Occlusive disease affecting the renal arteries ranks as the third most prevalent cause of hypertension in children, behind parenchymal renal disease and coarctation of the thoracic aorta.[38-40] The exact incidence of renovascular hypertension as a cause of secondary hypertension in the pediatric population is unknown, but is likely to account for 8% to 10% of those exhibiting marked blood pressure elevations.[41] Although the overall incidence is low, renovascular disease accounts for a much larger proportion of hypertension in children than in the adult population.

Hypertension due to suprarenal or intrarenal aortic narrowings may be compounded by occlusive lesions of the renal artery. The resulting secondary hypertension in these cases is often refractory to simple pharmacologic control. Encounters with such patients who are receiving three or more antihypertensive agents are commonplace. Lower extremity fatigue with exercise due to abdominal aortic narrowing has been reported infrequently as the presenting complaint, and true claudication is rare.[1]

Despite the high rate of CA and SMA occlusive involvement with developmental narrowing of the abdominal aorta, symptomatic intestinal ischemia affected only 6% of these cases.[1] When these patients have functionally relevant splanchnic arterial narrowings, they present with postprandial intestinal angina manifest by periumbilical discomfort that lasts for the duration of small bowel transit of ingested food. These patients develop a food adversion and exhibit weight loss from a failure to eat.

Initial presentations of pediatric renovascular hypertension are quite varied and include asymptomatic high blood pressure, headache, seizure, epistaxis, visual disturbances, and acute renal insufficiency. The spectrum of neurologic dysfunction includes an isolated facial nerve paralysis, reported as Bell's palsy.[41,42] More chronic effects of elevated blood pressure may be evident by the arrest of kidney growth or atrophy with chronic renal insufficiency.[43] When unrecognized and untreated, renovascular hypertension in children is associated with hemorrhagic stroke, hypertensive encephalopathy with impaired cognitive development, and failure to thrive. Poorly controlled hypertension also may result in severe diastolic dysfunction and left ventricular hypertrophy (LVH). When untreated, the resulting hypertensive cardiomyopathy can progress to heart failure. If the entire renal mass is involved, flash pulmonary edema associated with renal insufficiency may occur, although this is an uncommon complication.

Definition of Hypertension in Children

The National Health and Nutrition Examination Survey (NHANES) data are the basis for definitions of hypertension in children and adolescents. Blood pressure tables for the 50th, 90th, 95th, and 99th percentiles by sex, age, and height are included in The Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents published by the US Department of Health and Human Services (http://www.nhlbi.nih.gov/health/prof/heart/hbp/hbp_ped.pdf).[44]

Normal pressure is defined as systolic blood pressure (SBP) or diastolic blood pressure (DBP) that is less than the 90th percentile for sex, age, and height, whereas hypertension is defined as an average SBP or DBP that is greater than or equal to the 95th percentile for sex, age, and height on at least three separate occasions.

It is recommended that children older than 3 years of age who are seen in a medical setting have their blood pressure measured; the preferred method is by auscultation. It is critical that an appropriate sized cuff be used for the size of the child's upper arm. Children younger than 3 years of age should also have blood pressure evaluations if congenital heart disease is identified, if there are known renal diseases or urologic malformations, if they require hospitalization, or if other systemic illnesses associated with hypertension are identified (e.g., neurofibromatosis, tuberous sclerosis).

The prevalence of LVH in children and adolescents with hypertension underscores the importance of recognizing and treating this disease. Although 43% of hypertensive children in one study were being treated with antihypertensive medication at the time of evaluation, LVH was present by echocardiogram in 41% using pediatric criteria and in 16% using adult criteria.[43] Additional documented effects of pediatric hypertension include impaired cognition or failure to thrive.[45-47]

DIAGNOSTIC EVALUATION

Imaging to accurately define renal artery stenotic disease requires significant detail.[2,7,48,49] Renal Doppler sonography and axial imaging with both computed tomography angiography (CTA) and magnetic resonance angiography (MRA) are utilized increasingly as first-line imaging modalities for pediatric renovascular hypertension; their respective risks and benefits are outlined in Table 130.1.[50] Renal sonography is an appropriate first-line study to detect renin-mediated hypertension caused by aortic or main renal artery disease, offering up to 90% sensitivity and 68% specificity.[51] Axial imaging certainly produces increased anatomic yield. Moreover, contemporary low-dose CTA protocols may reduce radiation exposure in this sensitive age group, without compromising diagnostic imaging modality, and time-resolved three-dimensional (3D) cine phase-contrast MRI may permit the evaluation of renal blood flow pre- and postintervention.[52,53] If a strong suspicion of a renovascular lesion exists, then catheter-based digital subtraction angiography should be pursued, in that conventional angiography remains the most valuable diagnostic study for patients with renovascular hypertension and remains the authors' diagnostic modality of choice for preoperative planning.[1,2,49,54]

Cerebral vascular abnormalities are described in a small percentage of patients with MAS (3%-13%), including intracranial arterial occlusive disease and cerebral aneurysms.[55,56] For this reason, screening children with contrast-enhanced axial imaging (CTA or MRA) should be considered.

TABLE 130.1 Imaging Modalities for Pediatric Renovascular Hypertension

Diagnostic Modality	Risks	Benefits
Renal doppler sonography	• Operator dependent • Small vascular structures (i.e., accessory renal arteries and segmental branches) may be difficult to visualize directly	• No ionizing radiation • Relatively low cost • Widespread availability
CTA	• Ionizing radiation • Iodinated contrast	• Rapid imaging of thoracoabdominal arterial structures decreases motion-related artifact and decreases need for sedation • Excellent spatial resolution • Excellent contrast resolution • Permits high-quality multiplanar 2D re-formats and 3D reconstructions
MRA	• High cost • Limited availability • Lower spatial resolution (in comparison to CTA) that limits evaluation of small accessory arteries and intra-renal segmental branches • May exaggerate areas of arterial narrowing • Artifacts may result from implanted metal or patient motion • Younger patients may require sedation or general anesthesia during the study period	• Excellent contrast resolution allows for 2D reformats and 3D reconstructions • No ionizing radiation • May obtain images with and without intravenous contrast material
Conventional catheter-based digital subtraction angiogram	• Invasive with procedural risk • Younger patients may require general anesthesia • Ionizing radiation	• Best spatial and temporal resolution • Produces excellent images of the renal arterial lumens and branches • Advantage of concurrent therapeutic intervention

MEDICAL MANAGEMENT

Pharmacologic treatment of hypertension in a very young child may be difficult and requires frequent and careful monitoring. Failure of medical therapy to halt the progression or diminish LVH should be a reason to consider surgical or endovascular therapy.

All children with secondary hypertension should be treated. The goal of therapy is reduction of the pressure to the 95th percentile for sex, age, and height, unless LVH or other target organ damage is identified, in which case the goal should be less than the 90th percentile. Although no specific recommendations regarding pharmacologic agents have been made, there are accepted classes of medications used in the management of hypertension in children ages 1 to 17 years old.

Antihypertensive Drug Treatment

Common classes of antihypertensive drugs for the ambulatory management of hypertensive children include angiotensin converting enzyme (ACE) inhibitors (benazepril, captopril, enalapril, fosinopril, lisinopril, quinapril); angiotensin receptor blockers (ARBs; irbesartan, losartan); combined alpha and beta blockers (labetalol); beta blockers (atenolol, metoprolol, propranolol); combined beta blockers and diuretics (bisoprolol/hydrochlorothiazide [HCTZ]); central alpha agonists (clonidine); calcium channel blockers (amlodipine, felodipine, isradipine, extended-release nifedipine); diuretics (hydrodiuril, chlorthalidone, furosemide, spironolactone, triamterene, amiloride); peripheral alpha antagonists (doxazosin, prazosin, terazosin); and vasodilators (hydralazine, minoxidil).[44] It is recommended that a single agent be initiated until target blood pressure is reached or until maximum dose or a side effect of the drug is encountered, at which time an additional agent should be added.[44]

The nuances of medical pharmacologic treatment of renovascular hypertension are numerous and complicated, but several specifics deserve note. First, the ACE and/or ARB classes of medicine are potent antihypertensives, sometimes controlling blood pressures with monotherapy, whereas multiple agents from other classes of drugs fail. Antihypertensives that block any part of the renin-angiotensin-aldosterone system are relatively contraindicated until critical main renal artery stenosis or bilateral renal artery disease is excluded. When initiated, this medial therapy requires careful monitoring of serum potassium and creatinine. A decline in renal function is most apt to occur when blood flow to the entire renal mass is compromised (i.e., bilateral renal artery disease or unilateral disease in the presence of a solitary kidney). Discontinuation of these drugs usually results in a return to baseline renal function. Second, the existence of rebound hypertension and tachycardia seen with the sudden withdrawal of clonidine is particularly troublesome in children. When clonidine patches are used in a very young child, they may be accidentally detached, resulting in dramatic fluctuations in blood pressure and heart rate. A functioning, properly applied patch should be carefully monitored by those

caring for these children. In these cases, one should confirm the adequacy of the patch placement before undergoing a complex search for the cause of an abrupt change in blood pressure control. Finally, diuretics should be used as combination therapy, as their isolated use may increase renin release and exacerbate hypertension.[57]

SURGICAL TREATMENT

Isolated abdominal aortic coarctations are preferentially treated by patch aortoplasty when technically feasible, whereas thoracoabdominal bypass may be favored in patients in whom the hypoplastic segment of the aorta is too narrow to facilitate placement of a patch, or in cases of complex disease affecting the renal and splanchnic arteries.[1,58] Expanded polytetrafluoroethylene (ePTFE) grafts are favored over woven or knitted grafts for both patch aortoplasty and thoracoabdominal bypass grafting, due to the greater stability of ePTFE regarding postimplantation dilatation.

A novel treatment for MAS has more recently been described in a single case report involving the placement of a retroaortic tissue expander to induce longitudinal growth of the normal distal aorta.[59] The tissue expander is sequentially inflated through a subcutaneous port over the course of many months to elongate the nonaffected aorta such that it can be anastomosed to the proximal normal aorta, after resection of the aortic segment that is narrowed. Long-term follow-up of such therapy is lacking.

Patch Aortoplasty

Patch aortoplasty is performed when the narrowed segment of the aorta has a large enough diameter to allow completion of the anastomosis without an overlap of sutures from the opposite side of the patch. Aortic patches in children are sized large enough to facilitate and match the growth of the remaining aorta, but these patches are not so large as to favor low-velocity flow and potential thrombus formation (Fig. 130.7). Aortoplasty in these patients is often accompanied by complex renal and splanchnic arterial reconstructive procedures (Fig. 130.8).

Thoracoabdominal Bypass

Thoracoabdominal bypass grafts should originate above the narrowed area, either from the distal thoracic aorta above the diaphragm using a thoracoabdominal approach or from the supraceliac aorta at the diaphragmatic hiatus by an abdominal approach (Fig. 130.9). The grafts are positioned behind the left kidney with a gentle curve to the distal aorta. The sizing of bypass grafts follows the sizing principles used for patch aortoplasty. The intent is to use oversized grafts compared with the aorta, recognizing anticipated growth; otherwise the result is a graft that is too small to maintain normal distal pressures and flow. Basic diameter guidelines are as follows: 8- to 12-mm grafts in young children; 12- to 16-mm grafts for early adolescents; and 14- to 20-mm grafts in late adolescents and adults. It is not essential to leave significant graft redundancy in older children and adolescents, because axial growth from the diaphragm to the pelvis is not significant after reaching 9 or 10 years of age. Thoracoabdominal bypass procedures are frequently undertaken with concurrent complex renal and splanchnic artery reconstructions (Figs. 130.10 and 130.11).

In very early childhood, the use of large conduits may not be possible.[1] Aortic reoperations may be required for anastomotic narrowings, or if a patient outgrows the primary reconstructive

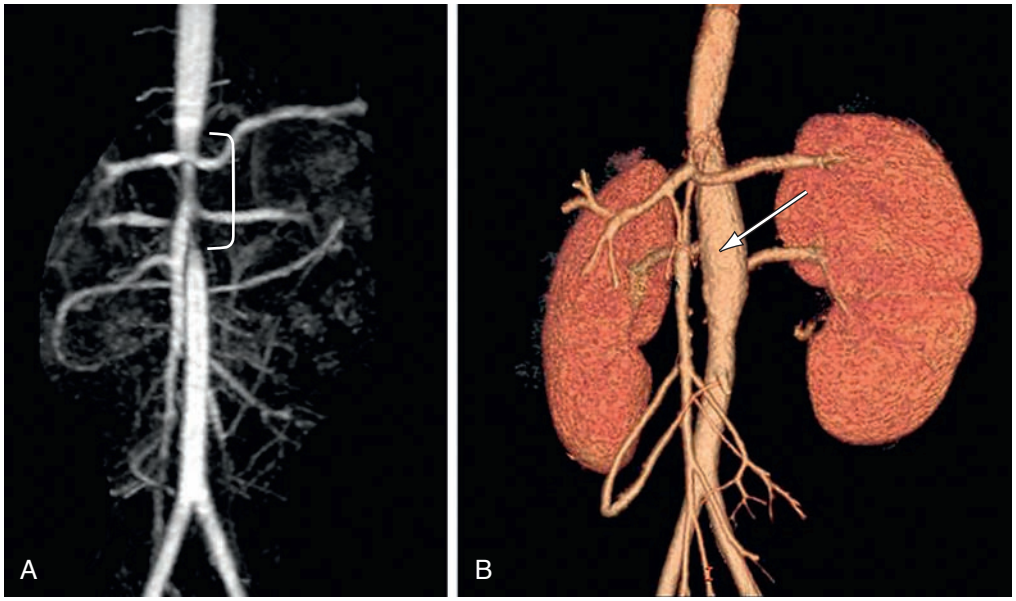

Figure 130.7 (A) Suprarenal coarctation *(bracket)* with bilateral renal artery ostial stenoses. Preoperative magnetic resonance angiography. (B) Subsequent patch aortoplasty *(broad arrow)*, with aortic diameter exceeding that of uninvolved proximal and distal aorta. Reimplantation of the renal arteries accompanied the aortic reconstruction. (From Stanley JC, Criado E, Eliason JL, et al. Abdominal aortic coarctation: surgical treatment of 53 patients with a thoracoabdominal bypass, patch aortoplasty, or interposition aortoaortic graft. *J Vasc Surg.* 2008;48:1073–1082.)

procedure. Long-term follow-up of these patients is essential for this reason.

Primary open surgical treatment of abdominal aortic coarctation for renovascular hypertension benefits more than 90% of patients when treated with a patch aortoplasty or a thoracoabdominal bypass.[1,58] Postoperative morbidity is low, with infrequent bleeding and postsurgical pancreatitis being the most noteworthy complications. Surgical mortality and unintended nephrectomy rates should approach zero. The patency of patch aortoplasty, thoracoabdominal aortic bypass, or endoluminal treatments may be followed indirectly by noninvasive blood pressure measurements of the upper and lower extremities, with and without exercise. If the ankle-brachial index measurements are noted to decline, then detailed imaging should be considered. MRA is favored to avoid excessive radiation exposure accompanying CT studies. Late, secondary operations at the authors' institution following surgical treatment of abdominal aortic coarctation or segmental hypoplasia approached 10% and were performed 5 to 12 years after the initial reconstruction.[1]

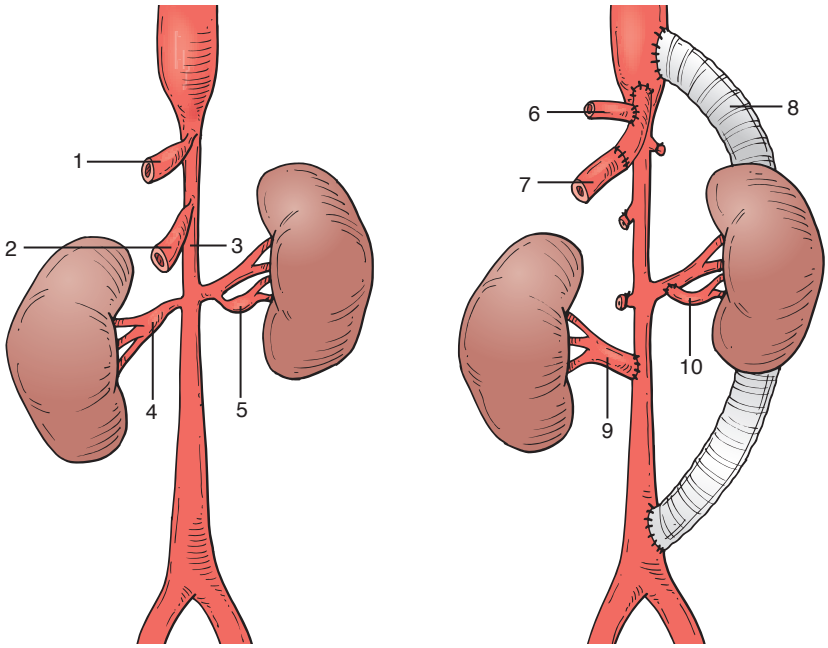

Figure 130.10 Complex aortic, splanchnic, and renal arterial reconstruction: *1*, Celiac artery (CA) stenosis; *2*, superior mesenteric artery (SMA) stenosis; *3*, suprarenal midabdominal aortic coarctation; *4*, right renal artery ostial stenosis; *5*, left segmental renal artery stenosis; *6*, CA implanted onto aorto-SMA bypass (with autogenous internal iliac artery graft); *7*, reconstructed SMA; *8*, thoracoabdominal aortic bypass; *9*, right renal artery reimplantation onto aorta; *10*, left segmental renal artery implantation onto adjacent segmental renal artery. Figure 130.11 (A) Absence of the abdominal aorta and agenesis of the proximal main renal arteries, with reconstitution of the distal renal arteries and iliac arteries by way of extensive collateral vessels. **(B)** Complex thoracic aortobi-iliac bypass with bilateral renal artery reconstructions.

Renal Artery Repair

Repair of renal artery stenoses found independently of an aortic narrowing or in conjunction with an aortic coarctation is most often undertaken to prevent long-term sequelae of hypertension. The surgical options and reconstructive configurations should be considered carefully to minimize kidney ischemic times and facilitate unobstructed and durable renal artery reconstructions (Figs. 130.12 and 130.13).[2,7]

There should be a degree of caution regarding the timing of operation. Significant technical challenges exist in reconstructing the very small and highly vasoactive arteries in infants. Uncontrolled severe hypertension or renal failure in a rare instance may require the surgeon to undertake an operation in the very young. However, renal revascularizations are more likely

Figure 130.12 Bilateral renal artery-aortic implantations. Note the residual origins of the native renal arteries. (From Stanley JC, Zelenock GB, Messina LM, Wakefield TW. Pediatric renovascular hypertension: a thirty-year experience of operative treatment. *J Vasc Surg*. 1995;21:212–227.)

Figure 130.13 Aortorenal bypass with an internal iliac artery graft. (From Stanley JC, Zelenock GB, Messina LM, Wakefield TW. Pediatric renovascular hypertension: a thirty-year experience of operative treatment. *J Vasc Surg*. 1995;21:212–227.)

to be successful and more durable after the age 3 years, and deferring reconstructive procedures in infants when possible is reasonable and appropriate.

