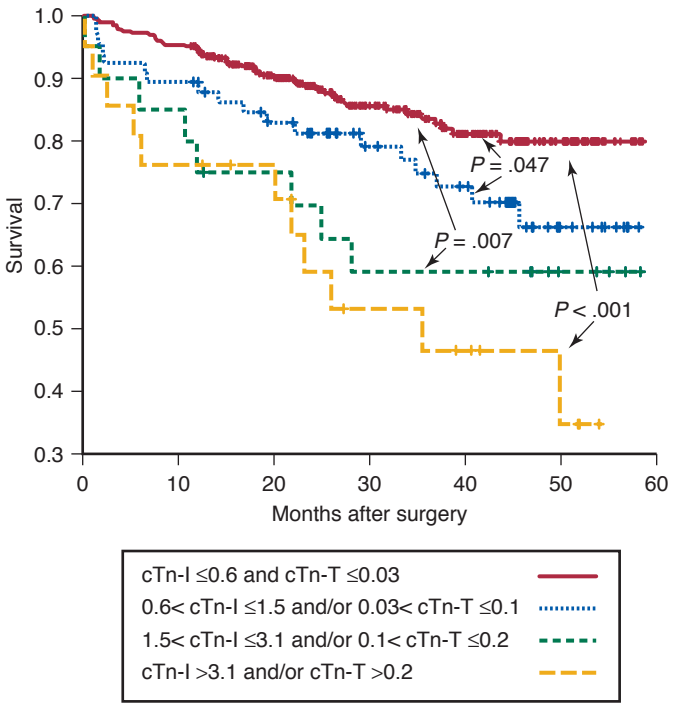

Figure 42.2 Long-term survival in 447 vascular surgery patients divided according to the highest troponin-T level in the first 3 postoperative days. (From Landesberg G, Luria MH, Cotev S, Eidelman LA, et al. Importance of long-duration postoperative ST-segment depression in cardiac morbidity after vascular surgery. *Lancet*. 1993, JACC 2003;341:715-719.)

be of transient nature, and the lack of routine monitoring of postoperative 12-lead EKG with ST-segment analysis leads to underdetection of postoperative ischemia.[16]

Recently it has been shown that postoperative troponin elevations in patients undergoing major abdominal surgery predict not only cardiac but also noncardiac complications and mortality.[22] Noncardiac complications pose a higher demand on the patient's heart, and thus it is not surprising that mortality is increased in those with underlying heart disease. Conversely, primary cardiac injury may lead to cardiac failure and a deterioration in other important systems, such as the kidneys, leading to what may appear to be a noncardiac cause of death.[23]

Incidence of Cardiac Complications Following Major Vascular Surgery

Abdominal Aortic Surgery

The incidence of major cardiac complications is dependent on patient characteristics, risk factors, symptomatology, and type of surgery. The incidence of major cardiac complications is displayed in Table 42.3.

Aortic surgery has the highest incidence of cardiac morbidity, which ranges from 1% in endovascular repair to more than 14% in open abdominal aortic aneurysm repair.[31] Generally, the events rates in randomized trials are half of those in registries. In addition, the cardiac event rate is higher in patients with larger aneurysms, in open versus endovascular repairs, in patients with known preoperative cardiac comorbidity, and in operations requiring higher aortic cross clamps (e.g., suprarenal vs. infrarenal).[29] Recently a comprehensive systematic review of all studies reporting survival after abdominal aortic aneurysm repair in the last 25 years, including altogether 65,557 patients, was published.[32] It showed that chronic obstructive pulmonary disease (COPD) requiring supplementary oxygen and/or ESRD/dialysis was associated with the highest risk of long-term mortality. Increased age, female gender, cardiac failure, renal impairment, COPD, cerebrovascular disease, PVD, diabetes, and IHD also significantly increased mortality.

Lower-Extremity Bypass

The cardiac event rate in lower extremity vascular surgery is dependent on symptoms, where patients with critical limb ischemia have more than 10% cardiac event rate that is three times that of patients with claudication only. One recent study reported that the presence of low-extremity arterial disease is associated with a twofold increase in the prevalence of CHF, and that CHF increases the complication rates for perioperative pneumonia, prolonged intubation, sepsis, return to the operating room, and mortality.[33]

Carotid Endarterectomy

Carotid surgery is associated with an approximately 2% to 3% rate of perioperative cardiac morbidity. The results from randomized trials are similar to those from registry data. The CREST trial[30] suggested a doubling in cardiac morbidity for surgery as opposed to a carotid stent procedure; however, this was offset by an increased stroke rate in patients having a stenting procedures.

PREOPERATIVE CARDIAC EVALUATION

Clinical Risk Assessment

Preoperative cardiac risk assessment is important, since it affects perioperative decision-making: (1) A high cardiac risk may influence both perioperative or long-term risk-benefit ratio of an elective vascular surgery and may therefore lead to its deferral. (2) Good cardiac risk assessment will enable preoperative optimization by using optimal medical therapy and in specific cases by preoperative coronary interventions to reduce perioperative and long-term cardiac risk. (3) Accurate preoperative knowledge of the patient's cardiac function and risk will allow better intraoperative and postoperative treatment and resource utilization, such as intraoperative monitoring and the need for postoperative intensive care unit (ICU) utilization. (4) Finally, understanding a patient's perioperative and long-term risks will allow the treating physician to provide the best possible consultation for optimal risk-benefit decision.

Cardiac Risk Indices

Numerous clinical risk indexes have been proposed. These include the seminal Goldman Cardiac Risk index,[34] the following Detsky's Risk index,[35] l'Italien,[36] and others. None of these has gained wide and lasting acceptance. In 1999, Lee and his colleagues constructed a simplified Revised Cardiac Risk Index (RCRI).[37] In a derivation cohort of 2893 consecutive patients, they identified six independent risk factors, including (1) a history of heart disease, (2) a history of CHF, (3) cerebral vascular disease, (4) insulin therapy, (5) chronic renal failure (defined as a preoperative creatinine of 177 mmol/L [2 g/L]), and (6) high-risk surgery (major vascular, thoracic, and upper abdominal). The validation cohort of 1422 patients showed that patients with none, one, two, and three of these factors had cardiac complications of 0.4%. 0.9%, 7%, and 11%, respectively. The overall accuracy ranged between 0.75 and 0.80, and was superior in their population to the other cardiac risk indices and the American Society of Anesthesiologists (ASA) classification. Since its publication, it has been widely used and adopted by the ACC/AHA guidelines committee for the preoperative stratification of patients perioperative cardiac risk.[38]

A recent meta-analysis of 24 studies including more than 750,000 patients showed that the RCRI discriminated moderately well in mixed surgical population with a sensitivity of 0.65 and

TABLE 42.4 Comparison of Two Cardiac Risk Indices

Revised Cardiac Risk Index[39]	Vascular Study Group of New England—CRI[28]
	Age 60-69 70-79 ≥80
	Smoking
Diabetes—insulin dependent	Diabetes—insulin dependent
CAD	CAD
CHF	CHF
Cerebrovascular disease	COPD
Creatinine ≥ 2 mg/mL	Creatinine ≥ 1.8 mg/mL
High-risk surgery	Abnormal cardiac stress test
	Chronic β-blockade

CAD, Coronary artery disease; *CHF*, congestive heart failure; *COPD*, chronic obstructive pulmonary disease; *CRI*, cardiac risk index.

specificity of 0.76.[39] When this meta-analysis was limited strictly of studies of vascular surgical populations, the RCRI had an aggregate sensitivity and specificity of 0.70 and 0.55, respectively. Therefore the RCRI alone is inadequate to reliably screen vascular surgery patients, and further information gained through laboratory testing were proposed to increase the accuracy of the preoperative cardiac investigation.

In 2010, the Vascular Study Group of New England (VSGNE; Table 42.4) developed a vascular surgery-specific model for the prediction of cardiac events following vascular surgery.[28] The authors studied 10,081 total patients who underwent various major arterial vascular procedures. They found that the RCRI predicted risk after carotid endarterectomy (CEA) reasonably well, but substantially underestimated the other procedures for low- and higher-risk patients. In a multivariate analysis of the VSGNE cohort, the independent predictors of adverse cardiac events that were found included: increasing age, smoking, insulin-dependent diabetes, CAD, congestive heart failure, abnormal cardiac stress test, long-term beta-blocker therapy, COPD, and elevated creatinine. The rates of cardiac complications for patients with zero to three, four, five, and greater than or equal to six Vascular Study Group of New England Cardiac Risk Index (VSG-CRI) risk factors were 3.1%, 5.0%, 6.8%, and 11.6% in the derivation cohort and 3.8%, 5.2%, 8.1%, and 10.1% in the validation cohort, respectively. The authors concluded that the VSG-CRI risk model more accurately predicted the actual risk of cardiac complications in vascular surgery patients than the RCRI.

Preoperative Laboratory Testing

Complete Blood Count

Preoperative anemia has been linked to increased cardiac morbidity.[40] Preoperative anemia is also linked to increased transfusion requirements that have been secondarily shown to increase cardiac morbidity. In particular, surgical patients chronically on beta-blockers do not tolerate acute anemia, which may lead to increased cardiac morbidity.[41]

Creatinine

The RCRI and the VSG-CRI show that chronic renal failure is independently associated with increased cardiac morbidity. However, creatinine is closely related to lean muscle mass. Thus many elderly patients with normal creatinine levels have chronic renal failure. The conversion of creatinine to glomerular filtration rate, through either the MDRD or Cockcroft-Gault equations that take account for patient age, may increase the sensitivity and specificity of the measurement.[42]

Blood Sugar

Diabetes is a common comorbidity in up to 50% of vascular surgical patients. Diabetes is strongly associated with most other risk factors, coronary disease, renal disease, and cerebral vascular disease. It is interesting to note that while insulin therapy was independently associated with cardiac morbidity in the derivation set of the RCRI, it was not in the validation set. Several observational trials have suggested that elevated levels of glycosylated hemoglobin (HbgA1c) are related to perioperative cardiovascular outcomes. Certainly HbA1c above 6.7% has been shown to be associated with increased morbidity after cardiac surgery[43] and PCIs. However, there is no good prospective data in vascular surgery to suggest that elevated HbA1c improves diagnostic accuracy over a history of diabetes alone. Tight glucose control in the perioperative period, the focus of several critical care randomized trials, failed to show any improvement in outcomes.[44]

Natriuretic Peptides

Increased preoperative levels of Plasma NT-proBNP and BNP have been associated with increased postoperative adverse outcomes. Rodseth and colleagues have completed a meta-analysis of six prospective observational trials of 850 vascular surgical patients.[45] Using a composite outcome of cardiovascular death and nonfatal MI, this meta-analysis showed that a BNP below 30 pg/mL has a low likelihood ratio of 0.11 for a postoperative cardiac event. For levels between 30 and 116 pg/mL, the positive likelihood ratio was 3.6. For levels above 116 pg/mL, the positive likelihood ratio was found to be 6.4.

Cardiac Troponin

The advent of high sensitivity troponin assays has led to the awareness that patients with cardiovascular anomalies have elevated troponin levels. Recently two studies have evaluated preoperative troponin levels as a prognostic indicator.[46,47] In a multicentered observational study, RCRI, BNP, and preoperative high sensitivity troponin elevation were associated with an increase in mortality. Preoperative troponin outperformed both RCRI and BNP as a prognostic indicator, suggesting that low-level troponin elevation existing before surgery represents preexisting cardiac abnormality or dysfunction.

C-Reactive Protein

Patients with systemic inflammation as evidenced by an elevated C-reactive protein (CRP; >5 mg/L) before surgery had higher major postoperative vascular event rates (60%) compared with a 32% rate in those with a baseline CRP of <5 mg/L (P = .004). Following multivariable analysis, elevated CRP correlated with adverse graft-related or cardiovascular events.[48] Vascular surgery patients with high preintervention values of both high sensitivity CRP and NT-BNP were 10.6 times more likely to experience major adverse cardiac events (MACE = stroke, MI, or death) than were patients with normal CRP and NT-BNP values.[49]

Rest Electrocardiogram

The resting EKG is mandatory tool for screening patients with suspected cardiac disease. ST-segment changes, either ST-elevation or depression, indicative of acute or recent ischemia, should be correlated with symptoms and compared with previous EKGs. Most other EKG changes represent chronic patterns of injury or conduction abnormalities. Pathologic Q-waves represent old MIs, and the more EKG leads with pathologic Q-waves, the wider the territory of infarcted myocardium. Tall R waves and wide QRS complexes with or without ST-T changes and inverted T-waves represent myocardial hypertrophy or dilation. EKG also detects and helps define abnormal rates and rhythms. These chronic pathologic ECG changes are associated with an increased risk for perioperative events.[37] In patients undergoing noncardiac surgery, Van Klei and colleagues found that while preoperative bundle branch blocks, Q waves, and ST-T changes were significant predictors of postoperative cardiac events, these EKG abnormalities did not remain predictive in a multivariable logistic regression that includes the six independent risk factors of the RCRI.[50] EKG changes are common in vascular surgery patients. A study in vascular surgery patients showed that 33% had pathologic Q-waves, 22% had baseline ST-segment changes, 38% had T-wave inversions, and 16% had voltage criteria for LVH. Patients with pathologic Q-waves or LVH are more likely to have perioperative ischemia or infarction[51]

Chest X-Ray

The chest x-ray is also an essential qualitative tool in screening cardiac patients, and its main value is to supplement the history and physical examination in identifying and assessing the severity of cardiac failure. Signs of cardiac failure on chest x-ray, recognizable by abnormal cardiac size and increased pulmonary vasculature, should trigger further examination to gain better understanding of the causes of cardiac dysfunction.

Echocardiography

Routine preoperative echocardiography is not recommended for routine screening in the absence of specific indications. Echocardiography is justified before major surgery to verify or evaluate significant valvular disease—in particular aortic stenosis. Severe aortic valvular stenosis is common in elderly patients and has been shown to correlate with perioperative complications and death. Severe aortic stenosis is also a relative contraindication for regional anesthesia. Significant mitral valvular disease predisposes the patient to congestive failure in the perioperative period, and its recognition before surgery may alter the approach to patients and their perioperative clinical management. Other important indications for preoperative echocardiography are to evaluate significantly reduced LV and/or right ventricular (RV) function, cardiomyopathies such as hypertrophic obstructive cardiomyopathy or dilated cardiomyopathy, and the presence and severity of pulmonary hypertension.[40] Resting echocardiography is not a good method to evaluate the severity of CAD and the risk of perioperative MI.

Ambulatory ST Segment Monitoring

Silent myocardial ischemia, defined as episodes of ST-segment depression on ambulatory EKG with ST-segment trend analysis that are not accompanied by chest pain, is a well-known phenomenon in elderly patients with CAD and has been shown to predict worse prognosis. Similarly, the detection of silent preoperative ischemia on preoperative Holter monitoring has been associated with increased postoperative morbidity. Raby and colleagues used Holter monitoring for 24 hours before vascular surgery and found that preoperative ischemia predicted postoperative cardiac complications with a sensitivity of 75% and specificity of 83%.[52] In contrast, however, meta-analysis of eight studies with more than 800 patients found a cumulative sensitivity of 52% and a specificity of 70%.[53] One major reason for this relative insensitivity is related to the fact that as many as 30% of vascular patients have preexisting ST-T changes, bundle branch block, or pacemakers, which make the interpretation of ST segments difficult. In addition, Holter monitoring uses only two, and rarely three modified EKG leads, and is susceptible to motion and other artifacts during normal daily activity.

Preoperative Investigation for Coronary Artery Disease

While coronary angiography is the gold standard for determining the existence and severity of CAD, its invasiveness and cost make it unsuitable for routine preoperative screening. Coronary angiography provides information on the major coronary anatomy but less so on the downstream minor vessels or on functional consequences of that anatomy. Nevertheless, Hertzer and colleagues performed routine coronary angiographies on all patients scheduled for major vascular surgery in the early 1980s, and patients with significant left main and triple vessel disease were treated with CABG.[51] In a retrospective analysis of 1522 of these patients, Ellis and Hertzer found that 81% of the patients with postoperative MI or cardiac death had at least one total coronary artery occlusion with collaterals compared with 29% in match-controlled patients without cardiac complications. In every other respect, patients with postoperative complications also had more severe CAD prior to surgery as compared with

the control group.[54] Based on this observation, it is possible to conclude that postoperative cardiac complications most likely occur in patients with preoperative long-standing severe CAD. This is also consistent with the previously described observations that postoperative MI and cardiac complications are the result of prolonged stress-induced ischemia in the presence of severe yet stable CAD. Therefore identifying patients with severe and often clinically silent coronary disease should be the focus of preoperative coronary investigations.

Noninvasive (Stress) Testing

The ACC/AHA guidelines suggest that patients who report limited functional capacity—that is, inability to climb at least two flights of stairs without chest pain or shortness of breath, the equivalent of four metabolic equivalents (METs)—are candidates for noninvasive cardiac stress testing before major noncardiac surgery.[40] Limited functional capacity is indeed a marker of higher perioperative risk. However, limited exercise tolerance may be due to numerous causes, including cardiac, pulmonary, orthopedic, neurologic, peripheral vascular, obesity, advanced age, or poor physical fitness. The noninvasive cardiac testing can help sort out the cardiac from other causes.

Exercise Stress Testing

The most common physiologic stress test for detecting myocardial ischemia uses a treadmill or cycle ergometer. Among its advantages, this test provides an estimate of functional capacity and hemodynamic response and detects myocardial ischemia through ST-segment changes. The accuracy of an exercise ECG varies widely among studies. A meta-analysis by Kertai and colleagues for the detection of myocardial ischemia with treadmill testing in vascular surgery patients showed a rather low sensitivity (74%) and specificity (69%).[54] The extremely low effort capacity in some vascular surgical patients limits the utility of this test and often leads to the use of pharmacologic stress testing. The most recent ACC/AHA guidelines (2014) designate only a Class IIb recommendation for preoperative cardiac exercise testing: (1) "In patients with elevated risk and unknown functional capacity, it may be reasonable to perform exercise testing to assess for functional capacity if it will change management (level of evidence: B)." (2) "In patients with elevated risk and poor (<4 METs) or unknown functional capacity, it may be reasonable to perform exercise testing with cardiac imaging to assess for myocardial (level of evidence: C)."[40]

Myocardial Perfusion Imaging

Single photon emission tomography (SPECT) with thallium-201 or technetium-based agents has been available since the 1970s and is still the most widely used noninvasive test. The test can be done with physiologic (treadmill/cycle ergometer) or pharmacologic (dipyridamole) stress. When the cardiac images acquired in a resting state are compared with the stressed state, the investigation is able to differentiate fixed from reversible filling defects in myocardial tracer uptake. These differences are suggestive of areas of infarct versus ischemia. A meta-analysis of 114 articles showed that the sensitivity and specificity of SPECT for detecting CAD with ≥50% stenosis are 88% and 61%, respectively[55] SPECT has a time-honored and important value in predicting long-term risk in patients with suspected CAD. A meta-analysis of 14 articles comprising more than 12,000 patients showed that negative and positive stress SPECT are associated with 0.6% and 7.4% annualized rate of hard events (nonfatal MI or death), respectively.[56] SPECT can also provide calculation of left ventricular ejection fraction during stress and rest. Transient left ventricular dilation and increased lung uptake during stress are additional parameters used to evaluate higher cardiac risk. A meta-analysis by Etchells and colleagues that investigated the prognostic value of semiquantitative dipyridamole myocardial perfusion imaging (MPI) for determining perioperative cardiac risk in patients undergoing vascular surgery found that reversible ischemia in less than 20% of the myocardial segments did not change the likelihood of perioperative complications, whereas greater extents of reversibility of myocardial perfusion defects were associated with increased risk of perioperative cardiac complications.[57] In contrast, however, a normal SPECT scan may occur in up to 15% of patients (false negative rate) with left main disease on account of balanced ischemia in multivessel disease. False positive tests are also common as a result of attenuation artifacts in obese patients, due to elevated diaphragm or breast artifacts.

Dobutamine Stress Echocardiography

This is a relatively low-cost, widely available test based on the assessment of increasing or new global or regional myocardial wall motion abnormalities during stress that are induced by increasing doses of dobutamine. Meta-analysis of 62 studies showed that the sensitivity of dobutamine stress echocardiography (DSE) is 83% in patients without prior MI but decreases to 74% when patients with prior MI were included. The specificity of DSE for detecting significant CAD is also approximately 80%. Long-term, a negative DSE test is associated with a 0.5% to 0.8% annualized risk of death or MI. A recent meta-analysis by Beattie and coworkers compared the value of DSE with MPI in predicting postoperative MI or in-hospital death.[58] This report included 25 studies (3373 patients) of mainly DSE, and 50 MPI studies with marked variability in results among the studies. The likelihood ratio for positive test was greater for DSE than for MPI, 4.1 versus 1.8, respectively, and the area under the ROC curve for the tests was 0.8 and 0.75, respectively. The recent ACC/AHA guidelines (2014) designate only a Class IIa recommendation for preoperative cardiac pharmacologic testing: "It is reasonable for patients who are at an elevated risk for noncardiac surgery and have poor functional capacity (<4 METs) to undergo noninvasive pharmacologic stress testing (either dobutamine stress echocardiogram [DSE] or pharmacologic stress MPI) if it will change management (level of evidence: B)."

Positron Emission Tomography

It is a newer, more expensive modality that is not widely available. Positron emission tomography (PET) includes both perfusion

(by Ru-82, N-13 ammonia or O-15 water) and functional metabolic (F-18 fluorodeoxyglucose [FDG]) imaging. Mismatch between perfusion and metabolism suggests viable ischemic area, while matched reduction in both blood flow and metabolism suggests an area of infarct. A meta-analysis of 19 studies showed that PET had a sensitivity of 92% and specificity of 85% for diagnosing significant CAD.[59]

Cardiac Magnetic Resonance Imaging

This is another new technology that may become the standard preoperative screening test in the future. Unlike SPECT and PET, cardiac MRI (CMR) has excellent spatial resolution and can provide accurate information on transient (ischemia) or fixed (infarction) hypoperfusion and scar tissue, even in small areas of the sub-endocardium. Myocardial perfusion is imaged during the first pass of a bolus of gadolinium during stress (achieved by adenosine or dipyridamole), rest and late gadolinium enhancement. In a meta-analysis, CMR was shown to have better sensitivity (89%) and specificity (76%) than SPECT for detecting significant CAD.[60] Contraindications to the CMR include patients with implanted metal, hypersensitivity to gadolinium, renal insufficiency, or sensitivity to the vasodilating agents, adenosine and dipyridamole, and patients with severe asthma or COPD.

Computed Tomography Coronary Angiography

This is an established noninvasive method for evaluating coronary anatomy as well as myocardial function. Studies showed that computed tomography coronary angiography (CTCA) has a high diagnostic accuracy for detecting the presence of coronary artery stenosis. A meta-analysis of 27 studies showed the sensitivity, specificity, PPV, and NPV were 97%, 91%, 93%, and 96% compared with conventional coronary angiography.[61] A more recent study showed that while the sensitivity of CTCA remains strong, the specificity declines to 66% in patients with coronary calcifications. One prospective study in 290 consecutive patients undergoing CTCA with a 64 row detector found that a higher RCRI, a high coronary artery calcium score (CACS >113), the presence of significant coronary artery stenosis, and multivessel CAD were significantly associated with postoperative cardiovascular events.[62] The promise of this technology will be realized with higher resolution scans.

Ahn and colleagues studied 239 patients who underwent CTCA before intermediate-risk noncardiac surgery, and noted that RCRI, CAC score, the presence of significant coronary artery stenosis (diameter stenosis ≥50%), and multivessel CAD were the strongest predictors of postoperative cardiac complications. Hwang and colleagues studied 844 patients who underwent coronary CTA for screening of CAD before noncardiac surgery.[63] The risk of perioperative major cardiac events was 14.0% in patients with significant CTA findings (>3 lesions), versus 2.2% in patients without significant CTA findings regardless of RCRI score. The sensitivity, specificity, positive, and negative predictive values were 76%, 73%, 8%, and 99%, respectively.

Preoperative Coronary Angiography and Revascularization

The detection of significant CAD by noninvasive testing is only the first step in investigating cardiac patients undergoing vascular surgery. The decision to proceed to coronary angiography based on the noninvasive testing depends on an assessment of whether the benefits of an intervention (prophylactic preoperative coronary revascularization) outweigh the risks associated with the intervention and delaying surgery.

Earlier retrospective studies suggested that preoperative coronary revascularization in vascular surgery patients was associated with better postoperative and long-term survival.[64,65] However, these studies suffered from the limitations of retrospective studies, among which was failure to include all patients who died or had serious complications from the preoperative revascularization and therefore could not undergo the expected vascular surgery. In 2004, McFalls and coworkers published the randomized Coronary Artery Prophylaxis (CARP)[3] trial that included 510 candidates for major vascular surgery.[66] After screening for cardiac risk, patients who had coronary angiography that showed one or more major coronary vessels with ≥70% stenosis were randomized to either coronary revascularization (by PCI or CABG) before vascular surgery or no coronary intervention prior to surgery. Patients were followed for a mean period of 2.5 years after surgery. The study showed no difference in survival between the two groups. However, this trial had two important limitations: (1) The screening process did not rigorously follow the ACC/AHA guidelines, so that only a minority of the patients had evidence of severe ischemia on noninvasive testing and the study was underpowered to assess this key aspect. (2) Patients with left main CAD and patients with severely reduced LVEF were excluded. Nevertheless, this trial had a strong impact worldwide on perioperative patient management by shifting the paradigm toward less coronary investigations and interventions before major noncardiac and vascular surgery. This trial coincided with the COURAGE trial,[67] which showed that PCI does not confer better survival than optimal medical treatment in patients with stable CAD, creating evidence that prophylactic re-vascularization by PCI was unwarranted in vascular surgery. Importantly however, subsequent publications from the CARP trial and registry reported that the following: (1) Patients who had CABG with more complete coronary revascularization had better survival than those revascularized by PCI.[68] (2) Patients with left main disease, excluded from the trial, had markedly better survival with coronary re-vascularization than without it.[69] (3) In a subset of 109 patients with ischemia on preoperative MPI, patients randomized to preoperative coronary revascularization had significantly better long-term survival free of MI than patients without revascularization, particularly if ischemia was in the anterior wall.[67]

Monaco and associates[3] randomized 208 consecutive patients with RCRI ≥ 2 scheduled for elective abdominal aortic surgery to either a "selective strategy" with coronary angiography only if their stress test was positive or a "systematic strategy" with routine

coronary angiography. The systematic strategy discovered 50% more patients with significant CAD than the selective strategy, had more subsequent coronary revascularizations (58% vs. 40%, respectively), and was associated with significantly better long-term survival and freedom from major adverse cardiac events. While this small study supports the concept of prophylactic preoperative coronary angiography and revascularization among patients at high clinical risk (RCRI ≥ 2), the routine use of coronary angiography without prior noninvasive screening is not established practice and merits further investigation. Another large sample (16,478 patients) representing real-world practice suggested that patients with a recent MI benefit from preoperative revascularization and that CABG improves outcomes more than coronary stenting, especially when surgery is deemed necessary within 1 month of the revascularization.[70] In contrast, another study that included 1104 vascular surgery patients confirmed the significance of ischemic heart disease (IHD) for postoperative survival of vascular surgery patients and that CR is associated with lower IHD-related death rates, yet CR in that study failed to provide an overall survival benefit because of increased rate of cardiovascular mortality unrelated to IHD.[71]

The latest ACC/AHA update "On Evaluation and Care for Non-Cardiac Surgery" (2014)[40] states the following:

CLASS I

Revascularization before noncardiac surgery is recommended in circumstances in which revascularization is indicated according to existing clinical practice guidelines (CPGs). (Level of Evidence: C)

CLASS III: NO BENEFIT

It is not recommended that routine coronary revascularization be performed before noncardiac surgery exclusively to reduce perioperative cardiac events. (Level of Evidence: B)

MEDICAL PROPHYLAXIS

Beta Blockade

Up to 25% of patients assessed for vascular surgery are taking beta-blockers. Beta blockade is indicated for the treatment of various comorbidities, including hypertension, CAD (both stable angina, and after acute MI), and congestive heart failure. Studies on stable angina pectoris show that beta-blockers provide excellent symptomatic improvement. Patients who are maintained on beta-blockers after MI show moderately improved long-term survival. In patients with congestive failure, beta-blockers also improve long-term survival. Nevertheless, there is a growing body of evidence showing that chronic beta blockade may also be harmful. A meta-analysis comparing beta blockade to other forms of antihypertensive therapies such as ASA and carotid endarterectomy (ACE) inhibitors and calcium channel blockers suggested that beta-blockers are associated with an increase in cerebral vascular accidents.[72] A recent large prospective observational trial showed that although chronic beta blockade in patients with prior MI is associated with improved long-term survival,[73] patients with CAD but without MI do not benefit after 4 years of follow-up, and patients with no CAD have an 18% increase in morbidity after 4 years compared with all other forms of therapy.

Postoperative MI is preceded by prolonged ST-depression type ischemia, and the ischemia itself is associated with a significant increase in heart rate. These findings gave impetus to the theory that perioperative beta blockade would reduce perioperative MI, leading to numerous clinical trials. In a high-quality meta-analysis of 33 trials involving more 12,000 patients, Bangalore and colleagues demonstrated that perioperative beta blockade was indeed associated with a 35% (95% CI 54% to 79%) reduction of nonfatal MI.[74] This was achieved, however, at the expense of a doubling in the stroke rate with no significant effect on all-cause mortality. The largest trial (POISE) in that meta-analysis showed that the beneficial effect on nonfatal MI was at the expense of both an increase in stroke and a 30% increase in all-cause mortality.[75] The POISE trial also showed that mortality was significantly higher in patients receiving beta-blockade if they developed serious infection or sepsis postoperatively. Lindenaurer, in an analysis of the Premier Prospective database, showed that postoperative mortality was reduced only in patients with RCRI of ≥2, but in patients with no risk factors mortality was increased by 30%.[74] A recent Cochrane meta-analysis also found no clear evidence that prophylactic perioperative beta-blockade reduces postoperative cardiac morbidity.[76]

On the basis of no improvement or even an increase in mortality and a doubling in postoperative strokes, the recommendation for prophylactic perioperative beta-blockade that was strongly advocated a decade ago (based on two relatively small, high-impact, yet questionable studies[77,78]) was stopped. Two independent investigations showed that major blood loss (or acute anemia) is associated with increased morbidity in beta-blocked patients.[43,79] Hence the increased mortality and stroke rate caused by prophylactic beta-blockade, despite the decrease in nonfatal MI, is most likely related to the potential detrimental effects of beta-blockade—that is, slowing heart rate and decreasing myocardial contractility in patients with postoperative anemia or infection who are at the greatest need for tachycardia and high cardiac output after surgery.

Statins

A recent meta-analysis in patients at risk of cardiovascular events, combining 27 prospective trials and over 174,000 patients, showed that for each 1 mmol decrease in LDL, statins reduced the long-term relative risk of a cardiovascular event by 24% (95% CI 21 to 27).[80] This reduction was seen across all risk populations, and reduced the need for revascularization, incidence of stroke, and other vascular events. Furthermore, these benefits far exceeded the risks of elevated liver enzymes, myopathy, or rhabdomyolysis. This study suggests that all vascular patients who have atherosclerosis should receive statins, if

tolerated, for management of their cardiovascular disease irrespective of the need for surgery. The Vascular Quality Initiative (VQI), including more than 14,000 patients who underwent major vascular surgery, found no association between the rate of in-hospital MI/death and the use of antiplatelet agents or statins.[81] Antiplatelet agents and statin medications appear to be more useful in reducing late mortality than early postoperative MI/death in VQI. However, they were not harmful, so their long-term benefit argues for continued use. Therefore regardless of the procedure or stress testing results, patients with symptomatic atherosclerosis (e.g., PAD, cerebrovascular disease) should be on antiplatelet and statin therapy according to the ACC/AHA guidelines.[81] Although no RCT showed improved in-hospital morbidity or mortality with statins, a recent meta-analysis of statin use in vascular surgery patients showed a significant risk reduction in postoperative cardiac morbidity as well as death.[82] In addition, a large institutional study including nearly 166 patients and a large registry study demonstrated a significant reduction in perioperative stroke and MI rates among patient undergoing CEA on statins compared to nonusers[83,84] Further, compliance with both antiplatelet therapy and statins in vascular surgical patients was associated with significantly improved long-term survival.[85] Currently, there is no clear prospective evidence to indicate how soon statins must be started preoperatively, if not administered chronically, to achieve a reduction in perioperative adverse events.

Aspirin

While the primary prevention of cardiovascular events by aspirin is still controversial,[86] the utility of aspirin as a secondary prevention of cardiovascular events is well established.[87] The benefits of aspirin in terms of reduction of re-infarction, stroke, and ischemia far outweigh the increased risks of bleeding in nonsurgical patients. The Anti-Thrombotic Trialist's Collaboration conducted a meta-analysis of 287 trials in more than 130,000 high-risk patients (with acute or previous vascular disease or some other predisposing condition) compared with a control group. MI was reduced by one-third, nonfatal stroke by one quarter, and vascular death by one-sixth. The absolute reduction in cardiovascular morbidity in high risk patients was 22 per 1000 patients after 2 years of therapy.[88] These results confirm that patients at risk of any recurrent vascular morbidity should be treated with ASA irrespective of their need of surgery.

In the perioperative setting, the large-scale POISE-2 RCT that included 10,010 noncardiac surgery patients (5% of them had vascular surgery) showed that aspirin given before surgery and throughout the early postsurgical period had no effect on composite death or nonfatal MI but increased the risk of major bleeding.[88] Among vascular surgery patients, the ACE (Aspirin in Carotid Endarterectomy) randomized trial compared four doses of aspirin in patients having elective CEA [89] and found that the risk of stroke, MI, and death within 30 days and 3 months of endarterectomy is lower for patients taking 81 mg or 325 mg acetylsalicylic acid daily than for those taking higher doses of aspirin. Unfortunately, the ACE trial did not have a placebo control. Another prospective two-arm comparative study in patients undergoing CEA showed that the overall cardiac and neurologic complication rate was lower in the aspirin group compared with the group not on aspirin (5.2% vs. 17.6%, respectively), with no significant increase of postoperative bleeding necessitating revision.[90]

Despite the clear advantages of secondary prevention, the effectiveness of low dose ASA, and grade 1A evidence of a low incidence of excess bleeding with a low dose ASA, this drug continues to be withdrawn prior to many nonvascular operations. Two meta-analyses of retrospective studies[91,92] demonstrated that aspirin withdrawal was associated with a threefold increased risk of a major adverse cardiovascular events on an average of 7 days after cessation. The major reason for withdrawal was an upcoming elective surgical procedure. The authors concluded that ASA should be maintained in all patients except for those who had the highest risk of bleeding. Unfortunately, there are no prospective studies assessing withdrawal of ASA in any surgical population.

Dual Antiplatelet Therapy After Coronary Stenting

More than 1 million PCI procedures are conducted annually in North America[93] alone, and more than 5% of these patients will undergo elective surgery within 1 year.[94] Patients who had recent revascularization using PCI and stents are treated initially with dual antiplatelet therapy for a variable period of time, aspirin, and a P2Y12 platelet receptor–inhibitor, usually clopidogrel, to prevent stent thrombosis. These patients require special consideration. Kaluza[95] drew attention to the increased mortality in patients having elective surgical procedures shortly after PCI. Mortality was related either to excessive bleeding due to continuation of the dual-antiplatelet therapy through surgery or to acute stent thrombosis and type-1 MI after the abrupt discontinuation of the antiplatelet medications. This case series was then quickly followed by a myriad of other case series showing increased morbidity when procedures were carried out within 90 days of PCI.[96,97] A retrospective analysis of 8116 stent patients from large a comprehensive stent registry linked to a Medicare administrative database confirmed that surgical procedures conducted within 45 days of a PCI are associated with high mortality.[98] However, after 45 days the risk was similar to patients with a RCRI of equal to or greater than 2% for both patients with bare metal or drug eluting stents. After 180 days, the risk of major cardiac morbidity is approximately 1%, which is similar to the morbidity of patients after PCI who do not undergo surgery. A recent retrospective study matched 20,590 surgical patients to 41,180 nonsurgical patients who underwent PCI in the Veterans Affairs (VA) hospital between the years 2000 and 2010.[99] During the 30-day interval following noncardiac surgery, the surgical cohort had higher rates of the composite cardiac endpoint (3.1% vs. 1.9%). The incremental risk of noncardiac surgery adjusted for surgical characteristics ranged from 3.5% immediately following stent implantation to 1% at 6 months, after which it remained

TABLE 42.5 Focused Update on Duration of Dual Antiplatelet Therapy

COR	LOE	Recommendations
I	B-NR	Elective noncardiac surgery should be delayed 30 days after BMS implantation and optimally 6 months after DES implantation (101-103, 143-146).
I	C-EO	In patients treated with DAPT after coronary stent implantation who must undergo surgical procedures that mandate the discontinuation of $P2Y_{12}$ inhibitor therapy, it is recommended that aspirin be continued if possible and the $P2Y_{12}$ platelet receptor inhibitor be restarted as soon as possible after surgery.
IIa	C-EO	When noncardiac surgery is required in patients currently taking a $P2Y_{12}$ inhibitor, a consensus decision among treating clinicians as to the relative risks of surgery and discontinuation or continuation of antiplatelet therapy can be useful.
IIb	C-EO	Elective noncardiac surgery after DES implantation in patients for whom $P2Y_{12}$ inhibitor therapy will need to be discontinued may be considered after 3 months if the risk of further delay of surgery is greater than the expected risks of stent thrombosis.
III: Harm	B-NR	Elective noncardiac surgery should not be performed within 30 days after BMS implantation or within 3 months after DES implantation in patients in whom DAPT will need to be discontinued perioperatively (101-103, 143-146).

stable out to 24 months. In addition, the authors observed that approximately 50% of the risk of adverse cardiac events was due to underlying cardiac risk factors and approximately 50% was due to surgical factors. After matching for cardiac risk factors, no significant difference was found in cumulative incidence of adverse cardiac event rates between the surgical population and the nonsurgical matches over the 24 months following stenting, although there was a higher mortality in the surgical population from noncardiac causes. There was also no significant difference in postoperative cardiac complications between patients with bare-metal stents and drug-eluting stents.

In patients undergoing CEA (the VQI)[100] patients on dual therapy were more likely to have multiple comorbidities, including CAD, congestive heart failure, and diabetes, and had increased rate of reoperation for bleeding but experienced a reduced rate of TIAs, stroke, and stroke/death.

See Table 42.5 for the most recent (2016) ACC/AHA guidelines for dual antiplatelet therapy in patients undergoing noncardiac surgery.[101]

TREATMENT

In treating patients at risk for postoperative cardiac complications, it is most important to recognize that the majority of postoperative cardiac complications are silent or begin as silent. High-risk vascular surgery patients have a high rate of silent ischemia, silent myocardial injury, and infarction, all of which are associated with higher in-hospital and long-term mortality.[102] Silent and overt cardiac complications are strongly linked to noncardiac complications, and both types precipitate each other.[103] For instance, perioperative hypotension,[104] systemic infection, serious bleeding, and anemia were all linked to postoperative cardiac morbidity and mortality. A high index of suspicion for silent cardiac complication is of greatest importance when dealing with cardiac patients undergoing major vascular surgery. If a patient is suspected of having postoperative ischemia or cardiac failure, the first diagnostic step would be to perform a 12-lead EKG. The presence of *ST-segment elevation ischemia or MI* is a medical emergency,[105] especially after surgery. A cardiologist must be consulted, and the possibility of immediate reperfusion with percutaneous transluminal coronary angioplasty with stenting should be considered. A special subset of patients who are prone to develop acute postoperative coronary thrombosis are those with fresh coronary stents in whom the antiplatelet therapy was stopped before surgery.

The more common situation is the occurrence of *ST-segment depression type ischemia or MI.* In these patients, diagnostic effort to find the potential causes for stress-induced, supply-demand imbalance type ischemia should be started and medical therapy should be implemented to relieve ischemia.[106] The importance of preventing even modest increases in heart rate cannot be overemphasized. The treatment of tachycardia and hypertension can be achieved with beta-blockers or calcium channel blockers or pain-killing medications. In contrast, treatment of tachycardia associated with hypotension is particularly challenging and requires an understanding of the patient's baseline and postoperative myocardial, valvular, and coronary physiology. These patients will require additional diagnostic tests, invasive monitoring, bedside echocardiography, and other imaging devices. Frequently, vasopressors to maintain blood pressure and beta-blockers to slow heart rate while fine tuning blood volume, postoperative pain, and respiratory function are necessary (Fig. 42.3). Management of patients with ischemia in the face of hypotension and hypoperfusion is often challenging, and the assistance of an intensive care unit and consultation with anesthesiologists, intensivists, and cardiologists is warranted.

Perioperative respiratory complications remain a major cause of morbidity and mortality in surgical patients.[1-10] Quality and safety of patient care relies on the anticipation and prevention of respiratory complications, as well as timely and effective management when complications do occur.[11-13] Broadly defined, perioperative respiratory complications include any conditions that affect the respiratory tract and adversely influence the course of a patient after surgery.[5] Common complications (Box 43.1) may include atelectasis, pneumonia, upper airway obstruction, acute respiratory distress syndrome (ARDS), and respiratory failure, which is often defined as mechanical ventilator dependence 48 hours after surgery.[5,10,14] This chapter will review approaches to preoperative risk stratification, perioperative risk reduction, and management of respiratory complications.

PREOPERATIVE RISK STRATIFICATION

Preoperative risk stratification for respiratory complications involves assessment of patient-related risk factors, procedure-related risk factors, and laboratory test risk factors (Table 43.1).[15-17] Pulmonary risk indices have been developed to assist with preoperative risk assessment and patient optimization prior to surgery.[7-10]

Patient-Related Risk Factors

A comprehensive systematic review conducted by Smetana et al. found good evidence to support advanced age, functional dependence, American Society of Anesthesiologists (ASA) Class II or greater, chronic obstructive pulmonary disease (COPD), and congestive heart failure (CHF) as risk factors for postoperative pulmonary complications in patients undergoing noncardiothoracic surgery.[8] Early studies identified advanced age as a potential risk factor for pulmonary complications after surgery, but they did not adjust for comorbid conditions and overall health of patients. The precise influence of age has not been clearly established, but the review by Smetana et al. adjusted for comorbidities and reported an independent incremental risk of postoperative pulmonary complications with increasing age.[8,18,19] Prospective studies have also identified advanced age as a risk factor, but age alone should not be considered a contraindication for a patient who is otherwise suitable for an operation.[7,9] Functional status and comorbidities, often assessed with the ASA classification system, are an important determinant of preoperative pulmonary risk. Several studies have shown that ASA class II or higher is associated with postoperative pulmonary complications.[2,8] Comorbidities of particular interest include COPD and CHF, as these may predict postoperative respiratory complications and associated mortality.[8,20-24] For patients undergoing endovascular aortic aneurysm repair (EVAR), preoperative COPD is a risk factor for mortality with hazard ratio 1.9 (95% CI 1.2-3.1).[25] Patients with COPD and CHF have a higher risk of mortality after below knee amputation (BKA) for critical limb ischemia when compared to patients without these comorbidities.[26] While comorbid disease should generally not preclude surgical intervention, patients should be carefully advised regarding risks.[27]

BOX 43.1 Common Postoperative Respiratory Complications

- Acute lung injury
- ARDS
- Aspiration/aspiration pneumonitis
- Atelectasis
- Bronchitis and tracheobronchitis
- Bronchospasm
- Exacerbation of chronic disease (e.g., chronic obstructive pulmonary disease)
- Healthcare-associated pneumonia (including hospital-acquired and ventilator-associated pneumonia)
- Hypoventilation (from analgesia or residual neuromuscular blockade)
- Pleural effusion
- Pneumothorax
- Pulmonary edema
- Pulmonary embolism
- Respiratory failure (ventilator dependence 48 hours after surgery)
- TRALI
- Upper airway obstruction

ARDS, Acute respiratory distress syndrome; *TRALI*, transfusion-related acute lung injury.

TABLE 43.1 Patient-Related, Procedure-Related, and Laboratory Test Risk Factors for Postoperative Pulmonary Complications

Patient-Related Risk Factors	Procedure-Related Risk Factors
• Advanced age • Functional dependence • ASA Class II or greater • COPD • CHF • Smoking/cigarette use • Poorly controlled asthma • Upper respiratory infection (during previous month) • OSA	• Surgery type (endovascular vs. open) • Surgical site • Duration of surgery 2 hours or longer • Upper abdominal or intrathoracic surgery • Type of anesthesia • Endotracheal intubation • Long-acting neuromuscular blockade • Perioperative blood transfusion • Emergency surgery

Laboratory Test Risk Factors

- Oxyhemoglobin saturation by pulse oximetry (SpO_2 < 90%)
- Albumin <35 g/L
- Blood urea nitrogen >21 mg/dL
- Anemia (preoperative hemoglobin ≤10 g/dL)

ASA, American Society of Anesthesiologists; *CHF*, Congestive Heart Failure; *COPD*, Chronic Obstructive Pulmonary Disease; *OSA*, Obstructive Sleep Apnea.

Current smoking increases the risk of postoperative pulmonary complications and a dose-dependent increase in pulmonary complications is based on pack-year exposure to cigarettes.[28,29] Some early studies suggested that recent smoking cessation (less than 4-8 weeks prior to surgery) actually *increased* the risk of postoperative pulmonary complications purportedly through increased sputum production.[29,30] However, a more recent meta-analysis determined that quitting smoking within 8 weeks of surgery was not associated with either an increase or decrease in overall postoperative complications or pulmonary complications.[31] Surgeons should encourage their patients to quit smoking as early as feasible and whenever possible in the preoperative setting.[32]

Well-controlled asthma is not considered a risk factor for postoperative pulmonary complications, although there is fair evidence that poorly controlled asthma is a risk factor.[8] While severe perioperative bronchospasm and other complications may occur in patients with asthma, the incidence is quite low.[33] The risk of these complications depends on the patient's airway hype-responsiveness, airflow obstruction, and history of prior surgeries which may predispose to latex and/or anesthetic agent sensitivity.[34] Patients with asthma should be maintained on their antiinflammatory and vasodilatory agents in the perioperative period and may benefit from a short course of oral corticosteroids to improve lung function preoperatively.

Obesity is associated with physiologic changes that affect pulmonary gas exchange including reduced lung volumes, ventilation-perfusion mismatch, and relative hypoxemia.[35-37] Upper airway obstruction and sleep-disordered breathing may also be common in this population.[37] However, whether obesity itself is a risk factor for postoperative pulmonary complications is debatable.[8,38-40] Thoughtful management is necessary to ensure the best outcomes for obese patients, which may include modified approaches to anesthesia and perioperative noninvasive ventilation or continuous positive airway pressure (CPAP).[37]

Obstructive sleep apnea (OSA) has been reported to be an independent risk factor for postoperative pulmonary complications.[41-43] A study using the National Inpatient Sample found significantly higher rates of postoperative pulmonary complications, including aspiration pneumonia and ARDS, among general surgery and orthopedic surgery patients with OSA compared to matched controls.[41] A recent meta-analysis concluded that patients with OSA have an increased risk of postoperative respiratory failure (OR 2.42 [95% CI 1.53-3.84]).[42]

Other patient-related risk factors may include recent acute upper respiratory infection (within 1 month), alcohol use, weight loss (>10% in previous 6 months), impaired sensorium, and abnormal findings on chest examination.[7,8,14,44] Careful assessment and optimization of modifiable risk factors in the preoperative setting is critical to ensure best outcomes.

Procedure-Related Risk Factors

Procedure-related risk factors include type of surgery, surgical site, duration of surgery, anesthesia considerations, perioperative blood transfusion, and emergency surgery.[7-9] Risk factors related to the procedure are perhaps more important than patient-related risk factors, but procedure risks are generally less modifiable.[1]

Good evidence suggests that vascular surgery, especially aortic surgery, confers a higher risk of postoperative respiratory complications than other types of surgery.[1,8] Open aortic surgeries were associated with the highest risk of pulmonary complications

in one review OR 6.90 (95% CI 2.74-17.36). A cohort study compared postoperative pulmonary complication rates for open versus endovascular repair of abdominal aortic aneurysms.[45] The multivariate odds ratio for pulmonary complications after endovascular repair was 0.14 (95% CI 0.04-0.47) compared with open surgery. More generally, surgical sites near the diaphragm such as upper abdominal and intrathoracic surgery have higher risk for postoperative pulmonary complications, likely through direct impairment of diaphragmatic and respiratory function.[7,46-48]

Operative duration 2 hours or longer is associated with higher risk of postoperative pulmonary complications.[7,8,49] The review by Smetana et al. identified five different studies evaluating extended duration of surgery, ranging from 2.5 to 4 hours, and determined the pooled odds ratio for respiratory complications was 2.26 (95% CI 1.47-3.47). This finding is in contrast with known risk factors for postoperative cardiac complications, where duration of surgery is not thought to increase the risk of cardiac complications.[50] When a less ambitious or briefer procedure is an option, it is prudent to avoid longer operative duration.

Select anesthesia considerations, including type of anesthesia and neuromuscular blockade, may confer increased risk of postoperative pulmonary complications.[51] Although these data are not definitive, neuraxial anesthesia, including spinal and epidural anesthesia, has been associated with fewer postoperative respiratory complications than general anesthesia alone.[52-57] Furthermore, postoperative pain relief may be superior with epidural analgesia compared to parenteral opioids.[57] A recent Cochrane review examined the use of neuraxial anesthesia for lower-limb revascularization procedures.[58] Postoperative pneumonia was lower with neuraxial anesthesia compared to general anesthesia, but no mortality benefit was identified. An older trial from our institution randomized patients undergoing abdominal aortic surgery to one of four treatment groups: thoracic epidural anesthesia combined with light general anesthesia or general anesthesia alone and either intravenous or epidural patient-controlled analgesia postoperatively.[59] Epidural patient-controlled analgesia correlated with a significantly shorter time to extubation, but otherwise, there were no significant differences in outcomes among the four groups, including postoperative pain scores. When possible, short or intermediate-acting neuromuscular blockade is preferred to limit residual neuromuscular blockade, which may perpetuate hypoxia through functional impairment of the diaphragm and muscles of the pharynx.[60]

Other procedure-related risk factors, including emergency surgery and perioperative blood transfusion, may also confer higher risk of pulmonary complications.[7-9] Emergency surgery appears to confer a modestly increased risk, OR 2.2 (95% CI 1.0-4.5).[7] Preoperative transfusion of 4 or more units of packed red blood cells, or intraoperative transfusion, appears to confer higher risk of postoperative pneumonia.[7,8] Although in many circumstances these factors may not be modifiable, it is important to recognize these risks and maintain a high index of suspicion to ensure timely diagnosis and management of postoperative complications.

Laboratory Test Risk Factors

Select laboratory tests or adjunct studies are not a substitute for appropriate clinical evaluation. However, some studies may be of use during the preoperative evaluation to assist with risk assessment for pulmonary complications. Preoperative oxyhemoglobin saturation by pulse oximetry (SpO_2) was found to be one of the strongest independent predictors of postoperative pulmonary complications in one large cohort of surgical patients.[7] Patients with a SpO_2 less than 90% (supine position on room air) had an odds ratio of 10.7 (95% CI 4.1-28.1) for pulmonary complications compared to patients with a preoperative SpO_2 greater than or equal to 96%. This study also identified preoperative anemia (hemoglobin ≤ 10 g/dL) as an independent predictor of pulmonary complications.[7] A systematic review found good evidence to support preoperative albumin level less than 35 g/L as a risk factor for pulmonary complications and at least fair evidence to support blood urea nitrogen (BUN) level greater than 21 mg per deciliter as a risk factor.[1,8]

Adjunct studies, including pulmonary function tests (PFTs), arterial blood gas measurements (ABG), and chest radiography, should not be considered routine preoperative studies. However, in specific circumstances, these studies may be helpful to assess risk in the preoperative setting. Among patients undergoing procedures other than pulmonary resection, there is considerable debate concerning the role of PFTs in preoperative risk stratification.[61-65] PFTs provide an estimate of forced expiratory volume (FEV_1) and forced vital capacity (FVC). Two scenarios may justify the use of preoperative PFTs in vascular surgery: (1) identification of patients for whom the risk of an open vascular surgical procedure may outweigh the benefit or for whom a percutaneous or endoluminal approach would be better tolerated, and (2) identification of patients at higher risk who would benefit from aggressive perioperative management. For example, PFTs may be useful in patients with COPD or asthma when clinical examination alone is unable to determine whether the patient is fully optimized for surgery. In some cases, these studies may change management by highlighting the need for perioperative corticosteroids or other treatments. However, most patients identified by PFTs as high risk are identified equally well by a careful history and physical examination.[22]

Similarly, ABG and chest radiography are not necessary for preoperative evaluation and should not be ordered routinely. No data suggest that hypercapnia identifies additional high-risk patients beyond those who would already be identified by clinical criteria. Chest radiographs are commonly ordered for preoperative evaluation, but these studies may add little to the clinical evaluation of healthy patients and very rarely influence preoperative management.[66] An older review included over 14,000 surgical patients and found abnormal chest radiographs in 10% of patients; however, only 1.3% of studies revealed an unexpected finding, and only 0.1% of studies influenced perioperative management.[67] Preoperative chest radiography should be considered in patients with known cardiopulmonary disease, especially among patients with a recent change in disease status. Patients older than 50 years who are current smokers should also be evaluated with preoperative chest radiography to evaluate for malignancy and pulmonary disease.[8]

Pulmonary Risk Indices

A thorough history and physical exam forms the basis of preoperative risk assessment. Pulmonary risk indices have been developed to assist in the evaluation and stratification of patient risk.[7-10] Canet et al. reported the development of a predictive index for postoperative pulmonary complications based on a prospective multicenter observational cohort study in a broad population of surgical patients.[7] This study identified independent risk factors for postoperative pulmonary complications including low preoperative SpO_2, acute respiratory infection during the previous month, age, preoperative anemia, upper abdominal or intrathoracic surgery, surgical duration of at least 2 hours, and emergency surgery. Using these seven predictors and assigning point values for each, the authors designed an index to predict postoperative pulmonary complications (Table 43.2). Arozullah et al. developed an index to predict the risk of postoperative pneumonia using the Veterans Administration database.[9] Risk factors were assigned points based on their strength in a multivariate analysis. Procedure-related risk factors dominate the index, but many modifiable risk factors are also identified including functional status, cigarette use, and alcohol use. A more recent risk calculator for postoperative respiratory failure was developed using the prospective National Surgical Quality Improvement Program (NSQIP) data set.[10] On multivariate analysis, five preoperative predictors were identified: type of surgery, emergency case, dependent functional status, preoperative sepsis, and higher ASA class. Many of the factors included in these indices are not modifiable or amenable to risk reduction strategies. However, these tools may best serve to predict risk and inform decisions about the magnitude of the planned procedure, timing of surgery, and candidacy for surgery.

TABLE 43.2 Prediction of Postoperative Pulmonary Complications

Preoperative Predictor	Odds Ratio (95% CI)	Point Value
Age (years)		
≤50	1	—
51-80	1.4 (0.6-3.3)	3
>80	5.1 (1.9-13.3)	16
Preoperative SpO_2 (%)		
≥96	1	—
91-95	2.2 (1.2-4.2)	8
≤90	10.7 (4.1-28.1)	24
Respiratory infection in last month	5.5 (2.6-11.5)	17
Preoperative anemia (≤10 g/dL)	3.0 (1.4-6.5)	11
Surgical Incision		
Peripheral	1	—
Upper abdominal	4.4 (2.3-8.5)	15
Intrathoracic	11.4 (4.9-26.0)	24
Duration of Surgery (hours)		
≤2	1	—
>2-3	4.9 (2.4-10.1)	16
>3	9.7 (4.7-19.9)	23
Emergency surgery	2.2 (1.0-4.5)	8

Class	*Point Total*	*Predicted Probability of Postoperative Pulmonary Complication (%)*
Low risk	<26	1.6 (0.6-2.6)
Intermediate risk	26-44	13.3 (7.6-19.0)
High risk	>45	42.1 (29.3-54.9)

CI, Confidence interval; *SpO_2*, oxyhemoglobin saturation by pulse oximetry breathing room air in supine position.
Modified from Canet J, Gallart L, Gomar C, et al. Prediction of postoperative pulmonary complications in a population-based surgical cohort. *Anesthesiology*. 2010;113:1338–1350.

PERIOPERATIVE RISK REDUCTION

Some risk factors for perioperative pulmonary complications are modifiable and risk may be reduced with appropriate attention to detail in the preoperative setting, the operating room, and the postoperative setting.

Preoperative Risk Reduction

Patient optimization in the preoperative setting may help prevent respiratory complications associated with surgery. Surgeons should encourage their patients to quit smoking as early as feasible before surgery but whenever possible in the preoperative setting.[32] Patients with comorbid pulmonary conditions, including COPD and asthma, should generally be optimized for elective surgery in the same manner they would be optimized in nonoperative settings.[33,34,68-71] Clinicians should not employ treatments specifically for upcoming surgery unless these treatments are otherwise indicated. Systemic preoperative corticosteroids may be appropriate in patients for whom peak airflow is not at the optimal baseline despite appropriate treatment with other therapies.[33,72] Corticosteroids may be safely used preoperatively without undue risk of infection or wound complications.[73,74] There is no role for routine antibiotics patients for respiratory prophylaxis prior to surgery. However, when a recent change in the chest radiograph or the amount or character of sputum indicates a respiratory tract infection, the patient should be treated for infection, and surgery should be delayed when possible.

Multimodality approaches for patients with COPD, including chest physical therapy, bronchodilators, antibiotics, and corticosteroids, may reduce the risk of postoperative pulmonary complications.[1,22] Inhaled therapies (including anticholinergics, beta-agonists, and corticosteroids) are standard treatment for

COPD and often used in combination depending on patient symptoms.[75,76] Pulmonary rehabilitation may also be appropriate in the preoperative setting for patients with symptomatic disease and FEV_1 less than 50% of predicted value.[69]

There is some evidence that preoperative inspiratory muscle training may be of general benefit to patients undergoing elective cardiac or major abdominal procedures. A recent Cochrane review determined that preoperative inspiratory muscle training was associated with a reduction in postoperative atelectasis, pneumonia, and duration of hospital stay.[77] The preoperative setting may also be the appropriate place to begin patient education regarding the importance of postoperative lung expansion maneuvers.[6]

Patients with asthma should be evaluated preoperatively with a thorough clinical history including medication use, examination, and review of symptoms. Measurement of PFTs may be an appropriate consideration in the preoperative setting.[34] When possible, lung function should be optimized to either the patient's predicted values or personal best values using a short course of oral systemic corticosteroids. Consideration for stress doses of corticosteroids at the time of surgery and during the postoperative period are appropriate for patients treated with corticosteroids during the previous 6 months or for those patients previously treated with high doses of inhaled corticosteroids.[34]

Intraoperative Risk Reduction

Many intraoperative factors may increase the risk of pulmonary complications, including type of surgery, site of surgery, and operative duration, but many procedure-related risk factors are not easily modifiable. When feasible as an alternative to open procedures, the benefits and risks of endovascular procedures should be considered. There is at least fair evidence that endovascular procedures are preferred to open procedures for the prevention of pulmonary complications, but the balance between benefit and harm may be too close to justify a general recommendation.[1,78]

Avoidance of long-acting neuromuscular blockade is appropriate to reduce the risk of perioperative pulmonary complications. There is at least fair evidence that the benefits of using agents for short-acting neuromuscular blockade outweigh any associated harm.[1] Intraoperative neuraxial blockade may confer some benefit in terms of reduction of pulmonary complications, alone or in combination with general anesthesia, but the data are conflicting and no definitive recommendation can be made at this time.[78]

General anesthesia is known to cause atelectasis, which can lead to impairment in respiratory function and associated complications. This risk may be compounded by use of one-lung ventilation commonly used during open thoracoabdominal aortic surgery to achieve surgical exposure.[79] Severe hypoxemia may result from one-lung ventilation secondary to right-to-left transpulmonary shunt.[80] The use of positive end-expiratory pressure (PEEP) intraoperatively may increase functional residual capacity and prevent airway collapse and atelectasis. Data at this time are insufficient to make any conclusions about the association of intraoperative PEEP and postoperative respiratory complications.[80,81]

Postoperative Risk Reduction

Risk reduction in the postoperative setting should focus on a number of different strategies: limiting the duration of intubation, preventing aspiration, increasing lung volume, preventing poor inspiratory effort, and avoiding overfeeding. Every effort should be made to extubate patients expeditiously because intubation significantly increases the risk of nosocomial pneumonia.[82,83] Ventilator-associated pneumonia (VAP) is the most common nosocomial infection among patients receiving mechanical ventilation and may occur in as many as 9% to 27% of intubated patients.[83] Protocols for daily weaning of sedation and trials of spontaneous respiration should be used to assess readiness for extubation; many of these protocols have been incorporated into VAP prevention bundles.[84,85] VAP prevention bundles, often championed as an effective approach to improve the practice of evidence-based medicine, have been shown to reduce respiratory complications in intubated patients.[85]

Aspiration prevention also comprises a major focus of VAP prevention bundles.[85] Strategies include head of bed elevation and subglottic suctioning of endotracheal tubes. Several studies have demonstrated that patients in the supine position are predisposed to microaspiration of gastric contents and subsequent nosocomial pneumonia as compared to patients kept in a semirecumbent position.[86-88] Aspirated secretions may pool above the cuff of the endotracheal tube; subglottic suctioning of these secretions has been demonstrated to significantly reduce the risk of associated pneumonia.[89-92] Other factors associated with aspiration and pneumonia include overaggressive use of restraints, immobility, toxic or metabolic causes of altered level of consciousness, and presence of nasogastric or other tubes that stent open both the upper and lower esophageal sphincters.[93,94] It is important to identify a purpose for nasogastric tube use and consider removal as soon as possible to help prevent pneumonia. Aggressive chlorhexidine oral hygiene will reduce bacterial load and colonization in the oropharynx and this strategy has been shown to reduce the incidence of aspiration pneumonia.[95-98] Stress ulcer prophylaxis is recommended for critically ill patients at risk of upper gastrointestinal mucosal bleeding; typically this is someone who will remain on a ventilator for more than 48 hours. However, acid suppressive medications, such as proton pump inhibitors and H2 blockers, may predispose patients to VAP by raising gastric pH and allowing bacterial overgrowth. The risk of VAP associated with stress ulcer prophylaxis remains controversial.[99]

Two prospective randomized trials have confirmed early tracheostomy is not associated with improved mortality or decreased incidence of VAP, though length of stay in the intensive care unit (ICU) may be decreased with early tracheostomy.[1,100,101] The TracMan trial compared early (4 days) versus late (10 days) tracheostomy among 909 patients requiring prolonged mechanical ventilation and found no differences in outcomes.[101] Other considerations, such as inability to protect the airway or patient comfort, may serve as indication for earlier tracheostomy.

Lung expansion modalities in the postoperative period may serve as a strategy to reduce postoperative pulmonary complications. These modalities range from simple and effort-dependent,

such as deep breathing exercises and incentive spirometry, to complex, expensive, and effort-independent, such as CPAP. There is evidence from a randomized controlled trial among patients undergoing thoracoabdominal aneurysm repair to support use of nasal CPAP immediately after extubation to reduce pulmonary complications.[102-104] However, a recent Cochrane review did not find the current evidence to be sufficient to confirm the benefits or harms of CPAP during the postoperative period following major abdominal surgery.[105] The evidence currently does not support one type of modality over another, and any lung expansion intervention may be better than no intervention.[78] However, a recent Cochrane review even calls in to question the effectiveness of incentive spirometry.[106] Given the expense of CPAP, as well as a small risk of barotrauma, this should not be considered a routine intervention and is best employed in patients unable to cooperate with effort-dependent lung expansion strategies. Inspiratory effort can be augmented through adequate pain control and careful attention to incision location, patient position, immobility, and location of chest tubes or binders that impede full chest wall excursion.

Malnutrition is considered a risk factor for postoperative pulmonary complications including pneumonia, but the data generally do not support total parenteral nutrition (TPN) or total enteral hyperalimentation over no hyperalimentation.[78] Patients should resume oral intake after surgery as soon as feasible; intestinal villi atrophy quickly without enteral intake and this may increase risk for bacterial translocation and subsequent sepsis. Swallow function should be assessed after extubation by bedside assessment to limit risk of aspiration. In cases of prolonged intubation or history of swallowing difficulty, the expertise of speech-language pathologists should be sought. Conversely, overfeeding should be avoided as this produces excess carbon dioxide, which may exceed the patient's capacity for removal through exhalation. Electrolyte abnormalities should be aggressively sought and corrected as these may contribute to a patient's failure to wean from mechanical ventilation. In particular, hypophosphatemia may limit the patient's energy (adenosine triphosphate) available for muscle contractility and may directly impair diaphragmatic function.