Determining the optimal surgical therapy depends on the specific character of the renal artery disease being treated. Considerations may include whether or not both renal arteries are involved, the length of the stenotic disease, and whether segmental renal branches are also narrowed. The most common method of surgical reconstruction has been renal artery implantation of the normal artery beyond the stenosis into the aorta or an undiseased adjacent artery.[2,7] Use of the internal iliac artery for aortorenal bypass grafts, when needed, has proven to be a suitable conduit and is currently recommended if reimplantation of the vessel cannot be performed.[2] An aortorenal bypass with a vein graft, as utilized in the past, is no longer recommended due to aneurysmal degeneration, seen in more than half of these grafts at follow-up.[60]

The common coexistence of splanchnic arterial narrowings in patients with renal artery stenoses and the propensity for the CA to develop stenosis as a young child grows are reasons why splenorenal reconstructions with a direct anastomosis of the involved vessels are not favored in the pediatric population. Using this type of reconstruction may perpetuate or result in a recurring hypertensive state.

Less common renal artery reconstructive procedures include resection of the stenotic segment of artery with a primary reanastomosis, a focal arterioplasty, or an open operative dilation. It may be necessary to consider nephrectomy in patients with nonreconstructable disease. Indications for nephrectomy include multiple intrarenal stenoses not amenable to open in-situ or endovascular treatment, or diminutive nonfunctioning kidneys 2 to 3 cm in size. Nephrectomy is only appropriate when the contralateral kidney is assumed to be sufficient in preventing the patient from going into renal failure, while partial nephrectomy may offer a nephron-sparing cure for segmental renovascular hypertension, as diagnosed by selective renal vein renin sampling.[61]

Large clinical experiences with pediatric-aged renovascular hypertension are uncommon.[7,62-69] The published University of Michigan series included 97 children (39 girls and 58 boys), ages 3 months to 17 years, who underwent operation from 1963 to 2006.[2] All but one patient had refractory hypertension not responsive to medical therapy. Renal artery stenoses in this series were developmental in 80% of cases. Mesenteric arterial occlusive lesions affected 24%, and abdominal coarctations affected 33%. Primary renal artery operations were performed 132 times, with procedures including resection beyond the stenosis and implantation into the aorta in 49 cases, renal artery in 7, or SMA in 3 cases; aortorenal and iliorenal bypasses with vein or iliac artery grafts in 40 cases; focal arterioplasty in 10 cases; resection with reanastomosis in 4; operative dilation in 4; splenorenal bypass in 2; and primary nephrectomy in 13, when arterial reconstructions proved impossible. The complexity of this disease is underscored by the fact that 32 children required bilateral renal artery operations, 17 patients underwent a simultaneous CA or SMA reconstruction, 19 had a patch aortoplasty, and 11 underwent a thoracoabdominal aorto-aortic bypass. Thirty secondary renal artery procedures were performed in 19 of this series' patients, including nine nephrectomies. Hypertension was cured in 68 children (70%), improved in 26 (27%), and was unchanged in 3 (3%). There was no perioperative mortality, and no patient required dialysis during a mean follow-up of 4.2 years.

Another large experience was reported from the Hospital Beaujon in France.[63] This series included 78 children (35 boys and 43 girls), ranging in age from 1.4 to 18 years. There were 91 primary revascularization procedures and 15 nephrectomies. These numbers were quite similar to the University of Michigan series. A third series from the Cleveland Clinic involved 56 children (23 boys and 33 girls), ranging in age from 8 months to 21 years.[65] They reported 46 primary operations and 10 primary nephrectomies. A fourth series, from both Vanderbilt University and the Children's Hospital of Philadelphia, included 50 children (24 boys and 26 girls), ranging in age from 5 months to 16 years.[66] The authors reported on 28 primary reconstructive procedures and an additional 12 primary nephrectomies. The latter two series, unlike the experiences at the University of Michigan or Hospital Beaujon, did not contain many patients treated for aortic or splanchnic arterial disease.

When blood pressure control outcomes were analyzed in the three major reports on pediatric renovascular hypertension from the University of Michigan, Vanderbilt University–Children's Hospital of Philadelphia, and the Cleveland Clinic, a great deal of similarity was found in the results. Respective

cure rates were 70%, 70%, and 66%; reported improvement rates were 27%, 26%, and 23%; and failure rates were 3%, 4%, and 11%. Each of these reports reflected the open surgical management of renal artery stenoses in children.

Renal autotransplantation has been suggested in case reports and more contemporary retrospective single institution series as safe and efficacious for complex and segmental renal artery disease without associated mortality, negligible morbidity, and reasonable long-term follow-up.[70-72] Hypertension cure rates in the latter setting may approach 62% and improvement rates 38% with concurrent preservation of renal function.

Splanchnic Artery Repair

Splanchnic artery repair depends on whether obstructions of the CA and SMA are symptomatic. Any mandate to reconstruct the CA or SMA applies only to symptomatic cases. A relative indication to prophylactically reconstruct these vessels exists when performance of an aortoplasty or renal revascularization would make a subsequent CA or SMA revascularization exceedingly difficult (Fig. 130.14).[73] Aortic reconstructions remote from the mesenteric vessels make prophylactic mesenteric revascularization less likely to be warranted.

The operative treatment of pediatric splanchnic arterial occlusive disease is complex. Internal iliac artery grafts are used to treat lengthy CA or SMA stenoses in young patients. Anastomoses are fashioned with interrupted sutures when reconstructing small arteries 2 to 3 mm in diameter. In older adolescents, a continuous suture may be used to complete anastomoses of larger splanchnic arteries. In other children, aortic implantation of the CA or SMA after spatulation of the transected vessel beyond its stenotic origin is favored over an aortosplanchnic bypass. Patients treated by both methods are quickly able to gain weight and are rapidly freed from abdominal discomfort. Developmental CA or SMA stenoses in adults may be reconstructed with either vein grafts or synthetic conduits. Percutaneous transluminal balloon angioplasty with or without stenting in children for these splanchnic ostial lesions is not appropriate and ill-advised.

Splanchnic arterial occlusive disease encountered in childhood has an uncertain natural history. Long-term follow-up of these children with periodic imaging studies in those operated upon seems appropriate, and regular clinical assessment of those not subjected to surgical therapy is recommended. With regard to the latter, it is important to remember that most CA and SMA stenoses are asymptomatic because of the inferior mesenteric artery serving effectively as a source of collateral circulation. Unoperated patients should be aware of their splanchnic arterial anatomy and be able to pass this information to a surgeon performing a later abdominal operation. Inadvertently interrupting the collateral circulation might cause catastrophic intestinal ischemia in these individuals.

Figure 130.14 Superior mesenteric artery implantation into infrarenal aorta *(arrow)*, as treatment of intestinal ischemia due to an ostial stenosis of this artery, in a child with near occlusion of the supraceliac abdominal aorta who underwent a concomitant thoracoabdominal bypass to the distal aorta (not visualized on this lateral aortogram).

ENDOVASCULAR TREATMENT

Endovascular treatment of abdominal aortic narrowings is increasingly reported. Endoluminal interventions may have utility in the treatment of select focal abdominal aortic coarctations distant from the renal and splanchnic branches, and this therapy has been most commonly employed for the treatment of stenotic disease due to an aortitis.[74-78] Developmental aortic narrowings are prone to significant recoil from the hypoplastic and fibrotic segments, and stenting may be required to overcome this.[79-81] Percutaneous measures may be successful in the procedural setting at decreasing a pressure gradient across a stenosis or reducing the degree of luminal stenosis, but at the cost of increased perioperative morbidity in comparison to open surgery, with complication rates that approach 30%, including aortorenal injury ("tears"), aneurysm formation at the site of angioplasty, and stent embolization.[55,56] In addition, endovascular treatments are associated with an increased incidence of restenosis and reintervention with freedom from reintervention of only 55% at 1 year and 33% at 5 years in larger series.[55] Long-term benefits of endovascular interventions remain unproven in children with developmental aortic narrowings, and subsequent operations following stent failure are considerably more difficult.

Endoluminal interventions have provided major benefits in treating renovascular disease, particularly in young adults with fibromuscular dysplasia, and are being utilized with increasing frequency in the treatment of pediatric renovascular disease with several contemporary reports suggesting success.[82-85] It warrants mention that in the largest published series, hypertension cure and improvement rates combined approximate 60%, with failure rates ranging 32% to 44% and high rates of early restenosis.[84-86] These results may be anticipated, given the

Figure 130.15 Renal arteriogram demonstrating incomplete stent expansion across an ostial, developmental renal artery stenosis with notable in-stent stenosis in a child with multidrug resistant renovascular hypertension.

underlying developmental arterial derangement associated with excessive elastic tissue and unyielding fibrosis, which may result in early postdilation arterial recoil. Importantly, the excessive degree of radial force required to dilate a fibrotic lesion and the accompanying injury to the diminutive artery risks thrombotic complications. The role of endovascular interventions in the treatment of pediatric renal artery stenoses remains controversial.[2,87-89] Remedial operations following failed endovascular therapy are more complex (e.g., distal bypass in lieu of direct aortic reimplantation) and are not as successful as primary operations.[89] Outcomes following remedial operations included hypertension cure rates of only 25% and improvement rates of 54% (in comparison to 70% and 27%, respectively, with open procedures). Patient selection for endovascular intervention should consider the small vessel size and fibrotic nature of these lesions. Stents are to be avoided, as they increase the risk of neointimal hyperplasia and recurrent stenosis and do not take into account later necessary growth of the artery, both in diameter and length (Fig. 130.15). Finally, endovascular therapies should only be performed at high volume centers by an experienced team.

The management of developmental aortic, renal, and splanchnic artery disease remains a complex process that is best managed with the collaboration of multiple specialties. Nephrology, vascular surgery, diagnostic and interventional radiology, and cardiology all may routinely contribute valuable insights into the diagnosis, follow-up, and management of these patients. A disease specific, multidisciplinary, patient- and family-centered focus will afford the most salutary outcomes.

Mesenteric ischemia occurs when perfusion of the visceral organs fails to meet normal metabolic requirements. This disorder is categorized as either acute or chronic, based on the duration of symptoms. Acute mesenteric ischemia (AMI) occurs rapidly over hours to days and frequently leads to acute intestinal infarction requiring resection (see Chapter 133). The most common causes are embolization to the mesenteric arteries or acute thrombosis related to a preexisting plaque. Chronic mesenteric ischemia (CMI) is a more insidious process and progresses over weeks to several months (see Chapter 132). The most common cause is progressive occlusive disease of the visceral arteries, usually related to atherosclerosis. Because CMI is relatively uncommon, it is frequently misdiagnosed as a gastrointestinal disorder. Patients typically have undergone an extensive workup for other potential etiologies before being diagnosed with CMI.

The first case of AMI was diagnosed and treated successfully with intestinal resection and re-anastomosis by Elliott in 1895. Goodman first described chronic intestinal angina as a clinical disorder in 1918.[1] Dunphy, a surgical resident at the Peter Bent Brigham Hospital in 1936, reported a case of a patient with weight loss and pain out of proportion to abdominal findings who subsequently died and was found to have mesenteric occlusive disease on autopsy. After reviewing the medical records of 12 patients who died of intestinal angina, he found that 7 of the 12 (58%) had a history of chronic abdominal pain, thus introducing the potential for early intervention to prevent disease

Abstract

Mesenteric ischemia occurs when perfusion of the visceral organs fails to meet normal metabolic requirements. This disorder is categorized as either acute or chronic, based on the duration of symptoms. The most common causes of acute mesenteric ischemia (AMI) are embolization to the mesenteric arteries or acute thrombosis related to a preexisting plaque. Chronic mesenteric ischemia (CMI) is a more insidious process and progresses over weeks to several months. The most common cause is progressive occlusive disease of the visceral arteries, usually related to atherosclerosis. Endovascular revascularization is now considered first-line therapy for CMI and is being increasingly used to manage AMI. However, it has been associated with high rates of symptom recurrence, restenosis, and reintervention.

progression and death.[2] Warren and Eberhard were the first to describe mesenteric venous thrombosis (MVT) as a distinct cause of intestinal infarction in 1935, differentiating it from occlusion of the mesenteric arteries.[3]

In the modern era, Klass performed the first superior mesenteric artery (SMA) embolectomy in 1950, avoiding intestinal resection.[4] Although the patient died several days later of a heart-related condition, autopsy revealed the bowel to be normal. In 1958, Shaw and Maynard performed the first successful thromboendarterectomy of the SMA at the Massachusetts General Hospital.[5] Morris and colleagues performed the first successful retrograde bypass graft from the infrarenal aorta to the SMA in 1962.[6] Stoney and Wylie at the University of California, San Francisco, first described antegrade aortovisceral bypass and transaortic visceral thromboendarterectomy in 1966.[7] Ushering in the current era of percutaneous treatment of visceral arterial occlusive disease, Furrer and Novelline separately published the initial reports of endovascular dilation of the SMA in 1980, and in 1992, Finch was the first to report of treatment of a celiac artery stenosis with a Palmaz stent.[8-10]

ANATOMY OF THE VISCERAL ARTERIES

The primitive dorsal aorta gives rise to the abdominal aorta during fetal development. Ventral segmental arteries emerge from the primitive ventral aorta, which disappears around the fourth week of gestation. Multiple segmental branches from the primitive ventral aorta—the 10th, 13th, and 21st—persist and develop into the celiac artery, SMA, and inferior mesenteric artery (IMA), respectively. Disparity in the regression of the primitive ventral aorta and its segmental branches infrequently causes deviations in the visceral arterial anatomy.

The celiac artery arises from the abdominal aorta just caudal to the diaphragm at the level of L1 and is bordered by the median arcuate ligament (MAL) at the aortic hiatus superiorly and the superior border of the pancreas inferiorly. Traditionally, the three branches from this common trunk include the left gastric, splenic, and common hepatic arteries. However, multiple variations of the true "trifurcation" can exist. Most frequently, the common hepatic artery and its branches arise from the SMA or directly from the abdominal aorta.

Exposure of the celiac trunk is best achieved through a midline transabdominal incision, which also allows visual assessment of bowel viability during surgical revascularization (see Chapter 54). The celiac trunk and its branches are surrounded by the celiac plexus of nerves, which must be divided for proximal exposure. A midline laparotomy is performed, and the triangular ligament is divided.

The SMA arises a few centimeters caudal to the celiac trunk; its origin is crossed by the neck of the pancreas and the splenic vein. It arises at a less acute and downward-sloped angle than the celiac trunk and lies superior to both the uncinate process of the pancreas and the third portion of the duodenum. The superior mesenteric vein runs parallel adjacent to the artery, usually along its right border. The first important branch of the SMA is usually the inferior pancreaticoduodenal artery, which supplies collateral circulation with the celiac artery through the gastroduodenal and superior pancreaticoduodenal arteries. The second major branch of the SMA is frequently the middle colic artery, which arises at the inferior border of the pancreas. The right colic, ileocolic, and third-order mesenteric branches arise distally, supplying the small bowel within the mesentery.

The IMA is usually located 3 to 4 cm cephalad to the aortic bifurcation, just to the left of midline, and usually arises at the level of the third lumbar vertebra. The main trunk frequently divides into sigmoidal branches and the left colic artery. The ascending left colic artery forms the inferior marginal artery of Drummond, which is the major collateral arcade between the SMA and IMA. The SMA and IMA are also linked by the meandering mesenteric artery (of Moskowitz), known historically as the "arc of Riolan." This vessel runs more centrally, medial to the mesenteric border of the colon and through the middle of the mesenteric arcade near the inferior mesenteric vein. The meandering mesenteric artery is likely produced by the dilation of a normal collateral vessel in response to significant stenosis or occlusion of the SMA and/or IMA.[11] Sigmoidal branches lead to the left and right superior rectal arteries, which collateralize with branches of the hypogastric arteries in the pelvis.

PHYSIOLOGY OF SPLANCHNIC BLOOD FLOW

Normal intestinal function and nutrient absorption rely on adequate perfusion and oxygenation to the microvascular splanchnic circulation. Various autoregulatory mechanisms ensure adequate gut circulation through both vasoconstriction and relaxation of arterial smooth muscle. The degree of visceral artery dilation and constriction determines the relatively large fluctuations in splanchnic blood flow during fasting, postprandial states, and periods of extreme stress. Visceral blood flow can vary dramatically, ranging from 10% of cardiac output in the setting of shock or hypovolemia, 20% to 25% at rest or while fasting, and up to 35% after a large carbohydrate meal.[12,13] Seventy to eighty percent of mesenteric blood flow supplies the mucosal and submucosal layers. The extremely diminished blood flow observed in patients with nonocclusive mesenteric ischemia results from severe vasospasm related to this process. Duplex studies demonstrate moderate to high arterial resistance in the SMA circulation, with low diastolic flow and slight flow reversal during fasting states. In the postprandial period, low-resistance signals are noted throughout both systole and diastole, indicative of dilated splanchnic arteriolar beds; flow reversal does not occur. In contrast, low arterial resistance signals are noted in the celiac artery circulation regardless of feeding, likely due to the influence of the low-resistance hepatic vascular bed. Perko and colleagues also noted that in fasting subjects performing submaximal exercise, splanchnic vascular resistance doubled and exhibited a 50% reduction in hepatosplenic blood flow and a 25% reduction in mesenteric blood flow.[14]

Multiple mechanisms are responsible for regulating mesenteric arteriolar smooth muscle tone, and they are often interdependent. Extrinsic factors include sympathetic efferent nerves in the prevertebral celiac and mesenteric ganglia, which initiate stimuli for arterial vasoconstriction. Hormonal pathways also contribute to extrinsic regulation of splanchnic blood flow. The renin-angiotensin feedback mechanism causes mesenteric vasoconstriction through the direct action of angiotensin II during hypovolemic states. Low-volume states and hyperosmolarity stimulate the neurohypophysis, which releases vasopressin,[15] a hormone that causes splanchnic vasoconstriction, reduction in portal venous pressure, and venodilation.[15] Additionally, when subjected to shear stress, activation of the nitric oxide synthase enzymes on the surface of red blood cell membranes occurs, leading to significant dilation of mesenteric arteries under hypoxic conditions.[16]

Intrinsic regulation also occurs through metabolic and myogenic feedback mechanisms.[15] In the metabolic pathway, mucosal ischemia prompts the release of metabolic byproducts, causing vasodilation in arteriolar smooth muscle and preferentially shunting increased blood flow to the intestinal mucosa. In the myogenic pathway, which dominates the regulation of blood flow in the small intestines,[17] abrupt decreases in perfusion pressure are sensed by arteriolar baroreceptors, which respond by decreasing arteriolar wall tension to maintain blood flow.[18] Together, these mechanisms maintain mucosal perfusion and integrity during periods of relative ischemia.