CLINICAL MANIFESTATIONS

Atelectasis

Atelectasis refers to collapse or closure of alveoli and commonly affects dependent portions of the lung. General anesthesia causes loss of the normal coordinated activity of respiratory muscles. These changes cause alterations in the shape and motion of the chest wall, which result in reduced lung volumes, abnormalities in regional gas exchange, and atelectasis.[107] Atelectasis is present in up to 90% of anesthetized patients, independent of the type of anesthesia used or patient demographics.[108-112] A goal-directed approach to perioperative mechanical ventilation, utilizing low tidal volume, low plateau pressures, and PEEP, may help mitigate pulmonary complications associated with atelectasis.[107]

Bronchospasm

Bronchospasm is the result of increased tone in the bronchial smooth muscles; subsequent narrowing of the bronchi may cause severe and life-threatening hypoxemia. Although intraoperative acute bronchospasm is rare, this complication may occur in susceptible patients such as those with asthma.[33] Bronchospasm may be provoked by mechanical manipulation of the airway such as laryngoscopy, intubation, extubation, or airway suctioning. Perioperative medications may also cause bronchospasm through release of histamine, muscarinic activity, or allergic reactions. Acute management of bronchospasm may include administration of beta-2 selective agonist by nebulizer, intravenous steroids, and/or intravenous epinephrine.

Pneumonia

Pneumonia is an acute infection of pulmonary parenchyma. Among hospital-acquired infections, pneumonia is the leading cause of death.[84,85,113] Guidelines from the American Thoracic Society and Infectious Diseases Society of America categorize pneumonia as hospital-acquired pneumonia (HAP), VAP, and healthcare-associated pneumonia (HCAP).[114] Community-acquired pneumonia (CAP) should be distinguished from these other categories of pneumonia since the causative pathogens and empiric treatment will differ. HAP is defined as a pneumonia occurring greater than 48 hours after hospital admission. VAP is a specific type of HAP that develops after greater than 48 hours following endotracheal intubation. HCAP is defined as a pneumonia occurring in a patient who meets 1 or more of the following criteria: hospitalization for at least 2 days in an acute care facility within 90 days of the infection, resident of a nursing home or long-term care facility at time of infection, patient who has received hemodialysis within 30 days, patient who has received any intravenous treatment or wound care within 30 days of infection, and any patient who is a family member of a known patient with a multidrug-resistant pathogen.

The etiology of VAP is related to (1) bacterial colonization of the aerodigestive tract or (2) aspiration of contaminated secretions of the lower airway.[1] The leading pathogen identified in cases of VAP is *Staphylococcus aureus*.[115-117] Other common organisms include *Pseudomonas aeruginosa*, *Enterobacter* species, *Acinetobacter baumanii*, and *Klebsiella pneumoniae*. Of considerable concern, many multi-drug-resistant organisms have been isolated in cases of VAP.[118] Methicillin resistance has been identified in as many as 54% to 82% of *S. aureus* isolates in cases of VAP.[118,119] Causative pathogens may vary among different institutions, and clinicians should be aware of specific pathogens and sensitivities within their institution and especially their ICUs. The highest rates of VAP are found in surgical ICUs, especially in burn and trauma ICUs.[1,118]

Diagnostic strategies and associated controversies regarding HAP and VAP are beyond the intended scope of this chapter. However, it is important to recognize that these infections are difficult to diagnose because the clinical findings are nonspecific.[1,120] There is ongoing debate about whether an aggressive

TABLE 43.3 Clinical Pulmonary Infection Score for Ventilator-Associated Pneumonia

	0 Points	1 Point	2 Points
Temperature (°C)	36.5-38.4	38.5-38.9	≤36.0 or ≥39
Peripheral WBC	4000-11,000	<4000 or >11,000	<4000 or >11,000 and >50% bands
Tracheal secretions	None	Nonpurulent	Purulent
Pulmonary radiography	No infiltrate	Diffuse/patchy infiltrates	Localized infiltrate
Culture of ET suction	No growth	Heavy growth	Heavy growth and positive gram stain
Oxygenation (PaO_2/FiO_2)	>240 or ARDS		≤240 and no ARDS

CPIS Score >6 is consistent with ventilator-associated pneumonia.
ARDS, Acute respiratory distress syndrome; *°C*, degrees Celsius; *ET*, endotracheal tube; *FiO_2*, fraction of inspired oxygen; *PaO_2*, partial pressure of oxygen in arterial blood; *WBC*, white blood cell count in cells/cubic milliliter of blood.
Modified from Pugin J, Auckenthaler R, Mili N, Janssens J, Lew PD, Suter PM. Diagnosis of ventilator-associated pneumonia by bacteriologic analysis of bronchoscopic and nonbronchoscopic "blind" bronchoalveolar lavage fluid. *Am Rev Respir Dis*. 1991;143:1121–1129.

strategy employing bronchoalveolar lavage (BAL) should be utilized in addition to clinical criteria for diagnosis and treatment.[121-125] Although there does not appear to be a mortality benefit with use of BAL to diagnosis pneumonia, this technique may help with prescription and deescalation of antibiotic treatment. The Centers for Disease Control and Prevention (CDC) define VAP using a combination of radiologic, clinical, and laboratory criteria.[126] In common practice, the Clinical Pulmonary Infection Score (CPIS) has emerged as a useful diagnostic tool for VAP.[127,128] Points are assigned based on temperature, white blood cell count, tracheal secretion character, radiograph findings, culture data, and oxygenation (Table 43.3). Patients with a CPIS score greater than 6 are likely to have VAP.

Successful treatment of HAP and VAP requires initiation of early and appropriate empiric broad-spectrum antibiotics to cover all potential causative pathogens. The initial choice of empiric antibiotic therapy should be based on national guidelines while also considering institution and ICU-specific antibiograms. Guidelines recommend that patients with no risk factors for multi-drug resistant organisms may be treated empirically with second- or third-generation cephalosporins, extended-spectrum fluoroquinolones, aminopenicillins, or narrow-spectrum carbapenems.[114] Patients with risk factors for multi-drug-resistant organisms should be treated with initial combination therapy to cover both gram-negative infections and gram-positive infections. Coverage of *P. aeruginosa* and methicillin-resistant *S. aureus* (MRSA) is especially important. Linezolid or vancomycin should be added when MRSA is suspected. Antibiotic therapy should be tailored to specific pathogens and sensitivities when culture data become available. Duration of therapy should generally be 8 days.[129]

Acute Respiratory Failure

Acute respiratory failure may result from failure to protect the airway, failure to oxygenate, and/or failure to ventilate. In some cases, acute respiratory failure will result from a combination of these abnormalities. Loss of airway protection may result from a number of circumstances including traumatic brain injury, neurologic impairment, absent cough and/or gag reflex, laryngeal edema, or residual effects of anesthesia and/or neuromuscular blockade.

Hypoxemic respiratory failure may be identified by a low partial pressure of oxygen in arterial blood (i.e., PaO_2 of less than 60 mm Hg).[1] The etiology of hypoxemic respiratory failure is attributed to either diffusion defects or ventilation-perfusion mismatch at the interface between the pulmonary capillary and the alveolus. Fluid filling of alveoli, as in the case of pulmonary edema, impairs diffusion of oxygen. Causes of pulmonary edema may include increased hydrostatic pressure from left cardiac ventricular failure, decreased plasma oncotic pressure from liver failure, or increased capillary permeability commonly seen with burns or sepsis. Alveolar collapse affects gas exchange by decreasing the functional residual capacity of the lung and creating ventilation-perfusion mismatch. Lung volume loss decreases lung compliance and makes ventilation more difficult. In this setting, PEEP is commonly used to "recruit" alveoli, increase the size of the functional lung, and improve both compliance and oxygenation. Increasing the fraction of inspired oxygen (FIO_2) through administration of oxygen-enriched air (by high-flow nasal cannula, face mask, intubation and mechanical ventilation, etc.) is also an important strategy to improve oxygenation in the acute setting.

Hypercapnic respiratory failure may be identified by a high partial pressure of carbon dioxide in arterial blood (i.e., $PaCO_2$ greater than 50 mm Hg).[1] Hypercapnic respiratory failure results from central loss of ventilation (sedation, stroke, etc.), impairment of the diaphragm/respiratory muscles (trauma, neurologic changes, etc.), or changes in chest wall mechanics (pneumothorax, effusion, etc.). The approach to this type of respiratory failure involves improvement of minute ventilation through increased respiratory rate and/or tidal volume. Other strategies, such as chest tube placement or thoracentesis, may be directed at the underlying pathology.

A systematic approach should be utilized to recognize the etiology of acute respiratory failure. For most postoperative patients with acute respiratory failure, consideration should be made for intubation and mechanical ventilation. A trial of

noninvasive ventilation strategies may be appropriate for some patients with reversible causes of respiratory failure. All patients with acute respiratory failure should be treated in an ICU setting.

Acute Respiratory Distress Syndrome

ARDS was originally defined in 1994 as a diffuse inflammatory process involving both lungs and arising in the setting of illness with a severe systemic inflammatory response.[130] The original definition stated that the onset of ARDS must be acute, the ratio of arterial partial pressure of oxygen to fraction of inspired oxygen (PaO_2:FIO_2 or P:F ratio) must be less than 200, chest radiograph must demonstrate new bilateral infiltrates (with no clinical suspicion of pneumonia), and left atrial pressure must be normal (with no clinical suspicion of cardiac failure). In cases of suspected left atrial pressure elevation, a pulmonary catheter wedge pressure less than 18 mm Hg was considered consistent with ARDS when the other criteria were also met. This definition was subsequently revised after a 2011 consensus conference reevaluated the reliability and validity of the definition of ARDS.[131] The revised definition, commonly known as the Berlin definition, introduced escalating stages of ARDS defined by mild, moderate, or severe oxygenation (Table 43.4). The escalating stages of ARDS, when empirically evaluated, were associated with incremental increases in mortality from 27% mortality for mild ARDS, 32% mortality for moderate ARDS, and 45% mortality for severe ARDS.[131]

TABLE 43.4 The Berlin Definition of Acute Respiratory Distress Syndrome

Timing	Within 1 week of a known clinical insult or new or worsening respiratory symptoms
Pulmonary radiography	Bilateral opacities not fully explained by effusions, lobar/lung collapse, or nodules
Origin of edema	Respiratory failure not fully explained by cardiac failure or fluid overload
Oxygenation	Need objective assessment (e.g., echocardiography) to exclude hydrostatic edema if no risk factor present
Mild ARDS	200 mm Hg < PaO_2/FiO_2 ≤ 300 mm Hg with PEEP or CPAP ≥ 5 cm H_2O
Moderate ARDS	100 mm Hg < PaO_2/FiO_2 ≤ 200 mm Hg with PEEP ≥ 5 cm H_2O
Severe ARDS	PaO_2/FiO_2 ≤ 100 mm Hg with PEEP ≥ 5 cm H_2O
Mortality	
Mild ARDS	27% (CI 24%-30%)
Moderate ARDS	32% (CI 29%-34%)
Severe ARDS	45% (CI 42%-48%)

ARDS, Acute respiratory distress syndrome; *CI*, 95% confidence interval; *CPAP*, continuous positive airway pressure; *FiO_2*, fraction of inspired oxygen; *PaO_2*, partial pressure of oxygen in arterial blood; *PEEP*, positive end-expiratory pressure.
Modified from ARDS Definition Task Force. Acute respiratory distress syndrome: the Berlin definition. *JAMA*. 2012;307(23):2526–2533.

The global epidemiology of ARDS was recently reported in a large prospective cohort study of patients undergoing invasive or noninvasive ventilation in 459 ICUs from 50 countries across five continents.[132] This study, known as LUNG SAFE, enrolled over 29,000 patients in participating ICUs and determined that 10.4% of ICU admissions met criteria for ARDS and 23.4% of patients requiring mechanical ventilation met criteria for ARDS. Not only was ARDS very common, it was also underrecognized: clinicians only recognized 51.3% and 78.5% of mild and severe ARDS cases, respectively. Finally, this study reported high hospital mortality, ranging from 34.9% for mild, 40.3% for moderate, and 46.1% for severe cases of ARDS.

Conditions that may predispose to ARDS include sepsis, pneumonia, pulmonary contusion, cardiopulmonary bypass, pancreatitis, and other diseases associated with a systemic inflammatory response. The pathogenesis behind ARDS is marked by dysregulated inflammation, inappropriate accumulation and activity of leukocytes and platelets, uncontrolled activation of coagulation pathways, and altered permeability of the alveolar endothelial and epithelial barriers.[133] ARDS is typically progressive in distinct stages with different clinicopathologic and radiographic stigmata at each stage. The acute or exudative phase is manifested by the rapid onset of respiratory failure and arterial hypoxemia refractory to supplemental oxygen. Computed tomography shows alveolar filling, consolidation, and atelectasis predominantly in the dependent lung zones; other lung areas may be relatively spared. Although the disease may resolve in some patients after the acute phase, it progresses in other patients to fibrosing alveolitis with persistent hypoxemia, increased alveolar dead space, and further compromised pulmonary compliance.

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) is the onset of respiratory distress after transfusion of one or more units of blood.[134] TRALI is recognized as a leading cause of transfusion-related mortality.[135] TRALI should be suspected in patients with acute onset of respiratory failure within 6 hours of blood transfusion, bilateral infiltrates on chest radiography, PaO_2:FIO_2 less than 300, no evidence of pulmonary edema, and no other risk factors for lung injury.[136] TRALI is not easily distinguished from other causes of acute lung injury and ARDS, and clinical management does not differ. However, the time course of TRALI is usually shorter than ARDS, and resolution is frequently observed with appropriate supportive care. Mortality from TRALI is quite low (5%-10%) compared to ARDS, and long-term prognosis is excellent in those surviving the initial pulmonary insult.[135,137]

MANAGEMENT STRATEGIES

Perioperative pulmonary complications may be managed with a number of different noninvasive and invasive strategies. For those patients requiring intubation and mechanical ventilation,

a number of adjuncts are available to assist with recovery and optimization of respiratory function.

High-Flow Nasal Oxygen

High-flow nasal cannula oxygen therapy has emerged as an effective modality for management of respiratory insufficiency in the perioperative setting. The nasal prong device is capable of delivering up to 60 L/min of adequately heated and humidified oxygen with physiologic benefits including reduced anatomic dead space and PEEP.[138] A randomized trial recently reported statistically significant differences in post-extubation respiratory failure rates and reintubation rates among patients with low risk for reintubation who were randomized to either 24 hours of high-flow nasal oxygen or conventional oxygen therapy following extubation.[139] Only 4.9% of patients who received high-flow nasal oxygen required reintubation within 72 hours compared to 12.2% of patients who received conventional oxygen therapy ($P = .004$). Post-extubation respiratory failure occurred in 14.4% of patients managed with conventional oxygen therapy versus 8.3% of patients managed with high-flow nasal oxygen ($P = .03$). High-flow nasal therapy is generally well tolerated by patients, because it is considered more comfortable than standard high-flow oxygen masks or noninvasive ventilation.[140] Furthermore, since the patient can talk and eat with the nasal therapy in place, patients often utilize the therapy more consistently.

Noninvasive Positive Pressure Ventilation

Noninvasive positive pressure ventilation (NPPV) refers to delivery of CPAP or bilevel positive airway pressure either by facemask or nasal cannula. These modalities utilize a combination of pressure support and PEEP and are used commonly in patients with reversible acute respiratory failure to avoid endotracheal intubation.[103,104,141,142] Through the application of extrinsic PEEP, NPPV counterbalances auto-PEEP in COPD and recruits flooded alveoli in pulmonary edema. Ultimately, this therapy serves to increase functional residual capacity, improve lung compliance, and optimize gas exchange.[143] NPPV is considered the best first approach for patients with COPD exacerbations and brings about rapid symptomatic and physiologic improvement as well as reduced rates of intubation and mortality.[144] For patients with asthma, data are inconclusive about the role of NPPV.[144] While a trial of NPPV may be warranted for asthmatic patients, close surveillance is critical, since these patients may deteriorate rapidly and require mechanical ventilation. NPPV may be of use in other patient populations including those with airway edema after extubation or in patients with OSA.[104,142] NPPV is associated with some complications including nasal bridge ulceration and gastric distention. Major complications, such as aspiration, are infrequent. A recent Cochrane review concluded that both CPAP and bilevel NPPV are effective and safe treatments for respiratory failure.[145] A randomized clinical trial has demonstrated that use of NPPV compared with standard oxygen therapy reduces the risk of reintubation among patients with hypoxemic respiratory failure after abdominal surgery.[146]

Mechanical Ventilation

Intubation and mechanical ventilation is generally required in most cases of ARDS and in cases of respiratory failure where noninvasive strategies have failed. Although mechanical ventilation is the cornerstone of respiratory failure management, this modality may also exacerbate lung injury through barotrauma such as pneumothorax or mediastinal emphysema. Ventilation strategies for ARDS protect the lungs by limiting barotrauma-associated injury.

Lung-protective mechanical ventilation utilizes low tidal volumes (6 mL/kg of predicted body weight), permissive hypercapnia, elevated PEEP, and use of pressure-limited ventilator modes.[147] This strategy recognizes that dependent, atelectatic portions of the lung do not open at normal physiologic tidal volumes. The remaining portion of the lung must accommodate the entire tidal volume, leading to elevated peak inspiratory and plateau pressures. Some alveoli may subsequently become overdistended, leading to increased vascular permeability, loss of surfactant, cytokine production, and further local and systemic injury. Through use of low tidal volumes and limited plateau pressures (less than 30 cm H_2O), further injury is limited or avoided. The seminal multicenter randomized trial by the ARDS Network compared traditional ventilation tidal volumes (12 mL/kg) with lower tidal volumes (6 mL/kg) and found that use of lower tidal volumes in ARDS resulted in fewer ventilator-dependent days and decreased mortality (39.8% with conventional versus 31.0% with protective lung ventilation, $P = .007$).[148] This strategy is used with the understanding that traditional goals of gas exchange must be modified with use of low tidal volumes, and permissive hypercapnia is often necessary.

Other advanced or nontraditional ventilatory modes have been proposed for management of ARDS, including high-frequency oscillatory ventilation (HFOV). However, the OSCAR trial found no mortality benefit for use of HFOV in patients with ARDS.[149] The OSCILLATE trial reported lack of efficacy of HFOV and possible harm to patients.[150] While there may be a role for HFOV in select rescue situations, this should not be considered a routine management strategy.

Adjuncts to Mechanical Ventilation

A number of adjunct strategies have been used in concert with lung-protective mechanical ventilation for the management of patients with acute respiratory failure and ARDS. Alveolar recruitment through use of higher PEEP has been suggested as a strategy to increase functional residual capacity, prevent alveolar collapse, and improve oxygenation. However, PEEP is also associated with circulatory compromise (from impaired venous return) and lung injury from overdistention. The ARDS Network group compared high versus low PEEP among patients with low tidal volumes and low plateau pressures and did not find a mortality benefit with use of high PEEP.[151]

Fluid management has also been an area of interest, since ARDS is marked by altered permeability at the level of the

alveolar endothelial and epithelial barriers with subsequent alveolar flooding. There has been some evidence that fluid restriction and use of furosemide may decrease duration of mechanical ventilation, but there is no mortality benefit.[152] High-volume hemofiltration may confer some benefits, but more data are needed.[153] Currently, the evidence does not support the use of any specific fluid strategy or invasive monitoring of fluid status in patients with ARDS.

Inhaled nitric oxide (iNO) has been used in some cases of severe, refractory hypoxemia, but this should not be considered a routine strategy and can only provide modest improvements in oxygenation over a short period. A meta-analysis has suggested that use of iNO confers no mortality benefit and may cause harm.[154]

Patients with ARDS and a PaO_2:FIO_2 less than 150 mm Hg may benefit from early treatment with a continuous infusion of cisatracurium for 48 hours. This treatment has been shown to reduce the rate of mortality at 90 days, increase the number of ventilator-free days, and decrease the number of ICU days.[155] The exact mechanism by which neuromuscular blockade improves outcomes in ARDS is unknown, but it is likely related to improvement in lung mechanics, uniform and synchronous lung recruitment, and improved lung compliance.

Prone positioning has been an area of considerable interest in the management of patients with ARDS. A number of randomized trials have evaluated the outcomes associated with this treatment strategy.[156-158] These studies have identified improvement in oxygenation with prone positioning, but the data are conflicting concerning any mortality benefit. Furthermore, there have been some safety concerns identified with use of prone positioning including endotracheal tube obstruction and pressure sores.[157] This strategy may best be employed when the critical care team is appropriately trained in this technique and has experience ensuring patient safety during prone positioning.

Veno-venous extracorporeal membrane oxygenation (ECMO) may be of benefit as salvage therapy in select patients with ARDS who continue to have profound gas-exchange abnormalities.[159-161] Generally, patients may be considered for this therapy when mechanical ventilation and the other available adjuncts are unable to maintain adequate oxygenation and removal of carbon dioxide to support life. The conventional ventilatory support versus ECMO for severe adult respiratory failure (CESAR) trial performed in the United Kingdom provided encouraging outcomes regarding the efficacy and economic assessment of this strategy.[162] However, this trial was criticized for methodological limitations: patients treated with ECMO were treated at a single center and those receiving conventional support were treated at a number of different centers where not all patients received best practice lung-protective ventilation strategies. The EOLIA trial is an ongoing effort comparing the efficacy of veno-venous ECMO in ARDS with tight parameters concerning the mechanical ventilation strategies employed in the control group.[163] ECMO remains an important rescue strategy in ARDS for select patients, but further evidence is needed to understand the benefits and risks of this therapy in larger populations.

A basic comprehension of renal anatomy and physiology is necessary to understand the complex changes in renal function that can occur during treatment of vascular disorders. This chapter will provide a brief summary, and more detail can easily be obtained from several standard texts.[1]

RENAL ANATOMY

Specific kidney components include the nephrons, the collecting ducts, and the microvasculature. The human kidney contains approximately 1 million nephrons, which are established before birth. Injured or lost nephrons cannot be replaced, so nephron preservation is essential to maintain normal renal function. There are two basic types of nephrons: those with short loops of Henle and those with long loops. The long loops extend to the inner medulla, and the short loops to either the outer medulla or the cortex. The collecting ducts descend within the medullary rays of the cortex, entering the inner medulla to form papillary ducts (Fig. 44.1A).

The renal artery divides into the interlobar arteries, which enter the cortex. The interlobar arteries divide into the arcuate arteries at the junction of the cortex and the medulla. These vessels then divide into the cortical radial arteries, which ascend through the cortex. No arteries penetrate the medulla. The cortical radial arteries give rise to the afferent arterioles, which supply the glomeruli. The glomeruli are drained by efferent arterioles that can be cortical or juxtamedullary. The cortical efferent arterioles are derived from the superficial and midcortical glomeruli and supply the capillary plexus of the cortex. The juxtamedullary efferent arterioles supply the renal medulla. At the level of the outer stripe of the medulla, the juxtamedullary efferent arterioles divide into the descending vasa recta, and from these vessels, leave at different levels to supply the adjacent medullary plexus. Ascending vasa recta drain the renal medulla and ascend as unbranched vessels. They then ascend and traverse the outer medulla and form the capillary plexus of the outer stripe. The ascending vasa recta then empty into the arcuate veins.

The microvasculature provides a unique countercurrent exchange between the blood entering and the blood leaving the medulla. The unique vascular anatomy also separates blood flow in the inner stripe from the inner medulla. The descending vasa recta supplying the inner medulla are not exposed to the tubules of the inner or outer stripe (outer medulla). Blood flow in the ascending vasa recta from the inner medulla and inner stripe perfuses the outer stripe. The physiologic significance has been postulated to be a mechanism to prevent loss of solute from the medulla. Venous drainage accompanies the arteries. Arcuate veins form anastomosing arches at the corticomedullary border and are fed by veins from the cortex and medulla. Arcuate

Abstract

A basic comprehension of renal anatomy and physiology to understand the complex changes in renal function that can occur during treatment of vascular disorders. Understanding the pathophysiology of renal injury can help the clinician identify those factors that predispose the patient to renal injury following open vascular surgery and endovascular procedures and thus help decrease rates of morbidity and mortality.

veins join to form the interlobar veins, which are parallel to the interlobar arteries (see Fig. 44.1A).[2]

RENAL FUNCTION

The kidney is the major site responsible for maintenance of intravascular volume and composition under normal conditions. Toward this end, the kidney provides three basic physiologic processes: glomerular filtration, selective tubular secretion, and selective tubular reabsorption.[3,4] The kidney receives a fourth of the cardiac output, and based on a cardiac output of 5 L/min, the kidney receives approximately 900 L/day of plasma flow. The glomeruli filter 20% of renal plasma flow and must reabsorb 99% of the 180 L of plasma filtered per day to provide a urine output of 1.8 L/day (for a 70-kg man). This ultrafiltrate has the same electrolyte and solute concentration as plasma, and is almost totally reabsorbed.[5] The solute content and volume of urine that enters the renal pelvis are very different from the solute content and volume of the glomerular filtrate. The filtrate flows through the different portions of the tubule, where the solute content and volume are altered by tubular reabsorption and tubular secretion. When the direction of solute movement is from the tubular lumen to the peritubular capillary plasma, the process is termed *tubular reabsorption*. Movement in the opposite direction is termed *tubular secretion*. For any particular substance, there is a unique combination of filtration, reabsorption, and secretion. The combination of filtration, secretion, and reabsorption is under physiologic control, which can alter the relative rates of each process. For example, after drinking a large quantity of water, the excess will be excreted within 1 to 2 hours because of an increase in the glomerular filtration rate (GFR) and a decreased water tubular reabsorption.

The descending loop of Henle is permeable to water but only minimally permeable to sodium and chloride, whereas the ascending loop is not permeable to water but has active transport mechanisms that readily transport the chloride ion with concomitant passive transport of sodium. This is the underlying basis for the countercurrent mechanisms that produce the medullary osmotic gradient that is important in the regulation of urine osmolarity. Reabsorption of sodium from the distal tubule and from the proximal collecting ducts is controlled by aldosterone secretion. The mechanisms responsible for sodium reabsorption by the kidney are remarkable in that only 50 to 200 mEq of sodium is excreted per day of the 25,000 mEq of sodium filtered daily by the kidney (see Fig. 44.1B). Potassium is reabsorbed in the proximal convoluted tubule and the thick ascending limb of Henle. Ten percent of the filtered load reaches the early distal tubule. Potassium secretion by connecting cells in the late distal tubule and/or cortical collecting system is variable and represents the major determinant of potassium excretion.[3-6]

Neuroendocrine Modulators of Renal Function

Intravascular volume is regulated primarily by a series of baroreceptors located in the arterial tree and the atria. Because these receptors not only sense changes in pressure or volume (atrial receptors) but also monitor the rates of change during the cardiac cycle, they govern the effective circulating volume. Factors that decrease cardiac performance and intravascular volume are perceived by these receptors, which then alter renal function to retain salt and water and thereby increase the effective circulating volume. Similarly, when the concentration of circulating plasma proteins is reduced, there is a net diffusion of intravascular water into the extravascular space secondary to the decreased intravascular oncotic pressure. This net decrease in circulating volume is sensed by these same receptors, and neuroendocrine regulators of urinary output inhibit the excretion of water to correct the volume deficiency. When the baroreceptors perceive a reduction in circulating volume, their afferent signals are reduced, which decreases their tonic inhibition over the neuroendocrine system. This reduced inhibition leads to increased secretion of vasopressin, 13-endorphins, growth hormone, adrenocorticotropic hormone through the central nervous system, and an increased release of epinephrine from the adrenal medulla.

At the local renal level, a reduction in arterial pressure or central venous pressure (or both) results in an increase in renal sympathetic nerve stimulation that reduces urinary sodium excretion via three mechanisms: (1) constriction of afferent and efferent arterioles, which reduces renal blood flow and GFR; (2) reabsorption of sodium in the proximal tubule and the thick ascending loop of Henle; and (3) stimulation of renin secretion. At the level of the nephron, baroreceptors within the macula densa cells of the juxtaglomerular apparatus perceive a decrease in intravascular pressure or plasma ion concentration and stimulate juxtaglomerular cells to release renin. Renin is an enzyme that is stored in the specialized macula densa cells that constitute part of the juxtaglomerular apparatus. It is released in response to an increase in sympathetic nerve activity, reduced stretch of the afferent arteriole, and decreased transport of NaCl to the macula densa. Renin catalyzes the release of angiotensin I from angiotensinogen. Angiotensin I is then converted to angiotensin II by angiotensin-converting enzyme (ACE). Angiotensin II has several important actions. First, it induces arteriolar constriction of the afferent and efferent arterioles and thereby causes an increase in blood pressure while decreasing renal blood flow; second, it stimulates renal sodium reabsorption in the proximal tubule; and third, it induces secretion of aldosterone from the zona glomerulosa of the adrenal cortex. Aldosterone secretion results in sodium reabsorption in the distal tubule and collecting duct.[1-6]

Paracrine and Endocrine Modulators of Renal Function

A number of endogenous and exogenous paracrine and endocrine substances influence renal function. An exhaustive list of these substances is beyond the scope of this chapter, but the major substances thought to be involved in normal and abnormal renal physiology are briefly presented. Eicosanoids are an important class of vasoactive metabolites of three different enzymes: cyclooxygenase (COX), lipoxygenase, and cytochrome P-450. COX is present as both constitutive (COX-1) and inducible forms (COX-2). Conversion of arachidonic acid to

prostaglandins and thromboxane occurs via both enzymes. The major renal eicosanoids are prostaglandin E2 (PGE2) and prostaglandin I2 (PGI2). These potent vasodilators buffer renal vasoconstrictors such as thromboxane A2, angiotensin II, and norepinephrine. Decreased synthesis of the renal vasodilators PGE2 and PGI2 has been associated with renal vasoconstriction and has been demonstrated after a number of injuries, including renal ischemia, renal ischemia-reperfusion, and intestinal ischemia-reperfusion.[7-15] PGE2 has been shown to inhibit sodium reabsorption from the thick ascending limb of Henle and thus contributes to protecting the renal medulla during hypoxia. COX-2 expression has been found in the macula densa and is thought to contribute to the release of renin via PGE2. This could be one of the mechanisms responsible for the low renin levels found in patients taking nonsteroidal antiinflammatory drugs (NSAIDs). The loss of COX-2 expression can also reduce medullary blood flow and cause apoptosis of medullary interstitial cells.

Nitric oxide (NO) is another potent endogenous renal vasodilator that has been shown to contribute to the maintenance of normal renal blood flow and function under normal physiologic conditions.[12-23] Zou and Cowley24 demonstrated that NO was synthesized in both the medulla and the cortex.[23] They concluded that NO might play a role in the control of vascular tone and tubular function in the kidney.[23] Loss of endogenous NO synthesis has been suggested to contribute to renal vasoconstriction after renal ischemia-reperfusion injury from either local or systemic causes.[12,13,16-24] Similar to the vasodilator prostaglandins, NO is present in the macula densa as the neuronal synthase form (nNOS). Downregulation of nNOS may contribute to arteriolar vasoconstriction by downregulating COX-2 (and subsequent PGE2 synthesis) through an adenosine or adenosine triphosphate (ATP) pathway. NO has also been shown to help mediate the increased natriuresis following an increase in renal interstitial hydrostatic pressure (caused by acute increases in blood pressure) without incurring a transforming growth factor (TGF)–mediated decrease in GFR.[25] Atrial natriuretic peptide is released from atrial myocytes after atrial stretch, secondary to increased blood volume. Atrial natriuretic peptide increases sodium excretion directly and by downregulating renin and aldosterone secretion.

Endothelins are a potent family of vasoconstrictor peptides. The kidney is a rich source of endothelins, which function as autocrine and paracrine substances. Endothelin-1 (ET-1) is synthesized in the afferent and efferent arterioles, where it induces vasoconstriction, and in mesangial cells, where it induces contraction. Upregulation of ET-1 synthesis induces a marked reduction in renal blood flow and GFR. ET-1 can inhibit sodium reabsorption in the medullary thick ascending limb, and this may be mediated by NO. Renal ischemia/reperfusion injury in rats demonstrated a potential benefit of bosentan, an endothelin antagonist.[2]

Purines are another complex class of autocrine substances that may be involved in renal physiology. Purinoreceptors are divided into P1 and P2 receptors. Purinogenic signaling is believed to be concentration dependent, with basal levels acting as a mediator of normal physiology and growth, and elevated concentrations of purines signaling adaptive pathways in response to inflammation of the kidney. P1 receptors are activated by adenosine. Higher concentrations of adenosine, such as in pathologic states, activate low affinity A3 receptors that mediate cell signaling via the inhibition of adenylate cyclase. P2 receptors are stimulated by nucleotides such as ATP and adenosine diphosphate (ADP). P2 receptors are subdivided into P2X (ligand-gated ion channels) and P2Y (metabotropic) receptors. P1 and P2X receptors are located in the afferent arteriole and contribute to vasoconstriction. P1, P2X, and P2Y receptors are located along the nephron. Specifically, the P2X7 receptor has been linked to downstream coupling to proinflammatory cascades, and this is in response to much higher levels of ATP and ADP, thought of as a "danger signal" for excessive local cellular damage. Endogenous adenosine enhances proximal tubular reabsorption, whereas luminal ADP inhibits it. In the collecting duct, basolateral ATP inhibits vasopressin-sensitive water reabsorption, and basolateral and luminal ATP inhibits sodium reabsorption. Uric acid (the end product of purine metabolism) may cause renal vasoconstriction, possibly by inhibiting release of NO and stimulation of renin.[26] Further studies will provide insight into the role of purines in renal physiology.[2]

ACUTE KIDNEY INJURY AFTER VASCULAR AND ENDOVASCULAR PROCEDURES

Acute kidney injury (AKI) after vascular and endovascular procedures can vary from mild natriuresis to fulminant acute tubular necrosis (ATN) and acute renal failure (ARF), requiring dialysis. Postoperative AKI can be classified as prerenal, renal, or postrenal (Fig. 44.2). Although the incidence of AKI complicating vascular and endovascular procedures has decreased with the development of appropriate perioperative fluid resuscitation, better surgical and endovascular techniques, and fewer nephrotoxic radiocontrast agents, the mortality associated with ARF remains high, ranging from 10% to 80% depending on the associated presence of multiorgan system failure.[27,28]

General Approach to Patients With Renal Dysfunction

Postoperative AKI is usually identified by oliguria or increases in serum creatinine. The evaluation of patients should include a thorough physical examination. Prerenal causes of AKI are most frequently encountered in the early postoperative period. Assessment of the patient's intravascular volume status and cardiac performance is required. A patient with signs of volume depletion requires replenishment of intravascular volume with physiologic saline (without potassium supplement until renal failure is ruled out). If examination reveals that diminished cardiac performance is responsible for the oliguria, judicious inotropic support is provided while indices of cardiac performance are measured.[29,30]

If correction of filling pressures or myocardial performance fails to improve urinary output, samples of urine and blood

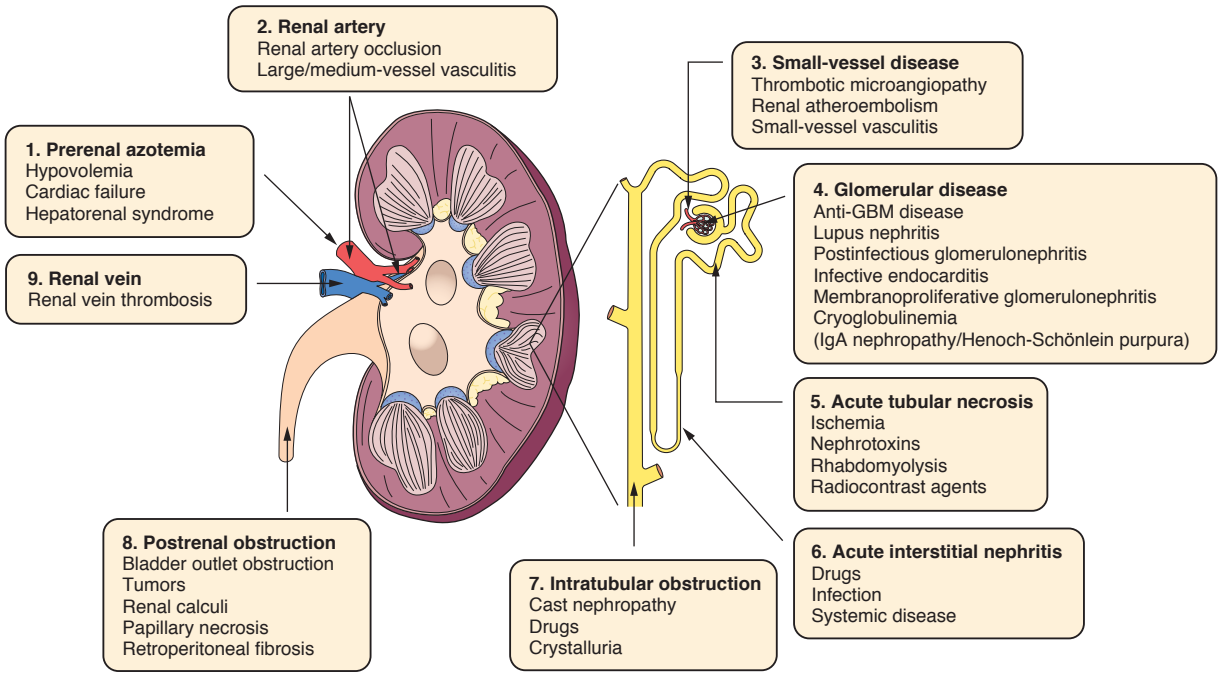

Figure 44.2 Causes of Acute Renal Failure. Acute renal failure is classified into prerenal, renal, and postrenal causes. *GBM*, Glomerular basement membrane; *IgA*, immunoglobulin A. (Adapted from Ashley J, et al. Pathophysiology and etiology of acute kidney injury. In: Floege J, Johnson R, Freehally J, eds. *Comprehensive Clinical Nephrology*. 4th ed. Philadelphia: Mosby Elsevier; 2010:798.)

are obtained, and diuretic therapy is considered. Serum electrolytes, blood counts, and urine studies (urinalysis, urine sodium, urea, creatinine, osmolality, estimation of the fractional excretion of sodium) allow evaluation of other possible sources of oliguria and renal failure, such as ATN or myoglobinuria.

Acute Kidney Injury: Causes—Prerenal

Prerenal causes are the most frequent source of AKI in the early postoperative period. Renal failure from a prerenal cause is usually the direct result of a contracted intravascular volume secondary to inadequate fluid replacement. Less commonly, it is secondary to a primary reduction in cardiac performance that triggers neurohormonal reflexes to enhance intravascular volume by increasing tubular reabsorption of sodium and water. In their pure forms, these two causes of reduced renal function are easily discernible. Hypovolemia is associated with flat neck veins, dry mucous membranes, and reduced pulmonary artery wedge pressure, whereas renal dysfunction secondary to poor cardiac performance is associated with distended neck veins, clinical fluid overload, and elevated pulmonary artery wedge pressure. Therapy for hypovolemic prerenal azotemia is to increase intravascular volume by administering balanced salt solution and red blood cells as needed. Therapy for renal dysfunction of cardiogenic origin is directed at improving myocardial performance by administering afterload-reducing and inotropic agents, and instituting diuretic therapy as needed to diminish the preload of the failing left ventricle.

Because an atherosclerotic patient who is undergoing major vascular and endovascular procedures frequently has associated coronary artery disease and impaired left ventricular function, distinction between these two causes of prerenal dysfunction (hypovolemic vs. cardiogenic) can be difficult. Preexisting heart disease may raise the baseline total body volume for an individual to higher central filling pressures, and apparently normal or low-normal cardiac filling pressures may reflect relative hypovolemia. In this clinical situation, one can maintain a constant infusion of afterload-reducing and inotropic agents (e.g., dobutamine) and cautiously administer small boluses of balanced salt solution while monitoring cardiac output and pulmonary artery wedge pressure. If no urinary response is noted when filling pressures begin to increase, diuretic therapy is added. Reliable estimates of cardiac function and filling pressures are needed before initiation of inotropic or diuretic therapy.[31,32]

Another important prerenal cause of acute and chronic renal insufficiency is renal artery stenosis. Also termed *ischemic nephropathy*, this diagnosis is made by exclusion of other causes. If other causes of prerenal dysfunction have been excluded, renal duplex sonography is used to determine whether renal artery occlusive disease is present. Hemodynamically significant renal artery stenosis or occlusion is characterized by a focal increase in peak systolic velocity (>1.8 m/sec), along with distal turbulent Doppler waveforms (i.e., stenosis) or absence of Doppler flow (i.e., occlusion; see Chapter 125). ATN is characterized by a marked decrease in diastolic velocity and an increased resistance index measured by spectral analysis of the renal artery. In the absence of acute or chronic renal parenchymal disease, diastolic velocity is increased as a result of a compensatory decrease in renovascular resistance. Correction of renal arterial stenosis or occlusion is contemplated, and the appropriate endovascular or operative intervention is instituted.[33]

Acute Kidney Injury Causes—Postrenal

Postrenal mechanisms represent the least frequent cause of postoperative oliguria leading to renal dysfunction. The pathophysiology involved in this process is obstructive, and it is usually at the level of the urethra or urinary catheter and less commonly at the level of the ureters. Hematuria or traumatic catheter insertion can predispose to clots and obstruction of indwelling urinary catheters. When rapid cessation of urine flow is detected, initial maneuvers should be directed toward catheter irrigation or replacement, which is usually successful in restoring urinary flow. Postrenal oliguria can also be caused by ureteral or renal pelvic obstruction, and these mechanisms should be investigated after exclusion of other causes of oliguria. Causes include iatrogenic injury or compression of the ureters associated with aortic surgery and stone disease. A preliminary diagnosis can be suggested on the basis of renal ultrasound or isotope renography, and can be confirmed with retrograde urography. Relief of obstruction may require the placement of ureteral stents or percutaneous nephrostomy.[29] Acute urinary retention from obstructive uropathy can rarely accompany removal of a urinary catheter. One important clinical situation occurs after urinary catheter removal in patients with epidural catheters placed for pain control and in patients with prostatic hypertrophy. Generally, one should allow 6 to 12 hours to elapse after epidural analgesia is discontinued before removal of urinary catheters. Prostatitis or traumatic urinary catheter insertion combined with general anesthesia can also precipitate acute urinary retention. If recognized early, both are easily treatable by catheter reinsertion.

Acute Kidney Injury Causes—Parenchymal

Parenchymal causes of AKI are diverse and pose the greatest risk for permanent renal failure. ATN describes all renal parenchymal causes of AKI. More specifically, the pathophysiologic mechanism of ATN involves a decrease in cellular ATP, which is associated with loss of the actin cytoskeleton; loss of the cytoskeleton causes a loss of renal tubular cell membrane polarity and subsequent loss of intercellular tight junctions. Shedding of the apical portion of tubular cells into the tubules can result in tubular obstruction and lead to a further reduction or cessation of glomerular filtration in the nephron. AKI is manifested clinically by an abrupt rise in serum creatinine, either with or without a change in urinary output (oliguria). Although ATN may be transient and self-limited, its causes related to vascular surgery include ischemic injury (shock, acute renal artery occlusion, multiorgan failure, and atheroembolic injury) and toxic injury (myoglobinuria, antibiotics, and contrast-related injury; Fig. 44.3).[29,30]

ISCHEMIC INJURY TO THE KIDNEY

Acute Ischemic Renal Injury

Postoperative acute ischemic renal injury is caused by either temporary periods of interruption of renal perfusion or periods of systemic hypoperfusion. The pathophysiology of acute ischemic injury is twofold. First, as a consequence of the magnitude and duration of ischemia, tubular cell swelling occurs after reperfusion. This swelling can cause tubular obstruction, leading to a further reduction or cessation of glomerular filtration in the nephron. Second, tubular cells either can lose their basement membrane attachment secondary to the interstitial edema that develops after reperfusion or can undergo cell death during ischemia and subsequently be sloughed into the tubule. The medullary thick ascending loop of Henle and the pars recta of the proximal tubule seem to be the tubular epithelium that are most sensitive to ischemia. After loss of the tubular cell, back leak of glomerular filtrate into the renal parenchyma occurs.[30-36] The risk for AKI after a vascular surgical intervention is greatest for aortic surgery.[37-47]

Acute renal artery occlusion (see Chapter 129) can be caused by emboli from a cardiac origin, by trauma, or by aortic or renal artery dissection. When related to a cardioembolic event, the diagnosis is often delayed, and ultimate recovery of renal function depends on the magnitude of the occlusion and the presence of preexisting collaterals to the kidneys. Back, flank, or abdominal pain; new onset of hypertension; hematuria; and elevated serum lactate dehydrogenase levels may provide a clue regarding the diagnosis and treatment.[48] Traumatic renal artery occlusion is suggested by the presence of hematuria and nonvisualization of the kidney on an intravenous pyelogram. Prompt angiography is necessary to confirm the process, although the success of revascularization largely depends on the duration of the ischemic period, which is frequently prolonged. Dissection of the renal artery can be due to catheter-related injury, or it can arise from preexisting disease (fibromuscular dysplasia). Treatment and the opportunity for functional recovery are based on the extent of the dissection, and in cases of complete occlusion of the renal artery, the time of ischemia.

Atheroembolism to the renal arteries has increasingly been recognized as a cause of AKI and can give rise to renal damage culminating in end-stage renal disease (ESRD). Catheter-based peripheral and coronary angiography and endoluminal interventions are well-recognized sources of renal atheroemboli. Up to 20% to 40% of patients with renal artery interventions have shown deterioration in GFR. It would seem logical to include the use of distal embolic protection during these procedures. This is supported by the study of Henry et al.,[49] which showed that 100% of the patients treated with renal artery angioplasty and stents with distal filter wire protection showed evidence of emboli on the filter. Cooper et al.[50] showed that, in addition to distal embolic protection, adjunct pharmacologic treatment (such as the platelet glycoprotein IIB/IIIa inhibitor, abciximab) may be required to minimize renal injury after endoluminal interventions. Atherosclerotic plaque from proximal diseased aortic segments can complicate suprarenal cross-clamping or manipulation of the aorta. Atheroembolism can also occur spontaneously from these proximal sources or from renal artery atherosclerotic plaque. The clinical diagnosis is suggested by deterioration of renal function in a patient who displays other extrarenal manifestations of atheroembolism (e.g., blue toe syndrome) and is highly suggested by the laboratory finding of eosinophilia (71%). The diagnosis is confirmed by renal biopsy, and treatment is supportive.[51-54]

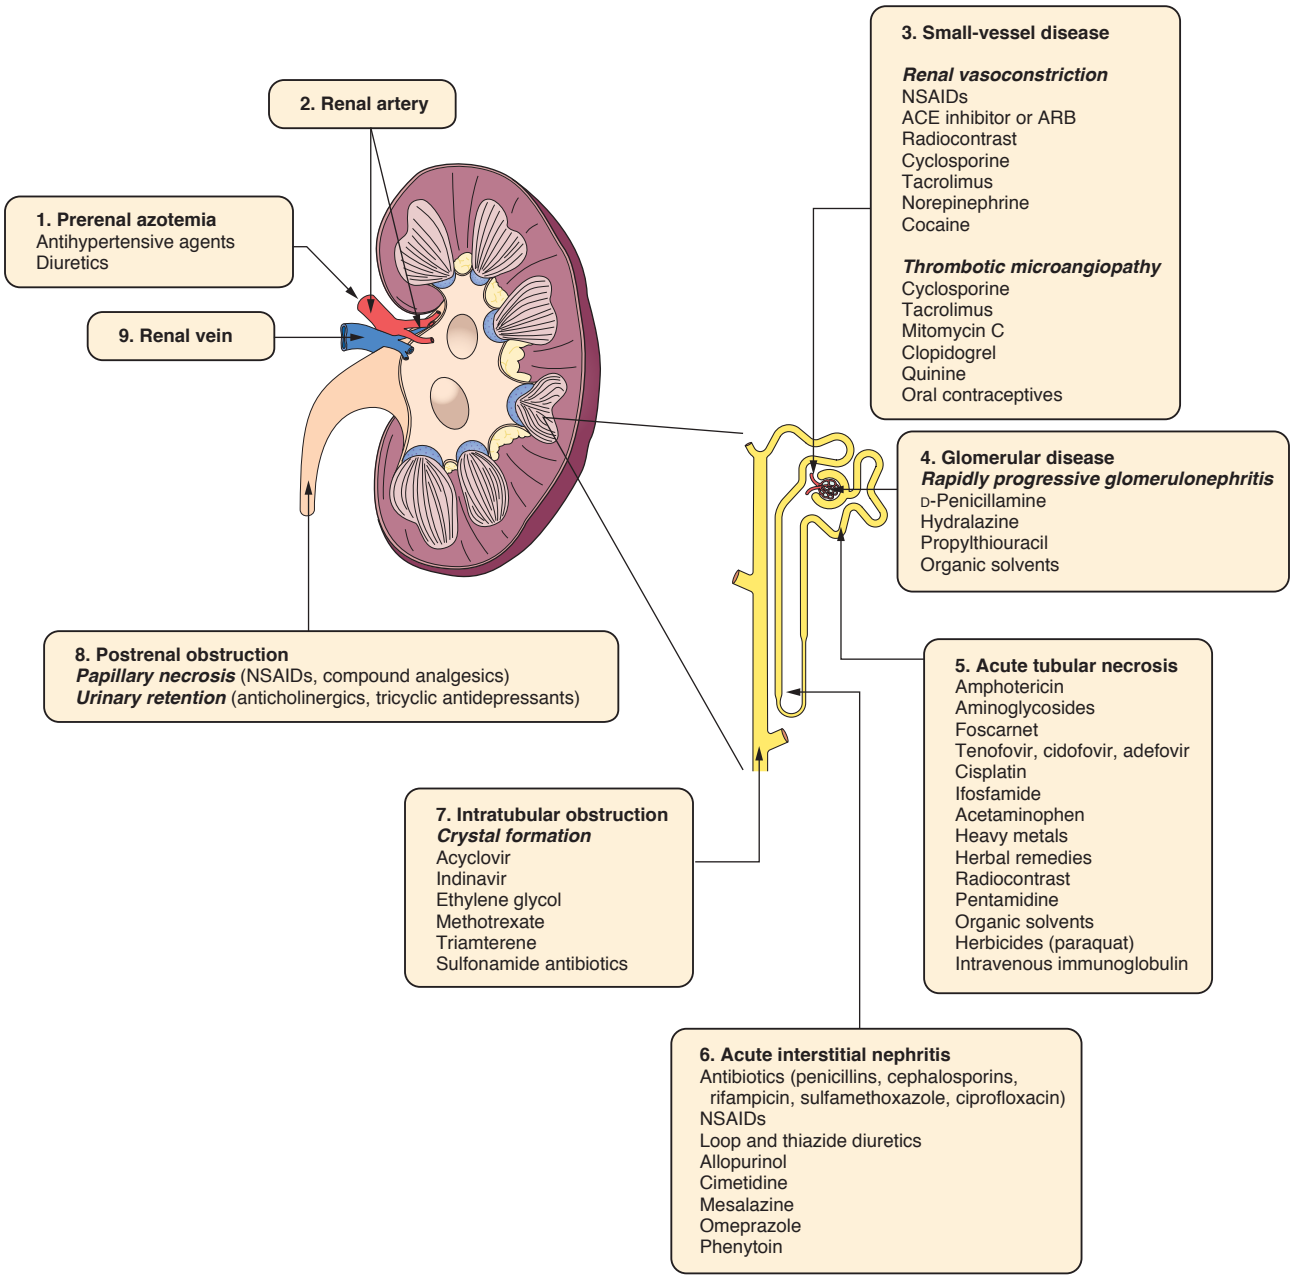

Figure 44.3 Nephrotoxic agents that lead to acute renal failure. *ACE*, Angiotensin-converting enzyme; *ARB*, angiotensin receptor blocker; *NSAIDs*, nonsteroidal anti-inflammatory drugs. (Adapted from Ashley J, et al. Pathophysiology and etiology of acute kidney disease. In: Floege J, Johnson R, Freehally J, eds. *Comprehensive Clinical Nephrology*. 4th ed. Philadelphia: Mosby Elsevier; 2010:804.)

Vascular procedures complicated by sepsis, myocardial dysfunction, and reperfusion injury can result in transient or permanent renal dysfunction. In these instances, recovery of excretory renal function depends on the elimination of the septic focus and improvement in left ventricular performance to ensure adequate renal perfusion.

Chronic Ischemia and Ischemic Nephropathy

Chronic ischemic nephropathy describes reduced renal excretory function in conjunction with renovascular disease and is discussed in Chapter 125. Usually the renovascular disease is bilateral or involves a solitary kidney, and diminished renal artery perfusion has been implicated as the cause of elevated serum creatinine. This condition tends to be rapidly progressive and is thought to be responsible for up to 20% of these patients becoming dependent on dialysis, as well as a rapid rate of death during follow-up, with a median survival of only 27 months after the initiation of dialysis and a 5-year survival rate of just 12%.[55-59]

Toxic Injury and Angiography

Chemical injury to the kidney can result from many sources (see Fig. 44.3). Nephrotoxic agents should be identified and

used with caution, particularly in a vascular patient with compromised renal clearance. Aminoglycosides are some of the most common compounds responsible for such injury in the postoperative period; myoglobin and radiologic contrast media have also been implicated. Aminoglycosides appear to exert their renal toxicity at the tubular cell by causing mitochondrial damage, destruction of the cell membrane, activation of phospholipase, or alteration in lysosomes. Because of this relationship and the frequent history of reduced renal function in postoperative vascular surgery patients, it is important to identify risk factors that can contribute to nephrotoxicity before the administration of aminoglycosides. Such risk factors include preexisting renal insufficiency, advanced age, extracellular volume depletion, and concomitant use of other nephrotoxins. The routine use of aminoglycoside blood levels to predict or prevent nephrotoxicity is probably not warranted. Although alternative antibiotics with less nephrotoxicity have reduced the use of aminoglycosides, all pharmacologic agents should be administered with caution, and the dosage adjusted for renal clearance.[60-62]

Myoglobinuria is an important cause of renal failure in patients who undergo revascularization after prolonged periods of limb ischemia. Circulating as a breakdown product of muscle death, myoglobin is filtered freely by the glomerulus. Myoglobin exerts its toxicity through direct tubular cell injury and via precipitation and obstruction of the tubule. Hematuria after reperfusion of a profoundly ischemic extremity suggests pigment toxicity and should prompt urinalysis. Myoglobinuria is suggested when the urine is dipstick positive for blood but no red blood cells are present on urinalysis and can be confirmed by testing for urine myoglobin. When diagnosed, renal injury may be lessened by maximizing the urine flow rate through the infusion of intravenous crystalloid and diuretics (mannitol) and by alkalinizing the urine.[63]

Contrast-Induced Acute Kidney Injury Nephropathy

Administration of contrast media continues to be a frequent cause of hospital-acquired renal failure. Over the past few years, the increasing number of diagnostic and interventional procedures requiring contrast agents has paralleled the increasing incidence of CI-AKI. CI-AKI now accounts for more than 10% of cases of hospital-acquired renal failure and is the third leading cause of iatrogenic AKI in hospitalized patients. CI-AKI is associated with an increase in hospital mortality, length of stay, and cost.[64-73]

Conventional contrast agents have iodine incorporated into their structure to absorb x-ray photons, thereby achieving visualization of the vasculature. The nephrotoxicity of such iodinated contrast agents has been recognized for many years. The principal site of contrast-induced nephrotoxicity is the renal tubule from transient regional renal ischemia; the effects on glomerular function seem to be mild.[74] Nonionic contrast agents are now available and provide comparable absorption of x-ray photons, yet are significantly less charged than traditional agents. However, severe adverse renal events still continue to plague the use of nonionic contrast media.[71] Renal nephrotoxicity after exposure to ionic agents occurs most commonly in patients with preexisting renal insufficiency (relative risk of 3.3) alone or in combination with diabetes mellitus, especially diabetes type 1. Other risk factors, such as dehydration, volume of contrast agent used, and simultaneous exposure to other nephrotoxins, contribute to the likelihood of acute contrast-induced nephrotoxicity.[70] Additional risk factors include multiple myeloma and heavy proteinuria. Overall, the incidence of acute renal dysfunction after contrast-enhanced angiography varies from 0% to 10%, although these estimates are skewed by several studies that included only diabetes type 1 patients. In one study, hospital-acquired nephropathy occurred in 12% of patients. In patients with normal renal function, however, the incidence of CMIN is just 1% to 2%.[71] Although diabetic and nondiabetic patients with renal insufficiency are at increased risk for contrast-induced ARF, diabetics seem to recover less often and are at greater risk for permanent dependence on dialysis as a consequence of contrast-induced ARF.[74-79]

One of the difficulties in treating or preventing renal failure after the administration of contrast media is that the biochemical mechanisms of CI-AKI have not been identified. One group of studies has hypothesized that NO contributes to preservation of renal blood flow and function in normal and pathologic states. Several studies have shown that inhibition of NO, before the administration of radiocontrast material, results in abolition of the medullary vasodilatory response and contributes to regional hypoxic renal tubular injury.[80-83] Heyman et al.[81] also suggested that maintenance of local vasodilatory prostaglandins, in particular PGE2, is likewise important in maintaining regional blood flow to the medulla. Myers et al.[84-86] combined the use of in vivo microdialysis and laser Doppler blood flow analysis to identify the clinically relevant intrarenal vasodilators (cortical and medullary) that are required to maintain microvascular blood flow during exposure to contrast material. The ionic agent Conray decreased superior mesenteric artery (SMA) blood flow, whereas the nonionic agent Optiray (Mallinckrodt) did not. Neither Conray nor Optiray altered total renal or aortic blood flow. Conray caused a marked decrease in cortical and medullary blood flow and NO synthesis, but did not alter PGI2 or PGE2. Optiray decreased medullary and cortical blood flow and cortical NO synthesis. Unlike Conray, Optiray did not decrease medullary NO synthesis, but profoundly decreased medullary and cortical PGE2 and PGI2 synthesis. These findings suggest that both Conray (ionic contrast agent) and Optiray (nonionic contrast agent) decrease renal cortical and medullary blood flow and renal function, although the intrarenal mechanisms differ. The decrease in renal cortical and medullary blood flow occurred without a decrease in total renal blood flow, thus suggesting that the decrease in renal microvascular blood flow induced by ionic and nonionic contrast agents occurs as an early injury. The Conray-induced fall in SMA blood flow may contribute to intestinal ischemia-reperfusion and distant organ dysfunction, including the kidney. These findings suggest that contrast-induced renal injury is due to local and systemic mechanisms. Preservation of normal levels of renal cortical and medullary NO synthesis and SMA blood flow may be required to prevent or lessen contrast-induced renal injury.[86,87]

Specific measures to minimize the risk for CI-AKI are controversial, and the results from controlled studies are largely inconclusive. Nevertheless, the basic relationship between the

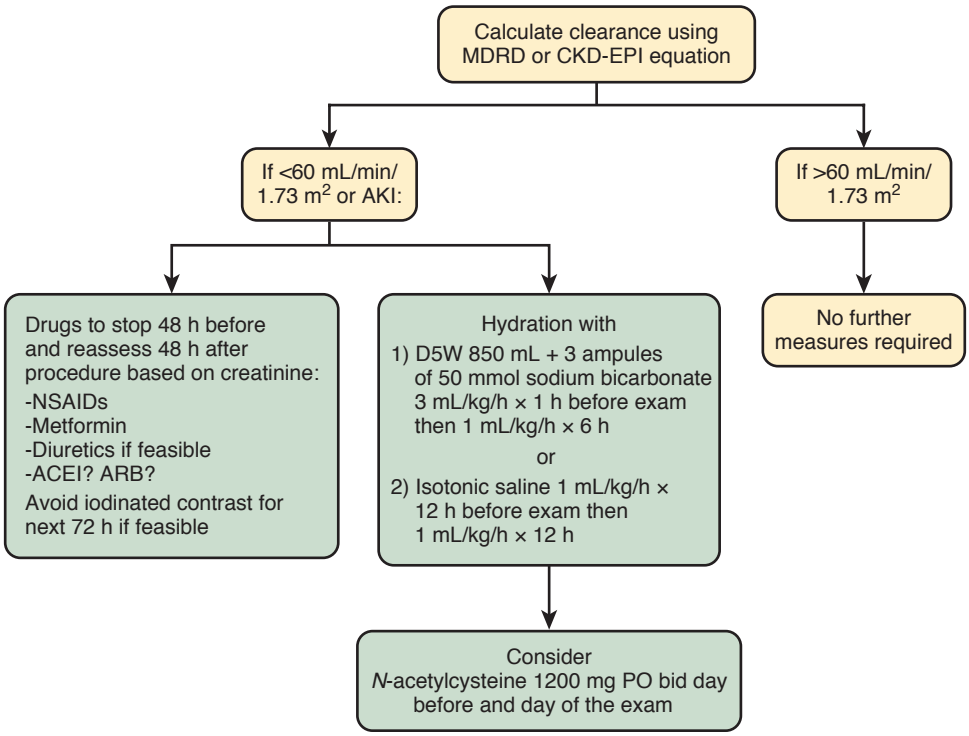

Figure 44.4 Management of patients receiving iodinated contrast media. *ACEI*, Angiotensin-converting enzyme inhibitor; *AKI*, acute kidney injury; *ARB*, angiotensin receptor blocker; *CKD-EPI*, Chronic Kidney Disease Epidemiology Collaboration; *D5W*, 5% dextrose in water; *MDRD*, modification of diet in renal disease; *NSAIDs*, nonsteroidal antiinflammatory drugs. Philadelphia: 2015: 842–854.)

use of contrast material and the risk for contrast-induced nephropathy seems to be related to the amount of time that the kidney is exposed to the contrast material. The Prevention of C-I AKI Consensus working panel recommends that measures to reduce the AKI risk should be implemented in patients with a baseline estimated GFR (eGFR) below 60 mL/min per 1.73 m^2, and are presented in Fig. 44.4. Maximizing the urine flow rate during and immediately after angiography and limiting the quantity of contrast agent used are important considerations.[88] The rationale for the use of isotonic sodium bicarbonate is based on animal studies showing that bicarbonate is capable of scavenging reactive oxygen species and that the increased pH in the proximal tubule could reduce superoxide levels. Merten et al.[89] demonstrated the potential efficacy of sodium bicarbonate hydration before, during, and after the use of contrast agents. The current recommendation for sodium bicarbonate use is presented in Fig. 44.4. We have successfully used this protocol over a 10-year period.

Although attempts to calculate a safe upper limit of contrast material have met with some success, no definitive limit currently exists.[90] It seems prudent to limit the quantity of non-ionized contrast agent to less than 50 to 75 mL in patients with a significant reduction in GFR (<20-30 mL/min). In some instances, digital subtraction techniques have been useful in limiting the quantity of contrast material required. Other adjuncts or alternatives to conventional angiography include carbon dioxide gas,[91] and abdominal ultrasound with visceral and/or renal artery duplex sonography. MR angiography with gadolinium is no longer considered a viable option because of reports of nephrogenic fibrosis in patients with compromised renal function.[92]

By scavenging reactive oxygen species, N acetylcysteine (NAC) may protect against contrast-induced nephrotoxicity. Tepel et al.[93] studied patients with chronic renal dysfunction who required administration of nonionic contrast for computed tomography. They documented a significant reduction in serum creatinine with the use of oral acetylcysteine and hydration versus placebo and hydration.[93] However, there are as many studies showing either a benefit or no benefit from the use of acetylcysteine.[93-96] If NAC is to be used, the current recommendation is 1200 mg administered twice daily on the day before and the day of the procedure (see Fig. 44.4). ACE inhibitors and angiotensin II receptor antagonists are withheld for at least 72 hours before aortic reconstruction or exposure to arterial contrast agents. Selective beta-blockers and calcium channel blockers are substituted when necessary.