EPIDEMIOLOGY

Asymptomatic occlusive disease of the visceral arteries is a common finding in elderly patients. Wilson and coworkers demonstrated that 17.5% of 553 consecutive patients older than 65 years examined with duplex ultrasonography (DUS) had a critical stenosis of at least one visceral vessel.[15] Additionally, autopsy studies have estimated the prevalence of atherosclerosis involving the mesenteric arteries to be between 6% and 10%.[19] Despite an aging population, the total number of deaths associated with CMI per year remained flat between 2000 and 2012 (0.7 per million to 0.6 per million, $P = .50$), while the total number of deaths associated with AMI have actually declined from 12.9 to 5.3 per million during this same time period.[20] Likely in part because of differences in longevity, AMI and CMI disproportionately affect women, with a female-to-male ratio of approximately 3:1.[21]

Since the majority of patients with mesenteric occlusive disease manifest no symptoms, the exact incidence of CMI is not known. Admissions for CMI account for fewer than 1 per 100,000 admissions[22]; however, they have been increasing steadily in recent years in the United States.[21] Whether these figures represent an actual increasing incidence or simply increased reintervention due to restenosis from endovascular therapy remains to be determined. Despite the high prevalence of individuals with asymptomatic mesenteric arterial occlusive disease, patients usually demonstrate involvement of two or more mesenteric vessels before symptoms arise owing to the development of extensive collateralization over time. In fact, in a study by Thomas et al., who followed 980 consecutive patients with asymptomatic significant (50%) stenosis of at least one mesenteric artery, only four patients developed mesenteric ischemia and all of them had significant three-vessel disease after follow-up of 1 to 6 years.[23] The variability of symptoms in patients with chronic abdominal pain often makes the diagnosis challenging, resulting in treatment delays and increased morbidity.

PATHOPHYSIOLOGY

Chronic Mesenteric Ischemia

Atherosclerosis is the most common cause of CMI, and these patients frequently have a history of smoking, hypertension, and hyperlipidemia. They may also have evidence of atherosclerotic disease in other vascular beds, particularly coronary, cerebrovascular, renal, aortailiac, and other peripheral arteries. Although much less common, CMI may also be seen in association with vasculitis and other inflammatory conditions, such as lupus, Buerger disease, and radiation arteritis. Median arcuate ligament syndrome (see Chapter 135) is a separate entity that may lead to symptoms of CMI and is caused by the compression of the celiac artery by the MAL.

Acute Mesenteric Ischemia

Arterial Embolism

Arterial emboli are the most common cause of AMI, comprising 40% to 50% of cases.[24] The proximal source of the embolus is frequently intracardiac mural thrombus that develops in patients with atrial tachyarrhythmias, myocardial infarction, cardiomyopathy, structural heart defects, and cardiac tumors. Endocarditis can result in septic emboli from affected valve leaflets. Mural thrombus in proximal aneurysms in the thoracic or proximal abdominal aorta can also serve as embolic sources, as can atheromatous plaque even in the absence of aneurysm. The SMA is the most common final destination for mesenteric emboli, perhaps because of its relative size and the decreased angle of takeoff from the abdominal aorta compared with the other mesenteric vessels. Additionally, such emboli tend to lodge several centimeters from the vessel's origin, usually distal to the middle colic artery (Fig. 131.1A). The angiographic hallmark of an embolic occlusion seen on CTA or MRA is an abrupt cutoff just beyond the origin of the middle colic artery.[25]

Arterial Thrombosis

Arterial thrombosis constitutes the next most common cause of AMI and occurs in 20% to 35% of cases.[26,27] Preexisting atherosclerotic plaque affecting all visceral vessels is the most common finding. Hypercoagulability syndromes can also predispose to acute visceral artery thrombosis. The affected segment of artery is usually its origin at the level of the aorta. Patients with acute arterial thrombosis frequently have preexisting symptoms of CMI. Schoots and associates reviewed 45 observational studies comprising 3692 patients with AMI

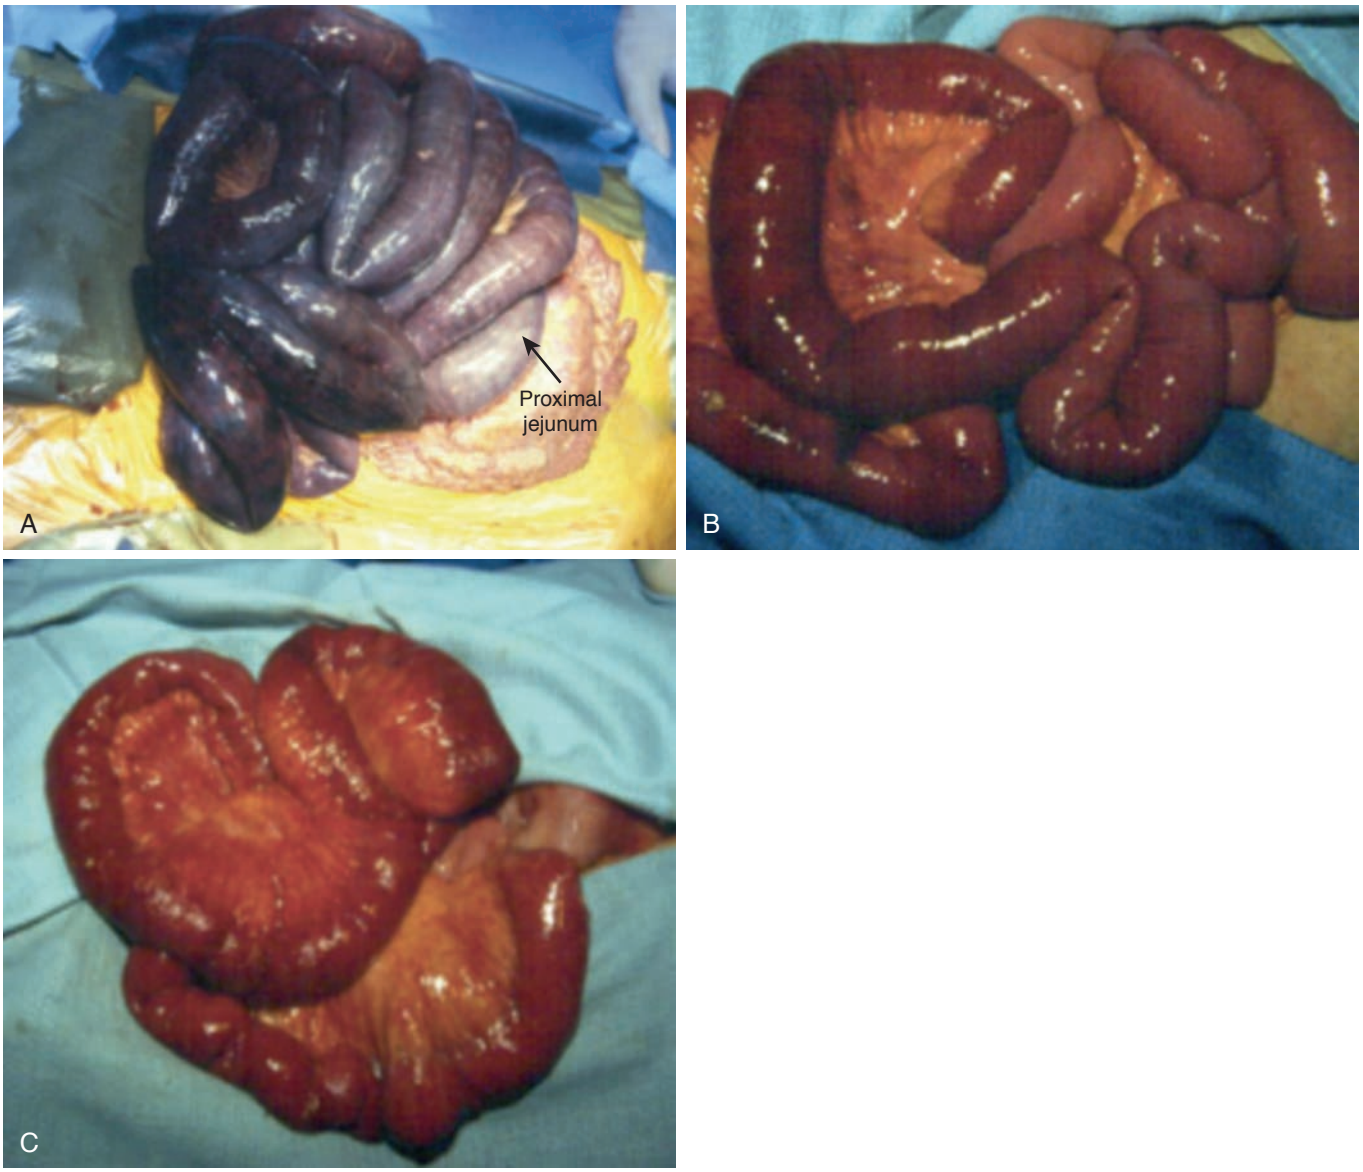

Figure 131.1 (A) Operative findings typical of acute mesenteric ischemia secondary to an embolus. Note that the first portion of the jejunum is spared because the embolus lodged distal to the middle colic artery. (B) Operative findings typical of acute mesenteric ischemia secondary to arterial thrombosis. Note that the entire bowel is affected. (C) Appearance of the small bowel at second-look surgery after revascularization. Note the hemorrhagic changes in the mesentery.

and found that mortality from acute thrombosis of a mesenteric artery was 77.4%, compared with 54.1% for patients with acute arterial embolism to visceral vascular beds.[28] This increased mortality is likely due to the involvement of larger segments of bowel, since occlusions are typically within the first 2 cm of the SMA origin (Fig. 131.1B). This theory was corroborated in a Swedish study, in which 213 patients with acute thromboembolic occlusion of the SMA and intestinal infarction were examined postmortem.[29] The cause of occlusion was embolic in 57.3% of patients and thrombotic in 41.3% (indeterminate in 1.4%). The extent of intestinal infarction was significantly greater in patients with SMA thrombosis compared with embolus. Acute extension of an aortic dissection can also serve as a mechanism for abrupt mesenteric vessel occlusion and thrombosis.

Nonocclusive Mesenteric Ischemia

Impaired intestinal perfusion in the absence of thromboembolic occlusion is termed nonocclusive mesenteric ischemia (NOMI) and makes up approximately 5% to 15% of cases.[30] Visceral ischemia can occur due to a low-flow state, which is exacerbated by the presence of any intestinal atherosclerotic disease. It is theorized that in such circumstances, in an effort to maintain cardiac and cerebral perfusion, excessive sympathetic output results in mesenteric vasospasm. NOMI most commonly occurs secondary to cardiac disease, particularly severe congestive heart

failure and in patients who have undergone cardiac surgery. Atrial fibrillation, commonly a cause of cardiac thrombi and visceral embolization, can also induce NOMI by reducing left ventricular function and causing low cardiac output. Other risk factors for NOMI include older age, hypovolemia, systemic vasoconstrictors, vasoactive drugs (e.g., digoxin, α-adrenergic agents, β-receptor blocking agents, cocaine), aortic insufficiency, cardiopulmonary bypass, abdominal and cardiovascular surgery, abdominal compartment syndrome, and liver failure.[24,31]

In recent years, NOMI has been increasingly observed in patients on hemodialysis (HD). Quiroga et al. reported incidence rates more than 40 times greater among patients on HD compared with the general population.[32] Using the Taiwan National Health Insurance Research Database, Li et al. similarly reported a 44-fold higher risk of mesenteric ischemia in patients on HD or peritoneal dialysis compared with the general population.[33] Older age and a heavier burden of cardiovascular risk factors undoubtedly contribute to these disparities. Additionally, patients with end-stage renal disease are frequently on erythropoietin, which elevates red cell mass and can lead to relative hyperviscosity. However, hypotension during dialysis has been implicated as the most important and immediate precipitating risk factor for development of NOMI.[34] Therefore special care should be taken to avoid dialysis-related hypotension in patients at particularly high risk. High-risk patients include those who are older, taking erythropoietin, have a longer history of dialysis, and diabetics.[32,34]

Mesenteric Venous Thrombosis

MVT constitutes 5% to 15% of all cases of mesenteric ischemia (see Chapter 136).[35,36] Involvement is usually limited to the superior mesenteric vein but can also involve the inferior mesenteric, splenic, and portal veins. MVT is classified as either primary (idiopathic) or secondary. Secondary MVT occurs when an underlying disease process is present; this type accounts for 90% of all patients with this disorder. Conditions associated with MVT can be grouped into three major categories: direct injury, local venous stasis/congestion, and thrombophilia. Causes of direct injury include abdominal surgery, trauma, and local inflammation, such as that seen with inflammatory bowel disease, pancreatitis, and diverticulitis.[37,38] Splanchnic venous stasis may occur in the case of increased intra-abdominal pressure, obesity, and with intraoperative manipulation of the mesenteric vessels. Inherited or acquired hypercoagulable diseases—including deficiency of proteins C and S, myeloproliferative disorders, antithrombin III deficiency, antiphospholipid antibody syndrome, and factor V Leiden mutation—are frequent causes of thrombophilia and thus also predispose to MVT.[39]

The extent of bowel ischemia depends largely on the degree of venous involvement and the presence of collateral vessels. The transition from normal to ischemic intestine is slower with MVT than with arterial occlusive disease.[24] Edema and hemorrhage of the intestinal wall are frequently seen, followed by focal sloughing of the mucosa.[24] The origin of thrombosis varies depending on the etiologic process. When an intra-abdominal process is the cause, thrombosis begins in the larger mesenteric veins and progresses to involve the smaller venous arcades and arcuate channels.[40] MVT caused by hypercoagulable conditions usually begins in the smaller mesenteric veins. Symptomatic acute MVT is associated with a 20% to 50% mortality rate.[40] A Swedish population-based autopsy study showed that MVT-related death is more likely in patients with portal vein thrombosis, systemic venous thromboembolism, and obesity.[41]

CLINICAL PRESENTATION

Acute Mesenteric Ischemia

The most common symptom of AMI associated with arterial thromboembolic disease is the sudden onset of abdominal pain. Due to a lack of collateral flow to the visceral organs, the presentation of AMI is dramatic and severe, often with rapid clinical deterioration. Nausea, vomiting, diarrhea, emptying symptoms, and abdominal pain and distention can also occur. Classically, the pain is out of proportion to the findings on physical examination. Initially, bowel sounds are hyperactive, as the failure to relax the bowel smooth muscle leads to emptying symptoms. Bowel sounds are typically diminished in the later stages. Abdominal guarding and rebound tenderness are absent in the early stages of AMI; however, as intestinal ischemia and infarction progress, these signs become more pronounced. They are typically late findings, so their absence should not delay the diagnosis and treatment of AMI. Other late findings include fever, oliguria, dehydration, confusion, tachycardia, and shock.[24] Metabolic abnormalities can include leukocytosis, metabolic acidosis, hyperamylasemia, elevated liver function values, and lactic acidemia.

Patients with NOMI or MVT typically present with a slower, more insidious clinical course. Frequently those with NOMI are critically ill, hospitalized, intubated patients who experience a sudden deterioration in their clinical condition. These patients are often administered intravenous pressors, worsening mesenteric vasoconstriction and thus decreasing splanchnic perfusion. In patients with MVT, fever, abdominal pain and distention, nausea/vomiting, and bloody stools are the most common findings. Dehydration and profound fluid shifts lead to bloody ascites and a hypovolemic state, causing further propagation of venous thrombosis.[24] Though nonspecific, normal D-dimer levels may help rule out MVT.[42]

In order to develop better diagnostic criteria to reduce delays in diagnosis, Mitsuyoshi et al. reviewed their 13-year experience treating 22 patients with NOMI.[43] Multidetector-row computed tomography (MDCT) was unavailable at the time the first 13 patients were treated, and 9 subsequently died owing to intestinal necrosis. These first 13 cases were used to devise four criteria for determining which patients warranted MDCT evaluation once this technology became available: (1) ileus or abdominal pain, (2) catecholamine requirement, (3) an episode of hypotension, and (4) a gradual rise in serum transaminase level. If three of the four criteria were present, patients received MDCT and underwent treatment with high-dose intravenous

Figure 131.2 Typical patient with chronic mesenteric ischemia with significant weight loss and cachexia. The patient is placed in a right semilateral decubitus position in preparation for retroperitoneal transaortic endarterectomy.

prostaglandin E1 (PGE1). Of the 9 patients treated using this algorithm, only 1 died.

Chronic Mesenteric Ischemia

Postprandial abdominal pain and progressive weight loss are the most common symptoms in patients with CMI. Pain is often described as dull and crampy located in the midepigastric region. Pain often occurs 15 to 45 minutes after a meal, and the severity varies according to the size and type of meal. Patients typically develop "food fear" and decrease their oral intake in anticipation of severe pain after meals. Consequently weight loss is a common finding; in fact, when present, it can help to distinguish CMI from other functional bowel disorders when the diagnosis is in question.[44] Changes in bowel habits, nausea, and vomiting are less common findings. CMI is seen more frequently in elderly women, who represent 70% of patients. The variable nature of symptoms often makes the diagnosis confusing and can result in delayed treatment. The traditional risk factors for atherosclerosis are usually present. A heavy smoking history is frequently obtained and the majority of patients also have a history of symptomatic manifestations in other vascular beds, most commonly cerebrovascular, coronary, and peripheral arteries.[45]

Physical examination findings are usually nonspecific. Patients are commonly undernourished and cachectic (Fig. 131.2). An abdominal bruit can sometimes be auscultated but is not always present. Bowel sounds are frequently hyperactive. Guarding and rebound tenderness are usually absent. Low prealbumin and albumin levels are often seen, owing to the patient's chronic malnourished state.

DIAGNOSTIC EVALUATION

Noninvasive Evaluation

DUS is a useful tool for the early, noninvasive diagnosis of visceral ischemic syndromes (see Chapter 21). Color Doppler scanning can be used to assess the flow velocities and resistance index in the splanchnic arteries and their arterial beds as well to evaluate end-organ vascularity. The intestinal wall can also be assessed with a high degree of accuracy using high-resolution transabdominal ultrasound.[46] Transmural hemorrhage, inflammation, and necrotic thickening in the bowel wall can be imaged sonographically. Asymmetric wall thickening with associated ileus can be seen in patients with AMI as well as ascites and free peritoneal air.[47] DUS combined with expiratory maneuvers is also an excellent screening exam for MAL syndrome. Limitations of transabdominal duplex scanning include the wide variation in examination quality, which is operator-dependent. Patient-related factors such as obesity, excessive intraluminal bowel gas, variation in local anatomy, and effects of respiration can affect image quality.[48] Care must be taken to clearly define the origin of each vessel to avoid inaccurate measurements. DUS is generally not recommended in the workup of AMI.

Moneta and colleagues performed blinded DUS studies in 100 patients who previously underwent arteriography of the celiac trunk and SMA.[49] They hypothesized that lack of flow or a peak systolic velocity (PSV) in the SMA of greater than 275 cm/s, or no flow, or a PSV of greater than 200 cm/s in the celiac trunk was a reliable indicator of 70% or greater angiographic stenosis.[50] Using these criteria, duplex sensitivity for detecting lesions in the SMA and celiac artery was 92% and 87%, respectively. Overall accuracy for detection of a 70% lesion in the SMA and celiac artery was 96% and 82%, respectively. The IMA is not generally assessed, since it is generally difficult to visualize and is of lower clinical importance. However, patency of the IMA can usually be determined. In a more recent study with the largest number of mesenteric duplex and angiography correlations to date (151 SMAs and 150 celiac arteries), AbuRahma et al. found that for the SMA, a PSV ≥295 cm/s had the highest accuracy for detecting ≥50% stenosis (sensitivity 87%, specificity 89%), whereas a PSV ≥400 cm/s had the highest accuracy for detecting ≥70% stenosis. The corresponding PSVs for the celiac artery were 240 cm/s and 320 cm/s, respectively.[51]

DUS is also the primary imaging modality used for surveillance following both bypass and stenting. However, duplex criteria used for diagnosing stenosis in the native mesenteric vessels have been shown to overestimate stenosis in stented vessels.[52] Baker and colleagues evaluated the accuracy and utility of DUS for detecting in-stent stenosis in 23 patients who underwent successful (<20% residual stenosis on completion angiography) mesenteric stenting for CMI (20 SMA alone, 3 both SMA and celiac artery).[53] Preprocedure DUS was performed on 13 patients, with a mean PSV of 464 cm/s. Initial surveillance DUS was performed in 21 patients at a mean of 0.9 months following revascularization. Mean PSV at this time was 335 cm/s and for 12 of these patients, the first postoperative PSV in

successfully stented vessels was higher than the 275 cm/s threshold used to diagnose high-grade native SMA stenosis. Additionally, there was no correlation between surveillance PSV and the degree of angiographic stenosis seen at the time of reintervention.

Similarly, in their review of 107 patients who underwent endovascular therapy for CMI,[54] Schoch et al. reported that although 83% of patients had recurrent stenosis on surveillance DUS, 53% of patients remained asymptomatic and required no further intervention. These findings therefore mandate obtaining an early baseline DUS against which future surveillance scans can be compared. They also stress the importance of considering the clinical context and symptom recurrence when making the decision to reintervene. Soult et al. analyzed 103 paired DUS and angiograms (66 SMA, 37 celiac arteries) to try to define duplex criteria for high-grade in-stent restenosis in previously treated mesenteric arteries. They proposed PSVs of ≥445 cm/s in stented SMAs and ≥289 cm/s in stented celiac arteries for detecting stenosis ≥70%.[55]

The predictive value of DUS for detecting disease recurrence after mesenteric bypass has also been studied. Liem and colleagues evaluated 167 duplex exams used in the surveillance of 43 bypass grafts in 38 patients.[56] Comparing antegrade and retrograde bypass configurations, differences in mean PSV were demonstrated only at the inflow artery. There were no differences in PSV at the proximal or distal anastomosis, the mid-graft, or in the outflow artery. Between the first postoperative DUS and the latest follow-up scan (on average 38 months), PSV measurements did not change significantly. Graft failure occurred in two patients, both of whom had no findings to suggest impending occlusion on the DUS exams immediately preceding failure. No predictors of graft thrombosis were identified on multivariable analysis.

Computed tomography (CT) is an accurate, noninvasive imaging modality for diagnosing mesenteric ischemia. Modern multidetector CT (MDCT) enables imaging with excellent spatial and temporal resolution. A meta-analysis of six studies published between 1996 and 2009 on the diagnostic accuracy of MDCT in AMI showed a pooled sensitivity of 93% and specificity of 96%.[57] Advantages over conventional angiography include the relative ease and speed of performance, the rapid infusion of contrast agent through peripheral intravenous lines, and the ability to simultaneously image the mesenteric arteries, veins, and visceral organs. CTA is also useful for evaluating patency of previous placed grafts and stents. Common radiographic findings in the bowel wall related to AMI include increased thickening, dilation, and attenuation, which can be easily detected using CT. Pneumatosis intestinalis, portal venous air, mesenteric edema, and ascites can also be detected. During the arterial phase of contrast infusion, the mesenteric vessels can be evaluated for thrombosis, embolus, dissection, and aneurysm. Venous engorgement and subtle intestinal findings may be identified in cases of mesenteric venous occlusion. A "target sign" may be seen in the SMV with thrombus in the center of the lumen and surrounding contrast enhanced blood flow peripherally. The portal venous phase is more accurate for diagnosing MVT and images during the venous phase may be acquired if the diagnosis is still in question or for surveillance of clot burden or extension in patients with MVT. In many centers a biphasic scan, which includes a delayed venous phase in addition to an arterial phase, has been used in the diagnosis of AMI, since it enables detection not only of arterial occlusion, but also MVT and improves the ability to detect changes in the bowel wall as well.

Disadvantages of CT include radiation, the risk of contrast nephropathy and hypersensitivity reactions to iodinated contrast agents. Inaccurate timing of contrast infusion during the arterial phase may provide indeterminate images and delay diagnosis. Because calcification at the vessel origins enhances in a similar fashion to intravenous contrast material, it is possible to underestimate the degree of stenosis. Therefore, the non–contrast-enhanced images should be reviewed. Additionally, with careful adjustment of the window and level, calcification can usually be distinguished from intravascular contrast. Last, CT serves strictly as a diagnostic modality; treatment must be performed via a separate angiographic procedure or laparotomy.

Magnetic resonance angiography (MRA) is useful for diagnosing mesenteric occlusive disease. Although MRA takes significantly longer to perform than CTA, it avoids the radiation exposure associated with CTA. Patients with hypersensitivity to iodinated contrast agents may also benefit from MRA. However, CTA has superior spatial resolution and allows better visualization of the IMA, peripheral splanchnic vessels, calcified plaque, and previously placed stents, giving it a distinct advantage.[25] For these same reasons CTA is also preferred over MRA for surveillance after revascularization. Our standard workup includes DUS to screen those suspected of having CMI. CTA is used routinely prior to intervention for AMI, CMI, and MVT.

Invasive Evaluation

Conventional angiography remains the "gold standard" in the diagnosis of mesenteric ischemia. Anteroposterior and lateral views of the visceral aorta (Fig. 131.3A–C), as well as selective catheterization of the celiac trunk, SMA, and IMA, provide the most accurate and specific localization of stenotic and occlusive lesions. Therapeutic alternatives such as balloon angioplasty, stenting, and thrombolysis and percutaneous thrombus extraction can all be used to restore luminal visceral blood flow.

Gastric tonometry, or the measurement of pCO_2 levels in the gastric, jejunal, or colonic mucosa via a nasogastric catheter, has been shown to be a useful adjunct for the diagnosis of mesenteric ischemia[58,59] but is not currently widely used in the United States.

TREATMENT OF ACUTE AND CHRONIC MESENTERIC ISCHEMIA

The goal of therapy for patients with mesenteric ischemia is the prompt restoration of blood flow to the visceral organs (see Chapters 132 and 133).

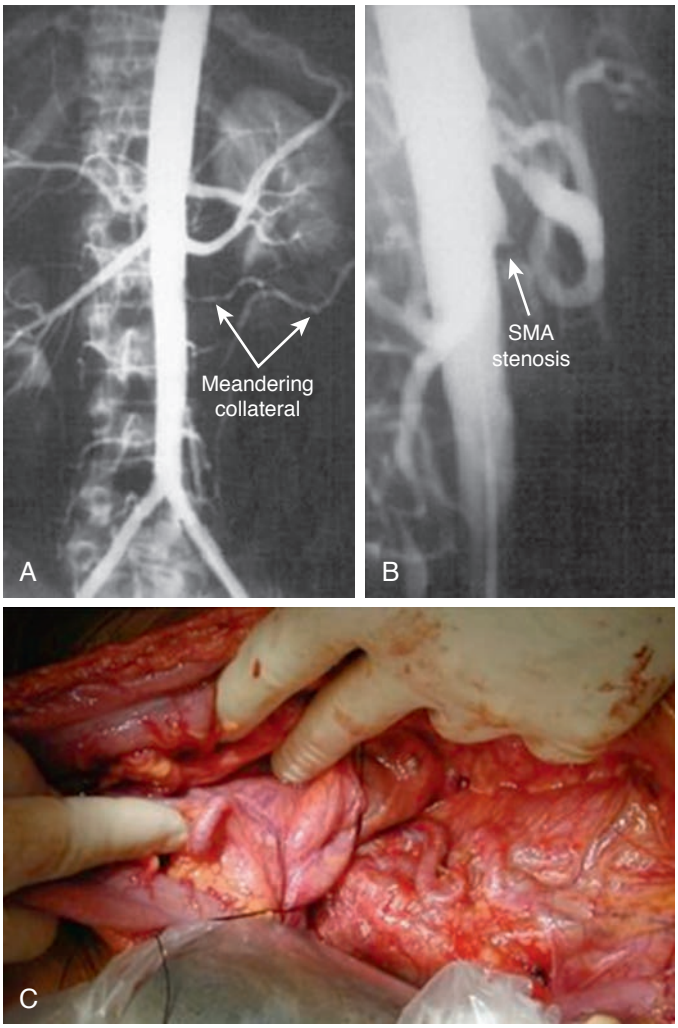

Figure 131.3 (A) Anteroposterior angiogram of a patient with chronic mesenteric ischemia. Note the meandering mesenteric collateral vessels. (B) Lateral aortogram of a patient with chronic mesenteric ischemia. Lesions are typically located at the origin of the vessel and often protrude into the aortic lumen. *SMA*, Superior mesenteric artery. (C) Meandering mesenteric collateral vessels in a patient with chronic mesenteric ischemia at the time of exploration. In patients undergoing surgery for other reasons, this finding should raise the suspicion of significant mesenteric occlusive disease.

Medical Treatment

Preventive risk factor modification helps control the progression of atherosclerosis in the mesenteric circulation. Statins have been shown to reduce the risk of cardiovascular events, cardiovascular mortality, and all-cause mortality.[60] High-intensity statins, in particular, reduce cardiovascular events in patients after stroke,[61] acute coronary syndrome,[62] and in those with stable coronary artery disease.[63] Though there are no studies specifically evaluating the role of statins in reducing ischemic events in patients with mesenteric insufficiency, it is reasonable to extrapolate to this population given the similar risk factor profile. Additionally, murine models have shown that statins may be able to mitigate reperfusion injury following gut ischemia.[64,65] Medical treatment alone is not effective in patients with symptomatic mesenteric ischemia. Patients with known risks for inheritable hypercoagulable disorders should undergo screening and should be treated with systemic anticoagulation if indicated.

Before operation, aggressive fluid resuscitation with restoration of adequate urine output is required, owing to the frequent finding of severe dehydration on presentation. Electrolyte abnormalities and metabolic acidosis should also be corrected. Patients with CMI are frequently malnourished, so albumin, prealbumin, transferrin, and C-reactive protein levels should be checked before revascularization. Preoperative total parenteral nutrition or enteral nutrition should be considered in severely malnourished patients. Finally, because the intestinal mucosa is damaged during periods of prolonged ischemia, bacterial translocation can occur, contributing to systemic sepsis. Broad-spectrum intravenous antibiotics with aggressive fluid resuscitation can lead to decreased mortality in these patients.[66] Treatment against gram-negative and anaerobic organisms is especially important.

Following mesenteric stenting, unless contraindicated, our practice is to administer an initial 300 mg clopidogrel load after the procedure followed by 1 to 3 months of treatment. Patients are also started and maintained on aspirin and high dose statins indefinitely.

Endovascular Treatment

Advances in endovascular techniques have greatly expanded the role of percutaneous interventions for patients with mesenteric ischemia in recent years. Balloon angioplasty and stenting has surpassed open surgery as the dominant method of revascularization for CMI and an endovascular approach is now generally accepted as primary therapy.[21,67-69] In contrast, the adoption of endovascular modalities for treating AMI has been slower and a decline in the number of open revascularization has not been observed.[21] This is likely because most patients with AMI have some degree of bowel ischemia and many require laparotomy for adequate evaluation and potential resection. In those with short-segment stenoses, cardiac and pulmonary co-morbidities, prior abdominal surgery, coagulopathy, or malnutrition, endovascular therapy is often favored.

Surgical Treatment

Laparotomy with visceral revascularization can be used to treat patients with both AMI and CMI. Patients presenting with signs and symptoms of AMI require urgent abdominal exploration, assessment of bowel viability, and revascularization. Several techniques for the restoration of intestinal perfusion are available to the vascular surgeon, and familiarity with a variety of options is crucial. Before revascularization, large segments of both small and large intestine may appear dusky, ischemic, or necrotic. Because SMA emboli typically lodge distal to its origin, the middle colic artery and ileocolic branches may remain patent. Thus, the pattern of bowel necrosis following embolus may be less extensive and spare the proximal jejunum and transverse colon distribution from ischemia (Fig. 131.1A). Acute thrombosis usually occurs at the orifice of the SMA, and a more extensive

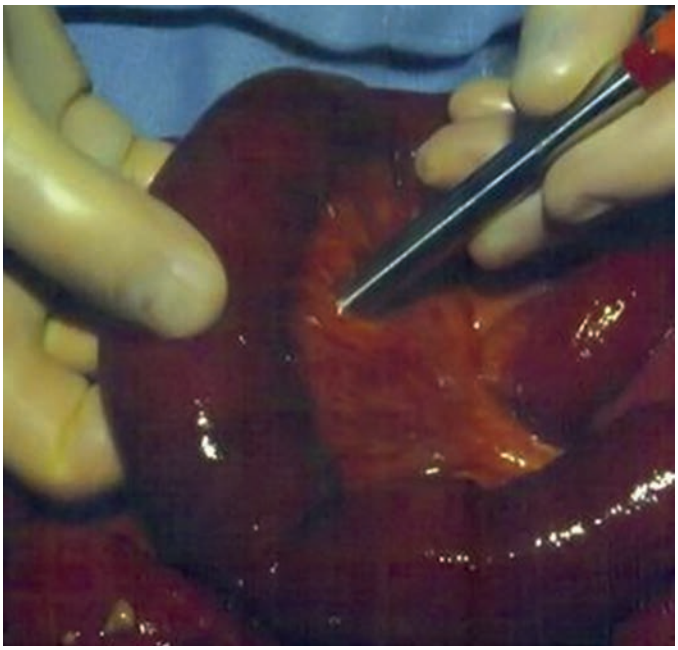

Figure 131.4 Doppler examination of the intestine should be done both at the mesentery and at the antimesenteric border. This is most useful following revascularization.

pattern of hypoperfusion and necrosis is present owing to the involvement of proximal SMA branches (Fig. 131.1B).

Following vascular reconstruction and reperfusion, the bowel should be reassessed. Segments of bowel that otherwise would have been resected may be spared owing to improvement following revascularization. A wide range of techniques to assess bowel viability have been described, including pulse oximetry, measurement of oxygen tension, spectrophotometry, Doppler ultrasound, fluorescein dye and examination with Wood's lamp, laser Doppler flowmetry and infrared imaging. At our institution, we favor a combination of clinical assessment (using criteria such as serosal color, bowel peristalsis, and vessel palpation) and Doppler ultrasound (Fig. 131.4). Intraoperative angiography following vascular reconstruction may be performed to accurately assess the restoration of mesenteric flow. Most patients should undergo "second-look" laparotomy in 24 hours to reassess bowel viability and the need for further resection (Fig. 131.1C). The decision to perform a second-look laparotomy should be made during the initial procedure and should not be changed based on subsequent clinical improvement. For those in whom bowel resection is performed at initial exploration the ends are stapled and no anastomosis is performed until second look laparotomy.

TREATMENT OF NONOCCLUSIVE MESENTERIC ISCHEMIA

NOMI represents an insidious disease process that is distinct from thromboembolic AMI but has a similarly high mortality. Cardiac surgery and low-flow states are the most common causes of this disorder, and treatment is directed toward improving circulatory support and increasing cardiac output. Selective mesenteric angiography remains the best invasive diagnostic modality, which can be followed by catheter-based interventions. These include direct infusion of intra-arterial vasodilators such as papaverine and prostaglandin E1(PGE1), as well as angioplasty and stenting if necessary.[27] Intravenous rather than intra-arterial PGE1 has also demonstrated efficacy in treatment of vasospasm associated with NOMI.[43] In a model of cardiac tamponade–induced acute NOMI, Kang and associates demonstrated that low doses of intra-arterial iloprost (prostacyclin), a potent inhibitor of platelet aggregation with fibrinolytic activity, exhibited a significant vasodilatory effect on mesenteric blood flow.[70]

TREATMENT OF MESENTERIC VENOUS THROMBOSIS

The mainstay of treatment for acute and subacute MVT is the prompt initiation of systemic anticoagulation, which improves survival and reduces the risk of recurrence.[40] (A detailed discussion of the diagnosis and treatment of MVT is contained in Chapter 136.)

Patients with suspected peritonitis, severe gastrointestinal bleeding, or intestinal stricture require abdominal exploration and resection of nonviable bowel. Bowel resection should be conservative in patients with MVT. We frequently perform a second-look laparotomy 24 hours after the initial operation, which helps avoid resection of viable bowel during the initial operation. Lifelong anticoagulation with vitamin K antagonists (VKAs) is recommended for patients with MVT, since recurrence is common (up to 36% without anticoagulation) and potentially catastrophic. Patients may be transitioned from heparin to a VKA once bowel function has normalized.

BACKGROUND

The term *intestinal angina* has been coined to describe the classic symptom of chronic abdominal pain that occurs after meals, which is the cardinal symptom of *chronic mesenteric ischemia* (CMI). Current estimates indicate that CMI accounts for less than 1 per 100,000 hospital admissions in the United States and less than 2% of all admissions for gastrointestinal conditions.[1] Since the first successful mesenteric endarterectomy by Shaw and Maynard in 1958, techniques of revascularization have greatly evolved.[2] Balloon angioplasty was first used to treat mesenteric arterial stenoses by Uflacker, Furrer, Gruntzig, and colleagues in 1980.[3,4] In the last 15 years, primary mesenteric stenting gained widespread acceptance and became the most frequently utilized treatment for CMI, relegating open surgery to patients who fail endovascular therapy or have complex lesions not amenable to endovascular intervention.[5] This chapter provides a comprehensive review of the clinical evaluation, treatment options, and results of mesenteric revascularization for patients with CMI.

PATHOPHYSIOLOGY

Approximately 20% of the cardiac output goes through the mesenteric arteries under normal conditions.[6] Blood flow to the gastrointestinal tract increases shortly after the ingestion of

a meal, remaining elevated at levels approaching 100% to 150% of normal (2000 mL/min) over the next 3 to 6 hours.[7] This normal hyperemic postprandial response is mediated by cardiovascular changes that accompany the ingestion and digestion of food, and its latency and duration depend upon the type and quantity of a meal, with high fat and protein-containing foods producing the most profound and sustained intestinal hyperemia.[8]

Patients with mesenteric ischemia fail to provide the postprandial hyperemic response that is required to supply oxygen for the metabolic processes of secretion and absorption, and for increased peristaltic activity.[9] Just as in the patient with ischemic cardiomyopathy, where angina pectoris occurs as a result from inadequate supply of oxygen, intestinal angina results from the relative imbalance between tissue supply and demand for oxygen and other metabolites. Because the mesenteric circulation has a rich collateral network, most patients only develop symptoms when at least two of the three mesenteric arteries are severely narrowed or occluded (Fig. 132.1). However, this is not an absolute requirement and some patients present with single vessel disease.[10,11] The clinical significance of ischemia correlates not only to the extent of disease, but also to the adequacy of collateral pathways, acuteness of symptoms, and presence of arterial steal.