ALTERED RENAL FUNCTION DURING AORTIC SURGERY

Fluid Shifts Associated With Aortic Surgery

Reconstruction of the abdominal aorta is associated with volume shifts within fluid compartments. These shifts stem from the

local tissue trauma that occurs with operative dissection, from hemodynamic consequences that occur with aortic clamping and unclamping, and from operative blood loss. In large part, the changes are mediated through transcapillary and transcellular movement of fluid. The net movement of water and solutes from the intravascular, extracellular compartment (plasma) to the interstitium (extracellular or third space) normally takes place at the precapillary level secondary to increased hydrostatic pressure. Reentry of fluid back into the intravascular compartment in the distal capillaries is favored by intravascular protein albumin, which exerts an oncotic pressure gradient. Normally 7% of the intravascular albumin arriving at the capillary level crosses the capillary membrane into the interstitial space. This extravascular protein eventually enters the lymphatics and ultimately returns to the intravascular pool. The operative dissection results in the disruption of lymphatic channels and the release of inflammatory mediators that cause local and systemic alterations in tissue perfusion, contributing to increased capillary membrane permeability to albumin.[97] The exact mechanisms involved are not currently understood, but the resultant effects are a flux of albumin into the interstitium and subsequent decrease in water reabsorption into the intravascular space. The decrease in intravascular volume activates neuroendocrine mechanisms that decrease renal excretion of sodium and free water. In addition, there is net movement of sodium and water into the intracellular space from the extracellular compartment. This process is due to a relative decline in the normal cellular transmembrane potential after ischemia-reperfusion, shock, or both, secondary to blood loss.[98] The causes of the decline in transmembrane potential are unclear, but are due, in part, to impaired function of the Na^+, K^+-adenosine triphosphatase pump and loss of active ion transport. This cellular swelling is also governed by a change in intracellular calcium homeostasis and an increase in the intracellular level of calcium.[99] During resuscitation, the abnormalities in intracellular sodium concentration and water are reversed.

The normal response to decreased circulating intravascular volume is to mobilize extracellular (third-space) interstitial fluid. Temporary ischemia in tissue beds during aortic surgery, the shift in acid-base balance in the involved tissue beds, the adverse impact of unreplaced blood loss, the potential reductions in cardiac and renal performance during aortic cross-clamping, and stimulation of stress-induced neuroendocrine mechanisms contribute to the injury-induced shift of total body water from the functional circulating blood volume into the third space.[100,101]

Determination of intravascular volume and its associated solutes after major surgery has been of dramatic benefit to the intraoperative and early postoperative fluid management of patients undergoing major vascular surgery. The increased obligatory losses of intravascular volume associated with major surgery have led to the current use of balanced salt solutions (5% dextrose, lactated Ringer solution) for volume replenishment.[102] Hourly postoperative fluid requirements may be several-fold higher than requirements during the resting nonoperative state. The increased need for fluid replacement continues in the immediate postoperative period because of continued sequestration of fluid into areas of the operative site and the persistent effects of a complex array of inflammatory mediators.[103] Mobilization of the sequestered third-space fluid is delayed for 2 to 5 days, depending on the magnitude of operative and postoperative stress, cardiac performance, and intravascular oncotic pressure. Reabsorption of third-space fluid usually begins on postoperative day 2 or 3. If not managed with an appropriate reduction in maintenance parenteral fluid administration or the addition of diuretic therapy, reabsorption of third-space fluid can lead to intravascular volume overload and acute congestive heart failure.

Although renal insufficiency continues to be a complication after treatment of suprarenal aneurysms and renal artery occlusive disease, very few studies have assessed the effect on renal function of clamping the aorta above and below the renal arteries. A series of studies by Myers et al.[84,104-105] examined the simple question of whether suprarenal aortic clamping and reperfusion (renal-SRACR) preserves renal function as opposed to clamping the renal arteries above the superior mesenteric artery (SMA-SRACR). In an experimental model, both SMA-SRACR and renal-SRACR were shown to decrease medullary and cortical blood flow and NO synthesis. SMA-SRACR downregulated cortical iNOS, whereas renal-SRACR did not. The use of superoxide dismutase (inhibitor of oxygen-derived free radicals [ODFRs]) restored cortical and medullary NO synthesis after SMA-SRACR (but not renal-SRACR), suggesting that the ODFRs generated during mesenteric ischemia-reperfusion were one of the systemic mechanisms contributing to decreased renal NO synthesis. SMA-SRACR profoundly decreased creatinine clearance, far greater than the decrease in clearance that occurred after renal-SRACR. These data suggest that clinically relevant cortical and medullary vasodilators (NO and vasodilator prostanoids) are required to maintain microvascular renal cortical and medullary blood flow after both SMA-SRACR and renal-SRACR. The data also suggest that maintaining SMA blood flow and preventing ODFR production could help maintain renal microvascular blood flow.[84,85,104-105]

Renal Failure Associated With Aortic Surgery

Aortic repair requiring suprarenal cross-clamping poses a significant risk for an ischemic renal insult. Rates of AKI approaching 18% have routinely been quoted for elective repair of thoracoabdominal aneurysms in larger series. Contemporary series report the occurrence of AKI after repair of infrarenal aortic aneurysms range from 1% to 13%.[37-47] The evolution of AKI depends on the clinical circumstances of the operation, the age of the patient, blood loss, myocardial dysfunction, the presence of sepsis, the level of aortic repair, preoperative renal function, intraoperative and postoperative events, and overall previous health of the patient. Mortality in patients with postoperative renal failure as an isolated system failure ranges from 25% for nonoliguric renal failure to 70% for oliguric renal failure.[37-47,106-109] Determinants of outcome include the preexisting disease and precipitating events. When renal failure is only one of several system failures, mortality is extremely high, approaching 100% for three or more organs failing simultaneously.[110-113] Unfortunately, the pathophysiology and

thus the prevention of multiorgan system failure have not been elucidated.

A temporary isolated period of renal ischemia caused by suprarenal aortic cross-clamping, temporary renal artery occlusion, a single episode of hypovolemic shock, post-cross-clamp hypotension, or cardiogenic shock in the perioperative period is the most common cause of acute renal dysfunction and renal failure associated with aortic surgery.[114-120] Studies in patients with postischemic AKI have shown minimal, if any, disturbance in glomerular architecture, yet profound tubular disruption supports the notion that the injury is initiated through tubular luminal obstruction caused by sloughed tubular cells.

Clinically observed rates of renal failure after aortic surgery suggest that the incidence of AKI can be correlated with the level of aortic repair. Svensson et al.[107] Kashyap et al.[108] and Allen et al.[109] reported an 18% incidence of renal failure (serum creatinine >3 mg/dL [>265 μmol/L]) and a 9% rate of dialysis-dependent renal failure in patients who underwent thoracoabdominal aneurysm repair. Series using regional renal hypothermia for renal protection and a clamp-and-sew technique identified the occurrence of AKI in 11.5% of patients.[101] Factors that predicted renal dysfunction included a preoperative creatinine level greater than 1.5 mg/dL (133 μmol/L) and a total cross-clamp time of more than 100 minutes. These results do not seem to differ from series in which partial left heart bypass and distal aortic perfusion were used.[108] In cases of juxtarenal and suprarenal abdominal aortic aneurysm (AAA) repair, preservation of renal function may be enhanced by renal hypothermia.[109] For elective infrarenal aortic surgery, a preoperative creatinine clearance of less than 45 mL/min has been associated with a significant risk for subsequent AKI. In the same series, no patient with a preoperative serum creatinine concentration of less than 1.5 mg/dL (133 μmol/L) required postoperative dialysis, whereas 8% of patients with a preoperative serum creatinine level greater than 1.8 mg/dL did.[109]

Another important cause of AKI in aortic surgery is renal atheroembolism.[121,122] The quantity of microembolization produced during surgery depends on the emboligenic potential of the atheromatous debris and the operative techniques used to prevent such an event. The clinical impact of renal microembolization depends on the quantity of functioning renal units before the procedure and the presence of other causes of AKI. In the absence of other factors favoring AKI and a normal mass of functioning nephron units, relatively large amounts of atheromatous microemboli can accumulate without an immediate impact on renal function, whereas in patients with minimal renal reserve, even minor microembolization can lead to AKI.[122]

The use of endovascular aneurysm repair (EVAR) has also been associated with an increased risk of renal dysfunction. This can be secondary to direct trauma to the renal arteries with suprarenal fixation barbs or dissection of the renal artery during the repositioning of a mal-deployed aortic endograft with suprarenal barbs.[123-128] In one series describing open and endovascular repair of ruptured AAAs, the incidence of AKI was 36%, with a higher incidence of AKI and mortality seen in the group treated with open surgical repair.[129]

Recently, there has been increasing experience with the use of chimney snorkel/periscope techniques and the introduction of fenestrated grafts for treatment of thoracoabdominal aneurysms; juxtarenal aneurysms; aneurysms with a short, severe angled proximal neck; and asymptomatic, symptomatic, and ruptured aneurysms. These technologies have allowed repair of these complex aneurysms with far less morbidity and mortality than open repair. However, they have a significant impact on perioperative renal function with rates of AKI between 10% and 36%.[130-136] In one study, fenestrated EVAR had a higher incidence of perioperative AKI than open repair, yet by 1-year follow-up, renal function was the same in both groups.[130]

Protection of Renal Function During Aortic Surgery

Renal function protection strategies during aortic surgery include limiting the period of warm renal ischemia (<40 minutes), providing intravenous fluid hydration preoperatively, adequate blood volume replacement, avoiding repetitive or prolonged renal ischemia, and maintaining maximal parameters of cardiac performance. In addition, other protective measures (currently used and experimental) include the use of routine heparinization, mannitol, furosemide, dopamine, fenaldopanan, atrial natriuretic peptide other diuretics, renal hypothermia, and renal vasodilating drugs and during thoracoabdominal aortic surgery patient-specific surgical adjuncts, including renal endarterectomy and open stent placement.[137-163] Use of all these measures is directed toward minimizing renal tubular ischemia and metabolic needs during periods of ischemia, or prevention of tubular obstruction by sloughed tubular cells. No single modality or combination of modalities entirely prevents renal injury during aortic surgery.

Distal aortic perfusion may be used to maintain renal perfusion during repair of thoracoabdominal aneurysms. This technique is most attractive during the repair of an isolated thoracoabdominal aneurysm[160,161] or when complex disease precludes prompt completion of the proximal thoracic aortic anastomosis.[162] Distal aortic perfusion may be modified with "octopus" catheters to perfuse the renal arteries directly during distal reconstruction.[163] Because the routine use of distal aortic perfusion in these cases has been associated with an increased incidence of AKI, other strategies to provide renal protection may be considered.

Regional renal hypothermia has been used sporadically for many years to protect renal function during ischemia, based on the premise that decreases in core temperature significantly reduce metabolic needs. The technique usually involves the renal infusion of 500 mL to 1 L of cold (4°C-5°C) crystalloid solution, with or without other additives. Animal studies have shown that the first 10°C reduction in tissue temperature seems to provide the greatest protection. Postoperative serum creatinine levels and renal tubular morphology data revealed that a protective effect occurs with a minimal sustained decrease in core temperature to 35°C.[164]

Operative technique during aortic reconstruction should avoid repetitive aortic cross-clamping. Some authors use temporary renal artery occlusion immediately before application

of the aortic cross-clamp whenever the aortogram suggests the presence of complicated peri-renal atherosclerosis. These authors believe that this maneuver has been an important adjunct in minimizing the incidence of postoperative ARF in their patients.

It is not uncommon that infrarenal AAAs may extend superiorly to the level of the renal arteries. In these cases, the surgeon may facilitate the exposure of the suprarenal aorta and expedite repair by transecting the left renal vein divided (LRVD). Because of the collateral drainage of the left kidney, it is thought that permanent ligation of the LRV may be a safe procedure, without reconstruction.[165-167] Several series have shown increased renal and pulmonary complications following LRVD,[165-168] so this technique should only be used when necessary.

In performing ligation of the LRV, one must remember that the main tributaries are the left gonadal vein, the left ureteral vein, capsular veins, lumbar veins, and the ascending lumbar vein from above, and the left middle suprarenal vein and the inferior phrenic vein from below. LRVD toward the inferior vena cava will spare the tributaries and thus preserve renal function. If the case has gone well, I would recommend reconstruction of the LRV to prevent a reduction in renal function, although only seen in a small number of patients. In vascular surgery patients, nerve damage can result from acute or chronic ischemia, trauma, compression, and associated comorbid disease. This chapter describes the following:

1. Ischemic neuropathy—an under-recognized form of peripheral nerve damage that must be distinguished from ischemic pain
2. Nerve trauma—which can be prevented by knowledge of the relevant anatomy
3. Other neuropathies encountered in vascular patients consequent to systemic diseases

STRUCTURE OF A PERIPHERAL NERVE

The peripheral nerves are composed of nerve fibers, Schwann cells, collagen, small vessels, and endoneurial fluid. Large nerves derive their nutrient and oxygen supply from the vasa nervorum, whereas smaller nerves are able to rely on diffusion through the interstitial space to supply their metabolic demands. The oxygen requirement of a mammalian nerve is less than that of other tissues, even when the requirement is increased by activity.[1] Hence,

Keywords

Ischemic Neuropathy
Ischemic Monomelic Neuropathy
Iatrogenic Nerve Injuries

peripheral nerves have an inherent resistance to ischemia. The large nerves of the extremities contain multiple redundant collateral networks of vasa nervorum supplied by sequential branches of adjacent arteries, while the inner portions of the nerves contain an extensive pattern of epineural vessels.[2,3] Due to rich collateralization, interruption of the blood supply to a segmental portion of the nerve usually does not result in ischemic nerve injury.[4,5] One notable exception is ischemic monomelic neuropathy (IMN), an infrequent ischemic nerve injury following acute limb malperfusion, which is characterized by multiple distal axonal infarctions and resultant motor and sensory mononeuropathies.[6,7]

CAUSES OF NERVE DAMAGE

Ischemic Nerve Injury

The true incidence of ischemic neuropathy in patients with peripheral arterial disease (PAD) is difficult to determine; the symptoms of ischemic nerve injury may mimic either rest pain associated with arterial insufficiency or decreased sensation due to diabetic neuropathy. Historically, the incidence of clinically detectable ischemic neuropathy associated with PAD has been estimated to be as high as 88%.[8] This has been confirmed in contemporary studies reporting similar incidence of pain and sensory disturbances in this cohort,[9] with nearly universal presence of occult nerve dysfunction detectible by electrophysiologic nerve conduction studies.[10-12] Both acute and chronic ischemic conditions have the potential to cause nerve injury, although the mechanism of ischemic injury specific to PAD has not been fully elucidated.

Acute Ischemic Neuropathy

Animal models of acute limb ischemia have demonstrated the ability of injured mammalian nerve tissue to recover after short periods of ischemia subsequent to occlusion of large inflow arteries[13] and smaller vasa nervosum.[14] There is, however, a certain time threshold in animal models, between 6 and 10 hours, beyond which the neurologic damage is irreversible.[15,16] Peripheral nerve tissue initially recruits oxygen and nutrient supply from the surrounding interstitial fluid. The rich collateral circulation within the nerve bundle itself is also protective against ischemic nerve injury. Eventually persistent hypoxemia and hypercapnia lead to hyperkalemia and acidosis, which in the local milieu of the ischemic nerve may contribute to irreversible depolarization of the axon cell membrane.[17,18] Exactly how much ischemia the human peripheral nerve is able to tolerate without irreversible injury is still unknown.

IMN, a subcategory of acute neuropathy, is relatively uncommon and the mechanism of injury is not completely understood. The pathophysiology of IMN does not result in the characteristic Wallerian degeneration seen histologically with other severe nerve injuries, where fragmentation of both the axon and myelin are early responses. Consequently, nerve biopsies following IMN will not display axonal degeneration and demyelination.[19] It is believed that altered blood flow through the vasa nervorum causes acute but reversible conduction block. Persistent malperfusion leads to distal axonal infarction and manifests as multiple axonal-loss mononeuropathies in the extremity.[20] IMN has been proposed to result from acute ischemia superimposed on predisposing factors such as diabetic neuropathy and peripheral vascular disease.

Chronic Ischemic Neuropathy

Since reliable experimental models for chronic limb ischemia are nonexistent, researchers have focused on using histologic findings of peripheral nerve specimens obtained from patients with chronic PAD. These specimens show segmental demyelination and remyelination, as well as axonal degeneration and regeneration.[8] The mechanism by which chronic limb ischemia produces changes in the peripheral nerve is still not known; however, similar morphologic changes in peripheral nerves were observed following both acute and chronic ischemia, thus suggesting that the lack of blood flow and oxygen delivery have the same ultimate effect when present acutely or over time.[21] The severity of the chronic ischemia so far has not been shown to correlate with the degree of histologic damage found in peripheral nerves.[22] Furthermore, Lacroix et al.[23] suggest that the injury observed in chronically ischemic limbs may not be a result of slow progression of the ischemic process but rather the accumulation of multiple repeated episodes of acute ischemia in the setting of chronic PAD. This is supported by more recent evidence that ischemic preconditioning, which tends to be beneficial to skeletal muscle tissue, is harmful to peripheral nerve tissue.[24]

Traumatic Nerve Injury

Peripheral nerves with anatomic proximity to the major arteries and veins of the extremities are at risk for iatrogenic injury during vascular interventions. Without a commanding knowledge of the anatomic relationships of structures within the major neurovascular bundles, vascular surgeons may successfully restore flow to an extremity yet leave significant neurologic deficits because of surgical trauma. Fortunately, most peripheral nerve injuries that occur during operative exposure result in transient nerve dysfunction (neurapraxia) that recovers with time.

Traumatic injury can occur via several mechanisms, and direct division or ligation of a nerve renders the nerve immediately and permanently damaged. Although reconstruction of divided nerves is possible with acceptable rates of functional recovery, the outcome is variable.[25-29] Other mechanisms include stretch injury from improper retractor placement and thermal injury from electrocautery devices. Compressive injury can result from hematoma formation or from improper patient positioning on the operating table. Nerves can also be injured by clamps or entrapped by sutures. The ability to avoid nerve injury during operative procedures is based on a high level of technical precision with constant vigilance for anatomic relationships. Except where the nerve is completely severed, the peripheral nerves have remarkable capacity to regenerate and functional outcome in most instances is favorable.[29-31]

Other Causes of Nerve Injury

A proportion of patients evaluated by a vascular specialist will have peripheral neuropathy that is not due to ischemia or trauma

BOX 45.1 Examples of Common Types of Neuropathy: Causes

Commonly Unilateral

- Entrapment
- Trauma
- Ischemia
- Vasculitis

Commonly Bilateral

- Metabolic (diabetes, uremia)
- Toxic (alcohol, drugs, metal)
- Connective tissue disease, vasculitis
- Deficiency (Vitamin)
- Inflammatory
- Monoclonal gammopathies
- Human immunodeficiency virus infection

and it is important to include these other causes in the differential diagnosis (Box 45.1). Diabetic neuropathy is the most commonly encountered alternative cause of peripheral neuropathy seen by vascular specialists.[32] Risk factors include increasing age, increasing length of time being diabetic, poor overall glycemic control, poor lipid metabolism, inadequate blood pressure control, obesity, and metabolic syndrome.[32-34] The etiology of the nerve damage is multifactorial and not completely understood, but the metabolic derangements associated with chronically elevated blood glucose levels and abnormal insulin homeostasis are thought to be the major determinants.[35] Vascular disease in the microcirculation is also believed to play a role in nerve damage, thus making the difference between diabetic neuropathy and ischemic neuropathy less distinct.[36] Other causes of peripheral neuropathy include alcoholism, uremia, drug intoxication, medication side effects, vasculitis, autoimmune disorders, infectious causes, and inflammatory causes. Most often, these neuropathies are symmetric.

DIAGNOSTIC EVALUATION

History and Physical Examination

Ischemic pain at rest is most often unilateral, involves the foot, is usually worse at night, and is generally relieved by placing the extremity in a dependent position to allow gravity to assist in blood flow. Neuropathic pain is usually constant and typically has no identifiable aggravating or alleviating factors. It is often described as shooting or burning pain associated with the sensation of numbness and tingling, and it is most severe distally in the toes or foot. These symptoms are unilateral in ischemic neuropathy but are bilateral and symmetric in metabolic neuropathies. After revascularization of a severely ischemic limb, persistent pain due to neuropathy rather than ischemia often emerges. The neuropathic pain is burning and paresthetic, is frequently worse with rest and at night, and is either unaffected or relieved by walking. The patient may perceive the foot to be cold, although it is, in fact, warm. The patient may also remark on stiffness or loss of mobility of the toes. Physical examination should include a detailed vascular examination supplemented by noninvasive vascular testing to document the degree of arterial ischemia.

Vascular Testing

Ankle pressure greater than 50 to 60 mm Hg or toe pressure greater than 30 mm Hg suggests adequate peripheral circulation, and ischemic rest pain is unlikely. Flat or monophasic Doppler waveforms indicate severe arterial insufficiency. When perfusion is inadequate, the pain may be due to ischemia, neuropathy, or both, and treatment should be directed first toward improvement of limb blood flow. If no ischemia is present, a neurologic evaluation should be performed. If ischemia is present, efforts should be made to correct the ischemia in parallel with any indicated neurologic testing.

Neurologic Testing

Ischemic neuropathy in the lower extremity may be accompanied by slight ankle weakness and depressed ankle reflex. There is unilateral sensory loss in a "stocking" distribution, particularly vibration sense. The small muscles of the affected foot may become atrophied. Unlike the findings in neuropathies caused by diabetes, uremia, drug intoxication, or alcoholism, the findings in ischemic neuropathy are asymmetric; sensory and motor findings occur exclusively or prominently in the limb that is affected by severe ischemia.

The peripheral neuropathy associated with diabetes is characterized by bilateral sensory loss, numbness and tingling, and pain in the hands, feet, fingers, and toes. Distal muscle weakness and muscle wasting are common, and ankle reflexes are absent. The pattern of distribution is symmetric over the involved extremities, in contrast to the unilateral pattern of ischemic neuropathy. Evaluation of individual nerves is discussed later under "Specific Nerve Injuries."

Electromyography and Nerve Conduction Studies

Electrophysiologic testing including motor nerve conduction studies, sensory nerve conduction studies, and needle electrode examination can establish the diagnosis and severity of ischemic neuropathy. With ischemic neuropathy, patients typically have a unilateral axonal neuropathy involving the distal tibial and peroneal nerves. Motor nerve conduction studies show decreased or absent compound muscle action potential amplitude following nerve stimulation in the affected foot.[37] Distal latency and the velocity of conduction in the calf portion of these nerves are relatively well preserved. These findings are in sharp contrast to diabetic and uremic neuropathy, where distal latencies and conduction velocities tend to be reduced below normal velocities at an early stage and in a bilateral, symmetrical pattern.

Sensory nerve conduction studies in ischemic neuropathy show decreased or absent sensory potential amplitudes from the sural, superficial peroneal, and plantar nerves, whereas sensory conduction velocity, when recordable, is normal.[37,38] Needle

electrode examination reveals muscle denervation in the small muscles of the affected foot, particularly in the sole of the foot, with fibrillation potentials at rest and large motor units of long duration in much reduced numbers. If the ischemia has been severe, denervation changes of a lesser degree are also seen in the muscles of the calf.[39]

GENERAL PRINCIPLES OF TREATMENT

Acute Ischemic Neuropathy

If a patient has acute arterial ischemia, revascularization will often improve the motor and sensory symptoms of ischemic neuropathy either immediately or over the first few weeks. If symptoms persist and the revascularization is deemed adequate, a neurologic cause of the pain should be suspected. The pain should be treated, and a neurologic consultation should be obtained.

Pain Control

Ideally, a neurologist or other specialist familiar with treating this condition should manage the pain from ischemic neuropathy. Treating the pain of ischemic neuropathy is often difficult, because the typical narcotic regimens used for postsurgical pain may not be effective, and individual response to commonly used drugs is highly unpredictable. Anti-inflammatory drugs and opiate medications are generally ineffective, although opioids or tramadol may be used to augment initial treatment during titration of other medications. First line therapy may include tricyclic antidepressants (TCAs) or selective serotonin and norepinephrine reuptake inhibitors (SSNRIs). Secondary amine TCAs (nortriptyline and desipramine) are generally better tolerated in the elderly than tertiary amine TCAs (amitriptyline and imipramine); however, all TCAs have potential cardiac toxicity and should be avoided in patients with ischemic heart disease.[40] SSNRIs (duloxetine and venlafaxine) have a more favorable side effect profile and less risk of cardiac toxicity, but analgesic efficacy is inconsistent.[41] Calcium channel α2-δ ligands (gabapentin and pregabalin) are also used for first line therapy but do not provide reliable relief for all patients. The most common dose-limiting side effects include somnolence and dizziness, and renal insufficiency requires dose reduction. Although well tolerated if titrated properly, it may take weeks to establish effective dosage.[41]

TRAUMA

Partial loss of nerve function after surgery will generally recover since nerves have the ability to regenerate. The rate of axonal regeneration is estimated to be 1 mm per day; thus, the recovery period may be lengthy.[19] In a patient with severe loss of motor and sensory function, surgical re-exploration should be considered. If a major nerve or branch is found to be divided, repair is indicated. If a nerve is acutely compressed because of a hematoma, surgical decompression should be performed promptly and will often result in the recovery of function. In cases in which symptoms persist without signs of healing and nerve conduction studies indicate loss of nerve function, surgical exploration with neurolysis and nerve grafting offers some hope of recovery of function, with encouraging results being reported in contemporary series.[26-31]

SPECIFIC NERVE INJURIES

Brachial Plexus and Upper Extremity Nerve Injuries

Anatomy

The brachial plexus gives rise to the five main terminal nerves of the upper extremity: the axillary nerve (C5, C6), the musculocutaneous nerve (C5, C6), the median nerve (C5–T1), the radial nerve (C5–C8), and the ulnar nerve (C8, T1). The superior, middle, and inferior trunks of the brachial plexus are intimately associated with the axillary artery, as they make the turn along the shoulder joint and become the lateral, posterior, and medial cords. Great care must be taken during operative exposure of the axillary artery to not injure the cords of the brachial plexus, because they are located on three of the four sides of the artery (Fig. 45.1).

The musculocutaneous and axillary nerves terminate in the upper part of the arm and are not routinely encountered during vascular exposure there. Likewise, the radial nerve is rarely encountered in its deep location posterior to the humerus, as it courses toward the extensor compartment of the forearm. However, in the upper part of the arm, the median and ulnar nerves are intimately associated with the brachial artery and basilic vein (Fig. 45.2). Avoiding the median nerve as it wraps around the brachial artery in a lateral-to-medial direction and

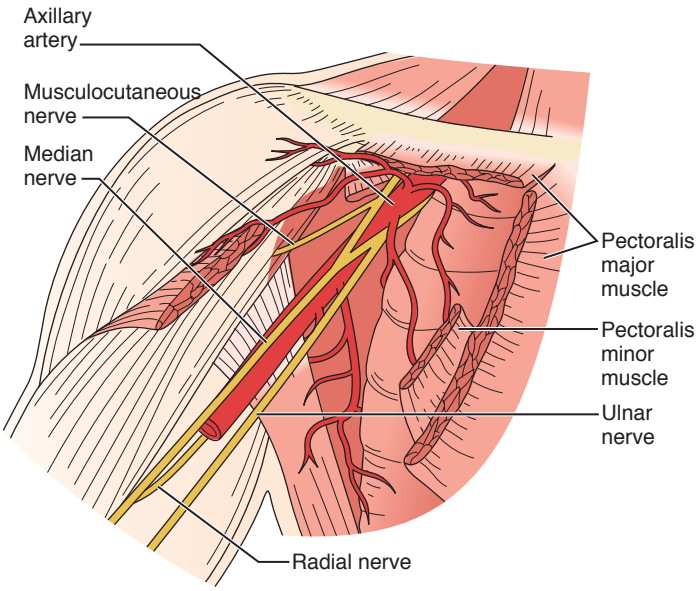

Figure 45.1 Relationship of the axillary artery to the brachial plexus nerves.

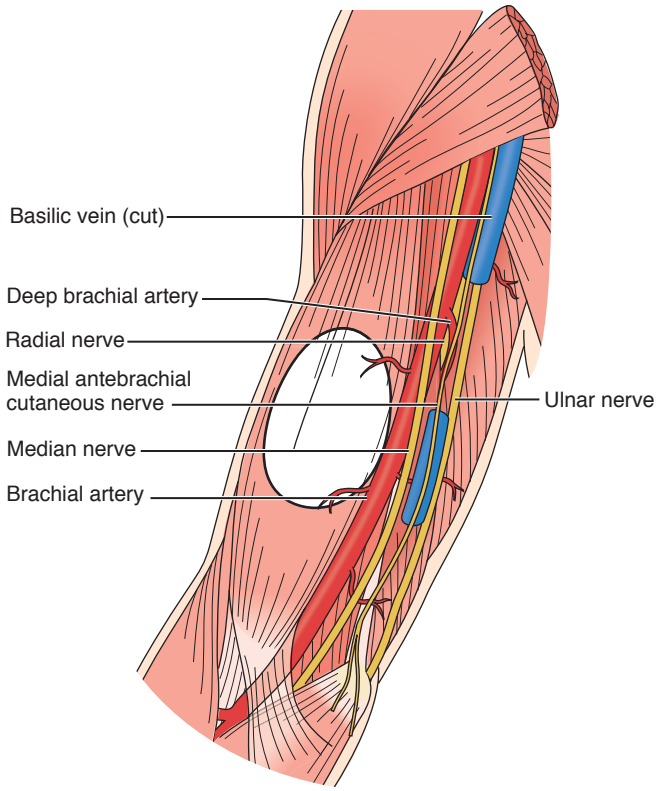

Figure 45.2 Relationship of the brachial artery and basilic vein to the median and ulnar nerves in the neurovascular bundle that runs deep to the medial brachial fascia.

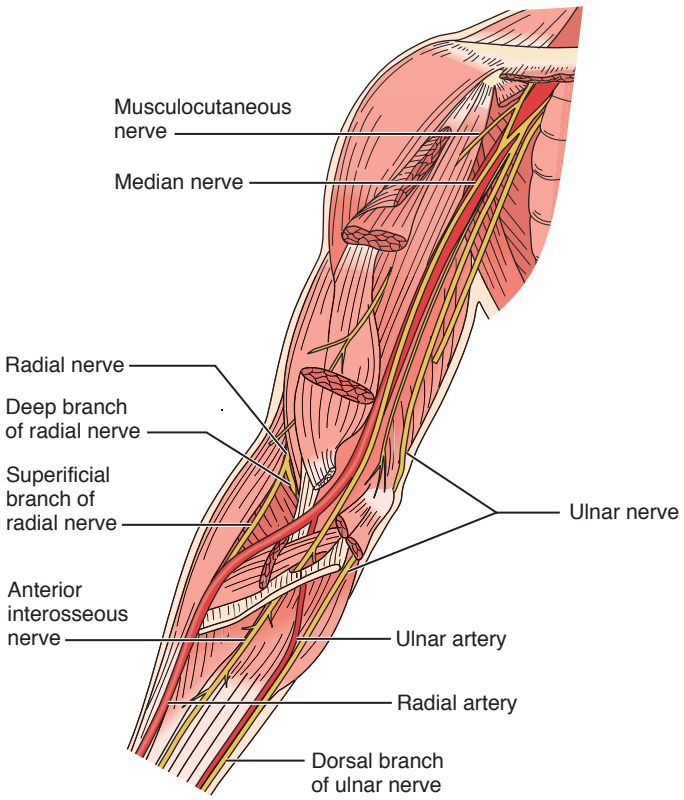

Figure 45.3 Relationship of named arteries and nerves of the upper extremity. Note that the ulnar nerve and ulnar artery are in close proximity at the wrist.

the ulnar nerve deep to the basilic vein is essential to prevent iatrogenic injury.

In the forearm, the median nerve is not routinely encountered, whereas the ulnar nerve, which runs adjacent to the ulnar artery into the hand, can be injured when the distal ulnar artery is exposed. The location of the ulnar nerve at the elbow also makes it vulnerable to compression injury from prolonged improper positioning (Fig. 45.3).

Etiology

The most common causes of injury to nerves in the upper extremities include direct surgical injury, compression, and traction. Procedures associated with injury include hemodialysis access, arterial puncture, radial artery harvesting, and venipuncture (Box 45.2).

Surgical Dissection

During thoracic outlet surgery, the brachial plexus can be injured by direct trauma or traction (see Chapter 124). Injury to the cords of the brachial plexus can also occur during exposure of the axillary artery, producing neurologic deficits in more than one peripheral nerve. In the upper part of the arm, the median nerve with its close proximity to the brachial artery and the ulnar nerve with its close proximity to the basilic vein can be injured by dissection of these vessels. The median and ulnar nerves in the upper part of the forearm can also be injured during surgical dissection of the major arteries.

BOX 45.2 Avoiding Upper Extremity Nerve Injuries

- Positioning patient: padding beneath elbow to avoid ulnar nerve injury
- Dissection: remember important anatomic relationships (median nerve/brachial artery, ulnar nerve/basilica vein)
- Careful hemostasis: avoid compression and nerve dysfunction secondary to hematoma
- Ultrasound guided percutaneous brachial access: avoid needle trauma to artery, leading to thrombosis/hematoma

Compression

The anatomic confines of the fascial compartments of the arm predispose the associated nerves to compression injury in the setting of compartmental swelling. Upper extremity nerves can be compressed by even a small hematoma, and peripheral neuropathy can occur secondary to hematoma formation in the neurovascular bundle following transaxial puncture.[39] Nerve injury during brachial artery catheterization has been reported at 0.2% to 1.4% resulting from direct needle trauma, compression from hematoma, and ischemia from brachial artery thrombosis.[42] Prompt surgical decompression of any postprocedure hematoma causing neurologic symptoms in the upper extremity may prevent permanent nerve damage.[43,44]

Hemodialysis Access

After hemodialysis access, patients may complain of pain and sensory loss in the hand and forearm from multiple causes. This may be the result of arterial steal syndrome or direct nerve compression by a hematoma or the arterialized vessel. Diagnosis, however, may be confounded in many patients because of coexistent diabetic or uremic neuropathy.[45-47] IMN is a distinct clinical entity characterized by severe neurologic impairment of multiple extremity nerves in the setting of normal or near normal blood flow. Although reported sporadically in the lower limb,[48] IMN is much more common after upper extremity procedures, particularly those involving the brachial artery.

Radial Artery Procedures

Studies evaluating the effects of radial artery harvest on the forearm have shown that neurovascular deficits in the immediate postoperative period usually resolve over time and suggest that ischemic injury is not very common.[49,50] The incidence of transient nerve dysfunction does not differ between harvest technique of sharp or electrocautery dissection.[51] Isolated nerve injury following transradial access for coronary artery catheterization is rare, but the use of larger sheath size may be associated with injury of the superficial radial nerve at the wrist.[52,53]

Clinical Findings

Upper extremity neuropathies are frequently misdiagnosed and mistaken for complications attributed to anesthesia or patient positioning. These types of nerve injury typically manifest in the immediate postprocedure period as motor and sensory deficits.

Axillary nerve injury results in weakness of shoulder abduction and sensory deficit over the deltoid muscle. Median nerve injury gives rise to sensory deficit in the first, second, third, and radial aspects of the fourth digits. There is concomitant weakness in the thenar muscles, which on occasion, extends to the flexors of the digits and wrist. Ulnar nerve injury results in numbness of the fifth digit and the ulnar aspect of the fourth digit, along with weakness of the hypothenar muscles. Abduction and adduction of all digits and flexion of the fourth and fifth fingers are also affected. Radial nerve injury results in weakness of wrist and finger extension.

IMN presents in the immediate postoperative period with intractable pain and variable, often severe, sensorimotor deficits which may involve any or all the upper extremity peripheral nerves. Arterial examination and noninvasive testing can be normal, but neurologic studies show decreased or absent amplitude with motor and sensory stimulation of the median, ulnar, and radial nerves in the presence of preserved conduction velocities.[54] Detailed evaluation with electrophysiologic studies helps determine the extent of involvement of the different peripheral nerves in these patients.

Treatment and Prognosis

Signs of nerve injury in the immediate postprocedure period warrant timely patient evaluation, assessment, and intervention. Any obvious sign of hematoma or bleeding complication in the presence of a neurologic deficit should prompt immediate wound exploration to relieve compression of the involved nerves. Occasionally, because small, clinically unapparent hematomas can cause compression and nerve dysfunction, exploration may be warranted even without external signs of hematoma. Imaging with ultrasound or computed tomography may aid in diagnosis. In patients with a delayed diagnosis or evaluation, the benefit of intervention decreases; however, operative reconstruction of traumatically injured nerves within 3 months of injury has shown acceptable rates of motor and sensory recovery.[55] Prompt recognition of IMN after arteriovenous fistula or graft with revision or ligation of the newly created access is essential; recovery of function and relief of pain is variable following access ligation, and in some individuals, sensory and motor deficits may be prolonged or permanent.[56]

SPINAL CORD AND LUMBOSACRAL PLEXUS INJURY

Anatomy

The spinal cord itself ends at L1–L2, but inferior to that level the thecal sac contains the branches of the cauda equina. The lumbosacral plexus provides the nerve fibers that supply innervation to the lower extremity. Fibers from the lumbar plexus form the lateral femoral cutaneous nerve (L2–L3), the femoral nerve (L2–L4), and the obturator nerve (L2–L4). Blood supply to the lumbosacral plexus is through five sets of paired lumbar arteries arising from the abdominal aorta, the deep circumflex iliac arteries (branches of the external iliac arteries), and the iliolumbar and gluteal branches of the internal iliac arteries. D fibers from the sacral plexus form the posterior femoral cutaneous nerve (S1–S3) and the sciatic nerve (L4–S3). The sciatic nerve divides in the posterior aspect of the mid-thigh into the common peroneal nerve (L4–S2) and the tibial nerve (L4–S3).

Etiology

Lower spinal cord injury and lumbosacral plexus injury can occur from dissection, traction, or compression after thoracic and aortoiliac interventions (Box 45.3). It is important to differentiate the two because the signs and symptoms are different, as are the outcomes.

Ischemia

Lumbosacral plexus neuropathy after aortobifemoral bypass grafting for aneurysm disease was described in 1970, evidenced by infarction of the plexus found on autopsy.[57] More recently, similar findings after open and endovascular aortoiliac procedures

BOX 45.3 Avoiding Lumbosacral Nerve Injury

- Dissection: iliac artery dissection—avoid nerves overlying psoas muscle
- Retraction: avoid self-retraining retractor compression of nerves
- Hemostasis: avoid hematoma compression of nerve structures

suggest that thrombosis of the internal iliac artery might play a causal role in the ischemic nerve injury.[58] The incidence of lumbosacral plexus injury after open aortoiliac operations may be as low as 0.3%, presumably secondary to pelvic ischemia, but the true incidence and risk factors remain ill-defined.[59-62] Case reports of lumbosacral nerve root injury and sciatic nerve injury have also been reported after endovascular stent-graft repair of the abdominal aorta,[63-65] with some authors reporting a lower incidence of nerve complications with endovascular repair compared to open repair.[66]

Trauma

The branches of the lumbosacral plexus are prone to direct injury during vascular surgical procedures. Exposure of the iliac arteries may require dissection and retraction of structures in the iliac fossa, with a corresponding risk of injury to the nerves coursing along the psoas major muscle. Improper or careless positioning of retractors (especially self-retaining devices) can lead to significant blunt injury to these nerve branches.

Compression

Another cause of lumbosacral plexus injury is acute compression from a retroperitoneal hematoma or chronic compression from iliac artery aneurysm or pseudoaneurysm.[67-69] Similarly, extraperitoneal hematomas from either surgical procedures or femoral catheterization may cause severe compression and injury to the femoral nerve in the iliac fossa.

Clinical Findings

Careful history and physical examination will reveal the level of injury when evaluating a patient with lower extremity sensory and motor dysfunction. Injury to the lumbosacral plexus most commonly produces unilateral motor and sensory loss and affects more than one peripheral nerve and dermatomal segment, unlike an injury in a peripheral nerve, which has a unique sensory and motor distribution. The weakness associated with a plexus injury may be in both the large proximal muscle groups and the smaller distal muscle groups, with flaccid paralysis, absence of reflexes, and a sensory deficit to pain, temperature, and vibration. Spinal cord injuries produce unilateral or bilateral dysfunction and spastic, hyperreflexic limbs with varying degrees of hip, knee, and ankle flexor weakness, along with an extensor plantar response. Typically, with an ischemic cord lesion, there is an identifiable sensory level deficit to pain and temperature, with preservation of position and vibration sense.

On electromyography, a lumbosacral plexus neuropathy will manifest as unilateral loss of sensory potentials, reduced motor conduction, absent paraspinal denervation, and the presence of denervation changes in muscles innervated by multiple nerves and roots. In spinal cord injuries, nerve conduction studies are normal, and there are no denervation changes.

Treatment and Prognosis

Overall, there is some evidence to suggest that lumbosacral plexus injury has a better prognosis than spinal cord injury, but definitive studies are lacking.[59] If the etiology can be determined, intervention may result in regaining nerve function. In the case of compression from hematoma or aneurysm, relief of the compression in the early stages of nerve dysfunction may improve the long-term outcome.[67-69] For nerves with ischemic injury, the likelihood of restoring nerve function with correction of the ischemia is less likely.

FEMORAL NERVE INJURY

Anatomy

The femoral nerve receives nerve fibers from L2 to L4, and it courses along the anterior surface or within the fibers of the psoas major muscle, passes deep to the inguinal ligament, and enters the femoral triangle immediately lateral to the common femoral artery. After exiting the femoral triangle, it forms multiple muscular branches to the muscles of the thigh and then continues to form its terminal branch, the saphenous nerve, which courses along the saphenous vein to the foot (Fig. 45.4). The main trunk of the femoral nerve receives its blood supply from the iliac branch of the iliolumbar artery, from the deep circumflex iliac artery, and from the lateral circumflex femoral artery in the femoral triangle.[4] This redundant blood supply provides protection against ischemic injury.

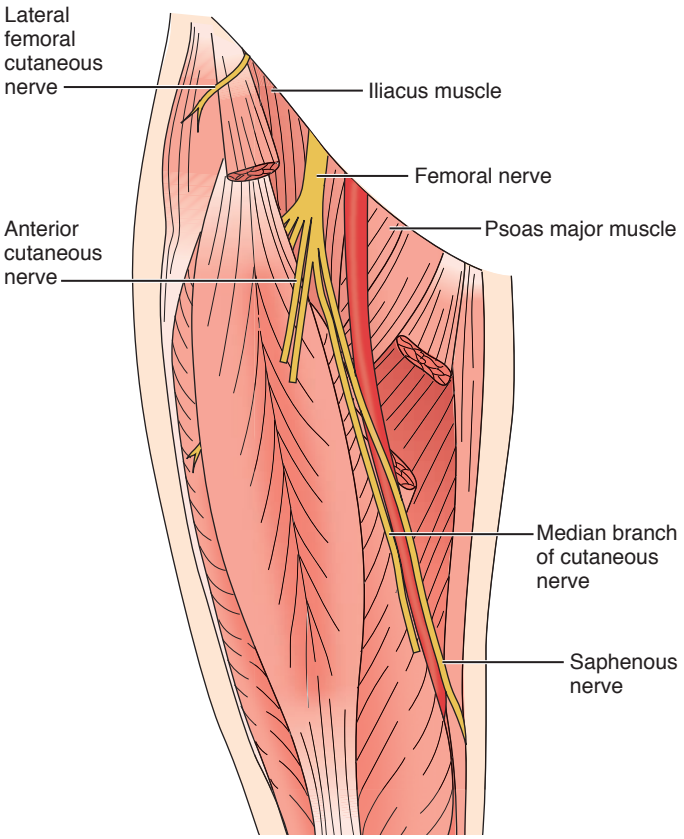

Figure 45.4 Anatomy of the femoral nerve.

BOX 45.4 Avoiding Femoral Nerve Injury

Traction: self-retaining retractors during pelvic surgery
Dissection: care in reoperative groin surgery
- Compression: postoperative and postcatheterization hematoma

Etiology

Femoral nerve injury is most commonly the result of traction injury, direct surgical trauma, electrocautery injury, compression injury, or ischemia (Box 45.4).

Traction

Most reported series suggest retraction injury to be the principal culprit, commonly from the use of self-retaining retractors placed to facilitate pelvic surgery. These injuries have been reported after urologic,[70] gynecologic,[71] colorectal,[72] laparoscopic,[73] orthopedic,[74] hernia,[75] spine,[76] and vascular[77] surgical procedures.

Surgical Trauma

The true incidence of iatrogenic femoral neuropathy remains unknown; most reports are retrospective and may not capture transient postoperative symptoms. Anecdotally, patients who undergo reoperative groin surgery may be at higher risk for postoperative femoral neuropathy, but conclusive evidence in the literature is lacking.[78] Electrocautery may be a factor in some cases; however, the impact of type of incision (vertical vs. oblique) on the development of a femoral neuropathy awaits further study.[79,80]

Compression

The presence of groin hematoma or retroperitoneal hematoma has been reported as a cause of femoral neuropathy.[40,81-83] Femoral neuropathy has been described following cardiac catheterization procedures using common femoral artery access in association with groin hematoma or false aneurysm at the access site.[84] Similarly, femoral neuropathy has also been associated with profunda femoris pseudoaneurysms compressing the adjacent femoral nerve following common femoral artery access.[85]

Ischemia

The true incidence of femoral neuropathy secondary to ischemia is unknown; it is presumably exceedingly low as the literature contains only case reports of femoral neuropathy caused by large-vessel occlusive disease.[86,87] Femoral neuropathy and lower extremity IMN have been reported with the use of intra-aortic balloon pump therapy.[48,88-90] It is unclear whether this is from prolonged presence of the large intra-arterial delivery system causing reduced flow, from thrombosis in the branch arteries that supply the femoral nerve, or from ischemic complications such as aortoiliac dissection and iliofemoral thrombosis.[89,91,92]

Clinical Findings

Femoral nerve injuries are manifested in the postoperative period as paresis or flaccid paralysis of the quadriceps muscle, diminished or absent extension of the knee, and reduced or absent patellar reflex. Loss of sensation is present along the course of the saphenous nerve, over the anteromedial aspect of the thigh and the inner aspect of the calf down to the medial malleolus. The discrete location of the signs and symptoms of femoral neuropathy are in contradistinction to a lumbosacral plexus lesion, which involves multiple peripheral nerves. The femoral nerve forms a medial cutaneous and an anterior cutaneous branch that produce isolated sensory symptoms when injury spares the motor branches.[93,94] The lateral cutaneous nerve of the thigh originates from the lumbosacral plexus directly and not from the femoral nerve and is more commonly injured during orthopedic pelvic surgery than vascular exposures.

Treatment and Prognosis

Additional testing consisting of motor and sensory nerve conduction studies and needle electrode examination is not usually necessary because the diagnosis can be made based on the history and physical examination. Fortunately, most femoral neuropathies from iatrogenic injury have an excellent prognosis. Treatment is conservative, and gradual return of nerve function is common.

SAPHENOUS NERVE AND SURAL NERVE INJURY

Anatomy

The terminal branch of the femoral nerve is the saphenous nerve. In the thigh, this nerve courses in the sub-fascial plane and accompanies the superficial femoral artery. In the proximal popliteal fossa, the saphenous nerve becomes more superficial as it penetrates the fascia and accompanies the great saphenous vein along the medial aspect of the extremity to the level of the ankle. The sural nerve arises from the tibial nerve in the popliteal fossa below the fascia, and descends laterally to the short saphenous vein in the groove between the medial and lateral heads of gastrocnemius muscle. A communicating branch from the peroneal nerve joins the sural nerve in the mid-calf, and there the nerve exits the fascia and courses down toward the lateral malleolus.

Etiology

The saphenous and sural nerves are closely associated with the great and short saphenous veins, respectively, in the lower leg and can be injured during vein harvest or venous extirpation with stripping and ablative procedures (Box 45.5).

Surgical Trauma

The saphenous nerve is prone to injury during harvesting and stripping of the great saphenous vein, especially below the knee. Over 60% of patients report some degree of sensory loss associated with great saphenous vein harvest incisions below the knee during lower extremity arterial reconstructions.[78] The rate of nerve injury was found to be 12.5% following endoscopic great

BOX 45.5 Avoiding Saphenous Nerve Injury

- Dissection: saphenous vein harvest, especially below the knee
- Thermal: endovenous ablation

saphenous vein harvest for coronary artery bypass grafting.[95] After great saphenous vein stripping, saphenous nerve injury was reported at rates from 27% to 40% based on subjective patient reports,[96-98] but with neurologic testing, the rate was found to be higher (58%).[97]

The sural nerve lies close and lateral to the short saphenous vein throughout its length and is at risk during harvest or stripping of the short saphenous vein, as well as dissection of the saphenopopliteal junction.[91,92] The occurrence of sural nerve injury with short saphenous vein surgery is thought to be lower than saphenous nerve injury following great saphenous vein harvest, although large series are lacking.[99]

Thermal Injury

The saphenous nerve is also prone to thermal injury during endovenous vein ablation, either with laser or with radiofrequency energy.[100] Some series have reported decreased incidence of saphenous nerve injury and duration of paresthesias with laser treatment compared to radiofrequency.[101,102] Ablation of the short saphenous vein may cause sural nerve injury in up to 4% of patients,[103] and nerve injury from ablation procedures can be mitigated with liberal use of circumferential tumescent anesthesia.[104]

Clinical Findings

Injuries to the saphenous nerve are uniformly manifested as sensory deficits (decreased sensation, paresthesias, and dysesthesias, in decreasing order of frequency)[105] in the anteromedial aspect of the calf to the level of the ankle.[78,95,97,98,105] Sural nerve injury presents with dysesthesias in the posterior calf or lateral ankle,[99] and there are no motor deficits associated with saphenous or sural nerve injury.

Treatment and Prognosis

Treatment of saphenous nerve injury is conservative, and the majority of patients report eventual resolution of symptoms[78,95,97,98,105] with infrequent reports (2.3%) of a negative impact on quality of life.[97] Rarely, patients with sural nerve injury may develop an unbearable chronic pain syndrome.[100]

TIBIAL AND PERONEAL NERVE INJURY

Anatomy

The sciatic nerve divides in the posterior portion of the midthigh into the common peroneal nerve and posterior tibial, or tibial nerve. The common peroneal nerve maintains a lateral course before dividing into superficial and deep branches. The tibial nerve accompanies the popliteal artery through the popliteal fossa and then continues distally within the posterior tibial neurovascular bundle (Fig. 45.5). The common peroneal nerve takes a lateral course from the posterior aspect of the midthigh, crosses the knee joint posterior to the fibular head, and wraps around the proximal fibula before dividing into the superficial and deep peroneal nerves. The superficial peroneal nerve runs deep to the fascia in the lateral compartment and extends to the foot unaccompanied by any major artery. In contrast, the deep peroneal nerve extends from its origin to enter the anterior compartment, where it descends along the intermuscular septum and accompanies the anterior tibial vessels to the foot. The tibial nerve continues its posterior course through the popliteal fossa adjacent to the popliteal artery before coursing through the deep posterior compartment and terminating in the medial and lateral plantar nerves that parallel the course of the posterior tibial artery and its branches.

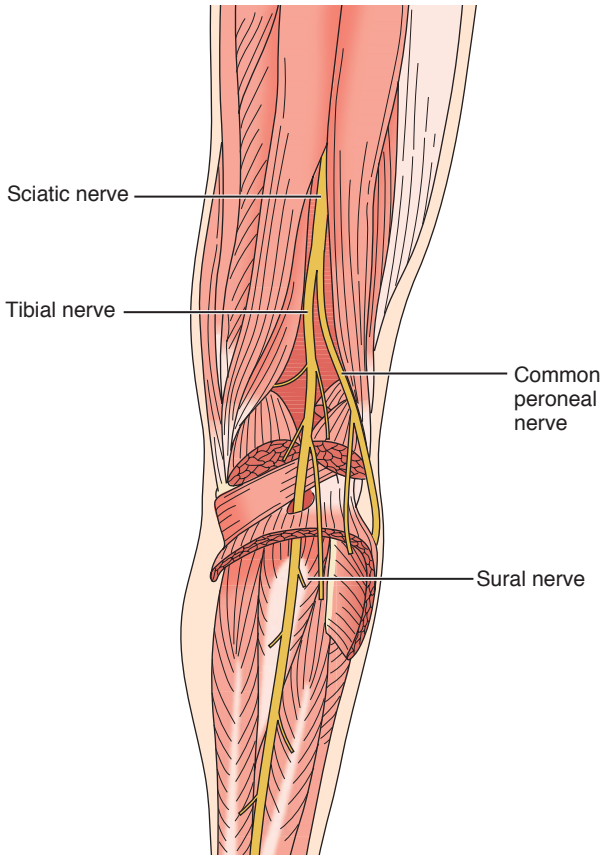

Figure 45.5 Anatomy of the sciatic, tibial, sural, and peroneal nerves.

Etiology

These nerves are vulnerable to iatrogenic injury due to proximity to the popliteal and tibial vessels and can be affected by episodic ischemia and high compartment pressure (Box 45.6).

Peroneal nerve injury is reported following surgical removal of the short saphenous vein (4.7%) and may be associated with

BOX 45.6 Avoiding Lower Leg Nerve Injury

- Dissection: popliteal/tibial exposure, lesser saphenous vein surgery
- Thermal: endovenous ablation lesser saphenous vein
- Compartment syndrome: prompt diagnosis and treatment

a saphenopopliteal junction located abnormally high above the popliteal skin crease.[106] Tibial and peroneal nerve injury complications have been reported in up to 20% of cases associated with short saphenous venous ablation techniques.[107] In a review by Drees et al.,[108] trauma and ischemia were the two most common causes of tibial neuropathy. Additionally, the deep peroneal nerve in the anterior compartment and the tibial nerve in the deep posterior compartment are at risk for injury from compartment syndrome in the leg, which is discussed in detail in Chapter 102.

Clinical Findings

Posterior tibial nerve injury causes weakness of plantar flexion of the ankle and toes with an absent ankle jerk and sensory loss on the sole and lateral aspect of the foot. Peroneal nerve injury is manifested as weakness of dorsiflexion, inversion, and eversion of the ankle, and weakness of dorsiflexion of the toes. These motor deficits are accompanied by loss of sensation in the dorsal aspect of the foot and toes with variable extension to the lateral aspect of the calf. Occasionally, these symptoms can be due to L5 or S1 nerve root compression; this can be differentiated by nerve condition studies and electromyography.

Treatment and Prognosis

The neurologic dysfunction associated with acute compartment syndrome can recover quickly with prompt decompression. Delayed decompression results in a greater degree of muscle damage and nerve injury and a poor prognosis for recovery. Ischemic peroneal and tibial neuropathies can only be managed expectantly, and accordingly, the prognosis for recovery is poor. Peroneal pressure palsies carry a good prognosis for recovery with conservative treatment. Traumatic injury to the peroneal and tibial nerves warrants surgical exploration if functional nerve loss is complete or if compression is suspected. Significant improvement in motor function and pain can be expected after operative repair of tibial and peroneal nerve injuries.

OTHER NERVES

Cranial nerve injury related to carotid artery surgery is described in detail in Chapter 91, and the autonomic nerves of the retroperitoneum and pelvis that are relevant to aortic surgery are discussed in Chapter 71 and Chapter 54.

Early Graft Failure (0 to 30 Days) 584
Late Graft Failure (>30 Days) 586

Postoperative graft thrombosis remains a significant clinical challenge in contemporary vascular surgical practice. Whether early or delayed, graft thrombosis continues to account for significant morbidity, limb loss, and mortality in patients requiring vascular intervention. Specifically, at 1 year after infrageniculate bypass graft failure, more than 50% of patients will have undergone major amputations.[1,2] Among the remaining patients, ischemic pain at rest or ulceration will have developed in 25%, and more than 15% will have died. Accordingly, underlying risk factors associated with graft failure continue to be the focus of vascular surgical outcomes analyses and regional quality improvement groups alike.[3-5]

The causes of graft thrombosis are multifactorial and involve patient demographics, risk factors, natural history, and comorbid conditions, as well as technical issues associated with arterial reconstruction. Such risk factors and technical aspects of reconstruction have an impact on graft patency (Table 46.1) from the initial operation through the entire follow-up period. With this in mind, technical precision at initial reconstruction is imperative to achieve an optimal outcome because technical errors account for 4% to 25% of early failure after revascularization.[6-8] Furthermore, optimal long-term graft durability remains, in part, predicated on lifetime surveillance, timely re-interventions, and vigilant risk factor modification.[9-12] To facilitate intraoperative assessment of the technical adequacy of the reconstruction at the time of surgery, numerous diagnostic tools are available to the surgeon, which we review. Thereafter, the discussion focuses primarily on surgical revascularization, including autogenous and prosthetic conduits and factors associated with their failure. Understanding the etiology and clinical manifestations of graft thrombosis and current experience with available treatment options is crucial for achieving the best and most durable results after initial failure of revascularization.

PREVENTION: INTRAOPERATIVE GRAFT ASSESSMENT

To ensure optimal patency after revascularization, it is imperative that the surgeon determine the technical adequacy of the reconstruction before leaving the operating room.

Inspection, Palpation, and Measurement of Flow

The most convenient and readily available methods for graft assessment include inspection and palpation of pulses. These processes involve not only inspection of the graft itself for kinks, twists, and stenoses, but also examination of the distal target vessel and of the revascularized tissue, if possible. Is the foot

Abstract

Postoperative graft thrombosis remains a significant clinical challenge. Etiologies are often multifactorial and include patient demographics, natural history, comorbidity conditions, and technical issues associated with arterial reconstruction. We review intraoperative modalities that aid in the assessment of the technical adequacy of an arterial revascularization. Further, we discuss the assessment and therapeutic approaches of grafts that fail in the early (<30 days) and late (>30 days) period following bypass grafting.

Keywords

Graft thrombosis
graft failure
intraoperative graft assessment
graft imaging modalities
thrombolytic therapy

TABLE 46.1 Definitions of Graft Patency

Term	Definition
Primary patency	The bypass graft remains patent without any subsequent intervention.
Primary assisted patency	The bypass graft undergoes a pre-emptive intervention to maintain patency, such as endovascular balloon angioplasty or anastomotic revision; however, the graft has never thrombosed.
Secondary patency	The bypass graft has thrombosed and is patent again following lysis and/or thrombectomy. A concomitant endovascular intervention and/or open revision may also have been performed to aid with subsequent patency.

pink and perfused? Has capillary refill time been shortened? Is a pulse now palpable in the foot?

The process is facilitated by having the target organ, as much as possible, included in the sterile field and available to the surgeon for intraoperative examination. For example, for aortobifemoral or more distal bypasses, covering the sterilely prepared feet with clear plastic bags permits rapid examination after completion of the bypass. However, inspection and palpation are subjective and thus susceptible to observer bias. After a complex reconstruction, the surgeon's expectations may cloud the evaluation of capillary refill time in the feet. Calcified arteries, secondary to long-standing diabetes, may not adequately transmit an improved pulse. The effects of anesthesia combined with concomitant chronic occlusion of runoff arteries may delay the appearance of adequate lower extremity reperfusion. More importantly, false-negative results can occur when a graft has a strong pulse, often called a "Water Hammer Pulse," because of distal outflow obstruction.

Measurement of arterial flow may be significantly affected by anesthesia. Furthermore, small, seemingly hemodynamically insignificant defects in the graft may also result in failure. Low-flow measurements may accurately predict graft failure, but this finding alone does not localize the specific defect. Studies using an ultrasound flowmeter have confirmed the inability of graft flow as an isolated parameter to predict future graft function.[13] Measurement of flow by ultrasonically measured transit times has been reported to be sensitive and specific for graft defects.[14] Performance of these studies is cumbersome, however, and requires additional adjunctive measures to both localize and identify specific graft defects. In our practice, we prefer the use of duplex ultrasound, as explained here, because this modality can assess graft flow and at the same time help visualize areas of graft defect. Therefore ultrasound flowmeters are used less frequently and usually more as perfunctory diagnostic adjuncts.

Arteriography

Since its introduction, intraoperative completion arteriography has been the "gold standard" for anatomic evaluation of the technical adequacy of arterial reconstructions. One appealing feature of arteriography is its ability to assess anatomic arterial outflow—the "runoff." This is particularly important in the clinical context of preoperative studies that fail to reveal adequate target vessels in diffusely diseased vascular systems. Although completion arteriography is an invasive procedure associated with potential complications because of arterial puncture (intimal injury, dissection), injection (air embolism), use of radiographic contrast agents (renal failure, anaphylaxis), and radiation exposure, the actual observed complication rate has been negligible in large series.[15,16]

The technique varies according to individual application but generally involves insertion of an 18- to 20-gauge plastic angiocatheter or 4- to 5-Fr sheath into the arterial graft to allow subsequent injection of 10 to 30 mL of radiographic contrast agent. Temporary occlusion of arterial inflow maximizes the concentration of contrast agent without the need for excessively rapid injection. Digital subtraction angiography, rather than simple fluoroscopy with concomitant contrast injection, will then provide clearer images and allow for visualization of vessel patency and runoff (Fig. 46.1).

Several weaknesses are inherent in the technique of completion arteriography, however. In lower extremity bypass grafts, the proximal anastomosis is frequently not evaluated, which may obviate detection of a proximal technical defect. Air bubbles or overlying structures may lead to false-positive interpretations. A potential source of false-negative results is the use of a single plane of view to analyze a multidimensional target; this method can result in underestimation of the stenosis from a small defect, such as an intimal flap or platelet aggregate.[17]

Ultrasonography

The development of ultrasound technology has provided multiple noninvasive modalities for the intraoperative and subsequent longitudinal assessment of arterial reconstructions.

Continuous-Wave Doppler

The simple and inexpensive continuous-wave Doppler 8- to 10-MHz pencil probe is nowadays readily available for intraoperative use. Its small size allows insonation of arteries in areas less accessible to larger probes. It is frequently used to assess flow in the target or outflow vessel(s). Further, the probe can be passed along the graft and anastomoses, where localized increases in the audible sound frequency or audible turbulence could indicate a potential defect. Patent residual vein branches of in-situ saphenous vein bypasses can be readily identified by locally increased frequency, continuous flow, and flow outside the graft boundary. Successively compressing the graft from the proximal to the distal end while listening for residual proximal flow with a Doppler device can also localize these arteriovenous fistulae.

Use of the audible continuous-wave Doppler technique is subjective and operator dependent. Considerable experience is required for maximum accuracy. The presence of high-frequency sound waves within the graft or at the distal anastomosis is worrisome. However, some investigators have shown that the

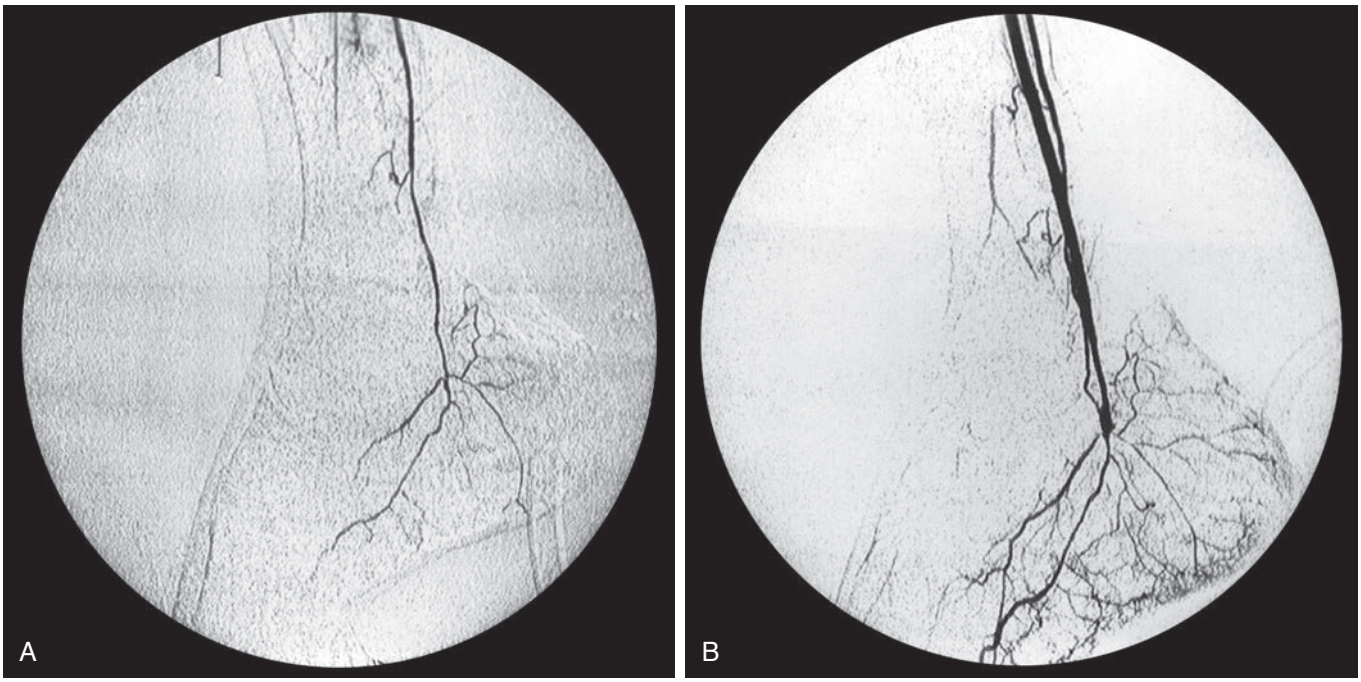

Figure 46.1 Intraoperative digital subtraction angiographic images of the plantar circulation performed (A) before and (B) after bypass.

continuous-wave Doppler device is not highly sensitive.[18] Most vascular surgeons use this modality as an easy, available, and inexpensive screening device to guide their use of a more precise evaluation technique.

B-Mode Ultrasonography

B-mode ultrasonography has been used intraoperatively to obtain anatomic images noninvasively, although it is more commonly used in conjunction with duplex ultrasonography. Initial experimental studies established that its ability to detect small defects in patients was comparable to that of arteriography.[19] In an evaluation of arterial defects created in dogs, both arteriography and B-mode ultrasonography were nearly 100% specific in excluding arterial defects. However, ultrasonography has significantly greater sensitivity in detecting defects, 92% overall, than serial biplanar arteriography at 70% and portable arteriography at 50%. These techniques have comparable accuracy in detecting stenoses.

B-mode ultrasonography has utility in assessing lower extremity arterial reconstructions. Kresowik et al.[20] reported that in 106 patients, intraoperative B-mode ultrasonography detected defects in 20% of patients, and that half of these defects were deemed important enough to warrant correction. In follow-up, there were no early graft occlusions in the B-mode group, and no residual defects were discovered with duplex scanning follow-up in the postoperative period.

Intraoperative use of B-mode ultrasonography, however, is not without its problems.[21] Because this modality does not evaluate blood flow, it cannot differentiate fresh thrombus from flowing blood, which has the same echogenicity. Compared with Doppler pencil probes, B-mode ultrasound probes are larger and cannot be sterilized, requiring a sterile covering containing a gel to maintain an appropriate acoustic interface. Significant operator experience is needed to obtain optimal images and make accurate interpretations.

Duplex Ultrasonography

With the addition of flow-measuring capability to B-mode ultrasonography, duplex scanning brings a more powerful tool to the operating room. Like B-mode ultrasound probes, duplex scanning probes are large, cannot be sterilized, and require considerable operator skill so that accurate velocity and imaging data can be obtained. Duplex color-flow technology provides continuous Doppler signals along the graft and artery at multiple points. Color imaging facilitates identification of areas of higher velocity, albeit at a significant increase in equipment cost.[22]

Duplex scanning provides an easier mechanism for identifying defects in proximal arterial anastomoses than arteriography does, because contrast-enhanced imaging of the proximal anastomosis from a more distally placed catheter is cumbersome and often difficult, and one would rather avoid an arterial puncture in the native inflow vessel due to potential later stenosis development or other complications at this site.[23] In addition, duplex scanning can identify low graft velocities that are undetectable by arteriography. Intraoperative experience with this imaging modality has shown greater sensitivity for detecting technical defects. Early results with intraoperative duplex scanning have demonstrated an association between these defects and suboptimal results in the postoperative period.[24,25] It is noteworthy that duplex scanning is unable to assess newly placed polytetrafluoroethylene (PTFE) and polyester (Dacron, Hemashield) grafts, because the graft walls contain air, which prevents penetration of the ultrasound waves.

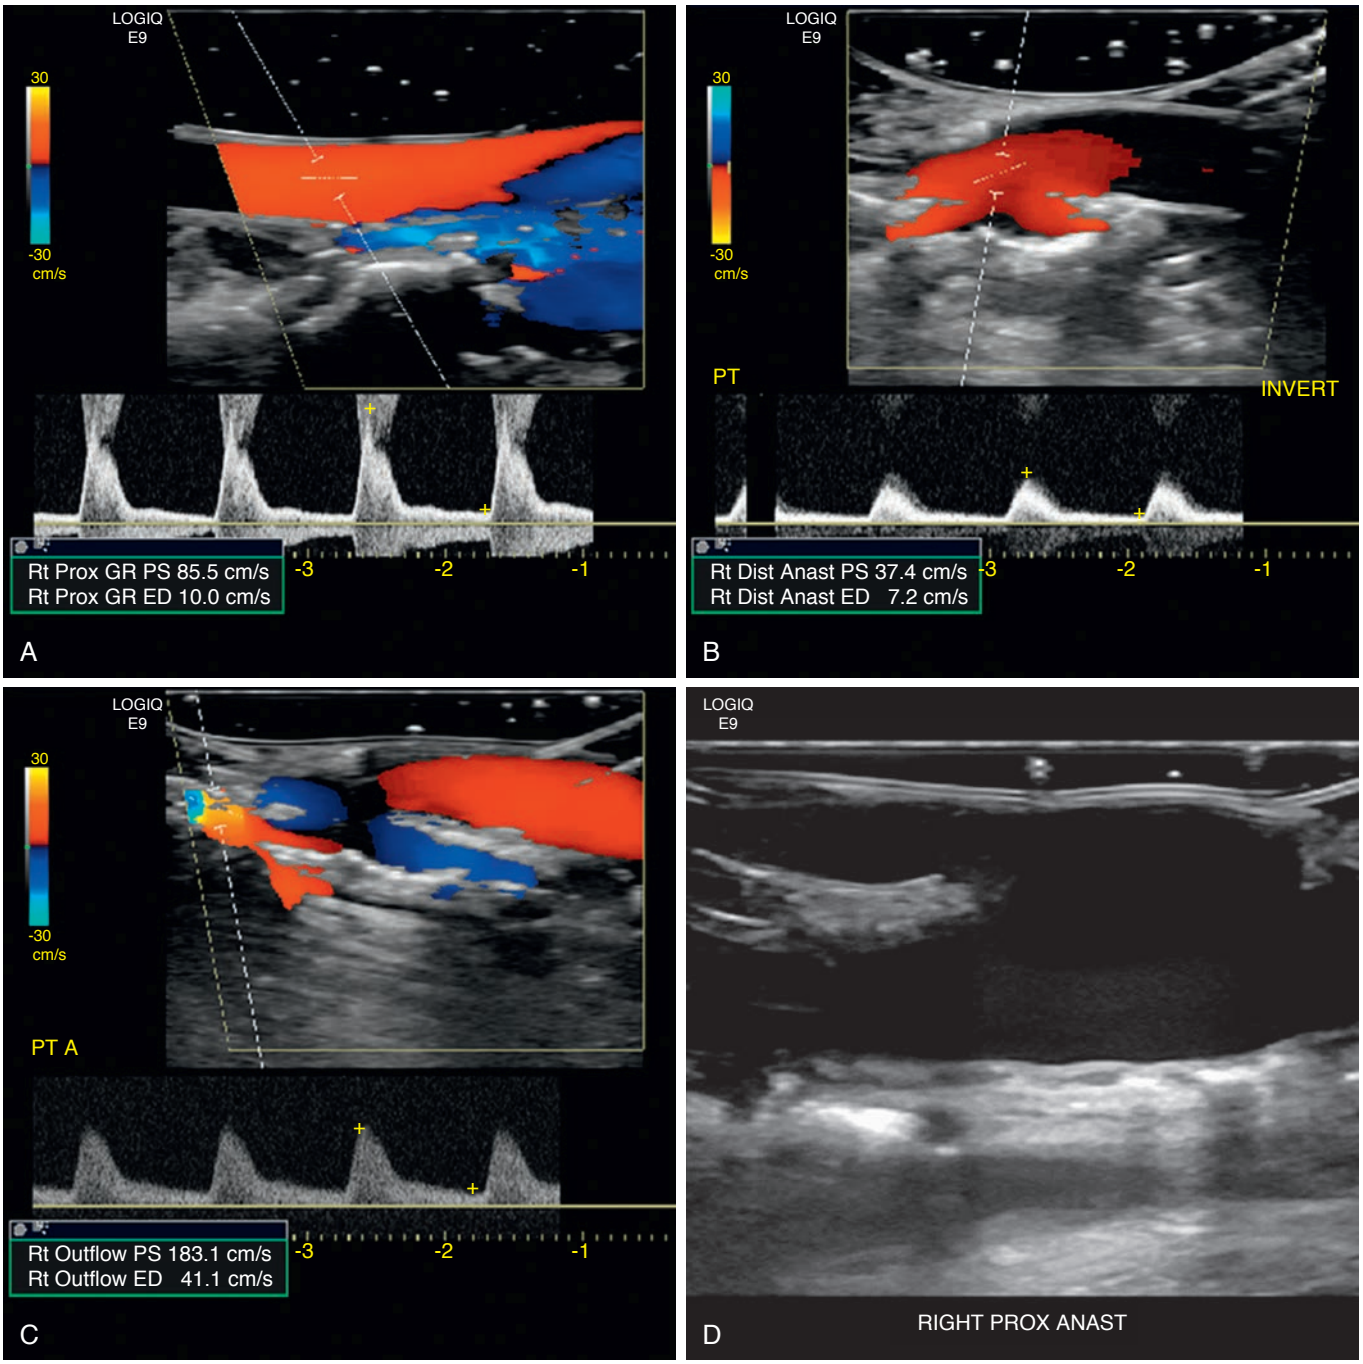

Figure 46.2 Intraoperative completion duplex ultrasound after a femoral to below-knee popliteal artery bypass graft with vein conduit. (A) The proximal part of the graft shows good diastolic flow as indicated by an end-diastolic (ED) velocity of 10 cm/s. (B) Patent distal anastomosis without stenosis as indicated by peak systolic (PS) velocity of 37.4 cm/s. (C) Antegrade blood flow in the native outflow artery with good diastolic flow as indicated by ED velocity of 41.4 cm/s. (D) No dissection flap, stenosis, or technical complication at the proximal anastomosis as seen on B-mode ultrasound.

A study by Rzucidlo et al.[26] reported intraoperative completion duplex scanning to be a useful tool after the completion of infrageniculate arterial reconstruction. Specifically, the authors documented that a 10-MHz, low-profile transducer could be used successfully to identify compromised grafts with a predilection for early failure. Moreover, it was determined that low end-diastolic velocity (EDV) was both associated with and predictive of early graft failure. Further, Scali et al.[27] validated the utility of intraoperative completion duplex scanning following distal bypass, documenting that EDV measurements less than 5 cm/s predicted early graft failure (Fig. 46.2).

Angioscopy

Intraoperative angioscopy has become an attractive technique for evaluation of arterial reconstructions and thorough interrogation

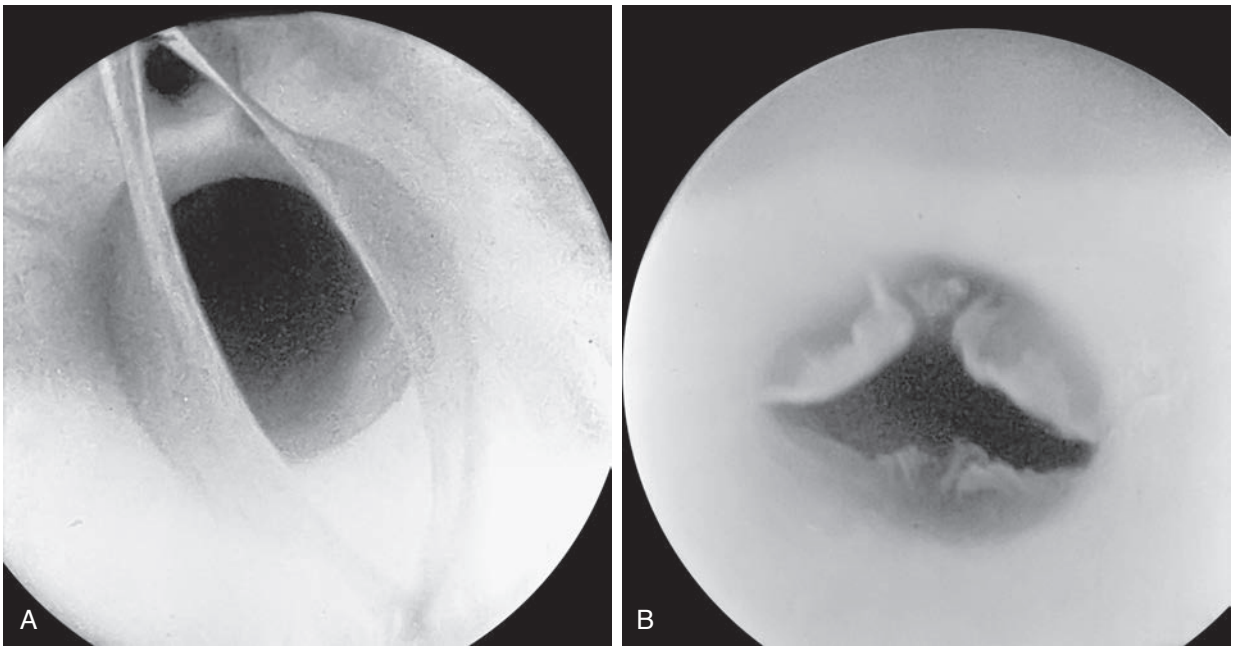

Figure 46.3 (A) Photograph of a valve via an angioscope before lysis. (B) Photograph of an angioscopic image of a valve after lysis. (B, From McCaughan JJ Jr, Walsh DB, Edgcomb LP, et al. In vitro observations of greater saphenous vein valves during pulsatile and nonpulsatile flow and following lysis. *J Vasc Surg*. 1984;1:356.)

of autogenous conduit. Angioscopy requires irrigation with saline accompanied by occlusion of inflow, and sometimes outflow, to provide a visually clear image. Many scopes have a separate lumen incorporated for irrigation or suctioning. The use of a specifically designed infusion pump with high- and low-flow rates has greatly facilitated angioscopy techniques.[28] As with duplex ultrasonography, experience is required to manipulate both the angioscope and the visual target to obtain adequate visualization.

Angioscopy has been most widely used for inspection of in-situ saphenous vein grafts to ensure complete valve lysis,[29] to exclude unligated venous branches, and to assess the quality of the venous conduit (Fig. 46.3). At our institution, vein graft valves are commonly lysed under direct visualization with the valvulotome and scope inserted at opposing ends of the conduit and following the valvulotome with the scope while the vein is irrigated and pressurized with heparinized saline. Angioscopy appears to be particularly important in detecting abnormalities within an arm vein conduit that may not be evident by external visual inspection, including important evaluations of venovenostomy anastomoses.[30-32]

It should be noted that experimental studies have documented that mild intimal injury may occur with angioscopy. However, such injury occurs only after multiple repeated passages of larger diameter scopes.[33] The long-term effects of this mild trauma have not been firmly established, but a few passes of a small-diameter (1.4 mm) angioscope in human vein grafts appear to have no significant late clinical consequences. Several studies have revealed that infusion of irrigation solution can be limited to 500 mL or less in most instances, an amount that has not been associated with complications, especially when planned as a part of the overall fluid administration during the procedure.[28,34] In a 2002 study from Lund, Sweden, the authors documented successful application of intraoperative angioscopy in a group of patients who underwent below-knee in-situ saphenous vein graft bypass; they demonstrated its utility in this setting and concluded that angioscopy has an impact on primary graft patency rates and therefore reduces the need for subsequent reintervention. Specifically, this adjunct was useful in identifying persistent saphenous vein branches, incomplete valve destruction, and partially occlusive intraluminal thrombus.[35]

Intravascular Ultrasonography

More frequently in contemporary practice, intravascular ultrasound (IVUS) has become a useful intraoperative imaging adjunct. This technology is based on a flexible catheter system and generates two-dimensional cross-sectional images through the circumferential rotation of a miniaturized (10 to 30 MHz) ultrasound crystal at the catheter tip. In experimental studies, IVUS has proved to be accurate in measuring luminal diameter and identifying stenoses caused by atherosclerosis or intimal hyperplasia.[36-38] This technology has significant appeal as an imaging modality in the setting of complex aortic procedures, in particular for acute aortic dissection.[39-41] Both IVUS and angioscopy were found to be 100% accurate in detecting 2-mm intimal flaps in canine femoral arteries, compared with only 60% accuracy for single-plane arteriography.[42]

Few clinical studies assessing the role of IVUS have established its efficacy and potential role in evaluating the technical adequacy of vascular surgical reconstructions. However, its utility appears

to be growing. Although IVUS appears to be useful in the evaluation of lesions appropriate for placement of devices such as bare-metal stents and stent-grafts,[43] it is unclear whether IVUS will provide information that is different and useful enough to justify its current cost in comparison to alternative intraoperative techniques. Nevertheless, this real-time, radiation-free, contrast-free dynamic imaging modality offers significant appeal.

Miscellaneous Modalities

Some indirect intraoperative methods can measure resistance within the graft or within the outflow bed, which may help evaluate the adequacy of revascularization. This is most easily accomplished with a continuous-wave Doppler probe placed over an outflow artery while the examiner listens for audible augmentation of the waveform after release of a temporary graft occlusion. This modality, however, provides little objective measure of the adequacy of reconstruction.

A more quantitative assessment can be obtained by measuring distal extremity pressure with a sterile blood pressure cuff during surgery. In patients with more proximal reconstructions and residual outflow abnormalities, ankle pressure may not be maximal immediately after revascularization, but rather may increase only gradually in the postoperative period. Thus this intraoperative pressure measurement does not provide absolute proof of the success of reconstruction, and therefore must be interpreted on the basis of the preoperative anatomy of each patient. Other similar modalities, including pulse volume recording (plethysmography), photoplethysmography, and even transcutaneous oxygen tension measurement, can be used intraoperatively as clinical adjuncts to evaluate the restoration of distal blood flow. In each, the surgeon should assess for a significant difference in magnitude with and without graft occlusion.

GRAFT THROMBOSIS: PATHOGENESIS

Despite meticulous attention to preoperative planning and to technical perfection in the operating room, revascularizations may be unsuccessful. Depending on the type of arterial reconstruction, between 0.3% and 10% fail in the early postoperative period, regardless of attempts by numerous groups to identify and abrogate factors associated with graft failure.[1,4,44] Early graft thrombosis has significant prognostic implications, in that a failed reconstruction is associated with poor clinical outcomes, particularly when performed for limb salvage indications.[45-47] Several studies have identified a variety of factors potentially contributing to graft failure, including patient demographics, risk factors, comorbid diseases, conduit characteristics, anesthesia type, adjuvant medical therapy, and technical precision.[4,48-52] A study from the Washington Hospital Center and Georgetown University Medical Center prospectively collected and analyzed the National Surgical Quality Improvement Program (NSQIP) database from 1995 to 2003 in an attempt to elucidate risk factors predictive of graft failure in patients who underwent infrainguinal arterial bypass. Multivariate logistic regression revealed that younger age (<60 years), African American race, and crural target vessel were associated with graft failure.[4] Furthermore, other modifiable factors predictive of graft failure have been identified and should be incorporated into treatment paradigms. Giswold et al.[1] documented that dialysis dependency, a known hypercoagulable state, ongoing smoking, and failure to undergo routine graft duplex surveillance were all independently associated with reversed vein graft occlusion. Further, Oresanya et al. added that a small vein graft diameter (<3 mm) and the nonadherence to ultrasound surveillance are independently associated with graft failure.[53] In addition, Nolan et al. indicate that bypass grafts performed in limbs where a previous endovascular intervention was performed have a significantly higher failure rate than grafts performed in limbs without a prior endovascular intervention (28% occlusion rate versus 18% occlusion rate).[54]

The role of hypercoagulability as a cause of graft failure has become increasingly recognized in contemporary practice. As the population ages, it has been hypothesized that the number of arterial reconstructions will increase.[1,45,55] This, coupled with the introduction and evolution of myriad percutaneous technologies, will lead to an increasing number of interventions that a typical patient will undergo, thereby compounding the impact of hypercoagulability in light of the inherent multiple previous exposures to heparin.[56-58]

Long-term follow-up has demonstrated that nearly 50% of vascular reconstructions are subject to some degree of restenosis or eventual occlusion,[44,59] and thus has confirmed the efficacy of aggressive graft surveillance and subsequent endovascular or conventional surgical revision in an attempt to identify and prospectively repair deteriorating grafts and prevent graft occlusion.[47,59-62]

When thrombosis does occur, therapeutic alternatives range from expectant supportive care to thrombectomy, thrombolysis, or placement of an entirely new arterial reconstruction. Optimal results in these most difficult circumstances require rapid decisions by the surgeon regarding the etiology of the graft failure and/or thrombosis, selection of either surgical or endovascular repair, timing of re-intervention, and assessment and modification of complex patient risk factors. This discussion summarizes therapeutic guidelines for the most frequently encountered scenarios after thrombosis of an arterial reconstruction.[63]

GRAFT THROMBOSIS: THERAPEUTIC APPROACH

Documentation of Graft Thrombosis

It is incumbent on the clinician to document graft thrombosis in a timely fashion. It may be as easy as noting the absence of a previously palpable pulse combined with dramatic progression or return of the patient's ischemic symptoms. In less obvious circumstances, noninvasive testing to measure the ankle-brachial index and the use of duplex ultrasonography to determine

patency and the location of the occlusion or restenosis may obviate the need for administration of contrast material. This is particularly germane in light of the fact that the patient will probably require further contrast as part of the definitive revision and/or reconstruction.

Assessment of Neurologic Status

A primary determinant of the necessity for and urgency of aggressive intervention is the patient's neurologic status at initial evaluation. As the level of neurologic dysfunction increases from dysesthesia to paralysis, the impetus for rapid resolution of the situation grows. Consequently, the time available for lengthy diagnostic or therapeutic measures outside the operating room decreases correspondingly. Considerable clinical judgment is required in these cases because delay in treatment may precipitate irreversible tissue injury and culminate in untoward outcomes, including limb loss or death. A standardized approach to and reporting of the acutely ischemic limb was published by Rutherford et al. in 1997.[64] We feel that the Rutherford criteria of acute limb ischemia based on sensory function, motor function, and presence or absence of ankle Doppler signals continue to provide a good measure of the degree of acute ischemia. This approach will aid the clinician in determining the rapidity with which revascularization is necessary or perhaps even contraindicated. A nonviable limb, Rutherford category III, would preclude an attempt at revascularization, while a Rutherford category IIb limb should prompt urgent revascularization.

If there is no neurologic compromise and the degree of tissue ischemia appears minimal, such as in Rutherford category IIa or category I, diagnostic or alternative therapeutic maneuvers, including thrombolysis, can be contemplated (see Chapter 41). This is predicated on recognition of the delayed therapeutic efficacy associated with thrombolytic therapy. Nevertheless, adequate clinical outcomes with thrombolytic therapy can be anticipated when applied in select clinical circumstances.[65-67] However, it should be emphasized that secondary patency after treatment of infrainguinal graft thrombosis is generally poor. If the initial reconstruction was performed for ongoing tissue loss, and the ulcer or amputation has subsequently healed, urgent revascularization may not be required. Likewise, graft failure in the setting of recurrent claudication may not warrant urgent reintervention, particularly if a patient has extensive medical comorbidities.

Anticoagulation

Once the diagnosis of graft thrombosis has been confirmed, immediate anticoagulation becomes imperative to minimize or halt thrombus propagation. A short interval to permit blood collection for determination of hypercoagulability is permissible. If regional anesthesia is preferred for a surgical attempt at graft salvage, systemic anticoagulation can be delayed until anesthesia is achieved. If immediate surgery is not required or regional anesthesia is contraindicated, either systemic heparinization or anticoagulation with an alternative agent, when appropriate, should be instituted to inhibit ongoing thrombosis.

Etiologic Assessment

Several factors that may contribute to any graft failure should be investigated. If not previously established, the patient's coagulation status should be determined. As noted earlier, graft thrombosis at any time after placement can be the consequence of a previously unrecognized hypercoagulable state (see Chapter 38).[57,68-70] A blood specimen should be collected and sent immediately (before anticoagulation) for measurement of standard coagulation parameters, including platelet count, functional activated protein C resistance, anticardiolipin antibodies, antithrombin III, and protein S. Previous exposure to heparin, with consequent heparin-associated antibodies causing platelet aggregation, should be investigated and routinely considered in current practice scenarios because previous exposure to heparin is becoming more common, perhaps secondary to the advent and application of less invasive percutaneous interventions.[57,71] Failure to recognize this insidious condition can lead to poor clinical outcomes and recurrent graft thrombosis.[68,72] As the incidence of heparin-induced thrombocytopenia becomes more prevalent, so too will the untoward effects of administration of unfractionated and low-molecular-weight heparin.[72] Alternatively, less likely causes of hypercoagulable complications leading to thrombosis include increased blood viscosity from dehydration, polycythemia, or sepsis, which can easily be diagnosed by physical examination and routine hematologic screening. Moreover, a multivariate analysis from NSQIP implicated thrombocytosis as being independently associated with early graft failure, although this has not been widely studied in other analyses.[3] Acute or chronic cardiac decompensation is an uncommon but real cause of failure of arterial revascularization; these conditions can be rapidly detected at initial patient evaluation with electrocardiography or echocardiography, as indicated. Rapid cardiac assessment is also critical in assessing the risk associated with various possible therapeutic options.

The first element fundamental to achieving successful treatment of a failed revascularization is accurate determination of the cause of the thrombosis. As noted previously, the incidence of technical errors as a cause of early graft failure has significantly decreased over the last 40 years. Technical errors now account for 20% or less of thromboses in arterial reconstructions in the early postoperative period, despite the historical supposition to the contrary. Other probable causes include inherent thrombogenicity of the graft conduit, underappreciated or unrecognized patient-related hypercoagulable states, and poor target artery selection with disadvantaged runoff.

One analysis of roughly 2500 patients from the regional Vascular Study Group of New England, a regional quality improvement initiative revealed several predictors of both early and late graft occlusion. Specifically, both a below-knee target and a tarsal distal target were predictive of diminished graft patency, as was a secondary reconstruction or "redo" revascularization in the early postoperative period. Analysis also determined that diabetes, preoperative tissue loss, greater body mass index (>35 kg/m^2), and reconstructions requiring early revision (primary-assisted patency) were predictive of diminished

long-term graft patency.[73] Similarly, a review of high-risk bypass grafts performed for critical limb ischemia by Rzucidlo et al.[26] found the rate of graft failure within 12 months to be 44%. Noted risk factors included compromised distal arteries that previously required thrombectomy, single-vessel outflow, inability to pass a 1 mm dilator into the outflow vessel, or disadvantaged vein conduits, such as venovenostomy, vein patch angioplasty, or prosthetic interposition.

An alternative approach to better determine the etiology of an unsuccessful arterial revascularization is to examine each of the elements required for effective durable graft patency. The five elements critical for sustained function of an arterial reconstruction are *inflow*, *outflow*, *conduit*, *operative technique*, and *coagulation profile*.

For any revascularization to function, blood pressure, and blood flow at the origin of the reconstruction must be the same as the systemic parameters. Compromised inflow noted by a gradient between the proximal reconstruction and central systemic arterial pressure demonstrates the existence of a significant proximal arterial stenosis. If uncorrected, suboptimal clinical outcomes and graft durability can be expected.

The quality of outflow for a revascularization can be extremely difficult to characterize. For example, in the setting of lower extremity revascularization, only a few small vessels may constitute the outflow runoff, which at arteriography appears too sparse to support durable graft function (Fig. 46.4). Despite attempts to correlate the radiographic features depicted on angiograms with impending graft thrombosis or failure, no consistent angiographic criteria have been determined to be reliable predictors of graft patency. In the limb shown in Fig. 46.4, the runoff bed is based on the lateral plantar artery. Despite conventional wisdom suggesting short-lived patency, this graft has remained patent for more than 5 years. However, this case proves the exception rather than the norm, as several large-cohort reviews have identified poor runoff as an independent risk factor for graft thrombosis.

When considering both the timing and the etiology of failed arterial reconstructions, two temporal categories should be taken into account as they dictate initial approach: early (within 30 days of placement) and late (after 30 days) (Table 46.2). This discussion focuses primarily on outcomes of infrainguinal revascularization, which forms the largest cohort of failed revascularizations.

Early Graft Failure (0 to 30 Days)

Despite improvement in infrainguinal vein graft revascularization techniques, 5% to 10% of grafts fail within 30 days of placement.[44] The time elapsed from initial revascularization is the single most important characteristic aiding in determination of the cause of the graft failure (Fig. 46.5). Early (<30 days) thrombosis of vascular reconstructions has historically been attributed to technical error.[6] In a review of the Dartmouth-Hitchcock experience, it was found that technical errors accounted for roughly 25% of early graft failures.[7] Since that time, the number of graft failures referable to technical error

TABLE 46.2 Classification of Graft Failure by Time Interval With Associated Causes and Treatments

Time	Etiology	Treatment
Early/mid-term failure	Technical Graft thrombogenicity Low flow Poor runoff	Thrombectomy Thrombolysis Patch angioplasty
Late failure	Graft abnormality Metachronous disease	Thrombolysis PTA Patch angioplasty Interposition graft

PTA, Percutaneous transluminal angioplasty.

Figure 46.4 Intraoperative completion arteriogram demonstrating sparse runoff from a lateral plantar artery.

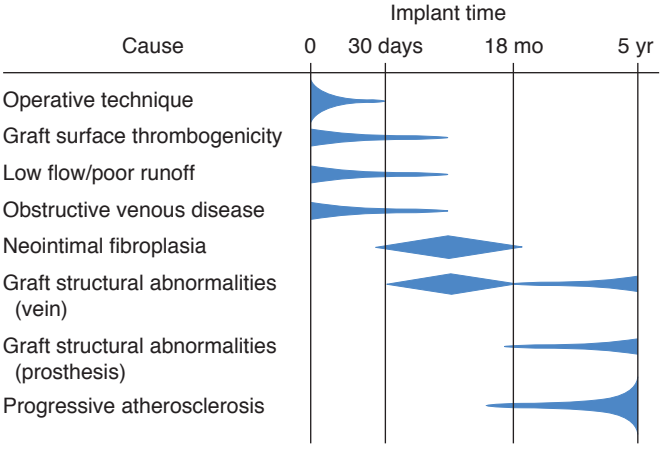

Figure 46.5 Factors Contributing to Graft Occlusion With Time. (Modified from Rutherford RB: The prevention and management of graft thrombosis. In Kempczinski RF, ed. *The Ischemic Leg*, Chicago, IL: Year Book Medical; 1985.)

has declined sharply (10%).[63] This improvement can be directly attributed to the routine use of angioscopy, duplex ultrasound scanning, and DSA to confirm the technical adequacy of the arterial reconstruction. Such confirmation also permits a prospective, qualitative determination of the likelihood that graft failure will occur, and a recognition that it is most likely related to the conduit or the quality of the runoff bed. In addition, thorough graft interrogation greatly simplifies further therapeutic clinical decision-making. For example, if a failed graft was constructed with the only available autogenous vein conduit to the only possible target runoff vessel, and it showed no evidence of an anastomotic or an intrinsic conduit problem at the time of placement, early amputation might represent the optimal strategy to achieve the best possible outcome. In other words, if such a patient undergoes further attempts at thrombectomy, revision of the anastomosis, replacement of the conduit, or substitution of the runoff, they are only likely to sustain increased morbidity, mortality, and expense, with little improvement in the chance for limb salvage.[45]

After diagnosis of a graft that failed early in the postoperative period, the surgeon must first determine whether to proceed with attempted salvage of the initial bypass graft. Commonly used options include either surgical thrombectomy or thrombolysis. The results of both techniques remain discouraging in the early postoperative time period, irrespective of the conduit used or the procedure performed. Furthermore, thrombolysis places the patient at significant bleeding risk, especially at recent surgical sites. A meta-analysis of three randomized studies and 14 review papers on thrombolysis for acute limb ischemia placed the risk of major hemorrhage associated with thrombolysis at nearly threefold higher than nonlytic therapy (OR 2.85).[74] A separate Cochrane review of thrombolysis for acute limb ischemia similarly identified a 200% increase in major bleeding risk.[75] The risk of major bleeding therefore could preclude a significant patient subset with graft thrombosis from undergoing thrombolysis.

After thrombolysis is attempted in the early postoperative period, the extended patency of thrombosed vein grafts ranges between 15% and 20% at 1 year.[67,76,77] In one series, 3% of patients died, 14% experienced bleeding complications requiring transfusion, and 13% developed thromboembolic complications. Despite these associated complications, 75% of the treated limbs had been salvaged at 1 year. Results with thrombolysis of prosthetic grafts are slightly better, although this difference is probably related to the better runoff than usually exists when prosthetic graft material is used as the conduit for the initial bypass procedure.[78] Vein graft longevity after thrombolytic intervention has been documented to correlate with the time interval since the vein graft was placed.[79] Specifically, a shorter interval to graft failure will have a diminished likelihood for success with thrombolytic therapy, particularly in patients with diabetes. Review of the Dartmouth experience found that no patient with diabetes and a recently placed graft achieved reasonable secondary graft patency with thrombolysis.[77] Of patients treated successfully with lytic therapy, 44% ultimately required early amputation, whereas in patients in whom thrombolysis failed, the amputation rate approached 69%.

Like lytic therapy, the results of surgical thrombectomy for early graft failure are also relatively disappointing, even with an adjunctive procedure such as patch angioplasty of the responsible lesion or lesions. Among 36 vein bypasses in which patency was reestablished within 1 month after surgery via mechanical thrombectomy, graft stenosis was noted in as many as 39% of arterial reconstructions. Such stenosis is possibly due to rapid degeneration of normal cellular function in the thrombosed vein wall.[80] Late bypass revisions, performed in 35% of grafts, did little to improve 1-year patency rates, which approached 38%.[81] Robinson et al.[45] reported a cumulative secondary patency rate of 47% at 1 year. In this series, 26% of the patients required amputation within 1 month of graft thrombectomy, and 41% required amputation by 1 year. The results of surgical thrombectomy were significantly improved if technical problems (e.g., a twist in the graft or a retained valve cusp in an in-situ saphenous vein bypass graft) were identified at exploration. Review of the Dartmouth experience was again similar, with long-term graft patency rates for grafts in which thrombosis occurred because of correctable, underlying technical problems approaching that for grafts without complications.

It should be reemphasized, however, that the incidence of graft failure referable to technical error has substantially decreased.[45] It is our practice to perform immediate reexploration in any patient with perioperative graft failure, irrespective of the conduit, when at initial surgery all components of the revascularization were judged technically optimal and in no way disadvantaged. In this setting, thrombolysis poses an additional risk of bleeding, delayed efficacy, and overall poor long-term results. Therefore, in such patients, thrombectomy, anticoagulation, and repair of any underlying potential technical problems yield superior results.[82-85]

In as many as 50% of patients who undergo reexploration for early graft failure, no underlying cause of thrombosis is found.[6] In such circumstances, when a correctable problem has not been detected, and poor conduit or disadvantaged runoff does not appear to be the cause of thrombosis, a 20-gauge polyethylene catheter can be placed in a proximal side branch of the vein graft after thrombectomy. Through this catheter, nitroglycerin (0.05 μg/min) and heparin (10 U/min) are infused while the patient is held in the postanesthesia recovery unit or the intensive care unit. This measure is an attempt to counteract potential underlying undocumented inherent thrombogenicity within the revascularization, whether related to runoff spasm or to graft harvest trauma. The catheter is removed at the bedside or in the operating room after 24 to 36 hours of infusion therapy. Although not routinely used, this adjunct has been documented to confer reasonable patency in 8 of 10 patients at a mean follow-up of 17 months.[7]

If attempts to salvage a thrombosed infrainguinal graft remain unsuccessful in the early postoperative period, two options remain. One management strategy includes expectant therapy and anticoagulation. Frequently, amputation will ensue, although limb loss is not inevitable.[85,86] An alternative strategy includes performing a second bypass procedure with the best available autogenous vein, assuming that there is adequate residual conduit length and an additional good quality target vessel. Although

seemingly difficult, this aggressive posture often leads to improved results.[87] In extenuating circumstances, alternative conduit options including cadaveric vein can be used though the results have not been particularly durable.[88] The advent and evolution of stem cell therapy for patients without additional reconstruction options may play a growing role in clinical practice in this circumstance; however, definitive results of clinical trials are still largely pending (see Chapter 7).[89-91]

Late Graft Failure (>30 Days)

Many of the aforementioned diagnostic and therapeutic decisions remain germane in the setting of delayed or late graft failure. There are, however, several distinctions. First, technical errors no longer constitute a significant cause of graft pathology. Second, thrombolytic therapy offers greater therapeutic utility in this time interval. Third, a greater magnitude of technical difficulty can be anticipated in the surgical dissection of previously operated vessels.

The time interval since arterial reconstruction can act as a positive predictor of the successful application of thrombolytic therapy. Specifically, the longer a graft has been in place, the greater the likelihood that thrombolytic therapy will confer graft patency. Two factors have been noted in the Dartmouth experience to be critical in predicting success after lytic therapy: graft age (since time of placement) of approximately 1 year or older, and the absence of diabetes. It was noted that although thrombolysis was successful in 15 failed grafts in patients with diabetes, only 1 graft was patent at 1 year. Conversely, in nondiabetic patients with at least 12 months of documented graft patency before thrombosis, 44% of patients achieved documented graft patency at 2 years.

After restoration of graft patency, it has been well-documented that further endovascular or surgical therapy may be required in up to 85% of cases to achieve sustained patency. Available therapeutic options in this setting include (1) balloon angioplasty of an intragraft or juxta-anastomotic stenoses, (2) open surgical vein patch angioplasty, and (3) interposition bypass reconstruction. Although the results of such techniques when applied to failed grafts successfully treated with lytic therapy (secondary patency) are not comparable to the documented outcomes observed when applied to maintain the patency of threatened grafts (assisted primary patency), the "threatened" group constitutes a larger cohort and provides a significant body of data from which the surgeon may guide clinical decision-making.

Several groups have reported patency rates from 40% to 86% following angioplasty or vein patch angioplasty for failing/threatened bypass grafts.[92,93] Our current policy reserves percutaneous transluminal angioplasty for maintenance of graft patency until operative repair can be undertaken, for the treatment of straightforward, short stenoses that are difficult to approach surgically, or for dilation of critical stenoses in patients with medical contraindications to anesthesia or surgery. Further, we have found cutting balloon angioplasty to be more effective than plain balloon angioplasty. In a patient with a failed prosthetic bypass graft secondary to progressive advanced atherosclerotic disease compromising outflow circulation, percutaneous treatment with angioplasty or other endovascular adjuncts is justified when no reasonable surgical alternatives are available.[94,95]

Selective application of patch angioplasty versus interposition grafting to address a vein graft lesion noted after successful thrombolysis should best be decided on the basis of lesion location and appearance, availability of adequate autogenous conduit, and surgeon preference. Review of both techniques demonstrates that similar results and outcomes can be expected.[38] Although some suggest superior outcomes with a vein interposition graft to treat an intimal hyperplastic lesion, the requisite additional anastomoses carry their own potential associated complications.

The optimal autogenous vein conduit for replacement of a short segment of vein graft is ideally derived from either the remaining ipsilateral saphenous vein or the lesser saphenous vein. Insertion of a segment of contralateral great saphenous or arm vein as a short interposition graft segment should be avoided to preserve these intact longer conduits for alternative or metachronous uses. In patients who have older grafts with acquired diffuse degeneration or in patients with diabetes whose grafts have failed in less than 1 year after implantation, thrombolysis is unlikely to confer any significant secondary graft patency. Rather, a repeat bypass is more likely to offer successful long-term patency. This supposition is predicated, however, on the availability of sufficient quality distal target vessels and adequate autogenous conduit. When these are available, there does appear to be an enhanced sustained benefit associated with repeat bypass when applicable.

The choice of conduit constitutes yet another example of the associated clinical decision-making complexity when confronted with a failed graft. Historically, the contralateral great saphenous vein has been thought to be the preferred source of conduit for bypass in the setting of an inadequate ipsilateral great saphenous vein because of either disease or previous use. Appropriate concern that the donor extremity will potentially require future bypass or that the saphenous vein might better be used for coronary artery bypass has traditionally been outweighed by the more immediate need and clinical gravity. However, there is reason to question this conduit selection algorithm. Review of the infrainguinal bypass experience at Dartmouth-Hitchcock Medical Center revealed that 20% of patients required contralateral lower extremity revascularization at a mean of 31 months after initial ipsilateral bypass.[96] The intervention rate in our patients, as calculated by life-table analysis, was nearly linear at 6% per year. Among these interventions, 83% were contralateral infrainguinal vein bypasses. Factors predictive of the need for future intervention at the time of initial ipsilateral revascularization included younger age, diabetes, coronary artery disease, and diminished contralateral ankle-brachial index.

By comparison, in patients with only unilateral lower extremity atherosclerosis warranting surgery, the likelihood of future contralateral intervention remained less than 10% during the following 5 years. Based on these findings, it could be argued that the contralateral saphenous vein should be utilized for revascularization of the index leg in elderly patients in whom atherosclerosis remains isolated to one limb. In these clinical

settings, the surgeon may proceed with confidence that the potential future requirement for use of this vein will be unlikely. Unfortunately, only 8% of patients who require infrainguinal revascularization have isolated unilateral lower extremity atherosclerosis.

In light of these findings, selection of the most appropriate bypass conduit, when the ipsilateral great saphenous vein is not available, remains a complex decision confronting the vascular surgeon. Arm veins, when deemed acceptable on preoperative duplex evaluation and intraoperative angioscopic examination, remain an appropriate alternative conduit for graft revision or secondary bypass. Although the need for graft revision remains greater in reconstructions in which an arm vein was used as the conduit, documented assisted primary patency rates approach 72% over 5 years.[97] Although alternative vein grafts spliced together from the lesser saphenous vein and the remaining ipsilateral saphenous vein have been documented to have equivalent patency to that of an arm vein, the associated added morbidity of distal incisions in an ischemic, previously operated limb should not be underestimated. Use of an arm vein conduit may also minimize the number of venovenostomies required in the scenario of small segments of a viable lower extremity conduit. Regular use of the profunda femoris artery and end-arterectomy of the superficial femoral artery to lessen the requisite conduit length for bypass are important surgical adjuncts that should be incorporated into treatment paradigms. Although some advocate repeat infragenicular bypass with either cadaveric vein or, more commonly, prosthetic conduit with or without a distal vein cuff or associated arteriovenous fistula, we seldom use these techniques unless confronted with dire limb salvage circumstances without other therapeutic alternatives.[98-101] In a comparative study of alternative graft conduits, Faries et al.[102,103] documented that autogenous arm vein grafts demonstrated better patency than prosthetic conduit when applied to below-knee popliteal and tibial configurations. Despite optimistic reports from other centers regarding the use of prosthetic conduit, results at Dartmouth-Hitchcock have not been comparable in similar cases to those of autogenous vein. In this setting, it is our continued preference to use autogenous vein when available and prosthetic grafts as a reasonable alternative to primary amputation, with cadaveric conduits reserved for extreme clinical circumstances in the setting of infection/tissue loss where less expensive prosthetic conduit might be at risk to become infected.

ACKNOWLEDGMENT

The authors would like to acknowledge Daniel J. Walsh, MD, Professor in Vascular Surgery at Dartmouth-Hitchcock Medical Center, for his mentorship and for his contribution to the evolution of this chapter.

The incidence of infection involving vascular prostheses is relatively low because of routine antibiotic prophylaxis before surgical procedures, refinements in the sterilization and packaging of devices, and careful adherence to aseptic procedural and surgical technique.

When infection does occur, detection and definitive therapy of the vascular prosthesis are often delayed, with potentially catastrophic consequences. If it is not recognized or treated promptly, implant failure will occur as a result of sepsis, vessel disruption and hemorrhage, or thrombosis with end-organ ischemia.[1-6] The clinical manifestations of prosthetic vascular infection vary depending on the anatomic location and the virulence of the pathogen.[1,3,5,7-9] In general, surgical therapy is always required, often coupled with excision of the prosthesis, because antibiotics alone are insufficient to eradicate an established infectious process. An appropriate treatment plan is influenced by the clinical findings, anatomic location, time since initial implantation, type of graft/device material, extent of infection, virulence of infecting organism, and the patient's underlying comorbid conditions.

Keys to a successful outcome include use of accurate diagnostics to identify the infecting organism and the extent of the graft infection; administration of culture-specific antibiotic therapy; well-planned surgical intervention(s) to preserve, excise, or replace the infected graft; sterilization of the local perigraft tissues; and maintenance of adequate distal organ/tissue perfusion. Improved results have been reported in the past 30 years after both graft excision coupled with extra-anatomic bypass

Abstract

The incidence of infection involving vascular prostheses is relatively low because of routine antibiotic prophylaxis before surgical procedures, refinements in the sterilization and packaging of devices, and careful adherence to aseptic procedural and surgical technique.

When infection does occur, detection and definitive therapy of the vascular prosthesis are often delayed, with potentially catastrophic consequences. If it is not recognized or treated promptly, implant failure will occur as a result of sepsis, vessel disruption and hemorrhage, or thrombosis with end-organ ischemia. The clinical manifestations of prosthetic vascular infection vary depending on the anatomic location and the virulence of the pathogen. In general, surgical therapy is always required, often coupled with excision of the prosthesis, because antibiotics alone are insufficient to eradicate an established infectious process. An appropriate treatment plan is influenced by the clinical findings, anatomic location, time since initial implantation, type of graft/device material, extent of infection, virulence of infecting organism, and the patient's underlying comorbid conditions.

Keywords

Vascular graft
Aortic graft infection
Biofilm infection
In-situ prosthetic replacement
cryopreserved allograft / homograft
neo-aorto-iliac system (NAIS)
femoral-popliteal vein graft
extra-cavitary graft infection
methicillin-resistant Staph aureus (MRSA)

extra-anatomic bypass

TABLE 47.1 Incidence of Prosthetic Graft and Endovascular Device Infection Relative to the Implant Site

Infection	Incidence (%)
Graft Implant Site	
Descending thoracic aorta/thoracoabdominal	0.5-1.9
Aortoiliac	0.2-1.3
Aortofemoral	0.5-3
Femorofemoral	1.3-3.6
Axillofemoral	5-8
Femoropopliteal	0.9-4.6
Femorotibial	2-3.4
Carotid patch	0.25-0.5
Carotid-subclavian	0.5-1.2
Axilloaxillary	1-4
Endovascular Device	
Aortic stent-graft	0.1-1.2
Peripheral stent	<0.1

BOX 47.1 Clinical Classifications of Prosthetic Graft Infections

Time of Appearance After Implantation

- Early: <4 months
- Late: >4 months

Relationship to Postoperative Wound Infection (Szilagyi's Classification)

- Grade I: cellulitis involving the wound
- Grade II: infection involving subcutaneous tissue
- Grade III: infection involving the vascular prosthesis

Extent of Graft Involvement (Bunt's Classification Modified)

- Peripheral graft infection:
  - P0 graft infection: Infection of a cavitary graft (e.g., aortic arch; abdominal and thoracic aortic interposition; aortoiliac, aortofemoral, iliofemoral graft infections)
  - P1 graft infection: Infection of a graft whose entire anatomic course is noncavitary (e.g., carotid-subclavian, axilloaxillary, axillofemoral, femorofemoral, femorodistal, dialysis access bridge graft infections)
  - P2 graft infection: Infection of the extracavitary portion of a graft whose origin is cavitary (e.g., infected groin segment of an aortofemoral or thoracofemoral graft, cervical infection of an aortocarotid graft)
  - P3 graft infection: Infection involving a prosthetic patch angioplasty (e.g., carotid and femoral endarterectomies with prosthetic patch closure)
  - Graft-enteric erosion (GEE)
  - Graft-enteric fistula (GEF)
  - Aortic stump sepsis after excision of an infected aortic graft

and in situ replacement procedures.[10-18] Because most patients with late manifestations have a low-virulence graft infection, in situ replacement therapy with autogenous venous conduits, cryopreserved allografts, or antibiotic-impregnated prostheses to replace the infected grafts has evolved to become a preferred treatment strategy.[10,12,13,18-26]

INCIDENCE

The reported incidence of infection involving a vascular prosthesis varies from 0.2% to 5% of open operations performed and is influenced by the implant site, indication for the intervention, underlying disease, and host defense mechanisms (Table 47.1).[1,4-6,8,25,27-34] Graft infection occurs much less frequently than wound infection, with the incidence of early (<30-day) graft infection being in the range of 1% to 2% of procedures. Infection is more likely to involve prosthetic grafts implanted during an emergency procedure, when the prosthesis is anastomosed to the femoral artery or placed in a subcutaneous tunnel. In a Canadian prospective multicenter trial of nonruptured AAA open repair, the incidence of graft infection was 0.2%,[23] similar to that reported after endovascular aneurysm repair (EVAR) employing a stent graft.[31,35-37] Infection can also develop after arterial deployment of a bare stent, but the incidence appears to be extremely low (<0.1%).

CLASSIFICATION

Prosthetic graft infections can be classified according to time of appearance after implantation, relationship to postoperative wound infection (Szilagyi's classification), and the extent of graft involvement (Bunt's classification) (Box 47.1).

Early (<4 months after graft implantation) infections correlate with Szilagyi grade III wound infections that involve vascular prostheses.[33] These infections are caused by virulent hospital-acquired bacteria and are associated with sepsis, manifested by fever, leukocytosis, bacteremia, and advanced wound infection. Early graft infections appear after patients have been discharged from the hospital and most involve extracavitary grafts. There is evidence that even Szilagyi grade I and II wound infections increase the likelihood of a late-appearing graft infection.

Late infections are the result of graft colonization by low-virulence organisms such as *Staphylococcus epidermidis* or, infrequently, *Candida* species.[1,10,17,19,28,38] The low titer of microorganisms on graft surfaces produces an indolent infection without signs of sepsis, and cultures of perigraft fluid or tissue may yield no growth. Most cavitary (i.e., aortic) graft infections occur as late (>4 months) infections with a mean time to appearance of more than 40 months.[6,10,39,40]

PATHOGENESIS

Etiology

The presence of a foreign body potentiates the infectivity of bacteria. In 1957, Elek and Conen[41] demonstrated that a single braided silk suture significantly reduces the inoculum of

staphylococci required to produce a local infection. The risk of foreign body infection is enhanced in the presence of a larger inoculum, more virulent bacterial strains, depressed host immune function, and invasion of sites more remote from host defenses.

Cellular and Biomolecular Events

The pathogenesis of biomaterial-associated infection involves the following fundamental steps: (1) adhesion of bacteria to graft or stent surfaces, (2) formation of microcolonies within a bacterial biofilm, (3) activation of host defenses (neutrophil chemotaxis, complement activation), and (4) an inflammatory response involving perigraft tissues and the graft-artery anastomoses.

After adherence of bacteria to the biomaterial surface, both graft and bacterial characteristics influence the likelihood of colonization. Bacterial adherence to polyester grafts is 10 to 100 times greater than adherence to polytetrafluoroethylene (PTFE) grafts. Gram-positive bacteria, such as staphylococci, produce an extracellular glycocalyx, or mucin, that promotes adherence to biomaterials in greater numbers than are seen with gram-negative bacteria. The increased adhesion of staphylococci to biomaterials is due to specific capsular adhesions that mediate the attachment and colonization of microorganisms.

The vascular prosthesis and adherent bacteria together stimulate the immune system through inflammatory cytokines. The local inflammatory response after implantation serves to establish connective tissue ingrowth ("incorporation") to the outer surface of the graft material. This healing process can be impaired by early perigraft seroma or hematoma formation, which increases the risk for bacterial adherence and colonization. The inflammatory response also creates an unfavorable healing environment characterized by local ischemia and an acidic pH that is potentially conducive to bacterial colonization. Local disruption of the fine balance between pro- and anti-inflammatory mediators may lead to excess production of matrix metalloproteinases (MMPs) by tumor necrosis factor–stimulated macrophages.[42] Excessive degradation of secreted extracellular matrix and angiogenic growth factors by MMPs may hinder optimal graft healing by restricting capillary ingrowth, tissue incorporation, and potential luminal endothelialization. Lack of perigraft ingrowth and vascularity also favors greater exposure of the implanted biomaterial to bacteria and sequestration within graft pores/interstices away from activated phagocytic cells. Neutrophil function can also be directly impaired in the presence of biomaterials. Decreased neutrophil opsonic, phagocytic, and bactericidal activity against *Staphylococcus aureus* has been observed in PTFE tissue cages implanted subcutaneously in guinea pigs.[43]

Clinical Sources of Infection

Exposure of a vascular prosthesis to microorganisms (bacteria or fungi) can result in clinical infection by any of four mechanisms: perioperative contamination via the surgical wound; bacteremic seeding; mechanical erosion into the bowel, genitourinary tract, or through the skin; and involvement in a contiguous infectious process. Underlying impairment of host defenses can further increase the risk for infection.

Perioperative Contamination

Skin and lymph nodes are major reservoirs of bacteria. Biomaterial surfaces can contact microorganisms (1) by a direct route during implantation, (2) through the surgical wound, or (3) by hematogenous or lymphatic sources arising from remote sites of infection. Potential sources of direct graft contamination include breaks in aseptic operative technique and contact with a patient's endogenous flora harbored within sweat glands, lymph nodes, diseased arterial walls (atherosclerotic plaque or aneurysm thrombus), disrupted lymphatics, and intestinal bag effluents as well as injury to the gastrointestinal or genitourinary tract. Reoperative and urgent/emergent vascular procedures and prolonged operative time also increase the risk of vascular surgical site infections (VSSIs).[44]

If the surgical wound does not develop a fibrin seal or heal promptly after surgery, the underlying vascular prosthesis is susceptible to colonization from any superficial wound complication (cellulitis, dermal necrosis, lymphocele). Wounds with persistent drainage indicate the presence of ischemia or tissue injury that can extend to deeper tissue and involve the prosthesis. Diseased arterial walls and reoperative wounds are an unappreciated source of bacteria, with microbiologic culture recovering pathogenic strains of staphylococci in 10% to 20% of cases.[1] Bacteria can be harbored in scar tissue or lymphoceles of healed wounds and can contact prosthetic grafts undergoing revision or arterial replacement. Culture of explanted graft material from such procedures has isolated microorganisms, typically *S. epidermidis*, from 50% to 70% of thrombosed grafts and from more than 80% of grafts associated with anastomotic aneurysms.[38]

Bacteremia

Bacterial seeding of the prosthesis via a hematogenous route is an uncommon but important mechanism of graft and stent infection. Experimentally, intravenous infusion of 10^7 colony-forming units of *S. aureus* administered within days of implantation produces a clinical graft infection in nearly 100% of animals.[45] Thus bacteremia arising from infected intravascular catheters, urinary tract infection, pneumonia, or infected foot wounds increases the risk of graft infection.

Parenteral antibiotic therapy has been shown experimentally to significantly decrease the risk of graft colonization from bacteremia; this is the rationale for both antibiotic prophylaxis and culture-specific antibiotic therapy in the patient with a known site of infection. As the prosthesis heals and becomes incorporated into surrounding tissue, susceptibility to bacteremic colonization decreases but vulnerability has been documented more than 1 year after implantation, with infection developing as a result of dental and gastrointestinal diagnostic procedures. Transient bacteremia, in conjunction with altered immune status, may account for some graft infections occurring years after the original operation.

Mechanical Erosion

Erosion of a prosthetic graft through the skin or into the gastrointestinal or genitourinary tract results in a perigraft infection that can spread along the length of the graft.

Graft-enteric erosion/graft-enteric fistula (GEE/GEF) can develop as a result of pulsatile movement of an aortic graft against adjacent bowel, most commonly without adequate intervening retroperitoneal soft tissue. Enteric erosion may involve the graft body or anastomotic sites with intact suture lines or pseudoaneurysm formation. A low-grade underlying graft infection has been found in a fraction of cases (confirmed by operative findings and recovery of staphylococcal species) and may provide an additional inflammatory stimulus for bowel adhesion.[46] The reported incidence of GEE/GEF after prosthetic aortic grafting is 0.4% to 2%.

Involvement by a Contiguous Infectious Process

Prosthetic grafts can become colonized as a result of an adjacent infection. The most common clinical scenarios are an aortofemoral graft limb infection associated with diverticulitis and a peripheral graft infection secondary to an infected lymphocele. Frequently the graft segment adjacent to the contiguous bowel or soft tissue infection may be involved.

Impaired Host Defenses

Impaired host defenses from underlying systemic conditions can also predispose patients to prosthetic graft infection.[47] The altered immune function associated with malnutrition, malignancy, lymphoproliferative disorders, autoimmune diseases, chronic renal insufficiency/uremia, advanced liver disease, drug administration (corticosteroids, antineoplastic and immune-modulating agents), and potentially diabetes mellitus may potentiate graft infection with lower numbers of contaminating bacteria.

Bacteriology

Although any microorganism can infect a vascular prosthesis, *S. aureus* is the most prevalent pathogen and accounts for 25% to 50% of infections, depending on the implant site (Table 47.2). Graft infections with *S. epidermidis* or gram-negative bacteria have increased in frequency. This change in the microbiology of graft infection is the result of reporting of both early- and late-appearing graft infections, including aortic graft infections associated with GEE/GEF. Coagulase-negative staphylococci are present in normal skin flora but have the ability to adhere to and colonize biomaterials, where growth occurs within a biofilm on the surface of prostheses. Surgeons have also become aware of microbiologic sampling errors in late infections because of low numbers of bacteria present within the graft surface biofilm and their slow growth.[48] Graft infections associated with negative culture results are caused by *S. epidermidis* or other coagulase-negative staphylococci and by *Candida* species. Infection with gram-negative bacteria such as *Escherichia coli* and *Pseudomonas*, *Klebsiella*, *Enterobacter*, *Serratia*, and *Proteus* species can be particularly virulent. The incidence of anastomotic dehiscence and arterial rupture is high because of the ability of the organisms to produce destructive endotoxins (elastase and alkaline protease) that compromise the structural integrity of the vessel wall. Fungal (*Candida* and *Aspergillus* species) and mycobacterial (tuberculous) infections of grafts are rare, and most patients with such infections are either severely immunosuppressed or have an established fungal or opportunistic infection elsewhere.

Plasmid-mediated genetic mutations have afforded *S. aureus* resistance against penicillin, β-lactams, and other antibiotics (aminoglycosides, erythromycin, tetracycline). Nosocomial and community-acquired infections caused by methicillin-resistant *S. aureus* (MRSA) have rapidly increased in prevalence over the past 15 years. Although estimates in the general population have shown MRSA skin colonization (nares and wounds) in less than 2% of individuals, a much higher prevalence is found in residents of long-term care facilities (23%-49%).[49-51] A study involving more than 13,000 surgical patients admitted to a tertiary hospital in Switzerland found that the overall incidence of MRSA carriers was 4%, but of those carriers, 64% were newly identified. Previous hospitalization, age greater than 75 years, and recent antibiotic treatment were each prognostic for unsuspected MRSA carriage.[52] The combination of increased prevalence, harboring in high-risk populations, multiple staphylococcal virulence factors, and rapidly evolving antibiotic resistance mechanisms makes emergence of MRSA a daunting

TABLE 47.2 Bacteriology of Prosthetic Vascular Graft Infections From Collected Series

medical challenge. British reports have documented MRSA as the most common pathogen involved in vascular wound and graft infections and concluded that it is associated with higher morbidity and mortality rates than infection with other microbes.[53,54] At the University of South Florida (USF), the prevalence of MRSA arterial graft infections increased fourfold over the past 25 years (from 11% before 2000 to 49% after 2000), with more than half of early extracavitary graft infections being the result of MRSA. Early mortality, limb loss, and infection recurrence rates have not been appreciably higher for MRSA in our experience. However, the future possibility of a higher overall incidence of graft or vascular device infections caused by more prevalent MRSA colonization in the vascular population is concerning.

Prevention Principles

Surgical site infection (SSI) guidelines have recently been updated and a comprehensive review has been generated by the American College of Surgeons and the Surgical Infection Society.[55]

VSSIs can be minimized if the following principles are applied:

1. Avoid a prolonged preoperative hospital stay to minimize the development of more resistant hospital-acquired bacterial strains.
2. Have patients shower, scrub, or wipe with an alcohol-based soap (e.g., chlorhexidine) for 1 to 3 days before the operation.
3. Control remote infections before an elective vascular operation.
4. Remove hair from the operative site immediately before the operation with care to avoid skin trauma.
5. Protect vascular grafts from contact with exposed skin in the operative field by using iodine-impregnated plastic drapes or antibiotic-soaked towels/sponges.
6. Avoid concomitant gastrointestinal procedures during cavitary grafting procedures.
7. Use prophylactic antibiotics (30-60 minutes before skin incision) prior to open surgical implantation of a prosthetic graft.
8. Longer (>24 hours) duration of periprocedural antibiotics may be considered when two or more patient-related high-risk factors for surgical wound infection are identified, including extremes of age, malnutrition, prolonged hospitalization, remote infections, immunosuppression, recent or "redo" operations, and previous irradiation of the surgical site.
9. Measures aimed at controlling MRSA include the use of disposable barriers (gowns, gloves, masks) by all individuals contacting MRSA carriers to reduce direct transmission within hospitals, routine MRSA screening (nares swab) of all admitted patients, and use of nasal mupirocin ointment and repeated chlorhexidine skin cleansing before operations.
10. Meticulous attention to sterile technique. Careful handling of tissues, prevention of hematoma formation, and closure of groin incisions in multiple layers to eliminate dead space with lymphatic resection/ligation are imperative to reduce wound complications. Skin reapproximation without tension minimizes the development of dermal ischemia and wound edge necrosis.

Topical Antibiotics

The addition of topical antibiotics (bacitracin or cefazolin) to irrigating solutions allows soaking of grafts before implantation and cleansing of wounds before closure and may contribute to decreased wound infection rates. Randomized clinical trials using rifampin-soaked (1 mg/mL) gelatin-impregnated polyester aortofemoral grafts have reported significantly reduced groin wound infection rates (4.4% without rifampin vs. 2.7% with rifampin), although the rates of subsequent graft infections were similar (0.6% vs. 0.3%).[56,57] All graft infections were caused by *S. aureus* in this study. On the basis of the absence of a longer-term benefit, routine rifampin treatment of polyester grafts for primary aortic reconstruction cannot currently be recommended.

Prophylactic Antibiotics

Prophylactic antibiotics should be infused before skin incision and at regular intervals during long procedures (>3 to 4 hours) to maintain tissue drug levels above the minimal bactericidal concentration for expected pathogens (Box 47.2). Prophylaxis should also be instituted before percutaneous puncture of existing prosthetic grafts (peripheral or coronary arteriography accessed through existing femoral grafts) or before selected endovascular interventions involving stent/stent-graft implantation. Culture-specific antibiotics should be prescribed for patients undergoing

BOX 47.2 Antibiotic Prophylaxis in Adults Undergoing "Clean" Prosthetic Graft or Patch Implantation and Selected Endovascular Procedures

- Precarotid endarterectomy, femoral patch, AAA open repair, or EVAR:
  Cefazolin 1-2 g IV 30 min before the procedure and repeated (1-2 g) q8h for 24 h or
  Cefuroxime 1.5 g IV and q12h for 24 h
- Single prophylactic dose before any endovascular procedure involving a prior access-site prosthesis, repuncture of a recent access site, prosthetic/device reintervention (secondary intervention), or an existing remote peripheral arterial device (e.g., prior stents, grafts):
  Cefazolin 1-2 g IV or cefuroxime, 1.5 g IV
- Before reoperation involving an existing prosthetic graft/patch:
  Vancomycin 1 g IV given 30-60 min before incision and continued q12h for 24-48 h
- Known patient MRSA colonization or prolonged or recurrent stay in hospital or chronic care facility (high MRSA risk):
  Vancomycin 1 g IV before the incision/procedure
- Alternatives for penicillin, cephalosporin, or vancomycin allergies:
  Daptomycin 4 mg/kg IV before procedure and daily for 24-48 h
  Levofloxacin 500 mg IV before the procedure and then daily for 24-48 h
  Clindamycin 900 mg IV before the procedure and then 450-900 mg q8h for 24-48 h

vascular graft implantation who have coexisting infections of the leg or another remote site.

After implantation of a prosthetic graft, patients should be informed of the potential risk for graft colonization and infection from transient bacteremia, especially after dental work, colonoscopy, or cystoscopy. Antibiotic prophylaxis is recommended if these procedures are performed within 3 months of the vascular operation. Amoxicillin 2 g orally 1 hour before the procedure can be used. For patients with penicillin allergy, clindamycin 600 mg orally 1 hour before the procedure is an alternative.