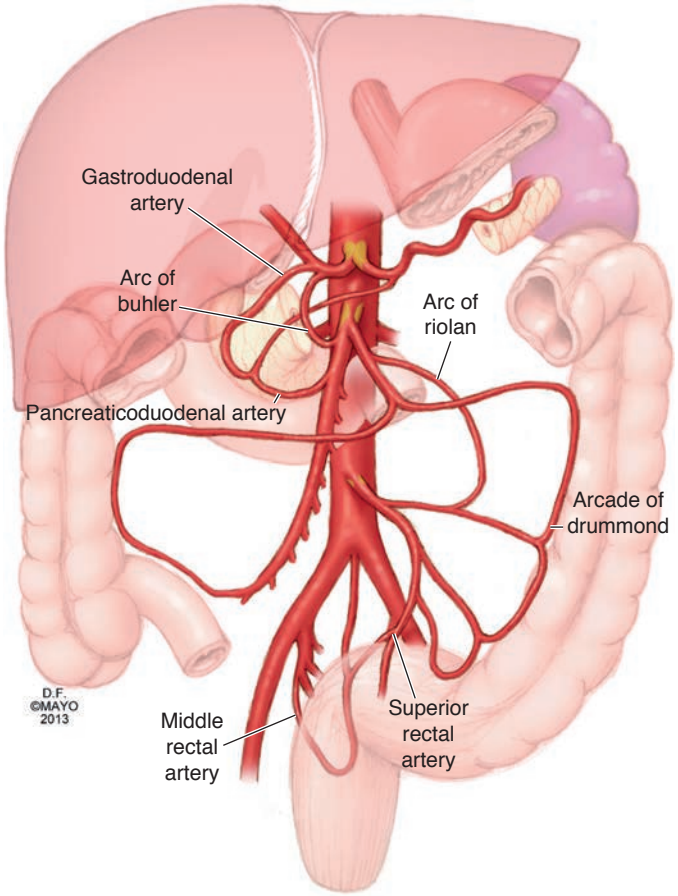

Figure 132.1 Mesenteric artery circulation and common collateral pathways in patients with severe occlusive mesenteric artery disease. Note severe disease at the celiac axis (CA), superior mesenteric artery (SMA), and inferior mesenteric artery (IMA). Common collateral pathways include the Arc of Riolan between the left colic artery (IMA) and middle colic artery (SMA). The CA and SMA have collateralization via pancreaticoduodenal arcade (Arc of Buhler) and the gastroduodenal arteries.

ETIOLOGY

The most common cause of CMI is atherosclerotic disease, accounting for more than 90% of cases in most series. Atherosclerotic lesions usually affect the origin or the proximal 2 to 3 cm of the mesenteric arteries, frequently with associated plaque in the aorta and renal arteries. Nonatherosclerotic lesions can also affect the mesenteric arteries. These patients tend to be younger. Nonatherosclerotic pathology includes vasculitis (giant cell arteritis, Takayasu disease, and polyarteritis nodosa), systemic lupus, Buerger disease, spontaneous dissections, fibromuscular dysplasia, neurofibromatosis, radiation arteritis, coarctation, mesenteric venous stenosis or occlusion, and drug-induced arteriopathy from cocaine or ergot use.

NATURAL HISTORY

Asymptomatic mesenteric stenoses carry a benign course. Nonetheless, 15% to 50% of patients who present with bowel gangrene have thrombosis of preexisting lesions with no antecedent warning signs.[12,13] Wilson and associates[14] reported a large prospective cohort study of 553 elderly patients who were screened with duplex ultrasound. The prevalence of mesenteric stenosis or occlusion was 18%, and none of the patients developed symptoms after a follow-up period of 7 years, but most had single-vessel disease. Thomas and associates reviewed 980 aortograms and found 60 patients (6%) with significant mesenteric artery disease.[15] Of these, 15 had involvement of all three visceral arteries. During follow-up of 2.6 years, four patients (27%) developed symptoms; three had successful revascularization, but one died from acute ischemia.

DIAGNOSTIC EVALUATION

The diagnosis of CMI is suggested by clinical history and confirmed by one or more diagnostic studies, such as duplex ultrasonography, magnetic resonance angiography (MRA), computed tomography angiography (CTA), or conventional aortography. Endoscopy with 24-hour or exercise tonometry, if available in centers with established protocols, can be useful in the differential diagnosis of patients with atypical symptoms, single-vessel disease, or median arcuate ligament syndrome (MALS; see Chapter 135). Tests of intestinal absorptive and excretory function have not been useful.[16]

CLINICAL PRESENTATION

The typical patient with CMI is female (3:1) with median age of 65 years, the age ranging from 40 to 90 years old.[5,17,18] The classic symptoms of CMI include abdominal pain, weight loss, and "food fear." The abdominal pain is often postprandial and begins within a few minutes to 30 minutes after meals, persisting for as long as 5 to 6 hours. It is usually midabdominal in

location, crampy, or dull. Patients may describe tolerance to certain types of food, and consequently they alter their eating habits to avoid foods that precipitate symptoms. In fact, some patients do not refer to any pain at the time of presentation because of their adaptive strategies to reduce or relieve it. Unintentional weight loss progresses to malnutrition and cachexia, which is often present at the time of intervention. In the last review of the Mayo Clinic experience with 357 consecutive patients, 96% had abdominal pain (postprandial in 74%) and 84% had weight loss. The average duration of symptoms prior to revascularization was 15 months. The pattern of symptoms often changes and progresses in intensity, frequency, and severity. Subacute mesenteric ischemia is characterized by progression of pain from intermittent to unremitting or continuous over days or a few weeks, warranting immediate revascularization. Atypical presentation such as diarrhea or bloating can occur in some patients. Physical examination is nonspecific, does not commonly reveal any pathognomonic findings, but can point to the diagnosis. Many individuals are thin at the onset of their symptoms and progress to cachexia. These patients have obvious signs of malnutrition, muscle wasting, and a flat or scaphoid abdomen. Pain may be present but not localized or aggravated by abdominal palpation; the finding of pain out of proportion to physical findings should point toward the diagnosis of acute mesenteric ischemia (see Chapter 133). An abdominal bruit may be noted in up to 50% of patients, and differs from the bruit caused by compression of the celiac axis (CA) by the median arcuate ligament, which is elicited by deep expiration and elevation of the diaphragm. A complete vascular examination may document diminished peripheral pulses and bruit. Laboratory tests are nonspecific or unremarkable in the absence of acute symptoms, but may demonstrate malnutrition.[19]

The clinical presentation can be less specific in some patients. Vague abdominal pain, nausea, vomiting, or change in bowel habits, without the classic postprandial component to the pain, can make the diagnosis difficult to ascertain. Diffuse small ulcerations in the stomach or proximal duodenum, liver function abnormalities, or patchy areas of ischemia in the colon are not uncommon. Previous history of smoking and the diagnoses of hypertension and hyperlipidemia are documented in more than 60% to 70%.[17,20,21] Consequently, patients often have other manifestations of atherosclerotic disease affecting the coronary (50%-70%), cerebrovascular (20%-45%), and peripheral arteries (20%-35%). Concomitant renal artery disease with difficult to control hypertension or ischemic nephropathy is common.[22]

DIAGNOSTIC IMAGING

It is not infrequent for patients with CMI to undergo an extensive evaluation to rule out other causes of chronic abdominal pain and weight loss. The differential diagnosis is extensive, including inflammatory, infectious, and malignant disease. The investigation often includes upper and lower gastrointestinal endoscopy and cross-sectional studies of the abdomen. Often the finding of mesenteric artery stenosis in an imaging study is the first clue to the diagnosis.

Mesenteric Duplex Ultrasound

Mesenteric duplex ultrasound is the recommended screening study (see Chapter 21). A negative duplex ultrasound study essentially excludes the diagnosis of mesenteric artery disease. In 1993, Moneta and associates reported the first prospective validation of mesenteric diagnostic criteria in 100 patients.[23] In that study, the most accurate criteria to indicate ≥70% stenosis was a peak systolic velocities greater than 275 cm/s for the superior mesenteric artery (SMA) and greater than 200 cm/s for the CA (Fig. 132.2).[23] As a criterion for ≥70% SMA stenosis, a peak systolic velocity greater than 275 cm/s had a sensitivity of 92%, specificity of 96%, positive predictive value of 80%, and a negative predictive value of 99%. A velocity of 200 cm/s in the CA as a predictor of a ≥70% stenosis had somewhat lower values. The Bowersox criteria,[24] later validated prospectively by the Dartmouth group,[25] is based on ≥50% arterial stenosis. For the SMA, an end diastolic flow velocity of 45 cm/s or higher had 90% sensitivity, 91% specificity, 90% positive predictive value, 91% negative predictive value, and 91% accuracy. For the CA, reversal of blood flow in the hepatic and splenic arteries was 100% predictive of stenosis. An end diastolic velocity greater than 55 cm/s or no flow signal had the best overall accuracy (95%), with high sensitivity (93%) and specificity (94%).

Multidetector Computed Tomography

Cross-sectional imaging of the abdomen provides an anatomic analysis to plan revascularization.[26-28] The choice of CTA or MRA is somewhat related to individual expertise at the institution. Multidetector computed tomography (MD-CT) technology is readily available in most centers, has the highest spatial resolution and finest image detail, and is considered by most the best study to evaluate anatomic characteristics (calcification, thrombus, diameters, and lengths) that are important to plan mesenteric interventions (Fig. 132.3). In patients with classic symptoms, CTA may supplement or even replace duplex ultrasound, and is often the only imaging study that is obtained prior to intervention. It is also useful to objectively assess patency of grafts and stents.

Magnetic Resonance Angiography

Gadolinium-enhanced MRA has advanced in recent years to provide improved imaging resolution with shorter acquisition times.[29,30] This imaging modality is used to a lesser extent, but provides functional information by integrating flow dynamics, and blood oxygen saturation techniques, with the anatomic detail, which can be useful in patients with questionable diagnosis of CMI.[31,32]

Contrast Arteriography

Diagnostic catheter-based arteriography is considered the "gold-standard" diagnostic study for evaluating mesenteric artery disease. However, its role as a confirmatory test and for planning revascularization has diminished, in favor of the aforementioned

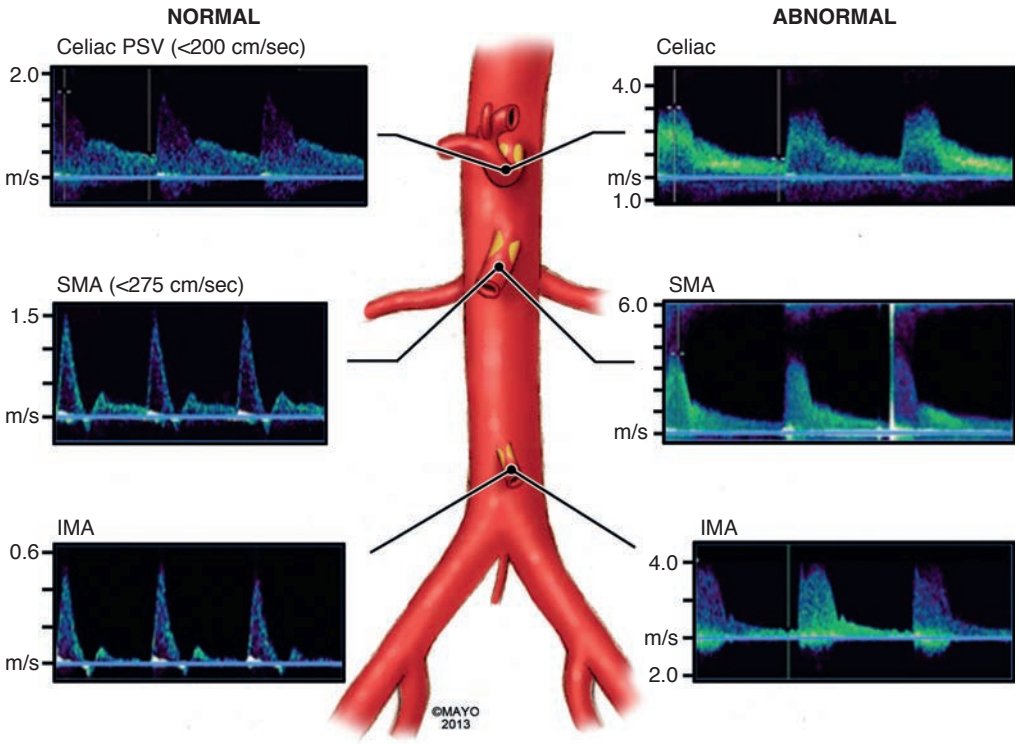

Figure 132.2 Mesenteric duplex ultrasound with normal and abnormal waveforms patterns during fasting state. *IMA*, Inferior mesenteric artery; *PSV*, peak systolic velocity; *SMA*, superior mesenteric artery.

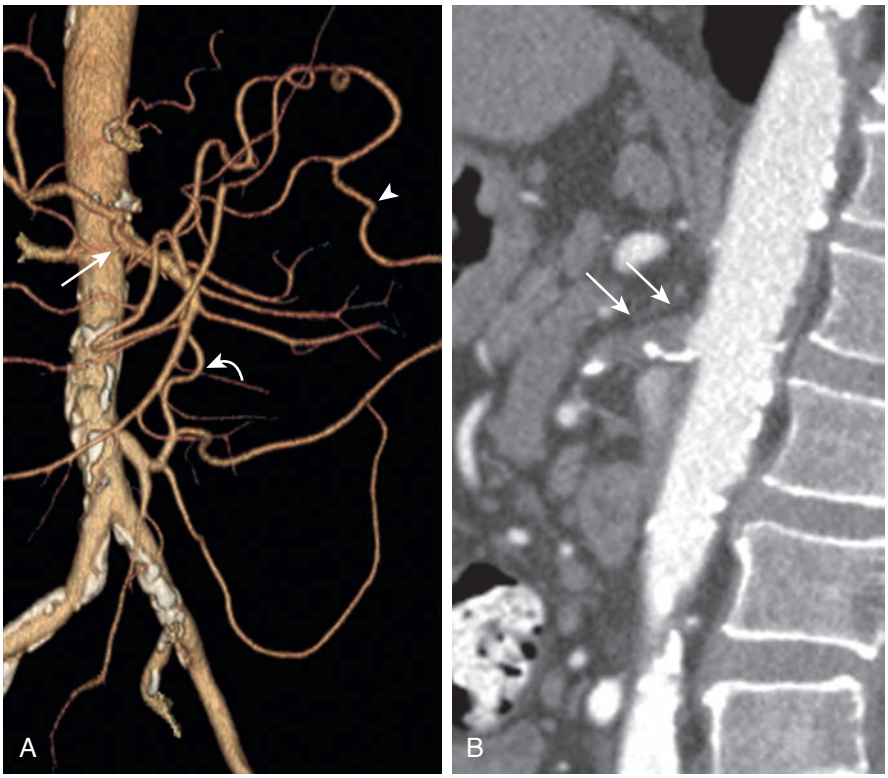

Figure 132.3 Computed tomography angiography with three-dimensional reconstruction in a patient with severe three-vessel mesenteric occlusive disease. Note occlusion of the celiac axis (CA) and superior mesenteric artery (SMA), with collateral flow via a large inferior mesenteric artery (IMA) and meandering artery. Collateralization is shown from the IMA to SMA via Arc of Riolan *(curved white arrow)* and Arcade of Drummond *(arrow head)*, and from the SMA to CA via large gastroduodenal artery *(straight white arrow)*, **(A)**. Axial views of the SMA demonstrate occlusion with a small stump *(double arrow)*, **(B)**.

noninvasive modalities. More frequently, angiography is obtained in conjunction with a planned endovascular intervention. Exceptions are patients with suboptimal imaging studies and those with extensive calcification, small vessels, or multiple prior stents causing metallic artifact.

Other Ancillary Studies

Endoscopy can demonstrate inflammatory and/or ischemic changes, most noticeable in the stomach, duodenum, or right colon. Erosive ischemic gastritis, gastroduodenitis, or ischemic

colitis noted on endoscopy have been described in association with CMI.[33] Gastric tonometry has been shown to be a valuable diagnostic test to assess intestinal perfusion.[33-39] Tonometry can be performed as part of a 24-hour monitoring study during fasting and postprandial state, or as an exercise test using a small nasogastric tonometry catheter with serial pCO_2 measurements in the stomach, duodenum, or upper jejunum.[35,36,38,40,41] Visible light spectroscopy is a new technique that enables noninvasive measurements of mucosal capillary hemoglobin oxygen saturation during endoscopy using white light from a fiber-optic probe.[42,43]

TREATMENT STRATEGIES

There is no role for a conservative approach with chronic parenteral nutrition and noninterventional therapy in patients with symptomatic mesenteric artery disease. Excessive delays in proceeding with definitive revascularization or use of parenteral nutrition alone have been associated with clinical deterioration, bowel infarction, and risk of sepsis from catheter-related complications.[44,45]

Indications for Revascularization

Revascularization is indicated in all patients with symptoms of CMI. Treatment goals are to relieve symptoms, restore normal weight, and prevent bowel infarction. The indication of prophylactic revascularization in patients with asymptomatic disease remains controversial. Based on the report by Thomas and colleagues, there may be a role for prophylactic revascularization in patients with severe three-vessel disease, particularly for those with difficult access to medical care who live in remote or underserved areas.[15] Our approach in these patients has been close surveillance and counseling regarding symptoms of mesenteric ischemia, with a low-threshold to proceed with revascularization if any gastrointestinal symptoms (e.g., bloating, diarrhea, atypical pain) arise. Revascularization has been advised in asymptomatic patients with severe three-vessel disease undergoing aortic reconstructions for other indications.

Choice of Open Versus Endovascular Revascularization

Treatment selection has evolved in most centers. The number of mesenteric revascularizations has increased 10-fold in the United States in the last decade, largely because of improved diagnosis and decreased morbidity of endovascular therapy.[5] Primary stenting is currently the first choice of treatment in greater than 80% patients with CMI who have suitable lesions, independent of their clinical risk (Fig. 132.4). A careful review of preprocedure CTA with attention to anatomic factors determines selection of an open or endovascular approach. The SMA is the primary target for revascularization, and as such the anatomy of the SMA is the most important determinant of choice of therapy. The ideal lesion for angioplasty and stenting is a short, focal stenosis or occlusion with minimal to moderate calcification or thrombus. For CA lesions, angioplasty and stenting carry higher rates of restenosis,[46] and should not be performed if there is active compression by the median arcuate ligament, unless this has been surgically released.