DIAGNOSIS

The prompt diagnosis and treatment of prosthetic graft infections is essential to avoid major complications (advanced sepsis and hemorrhage) and death. Clinical manifestations are varied and may be subtle, particularly when associated with late-appearing cavitary graft infections. The urgency of diagnostic evaluation depends on the clinical findings and the status of the patient.

Clinical Manifestations

Vascular surgeons should maintain a low threshold for proceeding with additional diagnostic testing when any symptom or sign suggests graft infection. In aortic grafts confined to the abdomen, unexplained sepsis, ileus, or abdominal distention might be the only clinical sign. If infection involves an extracavitary graft, the initial sign of infection is usually overlying inflammation/cellulitis, a cutaneous draining sinus tract, or an anastomotic pseudoaneurysm. Any patient with gastrointestinal bleeding and an aortic graft should be presumed to have graft infection and GEE/GEF until either another source of bleeding is conclusively identified on endoscopy or no graft-bowel communication is verified at surgery.

In patients with vague suggestive symptoms and ultrasound or computed tomography (CT) evidence of perigraft fluid, a thorough clinical history may furnish clues that further support the diagnosis of graft infection and provide the rationale for invasive diagnostic testing. The patient should also be queried about recent medical illnesses that may have resulted in hematogenous or lymphatic seeding of the graft with bacteria. Early graft infections with *S. aureus* or other gram-negative bacteria typically manifest within weeks of the procedure as fever, leukocytosis, wound complications, and perigraft purulent drainage. Bacteremia is a sign of an advanced graft infection associated with arterial wall or mural thrombus infection or the secondary development of endocarditis. Patients with grafts infected by *S. epidermidis* are typically seen years after graft implantation with graft-healing complications (anastomotic aneurysm, perigraft fluid cavity, or graft-cutaneous sinus tract). Signs of systemic sepsis are frequently absent.

An elevated white blood cell (WBC) count with a left-shifted differential count and an increased erythrocyte sedimentation rate are common but nonspecific findings in patients with graft infection and fever. Routine laboratory testing should also include urinalysis, blood culture, and cultures of other clinical sites of infection such as foot ulcers and surgical wound drainage. Positive blood culture results are uncommon (<5%), but when present they indicate an advanced graft infection, virulent organisms, or both. All laboratory test results may be normal in patients with late-appearing perigraft infections with *S. epidermidis.*

Imaging Studies

Vascular imaging is essential for the diagnosis and treatment of graft infection and its sequelae. Anatomic signs of graft infection—such as perigraft abscess, anastomotic aneurysm, and GEE/GEF—can be accurately identified (with >90% sensitivity) through a combination of ultrasonography, CT, magnetic resonance imaging (MRI), and endoscopy. Vascular imaging studies permit localization of involved prosthetic infection, related operative sites/tissues for abnormal healing and facilitate planning of surgical treatment options.

Contrast-Enhanced Computed Tomography and Computed Tomographic Angiography

CT is the preferred initial imaging technique for suspected graft infections in aortofemoral and abdominal vessels as well as the thoracic aorta and major cavitary branch vessels (P0, P2). CT is also preferred for cavitary graft infections involving the neck, torso, and proximal parts of the limbs (P1, P3) (see Chapter 49). It should be performed with and without intravenous contrast and oral contrast agents (to detail the relationship of adjacent enteric structures) should be used only in patients in whom GEE/GEF is suspected. The exact location and extent of polyester and PTFE grafts can best be seen on initial non–contrast-enhanced imaging. Review of delayed arterial-phase images or the "bone" preset window for early arterial-phase imaging best separates the detail of prosthetic graft, arterial, and venous structures from perigraft tissues and aids in image interpretation.

Diagnostic criteria consistent with infection include the loss of normal tissue planes (fat density) of the retroperitoneal or subcutaneous perigraft structures (indicative of inflammation), collections of fluid or gas around the graft (Fig. 47.1), the formation of false aneurysms, hydronephrosis, and adjacent vertebral or bony osteomyelitis. Any gas in periprosthetic tissues beyond 2 or 3 months after implantation is an abnormal CT finding suggestive of graft infection. CT angiography provides an assessment of continuity of the arterial lumen, associated distribution of occlusive disease, and the presence of thrombus at planned clamp sites; it may also enable operative planning for arterial reconstruction without invasive arteriography.

Ultrasonography

Ultrasonography can be performed urgently as a portable bedside examination in severely ill patients. It should be the initial imaging study for extracavitary (P1, P2, P3) graft infections. Color duplex scanning can reliably differentiate a perigraft fluid collection from an anastomotic pseudoaneurysm, hematoma, and soft tissue masses (enlarged lymph nodes). Ultrasonography has the advantage of being the most accurate vascular imaging technique for verifying vessel or graft patency and assessing

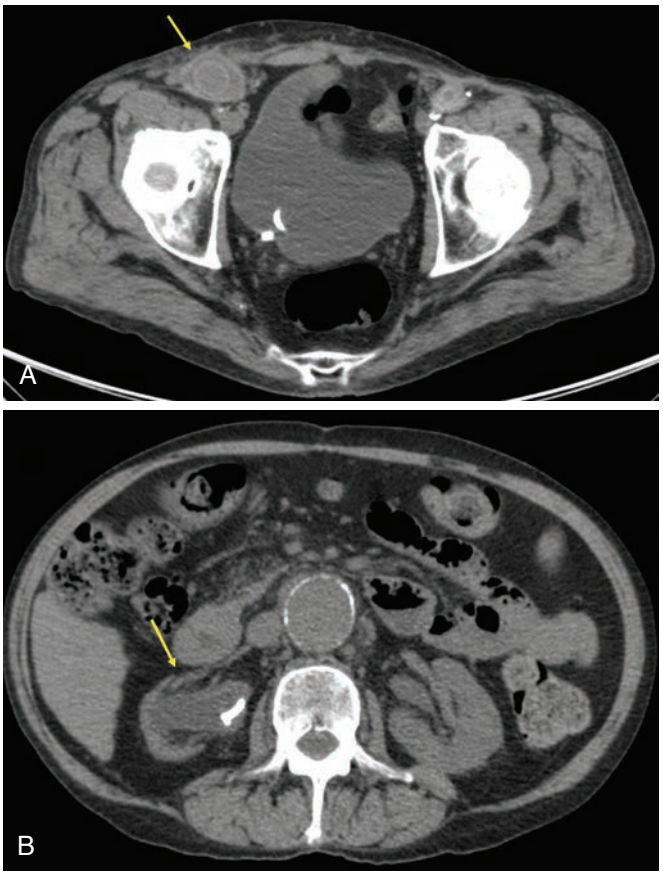

Figure 47.1 Non–contrast-enhanced CT scan showing an infected aortofemoral graft limb *(arrow)*. (A) Perigraft fluid and inflammation in the groin. (B) Infection-associated ipsilateral hydronephrosis, indwelling ureteral stent, and atrophic kidney.

pulsatile masses adjacent to grafts in the groin and limbs (see Chapter 48).

Magnetic Resonance Imaging

MRI provides anatomic imaging equivalent to that of CT but is better able to distinguish between perigraft fluid and fibrosis on the basis of differences in signal intensity between T1- and T2-weighted images. A gadolinium contrast agent enhances vascular luminal resolution (magnetic resonance angiography, or MRA) to allow planning of arterial reconstruction. Although less nephrotoxic than iodinated contrast agents, gadolinium has unfortunately been linked to a systemic fibrotic process in patients with renal insufficiency (see Chapter 28).

Functional White Blood Cell Scanning

All radionuclide imaging techniques aim to demonstrate abnormal accumulations of leukocytes in perigraft tissue for the diagnosis of graft infection, but they do not provide anatomic detail. However, they can be correlated with MRI and CT to delineate the anatomic extent of infection. The type of radionuclide used (gallium 67 citrate, indium 111–labeled leukocytes, technetium Tc 99m hexametazime–labeled leukocytes) can vary and will affect diagnostic accuracy. The accuracy (positive predictive value) of indium 111–labeled WBC scans approaches 80% to 90% in detecting graft infection.

Functional WBC scans are not useful, however, during the early postoperative course (3-6 months) because of nonspecific radionuclide uptake in the healing and inflamed perigraft tissue, resulting in a potential false-positive result. Normal scans (those showing no labeled WBC accumulation) have been reported in late-appearing aortic graft infection and documented cases of GEE/GEF (both false-negative results). Immunoglobulin G scans are sometimes preferred over WBC scans because of ease of preparation, lack of exposure to the patient's blood, absence of background red blood cell and platelet imaging, and the longer shelf life of IgG.

Endoscopy

With use of upper endoscopy, an important diagnostic modality for suspected GEE/GEF, the lumen of the esophagus, stomach, entire duodenum, and ideally the proximal jejunum can be inspected for sources of bleeding (a pediatric colonoscope should be used).

Computed Tomography—Guided Aspiration Versus Operative Findings

CT-guided aspiration of cavitary perigraft fluid collections is increasingly being used to differentiate uninfected seroma from abscess formation. Sampling error (limited sampling in septated perigraft fluid collections) is possible with percutaneous aspiration techniques, as is misinterpretation of negative culture results as indicating no graft infection in some cases of *S. epidermidis* biofilm infection. The definitive diagnostic test for suspected graft infection is operative exploration, especially with equivocal anatomic imaging results and suspected GEE/GEF. Direct exposure of the outer surface of the biomaterial through the typically thick fibrous capsule encompassing a polyester graft allows the detection of late indolent biofilm infections.

Culture Techniques

Standard swab cultures of material taken directly from the graft surfaces and perigraft fluid are usually sufficient in patients with obvious local or systemic sepsis caused by more virulent organisms, which are usually present in high numbers. However, surface swabs may not recover less virulent pathogens that do not invade perigraft tissues. An apparent negative result of Gram staining of tissue or fluid from around an unincorporated prosthetic graft showing no organisms (but typically the presence of WBCs) is not sufficient to exclude a low-grade graft infection because low numbers of slow-growing bacteria can reside within a surface biofilm.

For reliable recovery of microorganisms from within a biofilm infection, mechanical (tissue grinding) or ultrasound disruption of the biofilm of an explanted graft segment must be performed before incubation in a broth culture medium. Placement of a small graft segment in a trypticase soy broth medium is believed to maximize bacterial growth and recovery because the liquid medium allows submersion of the graft and optimal exposure of any adherent bacteria to the nutrient medium. The use of mechanical disruption and broth cultures is particularly helpful in confirming graft infection with *S. epidermidis.*

Culture tubes should be maintained for 5 to 7 days to exclude growth.

SURGICAL TREATMENT AND OUTCOMES

Treatment Considerations

The goals of managing vascular graft infections include initial and long-term eradication of the local and systemic septic process and maintenance of normal arterial perfusion to involved end-organ and limb tissues. Our USF group advocates a patient-specific treatment algorithm involving the use of conventional (total graft excision and extra-anatomic/remote bypass) or in situ replacement modalities and, occasionally, graft preservation techniques.[39]

Selection criteria for specific treatment modalities are based primarily on the clinical findings, extent of graft involvement, and microbiology (Table 47.3). Important adjuncts to attain wound sterilization for a VSSI, especially when in situ reconstruction or graft preservation is under consideration, include the use of multiple staged debridement and/or "washout" operative procedures (every 3-4 days) to minimize residual bacterial counts with more virulent infections; aggressive excision of involved arterial wall and perigraft tissues to healthy tissue planes; intraoperative mechanical and passive wound irrigation with cytotoxic agents (pulsed Clorpactin, passive dilute Betadine plus peroxide); temporary placement of antibiotic-loaded beads; soft tissue coverage of arterial repairs with uninfected, well-vascularized rotational muscle or fasciocutaneous flaps or omental pedicles; negative-pressure wound "sponge" therapy; closed suction drains and continuous dilute Betadine irrigation in grossly infected tissue beds; and culture-specific parenteral antibiotics.

Several general treatment tenets are imperative. Infection involving prosthetic biomaterials frequently requires partial or complete graft removal to eradicate the local septic process. Attempts to preserve prosthetic grafts are appropriate only in limited circumstances. Graft preservation is possible for most arterial infections involving autologous tissue reconstruction (vein bypass or patch). Like Calligaro and colleagues,[58] we at USF have seen more frequent successful graft preservation attempts with early-appearing extracavitary prosthetic infections and overall equivalent outcomes (operative mortality or limb loss) in early and late graft infections with use of a selected treatment regimen. The exception for preservation efforts is invasive infections (those producing local and systemic sepsis) caused by virulent *Pseudomonas*, *Klebsiella*, *Serratia*, *Proteus* spp., and *E. coli*. Autologous or prosthetic graft excision with ex situ revascularization is indicated in these scenarios.

Cavitary graft infections are less amenable than extracavitary infections to wound sterilization techniques involving multiple debridement procedures. Instead, a definitive procedure (simultaneous debridements) or two (staged) procedures that include total graft excision and in situ or ex situ reconstruction are required for cavitary infections. Because of the added invasiveness and physiologic stress of repeated cavitary exposure for the treatment of abdominal or thoracic graft infection, potential catastrophic cavitary graft disruption, and risk of development of enteric erosion or fistulization in the infected graft, preservation techniques should be attempted only rarely for cavitary graft infections.[59]

Graft Preservation

Attempts at graft preservation with just local measures are possible in limited circumstances. Patent grafts with infection involving a shorter length (segmental) and sparing anastomoses

TABLE 47.3 Selection Criteria for Appropriate Operative Management of Prosthetic Vascular Graft Infection

Treatment Option	Manifestations	Extent of Infection	Microbiology
Graft preservation/local therapy	Early infection, no sepsis	Not Dacron, graft body only, no anastomosis, segmental	Gram-positive organism, *Staphylococcus* spp.
Graft excision only	Graft thrombosis, viable limb, adequate collaterals	Any	Any organism
Excision and Ex Situ Bypass			
Simultaneous	Unstable patient, GEE/GEF, hemorrhage, severe sepsis	Invasive infection	Any organism
Staged	Stable patient, mild sepsis, GEE/GEF, no active bleeding	Invasive infection	Any organism
In Situ Replacement			
Prosthetic	No sepsis, no GEE/GEF	Biofilm infection, segmental	*Staphylococcus epidermidis*, gram-negative organism
Autologous vein	No sepsis, no GEE/GEF, severe occlusive disease	Invasive or biofilm, diffuse or segmental	Not *Pseudomonas*

GEE, Graft-enteric erosion; *GEF*, graft-enteric fistula.

(graft body only) can be considered for preservation. Results have been better with PTFE than with polyester conduits, with early (<4 months after implantation) rather than late (>4 months) infectious manifestations, with single gram-positive organisms than with polymicrobial or gram-negative infections, and with extracavitary rather than cavitary locations. Graft preservation should be attempted only for infections that are limited to the immediate perigraft region, caused by bacteria with low virulence and not associated with systemic sepsis.

Serial wound debridement in the operating room, use of cytotoxic irrigating solutions, and placement of antibiotic-loaded polymethyl methacrylate (PMMA) beads are necessary steps to minimize residual bacterial counts. Residual negative wound culture results are necessary for eventual rotational muscle flap coverage of the exposed graft segment, definitive skin closure, or both. More aggressive attempts at graft salvage by others, not necessarily adhering to the aforementioned criteria, have achieved complete graft preservation and wound healing in roughly 70% of patients with early aortofemoral graft limb[60] or infrainguinal prosthetic bypass infections.[21] However, initial treatment failures as a result of fatal graft disruption, persistent graft infection, and nonhealing wounds in 30% of cases limit broader application of this approach and emphasize the need to perform graft excision if local sepsis persists during serial treatments.[11] Mayer et al.,[61] advocating the use of debridement and negative-pressure wound therapy applied directly to exposed reconstructions for Szilagyi grade III (deep) infections, achieved 91% wound healing and 84% freedom from reinfection. However, in that cohort only 54% involved prosthetic graft infection. By comparison, with use of our stricter selection criteria, only 15% to 20% of our USF patients with early extracavitary prosthetic graft infections were deemed candidates, and they were successfully treated by preservation techniques.

Graft Excision and Extra-anatomic Bypass

Need for Revascularization

Graft excision without revascularization may be possible in some cases, including those in which claudication was the initial indication for intervention and when thrombosis of an infected graft does not result in critical limb ischemia. Arterial collaterals around a thrombosed or ligated bypass may take several weeks to develop, and inflow may be optimized by endovascular intervention if occlusive lesions are present in the native proximal vessels. Such an approach may be possible for a localized/segmental groin infection and aortofemoral graft via ligation of the affected limb through a clean retroperitoneal incision, segmental graft excision through the groin wound, endovascular recanalization of residual aortoiliac stenoses/occlusions, and femoral artery reconstruction (Fig. 47.2).

Intraoperative decisions regarding the need for immediate revascularization in patients with patent, infected grafts can be made with the use of temporary bypass occlusion, a sterile blood pressure cuff, and continuous-wave Doppler assessment of pedal outflow. Persistence of a pulsatile pedal arterial signal and ankle pressure greater than 40 mm Hg with bypass occlusion may allow initial graft excision and consideration of delayed revascularization after eradication of local infection. Absence of pulsatile pedal flow during temporary bypass occlusion would probably result in critical ischemic symptoms and risk of limb loss, thus mandating concomitant limb revascularization.

Graft Excision

Conventional management of an infected prosthetic arterial bypass involves total graft excision and revascularization via extra-anatomic/remote routes (ex situ) through uninfected tissue planes. This approach is generally required in patients with

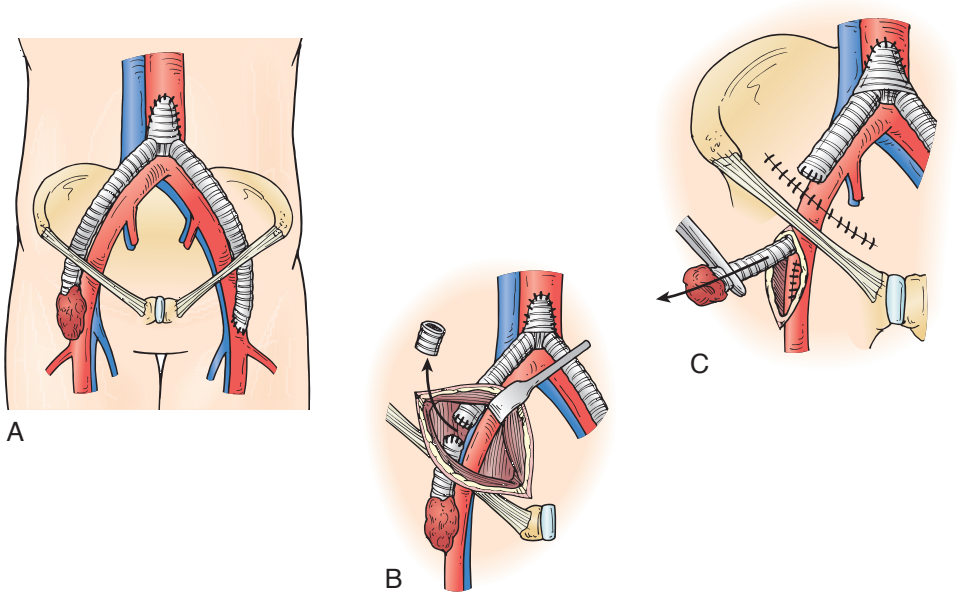

Figure 47.2 Excision of an infected distal aortofemoral graft segment. (A) Localized/segmental distal graft groin infection. (B) Retroperitoneal exposure of an uninfected graft limb through clean tissue planes. (C) Excision of an infected graft segment. In situ prosthetic or autologous vein replacement is performed if needed.

GEE/GEF and for more invasive infections associated with systemic sepsis or extensive perigraft infection (retroperitoneal/psoas abscess). Complete removal of diffusely infected aortoiliofemoral grafts (including anastomotic suture lines) is accomplished by repeat celiotomy or a left retroperitoneal exposure. The explanted graft material should always be cultured.

Proximal control/clamping of the supraceliac aorta may be necessary during exposure of an infrarenal anastomosis with significant retroperitoneal inflammation. Occluding Fogarty balloons may be used into patent iliac systems for hemostatic control. Ureters should be identified and protected during pelvic dissection, and preoperative placement of ureteral stents may be helpful to avoid injury when hydronephrosis and extensive retroperitoneal inflammation are present. The infrarenal aorta should be debrided back to normal-appearing wall. Pledgets of prosthetic material should be avoided, and a double layer of interrupted monofilament suture should be used for aortic ligation. A similar closure technique for the distal aortic or iliac arteries should be performed to maintain retrograde flow from extra-anatomic bypasses at the femoral level into at least one pelvic artery system (external iliac and hypogastric) to avoid pelvic ischemia.

Aggressive excisional debridement of infected perigraft tissue along with irrigation with cytotoxic agents and tunneling and placement of an omental pedicle to cover the aortic stump and retroperitoneal wound may reduce the risk of residual infection and later catastrophic "stump blowout." Temporary closed-suction drains and continuous dilute Betadine irrigation in the retroperitoneal wound bed can be considered in patients with abscess and extensive local infection. Repeat CT imaging within 7 to 10 days can confirm abscess cavity regression to allow removal of drains.

Timing of Limb Revascularization

In patients with aortic graft infection, the timing of limb revascularization depends on the clinical findings. Simultaneous ex situ bypass with graft excision is necessary in hemodynamically unstable patients with systemic sepsis, hemorrhage from dehiscence of the anastomosis, or GEE/GEF. However, staged management with initial axillofemoral PTFE bypass followed in 1 to 2 days by excision of the aortic graft has been associated with lower perioperative mortality than a simultaneous approach in stable patients.[15]

Several decades of experience with the conventional management of aortic graft infection has led to minimal changes in operative mortality but significant reductions in early limb loss, residual aortic stump infection and blowout, and recurrent infections involving ex situ prosthetic bypasses as well as improved midterm patient survival (Table 47.4).[62,63] The highest mortality rates continue to occur in patients with GEE/GEF or systemic sepsis; conventional management is preferred over in situ replacement techniques for such patients.

[b]Cross-femoral, axillofemoral.

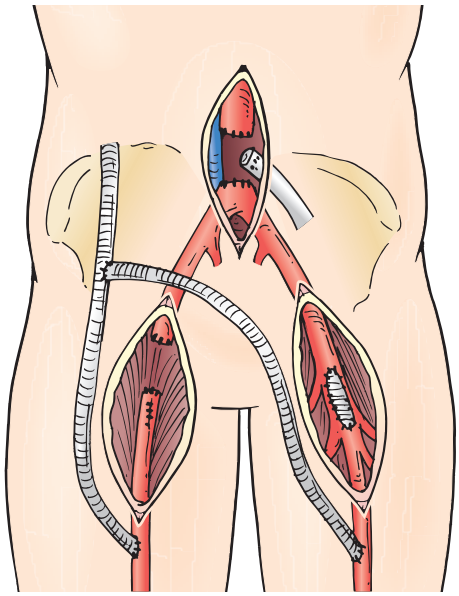

Figure 47.3 Excision of an infected aortobifemoral graft with extra-anatomic bypass.

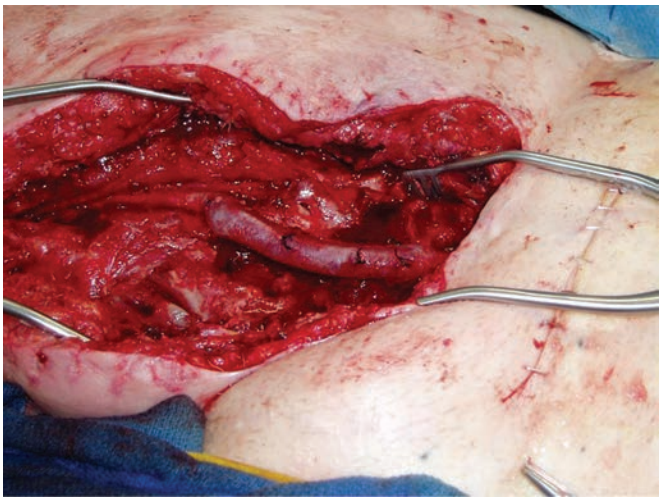

Figure 47.4 Interposition (in situ) replacement with a femoral vein segment after excision of an infected femoral prosthetic graft.

Diffuse aortobifemoral graft infections involving the groin region and with significant associated femoropopliteal occlusive disease can make ex situ approaches to revascularization challenging (Fig. 47.3). Limb loss is more frequent after aortofemoral graft infection than after aortoiliac reconstructions because of the higher risk for ex situ bypass thrombosis or recurrent infection. Unilateral axillofemoral bypasses to the profunda femoris or superficial femoral artery through an uninfected tissue plane have acceptable patency rates (94% at 6 months), but distal anastomoses to the popliteal artery are prone to early failure (42% at 6 months).[64] Preservation of retrograde flow into the common femoral artery by vein patching (and endarterectomy for occlusive disease) after excision of the infected aortofemoral graft is also important for maintaining pelvic flow. A further option for managing aortofemoral graft infection is a unilateral axillofemoral PTFE bypass through uninvolved/less involved tissue, autogenous deep vein cross-femoral bypass in infected fields, and total aortic graft excision.

In Situ Graft Replacement

Autologous Graft Replacement

The great saphenous vein (GSV) or a superficial upper extremity vein can be used for the reconstruction of infrainguinal, visceral, cervical, and upper extremity arteries after excision of an infected graft. However, use of GSV grafts for cross-femoral, iliofemoral, or common carotid/innominate replacement has resulted in limited patency because of size mismatch and occlusion from intimal proliferation.[65] Use of appropriate lengths of a femoropopliteal vein segment has allowed larger-diameter, autologous arterial reconstruction without causing significant morbidity in the donor limb (extensive deep venous thrombosis, limb edema, compartment syndrome) (Fig. 47.4). Preoperative ultrasonographic mapping of the GSV, arm vein, and the superficial femoropopliteal vein (SFPV) can be done in nonurgent scenarios to best match available autologous conduit and repair-site diameters. Adequacy of the femoral vein (absence of acute/chronic thrombus, diameter >5 to 6 mm) can be confirmed by ultrasound when a small-diameter GSV or arm vein (<4 mm) is seen.

Neo-Aortoiliac System Reconstruction

Construction of an in situ neo-aortoiliac system (NAIS) from SFPV after removal of an infected aortoiliofemoral graft was first described by Clagett et al.[66] and Nevelsteen et al.[25] Preoperative ultrasound mapping of the deep leg veins is recommended because long replacement lengths necessitate bilateral harvest. Longitudinal thigh incisions lateral to the sartorius muscle proximally and division of the adductor hiatus are needed, with double-ligation techniques to secure side branch origins. The vein is harvested distal to the profunda femoris origin of the common femoral vein, preserving collateral outflow. Prophylactic lower-dose anticoagulants (heparin, low-dose warfarin) are recommended, as are sequential compression devices applied to the calf regions to augment venous outflow and limit propagation of thrombus in the ligated segments. Patients with prior GSV harvest undergoing SFPV harvest are at higher risk for the development of calf compartment syndrome (up to 12% incidence), so a low threshold for calf fasciotomy should be maintained. Late venous insufficiency and chronic limb edema affects 15% of patients.

SFPV segments are used in a nonreversed configuration after vessel eversion and direct excision of valve cusps. In situ replacement after graft excision and perigraft debridement can be tailored depending on the length of reconstruction needed and available SFPV (Fig. 47.5). If a wide infrarenal aorta is present (18-26 mm), a "pantaloon" technique can be used, in which two SFPV segments are sutured together over half of their circumferences proximally to widen the conduit for end-to-end aortic anastomosis. Excessively large aortic necks (>28 mm) may require ligation and ex situ bypass. If bilateral aortofemoral

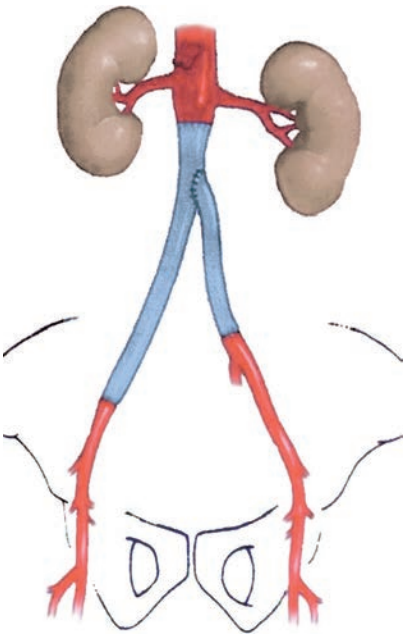

Figure 47.5 Schematic of deep venous replacement (neoaortoiliac system) after excision of an infected aortobi-iliac prosthetic graft. Shortening of the total bypass length (and necessary bilateral femoral vein harvest) is possible because the contralateral femoral vein segment (to the left leg) originates off the mid or distal region of the ipsilateral aortoiliofemoral graft (to the right leg). (From Jackson MR, et al. Excision and autogenous revascularization of an infected aortic stent graft resulting from a urinary tract infection. *J Vasc Surg.* 2002;36:622.)

reconstruction is needed in patients in whom limited lengths of SFPV are available, a unilateral aortofemoral SFPV segment can be used with a shorter cross-femoral SFPV segment between the longer limb and the contralateral groin.

When compared with excision/ex situ bypass, in situ SFPV replacement for diffuse aortoiliofemoral graft infection has been associated with lower mortality and amputation rates, improved graft patency rates, and a lower incidence of recurrent infection (see Table 47.4).[12] Longer-term audits of SFPV replacement by Clagett et al.[66-69] show a primary graft patency rate of 81%, a secondary/assisted patency rate of 91%, and a freedom from amputation rate of 89% at 6 years. This treatment approach has an operative mortality rate of 10% and a 5-year survival of 52%. Early deaths and/or recurrent/residual vein conduit infection and disruption occurred after treatment of GEE/GEF or identification of virulent gram-negative organisms. In situ SFPV replacement is contraindicated under these circumstances. Vein conduit restenosis has been more common with a smaller-diameter femoral vein (<7 mm) and in patients with coronary disease or a history of smoking.[67]

Antibiotic-Treated Prosthetic Grafts

Use of a prosthetic conduit for in situ replacement of infected grafts is a treatment option in selected circumstances. In situ prosthetic replacement with PTFE or polyester conduit has been associated with recurrent infection in 10% to 20% of cases, primarily with gram-negative bacteria and MRSA involvement. These results have increased interest in antibiotic-bonded prosthetic grafts to potentially improve results.[18,70,71]

BOX 47.3 Selection Criteria for and Treatment Components of In Situ Prosthetic Graft Replacement for Biofilm Graft Infection

Selection Criteria

- Clinical:
  - Evaluation months to years after graft implantation
  - No systemic signs of infection—afebrile, normal WBC count, sterile blood cultures
- Anatomic:
  - Limited local inflammation of tissue adjacent to the prosthetic graft
  - Perigraft cavity with absence of graft incorporation
  - Weakening of the graft-artery anastomosis (pseudoaneurysm)
- Microbiologic:
  - Perigraft fluid Gram stain with WBCs, no bacteria
  - Perigraft fluid culture with no growth
  - Graft biofilm culture—coagulase-negative staphylococci (*Staphylococcus epidermidis*)

Treatment Components

- Preoperative and perioperative administration of daptomycin or vancomycin beginning 3 days before replacement
- Wide debridement/excision of inflamed perigraft tissue and the sinus tract if present
- Excision of anastomotic sites
- Cleansing/debridement of tissues and the retained graft segment with cytotoxic wound irrigation
- Use of rifampin-soaked (60 mg/mL) polyester gelatin or collagen-impregnated polyester grafts
- Muscle flap coverage of the replaced graft segment in the groin, omental pedicle coverage of intra-abdominal aortoiliac graft
- Parenteral administration of culture-specific antibiotics for 6 weeks

WBC, White blood cell.

We have advocated graft excision and in situ prosthetic replacement for localized/segmental, low-grade biofilm infections caused primarily by coagulase-negative staphylococci *(S. epidermidis)* (see Table 47.3). More than 50% of late extracavitary graft infections met these criteria and were treated with in situ PTFE graft replacement, with a recurrent infection rate of less than 5%.

Limited morbidity has also been shown with in situ replacement using PTFE and rifampin-soaked (60 mg/mL) gelatin-sealed Dacron for low-grade aortoiliofemoral graft infections (see Table 47.4).[39] Recurrent infections were due to rifampin-resistant *S. epidermidis*, MRSA, or more extensive graft involvement (bilateral graft limbs or aortic graft body), thus emphasizing that optimal results appear to be confined to limited biofilm infections (distal aortofemoral graft). Despite the risk of recurrent/residual infection, in situ prosthetic replacement of a distal aortofemoral graft limb through a groin incision may be preferred over cavitary graft excision and aortic reconstruction in debilitated elderly patients presenting with low-grade biofilm infection and local groin sepsis. Our selection criteria and treatment specifics for in situ prosthetic graft replacement are detailed in Box 47.3. Alternatively, Oderich et al.[72] used in situ rifampin-soaked grafts with omental pedicle coverage to treat limited-involvement GEE/GEF (segmental enteric erosion onto aortic graft body or limb, no anastomosis/aneurysm, no

BOX 47.4 Operative Details of the Use of Cryopreserved Arterial Allografts for Aortic Infection

1. Excise the infected vascular segments and perform perivascular debridement.
2. Thaw and rinse allografts immediately before implantation.
3. Use an appropriate length of allograft to perform a tension-free anastomosis.
4. Perform through-and-through ligature of allograft side branches—avoid the use of metal clips.
5. Use end-to-end anastomosis to native arteries or the retained prosthetic graft—avoid allograft-to-allograft anastomoses and use a single aortoiliofemoral allograft segment to fit the needed anatomic replacement.
6. Provide anastomotic reinforcement with allograft strips.
7. Use gentamicin-impregnated fibrin glue at the suture lines.
8. Use aggressive wound irrigation; consider drainage catheters, muscle flap coverage of the groin allograft, omental pedicle coverage of aortic allograft.
9. Prescribe 6 weeks of parenteral culture-specific antibiotics.

retroperitoneal sepsis), reporting 9% early mortality and 4% reinfection rates. Partial excision of the existing aortic graft was possible in 43% of these selected cases.

Cryopreserved Arterial Allografts

A third option for in situ replacement is the use of aortic and iliofemoral arterial segments harvested from transplant donors and rendered nonantigenic by cryopreservation. Cryopreserved arterial allografts/homografts (CAHs) are now widely commercially available. Specific operative details for allograft implantation are provided in Box 47.4. Allograft replacement may have a primary role in mycotic or prosthetic graft infections of the thoracic or visceral aorta when in situ reconstruction is mandatory. Kieffer and colleagues reported an initial series in 1993 (36 patients)[24] and a more comprehensive experience in 2004 (179 patients)[63] with allograft replacement for infrarenal aortic graft infection. The higher operative mortality was influenced by adverse outcomes in the 30% of patients with GEE/GEF (see Table 47.4). The incidence of limb loss, recurrent infection, and midterm patient survival compares favorably with that for other methods of in situ replacement. However, allograft dilation/aneurysm formation (17%) or stenosis/occlusion (20%) occurred during late (>3 years) follow-up with earlier-generation CAH and fresh homografts. Three recent studies document in situ CAHs used in 151 total patients for arterial infectious pathologies (96 with infected prosthetic aortic grafts) with an overall operative mortality of 10% and a 5% conduit-related complication rate (graft occlusion/stenosis, reinfection, degeneration) during 1 to 3 years of follow-up.[73-75]

Treatment Adjuncts

Antimicrobial Agents

Parenteral antibiotics should be selected according to specific perigraft/graft culture results and adjustments should be made during serial/staged operations with repeated cultures obtained.

Upon presentation with suspected graft infection, empiric broad-spectrum parenteral therapy is indicated with vancomycin (dosing adjusted to renal function and serum levels) and piperacillin/tazobactam 3.375 g every 6 hours, cefepime 2 g every 8 to 12 hours, or levofloxacin 500 mg daily (for penicillin/cephalosporin allergy). On the basis of culture and Gram stain results, biofilm (*S. epidermidis* or *S. aureus*) infections are treated with parenteral vancomycin, and we have abandoned adjunctive oral or intravenous rifampicin (potential emergence of resistant *S. epidermidis* with continued use). Invasive and persistent MRSA soft tissue infection should be treated with higher-dose daptomycin, 6 mg/kg daily. Pseudomonal infections should be "double-covered" with combinations of third- or fourth-generation cephalosporins, piperacillin/tazobactam, aminoglycosides, fluoroquinolones, or carbapenem/monobactams. Parenteral antibiotics should be continued for a minimum of 2 weeks. More invasive infections require 4 to 6 weeks of parenteral antibiotics. Oral amoxicillin/clavulanate or a fluoroquinolone can be used for less invasive, non-MRSA infections after discharge. We use indefinite oral antibiotic therapy as prophylaxis against reinfection only in rare circumstances. Postoperative imaging (CT or ultrasound) should be performed out to 1 year to assure resolution of infection at the treated site.

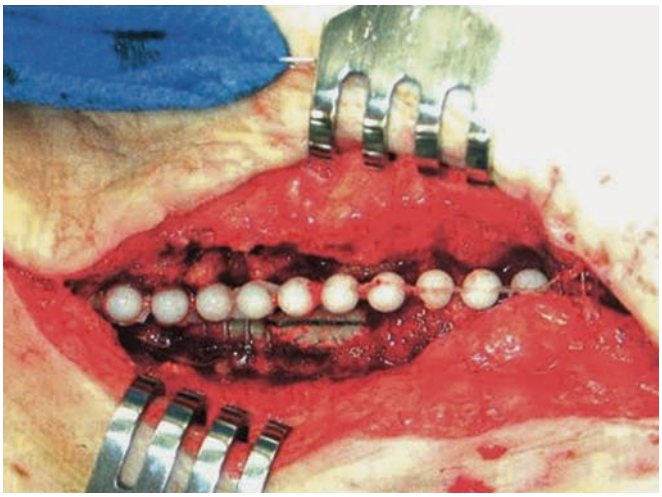

Figure 47.6 Antibiotic-loaded polymethyl methacrylate beads implanted adjacent to an infected polytetrafluoroethylene graft segment and polyester patch. Graft preservation will require further aggressive resection of the skin edges, subcutaneous abscess cavity, and perigraft tissue. (From Stone PA, et al. Use of antibiotic-loaded polymethylmethacrylate beads for the treatment of extra-cavitary prosthetic graft infection. *J Vasc Surg.* 2006;44:757.)

Antibiotic-Loaded Beads

We have used antibiotic-loaded PMMA beads in our wound sterilization algorithm to aid in the treatment of early and late extracavitary prosthetic graft infection.[76] Beads are made in the operating room with PMMA powder, liquid catalyst, and either vancomycin (1 g), daptomycin (1-1.5 g), tobramycin (1.2 g), or gentamicin (1 g) according to initial culture results. The hardening cement mix is molded into 5-mm beads on stainless steel wire mandrels and implanted in the depth of the wound with temporary skin closure and adjacent closed suction drainage (Fig. 47.6). MRSA was found in 44% of initial cultures in our series. After an average of 2.5 bead replacements (staged debridement/washout/beads every 3-4 days) per patient, culture-proven wound sterilization allowed graft preservation or

subsequent in situ reconstruction in all cases. Wound healing and avoidance of recurrent infection were achieved in 90% of cases during an average follow-up of 2 years.

Local Tissue Flap Coverage

Transfer or rotation of local soft tissue structures to provide coverage of preserved or new in situ grafts may be needed when surrounding tissues are inadequate or an excessive skin defect exists. Pedicles of omentum mobilized within the abdominal or lower thoracic cavity are useful for minimizing recurrence after the treatment of aortic graft infections. Use of sartorius muscle flaps has been the most commonly reported technique for groin wound involvement.[77] The muscle is typically exposed lateral to the femoral vessels, divided proximally from its iliac spine attachment, and mobilized medially without tension with preservation of as many segmental feeding vessels as possible (Fig. 47.7). Other muscle/fascial flaps can be used for groin wound VSSI adjuncts, including the rectus abdominis, rectus femoris, and gracilis.

We have used sartorius flaps in 21% (89/422) of groin-related, early and late VSSI cases, primarily as part of graft preservation or in situ replacement therapies.[78] Initial graft bed microbiology revealed 65% gram-positive, 20% gram-negative, and 15% mixed infections. An attempt was made to sterilize groin wounds with staged debridement and antibiotic-loaded beads to allow delayed application (after a mean 9 days) of sartorius flaps. However, immediate flap construction was required in 10% of patients because of extensive soft tissue loss with exposed graft/repair. Flap application was used in nearly half of the cases where the VSSI was improving clinically after staged debridement with no gross infection/exudate but with residual positive wound culture results. Six (7%) recurrent infections occurred over 4 to 5 years of follow-up. Sartorius flaps may not completely eliminate the risk of reinfection for incompletely sterilized graft beds, but muscle coverage can salvage complex groin wounds associated with VSSI.

Endograft Device Infection

The incidence of aortic endograft infection in large institutional experiences has been low (0.1%-1.2%),[79-81] but isolated case reports have evolved into multi-institutional modest-sized cohorts documented more recently (Fig. 47.8).[31,35-37,82,83] One-third of abdominal and thoracic aortic endograft infections manifest as

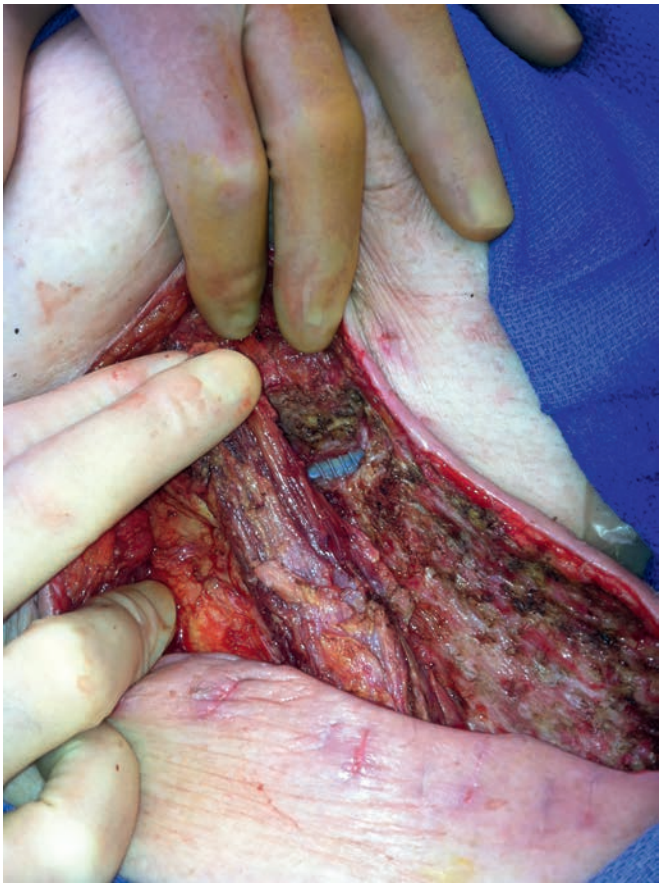

Figure 47.7 Sartorius muscle flap divided superiorly and mobilized toward the upper medial groin wound to cover exposed prosthetic cross-femoral graft after serial debridements of the abscess bed and adjunctive use of polymethyl methacrylate beads loaded with daptomycin plus tobramycin. Skin closure was possible over the sartorius flap, and a bulb-suction drain was placed in the lateral harvested sartorius bed. The patient's head is to the left of photo and the perineum is at the upper edge of the photo.

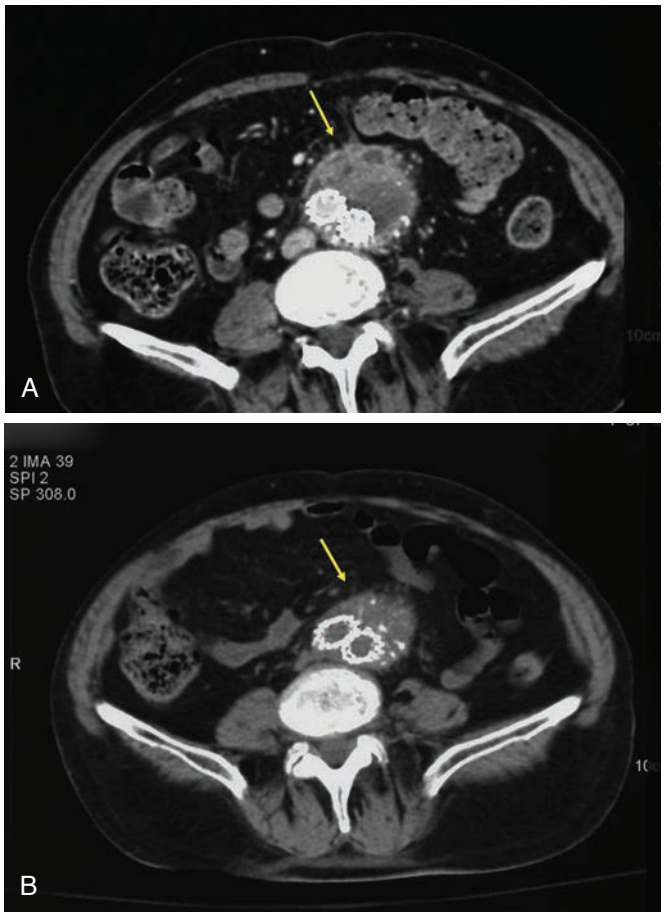

Figure 47.8 Infection associated with an abdominal aortic aneurysm endograft manifested as staphylococcal bacteremia and back pain. (A) Inflammation in the anterior region of the distal infrarenal sac with patent aortoiliac stent-graft limbs *(arrow)*. (B) Resolved inflammation/infection 16 months later, after a 3-month course of parenteral antibiotics *(arrow)*.

aortoenteric or bronchial fistulas, with speculation that residual inflammation results from large intact aneurysms with pulsatility, persistent endoleak, or sac pressurization. Bacteremic or direct seeding may be responsible for endograft infections associated with catheter-based endoleak embolizations.[84]

Definitive treatment of endoprosthesis infection after EVAR, similar to open aortic graft infections, has generally been managed by explantation of the device and ex situ bypass or in situ replacement with SFPV, cryopreserved allografts, or prosthetic graft. The operative mortality risk appears to be significant (10%-30%) for these definitive interventions, with reinfection occurring in 5% to 10% of patients. The potential use of endovascular techniques to treat endograft-related infected pseudoaneurysms or enteric erosions is extrapolated from limited experiences with endograft treatment of mycotic aneurysms or aortoenteric/bronchial fistulas.[85,86] Endovascular repair of primary and graft-related aortoenteric fistulas may be associated with lower morbidity but has shown limited durability and represents only a bridge to definitive open repair.[87]

Several reports have shown successful treatment of endograft infections without device explantation. This approach should be offered only to extremely high-risk patients without aortoenteric erosions who have a rapid, favorable clinical response to parenteral antibiotics (6 weeks' minimal duration). Recurrent or persistent sepsis mandates explantation.

In 1956, Birch et al. reported the first case of anastomotic aneurysm in a patient after prosthetic aortic graft placement.[1] Since then, anastomotic aneurysms have been recognized as an infrequent, although important, late complication of prosthetic arterial reconstruction. Although true native aneurysmal degeneration may occur at an anastomotic site, the majority of anastomotic aneurysms are false because they are composed of a fibrous pseudocapsule rather than the normal component layers of the arterial wall. Notably, anastomotic aneurysms have the potential for significant morbidity and mortality, and they present clinical challenges in their detection, evaluation, and management.

INCIDENCE AND ANATOMIC LOCATION

Overall, anastomotic aneurysms complicate 1% to 4% of arterial anastomoses.[2-5] The incidence of anastomotic aneurysms, however, is influenced substantially by anatomic location, surgical technique, time from anastomotic construction, integrity of the host artery at the original operation, and other local and systemic factors. When reporting incidence, anastomotic aneurysm formation may be described by the number of patients, or more accurately, by the number of anastomoses, as a patient with an aortobifemoral bypass, for instance, has one aortic anastomosis and two femoral anastomoses at risk.[6]

The interval to presentation of anastomotic aneurysm has increased.[7,8] Previously an early phenomenon, anastomotic aneurysms in most modern series present at a mean of 6 years following graft implantation,[8-13] although associated infection can shorten this interval dramatically.[14] Anastomotic aneurysms after reconstruction for aortoiliac occlusive disease are more likely to have late presentations (16 years vs. 9 years for aneurysmal aortic disease)[15] and are more likely to represent degeneration of the anastomosis rather than true aneurysmal change.[16]

The most common anatomic site of anastomotic aneurysm formation is the femoral artery, complicating from 0.5% to 24% of reconstructions. In a large retrospective analysis of

anastomotic aneurysms after prosthetic reconstructions for aortoiliac occlusive disease, van den Akker et al.[17] reported an overall incidence per patient of 13% and an incidence per anastomotic site of 4.8%, 6.3%, and 14% for aortic, iliac, and femoral anastomoses, respectively. In addition, the cumulative freedom from anastomotic aneurysm formation at 15 years was 92%, 84%, and 76% for aortic, iliac, and femoral sites. This propensity of anastomotic aneurysms to form at the femoral location has been documented by others.[6,9]

Large retrospective studies of graft-related complications for abdominal aortic aneurysm repair report a cumulative incidence of anastomotic aneurysm of 1.3% to 3.0%.[18,19] The incidence of aortic and iliac anastomotic aneurysms, however, is probably underestimated because of inadequate surveillance, prolonged time to recognition, and their initially quiescent behavior.[20] Studies with routine radiologic surveillance estimate the incidence of anastomotic aneurysms of the aorta and iliac arteries to be approximately 10%, and may reach 36% by Kaplan-Meier analysis at 15 years.[17,21,22]

The documented incidence of anastomotic aneurysms following carotid endarterectomy (with or without patch angioplasty) is much less, at around 0.3%.[23] However, following repair of extracranial carotid aneurysms, anastomotic aneurysms can complicate 13% to 57% of cases.[24] The interval to presentation may occur as early as weeks following carotid intervention, although the majority of reported cases present from 5 to 12 years after reconstruction. With improved operative technique and the introduction of superior prosthetic materials, carotid anastomotic aneurysms are most commonly associated with surgical site infection and, more specifically, prosthetic infection (see Chapter 94).[25]

PATHOGENESIS

An anastomosis between two vascular structures is potentially subject to failure and hence aneurysm formation. Anastomotic aneurysms occur almost exclusively between prosthetic grafts and native arteries, with only rare occurrences in completely autogenous anastomoses.

When a suture line between two vascular structures is disrupted, an anastomotic aneurysm may form. The egress of blood from the defect forms a pulsatile hematoma that, while in continuity with the bloodstream, becomes lined peripherally with laminated thrombus that eventually becomes encapsulated by surrounding host tissue. A fibroblastic process that initiates the formation of a tissue capsule ensues. The capsule, essentially a false aneurysm cavity, is subjected to systemic arterial pressure and may gradually enlarge, occasionally resulting in local complications of expansion, distal embolization, or rupture.

Several etiologic factors have been implicated in the pathogenesis of anastomotic aneurysms, yet the relative importance ascribed to each factor varies substantially by author or institutional experience. Nonetheless, because anastomotic disruption is pivotal in anastomotic aneurysm formation, the pathogenesis may be conceptualized simplistically by considering local and systemic etiologic factors. Each factor may induce or contribute to anastomotic failure, and each has assumed prominence during various time periods. Because no robust data exist to corroborate the contribution of some of these factors to the development of anastomotic aneurysms, several factors are accepted on a theoretical basis alone (Box 48.1).

BOX 48.1 Factors Associated With the Development of Anastomotic Aneurysms

Local

- Arterial wall degeneration
- Suture line disruption
- Prosthetic graft failure
- Infection/inflammation
- Technical errors
- Mechanical stress

Systemic

- Smoking
- Hyperlipidemia
- Hypertension
- Anticoagulation
- Systemic vasculitides
- Generalized arterial weakness

Local Factors

Arterial Wall Degeneration

Degeneration of the host arterial wall is often associated with progression of atherosclerosis, which compromises vessel integrity and impairs a critical component of the vascular anastomosis.[18,25,26] A consistent operative finding at exploration for anastomotic aneurysm is an intact unit of suture and prosthesis that has nonetheless separated from an attenuated arterial wall. In a cohort of 45 patients with 49 anastomotic aneurysms, Skourtis et al.[12] demonstrated the contribution of host arterial degeneration. After operative treatment, 28 arterial specimens were examined microscopically and demonstrated a reduction or absence of elastic fibers in the media and replacement of smooth muscle cells by acellular fibrous connective tissue. Hyaline degeneration of the media and adventitia was also appreciated. In these instances, however, it can be difficult to differentiate anastomotic false aneurysm development from true aneurysmal degeneration of the native vessel.

Suture Line Disruption

Prosthetic graft anastomosis with a native artery depends indefinitely upon the integrity of the suture line, as no lasting union occurs as would between two native vessels. Suture material, particularly silk, was recognized as a central factor contributing to anastomotic aneurysm formation in early reports. Silk suture gradually dissolves and is eventually resorbed by phagocytosis and other processes. This discovery culminated in the abandonment of silk suture for vascular anastomosis. Unfortunately, several successors of silk, including polyethylene and nylon, were also implicated in anastomotic aneurysm development, in general because of loss of tensile strength and ultimate suture disruption.[26] Monofilament polypropylene (Prolene, Ethicon, Livingston, Scotland) suture was introduced

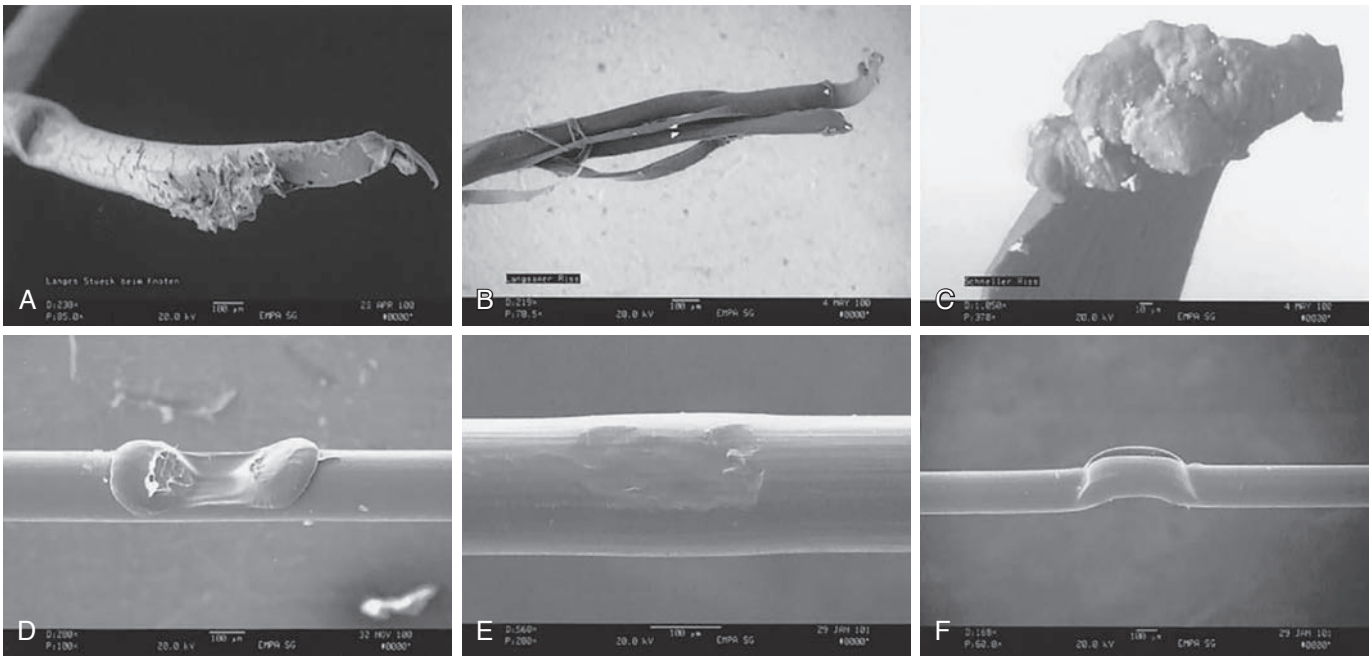

Figure 48.1 Electron Microscopy of Polypropylene Suture. (A) Unexplained suture rupture extracted from an anastomotic aneurysm. (B) Damage from manual slow pulling. (C) Damage from fast pulling. (D) Thermal damage from electrocoagulation with a very short contact time. (E) Damage after soft compression with surgical forceps. (F) Damage after arterial clamp placement. (Reprinted from Huber C, Eckstein FS, Halbeisen M, Carrel TP. Rupture of a polypropylene suture after aortic operation: a scanning electronic microscopical assessment of potential mechanisms. *Ann Thorac Surg*. 2003;75(4):1318–1321 with permission from Elsevier.)

commercially in 1969 and has enjoyed favor among vascular surgeons primarily because of its minimal tissue reactivity, low thrombogenicity, inherent resistance to infection, low coefficient of friction during suturing, and excellent maintenance of tensile strength without biodegradation.[27] Despite these advantages, polypropylene suture readily frays and fractures, particularly with instrumentation and indiscriminate handling (Fig. 48.1).[28] Polytetrafluoroethylene (PTFE) suture is preferred by some surgeons because of its favorable suturing characteristics and relatively inert behavior in tissues, although its breaking strength is half that of polypropylene.[29]

Nonsuture methods of vascular anastomosis that have recently been explored include rings, staples, clips, cuffs, stents, and adhesives.[30-34] Purported advantages of nonsuture methods include decreased tissue reactivity, diminished vessel trauma, and technical simplicity and efficiency. Only clips are associated with an acceptable complication profile.[35] However, these methods have been reported in only small case series, and before adoption can become widespread, long-term data are needed, especially regarding the incidence of anastomotic aneurysm formation.

Graft Failure

Both early and modern generations of prosthetic grafts have infrequently been incriminated as important factors in anastomotic aneurysm formation. Although knitted and, less commonly, woven polyester grafts dilate over time, they consistently maintain their structural integrity. Notwithstanding, several investigators have associated textile graft dilatation and compliance mismatch between the graft and host artery with development of anastomotic aneurysms. Thus prosthetic grafts may indirectly contribute to late anastomotic disruption.[13,36,37] A potential disadvantage of woven polyester grafts is their tendency to fray with handling. However, incorporation of a greater margin of graft into the anastomosis functionally eliminates this feature as a cause of late anastomotic failure (see Chapter 64).

Infection and/or Inflammation

Inflammatory states are recognized causes of anastomotic aneurysms, and are frequently the etiology of early postoperative anastomotic aneurysms. An inflammatory process may occur in response to implantation of prosthetic materials, postsurgical hematoma or lymphocele, or acquired vasculitides, such as Behçet's disease.[38] Inflammation caused by acute or indolent graft infection may also lead to anastomotic aneurysm formation (Fig. 48.2). Even in the absence of clinical signs of infection, bacterial isolates, especially coagulase-negative Staphylococci, have been isolated from as many as 60% to 80% of excised graft material.[39-41]

Technical Errors

Meticulous attention to suturing, including incorporation of generous portions of the arterial wall, especially in arteries subjected to concurrent endarterectomy, is paramount in preventing eventual anastomotic breakdown. Graft tension during construction of an anastomosis also contributes to late disruption and aneurysm formation. Incorrect suture handling, such as

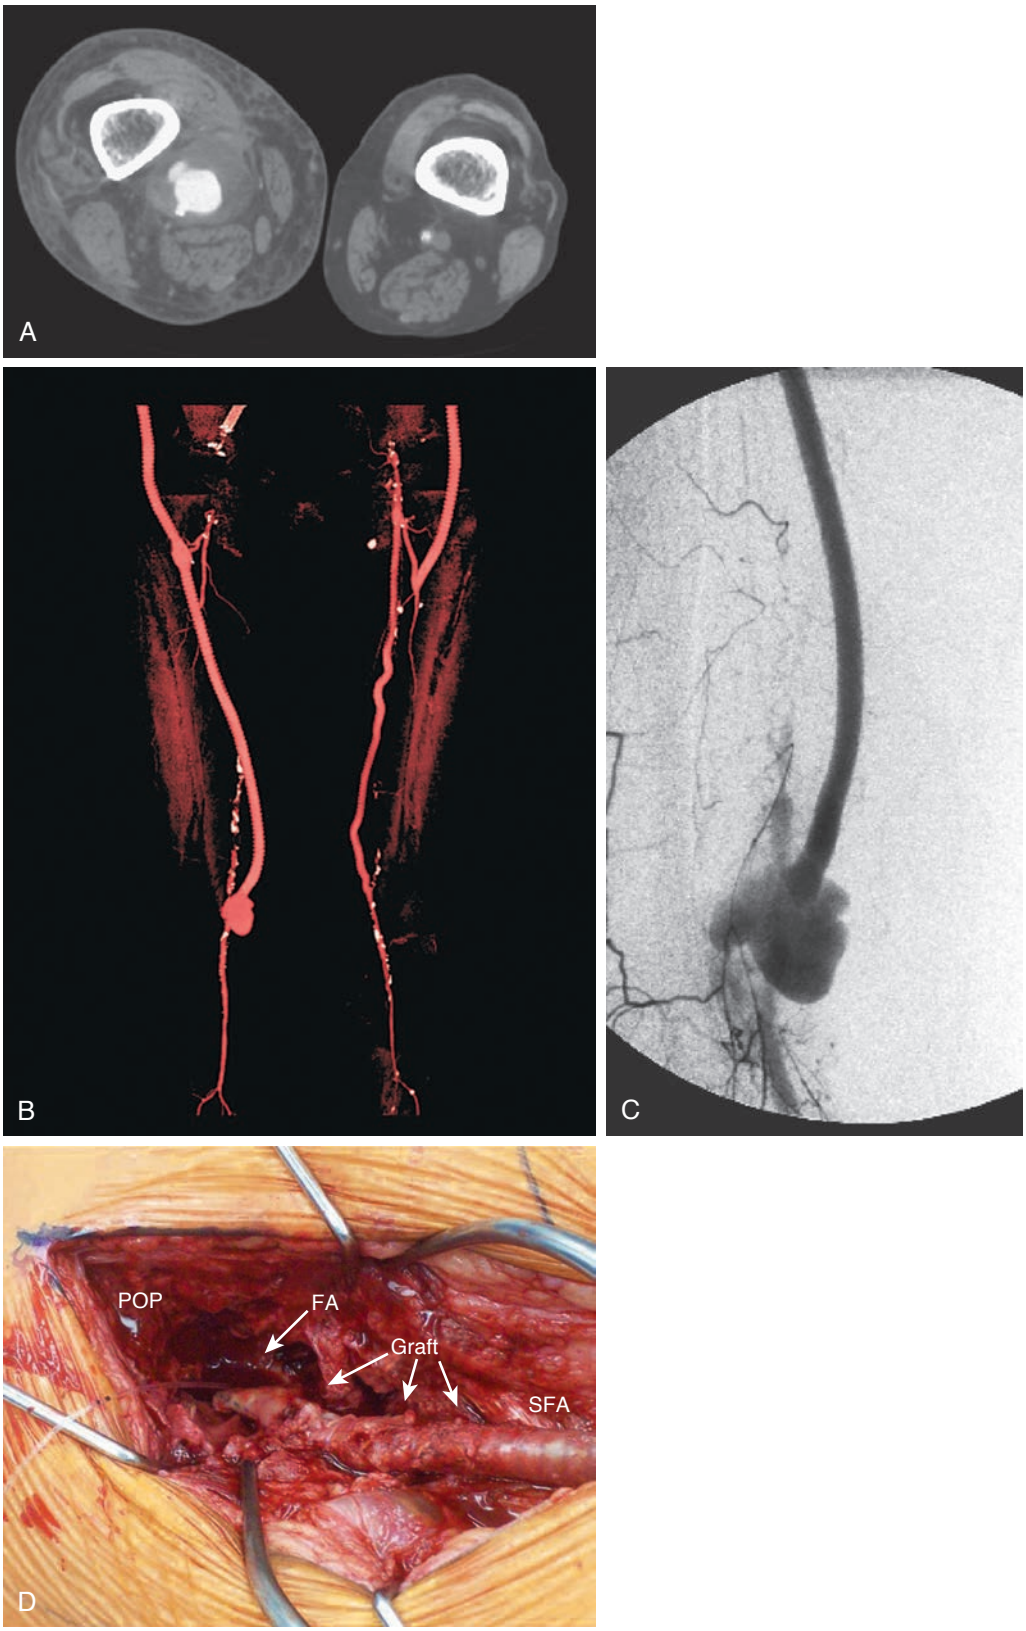

Figure 48.2 Infected Anastomotic Aneurysm Involving the Distal Femoropopliteal Bypass Graft. (A) Axial computed tomographic images from a preoperative angiogram. (B) Reconstructed images from a preoperative computed tomographic angiogram. (C) Intraoperative angiogram demonstrating a false aneurysm. (D) Degenerated polytetrafluoroethylene graft to the popliteal artery (POP) anastomosis. *FA*, False aneurysm; *SFA*, superior femoral artery.

grasping the suture with forceps or clamps, may fracture sutures and predispose an anastomosis to late failure. The use of sutures of adequate strength and size also assists in minimizing technical errors.

Mechanical Stress

Myriad mechanical forces operate at an anastomosis and may differentially contribute to anastomotic aneurysm development. Formation of an anastomosis between a prosthetic graft and an artery establishes compliance mismatch. The inherent properties of a prosthetic graft include nondistensibility and a tendency for latent dilatation, both of which impose mechanical, or shear, stresses on an anastomosis. Laplace's law states that wall tension increases proportionally with radius and pressure. By this, prosthetic dilatation may transmit tension to the suture line and adjacent host artery, resulting in anastomotic disruption. An additional application of this physical principle relates to the diameter of the anastomosis: the greater the diameter, particularly in end-to-side anastomoses, the greater the tension imposed on a suture line.[36,37] Extraneous tension on the anastomosis may result in elastic recoil of the graft, leading to separation from the vessel wall.

According to laws of fluid mechanics, the larger the incident angle between the graft and recipient artery, the lower the flow rate through the anastomosis and the greater the associated turbulence and shear stress on the suture line. Hence minimizing the angle between the host artery and the graft may impart a hemodynamic benefit and prevent late anastomotic complications. In particular, end-to-end, rather than end-to-side, anastomoses better establish optimal hemodynamic conditions and reduce anastomotic turbulence.[42]

Systemic Factors

Several systemic factors are thought to contribute to anastomotic aneurysm formation. Smoking, hypertension, and hyperlipidemia may facilitate anastomotic failure through local effects on arterial wall integrity. Perioperative systemic anticoagulation occasionally complicates the postoperative course through local wound hematoma, a recognized local etiologic factor in anastomotic aneurysm development. Acquired vasculitides are also associated with anastomotic aneurysm development. Behçet's disease, an autoimmune vasculitis, is a multisystem disorder characterized by severe arterial and venous manifestations (see Chapter 137). Operative intervention in patients with Behçet's disease is complicated by anastomotic aneurysm formation in 30% to 50% of these patients because of chronic vasculitis and arterial wall fragility.[38,43] Similar manifestations and complications are observed in Takayasu arteritis and in the connective tissue disorder Ehlers-Danlos syndrome type IV (see Chapter 139 and Chapter 140).[44]

Prevention

An understanding of the pathogenesis and risk factors associated with anastomotic aneurysms contributes to their prevention. Deliberate attention to surgical technique is paramount. Anastomoses must be constructed without excessive tension and by incorporating sufficient graft and arterial wall into the suture line, especially if concurrent endarterectomy is performed. Judicious use of adjunctive endarterectomy is advisable. When feasible, an end-to-end anastomosis should be selected unless preservation of critical vascular beds is required (e.g., retrograde iliac perfusion). If an end-to-side anastomosis is performed, a minimum incident angle should be achieved at the anastomotic site.[2] In the modern era, the choice of suture and graft material is probably irrelevant and subject to the surgeon's discretion. Nonetheless, it is recommended that the selected prosthesis have a diameter equal to that of the recipient artery. Strict attention to skin preparation and aseptic operative technique is critical, as is preoperative antibiotic administration. Additional prophylactic strategies include meticulously achieving hemostasis, minimizing lymphatic disruption, avoiding adventitial dissection (i.e., ex-arterectomy), and accurate wound closure.[9,11,42] Despite adherence to the aforementioned principles, anastomotic aneurysms may not be preventable, so periodic surveillance should be conducted to decrease related complications. All patients treated with graft material should undergo long-term evaluation, including clinical examination, color Doppler ultrasound, and if necessary, angiographic computed tomography (CT).

CLINICAL DIAGNOSIS

The diverse clinical manifestations of anastomotic aneurysms are determined largely by anatomic site. Because most anastomotic aneurysms are asymptomatic, they are generally discovered incidentally during routine surveillance or radiologic examinations for unrelated clinical problems.

HISTORY AND PHYSICAL EXAMINATION

A careful, systematic physical examination will detect most femoral and other superficially located anastomotic aneurysms. In clinical practice, an anastomotic aneurysm is detected by examination as a palpable, occasionally tender, pulsatile mass. Thus periodic clinical evaluation with directed physical examination is recommended indefinitely after construction of prosthetic femoral anastomoses. Over a 15-year period, Demarche et al.[9] retrospectively described their extensive experience with femoral anastomotic aneurysms. Of 142 anastomotic femoral aneurysms, 64% presented as an asymptomatic pulsatile mass, 19% presented with acute limb ischemia, 9% presented as a painful groin mass, and 7% presented with acute hemorrhage. Two patients (1%) presented with distal microemboli and limb edema, respectively. Overt infection complicated the presentation of 7% of anastomotic aneurysms. The majority of other series reported similar presentations.[11,13,45] Thrombosis, embolization, and venous or neurogenic compression are also well-documented complications of femoral anastomotic aneurysms.[14]

Intraabdominal anastomotic aneurysms may evade clinical detection until they cause symptoms or enlarge sufficiently that they become palpable. Most aortic and iliac anastomotic

aneurysms present as an asymptomatic pulsatile mass or with abdominal or back pain, but they can produce more threatening clinical manifestations such as rupture, infection, distal embolization, erosion with fistulization, or hemorrhage.[10,12] Occasionally, aortic and iliac anastomotic aneurysms are discovered incidentally during radiologic examinations for unrelated clinical problems. Many large intraabdominal anastomotic aneurysms are palpable on physical examination, particularly in nonobese patients. Small or intracavitary anastomotic aneurysms, however, are often not appreciated by physical examination and require focused radiologic studies for diagnosis. Despite the relatively high incidence of anastomotic aneurysms long-term from the operating room, there are no clear guidelines in place for routine imaging follow-up of patients with aortic and iliac artery anastomoses.

Many carotid anastomotic aneurysms display progressive asymptomatic enlargement, which is rarely appreciated on physical exam. However, local compression, distal embolization, neurologic symptoms, and even rupture are notable manifestations. Rupture is fortunately infrequent, but may occur in approximately 3% of cases.[24]

Imaging

During surveillance or when an anastomotic aneurysm is suspected but cannot be confirmed by examination, ultrasonography, computed tomographic arteriography (CTA), and magnetic resonance arteriography (MRA) are reliable diagnostic modalities. The quality and resolution of modern CTA and MRA often obviate the need for conventional catheter-based arteriography (Fig. 48.3). Moreover, conventional arteriography often cannot identify or provide size information for anastomotic aneurysms because the true diameter is obscured by thrombus.[46,47] To determine the validity of several current vascular imaging modalities in diagnosing aortic anastomotic aneurysms, Bastounis et al.[48] performed a cross-sectional study comparing B-mode ultrasonography, CT, magnetic resonance imaging (MRI), and digital subtraction angiography (DSA). Defining color-coded Doppler imaging as the "gold standard," they determined that all modalities had sensitivities of 100%, but only MRI, DSA, and enhanced CT possessed sufficient specificity, and only MRI possessed sufficient positive predictive value for diagnostic utility. Although interesting, this study's applicability is limited by the small number of anastomotic aneurysms encountered and by modern technologic improvements in CT and MRI scanners.

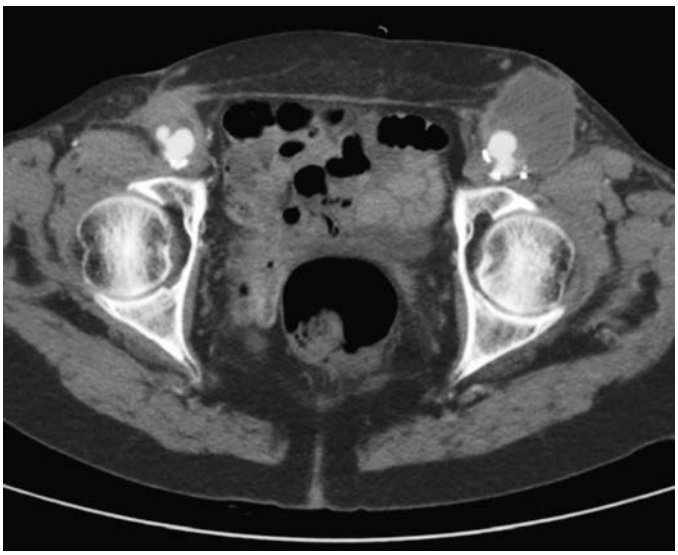

Figure 48.3 Axial computed tomographic image of bilateral femoral anastomotic aneurysm after aortobifemoral bypass.

The discovery of an anastomotic aneurysm at one site, particularly if femoral, necessitates definitive radiologic evaluation of the remaining anastomoses, because synchronous anastomotic aneurysms are often detected and may occur in up to 36% of patients.[17] Similarly, 13% of patients with abdominal anastomotic aneurysms concurrently harbor femoral anastomotic aneurysms.[49]

When an infected anastomotic aneurysm is suspected, nonspecific serum markers such as erythrocyte sedimentation rate and C-reactive protein levels may suggest a systemic inflammatory state. A technetium-labeled white blood cell scan may also assist in determining the probability of an infected anastomotic aneurysm.[50]

SURGICAL TREATMENT

Indications for Treatment

The indications for intervention when an anastomotic aneurysm is detected depend on several interrelated variables, including size, location, symptom status, and suspected etiology. Most concur that femoral anastomotic aneurysms may be safely observed until they achieve a diameter of 2 to 2.5 cm, or until they produce symptoms because of local expansion or distal embolization.[51] While data on rupture risk as a function of size are not available, it is generally accepted that this probability increases as they grow larger.[52] Early appearance of an anastomotic aneurysm often signals a more ominous etiology and frequently requires additional evaluation and earlier intervention. Urgent treatment is required for severe manifestations of anastomotic aneurysms, such as hemorrhage, graft thrombosis, and embolization.

Although less common, aortic and iliac anastomotic aneurysms should be considered for repair at discovery because of difficulties in surveillance and the seriousness of their potential complications.[3,21,22,53] However, some authors recommend selective intervention for aortic and iliac anastomotic aneurysms.[15,47] The decision for repair should be based on assessment of operative risk, and those who do not undergo immediate repair should undergo periodic clinical and radiologic surveillance. Saccular aortic and iliac anastomotic aneurysms represent a special population that historically behave more aggressively and thus may not be amenable to extended surveillance.[54]

Carotid anastomotic aneurysms are rarely encountered in clinical practice but deserve special attention. The morbidity and mortality attributable to these lesions obligate consideration for surgical intervention.[24,55] When infection is suspected or clinically apparent, expeditious intervention is warranted.

Principles of Treatment

Each anastomotic aneurysm should be approached after considering its etiology and how this factor influences its management. Infection should be presumed until definitively excluded by exploration and standard microbiologic techniques. The management of infected anastomotic aneurysms, suggested by perigraft fluid or poor tissue incorporation, often requires complex reconstruction and is associated with increased morbidity and mortality, especially under urgent circumstances.[14,53]

If using an open technique for repair, operative goals include safely obtaining proximal and distal vascular control, careful preservation of important arterial branches and collateral vessels, and replacement or exclusion of the aneurysm to prevent or limit complications. Tedious and hazardous dissection, often in a densely scarred, altered surgical field, is characteristic of such therapeutic endeavors. Care and judgment is required to prevent premature aneurysm disruption that may result in significant hemorrhage. Excessive mobilization should also be avoided to prevent dislodgement and distal embolization of mural thrombus. In particularly difficult dissections, intraluminal balloon occlusion may assist in controlling inflow or outflow arteries and circumvent an otherwise perilous situation.

Although open surgical techniques have predominated in the literature concerning management of anastomotic aneurysms, several authors have published reports of successful endovascular treatment. Endovascular techniques are particularly suitable for treatment of aortic and iliac anastomotic aneurysms, especially with the advent of fenestrated and branched endovascular devices, and in many circumstances they have supplanted conventional treatment strategies (Table 48.1; see Chapter 80).

Open Repair

When suture disruption is the apparent etiology, especially when anastomotic failure occurs early, simple repair of the anastomosis is an option. However, when arterial wall degeneration, or less commonly, graft deterioration is discovered, insertion of an interposition graft is preferred; this technique is associated with excellent patency and low risk of recurrence.

Femoral Anastomosis

Detailed preoperative arteriography assists in operative planning and provides critical information by documenting the patency and location of the involved arteries, the status of the pelvic circulation, and the likelihood of infection. The existing graft is identified through the previous incision and controlled for later occlusion (Fig. 48.4). Large femoral anastomotic aneurysms may necessitate proximal control through a suprainguinal incision. In this approach, an incision is made between the anterior superior iliac spine and a point halfway between the pubis and the umbilicus. The abdominal wall muscles are divided, and the preperitoneal plane is identified. Exposure is carried posteriorly using blunt dissection. The external iliac artery is identified in association with the vein. Circumferential dissection of the artery allows for loop control or clamping. Alternatively, it is often convenient to employ balloon occlusion of the external iliac artery after dissecting the false aneurysm in the groin. Distal control is next secured by careful dissection of the superficial and deep femoral arteries and other important collateral branches. Balloon occlusion may also be used for any branches that are obscured by dense scar tissue, including the profunda femoris artery.

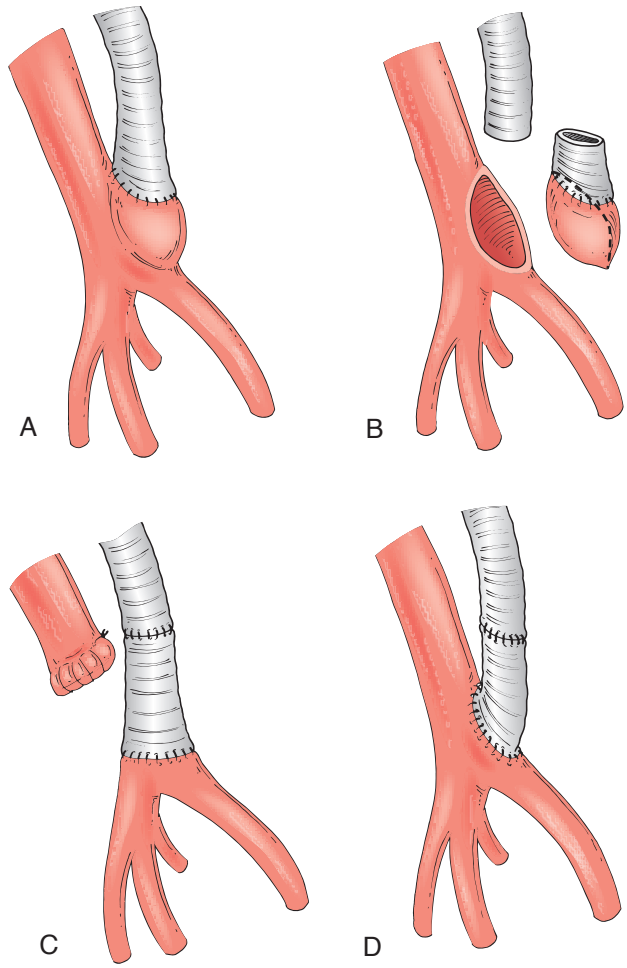

Figure 48.4 (A) Depiction of a femoral anastomotic aneurysm with arterial wall degeneration. (B) View of the femoral anastomotic aneurysm after excision of the false aneurysm. (C) Repair of the femoral anastomotic aneurysm with an interposition graft (end-to-end anastomosis). (D) Repair of the femoral anastomotic aneurysm with an interposition graft (end-to-side anastomosis).

Following systemic anticoagulation, inflow and outflow arteries are occluded atraumatically, and the anastomotic aneurysm is entered. Local signs of infection, such as purulence, perigraft fluid, and poor graft incorporation, are sought. In the absence of overt infection, a tissue or graft specimen is submitted for microbiologic analysis. If the etiology appears noninfectious, interposition graft replacement is performed. If overt infection is present, an extraanatomic reconstruction may be warranted.

The false aneurysm including the distal graft and degenerative native arterial wall is debrided, and an interposition graft of a diameter similar to that of the recipient artery is selected. Some authors prefer polytetrafluoroethylene in their choice of conduit

because of its reduced propensity for dilatation, potentially reducing the incidence of late anastomotic aneurysm recurrence. When permissible, an end-to-end anastomotic configuration is recommended. However, if an end-to-end anastomosis compromises flow to critical vascular beds, such as the pelvic circulation, an end-to-side anastomosis is constructed with care to maintain a minimal incident angle between the graft and host artery. When managing a large false aneurysm, vascularized soft tissue coverage can be achieved with rotational muscle flaps. Several authors strongly advocate similar management techniques.[14,74,75]

Aortic Anastomosis

Preoperative imaging with noninvasive radiologic studies provides vital information regarding signs of graft infection, selection of a proximal clamp location, aneurysm proximity to visceral branches (especially the renal arteries), and the location of retroperitoneal and intraperitoneal structures (Fig. 48.5). Operative approaches vary by surgeon experience and preference, but both retroperitoneal and transperitoneal approaches have distinct advantages and disadvantages. Frequently, a suprarenal clamp location may be necessary if the anastomotic aneurysm is juxtarenal, and proximal control may be more safely obtained, especially in the presence of scar tissue, via a retroperitoneal approach, especially if it helps avoid the previous operative field.

When open repair is contemplated, most frequently an aortoaortic bypass is performed with a tubular prosthesis that originates from the proximal normal, nonaneurysmal aorta to the existing graft distally. Occasionally, visceral branch bypass is required to ensure a secure proximal anastomosis. Less frequently, and if distal anastomotic revision is required concurrently, implantation of a bifurcated graft (aortobiiliac or aortobifemoral) is expeditious.[76] If an infectious etiology is discovered intraoperatively, graft excision with extraanatomic bypass or autogenous in situ reconstruction is performed. In cases of infected aortic grafts involving the visceral or renal branches, direct reconstruction with nonautologous conduit may be unavoidable.

Iliac Anastomosis

As with aortic anastomotic aneurysms, intervention for iliac anastomotic aneurysms relies on accurate, high-quality noninvasive imaging for operative planning. Often the aneurysm involves the distal anastomosis of a bifurcated prosthesis and is located at or close to the iliac bifurcation. A retroperitoneal (flank) approach provides adequate exposure. Operative principles parallel those employed at aortic locations. Preservation of the internal iliac artery often complicates reconstruction, but may be accomplished with a separate bypass. The ureter should be carefully identified and protected, especially when managing large or inflammatory anastomotic aneurysms. Methods of ureteral protection include identification of the ureter in proximal unaltered tissue planes and preoperative placement of a ureteral stent.

Carotid Anastomosis

Based on clinical experience with primary carotid artery aneurysms, anastomotic aneurysm management using nonoperative strategies is thought to yield excessive morbidity and mortality.[77] Traditional management of carotid anastomotic aneurysms depends largely on the clinical suspicion or subsequent intraoperative discovery of infection, especially when a prosthetic patch is present. The preferred method of reconstruction is resection of the aneurysm with interposition bypass grafting or repair with patch angioplasty. Resection with primary anastomosis, extracranial to intracranial carotid bypass, and carotid ligation have also been described.[23] When infection is the presumed etiology, reconstruction with the saphenous vein is indicated. Carotid ligation has generally been limited to use in failed reconstruction attempts, and has been associated with a mortality rate of 28% to 50%.[23,77,78]

Endovascular Repair

Femoral Anastomosis

Open operation represents the traditional management strategy for femoral anastomotic aneurysms. Endovascular repair of anastomotic aneurysms at this location is problematic because of chronic hip motion that may cause deformation, fracture, or migration of implanted stents. Successful endovascular management of ruptured and nonruptured femoral anastomotic aneurysms, however, has been reported in cases of prohibitive operative risk.[78,79]

Aortic Anastomosis

Conventional open repair of aortic anastomotic aneurysms is formidable and is associated with mortality rates of 3% to 17%.[21,70] By avoiding the risks of re-operative aortic exposure and suprarenal aortic clamping, endovascular repair presents an attractive therapeutic alternative. Endovascular exclusion of aortic anastomotic aneurysms has been successfully described with both homemade and commercially manufactured stent-grafts, including tubular, bifurcated, and aortic uni-iliac stent-graft configurations.[15,64,70,80,81] Additionally, fenestrated, branched, and chimney devices are being increasingly used for proximal aortic anastomotic aneurysms involving the visceral vessels.[56-58,63,68,73,82-84] Stent-graft repair of ruptured anastomotic aneurysms is equally efficacious and advantageous.[73]

Important considerations include the ability to obtain detailed and high-definition CTA with multiplanar reconstructions for precise aortic measurement and graft selection. Particular attention is directed toward the proximal neck to ensure that adequate conditions exist for successful sealing. Neck diameter and length from the lowest renal artery to the flow divider of the existing graft are critical factors. A segment of nonaneurysmal aorta adjacent to the anastomotic aneurysm (the "neck") is vital to allow endograft fixation and aneurysm exclusion. The availability of a suitable neck is often the limiting factor in this form of therapy. Suprarenal fixation may provide additional proximal stability without an adverse effect on renal function.[73] Several investigators have noted late complications of endoleak and rupture when tubular endografts are employed because of insecure fixation to polyester graft and exclusive reliance on radial force.[19] However, sufficient graft oversizing (10%-20%) should permit secure sealing.[73]

When the distance from the lowest renal artery to the flow divider is insufficient to permit deployment of a modular bifurcated endograft, an aortic uni-iliac graft may be inserted with adjunctive femorofemoral bypass. As with endovascular repair of de novo aortoiliac aneurysms, internal iliac artery occlusion is occasionally necessary to achieve distal fixation without endoleak.[70,73] To avoid the risks of buttock claudication, pelvic ischemia, and rarely spinal cord ischemia, pelvic collateral circulation must be carefully investigated. Efforts to preserve at least one internal iliac artery are prudent.[57] When intentional internal iliac artery occlusion is planned, proximal embolization is recommended to prevent interruption of important collateral branches.

Increasing use of fenestrated and branched endovascular stent-grafts for the repair of proximal aortic anastomotic aneurysms has been reported, especially in cases where the length or quality of the proximal neck is insufficient.[56,84] Beck et al. described 18 patients with previous aortic reconstruction who developed juxtarenal aortic aneurysms from 2004 to 2008.[57] Technically successful treatment with fenestrated and branched endovascular stent-grafts occurred in all cases, and perioperative complications, including congestive heart failure and myocardial infarction, only occurred in two patients. Thirty-day and 1-year mortality were 0% and 11%, respectively. Mean follow-up was 23 months, with a cumulative primary patency at 95%. Zeigler et al. retrospectively reviewed their experience with the use of fenestrated and branched grafts for para-anastomotic aortic aneurysm repair in patients who were considered high risk for open surgical repair.[73] Of the nine patients who received fenestrated endoprostheses, technical success was achieved in all. Transient kidney injury was seen in three patients, and permanent renal impairment was seen in one. More recently, Reyes et al. reported on a series of 34 patients undergoing endovascular repair for pararenal aneurysms after prior open abdominal aortic repair.[68] While the majority of patients underwent fenestrated or branched graft repair, four patients underwent chimney-EVAR. The technical success rate was 97%, with a 3% 30-day mortality. During follow-up, six patients (18%) underwent reintervention, although primary patency of the target aortic branches was 98%. While short- and mid-term outcomes of fenestrated and branched EVAR are promising, long-term outcomes are still largely unknown. Furthermore, specific complications from using these complex techniques, such as target vessel occlusion and type III endoleaks at the side branch joints should be considered during the initial perioperative period and throughout follow-up.

In complicated cases in which the anastomotic aneurysm encroaches on the renal arteries, superior mesenteric artery or celiac trunk, an alternative to a completely endovascular fenestrated or branched repair is a hybrid repair.[83,85] In a review of their experience with complicated pararenal and thoracoabdominal aortic pathologies treated with hybrid approaches, Böckler et al. described two para-anastomotic aneurysms treated with commercially available endografts after open revascularization of visceral and renal arteries.[85]

Concurrent infection should generally be excluded before committing to an endovascular repair strategy, a decision that relies on clinical and radiologic data. When an aortoenteric fistula is present, stent-graft repair may function as a bridge until definitive therapy can be accomplished. If endovascular repair is performed as definitive therapy, it should be used in conjunction with extended antibiotic treatment with possible lifelong antibiotic prophylaxis.[16,57,86]

Isolated reports also chronicle the management of both aortic and iliac anastomotic aneurysms with percutaneous embolization using traditional coils, *n*-butyl cyanoacrylate, and Amplatzer (AGA Medical Corp., Plymouth, Minnesota) atrial septal defect occluder devices.[87-89] Badran et al. reported a case of embolization with transcatheter delivery of thrombin to a thoracic aortic pseudoaneurysm at the anastomosis between graft and native aorta patch.[90] It is important to note that the neck

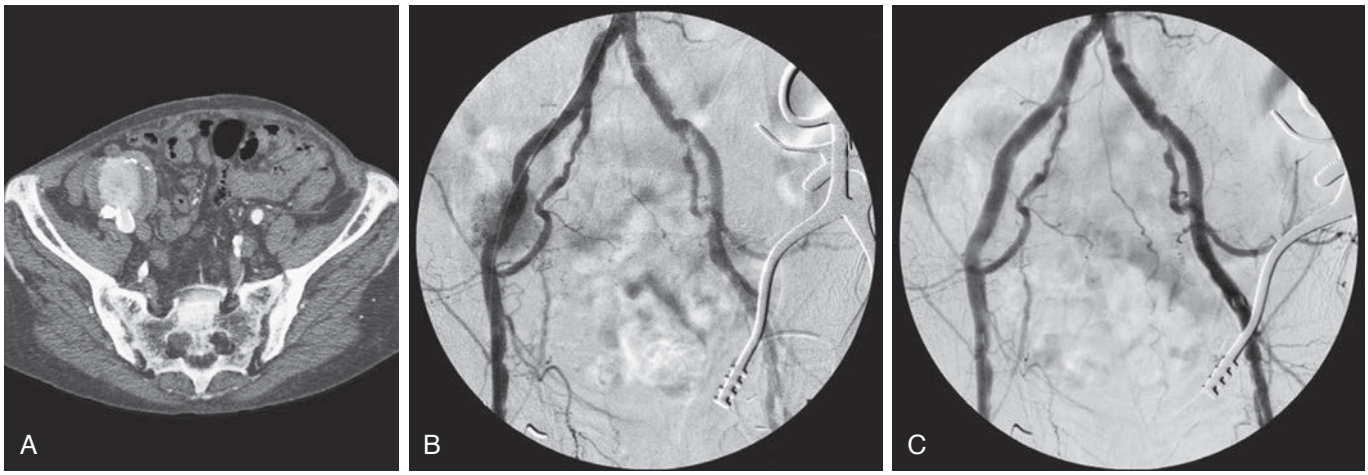

Figure 48.6 (A) Axial computed tomography of a right external iliac anastomotic aneurysm. (B) Diagnostic arteriogram demonstrating a right external iliac anastomotic aneurysm. (C) Successful exclusion of the external iliac anastomotic aneurysm with a covered stent.

of this pseudoaneurysm was narrow, and catheter placement actually occluded the neck, which allowed for successful intervention, emphasizing that practice must be tailored to well-suited cases.

Iliac Anastomosis

Open repair of iliac anastomotic aneurysms is also technically challenging and is associated with significantly higher morbidity and mortality than primary iliac aneurysm reconstruction.[91,92] Endovascular treatment principles are similar to those employed in the management of aortic anastomotic aneurysms, and successful intervention has been described (Fig. 48.6).[93] Management is frequently complicated by a patent internal iliac artery that requires embolization and coverage for successful aneurysm exclusion.[94] However, when preservation of the artery is necessary, separate revascularization with bypass is a durable solution. Hybrid techniques combining open and endovascular repairs have been successfully used in both symptomatic and ruptured iliac aneurysms.[95,96]

Carotid Anastomosis

Endovascular techniques recently have been adapted to the management of carotid anastomotic aneurysms. To avoid a difficult dissection and ameliorate the risk of cranial nerve injury, a few investigators have reported successful management of extracranial carotid aneurysms with stent-grafts, endovascular balloon occlusion, and bare-metal stents with adjunctive coil embolization. Zhou et al. reported their experience with the endovascular treatment of 14 carotid anastomotic aneurysms over a 10-year interval.[24] Length of hospital stay, cranial nerve injury, and 30-day mortality and stroke rates were significantly lower than those in patients managed with conventional open reconstruction during earlier and concurrent periods. Primary patency of endovascular intervention appears acceptable during early and intermediate follow-up,[97] and no progression of neurologic symptoms has been reported.[98] However, long-term results are currently unavailable.

OUTCOMES

Compared with treatment of de novo arterial aneurysms, therapy for anastomotic aneurysms is associated with greater morbidity and mortality primarily because of challenges associated with remedial intervention and advanced medical illness in elderly populations. Mulder et al., in a retrospective analysis of 220 noninfected anastomotic aortic aneurysms managed surgically, reported overall intraoperative mortality rates of 4.5% and 24% in elective and emergency circumstances, respectively.[53] Similarly, open repair involved an overall morbidity rate of 53% (50% in elective and 70% in emergency operations), with a 14% rate of re-intervention and a 2.6% amputation rate.

As with de novo aneurysms, the mortality rate associated with ruptured aortic anastomotic aneurysms is dismal, estimated at 67% to 100%.[47,53] The discrepancy in mortality and morbidity between elective and emergency repair of anastomotic aneurysms highlights the argument for early elective repair. For example, Bianchi et al. found 31 treated anastomotic aneurysms in their single institution review over a 25-year period.[99] The mortality rates among the elective and emergency cases were 5% and 66.6%, respectively, and the morbidity rates were 57.8% and 75%, respectively. In addition, the survival rate during follow-up was significantly higher for elective than emergency cases. While elective repair of anastomotic aneurysms carries a higher operative risk than the initial grafting procedure, it appears to be acceptable when compared with the risk of emergency repair following rupture.

Endovascular repair of aortic and iliac anastomotic aneurysms is associated with high technical success and reduced early- and intermediate-term morbidity and mortality compared with open repair. At intermediate follow-up, aneurysm exclusion is consistently observed without a significant incidence of endoleak or conversion to open repair.[73] Bosch et al. demonstrated the durability of endovascular repair of anastomotic aneurysms after previous open aortoiliac reconstruction.[58] The retrospective review of four centers' experience with anastomotic aneurysms

in 80 aortic and iliac anastomoses demonstrated high technical success rates and acceptable mortality and morbidity. Exclusion was successfully maintained in 86% of the anastomotic aneurysms over a mean follow-up of 41 months (range 0-106 months).

With modern techniques—namely, interposition grafting—recurrence rates after repair of femoral anastomotic aneurysms have improved.[11,83,100] Recurrences after initial operative repair occurred in 9.5% to 19% of patients.[53,101] The risk of recurrence increased with graft dilation and continued arterial wall degradation, as well as with local wound complications and female sex.[4,102] Compared with the primary operation, repair of femoral anastomotic aneurysms was associated with increased morbidity, including a significant incidence of perioperative hemorrhage and wound infection.[103] The effect of different repair techniques on postoperative complication rates has not been reported.

Aortoenteric fistula (AEF) is defined as a communication between the aorta and gastrointestinal (GI) tract. AEF is classified as primary or secondary based on the underlying cause leading to the fistula development. Primary AEF is a communication between the native aorta and GI tract; secondary AEF is a communication between a reconstructed aorta (for either aneurysmal or occlusive disease) and the GI tract.

Sir Astley Cooper was the first to describe a primary AEF in a publication in 1829. He referred to it as a "sometimes but serious complication of an aneurysmal aorta."[1] Brock published the first report of a secondary AEF in 1953, wherein he described a fistula between the proximal anastomosis of an aortic homograft and the duodenum.[2] Zenker performed the first repair of a primary AEF in 1954 by primary closure,[3] and MacKenzie et al.[4] performed the first successful repair of a secondary AEF in 1958.

AEF presents a particularly complicated challenge for the vascular surgeon. When it is left untreated, the outcome is almost universally fatal. However, surgical repair is fraught with complications, and despite continued advances in medicine and critical care, morbidity and mortality rates remain high.

In addition to the difficulties encountered with surgical treatment, AEF is notoriously difficult to diagnose, and as such, a high index of suspicion is required in approaching any patient with GI hemorrhage and history of aortic disease. This chapter reviews the pathogenesis, etiology, diagnostic methods, and treatment options for AEF.

PRIMARY AORTOENTERIC FISTULA

Incidence, Etiology, and Pathogenesis

The incidence of primary AEF has been reported at 0.04% to 0.07% in large autopsy series.[5] The body of literature available on the subject of primary AEF is small, with approximately 251 cases available in the published literature.

Despite the rarity of primary AEF in the population overall, the incidence in patients with aneurysms of the abdominal aorta is 0.69% to 2.36%.[6] In the majority of cases (83%), an aneurysmal aorta is associated with primary AEF; foreign bodies, tumors, radiotherapy, infection (historically due to tuberculosis and syphilis but now most commonly caused by *Klebsiella* and

Salmonella), and GI tract disease (peptic ulcer disease and perforating biliary stones) account for the remainder of AEF. The mean diameter of the aorta with primary AEF is 6.2 cm; the mean age of patients is 64 years, with a male-to-female ratio of 3:1.[7]

The most commonly described GI tract location for primary AEF is the third and fourth portion of the duodenum (54%). It is presumed that this is due to the tethering effect of the ligament of Treitz, leaving this portion of the duodenum exposed to the direct pulsatile pressure of the aorta. Primary AEF has also been described in the following locations: esophagus (28%), small and large bowel (15%), and stomach (2%).[7]

Overall, the pathogenesis of primary AEF is uncertain. The proposed mechanisms are mechanical, infectious, and inflammatory (Fig. 49.1). In the majority of cases, the mechanical component is caused by the pulsatile pressure of an expanding aorta against the wall of the GI tract. This leads to local compression and ischemia, with weakening of the wall and eventual erosion with fistula formation.

SECONDARY AORTOENTERIC FISTULA

Incidence and Etiology

Secondary AEF is more common than primary AEF and is related to prior vascular surgery, with an incidence of 0.36%[8] to 1.6%[9] reported after open abdominal aortic graft reconstruction. The interval from aortic reconstruction to onset of symptoms is on average 2 to 6 years after graft placement. Secondary AEF involves fistulization between the GI tract and a prior vascular reconstruction for either aneurysmal or occlusive disease. Although it is typically described as occurring in the setting of a synthetic graft, secondary AEF has also been reported with aortic homograft reconstruction and allografts. Similar to primary AEF, the most common location described for secondary AEF is the distal duodenum and proximal jejunum. However, secondary AEF has been described at multiple GI sites depending on the location of the prosthetic graft.

Secondary AEF has been further classified based on the location of the fistula regarding the suture line of the graft (Fig. 49.2). A fistula that has a direct communication between the arterial circulation and the GI tract at the level of the suture line is classified as a graft enteric fistula. Communication between the GI tract and the graft interstices (but not at the suture line) is referred to as a graft enteric erosion. Both entities are highly morbid complications that require urgent management; however, the etiology and presentation may differ. The graft enteric fistula's

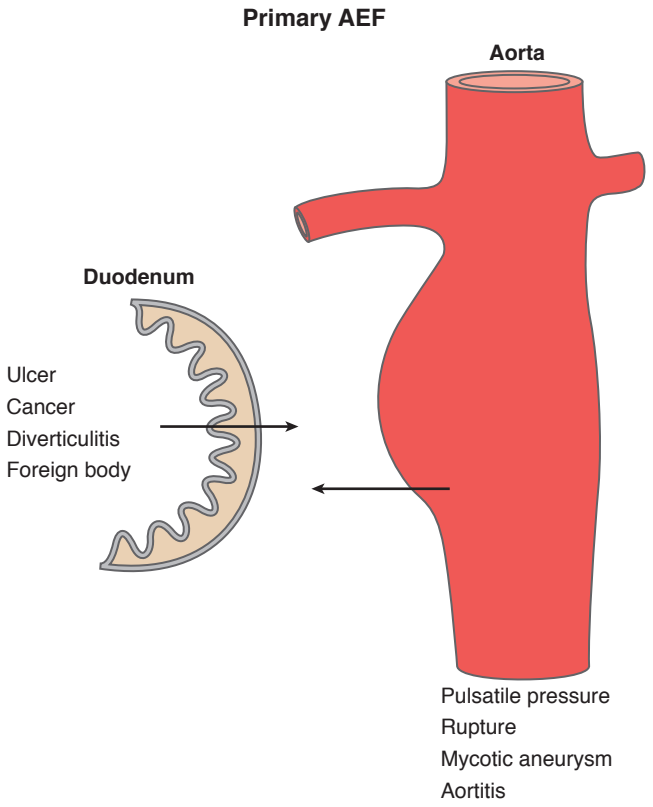

Figure 49.1 Etiologic factors for primary aortoenteric fistula (AEF). Pulsatile pressure from an expanding aneurysm is thought to be the predominant feature in the development of primary AEF. Other factors related to intrinsic bowel conditions may play a role in the development of primary AEF in a minority of cases.

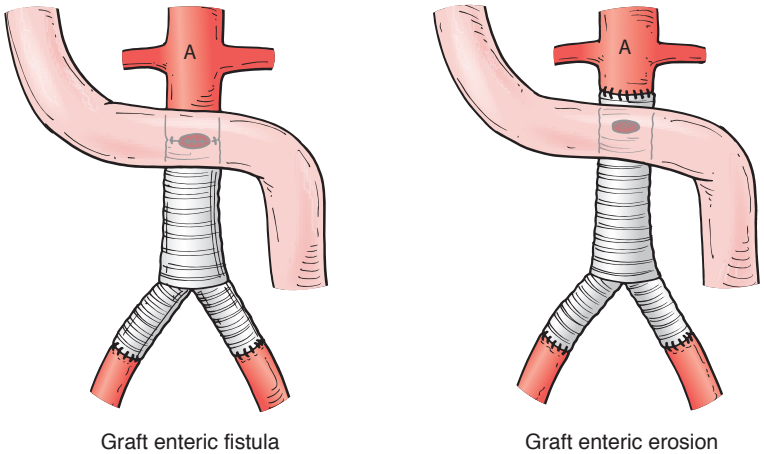

Figure 49.2 Graft enteric fistula versus graft enteric erosion. Graft enteric fistula has a communication between the bowel and the arterial circulation at the level of an arterial prosthetic suture line. Graft enteric erosion has a communication between the bowel and the interstices of an arterial prosthetic graft without involvement of the suture line.[10]

involvement of the suture line will disrupt the arterial anastomosis and causes dramatic hemorrhage, whereas graft enteric erosion may be manifested first with infectious symptoms as a result of direct contact of the graft material with the GI tract, allowing bacterial translocation to occur between the interstices of the graft from the GI tract.

The etiology of secondary AEF includes both patient and surgical factors that occur during the initial placement of the graft. A history of multiple vascular procedures, wound complications, infection, emergency operation, and technical error have been found to predispose to secondary AEF formation.[11]

Pathogenesis

The proposed mechanisms of secondary AEF pathogenesis are infection, pulsatile pressure, and technical error.

Infection

Infection, introduced either at the time of initial surgery or through bacteremia, is an important cause of secondary AEF formation. Graft infection leads to local inflammation and results in breakdown of the suture line, pseudoaneurysm (PSA) formation, and eventual rupture into surrounding structures. The majority of patients described in case reports with AEF have clinical and bacteriologic evidence of graft infection at the time of reoperation. A study by Busuttil et al.[12] demonstrated the role of infection in the pathogenesis of AEF with a canine model of 24 animals divided into four groups. In group 1, the duodenum was fixed to the proximal suture line of a Dacron aortic interposition graft. Group 2 underwent the same procedure but was subjected to an infusion of *Staphylococcus aureus*. In group 3, a false aneurysm was created with a patch of duodenum incorporated onto the anterior aspect of the proximal suture line. The same procedure was performed in group 4; however, this group was also subjected to *S. aureus* infusion. At the end of 6 weeks, no dogs in group 1 had an AEF, two of six dogs in group 2 had an AEF, three of six dogs in group 3 had an AEF, and five of six dogs in group 4 had an AEF. This study clearly demonstrated that infection is a key factor in the formation of AEF, independent of any mechanical or technical factors.

Pulsatile Pressure

Pulsatile pressure also remains a factor in the proposed mechanism of AEF formation. As described earlier, pressure from a noncompliant prosthesis against the bowel wall may lead to ischemia to the surrounding tissue and eventual erosion. Another mechanism described is suture line disruption, leading to the formation of an expanding PSA, compressing surrounding structures and eventually eroding into the bowel. Despite the intuitive nature of this mechanism, the majority of studies continue to point to the issue of infection as the root cause of AEF.

Technical Error

The final factor in the formation of AEF is technical error. This includes inoculation of the prosthesis at time of implantation as well as duodenal injury, serosal thinning, and ischemia during the operation. Changes in standards in patient preparation and appropriate antibiotic administration intraoperatively have decreased the overall rate of aortic graft infection. Operative trauma to the bowel, however, remains an issue. The bowel can be injured during the initial dissection and exposure either directly with sharp injury and heat transfer from cautery or indirectly by overretraction and tension. Retraction injury may occur from the retractor blades directly; however, it may also occur by overcompression of the bowel, causing ischemia, or by allowing the bowel to become dehydrated outside of the body. Methods to reduce bowel trauma include wrapping the bowel in warm moist laparotomy sponges during the procedure (being mindful to resoak the sponges intermittently), keeping the bowel intraperitoneal by packing it above the liver (which can be difficult in larger patients), and using an isolation bag to keep the bowel moist and protected (but still visible) while it is outside the abdomen. Another method to reduce bowel trauma is by using a retroperitoneal approach and interposing tissue between the aorta and the graft at the end. Proponents of the retroperitoneal approach believe that avoiding division of the parietal peritoneum to expose the aorta limits the devitalization of tissue and development of adhesions between the graft material and bowel. Regarding interposition of tissue between the aorta and graft, aortic sac closure followed by a second layer of retroperitoneal tissue and parietal peritoneum is the preferred approach. If that is unavailable, a flap of greater omentum or a layer of bovine pericardium patch material may be used. Omental coverage may be necessary more commonly in end-to-side graft anastomoses to the aorta, rather than in end-to-end anastomoses, and in thin patients.

Aortoenteric Fistula After Endovascular Repair

There is a growing body of literature documenting reports of AEF after endovascular aneurysm repair (EVAR) and thoracic endovascular aneurysm repair (TEVAR). There have been approximately 20 aortoenteric fistulae reported in the case of EVAR and 20 aortoesophageal and aortobronchial fistulae reported in the case of TEVAR. Proposed mechanisms in the case of endovascular repair include persistent endoleak with growth of the residual sac, multiple coiling efforts to repair an endoleak, erosion of the stent-graft through the aorta, endotension, and infection at the time of graft placement.[13,14] More recently, the Multicenter Study on Aortoenteric Fistulization After Stent Grafting of the Abdominal Aorta (MAEFISTO) study evaluated 3932 patients who underwent EVAR between 1997 and 2013 at eight Italian centers with EVAR programs. Of the patients who underwent EVAR at the participating centers, 22 presented with AEF on follow up, 15 of which underwent EVAR for atherosclerotic aneurysmal disease and 7 for postsurgical PSA. On subgroup analysis, they found that the incidence of AEF development of EVAR was 0.46% in patients undergoing EVAR for atherosclerotic aneurysmal disease and 3.9% when performed for PSA. Anastomotic PSA as indication for EVAR, and urgent/emergency EVAR were significantly associated with AEF development. There were no significant associations between choice of endograft and fistula

formation. The increased risk of AEF after EVAR for PSA does suggest that a preexisting infectious process or even subclinical AEF formation may have already been present at the time of EVAR placement in these cases. In urgent/emergency surgery, the presence of a hematoma compressing surrounding structures or the overall increase in local inflammation in emergency repair may contribute to the formation of AEF.[15]

CLINICAL PRESENTATION

The classic clinical triad for primary AEF as described by Sir Astley Cooper in 1829 consists of GI bleeding, abdominal pain, and a pulsatile mass. Recent reviews note the incidence to be 64% to 94% for GI bleeding, 32% to 48% for abdominal pain, and 17% to 25% for a pulsatile abdominal mass, with all three of these symptoms occurring concurrently in only 11% of cases.[16] Other symptoms reported include back pain, fever, and sepsis. Laboratory findings have been reported in only half of the studies, and only two thirds of patients demonstrated a hemoglobin level lower than normal (8 mmol/L). One-quarter of patients had leukocyte counts above the upper limit of normal (10×10^9).[12]

In the case of secondary AEF, hemorrhage remains an important feature of the presenting symptoms. In a recent retrospective review of 4137 patients who underwent aortic reconstruction between 2000 and 2008, 37 patients (0.08%) presented with secondary AEF. Of these patients, 73% presented with some form of hemorrhage, 41% with sepsis, 22% with abdominal or back pain, 14% with graft limb thrombosis, 11% with a groin fistula, 8% with a peripheral abscess, 5% with a femoral PSA, and 5% with peritonitis.[17]

In both primary and secondary AEF, a classic clinical feature is the "herald bleed." This is a minor bleed that is self-limited because of vasospasm and thrombus formation. Herald bleeds may lead to hospital admission immediately; however, some patients experience multiple episodes of recurrent bleeding. Regardless of the initial presentation, an untreated herald bleed is commonly followed by an exsanguinating bleed within hours to months.

DIAGNOSIS

The diagnostic approach to the evaluation of AEF is dependent on the patient's hemodynamic status on presentation. In general, a high level of suspicion should be maintained in approaching any patient with massive GI bleeding and a history of an aortic aneurysm or previous aortic revascularization. In such cases of massive bleeding, diagnosis will often be made during exploratory laparotomy. If the patient is stable, the three major diagnostic modalities are computed tomography (CT) with iodinated contrast enhancement, esophagogastroduodenoscopy (EGD), and angiography. There has been some controversy in the past about which study should be done first; some authors have recommended EGD, followed by CT scan, followed by visceral angiography if no source is found. However, with the improvements of radiologic imaging, CT scan has become a preferred initial diagnostic test; CT scans are less invasive than EGD or angiography, are easy to obtain, and do not risk thrombus dislodgment.[18]

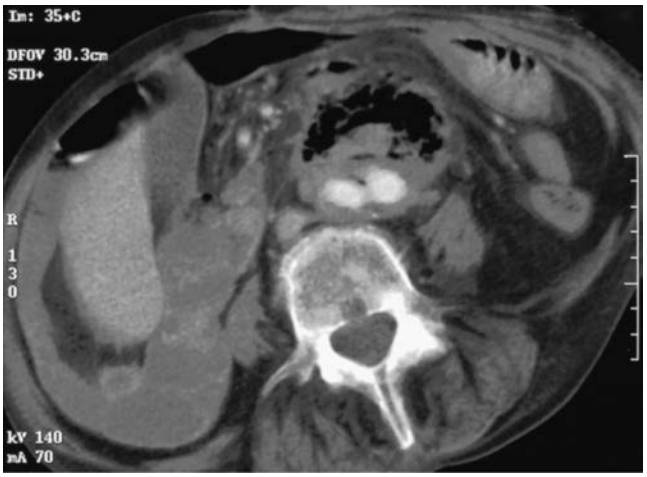

Figure 49.3 Contrast-enhanced computed tomography scan of a patient with a secondary aortoenteric fistula. Note the accumulation of gas and retroperitoneal inflammation surrounding a bifurcated aortic prosthesis.

Investigations

Computed Tomography

Common findings on CT scan include effacement of the fat planes around the aorta, perigraft fluid and soft tissue thickening, ectopic gas (Fig. 49.3), tethering of adjacent thickened bowel loops toward the aortic graft, and, in rare cases, extravasation of contrast material from the aorta into the involved segment of bowel.[19] The detection rate of CT for AEF is the highest of all modalities (61%),[13] and CT also can be used to assess the peripheral vasculature to assist with revascularization plans during repair.

Esophagogastroduodenoscopy

Endoscopy plays an essential role in the management of acute GI bleeding. Although it does not rule out AEF, it can exclude other sources of bleeding. The detection rate of AEF by EGD is 25%, and it is essential that the third and fourth portions of the duodenum be visualized for a complete study. Endoscopy may be facilitated by using a pediatric enteroscope or a side-viewing endoscope. A careful study by an experienced endoscopist with a high level of suspicion may reveal a graft (Fig. 49.4), ulcer, erosion with adherent clot, or extrinsic pulsatile mass. This is uncommon, however, and the primary purpose of EGD is to exclude other pathologic processes as the source of GI blood loss. Only hemodynamically stable patients should undergo EGD, and some surgeons recommend that EGD be performed in the operating room so that laparotomy can be done should a tamponading thrombus become dislodged during the study and lead to severe hemorrhage.

Angiography

The role of angiography as a diagnostic modality for AEF is limited. It may be useful to delineate arterial anatomy for

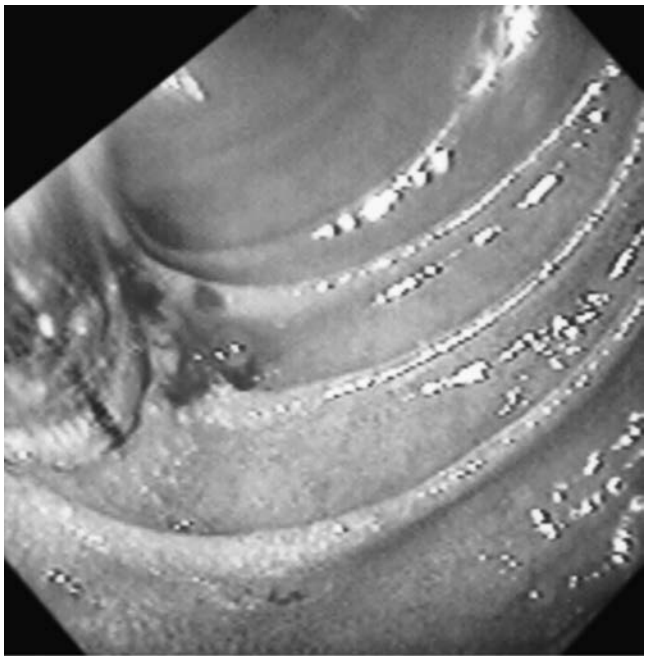

Figure 49.4 Esophagogastroduodenoscopy revealing an exposed Dacron graft that has eroded into the duodenum. Although this finding is unusual, esophagogastroduodenoscopy should be performed to visualize the fourth portion of the duodenum in most patients with gastrointestinal bleeding and previous aortic reconstruction.

Figure 49.5 Aortography revealing a secondary aortoenteric fistula arising from the proximal anastomosis of a bifurcated aortic prosthesis. Note the contrast material in the bowel lumen. Angiography is useful in planning reconstruction after graft excision but will only rarely document an aortoenteric fistula because most stable patients will have an occlusive thrombus sealing the fistula. (From O'Hara PJ. Surgical management of infected abdominal aortic grafts. In: Cowgill LD, ed. *Cardiac Surgery: State of the Art Reviews*. Philadelphia: Hanley & Belfus; 1987.)

potential reconstruction and to identify secondary AEF by finding PSA formation at the proximal anastomosis of grafts (Fig. 49.5), kinking of graft limbs, or bulges in deteriorating prosthetic material. However, because a stable patient is likely to have an occlusive thrombus sealing the fistula at the time of the examination, its use in diagnosis is limited, with an AEF detection rate of 26%. As part of a treatment modality, angiography can be useful to place a proximal occlusion balloon prior to laparotomy.

Other Tests

Other tests, including leukocyte- and erythrocyte-tagged nuclear scanning, magnetic resonance imaging, ultrasound, and contrast-enhanced GI studies, are potentially useful but usually less accurate and more time intensive. Both magnetic resonance imaging and magnetic resonance angiography may aid in the diagnosis of graft infection and AEF[20] but are more difficult to perform in critically ill patients. Nuclear imaging techniques using indium In 111–labeled leukocytes[21] or immunoglobulin G[22] and technetium Tc 99m hexamethylpropyleneamine oxime (^{99m}Tc-HMPAO)–labeled leukocytes[23] have high sensitivity in detecting graft infection, but their role in detecting AEF is less clear. Contrast-enhanced GI studies should be avoided, because they rarely help make the diagnosis, are time intensive, and can obscure findings in subsequent angiographic or contrast-enhanced CT studies.

A rare type of AEF is an aortoappendiceal fistula, which, given the location of the fistula and the quick transit time of blood through the large bowel, can cause patients to have bright red blood per rectum. In this situation, colonoscopy and tagged red blood cell scans may be needed for the diagnosis to be made.[24] Rarely, plain skeletal radiography reveals changes consistent with systemic infection. Unilateral lower limb hypertrophic osteoarthropathy[25,26] and multifocal osteomyelitis[27] have also been associated with AEF.

TREATMENT

Conservative nonoperative therapy for AEF is uniformly fatal,[28] and surgery is the only treatment option with the potential for success. The important factors to be considered to coordinate effective surgical management are the presence of active hemorrhage, the classification of the AEF (primary or secondary), the presence of sepsis, and the anatomic distribution of the patient's aneurysmal or occlusive disease.

The first priority in treatment is to preserve the patient's life; the second is limb preservation. Whereas hemodynamically unstable patients with active GI hemorrhage or sepsis require urgent operative intervention, stable patients with a resolved herald bleed may be further evaluated and optimized. These patients must be monitored closely, however, and should proceed to surgery as soon as possible as the risk of fatal rebleeding is high; 30% of patients rebleed within 6 hours, and 50% of patients rebleed within 24 hours.[13]

Urgent Surgical Treatment of Hemorrhage

In instances of massive GI bleeding, central venous access, volume resuscitation, and broad-spectrum gram-negative and gram-positive

antibiotic therapy should be initiated. In both primary and secondary AEF, the operative approach should be a midline incision, followed by rapid proximal aortic control. Infrarenal aorta control is preferable; however, supraceliac clamping may be required initially. If fluoroscopy or a hybrid OR is available emergently, proximal control via balloon occlusion should be considered. Distal control may be obtained with iliac clamping or occlusion balloons. Once the aorta has been controlled, the bowel should be sharply dissected off of the aneurysm/prosthesis; noncrushing bowel clamps or sutures can be used to control enteric spillage. If the bowel defect is small, it may be closed primarily; otherwise, a bowel resection and anastomosis should be performed after the aorta has been managed.

It should be noted that a recent review of aortoduodenal AEF bowel repair found higher rates of recurrent fistula after simple closure compared to complex (resection or diversion) bowel repair (48.9% vs. 11.1% $P = .036$). This same study found that on multivariate analysis, omentum (or any other structure) interposition between the bowel repair and artery was associated with lower mortality regardless of the technique used to close the bowel wall (OR 0.385, 95% CI 0.221-0.669).[29] In cases in which there is no evidence of infection, in-situ repair may be performed with prosthetic graft, cadaveric artery, or femoral vein. Care should be taken to separate the graft from the GI tract with the posterior peritoneum or omentum. If there is evidence of local infection, the aortic stump should be oversewn and covered with omentum; this should be followed by retroperitoneal débridement, drain placement, and extraanatomic bypass.

Surgical Treatment in Stable Patients

In the case of a hemodynamically stable patient with no active bleeding, more time can be spent evaluating and planning the procedure. This allows the order of the operation to be reversed, with extraanatomic bypass performed first (although initially a concern, the issue of graft infection of the newly placed prosthesis in the presence of a known infected abdominal graft has not been realized).[14,30] This may be particularly useful in patients with known infection with a functional graft or in patients with anticipated prolonged clamp time, as it allows both limbs and the pelvic vasculature to remain perfused throughout the case, thereby reducing the risk of amputation and bowel ischemia. Cystoscopy with placement of ureteral stents can also be performed before laparotomy, which may assist in reducing ureteral injury during dissection in an inflamed retroperitoneum.

Primary Aortoenteric Fistula

Management of primary AEF depends on whether infection is present in the aortic bed at the time of surgical intervention. In the case of mild contamination, in-situ replacement of the aorta with local débridement and long-term antibiotic therapy is the favored approach. In the case of gross retroperitoneal contamination and sepsis, aneurysm resection, omentoplasty, retroperitoneal débridement, and extra-anatomic bypass should be performed. The latter approach is considered inferior because of higher reported rates of mortality and limb loss, and most authors agree that it should be reserved for cases of gross contamination (defined as widespread aortic or retroperitoneal gross purulence or inflammation[31]) if possible.[32]

The majority of primary AEFs are in the duodenum and proximal small bowel, which is associated with less bacterial contamination because of differing flora and bacterial loads compared with more distal locations such as the colon. Regardless, all primary AEFs should be treated with antibiotics in the postoperative period. Broad-spectrum antibiotics should be used until culture results are available, and then antibiotic therapy should be tailored appropriately. In the case of a negative culture, antibiotic therapy can be discontinued after 1 week; positive cultures necessitate a 4- to 6-week course.[33]

Secondary Aortoenteric Fistula

The available operative choices for secondary AEF are graft excision alone, in-situ replacement, graft excision and reconstruction with autogenous vein (i.e., the neo-aortoiliac system procedure), extraanatomic revascularization and graft excision, and endovascular repair with lifelong antibiotics.

It is generally agreed that all infected synthetic material must be resected if there is clear evidence of graft and retroperitoneal contamination, which is more likely with AEF involving the distal GI tract and fistulae that have been chronic. The infected arterial tissue should be debrided back to grossly healthy tissue and closed with monofilament permanent suture material, preferably in two layers. The defect in the GI tract should be repaired with conventional techniques appropriate for the location of the fistula and retroperitoneal drains placed to minimize the risk of persisting sepsis causing breakdown or PSA formation at the site of arterial closure. If it is feasible, a flap of omentum should be placed to separate the bowel from the aortic stump closure and to fill the dead space resulting from excision of the graft. Despite this additional procedure, there still remains concern for the integrity of the aortic closure when infection is present. The aortic closure is at risk of "blowout," which would lead to massive hemorrhage and a life-threatening emergency requiring emergent laparotomy.

Graft Excision Without Replacement

If the graft has been placed for occlusive disease or has been chronically occluded, it is possible to resect the graft without reconstruction. This will be possible only if the patient has sufficient collateralization, and CT or angiography may be helpful in assessing the patient preoperatively. If the original graft was placed in an end-to-side configuration, endarterectomy and patch angioplasty of the aorta and distal vessels may allow uninterrupted perfusion. Patch material such as vein or bovine pericardium should be considered. This approach should not be considered in patients with patent grafts, patients with grafts placed for aneurysmal disease, or patients with palpable distal pulses. The concern in these clinical scenarios is that removal of the graft will lead to profound ischemia and the risk of amputation. The patient needs to be critically assessed for a

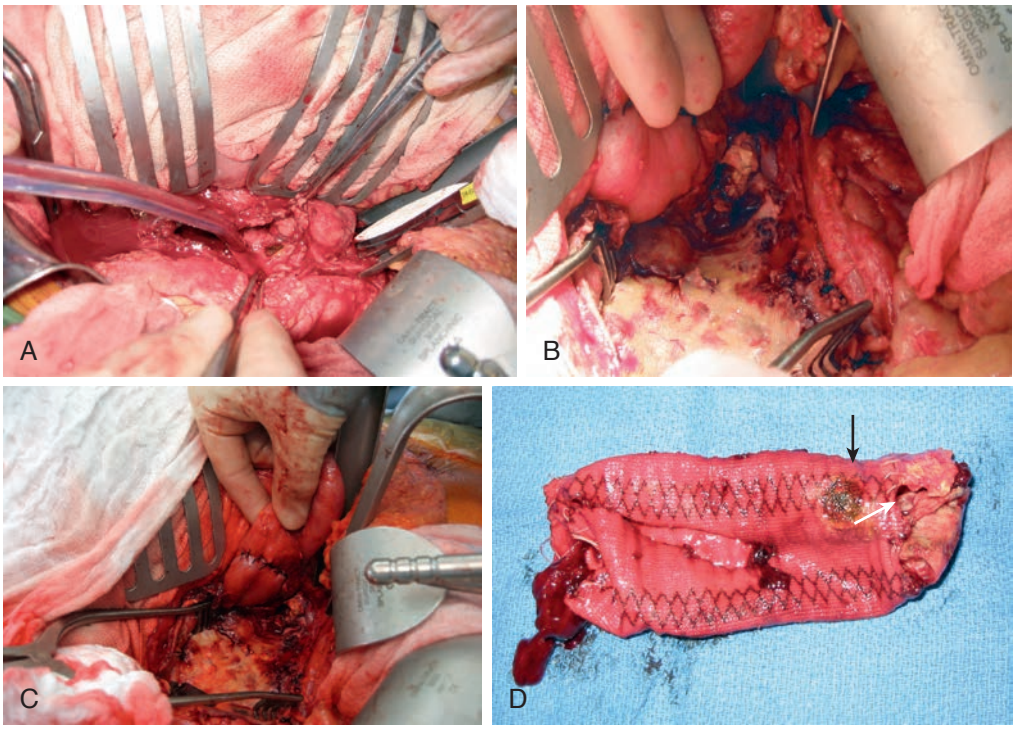

Figure 49.6 Intraoperative images of aortoenteric fistula repair with excision of aortic graft and extraanatomic revascularization: (A) aortoenteric fistula in situ, (B) remaining aortic stump, (C) duodenal closure, (D) remnant graft with fistula site *(arrow)* next to the former proximal anastomosis. (Courtesy Robert Steppacher, MD.)

means of arterial reconstruction that will allow adequate perfusion but not lead to a high risk of recurrent infection.

In-Situ Aortic Graft Replacement

In-situ reconstruction may be attempted with use of cryopreserved allografts (Fig. 49.6), antibiotic-soaked synthetic graft, or silver-coated Dacron. As previously discussed, this approach remains controversial; however, in recent years, it has become an increasingly accepted strategy. Advocates of in-situ reconstruction cite the following benefits: improved long-term patency, decreased risk of stump blowout, decreased risk of thrombosis ascending to the renal arteries after resection, and maintenance of blood supply to the colon and pelvis. Studies have also begun to demonstrate the potential benefit of in-situ reconstruction; a meta-analysis in 2006 demonstrated a lower operative mortality for in-situ reconstruction with rifampin-bonded prosthesis compared with extraanatomic reconstruction in patients with aortic graft infections,[34] and a retrospective study of in-situ reconstruction for secondary AEFs published in 2011 demonstrated no difference in operative mortality between in-situ reconstruction and extraanatomic reconstruction.[18] Another important factor crucial to the success of secondary AEF repair underlined by this study was the role of carefully performed, effective visceral repair, as bowel leakage was a significant predictor of fatal outcome.

Neo-Aortoiliac System Procedure

The neo-aortoiliac system procedure uses the femoropopliteal vein to reconstruct an autogenous neo-aortoiliac system. Chung et al.[35] have advocated this technique in the setting of graft infection, as it allows infection-resistant autologous tissue to be placed in the operative field and avoids the pitfalls of the aortic stump. Another benefit to this procedure is that use of autologous vein is relatively inexpensive compared with the use of cadaveric graft or other treated prosthetics, and it does not require lifelong anticoagulation as is the case with cadaveric allograft. The principal disadvantages of this procedure are the length of time required to harvest the deep vein and that it cannot be staged. Other drawbacks include the risk of venous insufficiency in the harvest limb leading to compartment syndrome and fasciotomy. These issues may be improved with multiple surgical teams and growing center experience. More data are required to determine if the benefits seen in patients with aortic graft infection with this approach can be extrapolated to patients with AEF.

Extraanatomic Revascularization

Extraanatomic revascularization is performed with externally supported (ringed) polytetrafluoroethylene and may be performed after abdominal closure with a fresh set of clean instruments to restore flow to the extremities. Alternatively, if the patient is stable and not actively bleeding, a preliminary extraanatomic revascularization may be performed before the aortic procedure. This allows uninterrupted flow to the extremities throughout the procedure and reduces the risk of limb ischemia and amputation. The interval between the procedures should not be too lengthy, however, as there is the potential for graft occlusion due to competitive flow as well as recurrent GI bleed.