The technical difficulty of endovascular procedures is increased by the presence of severe eccentric calcification, flush occlusion, and in patients with longer lesions, small vessels, and tandem lesions affecting branches. Although these anatomic features do not contraindicate the use of stents, the technical result is often not optimal, and there is increased risk of arterial complications (e.g., distal embolization, dissection) and restenosis.[47,48] Our preference in lower risk groups has been to offer open revascularization if the anatomy is unfavorable for angioplasty and stenting.[49,50] Mesenteric bypass has also been indicated in patients who have failed a percutaneous intervention, in those with recurrent in-stent stenosis after multiple failed reinterventions, and for nonatherosclerotic lesions.

PREPROCEDURE EVALUATION

Preoperative evaluation should focus on a critical review of surgical risk, nutritional status, and anatomic factors that affect choice of reconstruction. Mesenteric revascularization carries definitive risk, regardless of which technique is used. These patients typically undergo a comprehensive medical evaluation to identify and optimize cardiovascular risk factors and their nutritional status. The evaluation should be tailored but typically includes noninvasive cardiac stress test, pulmonary function tests, carotid ultrasound, and noninvasive lower extremity arterial studies. Optimal medical therapy in these patients ideally should include cessation of cigarette smoking, acetylsalicylic acid, and beta-blocker and cholesterol lowering medication, preferentially a statin.

Revascularization should not be excessively delayed. Patients who present with deterioration of symptoms should be admitted, given nothing by mouth, started on intravenous heparin, and treated urgently within 24 to 48 hours. Patients with iodinated contrast allergy should be premedicated with steroid preparation. Those with chronic kidney disease with a serum creatinine level greater than 1.5 to 2.0 mg/dL (133-177 mmol/L) undergo intravenous hydration with sodium bicarbonate and oral acetylcysteine, starting the day prior to intervention, although there is conflicting data on its benefit.

ENDOVASCULAR REVASCULARIZATION

Diagnostic Angiography

Diagnostic angiography (Fig. 132.5) is most often done immediately prior to a planned intervention, either through the femoral or brachial approach. Access is established using ultrasound guidance and 0.035-inch guide-wire system. A 5 Fr sheath is positioned in the external iliac artery, and a 5 Fr diagnostic flush catheter is advanced to T12 level over a 0.035-inch guide wire. Modest intravenous heparinization (40 units/kg) is recommended prior to selective catheterization of

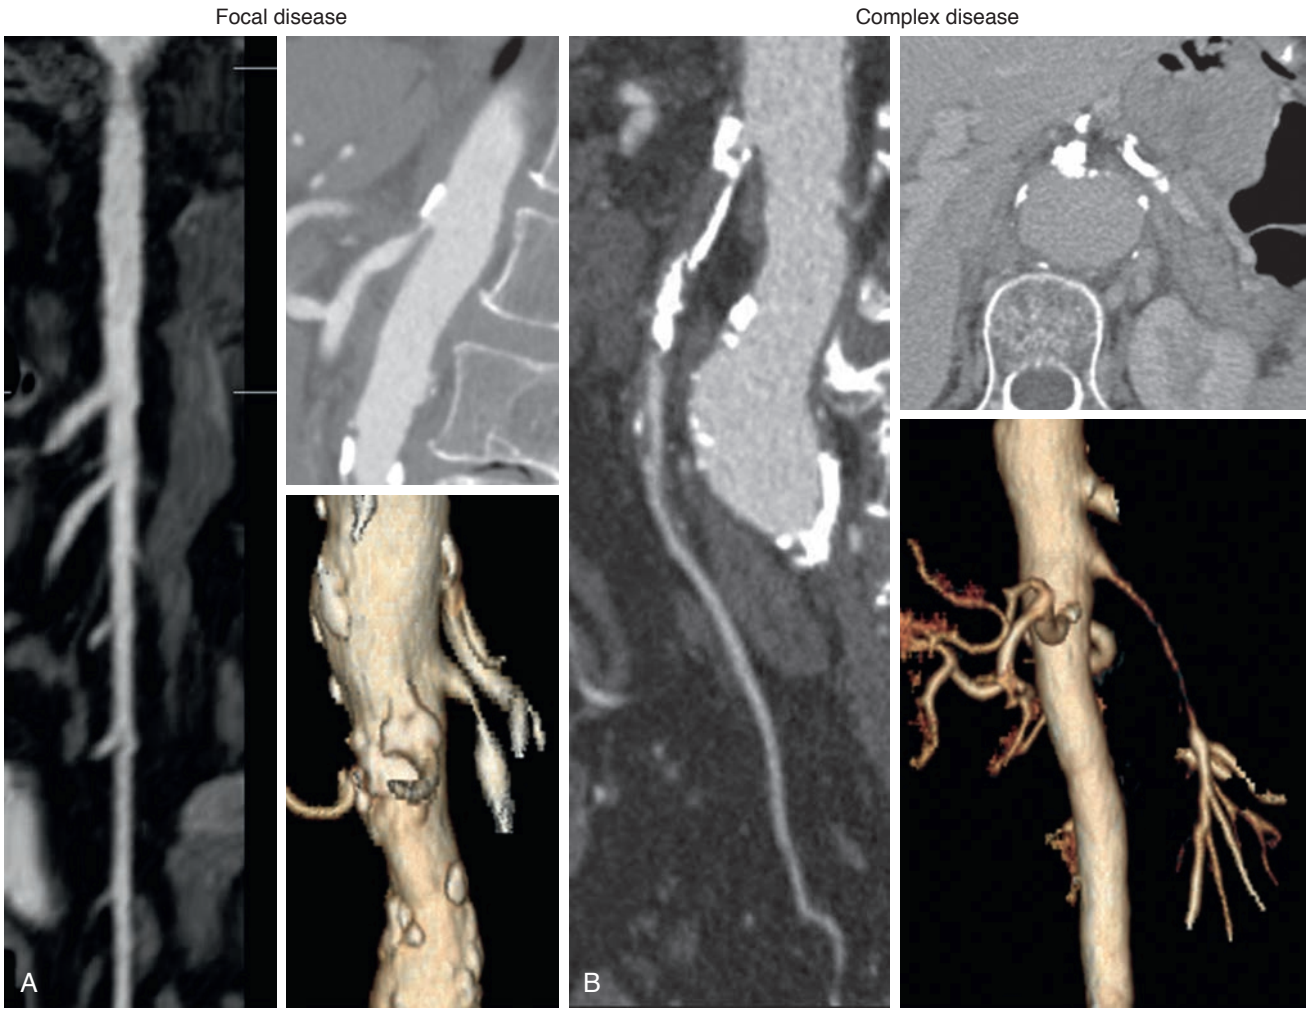

Figure 132.4 Computed tomography angiography is the most useful imaging study to plan revascularization. Anatomic characteristics of the superior mesenteric artery can be used to identify patients with focal disease where angioplasty and stenting is favored **(A)**, or patients with complex disease where endovascular therapy is technically more challenging **(B)**. Lesions with unfavorable anatomy for stenting include heavily calcified occlusions, long segment occlusions, and long segment stenosis involving multiple branches.

the mesenteric arteries. Low-osmolar contrast agent (e.g., Visipaque) minimizes abdominal discomfort during selective injections. Choice of catheter shape is dependent upon access site, angle of origin, and individual preference. The MPA catheter is ideal for selective catheterization via the brachial approach, whereas a secondary curve catheter (e.g., SOS or Simmons) or a catheter with more acute curve (e.g., Cobra 2) can be used for interventions done via a femoral approach. A complete study includes abdominal aortogram with anterior-posterior and lateral views to define the location, severity, and extent of visceral artery involvement, and to identify concomitant lesions in the aorta, renal, or iliac arteries. The optimal projection to display the proximal CA and SMA is a lateral view, and for the origin of the inferior mesenteric artery (IMA), it is a 15-degree right lateral-oblique view. Selective angiography is necessary to confirm the severity of disease and to identify tandem lesions and collateral patterns. In patients with questionable lesions, pressure gradients can be measured using pressure wire, "pull-back," or simultaneous pressure measurement technique.[51]

Angioplasty and Stenting

The primary goal of percutaneous treatment is to restore antegrade flow into at least one of the three mesenteric arteries, preferentially the SMA. Routine stenting is recommended because of elastic recoil and restenosis that occurs with angioplasty of ostial lesions. In patients with CA compression by the median arcuate ligament, there is risk of stent fracture and compression. There is no proven benefit that routine two-vessel stenting provides more durable relief, and a second intervention adds cost and potential risk of complications.[46,52]

The intervention can be done via a brachial or femoral approach. Access via the brachial artery is preferred for patients with a very acute origin of the SMA from the aorta and in those with occlusions. The authors prefer the brachial artery approach whenever possible (Fig. 132.6). This offers excellent support with smaller profile system and precise stent deployment in patients with an acute SMA angle. To minimize the risk of puncture-related complications with brachial access, a small

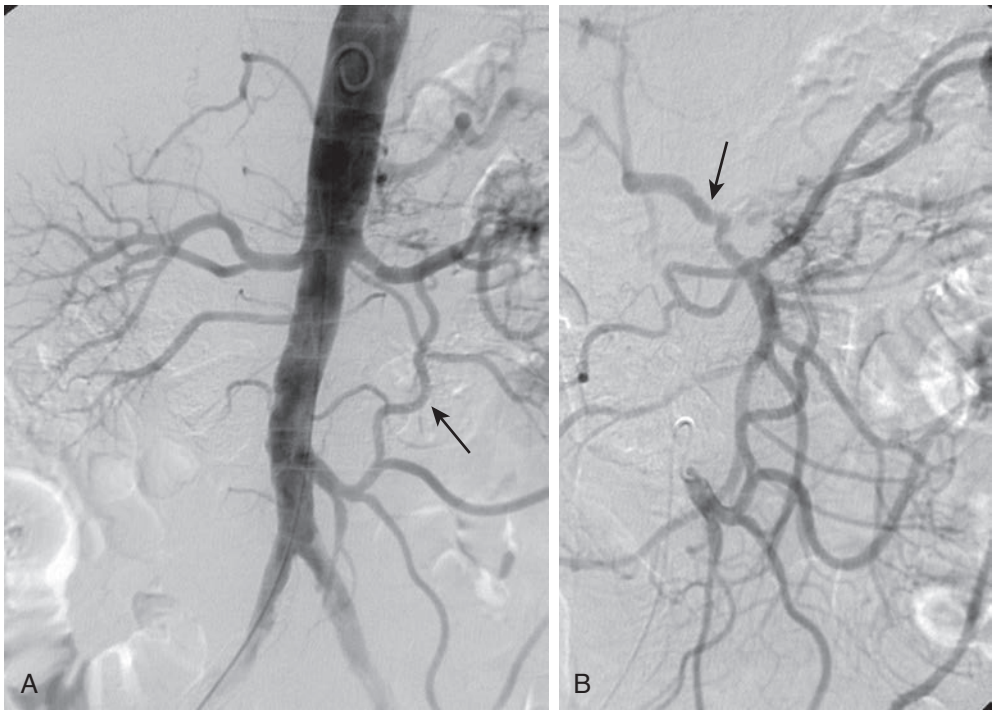

Figure 132.5 Abdominal aortogram with right anterior-oblique view demonstrates large patent inferior mesenteric artery (IMA), **(A)**. Selective IMA angiography confirms collateralization to the superior mesenteric artery via arc of Riolan *(arrow)*, and collateralization to the celiac axis via gastroduodenal artery *(arrow)* **(B)**.

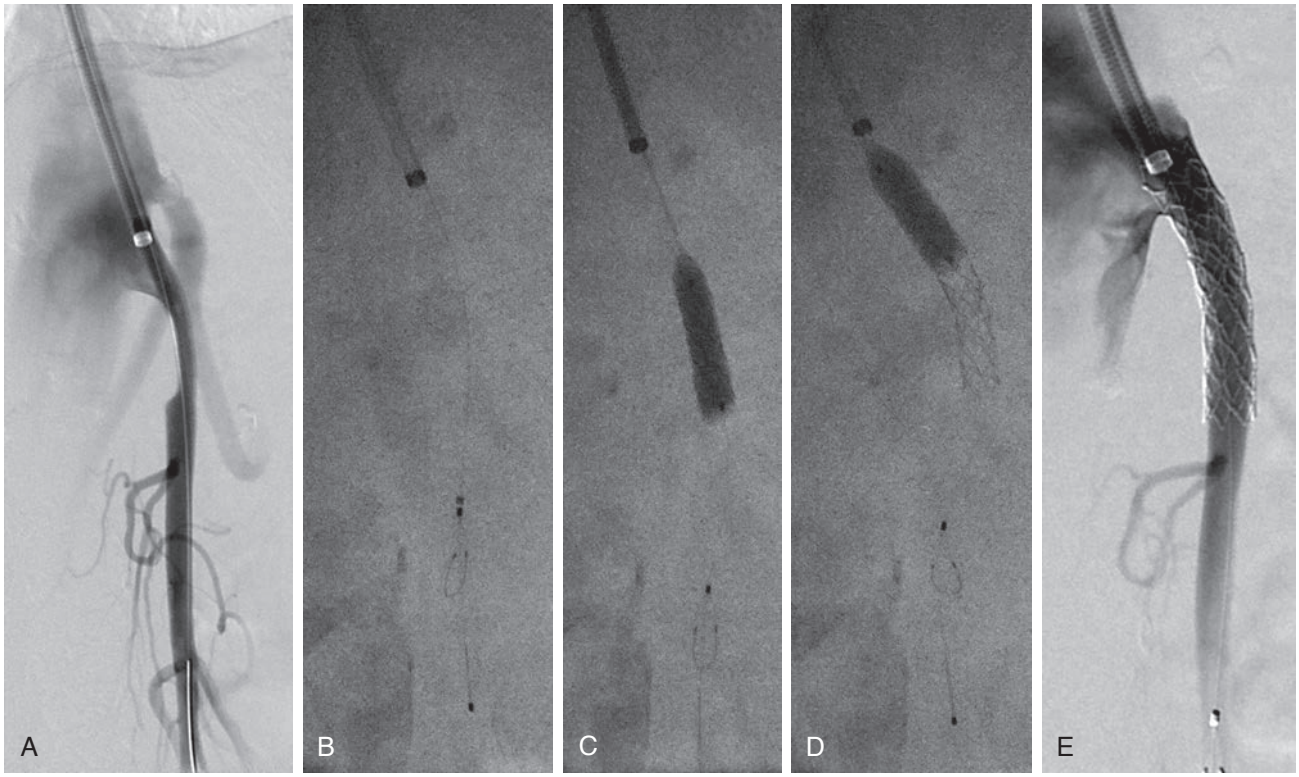

Figure 132.6 Angioplasty and stenting of a focal stenosis of the superior mesenteric artery (SMA) stenosis using brachial approach. After selective angiography (A), the lesion is crossed and a 0.014-inch Spider Rx filter wire (Covidean, Plymouth, Minnesota) is deployed in the main trunk of the SMA (B), avoiding jejunal branches. The entire lesion is treated by balloon-expandable stent (C), which is extended 1-2 mm into the aorta and flared proximally (D). Completion angiography demonstrates the patency of the stent without embolization or dissection (E).

1- to 2-cm incision just above the antecubital crease is used to expose and repair the brachial artery.[53]

Percutaneous access is established with a micropuncture set, which is exchanged to a 0.035-inch system. Full systemic heparinization (80 mg/kg) is administered prior to catheter manipulations. A 6 or 7 Fr 90-cm hydrophilic sheath is positioned in the descending thoracic aorta, and mesenteric catheterization is done with a 5 Fr MPA catheter. A SOS or VS1 catheter can be used if the procedure is performed from the femoral approach. The initial selective angiogram should demonstrate the area of stenosis and should document the distal runoff branches for comparison with postintervention views. The target lesion is initially crossed using a 0.035-inch soft angled glide wire, which is exchanged for the interventional wire of choice. The tip of the guide wire should be visualized and positioned within the main trunk of the SMA, rather than within small jejunal branches, which are prone to perforate or dissect (Fig. 132.7). Embolic protection may be useful in select patients with occlusions, long lesions (>30 mm length), severe calcification, thrombus, acute, or subacute symptoms. When utilized, the author's preference is to use a 320-cm working length 0.014-inch filter wire (Spider RX, Medtronic Covidean, Plymouth, Minnesota). If an over-the-wire 0.035-inch stent is selected, a two-wire technique can be used by combining a 0.014-inch filter wire with a 0.018-inch "buddy wire." Most recently, our practice has changed to covered stents (0.035-inch), based on a recent report that indicates superior patency rates compared with bare metal stents.[54] The stent is introduced via both wires for better support and to facilitate subsequent retrieval of the embolic protection device (Fig. 132.8). Predilatation is recommended only if there is a tight stenosis, occlusion, severe calcification, or to size stents. A balloon-expandable stent with

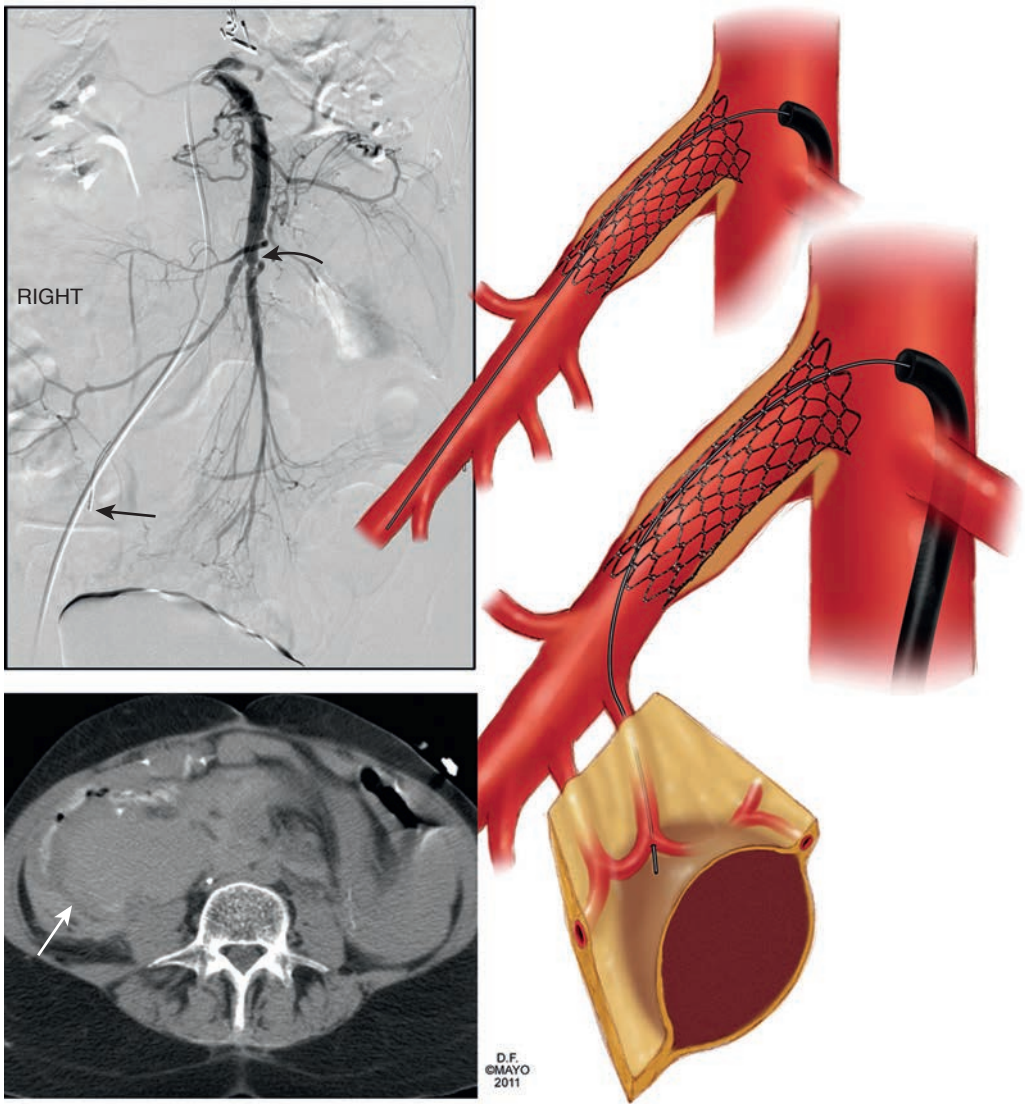

Figure 132.7 An important technical point is to visualize the tip of the guide wire during the intervention and to position the guide wire in the main trunk of the superior mesenteric artery *(curved black arrow)* as opposed to distal jejunal branches *(black straight arrow)*, which are prone to perforation resulting in a mesenteric hematoma *(white straight arrow)*.

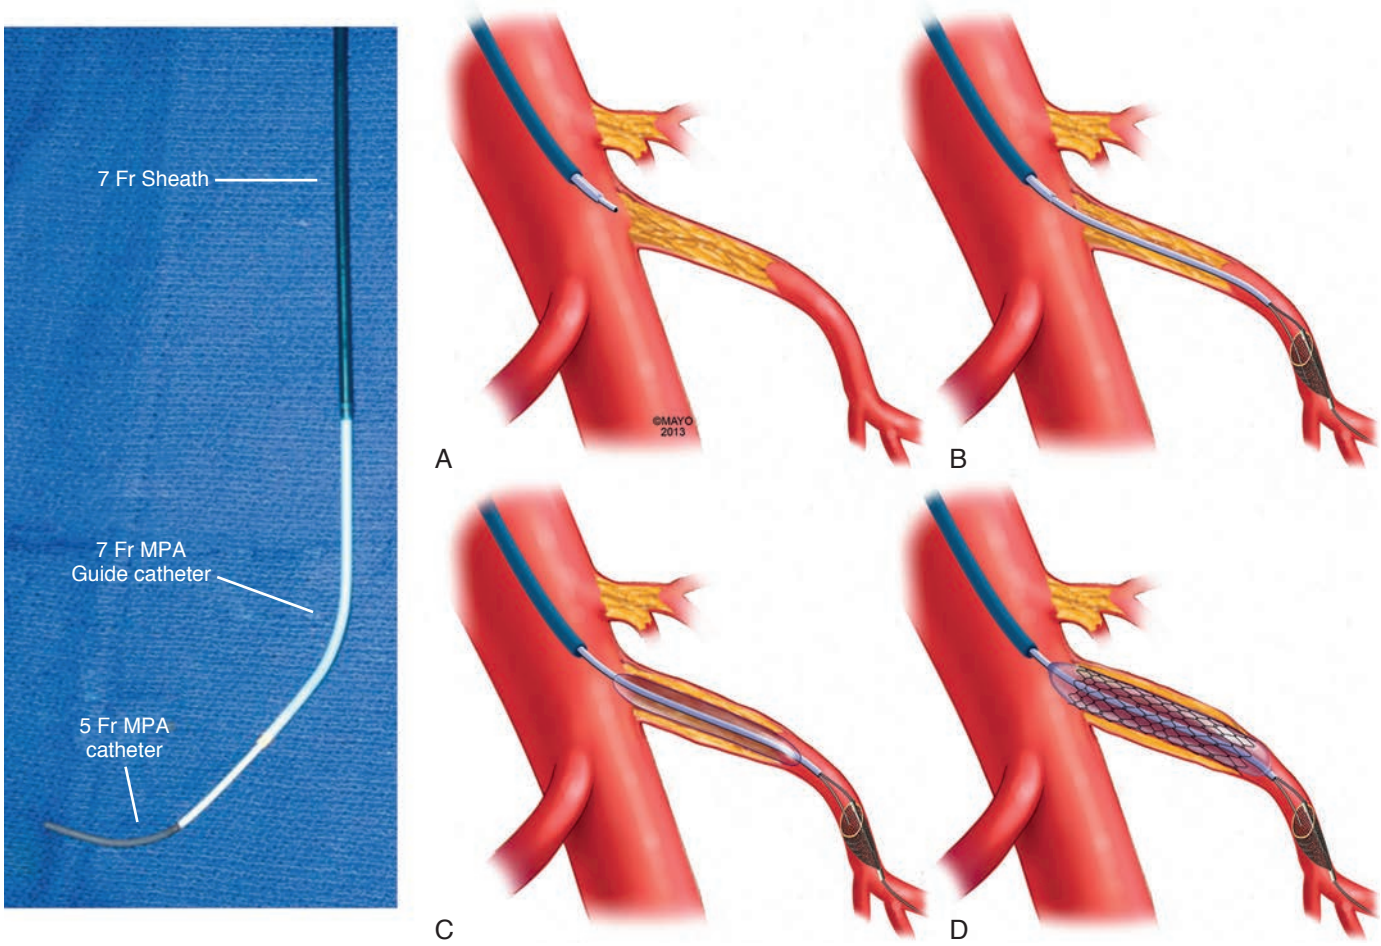

Figure 132.8 Technique of recanalization and primary stenting of a total superior mesenteric artery (SMA) occlusion. In these cases, a coaxial stiff support system is built, with combination of a 7 Fr 90-cm hydrophilic sheath, 7 Fr 100-cm MPA guide catheter, and 5 Fr 125-cm MPA catheter. The stump of the occluded SMA is engaged by the sheath-catheter combination (A); the lesion is crossed using a straight glide wire. After true lumen access is confirmed, a 0.014-inch filter wire and a 0.018-inch buddy wire are deployed into SMA via 0.035-inch catheter (B); the lesion is predilated (C) and stented using a balloon-expandable stent (D).

diameters ranging from 5 to 8 mm is used in greater than 95% of cases, allowing precise deployment and greater radial force. The stent should cover slightly more than the entire length of the lesion and should be 1 to 2 mm into the aortic lumen. Ideally the stent should be flared gently into the aorta to prevent missing the ostia and to facilitate recatheterization if needed. Occasionally a self-expandable stent is used to treat narrowing in tortuous segments.

Recanalization of Mesenteric Occlusions

Occlusions require a stiffer support system to cross the lesion and deliver the stent. A coaxial support system uses a 7 Fr sheath, 7 Fr MPA guide catheter, and 5 Fr MPA catheter (see Fig. 132.8). Attempting difficult recanalization from the femoral approach adds time, contrast, catheter manipulations, and is fraught with failure. The tip of the MPA catheter engages the stump of the occluded SMA (Fig. 132.9), whereas the support system allows the lesion to be crossed using a straight tip, hydrophilic, soft 0.035-inch glide wire. Occasionally, 0.018 or 0.014-inch guide wires are needed. It is important to avoid the subintimal plane because of risk of dissection or disruption, which is best achieved using straight tip guide wires. A Quick-cross catheter (Spectranetics, Colorado Springs, Colorado) or an alternative support catheter, or even a small coronary balloon, may be needed to cross a tight lesion. Once the lesion is crossed, access into the true lumen should be confirmed. Our preference has been to use an embolic protection device with a two-wire technique routinely in cases of total occlusion.

Following deployment and flaring of the stent, the embolic protection device is retrieved with careful attention to avoid entrapment into the stent. The basket is examined for debris. A formal completion angiography should be obtained. The angiogram should provide a focal magnified view of the stent with the sheath in the aorta. Demonstration of the vessel origin and a panoramic view of the entire SMA and its branches to rule out embolization or perforation are critical. The stiff guide

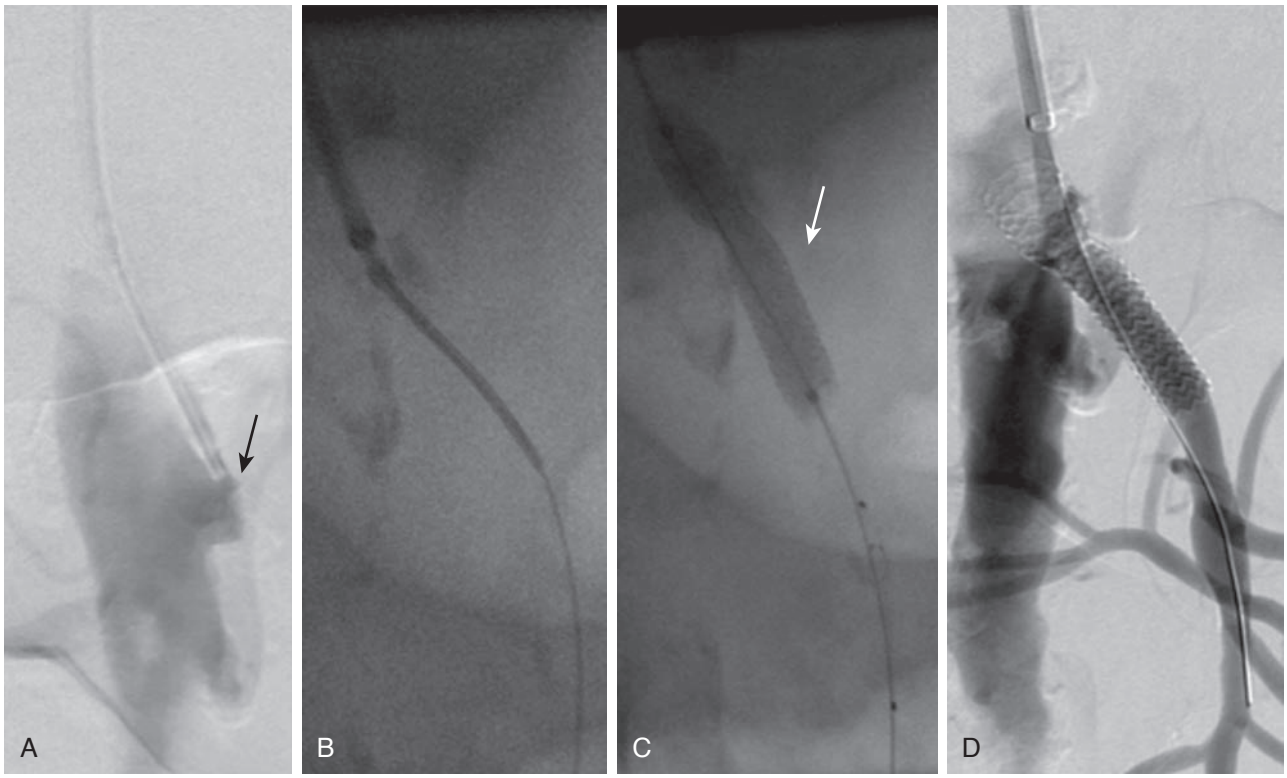

Figure 132.9 Recanalization of superior mesenteric artery (SMA) occlusion utilizing the technique described in Fig. 151.8. After the stump is engaged by the catheter, guide catheter, and sheath (A, *black arrow*), the lesion was crossed (B) and stented using embolic protection (C). Note that the balloon is used to flare the proximal part of the stent (C, *white arrow*). Completion angiography shows a flared widely patent SMA stent (D).

wire should be retracted, and nitroglycerin may be administered via the sheath to minimize spasm or kinks caused by the guidewire tip.

Adjunctive Techniques

A number of adjunctive techniques can be used to optimize results in complex lesions, but the authors acknowledge that these techniques are anecdotal. The presence of acute and subacute symptoms suggests fresh thrombus or a complicated plaque. In these cases local administration of t-PA into the diseased segment 20 to 30 minutes prior to stent placement may improve technical success. For eccentric, calcified lesions, percutaneous atherectomy has been used selectively.[55] It is critical to have an appreciation of the limitations of this technique when applied as an off-label use in the mesenteric arteries.

Complications

The most common causes of death after mesenteric stenting are cardiac events, gastrointestinal bleeding, and bowel ischemia. The latter is typically associated with intraprocedural complications such as distal embolization, thrombosis, or dissection. Distal embolization occurs in 8% of patients treated by SMA stents without embolic protection, with higher rates among patients with subacute symptoms, SMA occlusion, long lesions (>30 mm), and severe calcification.[50] The most commonly reported complications are access-related problems in 3% to 16%, renal insufficiency in 2% to 8%, acute bowel ischemia in 1% to 7%, gastrointestinal bleeding in 1% to 5%, cardiac events in 1% to 7%, and respiratory complications in 1% to 7%.[17,21,52,56-68]

Postprocedure Management

The postprocedure care after mesenteric interventions is comparable to that of other peripheral endovascular procedures. All patients are admitted for observation overnight. Worsening abdominal pain after the procedure is unusual and warrants evaluation to rule out thrombosis, embolization, or a mesenteric hematoma from jejunal branch perforation (see Fig. 132.7). Patients are allowed to resume a regular diet within 6 to 8 hours. Antiplatelet therapy is typically started prior to the intervention with acetylsalicylic acid, and continued indefinitely thereafter. Clopidogrel is started the day of the intervention with a loading dose of 300 mg followed by a dose of 75 mg daily for 6 to 8 weeks as a dual antiplatelet agent, or indefinitely if a covered stent is used. A duplex ultrasound scan prior to discharge or within the first few days after the procedure serves as a baseline for future comparison. Follow-up includes clinical examination and duplex ultrasound every 6 months during the first year and annually thereafter.

OPEN REVASCULARIZATION

Choice of Open Surgical Revascularization

A variety of open surgical techniques have been described to revascularize the mesenteric arteries. Selection involves the type of incision (transperitoneal vs. retroperitoneal), conduit (vein vs. prosthetic), graft configuration (antegrade vs. retrograde), source of inflow (aortic vs. iliac), and the number of vessels to be reconstructed (single vs. multiple).

The type of open reconstruction is selected on the basis of the anatomy and the patient's clinical risk assessment.[26] Two-vessel reconstructions (CA and SMA) using a bifurcated polyester graft from the supraceliac aorta compromises more than 80% of open mesenteric reconstructions.[17,26,69] This approach is selected in lower risk patients who are not candidates for endovascular treatment and have multivessel disease, with no evidence of significant supraceliac aortic calcification or thrombus. Elderly patients and those with cachexia or severe cardiac, pulmonary, and renal dysfunction are not good candidates for supraceliac aortic-based procedures, and are best treated with retrograde grafts based in the infrarenal aorta or the iliac arteries. A hybrid approach using retrograde open mesenteric stent via midline laparotomy may be selected for patients with extensive aortoiliac disease and no good source of inflow.[70,71] Transaortic endarterectomy is rarely indicated, but may be considered in patients who failed or are not candidates for endovascular therapy and have bacterial contamination or perforated bowel, previous abdominal irradiation, extensive abdominal wall hernias, or other hostile conditions.

Antegrade Mesenteric Bypass

The distal thoracic or supraceliac aorta is often spared from severe atherosclerotic disease. Bypass with antegrade graft configuration based in the supraceliac or lower thoracic aorta[72] offers potential hemodynamic advantage, while avoiding kinks that can occur with grafts placed in retrograde fashion. The operation is done through a transperitoneal upper midline or bilateral subcostal incision, depending on the patient's body habitus and costal cartilage flare (see Chapter 54). Abdominal exploration includes an evaluation for other intraabdominal pathology and careful inspection of the small bowel for unsuspected ischemic perforations. A third arm retractor or an Omni self-retaining retractor can be used. The lesser omentum is opened and the left lobe of the liver is retracted after division of the left triangular ligament. The esophagus is retracted toward the patient's left side with a nasogastric tube in place, and the stomach is gently retracted caudally. The diaphragmatic crura are divided longitudinally to expose the supraceliac aorta (Fig. 132.10). Approximately 5 to 10 cm is dissected free in preparation for clamping. While doing so, care should be taken not to enter the pleural cavity on either side of the aorta. Usually only the celiac trunk and the proximal hepatic and splenic arteries need isolation, but with more extensive disease, the common hepatic artery may be a better target for the anastomosis. The left gastric artery is often small and may be divided without sequela, which facilitates celiac anastomosis and makes tunneling of the SMA graft behind the pancreas easier.

The transverse mesocolon is retracted cephalad, and the root of the mesentery is incised longitudinally over the SMA just below the pancreas. Several lymphatic and small venous tributaries require meticulous ligation. The SMA and several jejunal branches are dissected free and carefully controlled with Silastic vessel loops. Excessive traction on these vessel loops can easily result in avulsion of small branches and should be avoided. In most cases, as much as 4 to 5 cm of the SMA is dissected distal to the lower border of the pancreas, but additional dissection may be required in patients with extensive disease. In these cases, one or more crossing venous branches from the superior mesenteric vein may require ligation and division to allow exposure of the SMA.

Patients are given systemic heparin (60-80 mg/kg), and diuresis is induced with mannitol prior to placement of the supraceliac clamp. Partial aortic cross clamping can be performed using a Satinsky or multipurpose clamp, or alternatively total aortic clamping with two cross-clamps affords better exposure for the proximal aortic-graft anastomosis. A straight or angled aortic clamp (Cherry supraceliac clamp) and a Wylie hypogastric clamp work well (see Fig. 132.10). Placed appropriately, occlusion of the lumbar vessels is achieved as well. A gentle slightly oblique or vertical aortotomy is made. A 14×7 mm knitted polyester graft is beveled in an oblique fashion with a short main body and anastomosed to the supraceliac aorta in an end-to-side fashion using running 4-0 Prolene suture. Aortic cross-clamp time rarely exceeds 20 minutes and most often ranges from 12 to 15 minutes. The risk of renal ischemia or embolization is low when patients are properly selected and have a relatively disease-free supraceliac aorta.

The left limb of the bifurcated graft is positioned slightly posterior and is tunneled retro-pancreatic and anterior to the left renal vein toward the SMA (Fig. 132.11). The anastomosis to the SMA is performed in an end-to-side fashion when the anastomosis is performed at the base of the mesentery below the pancreas. If the SMA is extensively diseased or the patient has had prior stents, the lumen may require modest endarterectomy or removal of stent struts. Any endarterectomy should be done carefully, so not to result in tear or an excessively thin arterial wall that cannot be reconstructed. In a few cases with very extensive plaque, the distal graft can be beveled into a long patch or anastomosed end-to-side into a bovine pericardium patch. It is important to relax retraction when cutting the graft limbs to length to avoid angulation or kinking with either an antegrade or retrograde bypass. Next, the celiac axis anastomosis is performed in end-to-end fashion, or more frequently the anastomosis may be performed end-to-side to the common hepatic artery.