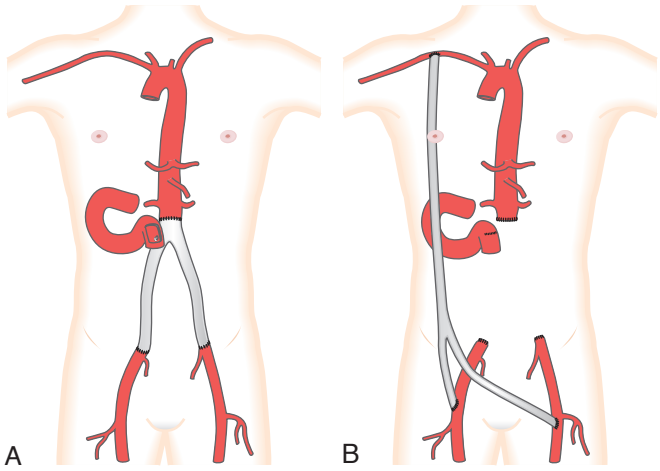

Figure 49.7 (A) Secondary development of aortoenteric fistula after synthetic aortobiiliac graft placement. (B) Surgical management includes extraanatomic bypass with an axillobifemoral graft, resection of all abdominal prosthetic material, retroperitoneal débridement, and closure of the bowel defect. (Modified from O'Hara PJ. Surgical management of infected abdominal aortic grafts. In: Cowgill LD, ed. *Cardiac Surgery: State of the Art Reviews*. Philadelphia: Hanley & Belfus; 1987.)

Regarding graft configuration, if the previous aortic synthetic graft reconstruction was intra-abdominal, axillobifemoral grafting is feasible (Fig. 49.7). However, if the graft infection has extended to the femoral arteries, as in the case of previous aortobifemoral graft placement, bilateral axillo-unifemoral grafts tunneled laterally to the available superficial femoral, profunda femoris, or popliteal arteries may be required. Tunneling of the left extraanatomic bypass may be a problem if a left retroperitoneal incision was used for the initial graft excision. A variation on this approach involves the use of a composite graft consisting of placement of a synthetic extraanatomic graft in a noncontaminated tissue plane with the autogenous graft component extending to the débrided, contaminated femoral vessels. Care must be taken to avoid contamination of the synthetic component, and the surgeon should be familiar with techniques such as sartorius muscle flap rotation to provide adequate soft tissue coverage of the femoral vessels. Appropriate antibiotic coverage is important to minimize the risk of seeding the extraanatomic bypass graft, which can occur in approximately 15% to 25% of patients.[14]

Endovascular Repair

With the technical difficulty and resulting morbidity and mortality of current open operative approaches, endovascular repair offers an appealing solution, as it allows rapid control of hemorrhage with minimal physiologic impact on the patient. In the last decade, a growing number of case reports have described endoluminal stent-grafting (EVAR) for AEF. The use of endografting is particularly interesting as it violates the basic principles of surgical treatment of AEF; the enteric fistula is not treated, the retroperitoneal tissue is not débrided, and the infected aorta/prosthetic graft is not removed. Despite this, a 2009 systematic review of the literature[36] identified 33 reports that included 41 patients with AEF who had EVAR as initial management. In this review, all patients underwent successful endograft implantation, and 20% had concurrent repair (open or endoscopic) of the contributing portion of the GI tract. Unfortunately, a significantly high complication rate was found after follow-up of 13 months, with 44% of patients developing persistent, recurrent, or new infection or hemorrhage and 29% of patients expiring, mainly as a result of septic complications. In the study, the major significant factors for poor outcomes were preoperative infection and complications that developed at any time after endovascular treatment. The overall conclusion of this study is that endovascular repair should be considered only a temporizing strategy until definitive repair can be performed. A similar conclusion was drawn from a multicenter retrospective study in 2011,[37] which reported the outcome of endovascular repair and open repair of AEF in 25 patients. The study found a statistically significant difference in overall morbidity in the short term (77% for open vs. 25% for endovascular); however, the early benefit of endovascular repair in the early operative period was lost by the second postprocedural year because of an increased recurrence of bleeding, sepsis, and AEF in the endovascular group. Despite these discouraging results, enthusiasm for endograft placement remains, and the practice of endograft placement with or without surgical management of the GI tract, long-term antibiotics, and "close surveillance" continues to be performed. This is particularly concerning, as recent reviews of the literature evaluating infectious complications after endograft placement have found that patients presenting with recurrent AEF or infection after endograft placement for the indication of AEF have uniformly fatal outcomes. In one study, which treated patients without explanation, but with antibiotics and surgical intervention for the bowel, 7/7 recurrent AEF patients died.[28] A second study, evaluating the outcomes of late open conversion for infected aortic endografts found that 6/6 recurrent AEF patients died.[38]

In the case of aortoesophageal fistula, there has been interest in TEVAR as a means to control bleeding and reduce the 55.5% mortality associated with open repair of this condition. A 2014 meta-analysis documented similar overall mortalities for TEVAR alone; however, there was a significant decrease in mortality (52.5% vs. 25% [$P = .029$]) on univariate analysis when the TEVAR was used as part of combined approach (e.g., with a staged graft excision and esophageal resection or staged esophageal resection and debridement). This paper also noted a decrease in mortality, bleeding, and AEF recurrence with the use of greater than 4 weeks of antibiotic on multivariate analysis (OR 0.03, 95% CI 0.001-0.21, $P = .0039$).[39]

In summary, endovascular repair should be reserved as a bridge to open repair once patients have stabilized and local infection control is established. It is also an acceptable treatment modality for patients with a limited life expectancy who would benefit from a short hospital stay and earlier discharge and will not be exposed to the long-term risks.[40]

RESULTS AND CONCLUSIONS

In primary AEF, standard aortic reconstruction with repair of the associated bowel defect has been successful. In a collective

review of 118 cases in the literature by Sweeney and Gadacz,[33] nonoperative management was uniformly fatal. Thirty-three patients were treated surgically, with an operative mortality of 36%. Standard aortic reconstruction with duodenal repair was performed in 19 of 22 survivors with minimal long-term sequelae. Similar results have been reported in an additional 35 cases in the Netherlands, thus indicating that placing a prosthesis in patients with primary AEF appears to be safe.[41]

The natural history of untreated secondary AEF is hemorrhage, continued sepsis, and eventually death. Operative mortality ranges from 13% to 86%, with an average mortality of 30% to 40%. Amputation rates hover at 10%, and long-term survival approximates 50% at 3 years. Taken together, these results attest to the tremendous physiologic stress from the AEF itself and the magnitude of operative repair of AEF. Of note, multiple authors have documented higher mortality rates in patients treated for AEF than in those treated for aortic graft infection alone. In a report of 61 patients, AEF operative treatment required longer hospitalization and more blood transfusion. Furthermore, operative mortality was higher (35% vs. 17%), and 12-month survival diminished (25% vs. 60%) for AEF versus aortic graft infection.[10]

Multiple strategies have been advocated for the operative management of AEF, and controversies continue to abound. In the appropriate patient with chronic graft occlusion or severe aortic occlusive disease, simple graft excision may be the only treatment required. In-situ repair with allograft, antibiotic-impregnated graft, or silver-coated graft has become an increasingly valid option in the appropriate patient population, as has the neo-aortoiliac system procedure. Extraanatomic reconstruction remains a safe alternative in the setting of gross contamination and can be particularly useful if it can be staged before the aortic graft resection. EVAR continues to make strides and has the greatest potential to minimize overall morbidity and mortality; however, it currently remains a temporary measure to bridge patients to definitive repair. In summary, the key features to successful treatment are timely intervention, appropriate patient selection, effective bowel repair, and long-term follow-up.

Inferior Vena Cava Filter Complications 635

INTRODUCTION

Endovascular procedures have become increasingly more common and in many cases are the first-line treatment for occlusive peripheral vascular disease.[1,2] Although less invasive, endovascular procedures can have unique complications differing from open repair that the surgeon should be prepared to treat.[3,4] These complications range from minor, which can be treated with minimally invasive intervention, to serious life- or limb-threatening conditions that require urgent operative or percutaneous interventions. Currently the majority of percutaneous peripheral interventions are performed with common femoral artery access.[5] Historical coronary data have shown an access site complication rate of up to 6.1%, with 2.3% requiring

Abstract:

Endovascular procedures have become increasingly more common. Although overall less invasive in nature, these procedures can have unique complications differing form open repair that the surgeon should be prepared to treat. These complications range from being to serious and life-threatening. Some of the most common complications are access site complications. These including a wide range of bleeding and occlusive complications. Complications during the procedure include vessel occlusion, dissection, rupture, and embolization. Device specific complications include device fracture and embolization. This chapter will outline complications unique to endovascular interventions and discuss treatment.

surgical repair.[6] A higher complication rate has been reported when an intervention is performed, rather than it being just a diagnostic study.[7] Contemporary data from the Vascular Quality Initiative looking at patients with critical limb ischemia show the rate of access site hematoma was 3% overall and access site occlusion or stenosis was 0.2%.[8]

Predicting which patients are at greatest risk for access site injury is crucial for the interventionalist. Risk factors for access site complications are listed in Table 50.1.[9-11] By identifying higher-risk patient groups, risk reduction strategies can be implemented and complications can be decreased.

GROIN HEMATOMA

One of the most common complications of percutaneous access is the development of a groin hematoma. Contemporary rates for groin hematoma during peripheral interventions have been reported as 3%.[8] The clinical manifestation of a groin hematoma varies widely. In most circumstances, postprocedure groin swelling is the only clinical finding. Other common signs and symptoms include pain, skin ecchymosis, bleeding at the puncture site, neuropathy secondary to nerve compression, anemia, and in more advanced cases hypotension.

Etiology and Manifestations

Hematomas can develop from difficult access, multiple access attempts, or inadequate closure or compression at the completion of the procedure. For access, adequate compression should be used after an attempt to obtain hemostasis; this can be variable based on needle size. Further, back wall injury or leakage around the sheath can contribute to hematoma formation.

Routine ultrasound use has been shown to decrease the risk of postprocedure hematoma. Routine and selective ultrasound guidance was used by 27% and 73% of interventionalists in the Vascular Study Group of New England. The overall post-procedural groin hematoma rate after PVI was 4.5%. However, the rate of combined moderate and major hematoma was 0.8%. Routine ultrasound use was protective against hematoma overall and particularly in patients aged greater than 80 years, obese patients, and those with a sheath size greater than 6 F.[12]

Figure 50.1 Left groin hematoma *(arrow)* after percutaneous access.

Management

Treatment strategies for groin hematomas generally consist of observation as well as correction of any underlying coagulopathy. Transfusion may be required. Manual compression should be applied to hematomas that have been identified in the acute setting. Similarly, mechanical compression devices such as the FemoStop (Radi Medical Systems, Wilmington, Massachusetts) or C-clamp have demonstrated benefit in reducing bleeding complications.[13] Computed tomography (CT) is useful to gauge the extent of the hematoma and assess for active bleeding, as evidenced by a contrast-induced blush (Fig. 50.1). Moreover, imaging is prudent with large hematomas to rule out extension into the retroperitoneum, especially when associated with hemodynamic instability. Laboratory assessment of hematocrit levels should be performed every 4 to 6 hours until stabilization. Furthermore, interval duplex assessment should be performed to rule out the development of a pseudoaneurysm. Although most of these patients can avoid surgical exploration, the time to ambulation is delayed and length of stay increases.[14] The incidence of hematomas requiring transfusions in the coronary literature has been reported as 1.8%. This was associated with both in-hospital mortality and 1-year mortality.[15] Groin exploration with evacuation of the hematoma is warranted in the setting of hemodynamic instability, persistent anemia despite transfusions, skin necrosis, nerve compression, or severe pain.

RETROPERITONEAL HEMATOMA

High punctures at the groin, particularly above the most inferior border of the inferior epigastric artery, present increased risk for the development of access site complications, including retroperitoneal hematoma (RPH).[16] Though rare, RPH has the potential for severe morbidity and even death if not detected. Bleeding that extends into the retroperitoneum is less likely to be tamponaded by surrounding structures (Fig. 50.2). Independent predictors of RPH include male gender, low body surface area, less than 1.73 m^2, and higher femoral artery puncture.[14]

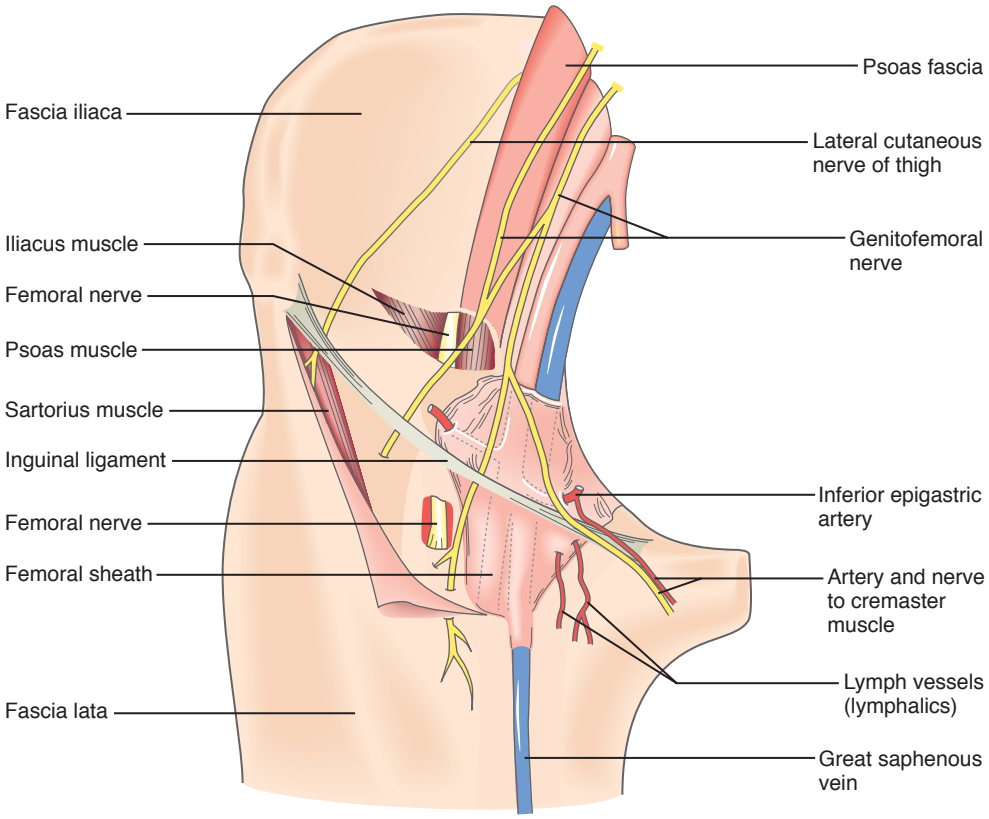

Figure 50.2 Relative anatomy of common few oral artery for access.

Manifestations and Diagnosis

Clinical findings of RPH are often subtle and less obvious than with groin hematomas. The most common symptoms are hypotension followed by diaphoresis, groin pain, abdominal pain bradycardia, and back pain.[14] The diagnostic test of choice for RPH is abdominopelvic CT (Fig. 50.3).

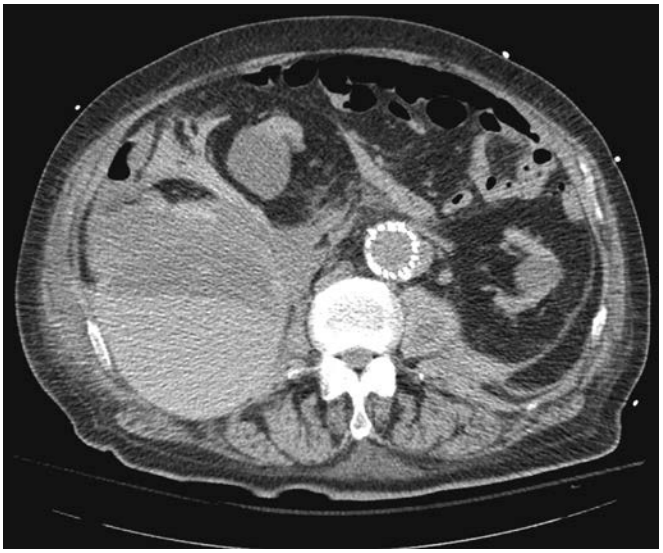

Figure 50.3 Computed tomography scan showing large retroperitoneal hematoma.

Management

Treatment for RPH is tailored to the clinical status of the patient. Indications for intervention include neurologic deficits in the affected extremity, hemodynamic instability, ongoing blood loss, and severe pain.[17] Decompression of an RPH can be performed either through a groin incision or through an incision above the inguinal ligament to gain direct access to the retroperitoneum and iliac vessels. Either way, the arteriotomy must be investigated and repaired for optimal therapy. A covered stent can also be used to obtain control of bleeding, especially if the arterial injury is above the inguinal ligament, avoiding a more morbid operation.[18]

ARTERIOVENOUS FISTULA

Etiology, Manifestations, and Incidence

An arteriovenous fistula (AVF) in the groin is a rare complication of percutaneous access and involves a communication between the femoral artery and vein. The incidence has been reported as 0.5% to 0.86%.[9,19,20] AVF after coronary interventions has been associated with high heparin dosage, warfarin use, left-sided access, hypertension, simultaneous femoral artery, and vein access and female gender. Within 12 months, 38% of all AVF closed spontaneously. None of the risk factors for AVF influenced the incidence or the rate of AVF closure.[19] AVF usually occurs

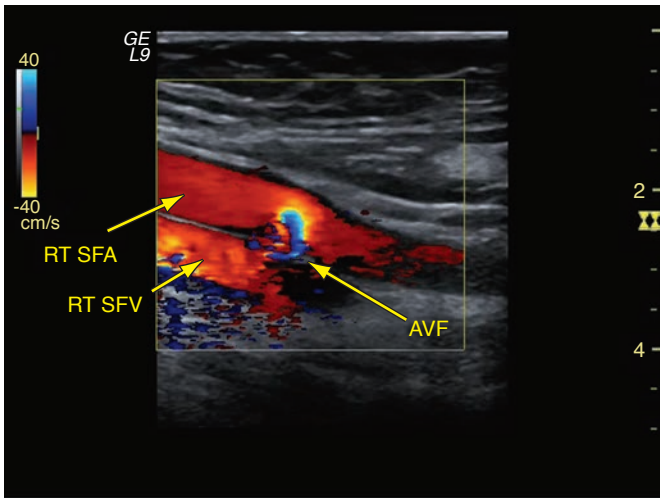

Figure 50.4 Duplex demonstrating the characteristic systolic-diastolic flow pattern seen with a femoral artery to vein arteriovenous fistula.

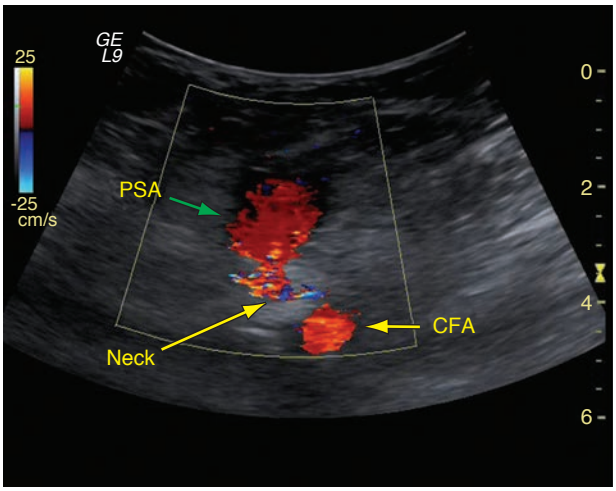

Figure 50.5 Duplex of a femoral artery pseudoaneurysm.

after inadvertent low puncture of the CFA bifurcation or the profunda femoris artery and vein, which run near the superficial femoral artery (SFA). However, AVF may also develop after through-and-through puncture of the CFA or SFA into the common femoral vein. Groin AVFs are generally asymptomatic and detected on physical examination by the presence of a palpable thrill in the groin or auscultation of a continuous bruit. Duplex ultrasound is the imaging study of choice and demonstrates the characteristic systolic-diastolic flow pattern with arterialization of the venous signal (Fig. 50.4).

Management

Treatment options include observation alone, surgical repair, and endovascular repair. While ultrasound-guided compression had historically been used to treat groin AVF, success rates are low.[21] If conservative management is implemented, patients should have follow-up duplex surveillance and physical examination. If symptoms do arise or the fistula increases in size, surgical treatment is indicated. Endovascular management of femoral AVFs has been reported with the advent of balloon-expandable stent-grafts.[22-24] Coverage of the fistula with a covered stent-graft results in immediate abolishment of the AVF without the need for surgery and therefore is optimal for high-risk candidates who may have failed conservative management. The decision whether to treat an AVF with open, endovascular, or conservative measures is still under debate and should be driven by surgeon experience and the patient's overall symptomatology and comorbid conditions.

PSEUDOANEURYSM

Etiology and Manifestations

PSAs develop postprocedure if the arteriotomy has not adequately sealed once the sheath is removed. There is communication with the arterial lumen, and blood spreads into the surrounding soft tissue. It is a "pseudo" aneurysm, in that no elements of the arterial wall are incorporated in the aneurysm sac; the wall of the PSA consists solely of compressed thrombus and surrounding soft tissue. PSAs can be differentiated from hematomas in that there is arterial flow into the PSA with a defined neck that tracks to the arteriotomy. The incidence of PSA formation after percutaneous procedures in contemporary series is less than 1%.[9,25]

The cause of a PSA is often related to an inability to adequately compress the vessel or closure device failure after removal of the sheath. This occurs most frequently with SFA or low CFA puncture because the femoral head sits more cephalic and compression is insufficient. On physical examination, a systolic bruit can be auscultated and is associated with the pulsatile groin mass. When there is clinical suspicion of a PSA, groin arterial duplex examination should be performed. The typical ultrasound appearance of a PSA is an echolucent sac that is pulsatile, and with the addition of color Doppler, a swirling flow pattern is noted within this sac (Fig. 50.5). On spectral waveform analysis, the characteristic "to-and-fro" flow pattern can be discerned and is pathognomonic for PSA.[26,27] If the PSA has significant extension into the retroperitoneum, abdominopelvic contrast-enhanced CT may be of benefit to evaluate its size, as well as to identify additional arterial injury sites.

Management

Before the 1990s, an operation was the primary recommended therapy for large or expanding PSAs, to decrease the complications of nerve compression, distal embolization, or skin necrosis. Subsequently, ultrasound-guided compression was performed. In the largest series published to date, success rates ranged from 74% to 93%.[28-30] The main factors impeding successful ultrasound-guided compression include anticoagulation at the time of compression, size of the PSA, and patient discomfort. Risks associated with ultrasound-guided compression include PSA rupture, distal embolization, and thrombosis of the femoral vein or artery.[28-30]

Ultrasound-Guided Thrombin Injection

The disadvantages of ultrasound-guided compression, including patient and ultrasound technician discomfort and only moderate success, prompted the development of the practice of injection of thrombin directly into the PSA under ultrasound guidance. The principle of this technique is based on the necessity of thrombin for conversion of fibrinogen to fibrin. When blood is exposed to high-dose thrombin within the aneurysm sac, fibrin clot forms and instantaneously results in thrombosis of the PSA. It should be noted, however, that this still remains an off-label use for thrombin, which was produced as a topical hemostatic agent.[31-34] Lonn et al. performed a randomized prospective study comparing thrombin injection to compression. Thrombosis within 24 hours was achieved in 15 (100%) patients given thrombin versus 2 (13%) in the compression group ($P < .001$). The most significant complications of this procedure include thrombosis of the native artery or vein if thrombin is inadvertently injected into these vessels. Anaphylaxis has also been reported anecdotally, especially with bovine preparations of thrombin, but this complication is very rare.[35] For PSAs that are small, observation alone is a reasonable treatment strategy.[36,37]

Surgical Management

Despite the excellent results with thrombin injection, there still remains a role for surgical repair of PSAs. These include larger pseudoaneurysms and those without a narrow neck, and those that have failed compression or thrombin injection. Techniques of PSA repair include direct surgical repair and endovascular options.[38,39] Endovascular options for postangiography PSA include using a covered stent, but they have not been adequately studied to date.[40,41]

Thrombosis

CFA thrombosis at the site of an endovascular procedure is a known complication of catheter-based interventions. Simple compression of the CFA after removal of the sheath can lead to thrombosis, especially in the presence of significant CFA atherosclerotic disease or previous groin reconstruction. CFA occlusion in a contemporary series in the treatment of critical limb ischemia in the Vascular Quality Initiative has been shown to be 0.2%.[8]

Thrombosis usually becomes apparent after the sheath has been removed and manual compression has been completed. Treatment consists of groin exploration with femoral endarterectomy, patch angioplasty, and thromboembolectomy. Alternatively, patients may benefit from endovascular interventions, including mechanical thrombectomy, thrombolysis, or atherectomy, to remove or dissolve the obstruction.

AXILLARY AND BRACHIAL ACCESS COMPLICATIONS

Although the vast majority of peripheral interventions are performed through the groin, severe atherosclerotic disease of the femoral or iliac vessels can often make this approach difficult. As an alternative, the brachial and axillary arteries have demonstrated adequacy as access vessels to perform lower extremity, visceral, or carotid interventions. These are becoming more frequent with complex aneurysm repair. In the Vascular Quality Initiative, brachial access was performed in 1.6% of vascular procedures. Brachial access was associated with an increased complication rate compared with femoral access (9.0% vs. 3.3%; $P < .001$), including more hematomas (7.2% vs. 3.0%; $P < .001$) and access site stenosis/occlusion (2.1% vs. 0.4%; $P < .001$). Neither the surgeons' overall peripheral vascular intervention experience nor prior experience with brachial access predicted likelihood of adverse events.[42] Larger sheath sizes (>5 F), percutaneous access, and female gender were risk factors for complications. In a cardiac catheterization study in which up to 7 Fr sheaths were used, the major complication rate was approximately 5%.[43] In evaluating the transaxillary approach, Chitwood and associates found a 2.3% incidence of complications, and the most common was nerve injury.[44] Risk factors identified for axillary artery injury included female gender, hypertension, periprocedural anticoagulation, thrombolysis, and prolonged (>90 minutes) procedures.

Nerve Injury

It is important to maintain high vigilance for nerve injury with transbrachial/transaxillary access because of the potential for permanent devastating disability of the upper extremity. When compared with the groin, where the incidence of nerve injury from percutaneous procedures is extremely low (0.2%), brachial access can be associated with clinically significant neuropathy of the various terminal nerves of the infraclavicular brachial plexus at an incidence ranging between 0.4% and 12.7%.[44-46] This neuropathy probably occurs because anatomically the median nerve and brachial artery are in close association and travel within the medial brachial fascial compartment (Fig. 50.6). Patients complain of pain radiating down the arm with associated muscle weakness and paresthesias. The most common and treatable

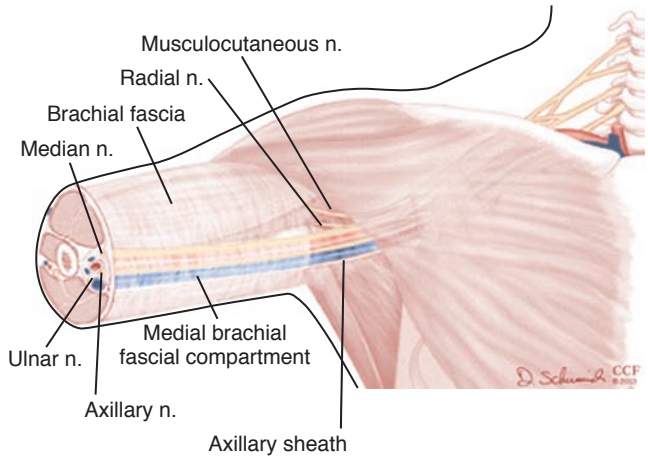

Figure 50.6 Relative anatomy of the brachial and axillary arteries.

cause of neurologic dysfunction is compression from an axillary sheath hematoma. Treatment involves decompression of the fascial compartment with exposure of the brachial artery and repair of the arteriotomy.

Thrombosis

The small diameter of the brachial artery makes it more prone to thrombosis. The diagnosis may become evident if the patient complains of hand symptoms, including pain, numbness, or tingling. This should prompt rapid removal of the sheath. For closure, manual compression should be applied with just enough pressure to prevent bleeding and hematoma while maintaining perfusion to the hand.

Radial artery access is becoming increasingly used for coronary interventions.[47] Radial artery occlusion has been seen postprocedure at a rate of 7.7% at 24 hours, which decreased to 5.5% at greater than 1 week follow-up. Higher doses of heparin, shorter compression time, advanced age, female gender, sheath size, and smaller diameter of radial artery have been shown to be associated with radial artery occlusion.[48] Radial artery occlusion is often without clinical sequelae due to collaterals in the hand.[49] Radial artery pseudoaneurysm has been shown to have an incidence of 0.08 %, with the majority of cases (80%) being treated with surgical repair.[50]

Pedal Access

Retrograde pedal access is more often used for tibial lesions that cannot be crossed antegrade or retrograde. Treatment could be accomplished either by snaring from above and treating antegrade or by placing a sheath in the pedal vessels. Although reports contain low numbers, pedal access appears safe with no local complications reported peri-procedurally, although the data is not clear about whether the target vessel for revascularization is altered.[51-53]

PERCUTANEOUS CLOSURE DEVICE COMPLICATIONS

Vascular closure devices (VCDs) allow for rapid arteriotomy closure after percutaneous interventions. They allow early ambulation and discharge after groin puncture and mitigate patient discomfort from extended manual compression. In addition, when compared with manual compression, which requires normalization of the activated clotting time (ACT) before pulling the sheath, VCDs are used immediately once the procedure has concluded. However, despite the obvious benefits of VCDs, they have not gained universal adoption among interventionalists. A Cochrane analysis of 52 studies showed that VCDs were associated with reduced time to hemostasis when compared with extrinsic compression. No deaths were reported secondary to VCDs. There were no differences in the incidence of infection between closure device type and extrinsic compression. Limited data were obtained when VCDs were compared with each other.[53]

TABLE 50.2 Risk Factors for "Preclose" Failure

Obesity

Hu G, Chen B, Fu W, et al. Predictors and treatments of Proglide-related complications in percutaneous endovascular aortic repair. *PLoS One*. 2015;10(4):e0123739.

Perclose

The primary suture-based closure device is the Perclose (Perclose, Abbott Vascular, Redwood City, California). It is a 6 Fr sheath mediated VCD that fires a single monofilament polypropylene suture. For sheath sizes greater than 8 Fr, more than one device is recommended. A prospective randomized study looking at the Perclose Proglide device compared with manual compression showed that there was shorter time to hemostasis, ambulation, and discharge with suture mediated closure. There was no difference in overall complication rate between the two treatment groups.[54]

Perclose is increasingly used to "preclose" the common femoral artery before endovascular aortic aneurysm repair (EVAR). Technical success rates of approximately 90% have been reported. Device failure can be treated with manual compression, additional Perclose use, or open repair. Predictors of failure include obesity, thoracic aneurysm repair, CFA calcification, CFA depth greater than 4 cm, and sheath size greater than 20 Fr, though the double closure technique has been effective for 24 F sheaths (Table 50.2).[55]

Starclose

The Starclose VCD delivers a nitinol clip to close the access site. A randomized prospective study comparing Starclose to manual compression showed no difference in complications. The results of the diagnostic Starclose cohort have been reported separately. Results for the interventional arm revealed major vascular complications occurring in 1.1% of Starclose subjects and 1.1% in manual compression subjects (P = 1.00). No infections were seen in either cohort. Minor complications in the Starclose interventional group occurred at a rate of 4.3% and with compression at 9.9% (P = .107). Procedural success ranges from 93.9% to 100%.[56-58]

Exoseal

Exoseal is a percutaneous vascular closure system based on an extravascular, bioabsorbable polyglycolic plug and comes in a 5 Fr device. A large retrospective review showed that immediate hemostasis was achieved in 93.9% of cases. Difficulty with deployment was attributable to malfunctioning of the device, massive vascular wall calcifications, postoperative scar tissue, or too steep a puncture angle. Minor complications were observed

in 7.4% of cases, with PSA (1%), inguinal hematomas (6.3%), and stenosis (0.1%).[59] Boschewitz et al. showed a 98% technical success rate with no major complications and a 0.7% minor complication rate.[60] A prospective analysis comparing Exoseal to manual compression showed no device failures and no major complications in the Exoseal group. Patient pain scores and satisfaction were higher with Exoseal than manual compression.[61]

Angio-Seal

Angio-Seal (St. Jude Medical, St. Paul, Minnesota) is a collagen plug closure device. Its use has been associated with less time to hemostasis and earlier ambulation compared to manual compression. The Angio-Seal device has been associated with ischemic complications when the device is deployed incorrectly.[62-65] However, the overall major complication rate is similar to other devices.[66,67]

Mynxgrip (Mynx)

The Mynxgrip (Mynx) closure device (Cordis, Milpitas, California) is a closure system that creates an immediate seal through the delivery of a polyethylene glycol plug external to the arteriotomy at the sheath access point. The sealant expands as red blood cells and platelets enter its porous membranes, further covering the access site, and within 30 days, the sealant is dissolved completely by hydrolysis, leaving no intravascular or foreign substances behind. In a registry report including 73,124 patients who had received Mynx devices after PCI procedures with femoral access from January 1, 2011, to September 30, 2013, the Mynx device was associated with a significantly greater risk of any vascular complication than alternative vascular-closure devices (absolute risk, 1.2% vs. 0.8%; relative risk, 1.59; 95% confidence interval [CI], 1.42 to 1.78; $P < .001$); there was also a significantly greater risk of access-site bleeding (absolute risk, 0.4% vs. 0.3%; relative risk, 1.34; 95% CI, 1.10 to 1.62; $P = .001$) and transfusion (absolute risk, 1.8% vs. 1.5%; relative risk, 1.23; 95% CI, 1.13 to 1.34; $P < .001$).[68]

BLEEDING COMPLICATIONS

The most common complication of VCD is device failure resulting in bleeding. For the Perclose Proglide, a wire can be replaced through the barrel of the device to permit replacement of a sheath or the use of another closure device. This allows time for normalization of the ACT, and removal with manual compression. However, if salvage of the sheath is not possible, adjunctive manual compression is required immediately. Protamine can also be given at this time to help facilitate hemostasis.

ISCHEMIC COMPLICATIONS

Less commonly, VCD malfunction can result in lower limb ischemia (Fig. 50.7). Either signs of ischemia develop immediately, or new-onset claudication or pain at rest may arise later.

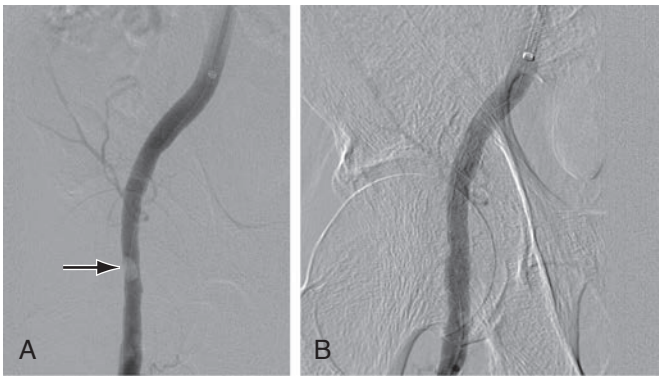

Figure 50.7 (A) Maldeployment of a vascular closure device causing arterial occlusion *(arrow)*. (B) Successful treatment of occlusion with atherectomy.

It is therefore prudent to obtain a baseline pulse and Doppler evaluation before an endovascular intervention and then recheck both lower extremities immediately after the procedure. The etiology of these adverse events is dependent on the device. On exploration, suture-mediated VCDs may have disrupted the back wall intima and caused an occlusive dissection flap that resulted in thrombosis. For the collagen or hydrogel matrix plug VCDs, ischemic complications occur when the prothrombotic material is inadvertently advanced through the arteriotomy, which can potentially embolize or cause local thrombosis. Treatment options for these complications include groin exploration with standard surgical thrombectomy, primary repair, or bypass.

PROCEDURE-SPECIFIC COMPLICATIONS

All endovascular procedures are dependent on the use of a combination of wires, catheters, sheaths, balloons, stents, and interventional devices. Complications caused by these devices can potentially be limb or life threatening, but in many cases they can be treated with adjunctive endovascular interventions. For a safe and successful intervention, it is critical that high-risk vessels be identified on either preoperative imaging or initial angiography. This may prompt earlier anticoagulation, use of protection devices, or use of smaller catheters and sheaths to prevent adverse outcomes.

Dissection

Balloon Angioplasty Dissection

One of the more commonly encountered problems during percutaneous procedures is intimal/medial dissection. This has been reported up to 7% of the time after balloon angioplasty.[69] Balloon angioplasty of atherosclerotic vessels almost always results in intimal dissection. Balloon inflation causes stretching and disruption of the plaque and overlying intima that result in a tear or dissection. Pulsatile arterial flow can then propagate the dissection distally and result in flow-limiting obstruction or arterial occlusion. Arteriography depicts the typical luminal

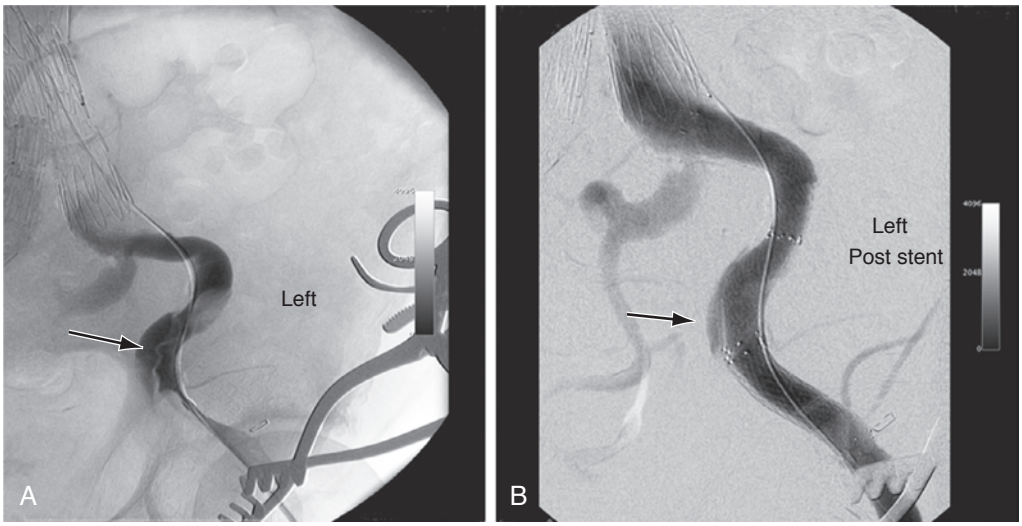

Figure 50.8 (A) Arterial dissection causing occlusion. (B) Successful treatment of occlusion with stent.

flap appearance with contrast media present on both sides of the dissection. Overdistention of a balloon in a normal vessel can also result in dissection. Postangioplasty dissections are initially treated by sustained inflation of a low-pressure angioplasty balloon in an attempt to "tack down" the dissection flap. If low-pressure angioplasty is unsuccessful and there is still a significant (>30% or flow-limiting) dissection, a self-expandable or balloon-expandable stent may be used to repair the dissection. Theoretically, the stent tacks the intima, increases the luminal diameter, and prevents further propagation of the dissection flap. Focal dissections in the infrainguinal vessels can also be treated by excision with a directional atherectomy device. If there is any question that a wire, catheter, or device is subintimal, the procedure should be halted and a low-profile catheter advanced to the point of resistance. If blood cannot be aspirated from the catheter, it is probably subintimal and should be withdrawn until blood can be aspirated. Low-pressure hand injection can then be performed. A subintimal position will be demonstrated by contrast material stagnating within the dissection plane without washout.

Small dissection planes that have been created in normal, nondiseased arterial segments, especially in large-caliber vessels such as the iliac arteries, can be tolerated if there has been no narrowing of the lumen and no evidence of thrombus development, particularly if the dissection is retrograde to the flow of blood. Alternatively, large iatrogenic dissections with a high probability of occluding the vessel or thrombosing require intervention (Fig. 50.8).

Subintimal Angioplasty

In certain circumstances, such as crossing chronic total occlusions, the creation of a dissection plane and subintimal advancement are done intentionally. It is critical that the point of reconstitution distal to the chronic total occlusion be exactly identified and the wire not be allowed to traverse more than 1 or 2 cm beyond the reconstitution point while in the subintimal plane. If accessing the native lumen is difficult, reentry devices such as the Outback catheter (Cordis, Johnson and Johnson, New Brunswick, New Jersey) can be used.[70,71] This has been associated with a low complication rate.

Figure 50.9 Distal embolization after proximal endovascular intervention.

Embolization

Embolization can be a devastating complication of endovascular procedures. It can transform a relatively straightforward procedure performed for claudication into a complex high-risk limb salvage endeavor (Fig. 50.9). In patients with large-volume atheromatous

disease, any wire, catheter, or sheath manipulation can result in distal embolization. Catheter movement across friable thrombus or atheromatous plaque, especially in aneurysmal vessels or a diseased aortic arch, can liberate embolic debris. Depending on location, this can result in "trashing" of runoff vessels, and if in the aortic arch, it can lead to stroke. The rates of lower extremity embolism have been reported from 1% to 3.8%, although not all are clinically significant if there is alternate distal flow. Atherectomy devices have been associated with higher distal embolization.[72] Also, the presence of thrombus in the lesion and TASC C and D lesions have also been shown to be associated with embolus.[72,73]

Management

Prevention of distal embolization is best achieved by recognition of high-risk vessels on preintervention imaging. It is then prudent to institute anticoagulation early and minimize manipulation across the lesion. Moreover, some groups have used embolic protection devices in lower extremity interventions by extrapolation from the carotid angioplasty and stenting experience, especially in the setting of large-volume plaque burden, significant thrombus burden, or single-vessel runoff.[74] If embolization does occur, endovascular rescue can be implemented for salvage of the vessel. First, the patient should be heparinized with confirmation of adequate anticoagulation by the ACT, and if needed, additional heparin should be administered. Aspiration catheters (Export catheter, Medtronic, Minneapolis, Minnesota; Pronto catheter, Vascular Solutions, Inc., Minneapolis, Minnesota) can then be used to remove obstructing thrombus or free-floating plaque.[75] Percutaneous embolectomy is another option that has demonstrated favorable results with acute embolic occlusions,[76] or AngioJet (Possis Medical, Minneapolis, Minnesota) can be used to diminish thrombus burden in the event of distal embolization. The Penumbra device is a newer thromboaspiration device that is being increasingly used in the periphery for embolectomy or thrombectomy.[77] Finally, thrombolytic agents can be administered as an adjunct to the aforementioned maneuvers to dissolve potential thrombotic emboli or if there is concern for possible in situ thrombosis after an embolus has occurred. If these techniques are unsuccessful and the patient has signs of acute ischemia, standard open surgical techniques are warranted, including open thromboembolectomy and, if necessary, surgical bypass.

Wire Perforation

Isolated wire perforations, especially in lower extremity vessels, usually seal with conservative management (Fig. 50.10). Stiffer wires have a higher propensity to perforate and should therefore be avoided as an initial navigation wire or in small, highly diseased vessels. Wires that have perforated a vessel can often be seen on fluoroscopy as traveling outside the normal course of the arterial anatomy, and the tip of the wire will curl abnormally as it enters the soft tissue planes. Once the wire is removed, angiography may reveal extravasation of contrast material. Recognition of this problem is essential before advancing catheters or devices, and the wire should be withdrawn and an attempt made to find a new subintimal plane to traverse the lesion.

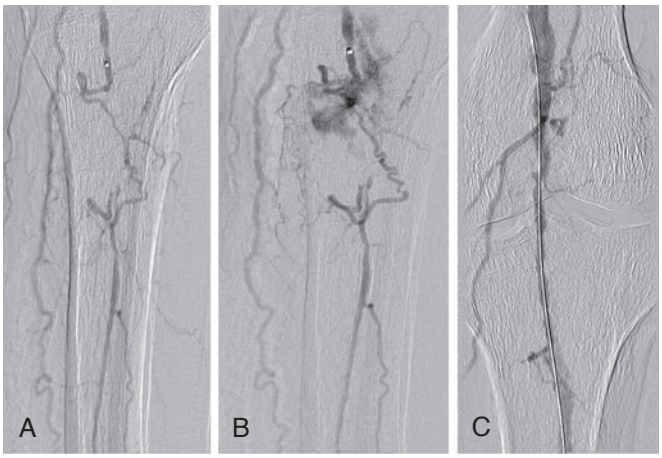

Figure 50.10 Wire perforation after attempted subintimal recanalization. A, Before attempting to cross occlusion; B, wire perforation of vessel; C, successful recanalization.

Figure 50.11 Right kidney iatrogenic perforation.

When performing interventions on the visceral arteries, wire advancement can lead to perforation of the end organ. For example, renal angioplasty requires positioning of a stiff wire in the distal renal artery to allow placement of a sheath and eventual angioplasty and stenting. In rare circumstances, the wire is advanced too far distally and can potentially perforate an intraparenchymal vessel or the kidney capsule itself. Such perforation inevitably results in trauma to the kidney with subsequent hemorrhage into the retroperitoneum (Fig. 50.11). Treatment of this complication depends on the patient's clinical status.

Angioplasty Perforation

Perforation secondary to angioplasty can result in life-threatening bleeding, especially in atherosclerotic vessels. Overdistention of a calcified vessel that has lost its elastic compliance can result

Figure 50.12 Retroperitoneal hemorrhage as seen by extravasation of contrast material.

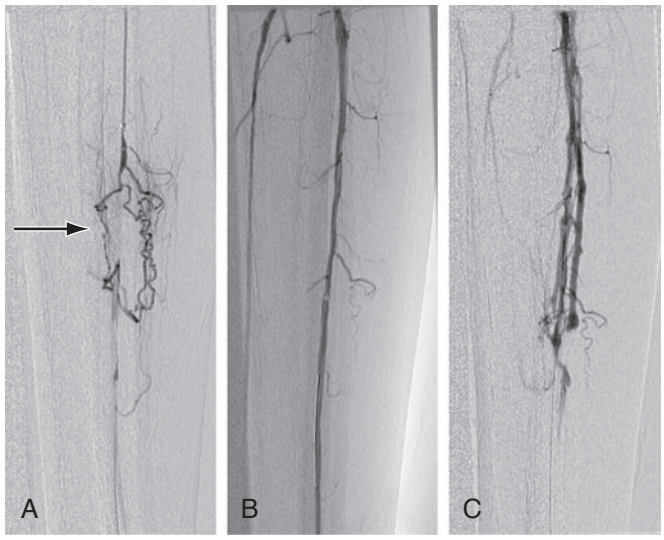

Figure 50.13 Atherectomy-induced arteriovenous fistula characterized on angiography by rapid venous filling. A, Before attempting to cross occlusion; B, successful recanalization; C, delayed filling showing arteriovenous fistula.

in disruption of all layers of the arterial wall and frank perforation. For iliac lesions, perforation can potentially cause massive hemorrhage into the retroperitoneum. Angiography will delineate the extent of rupture based on extravasation of contrast material (Fig. 50.12). Once the perforation is identified, a large compliant balloon should be placed across the injured segment and gently inflated until it tamponades the bleeding site. A covered stent can be used for repair, although sometimes open repair is required.[18,79] For aortic bifurcation lesions or proximal iliac perforation, aortic stent-grafting or aortouniiliac with femorofemoral bypass may be an option. If endovascular repair is not an alternative, the occluding balloon can be left in place while the patient is prepared for open surgical repair.

Angioplasty-induced rupture of the infrainguinal vessels is rarely a life-threatening condition, although it can result in PSA formation or arterial occlusion. In a study of 1409 patients undergoing peripheral angioplasty, 52 (3.7%) experienced arterial perforation.[80] Risk factors for perforation included advanced age, diabetes, and subintimal angioplasty. There were no deaths, and no patients required surgery at the site of perforation; of note, 27 of the 52 procedures were completed successfully, despite the complication.

Atherectomy Perforation

Atherectomy devices, when allowed to excise too deeply, can result in arterial perforation. Generally this is a rare phenomenon that occurs in less than 1% of cases.[5] Oversizing of the device and use near bifurcations can also result in perforation. Prevention of this injury rests on knowing the level of excision within the arterial wall. It is also useful to image the artery orthogonally; multiple views facilitate localization of the device relative to the arterial wall. Intravascular ultrasound can also be performed to determine the depth of plaque excision. Use in heavily diseased arteries with multiple passes along one plane causes an asymmetric excision that can thin the wall down to the subadventitial space. This places the vessel at high risk for the development of an acute or subacute AVF and, in rare cases, PSA formation.

Atherectomy-induced AVF is characterized on angiography by rapid venous filling and, with large AVFs, by diminished or abolished distal arterial outflow (Fig. 50.13). With involvement of the SFA, the majority of fistulae are of no clinical significance and will thrombose spontaneously. If the fistula causes compromised distal perfusion, treatment is warranted. Initial treatment is prolonged low-pressure balloon inflation. If this is unsuccessful, reversal of the anticoagulation is indicated, and if this fails, placement of a covered stent is an option. Under conditions of worsened ischemia that can be attributable to the fistula, surgery may be required if endovascular maneuvers fail. Surgical options include ligation of the vein above and below the site of the fistula or, if necessary, bypass.

Endovascular Aneurysm Repair Access Sites

Stent-graft implantation for the abdominal or thoracic aorta requires the use of large (18 to 24 Fr) sheaths for delivery of the device (see Chapter 73). Proper preoperative assessment of access site vessels, including the femoral and iliac arteries, is a requirement for safe deployment of these grafts. Despite appropriate planning, however, iliac tortuosity, vessel diameter, atherosclerotic disease, and calcification can be limiting factors. Contemporary incidence of iliac artery rupture reported in a single center review during EVAR was reported as 3%, with the common iliac artery being most affected. More than half of the patients became hypotensive after the rupture. The majority underwent endovascular repair, with 25% requiring open repair. There were no intraoperative deaths, but the postoperative mortality rate was 20%.[81] Fernandez et al. analyzed

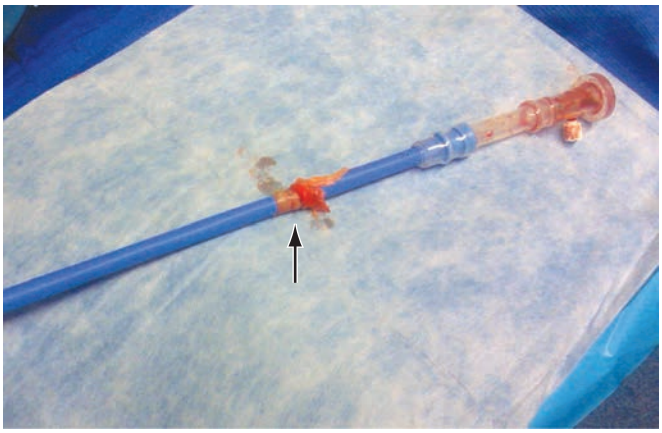

Figure 50.14 "Iliac artery on a stick"—an everted cast of the iliac artery is stuck to the sheath and avulsed on removal of the sheath.

rates with both EVAR and TEVAR. Iliac rupture was more likely to occur during TEVAR (8.9%) than EVAR (2.98%) and in women. Patients in the ruptured group had longer lengths of stay and a higher procedure-related mortality.[82]

Therefore with evolving experience with these devices, many investigators have instituted a lower threshold for using an iliofemoral or iliac artery conduit to gain larger, more proximal access, although this has been shown to increase perioperative morbidity and mortality.[83] Despite even the most diligent preparation, rupture of the access vessels can occur, and operators should be prepared to manage this devastating complication by having appropriately sized balloons and covered stents immediately available in the area where the aortic stent-graft surgery is being performed. Most ruptures are detected at the conclusion of the procedure when the sheaths are being removed from the iliac/femoral vessel. Before removal of the sheath, the sheath itself is occluding the ruptured iliac vessel. The patient will not begin to hemorrhage from the perforation until the sheath is removed. Ruptured iliac vessels will usually cause acute and profound hypotension. It is crucial that wire access be maintained to allow placement of an occlusion balloon in all cases until it is proved that the patient is hemodynamically stable after removal of the sheath. In extreme cases, operators may encounter the "iliac artery on a stick," in which an everted cast of the iliac artery is stuck to the sheath and avulsed on removal of the sheath (Fig. 50.14). Definitive treatment of this adverse event can be accomplished by placing multiple covered stents that span the area of rupture. At any time, however, surgical repair may be required to repair an injury that has not completely sealed or was not amenable to stent coverage.

OTHER COMPLICATIONS OF ENDOVASCULAR PROCEDURES

Thrombolysis

Catheter-directed thrombolysis has become the first line of treatment at many institutions for deep venous thrombosis, acute arterial ischemia, and pulmonary embolism.[84-86] Major complications have been associated with several thrombolytic agents (see Chapter 41). In two of the major trials comparing surgery and thrombolysis (TOPAS [Thrombolysis or Peripheral Arterial Surgery] and STILE [Surgery vs. Thrombolysis for Ischemia of the Lower Extremity]), the life-threatening hemorrhage rates were 13% and 5.6%, respectively.[87,88] The most common complication is a hematoma at the access site.[85] Intracranial hemorrhage has been reported 0.7% of the time and gastrointestinal hemorrhage in 1.6% of cases.[90] Treatment of minor bleeding is primarily application of continuous pressure locally. Patients receiving thrombolytic therapy should be monitored by serial hematocrit determination and coagulation studies. A profound decline in fibrinogen levels (<150 mg/dL) should at the minimum raise concern for increased bleeding risk. A drop in hematocrit, especially with hemodynamic instability, should prompt concern for retroperitoneal hemorrhage, and a CT scan should be obtained. If the bleeding is significant and requires transfusion, lytic treatment should be halted. Similarly, a change in mental status should prompt stoppage of thrombolytic therapy, given the risk for intracerebral bleeding, and imaging of the brain with either CT or magnetic resonance imaging should be performed.

Device Infection

Endovascular Stent-Grafts

Infections of EVAR and TEVAR grafts are rare but potentially devastating complications. The reported incidence ranges from 0.6% to 0.77% (see Chapter 72).[91,92]

Stents

Infection of bare-metal stents is also a rare complication of endovascular interventions. These have been reported more in noncoronary rather than coronary stents.[93] PET-CT has been helpful at identifying stent infections. Breaks in sterile technique, occult glove perforation, inadequate skin preparation, repeat puncture of the same arterial access site, prolonged use or reuse of an indwelling catheter, increased procedure time, puncture site hematoma, other sources of coincident bacteremia, and nonsterile angiography suites may contribute to this, although there are no clear data.[94] As noted, infections have also been reported in stent-grafts, with reports of stent-graft preservation with antibiotic therapy.[95,96]

Patients with stent infections often have clinical signs of bacteremia consisting of fever, chills, and rigors, and this should prompt a standard evaluation for other sources of infection. Once these are ruled out, stent infection should be considered, but the rarity of this complication makes it a diagnosis of exclusion. *Staphylococcus aureus* is the most common organism isolated in cases of stent infection.[94] Imaging modalities that are helpful in making the diagnosis include CT, angiography, duplex ultrasonography, and tagged white blood cell scans. Treatment should be aggressive and consist of removal of the stent and all surrounding infected tissue, which often includes a large portion of the artery. The principles of management of

prosthetic graft infection should be applied so that most patients will require bypass with autogenous conduit or extra-anatomic reconstruction with prosthetic material. Definitive preventive measures for stent infections are unknown at this time.

Device Fracture or Embolization

In view of the vast array of equipment used during complex percutaneous procedures, it is not uncommon to encounter device or instrument malfunction. For example, wires, catheters, or sheaths can break and leave residual, free-floating fragments within the arterial lumen. This necessitates prompt retrieval to avoid distal embolization or arterial thrombosis. The most common technique used to retrieve foreign bodies within the vasculature involves the use of endovascular snares or biopsy forceps. If a broken wire is positioned within a sheath, it is also possible to advance a balloon alongside the wire, inflate it, and drag the wire to the origin of the sheath. This technique can also be used to retrieve broken sheaths.[98]

Figure 50.15 Dislodged inferior vena cava filter.

Improper sizing of the vessel lumen can cause a mismatch between the stent diameter and the size of the vessel. If the stent is too small, it can migrate distally and essentially embolize and lodge at a branch point or a smaller portion of the vessel. Inadvertent displacement of a stent can occur during passage of the device. For example, in patients with iliac disease that has been stented in the past, passage of the device through these iliac vessels risks stent dislodgement and embolization. Balloon expandable stents should be advanced through the stenotic area in the sheath to avoid dislodging the stent from the balloon.

Venous

Angioplasty and Stenting

Venous angioplasty with stenting is a commonly performed procedure for patients with central venous stenosis (see Chapter 161). Vein rupture with aggressive angioplasty may occur in the setting of highly scarred or chronically occluded vessels. Generally, vein perforations can be managed conservatively because the low-pressure system allows the injury to seal spontaneously with manual compression therapy alone.

Venous stent migration has been reported to occur, and in the most severe cases these stents can embolize to the heart. This has been reported in the setting of iliac vein stenting, superior vena cava (SVC) syndrome, and stenting of the renal vein for Nutcracker syndrome.[99-101] Retrieval of migrated venous stents can usually be accomplished with snares; however, in some instances, open operation is required for stent removal.

Inferior Vena Cava Filter Complications

Inferior vena cava (IVC) filter placement is rarely associated with complications (see Chapter 152).[102] Procedure-related complications can occur either in the acute period or months to years later. Late filter complications carry the highest morbidity and mortality rates for filters and include embolization, vessel penetration, and thrombosis of the filter.[103-108] Embolization of the filter or filter struts can go into the heart or the pulmonary arteries and can potentially induce fatal arrhythmias.[103,104]

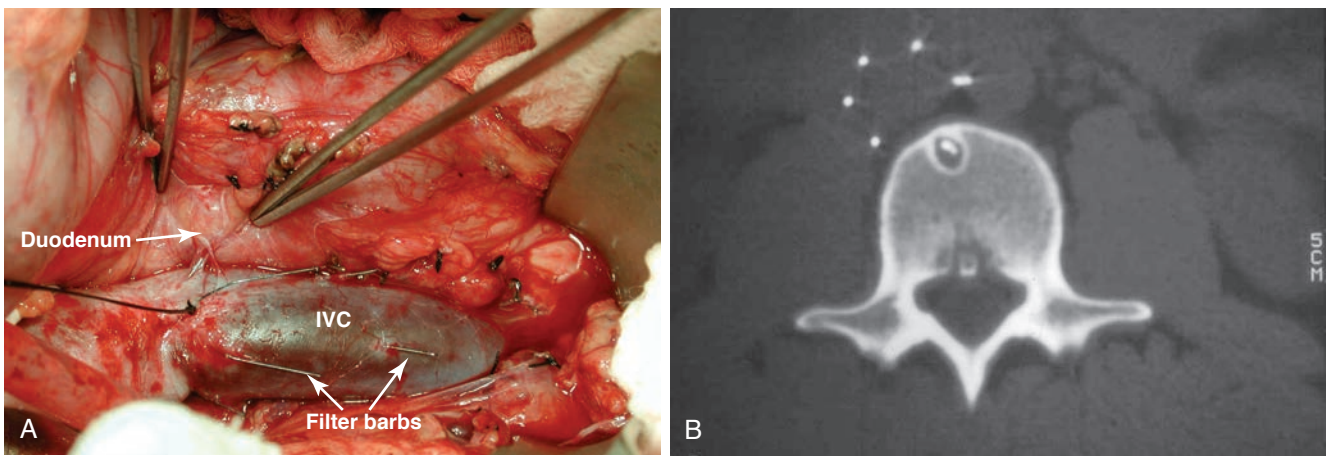

Figure 50.16 Protrusion of prongs of IVC filter into adjacent structures (A) bowel, (B) spine. IVC, Inferior vena cava.

Embolization or dislodgement can also occur during either internal jugular or lower extremity venous catheter exchange (Fig. 50.15).

Long term, the barbs on the filter erode through the IVC. Although most cases are asymptomatic, penetration into adjacent structures such as the duodenum, aorta, or vertebral bodies can occur (Fig. 50.16).[105] The duration of filter placement is associated with the risks of penetration. Treatment of bowel perforation involves open removal of the filter and repair of the intestinal injury and the caval wall.[106] The development of thrombus at the level of the filter is another complication that can cause complete occlusion of the IVC with resultant venous obstructive complications, including phlegmasia, recurrent deep venous thrombosis, and postphlebitic syndrome.[107] IVC filter occlusion has been associated with pulmonary embolism that has failed anticoagulation as an indication for placement.[108] This complication should be considered when planning filter placement in young individuals and provides justification for the placement of temporary filters.

In vascular surgery, venous complications arise from different mechanisms, ranging from traumatic to iatrogenic injury, both directly and indirectly. Complications may present as bleeding and hematoma immediately after venous injury or as occult thrombosis or fistula detected only after many months following the incident. Presentations of venous complications are highly variable and can range from subtle to obvious. In general, the greater the severity of the clinical presentation of the venous complication, the greater the magnitude of the treatment required, and because of this, treatment options are often up for debate.

INCIDENCE OF VENOUS COMPLICATIONS

The most common venous complication after any type of surgery or illness is deep venous thrombosis (DVT) (see Chapters 147-149). Although not necessarily a direct venous injury, the incidence of DVT after vascular surgery has been reported as high as 20%.[1] The incidence of DVT after venous puncture is not widely reported but was found to be up to 60% without anticoagulation during cardiac procedures[2] and in 36% of patients with an existing clot who received an inferior vena cava (IVC) filter.[3]

Direct venous injury requiring dedicated repair is most commonly seen in trauma patients and as a procedural complication. These injuries can lead to bleeding, thrombosis or, more rarely, arteriovenous fistula (AVF). Venous injury in trauma has been reported as high as 28% of penetrating wounds and is usually associated with arterial injury.[4] Iatrogenic injuries during other surgeries are rarely reported, but the Mayo clinic reported on 44 injuries during major abdominal surgery over 17 years. Average blood loss from these injuries was nearly 4 L, and there was an 18% mortality rate.[5]

Direct Venous Injury

Direct venous injury involves trauma to a vein. The expanding field of endovascular therapy for the treatment of vascular disease has steadily increased the number of access site procedural complications. (See Chapter 50: Local Endovascular Complications and Their Management.) Since 1995, there has been approximately a 10-fold increase in the rate of peripheral vascular interventions.[6] Access site complications occur in 1.0% to 11% of these procedures.[7-10] Central line placement can also cause direct injury to the vessels. Injury is often obvious, but hypotension after a percutaneous intervention should always include the differential diagnosis of a remote hematoma. After femoral interventions, an acute drop in hemoglobin level and lower abdominal/flank pain should raise suspicion for a retroperitoneal hematoma.

Isolated venous injury during dissection of the adjacent arterial or nerve structures or other surgical exposures often goes unreported. Injuries are commonly repaired primarily, or the affected veins may be ligated, relying on collateral circulation. Direct venous injuries are often only diagnosed and reported when a life-threatening hemorrhage or hemodynamic instability occurs.

Abstract

Complications from venous injury can have varied clinical presentations, ranging from minor acute subtle hematomas occurring minutes after a procedure to large arteriovenous fistulas that progress to congestive heart failure months after an intervention. This chapter explores several specific types of venous complications, including direct and indirect venous injury from open and endovascular therapies, their diagnostic evaluations, and comprehensive management. A fuller understanding of the common pitfalls that cause venous injury often limits its occurrence, aids in immediate diagnosis, and improves clinical outcomes.

Keywords

Venous injury
Venous complications
Arteriovenous fistulas traumatic
Arteriovenous fistulas iatrogenic
Venous thrombosis
Venous stent complications
Retroperitoneal hematomas venous
Inferior vena cava filter complications

The risk of direct venous injury can be minimized by proper technique and recognition of high-risk patients. Predictors of groin complications from any vascular access have been well described. Obesity, large sheath size, previous catheterization, and anticoagulation are notable risk factors for all access site complications.[11] For percutaneous interventions, including central line placements, ultrasound guidance and the Seldinger technique are considered standard of care procedural steps.[12,13]

Diagnostic Evaluation of Direct Venous Injury

During percutaneous interventions, a hematoma is most telling of a complication from a venous injury. A hematoma may present as obvious swelling, but other more subtle signs and symptoms include access site pain, skin ecchymosis, continued bleeding through the puncture site, and hypotension. Duplex ultrasound of the localized hematoma is often necessary, especially if the hematoma is pulsatile, has a bruit over it, or is exquisitely tender, to rule out arterial pseudoaneurysm or AVF. Venous extravasation is generally not seen on ultrasound, but is instead seen as hematoma. Venous compression or thrombosis from the hematoma can also be seen.

Retroperitoneal hematomas are a clinical diagnosis. Retroperitoneal hematomas from femoral venous accesses are often subtle but can have severe morbidity and mortality if not identified. The retroperitoneal space accommodates a large amount of blood without tamponade from surrounding structures, and thus, complaints of back or lower abdominal pain, hypotension, tachycardia, and oliguria should raise suspicion to diagnose and manage urgently. Patients should promptly be considered for a CT scan. By using contrast, an abdominal and pelvic CT scan can readily identify arterial or venous injury and resulting hematoma, pseudoaneurysm, or extravasation (Fig. 51.1).

Venous injuries during open surgical approaches are often diagnosed by direct visualization. However, if clinically occult, computed tomography and magnetic resonance angiography in the delayed phase can provide a diagnosis.

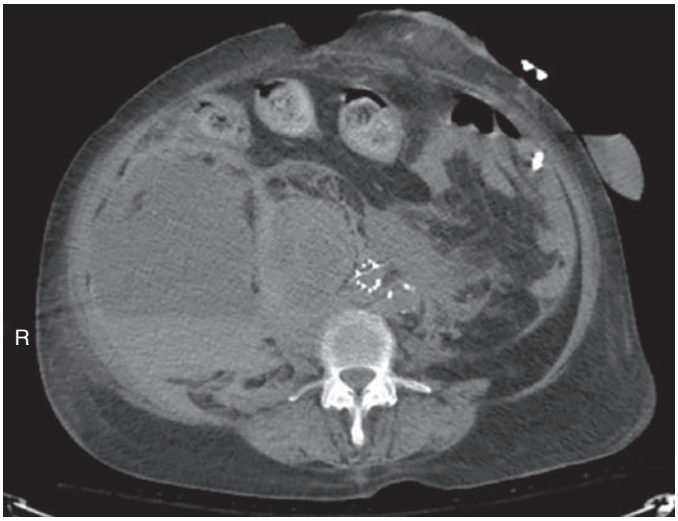

Figure 51.1 Large retroperitoneal hematoma. Note the indistinct border of the inferior vena cava (IVC). This patient had an IVC filter placed shortly before this scan.

Management of Direct Venous Injury

Venous access site injury during a percutaneous intervention often results in hematoma formation. Early recognition limits significant morbidity. Although often self-limiting, pressure over the puncture site is recommended. The area should be marked to evaluate for any expansion and be serially monitored. Monitoring serial hemoglobin levels and prolonging bedrest is recommended. Most hematomas resolve within a few weeks. Hematoma size varies, and if skin compromise is evident, evacuation and debridement of the affected area is necessary.

In coagulopathic patients, however, aggressive resuscitation with blood products may be required, especially if a retroperitoneal hematoma is suspected. Although most retroperitoneal hematomas can be managed with resuscitation, bedrest, and monitoring serial hematocrit levels, hemodynamic instability, ongoing blood loss, and neurologic deficits due to compression of adjacent nerves are indications for further imaging and possibly open surgical exploration. Complications from venous intervention remote from the access area are now recognized as increasingly common. Treatment of these complications is an evolving area of vascular surgery and is individually determined on a symptomatic basis.

Venous injury during open surgical procedure, such as an iliac vein injury during an aortobifemoral bypass, ranges from small adventitial hematomas to complete transections. Small injuries often are managed conservatively with direct pressure. However, tears and lacerations can be repaired with 5-0, 6-0, or 7-0 prolene sutures as appropriate for vein size. Proximal and distal control is often not necessary but can be done gently with sponge sticks if required. Encircling and clamping veins to assist in repairing injuries frequently causes additional trauma and bleeding as small branches may be sheared and large soft veins are susceptible to clamp trauma. In general, when severely injured and resulting in hemodynamic instability, the brachiocephalic, internal jugular, subclavian, and extremity veins can be ligated, especially if the contralateral side is patent. Open repair however, is preferred. Caval, femoral, brachiocephalic, or subclavian/axillary vein injuries can be closed with a transverse primary repair with 4-0 or 5-0 prolene suture if there is no loss of domain. With a loss of domain, it is necessary to replace this lost segment, usually with lateral venorrhaphy and a bovine pericardial patch in the IVC or vein patch in smaller vessels, to avoid tension or stricture. Large abdominal veins such as the renal or superior mesenteric veins should be repaired as needed. However, in the context of hemodynamic instability, vein ligation of even these vessels may be necessary.

For caval injuries, endovascular repair options include balloon occlusion or control, and even coverage with a covered stent or aortic cuff. These interventions are usually performed in a hybrid OR. Balloon occlusion with large, low-pressure balloons from above and below the injury, either inserted percutaneously from the jugular and femoral sites or inserted through the injury, can slow down blood loss and may allow enough

visualization for an open repair. If the injury is being managed percutaneously, there are reports of covered stent grafts in the IVC.[14-17] These are difficult to size, as the injured cava may have ill-defined walls and the size of the tear may be difficult to appreciate on CT or venogram. In addition, there may be spasm of the IVC or underfilling from blood loss that leads to placement of cuffs that could embolize once the cava is fully expanded.

In the event of a posterior vena caval injury, this difficult problem can possibly be managed by control of the cava and opening the cava on the anterior surface to visualize the posterior tear. This can then be repaired from inside the cava and the anterior exposure site can be primarily closed in a transverse manner. If there is a significant loss of domain in any of these large veins, and the patient is hemodynamically stable, the injured section of vein can be replaced with a Dacron prosthetic graft, usually 20–24 mm in diameter, or a spiral vein graft if time allows. If a prosthetic graft is used, consideration should be given to prolonged systemic anticoagulation, a distal arteriovenous fistula, or both to optimize patency. Severe venous injuries, especially in the infra or suprahepatic regions of the IVC, carry a very high morbidity and mortality.[18]

Arteriovenous Fistulas

An AVF is a direct communication between an artery and a vein. AVFs often can occur after penetrating trauma, where ongoing bleeding from an artery decompresses into an adjacent venous injury (Fig. 51.2). With increasing numbers of invasive percutaneous procedures, vascular cannulation accounts for most AVFs.[19] The incidence ranges from 0.0006% to 0.88%.[20-22] Total knee replacements, lumbar disc surgery,[23,24] and percutaneous biopsies, such as in transplant kidneys, may also result in AVFs.

Venous Thrombosis

The topic of DVT is extensively discussed in Section 22. DVTs can manifest with varied signs and symptoms but is particularly an important clinical diagnosis to keep in mind after any venous injury or intervention. After percutaneous interventions such as IVC filter placement, compression of the punctured vein after instrumentation predisposes to thrombus formation.[25] Furthermore, any instrumentation or catheter placement within the vein activates the clotting cascade by virtue of the venous trauma involved (Fig. 51.3).[26] Surgical repair after direct injury to a vein can also be a nidus for thrombus formation.

Diagnostic evaluation and management of venous thrombosis is discussed in detail in Chapter 146: Venous Thromboembolic Disease: Epidemiology, Pathophysiology, Natural History; Chapter 147: Acute Lower Extremity Venous Thrombosis: Presentation, Diagnosis, and Medical Management; Chapter 148: Acute Lower Extremity Deep Venous Thrombosis: Surgical and Interventional Treatment; and Chapter 149: Acute Upper Extremity and Catheter-Related Venous Thrombosis.

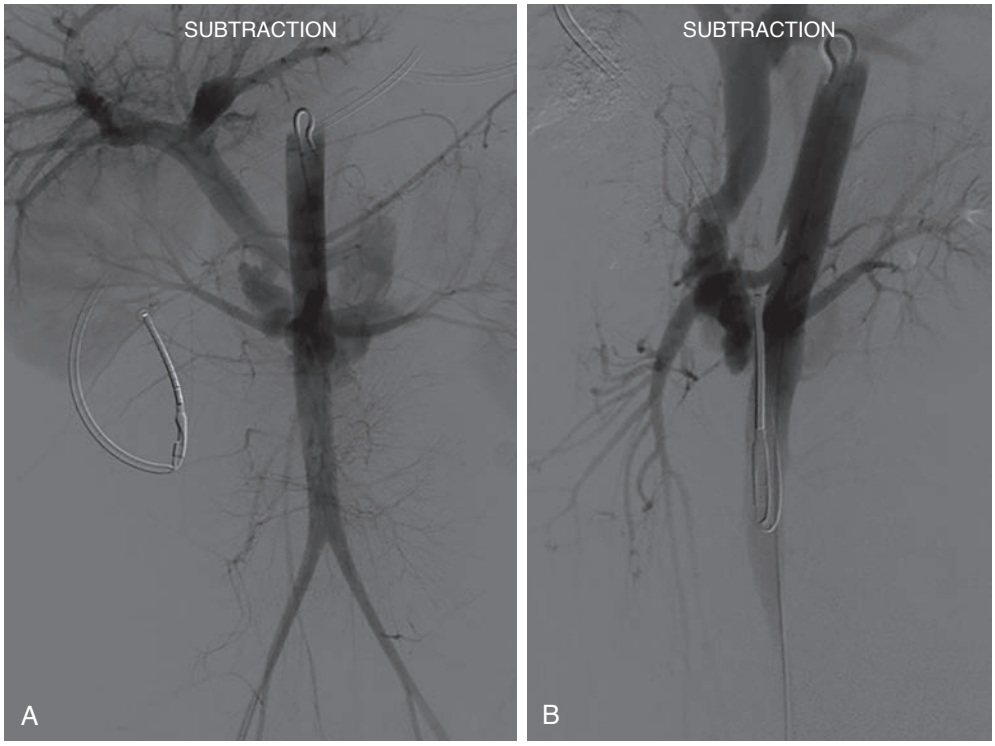

Figure 51.2 Aorto-superior mesenteric vein fistula draining into the portal vein in AP (A) and lateral (B) projections after a gunshot wound to the abdomen. Both vessels were repaired primarily. (Image courtesy of Mitchell W. Cox, MD.)

Endovascular Complications From Venous Interventions

Venous angioplasty and stenting are instrumental in salvaging hemodialysis access. Outflow and central venous stenosis are often treated with balloons and stents to improve secondary patency of hemodialysis fistulas and grafts. Left iliac vein angioplasty and stenting is common in relieving left leg swelling for patients with May-Thurner and postthrombotic syndromes. Caval recanalization and reconstruction with stents have been shown to improve venous ulcer healing.[27] Venous stenosis, especially within veins arterialized from hemodialysis access, may be difficult to dilate and require high-pressure balloons. However, not infrequently, high-pressure inflations cause venous rupture (see Chapter 161: Iliocaval Venous Obstruction: Endovascular Treatment).

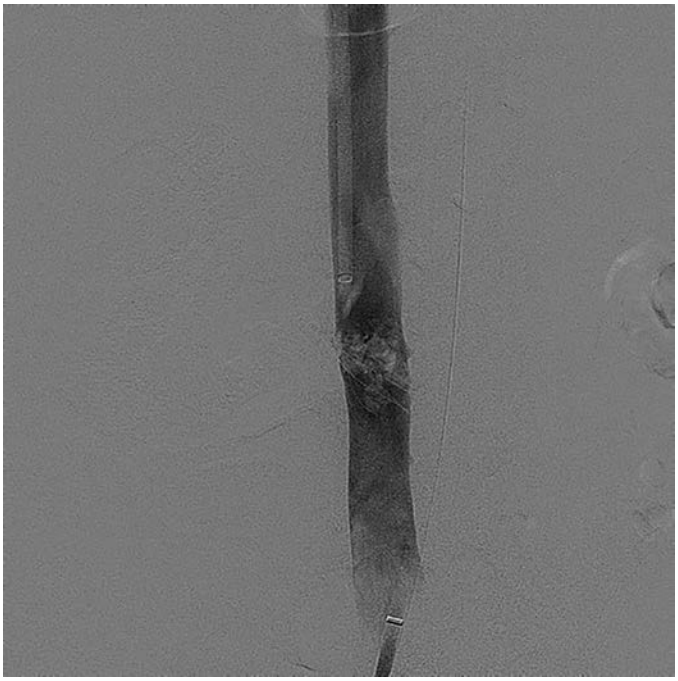

Figure 51.3 New thrombus after attempts to retrieve tilted inferior vena cava filter. Filling voids can be seen from the draining renal veins near the superior sheath tip, and new thrombus surrounds the tilted filter directly below. This thrombus occurred after prolonged attempt to remove the filter. (Image courtesy of Mitchell W. Cox, MD.)

Migration is another potential complication of endovascular intervention and is usually associated with central vein stent deployment.[28] Central veins are more compliant and thus, without adequate stent oversizing, venous stents are more prone to migration. Intravascular ultrasound aids in accurately measuring the diameters of these compliant lumens intraoperatively. In addition to adequate oversizing, accurate proximal and distal positioning of the stent with adequate anchors limits migration.[29]

Wire perforation from endovascular venous interventions is rare but can happen when recanalizing chronic occlusions, such as during iliocaval reconstructions. Stiffer wires have a higher propensity to injure the vessel and should be used cautiously. However, significant bleeding from wire perforation is uncommon, as the occluded veins have low flow.

Diagnostic Evaluation of Endovascular Complications From Venous Interventions

Most endovascular complications of venous interventions occur intraoperatively as, for example, when a venous stent "watermelon seeds" into the right side of the heart (Fig. 51.4). Therefore,

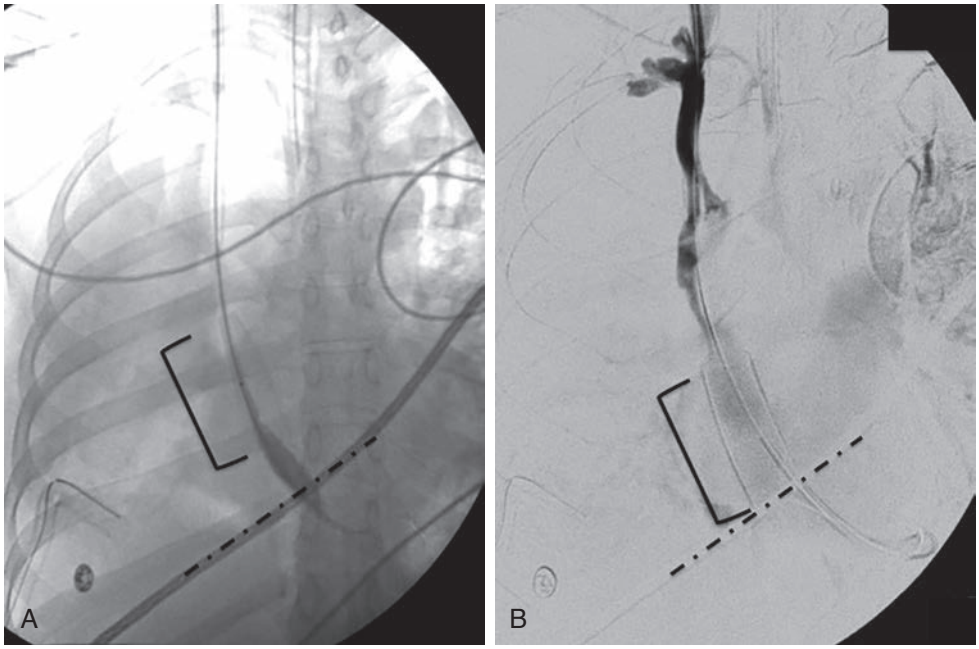

Figure 51.4 Embolization of a stent from the superior vena cava into the right atrium. Note the position of the stent *(brackets)* in relation to the fixed wire *(dashed line)* overlying the patient at deployment (A) and after ballooning (B).

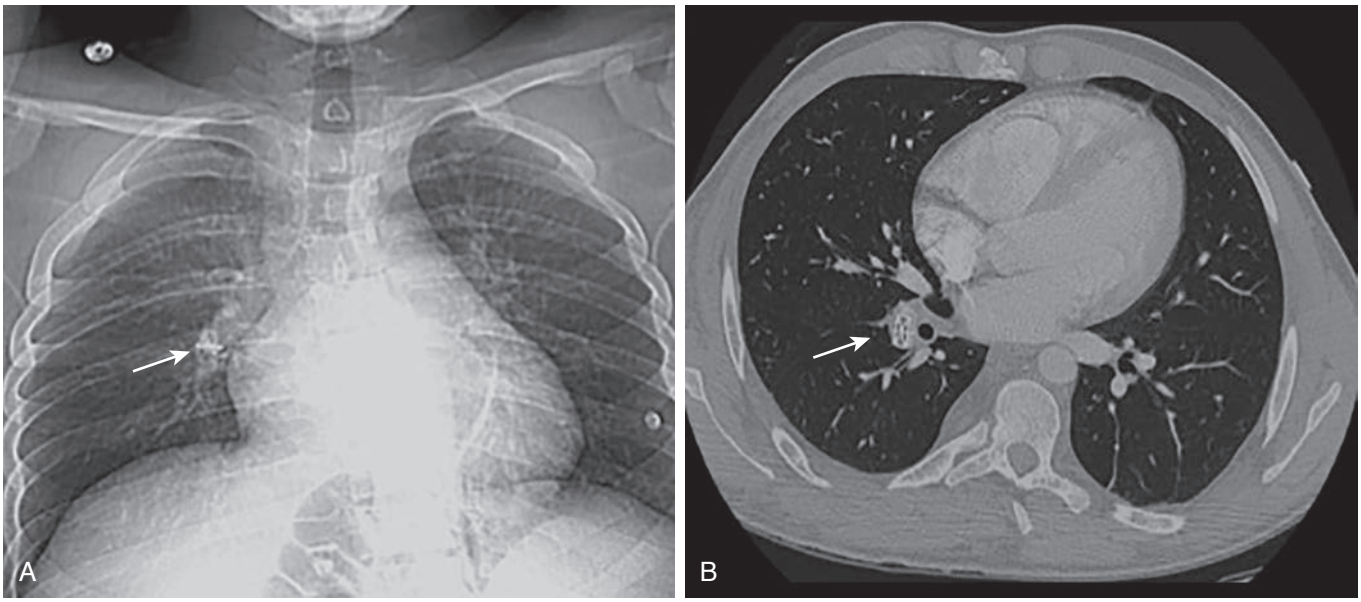

Figure 51.5 Embolization of an occlusion plug *(arrows)* from the right internal iliac vein into the pulmonary circulation, seen on chest x-ray (A) and CT scan (B).

diagnosis is immediate. Perforations after venous angioplasty are quite evident when a post-angioplasty image is taken and can be addressed immediately, and a hematoma may be present in the affected extremity.

Management of Endovascular Complications From Venous Interventions

Most venous ruptures are self-limiting due to the low pressure of the venous system and will seal after a brief period of balloon tamponade. A balloon slightly smaller than the surrounding venous diameter should be placed across the perforated venous segment and gently inflated to low pressure (<5 atm) for at least 5 minutes. If there is still extravasation after this maneuver is performed, a covered or even bare metal stent can be placed across the perforation to achieve hemostasis.

Migrated stents are often percutaneously retrieved with snares if they can be pulled into a large sheath. Migrated stents can also be removed through surgical cutdowns, and the venous system may need to be reconstructed.[30]

Venous embolization devices can also migrate. Coils and plugs have been found in the heart and lungs (Fig. 51.5), as the venous diameter has a large variation and may be in spasm at the time of instrumentation. Placing plugs or coils in the internal iliac veins should be done with great caution, as these can embolize.[31] If this vessel needs to be coiled, the ends of the coils should be anchored in branch vessels and extended into the larger veins (Fig. 51.6).

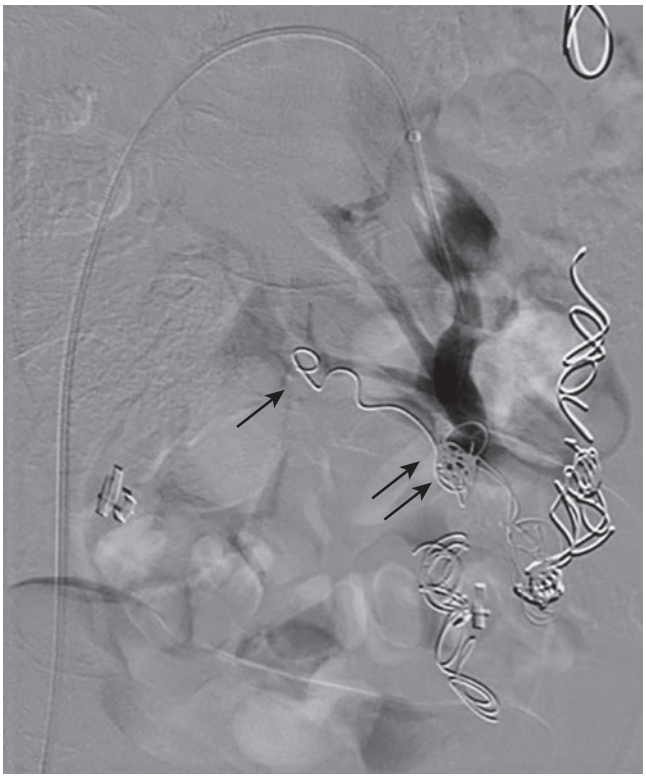

Figure 51.6 Internal iliac vein coiling in a patient with severe pelvic congestion. Sheath extends from the right iliac vein up and over to the left. Coils were anchored in the branches of the iliac vein *(single arrow)* and extended into the internal iliac *(double arrow)* for occlusion.

Inferior Vena Cava Filter Complications

Inferior vena cava filter (IVCF) placements are performed to prevent venous thromboembolism. These filters and procedure-related complications have been well studied (see Chapter 152: Vena Cava Interruption). Misplaced IVCFs, pneumothorax, hematoma, air embolism, AVF, insertion site thrombosis, and carotid puncture are a few of the well-described procedural complications.[32,33] Late complications include IVCF thrombosis, embolization from a thrombosed IVCF, and perforation into

adjacent structures.[34] Migration of IVCF into the right heart carries high morbidity and mortality,[35] and it often occurs when the cava is too large to anchor commercial IVCFs or wires manipulate the filter during venous catheter exchanges (Fig. 51.7).

Figure 51.7 Undersized inferior vena cava (IVC) filter placed near the hepatic veins in the IVC for caval thrombus extending above the renal veins.

Diagnostic Evaluation of Inferior Vena Cava Filter Complications

Migration of IVCFs often is diagnosed intraoperatively or when a diagnostic imaging scan is performed for subsequent symptoms resulting from the migration. Thrombosis of the IVCF can also be diagnosed with a CT scan in the venous phase or venography. Late complications such as perforation or migration are usually detected by a CT performed for symptoms or unrelated problems (Fig. 51.8).

Management of Inferior Vena Cava Filter Complications

IVCF migration can be largely prevented with appropriate sizing and preoperative planning. When wire exchanges are necessary for line exchanges in the context of a patient with an IVCF, direct fluoroscopic wire exchanges limit manipulation of the existing IVCF. Retrieval of a migrated IVCF usually involves percutaneous access of the internal jugular vein and femoral vein, while using large diameter sheaths to accommodate buddy wires, snares, and catheters. Filters may need to be crushed into large sheaths and extracted with a cutdown on the femoral or internal jugular vein. If percutaneous methods fail, surgical exploration and extraction may be required, especially if lodged in the pulmonary artery and causing cardiac complications.

Perforations of the IVCF legs are most often found incidentally on imaging studies. Most cases are asymptomatic, but symptoms from penetration into adjacent structures such as the duodenum can occur. Treatment may require removal of the offending IVCF and open repair of the organ injury.

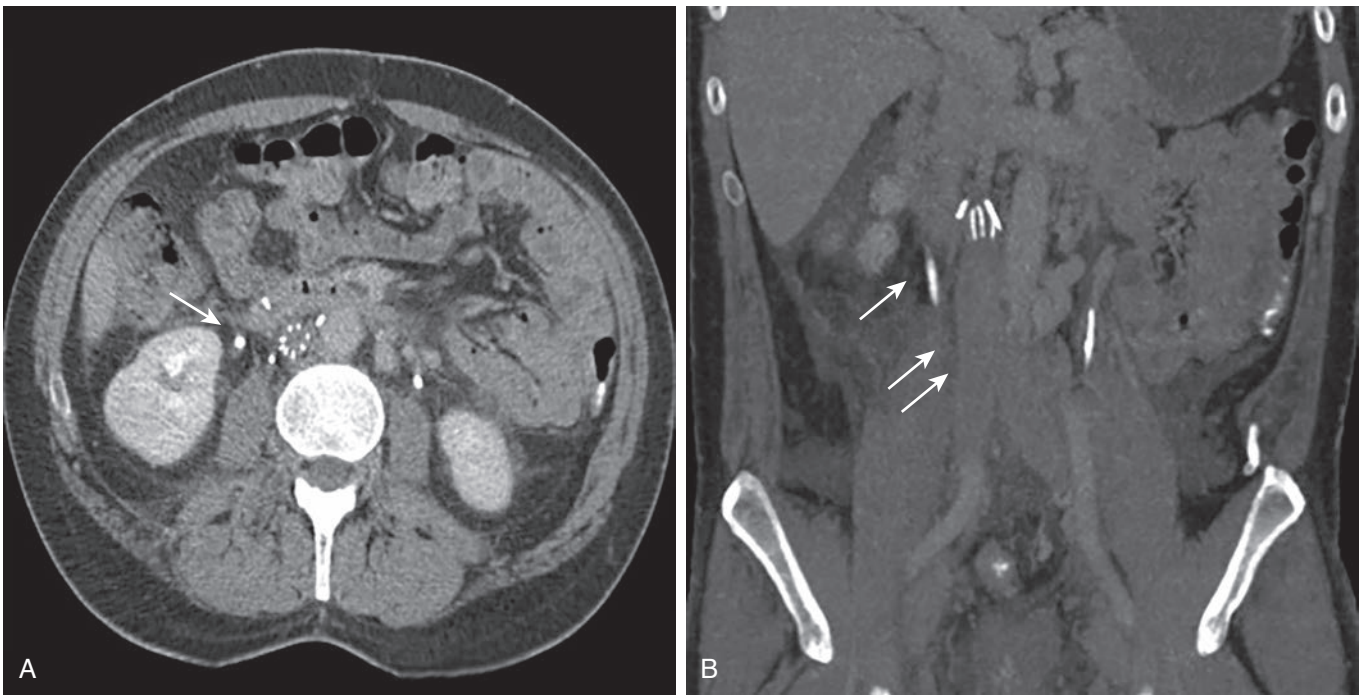

Figure 51.8 CT scan for abdomen and pelvis in sagittal (A) and reconstructed (B) views demonstrating strut fracture and migration *(single arrow)*, thrombosis of inferior vena cava inferior to the filter *(double arrows)* and perforation of filter struts in the bowel retroperitoneum and near the aorta.

Figure 51.9 Inferior vena cava thrombus at time of filter retrieval.

Thrombosed IVCF most often manifests with lower extremity swelling but can also be associated with chronic postphlebitic syndrome, phlegmasia, and renal failure. Patency rates of IVCFs decreases with time; thus, filters should be removed as soon as clinically possible.[36] Patients with IVCF thrombosis (Fig. 51.9) can be considered for thrombolysis and removal of the IVCF, assuming no contraindications. In addition, patients with chronic caval obstruction may be considered for iliocaval venous reconstruction, especially to address lower extremity symptoms.[37]

CONCLUSIONS

Venous complications typically arise because of trauma or iatrogenic injury. DVT is the most common venous complication and is treated with anticoagulation in most cases. Direct injury can be treated with repair or ligation, depending on the location. Late complications, such as AV fistula or migration of a venous device, are treated based on symptoms.

Due to the close anatomic association between fine lymph vessels, lymph nodes, and corresponding arteries and veins, the possibility of lymphatic complications should always be considered when proceeding with vascular operations. Although the ability of transected or ligated lymphatics to regenerate and reestablish normal lymphatic transport is remarkable, extremity edema after vascular intervention is one of the most common complications. Injury to the lymphatics is a major contributor to the development of lower extremity edema after infrainguinal reconstruction.[1-11] Interruption of lymphatic vessels during surgical dissection may also cause a lymphatic fistula[12-17] or lymphocele.[17-27] Rarely, injury to the para-aortic or mesenteric lymphatics may result in chylous ascites.[22,28-46] Thoracic duct injury may occur during cervical, thoracic, or thoracoabdominal aortic reconstruction,[31,47-56] and chylothorax may occur after high translumbar aortography.[57]

This chapter reviews the pathophysiology, diagnosis, and management of the most frequent lymphatic complications after vascular reconstruction and suggests guidelines for prevention.

POST-BYPASS EDEMA

Lower extremity edema occurs in 50% to 100% of patients who undergo open infrainguinal arterial reconstruction for chronic ischemia.[2,7] Leg swelling after femoropopliteal or femorotibial bypass becomes evident with dependency, usually when the patient resumes ambulation. Pitting edema generally subsides within 2 to 3 months after reconstruction, although it may be persistent in some patients. Significant lymphedema can impair normal ambulation or delay wound healing despite successful arterial reconstruction.

Etiology and Pathogenesis

Lymphedema develops when the rate of production of protein-rich interstitial fluid exceeds the capacity of the lymphatic system to remove the increased lymph volume. When lymphatic transport fails, post-bypass edema occurs.[58] Lymphatic insufficiency has two main causes. First, increased production of interstitial fluid after successful revascularization results in a significant increase in the lymphatic load. Second, the transport capacity of the lymphatic system is reduced because of lymphatic injury and obstruction of deep and superficial lymph channels during dissection in the groin and popliteal space and along the great saphenous vein.

Increased capillary filtration results from elevated arterial pressure after revascularization, alterations in the regulation of microcirculatory flow, and probable endothelial and smooth

Abstract

Due to the close anatomic association between fine lymph vessels, lymph nodes, and corresponding arteries and veins, the possibility of lymphatic complications should always be considered when proceeding with vascular operations. This chapter reviews the pathophysiology, diagnosis, and management of the most frequent lymphatic complications after vascular reconstruction and suggests guidelines for prevention. Frequent complications such as extremity edema, as well as lymphatic fistula or lymphocele will be reviewed. In addition, central lymphatic injury resulting in chylous ascites or chylothorax will be discussed.

muscle injury from chronic ischemia.[1,7] Eickhoff[8] demonstrated that abnormalities in local blood flow regulation normalize approximately within a week after reconstruction, whereas edema persists much longer in these patients. Although derangement of the microcirculation contributes to post-bypass edema to some degree, Eickhoff's experiments support the theory that lymphatic obstruction secondary to surgical injury is the most important cause of post-bypass edema.

If the number of functioning major lymph channels decreases to a critical level, lymphedema develops. In one study in which patients underwent lymphangiography after infrainguinal bypass, the average number of patent superficial lymph vessels visualized was reduced to 1.7 per patient compared with the normal average of 9.5.[1] In a similar series of 37 patients, edema was not significant when more than three intact superficial lymph vessels were visualized on the postoperative lymphangiogram.[4] AbuRahma et al.[9] examined the involvement of the lymphatic system in the pathophysiology of edema formation in patients who underwent femoropopliteal bypass grafting. Edema developed in 29 of the 72 patients (40%). Leg swelling occurred in 85% (17 of 20) of the patients treated by conventional dissection of the femoropopliteal arteries. When careful dissection preserving lymphatics was performed, edema developed in only 2 of 20 patients (10%). Postoperative lymphangiography showed normal anatomy in six of the eight patients without edema, but markedly abnormal anatomy was in all eight patients with edema.

Persson et al.[10] found less edema in patients who needed less dissection; that is, less edema in patients with prosthetic grafts compared to those with vein grafts. Patients with above-knee grafts also had less edema than those with below-knee bypasses.[10] Studies using albumin clearance in patients with edema after revascularization also supported the idea that edema is mainly lymphatic in origin. A reduction in the plasma albumin level with a concomitant increase in albumin content in the extremity was noted after femoropopliteal bypass.[59] The increase in albumin content was three times greater in limbs revascularized by femoropopliteal bypass than in those revascularized with aortoiliac grafts. These data correspond to the clinical observation that edema rarely develops after aortofemoral revascularization.

Lymphedema with lymphocele has also been reported following varicose vein surgery. There is an association of lymphatic dysfunction in patients with incompetent varicose veins, and therefore one must take the same care to protect lymphatics during open vein surgery.[60]

Although venous thrombosis has been proposed as a cause of postoperative leg edema,[61,62] studies have demonstrated a low incidence of deep venous thrombosis in patients with post-bypass edema.[63,64] In one series, normal venous hemodynamics and morphology were confirmed in 41 of 45 patients with leg edema after arterial bypass.[65] The incidence of deep venous thrombosis after femoropopliteal bypass was found to be similar in patients who had edema (7%) and in those who did not (10%).[9] Deep venous thrombosis therefore seems to play a minor role in post-bypass edema in most patients.[7,58,66]

Diagnosis

Mild, partially pitting ankle edema appears on the second or third postoperative day and resolves almost completely with leg elevation and bed rest. Lymphedema is frequently unilateral and involves the dorsum of the foot ("buffalo hump") and the toes ("squaring"). The differential diagnosis of postoperative limb swelling includes deep venous thrombosis, infection with cellulitis, and compartment syndrome. The history and physical examination can aid in identifying cellulitis or compartment syndrome, and duplex scanning of the deep veins is the test of choice for excluding deep venous thrombosis. If the cause of the edema is still in question, lymphoscintigraphy can confirm the presence of lymphedema (Fig. 52.1).

Management

Postoperatively, mild edema of the extremity should be treated by frequent elevation of the limb. Some surgeons advocate for strict bedrest. Cardiac failure should be treated promptly to help preserve the normal pressure gradient and allow venous return and lymph flow toward the heart. Moderate to severe post-bypass edema is treated with compression wrapping until the incisions have healed, followed by calf-length, 30- to 40-mm Hg compression stockings. For patients with a below-knee, in-situ bypass or any bypass to the distal tibial or pedal arteries, management is individualized to avoid direct compression of the subcutaneous vein graft. Attempts to prevent or limit post-bypass edema pharmacologically with steroids, mannitol, terbutaline, or furosemide have not proved effective[10] and are not recommended.

Prevention

Meticulous, lymph-preserving surgical dissection is needed to minimize post-bypass edema.[9,58] For infrainguinal bypass, a vertical groin incision slightly lateral to the femoral pulse should be made in an attempt to preserve the patency and integrity of the lymph nodes.[67] The inguinal lymphatics should be retracted medially, and a vertical incision should be made in the femoral sheath to dissect the femoral arteries. Loupe magnification facilitates identification of the lymph nodes and lymph vessels. The lymphatics should be carefully preserved; if they must be divided, they should be ligated to avoid leakage of lymph. Attempts should be made to preserve as much lymphatic tissue as possible between the saphenofemoral junction and the femoral artery.

Multiple short skin incisions to harvest the saphenous vein may disrupt fewer superficial lymphatics.[9] In theory, endoscopic video-assisted vein harvest may also cause less lymphatic injury and decrease wound-healing problems without compromising vein conduit quality. In a series of 68 lower extremity bypass procedures, only one bleeding complication was related to the video-assisted harvest, and two seromas developed at the arterial dissection sites.[68] The benefit of endoscopic versus open vein harvesting in terms of a reduced rate of lymphatic complications was confirmed in prospective randomized

Figure 52.1 (A) Edema of the left lower extremity in an 88-year-old man 4 weeks after left femoropopliteal saphenous vein bypass performed for severe chronic ischemia. (B) Lymphoscintigraphy confirmed severe lymphedema of the left leg with no visualization of the lymph vessels or inguinal lymph nodes. Lymphatic transport was normal on the right.

studies,[69,70] and such harvesting can result in a reduction in postoperative wound infections.[71,72] Dissection around the popliteal artery should be performed with the same care to avoid lymphatic disruption. The vascular sheath should be opened longitudinally without dissection of the popliteal vein or the posterior tibial nerve in the neurovascular bundle. Fibroadipose tissue, which contains the deep lymphatics in the popliteal fossa, should be left intact. Obara et al. reviewed 1580 open and endovascular surgery procedures and concluded that significant reductions in lymphatic complications occur with planned procedure, and endovascular procedures, as well as using minimal incision techniques for femoral artery exposures when possible.[73]

LYMPHATIC FISTULA

Because of the rich lymphatic network in the femoral triangle, lymphatic fistulae after vascular reconstruction most often occur at the groin. In 4000 vascular operations, Kalman et al.[16] observed lymphatic fistulae in 45 (0.1%) patients. The incidence of this complication was similar in other series and ranged from 0.8% to 6.4%.[13,74,75]

Etiology

Important factors that contribute to lymphatic leakage are failure to ligate or cauterize divided lymphatics and failure to approximate the tissue layers properly at closure. Lymphatic leakage occurs more frequently in older diabetic patients with poor wound healing. Excessive early limb motion, infection of the operated leg or foot, reoperation, and placement of a prosthetic graft to the groin are other possible causes.[16]

Diagnosis

Persistent leakage of clear or yellow fluid from a groin incision establishes the diagnosis. Lymphoscintigraphy to confirm that the fluid is of lymphatic origin is seldom necessary when the fistula develops within days or a few weeks after the operation. When lymphatic leakage occurs several months or years after vascular reconstruction, lymphoscintigraphy is helpful; in such cases, however, computed tomography (CT) white blood cell scanning, and sometimes fistulography, must be performed to exclude infection of an underlying vascular graft (see Chapter 47). CT is also valuable for the diagnosis of concomitant retroperitoneal lymphatic injury, because a retroperitoneal lymphocele or chylous ascites can manifest as a lymphatic fistula at the groin.[58]

Management

Early diagnosis and management of a lymphatic fistula are important to prevent prolonged hospitalization and delayed wound healing. Although infection of an underlying vascular graft may be rare, most studies have reported a small but definite risk of deep wound infection from persistent leakage of lymph.[13,16] Conservative management is indicated in the first few days and should include local wound care, administration of systemic antibiotics, and bed rest with leg elevation to reduce lymph flow. Ideally, all lymphatic leakage will cease 7 to 12 days after initial drainage with conservative measures.[73]

When the fistula continues to produce large volumes despite several days of conservative management, surgical closure in the operating room is the best therapeutic option.[13,16] Approximately 30 to 60 minutes preoperatively, 5 mL of isosulfan blue

(Lymphazurin; United States Surgical, Norwalk, Connecticut) dye is injected subcutaneously into the first and third interdigital spaces in the foot (Fig. 52.2).[15,58] A sequential compression pump is placed on the affected leg to increase lymphatic and venous drainage. The groin incision is then opened, and the site of the lymphatic injury is apparent by the leakage of blue fluid (Fig. 52.3). The area is oversewn, and the wound is closed in multiple layers. If isosulfan blue is not visualized, the incision is irrigated and closed in layers with interrupted suture. When it is impossible to oversew the damaged tissue, injection of fibrin glue may also be useful.

Recently, the widespread use of vacuum-assisted closure (VAC) therapy has been suggested in the use of lymphocutaneous fistulae.[76] By placing VAC devices on 10 patients with either lymphocutaneous fistulae (4 patients) or lymphoceles (6 patients), which converted to fistulae, the authors were able to treat all incisions without recurrence with a median outpatient VAC treatment duration of 16 days. Although this was an early study, it suggests that VAC therapy may be useful in recurrent lymphoceles or difficult-to-manage wounds.

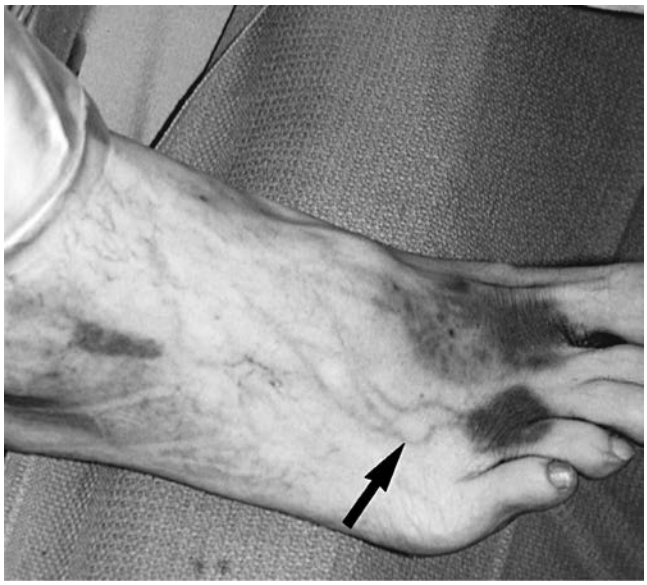

Figure 52.2 Injection of isosulfan blue (Lymphazurin) dye into the first and third interdigital spaces of the foot immediately visualizes the foot lymphatics *(arrow)* and during surgery helps identify the site of lymphatic injury at the groin.

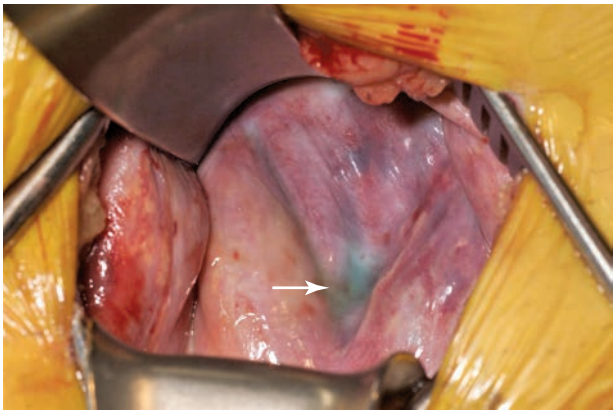

Figure 52.3 Intraoperative photograph of groin re-exploration demonstrating isosulfan blue (Lymphazurin) dye at the base of the incision *(arrow)*. The dye allows localization of the lymphatic injury to facilitate ligation and fistula control.

LYMPHOCELE

A lymphocele is a localized collection of lymph. Early after injury to the lymphatic pathways, the lymph collects between tissue planes. Unless the lymph is reabsorbed spontaneously or drains through a cutaneous fistula, a pseudocapsule develops. In contrast to a seroma, a lymphocele usually has a well-localized connection with one or more of the lymphatic channels. For this reason, lymphoscintigraphy can readily demonstrate a lymphocele (Fig. 52.4).

Groin Lymphocele

As with lymphatic fistulae, the most frequent site of lymphoceles after vascular reconstruction is the groin, often appearing within the first postoperative month. Large lymphoceles cause local discomfort, pain, and leg swelling. Hematoma, seroma, and wound infection should be considered in the differential diagnosis. The presence of a soft, fluid-filled cyst and intermittent drainage of clear lymph through a fistula confirm the diagnosis of lymphocele. Ultrasonography is helpful in distinguishing a solid, dense hematoma from a cystic lymphocele. CT is performed when a lymphocele develops several weeks to months after the operation by excluding graft infection or identifying a retroperitoneal lymphocele extending to the groin.

Small lymphoceles can be observed because they may reabsorb spontaneously. For enlarging or symptomatic lymphoceles or lymphoceles that lie close to a prosthetic graft, early surgery to reduce the chance of graft infection should be performed. Injection of isosulfan blue into the foot is helpful for identifying the lymphatic channels supplying the lymphocele. The lymphocele is excised, and the lymphatic pedicle is ligated or

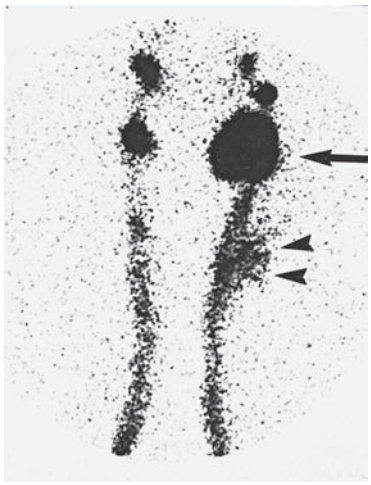

Figure 52.4 Bilateral lower extremity lymphoscintigraphy demonstrating a large left groin lymphocele *(arrow)* and extravasation of colloid in the left side of the thigh *(arrowheads)*.

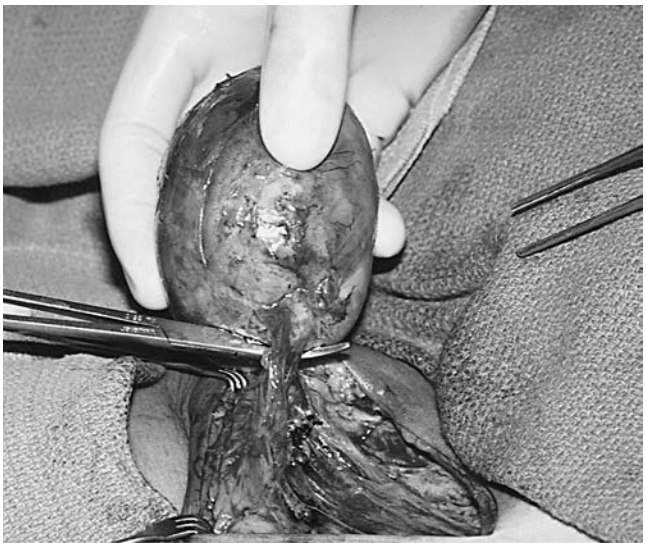

Figure 52.5 Intraoperative photograph of a dissected left groin lymphocele with an easily identifiable lymphatic pedicle. The pedicle was ligated, and the lymphocele was removed.

oversewn (Fig. 52.5). The wound is closed in multiple layers over a small subcutaneous drain. Sclerotherapy, performed more frequently for retroperitoneal lymphoceles, can also be used for groin lymphoceles.

Groin muscle flap coverage can be used to fill defects and provide a single-intervention management of lymphoceles. Shermak et al. reviewed the 22 muscle flaps (19 gracilis, 1 sartorius, 1 rectus abdominis, 1 rectus femoris) placed for lymphoceles. They found that biopsy specimens of the healed muscle at 1 year identified lymphatic channels, indicating that the muscle flap becomes a new path for lymphatic drainage.[77]

Retroperitoneal Lymphocele

Symptomatic retroperitoneal lymphoceles are rare. In a review of more than 4000 aortic reconstructions, an incidence of 0.1% was reported by Garrett et al.[25] In reviewing the literature,[18,19,21-23,25,58] 11 well-documented cases of this complication were found after aortic reconstruction. The number of unreported and asymptomatic cases is undoubtedly higher. Retroperitoneal lymphoceles have been reported more frequently after renal transplantation (incidence of 0.6%-18%).[26,78-80] In these patients, however, a lymphocele develops not only because of injury to the recipient pelvic lymphatics but also because of increased lymph production and leakage from the donor kidney.[26]

Diagnosis

The most common symptoms of retroperitoneal lymphocele are abdominal distention, nausea, and abdominal pain, and the most frequent finding is an abdominal or flank mass. Although signs or symptoms may develop early, in almost half of patients, the lymphocele is discovered a year or several years after the operation.[58] Patients with signs or symptoms of a retroperitoneal lymphocele should be examined with CT (Fig. 52.6). In 5 of 11 published cases of retroperitoneal lymphocele, a groin mass was also present.[58] Evaluation of these patients showed communication between the groin lymphocele and a retroperitoneal lymphocele. This observation illustrates the importance of CT when a groin mass develops after aortofemoral reconstruction. If infection is suspected, white blood cell scanning should also be performed, unless CT has already confirmed graft infection (see Chapter 47). Lymphoscintigraphy can be diagnostic of a retroperitoneal lymphocele and should distinguish it from perigraft seroma. Nevertheless, lymphoscintigraphic confirmation of a lymphocele does not rule out graft infection.

Figure 52.6 Computed tomography in a 70-year-old woman reveals a large left retroperitoneal lymphocele 9 months after repair of a thoracoabdominal aortic aneurysm.

Management

For patients with a small asymptomatic retroperitoneal lymphocele, observation with serial ultrasonography or CT is warranted. If the lymphocele enlarges or causes local compression of adjacent structures, needle aspiration under CT or ultrasound guidance is performed. This maneuver is both diagnostic and therapeutic. In 4 of 11 patients, aspiration alone was used with success.[58] Placement of an indwelling irrigation-drainage system is associated with a risk for infection. Garrett et al.[25] discussed two patients whose prosthetic grafts became infected after an irrigation-drainage system was placed for a retroperitoneal lymphocele. Therefore, when repeated aspiration is unsuccessful, sclerotherapy or operative repair should be considered. Abdominal exploration is performed after injection of 5 mL of isosulfan blue into the ipsilateral foot according to the technique detailed earlier. The lymphocele is unroofed, and the site of the lymphatic injury is oversewn, ligated, or both. If the prosthetic graft is exposed, it is covered by retroperitoneal tissue or omentum. When preoperative aspiration confirms the presence of chyle in the cyst, 24 oz of whipping cream is administered through a nasogastric tube 4 hours before exploration. Absorption of the cream helps identify the site of lymphatic leakage in the mesenteric lymphatics around the left renal vein or at the cisterna chyli (Fig. 52.7). Although the mesenteric lymphatic trunks

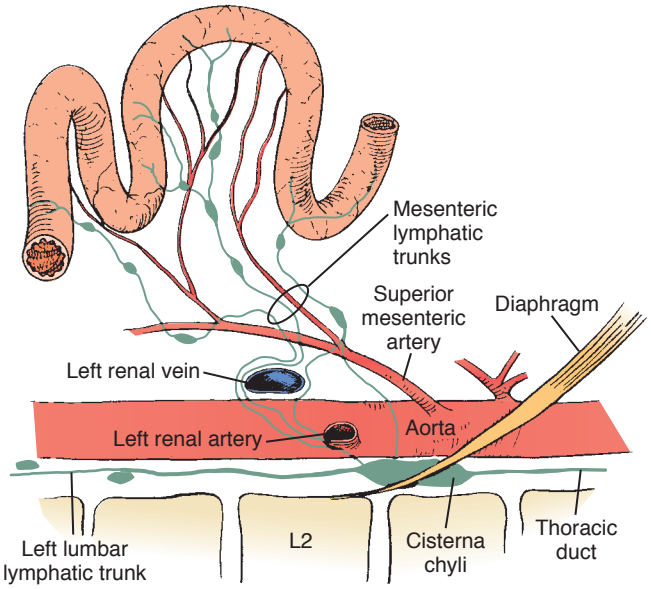

Figure 52.7 Anatomy of the mesenteric and ascending lumbar lymphatic trunks and the cisterna chyli. (Modified from Gloviczki P, Bergman RT. Lymphatic problems and revascularization edema. In: Bernhard VM, Towne JB, eds. *Complications in Vascular Surgery.* 2nd ed. St. Louis, MO: Quality Medical Publishing; 1991:366.)

should be ligated or oversewn, lateral closure of the cisterna may be attempted first with loupe magnification.

For post-transplant lymphocele, peritoneal fenestration has been recommended for treatment.[78-80] Since the advent of surgical laparoscopy, however, several reports have described aspiration and peritoneal fenestration under laparoscopic visualization.[79,80] A tongue of omentum is brought down and placed through the peritoneal window to prevent premature closure and recurrence of the cyst. One study analyzed the results of 12 laparoscopic and 23 open surgical internal marsupializations of pelvic lymphoceles. Laparoscopic lymphocelectomy required a longer operative time, but it resulted in a shorter hospital stay, faster convalescence, and fewer recurrences of the lymphocele.[78] Laparoscopic transperitoneal drainage may become a useful addition to the vascular surgeon's armamentarium for the occasional treatment of lymphoceles after vascular reconstruction.

Percutaneous sclerotherapy has been used with increasing success as the definitive treatment of lymphoceles. Injection of talcum, bleomycin, doxycycline, povidone-iodine, fibrin sealant, and absolute alcohol has been reported, with good results in most cases.[81-88] Treatment with repeated injections may be necessary.

CHYLOUS ASCITES

The development of chylous ascites after abdominal aortic reconstruction is rare, but the morbidity and mortality related to this complication can be significant. In a review of the literature, 23 patients were reported to have chylous ascites after aortic reconstruction.[22,28-46,80] Eighteen patients (78%) underwent repair of an abdominal aortic aneurysm, and five (22%) had surgery for occlusive disease. Ascites developed in the first 6 weeks after surgery in all but one patient.

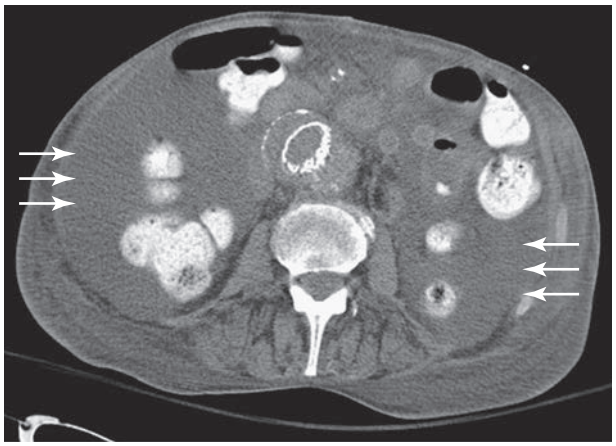

Figure 52.8 Computed tomography scan demonstrating diffuse ascites *(arrows)* in a patient 3 months after abdominal debranching and endovascular repair of a paravisceral aneurysm. Paracentesis confirmed the presence of chyle.

Diagnosis

Symptoms of chylous ascites include progressive abdominal pain, dyspnea, and nausea. Abdominal distention can be significant, and the loss of proteins and fat may result in malnourishment. Lymphopenia and anemia can also develop and frequently result in poor immune function. Ascites can usually be detected by physical examination and confirmed by ultrasonography or CT (Fig. 52.8). Paracentesis is necessary to verify the presence of chyle in the ascitic fluid. Chyle is an odorless, sterile, alkaline fluid that is milky in appearance. Its specific gravity is higher than 1.012. Its protein content is usually more than 3 g/dL, and its fat content ranges from 0.4 to 4 g/dL. The fat in the fluid stains with Sudan stain.

Management

Although chylous ascites in patients with abdominal malignancies carries an ominous prognosis, the outcome when chylous ascites develops after open aortic surgery is somewhat better. Nevertheless, in one series, 4 of 23 patients with this complication after open aortic surgery died (mortality rate, 17%).[22,31,47,89] The cause of death was sepsis in two patients, pulmonary embolism in one patient, and malnutrition in one patient.[22,31,42,89] Most patients with chylous ascites after aortic surgery can be treated successfully without an operation.[90] The mainstay of treatment in patients with mild to moderate ascites is a medium-chain triglyceride diet to decrease chyle formation.[90] For severe cases, however, complete bowel rest and total parenteral nutrition must be instituted. Repeated paracentesis results in resolution of the symptoms in most patients. Placement of a peritoneovenous shunt has been reported, but may cause sepsis, leading to death.[80,91] If repeated paracentesis is unsuccessful, exploration after ingestion of a fatty meal and closure of the site of the lymphatic injury should be performed (Fig. 52.9). Larger mesenteric or para-aortic lymphatic channels should be ligated or oversewn, but lateral closure of the injured cisterna chyli can be attempted with fine monofilament suture, as mentioned

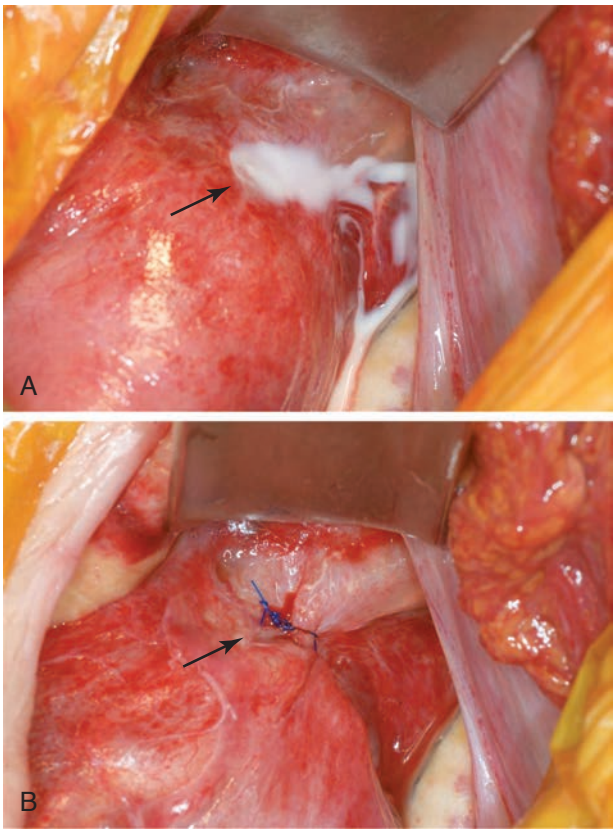

Figure 52.9 Intraoperative photographs of the patient described in Fig. 52.8. (A) After ingestion of a fatty meal, chyle is easily visualized at the base of the mesentery *(arrow)* during abdominal re-exploration. (B) Successful ligation of the chylous injury and control of leakage *(arrow)*.

earlier. Of six reported patients who underwent exploration and surgical closure of the fistula, all recovered without recurrence.[28,34,39,41,44,45]

Several case reports have described the use of laparoscopic techniques to control chylous ascites complicating nonvascular procedures.[92-95] It is possible that these techniques may be used in patients with chylous ascites who do not respond to bowel rest and total parenteral nutrition after vascular procedures. In these cases, the patient first ingests a fatty meal. Laparoscopic lymphostasis is performed with a combination of laparoscopic clipping, electrocautery, and fibrin glue. Somatostatin and a low-fat diet may be used adjunctively in the postoperative period.[92,95] Although these reports are preliminary, the concept of minimal-incision re-exploration is enticing, and early reports appear promising.

Prevention

Injury to the retroperitoneal and mesenteric lymphatics during aortic dissection should be carefully avoided. The cisterna chyli is formed by the right and left lumbar and the mesenteric lymphatic trunks; it is usually located at the level of the second lumbar vertebra, between the inferior vena cava and the abdominal aorta.[58] In half of patients, a well-developed cisterna chyli is absent. Several large mesenteric lymph vessels are located on the anteroinferior aspect of the left renal vein (see Fig. 52.7). Injury to these vessels results in leakage of chyle. Failure to close the divided lymphatics may lead to the development of chylous ascites or retroperitoneal lymphocele. All large lumbar, para-aortic, and mesenteric lymph vessels should be ligated or clipped when division is necessary during aortic dissection. Lateral closure of the injured cisterna chyli should be attempted with 7-0 monofilament suture.

THORACIC DUCT FISTULA

Injury to the thoracic duct may occur after dissection of the proximal left common carotid artery or after left subclavian or vertebral artery dissection.[22] Neglected cases of thoracic duct cutaneous fistula may lead to malnutrition, lymphocytopenia, anemia, or infection of an underlying prosthetic graft. Early surgery plus lateral closure with 7-0 or 8-0 nonabsorbable monofilament suture is the optimal treatment. If lateral closure is not possible, ligation of the thoracic duct at the neck is an accepted alternative because the collateral lymphatic circulation is usually adequate. The incision is closed over a subcutaneous drain, which is left in place for a short time postoperatively.

CHYLOTHORAX

Effusion of chyle into the pleural cavity after vascular procedures is uncommon; it occurs in just 0.2% to 1% of cases after cardiothoracic surgery.[55] It is more common in neonates and small children operated on for congenital vascular anomalies, most frequently for aortic coarctation.[51-56] Chylothorax after repair of a thoracic aortic aneurysm has been reported,[47-50] and in one patient it occurred after repair of an abdominal aortic aneurysm.[31] Chylothorax may develop as a complication of transthoracic dorsal sympathectomy[48] or after high translumbar aortography.[57]

Diagnosis

Pleural effusion is confirmed by chest x-ray studies or CT. Thoracentesis reveals milky fluid rich in albumin and lipids. Diagnostic criteria include a milky appearance, separation into a creamy layer on standing, absence of odor, specific gravity above 1.012, and triglyceride levels higher than 110 mg/dL (1.24 mmol/L).[96,97] Analysis of the fluid obtained by thoracentesis or through the thoracostomy tube confirms the diagnosis. Laboratory analysis of the milky or serous fluid is similar to that described for chylous ascites. CT is performed to confirm effusion and exclude malignancy, although dilated lymphatics may also be seen on magnetic resonance imaging. Lymphoscintigraphy or lymphangiography is rarely required to identify the source of the chyle leak.[98]

Management

Because respiratory embarrassment is frequent, drainage of the chylous fluid through a thoracostomy tube is usually necessary. The principles of treatment to decrease chyle formation are the

same as those for chylous ascites. Conservative management consisting of closed drainage through a thoracostomy tube and nutritional support has been effective in most cases. If a low-fat, high-protein diet with medium-chain triglyceride supplementation is not successful, intravenous hyperalimentation is started. Rarely, surgical closure of the site of leakage by oversewing or ligating the thoracic duct must be performed. Pleurodesis facilitates closure of the pleural space and decreases the potential for recurrence. Parietal pleurectomy is the most successful treatment when no distinct chylous leak can be identified.[96] Of six patients in whom chylothorax developed after aortic aneurysm repair, only one needed thoracotomy to treat a large chylous pseudocyst[47]; however, one patient who was treated conservatively died after a long postoperative course that was complicated by both chylous ascites and chylothorax.[31]

Cerfolio et al.[97] at the Mayo Clinic reported 47 patients in whom chylothorax developed after thoracic operations. Nonoperative therapy was successful in a third, but 32 patients required ligation of the thoracic duct, and 2 were treated with mechanical pleurodesis and fibrin glue. Reoperation was successful in 31 of the 34 patients (91.2%). These authors recommended early reoperation and ligation of the thoracic duct when drainage was more than 1000 mL/day.

Multiple case reports have been published illustrating the role of thoracoscopic thoracic duct ligation in the treatment of chylothorax.[99-107] With progress in thoracoscopic surgery, thoracoscopic clipping of the thoracic duct has replaced open thoracotomy in many patients.[98] An early report from Cope and Kaiser[100] described percutaneous cannulation of the cisterna chyli and embolization of the thoracic duct with microcoils, particles, and glue. They reported on 42 patients who underwent percutaneous transabdominal catheter embolization or needle disruption of the retroperitoneum.[100] Cure or improvement was documented in 74% of the patients. The authors recommend this procedure particularly for ill and high-risk patients. Although rare, chylous ascites occurring after lymphatic puncture for thorax duct embolization for chylothorax has been reported.[108] Recently, a technique of direct lymphangiography using hybrid CT and fluoroscopy imaging that allowed direct placement of a 21-gauge needle into the cisterna chyli was described in two patients.[109]

A summary paper from Kumar and Pawar in 2004 reported a total of 21 cases of video-assisted thoracoscopic surgery (VATS) for the treatment of chylothorax (16 patients), chylopericardium (4 patients), and cervical chylous leak (1 patient).[101] A trial of conservative therapy had failed in all patients, who then underwent clipping or ligation of the thoracic duct, except for one patient who had glue applied to the chylous leak site. All procedures were successful without complications. Ligation of the thoracic duct far above the diaphragm may be more successful than clipping of the cut near the diaphragm.[101] In addition, if extensive fibrosis is present, and the thoracic duct is not easily identified, VATS may be used to ligate the mass of tissue between the azygos vein and the aorta with good success.[101] One specific advantage of VATS for the treatment of chylothorax is that magnification of the thoracic structures can facilitate ligation. Because of the efficacy, low expense, and low morbidity of VATS for the management of chylothorax, early reoperation is recommended to avoid a lengthy conservative course with concomitant loss of chyle and a long hospital stay. Early intervention with VATS is recommended for patients with a high-output fistula (>1000 mL/24 hours), and a 1-week trial of conservative therapy is recommended in others.[101] However, if the chylous output remains greater than 200 mL/24 hours after 1 week, VATS intervention should be considered.[101]

Prevention

Injury to the thoracic duct during thoracic aortic dissection should be carefully avoided. The thoracic duct extends upward from the cisterna chyli and enters the posterior mediastinum through the aortic hiatus, slightly to the right of the aorta and to the left of the azygos vein (Fig. 52.10). In the posterior mediastinum, it is mostly a right-sided structure. The thoracic duct enters the superior mediastinum behind the aortic arch and subclavian artery, to the left of the esophagus. It is thus exposed to injury during dissection of the proximal thoracic aorta, the aortic arch, or the proximal subclavian artery. Once injury to the thoracic duct is recognized, an attempt at lateral closure with 7-0 monofilament suture should be made with loupe magnification. If it is not successful, ligation of the thoracic duct should be performed. Adequate collateral lymphatic circulation usually develops.