Retrograde Mesenteric Bypass

Sources of inflow for retrograde grafts are the infrarenal aorta, prior infrarenal aortic grafts, or the iliac arteries (Fig. 132.12). In general, we reconstruct only one artery (SMA) if a retrograde graft is used. The infrarenal aorta may be replaced, if diseased,

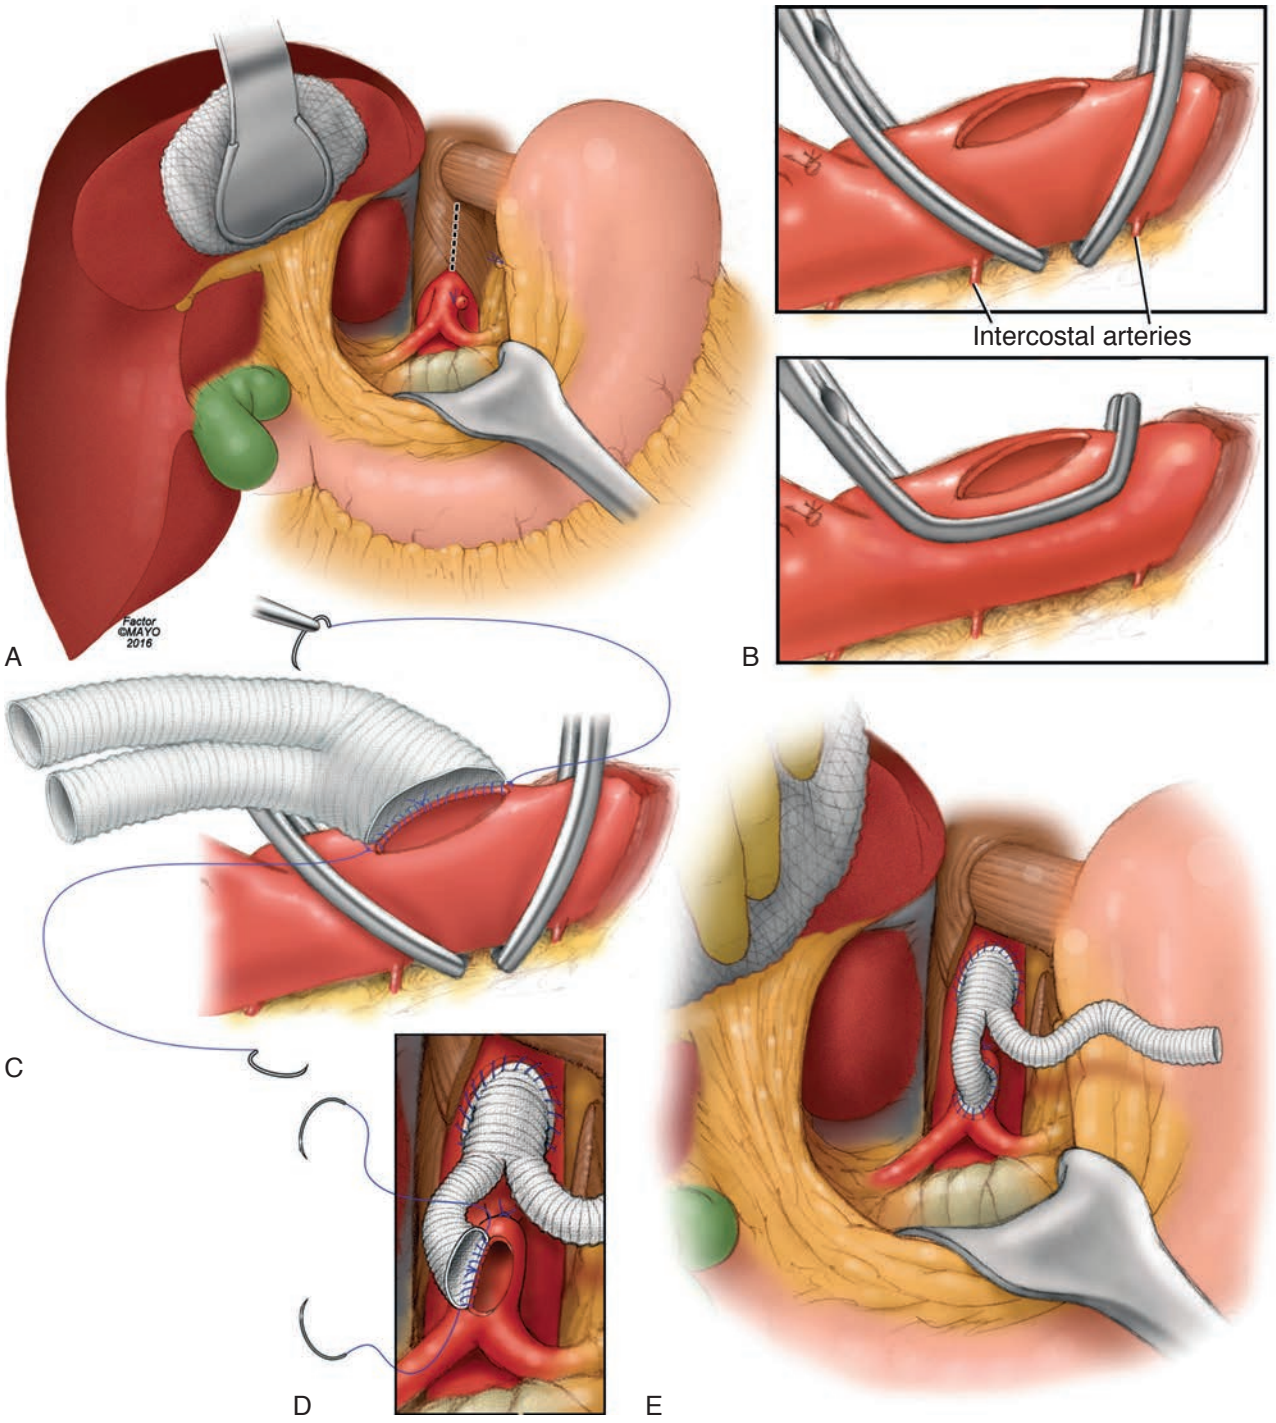

Figure 132.10 The supraceliac aorta is exposed after division of the diaphragmatic crura (A). Following systemic heparin, the supraceliac is clamped using either two aortic clamps or a Satinsky clamp (B). A slightly oblique aortotomy is made for the proximal anastomosis of the bifurcated graft (C). Note that the graft is gently beveled and that the right graft limb is anastomosed end-to-side to the celiac axis or hepatic artery (D). The left limb of the graft is tunneled behind the pancreas (E).

but concomitant aortic reconstruction increases operative mortality and should be avoided unless absolutely necessary.[17] The proximal anastomosis is performed to the anterolateral wall of the aorta and can be done with either two cross-clamps or a partial occlusion clamp, depending on the aortic size and the presence of atherosclerosis or calcification within that segment. A 6-mm coronary punch can be used to remove portion of the aortic wall. However, our preference is to select the common iliac artery as source of inflow whenever possible, thus avoiding an aortic cross-clamp.

The key to prevention of graft elongation, angulation, or kinking is to cut it to length, with the SMA in a nearly anatomic

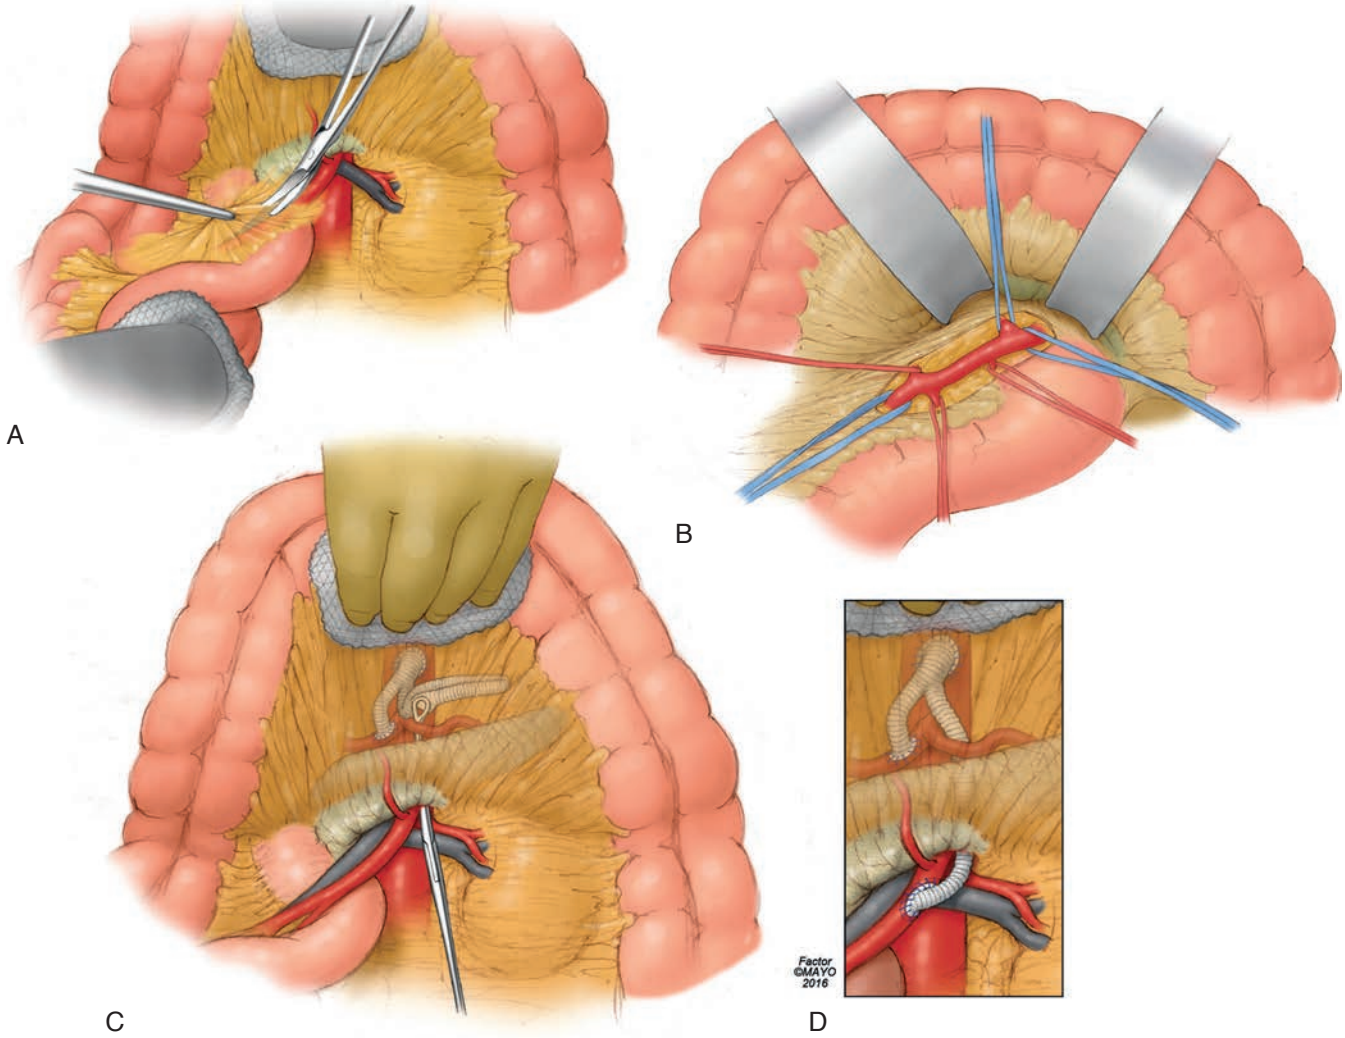

Figure 132.11 The superior mesenteric artery (SMA) is dissected free in the mesentery after the transverse colon is retracted cephalad (A). Once the SMA and branches are dissected and controlled with silastic vessel loops (B), the left limb of the graft is tunneled behind the pancreas (C) and anastomosed end-to-side to the SMA (D).

position. This is done by relaxing the retractors prior to cutting the graft and after the proximal or distal anastomosis is done. A large 8- or 10-mm graft should be used for a retrograde, straight aortomesenteric graft, and it is imperative to perform the distal anastomosis first and then push the mesentery close to the aorta and select the appropriate aortic site for the anastomosis. We prefer a C-shaped graft when the iliac artery is the source of inflow. In these cases, the proximal anastomosis may be done first to the iliac artery or distal aorta, followed by the distal anastomosis to the SMA. There are some patients who have extensive circumferential aortic calcification but soft common or external iliac arteries, which can serve as good donor vessels. Either the right or left common iliac artery can be chosen for inflow, depending on the orientation of that artery to the normal anatomic position of the SMA. In general, the right iliac artery lays better if both vessels are suitable. Two-vessel reconstructions can also be performed with retrograde grafts by doing a side-to-side anastomosis to the SMA and an end-to-side anastomosis to the common hepatic artery. These grafts may be passed on top of or beneath the pancreas and curved in a C-fashion toward the hepatic artery.

Retrograde Open Mesenteric Stenting

A hybrid approach using retrograde open mesenteric stenting (ROMS) via midline laparotomy to expose the SMA (Fig. 132.13) has been reported by Milner and colleagues from the University of Pennsylvania and Dartmouth Group.[70,73] This option is selected in patients with acute mesenteric ischemia due to in situ thrombosis when there is an indication for laparotomy. It is also well suited in patients with severe aortic and iliac calcifications when there is not a good source of inflow for bypass. The SMA is dissected below the pancreas as previously described. Several jejunal branches are controlled with Silastic vessel loops and occluded prior to manipulation to avoid distal embolization. Retrograde SMA access is established using a micropuncture set with 0.018-inch guide wire. This is exchanged for a 0.035-inch guide-wire system, and a 6 to 7 Fr sheath is advanced to the

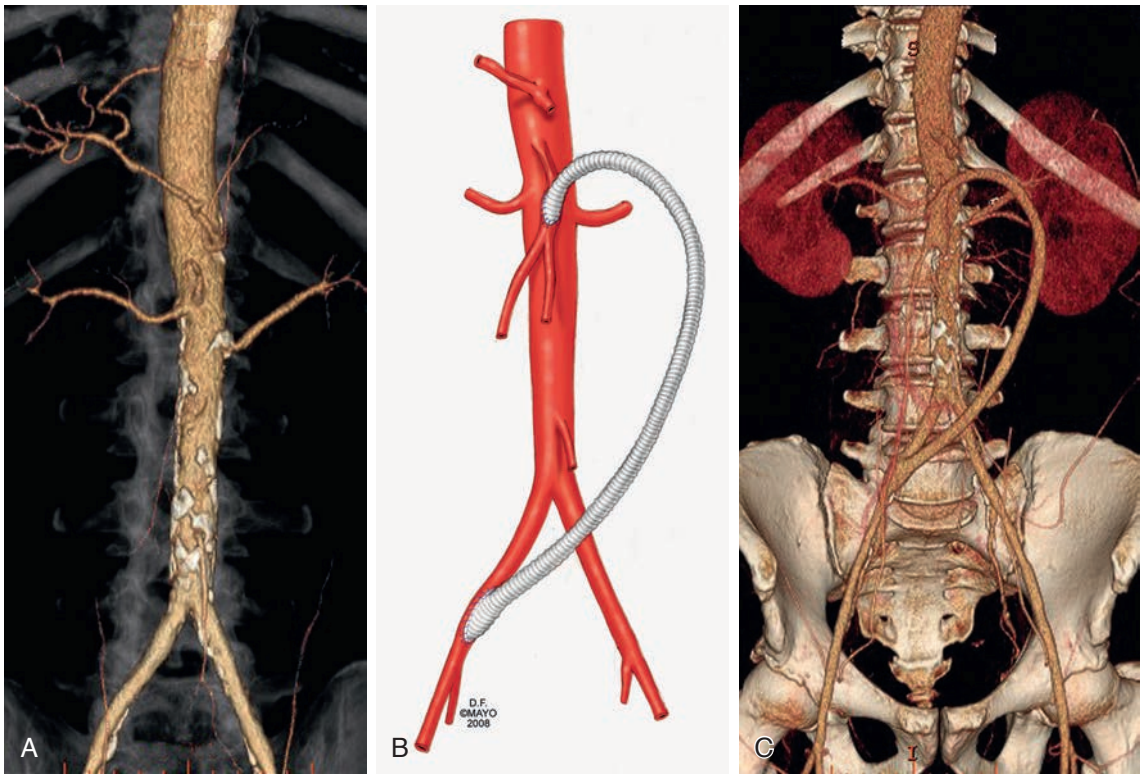

Figure 132.12 Computed tomography angiography (CTA) of a patient with vasculitis and occlusion of the superior mesenteric artery **(A)**. The patient was treated by retrograde C-shaped iliac artery to superior mesenteric artery bypass **(B)**. Follow-up CTA revealed widely patent bypass graft **(C)**.

SMA. Retrograde angiography is obtained and the SMA occlusion or stenosis is crossed, predilated, and stented with a balloon-expandable stent. Prior to restoring antegrade flow to the SMA, the sheath is flushed to prevent distal embolization. The puncture site may be closed with interrupted sutures or opened longitudinally and closed over a patch if severely diseased.

Transaortic Mesenteric Endarterectomy

Transaortic endarterectomy is performed using a full-length midline abdominal or subcostal incision or a thoracoabdominal incision for patients who have narrow costal flares or are truly obese (see Chapter 54). The aorta is exposed using medial visceral rotation with the left kidney remaining in its bed and dissection carried anterior to the renal vein. The diaphragmatic crura is transected longitudinally, allowing exposure of the left anterior-lateral wall of the aorta and origins of the SMA and celiac axis (Fig. 132.14). The SMA is dissected free over several centimeters. After systemic heparin and induced diureses, the supraceliac and infrarenal aorta are clamped. A longitudinal or trapdoor aortotomy is performed, starting at the level of the renal arteries up to just above the celiac axis origin. Endarterectomy of the paravisceral aorta, the celiac, and SMA is performed, ending at the renal artery orifices. In the rare patient in whom there is symptomatic renal artery stenosis, the endarterectomy should include the renal artery ostia as well. The aortotomy is closed longitudinally and rarely requires a patch. Endarterectomy of the celiac artery usually has an endpoint at its bifurcation, whereas SMA disease may extend beyond the limits of the ostial endarterectomy. This requires a separate transverse or longitudinal SMA arteriotomy after flow is restored through the distal aorta and celiac artery. If a longitudinal arteriotomy is done, this can be closed with a patch.

Intraoperative Duplex Ultrasound Monitoring

Technical imperfections may be a cause of early graft failure after mesenteric revascularization. We have routinely performed intraoperative duplex ultrasound (IOUS) surveillance in all patients who undergo open mesenteric or renal reconstructions. We have found technical defects in 15% of the reconstructions. Minor defects (7%) are typically left untreated and include arterial abnormalities with normal velocities such as small kinks, mild residual stenosis, and small intimal flaps. Major defects (9%) consist of hemodynamically significant arterial abnormalities such as significant stenosis, kinks, thrombus, and large intimal flaps. These require prompt immediate revision.

Complications

Complication rates after open mesenteric revascularization average 20% to 40%.[5,18,74-79] Pulmonary (15%), gastrointestinal (14%), cardiac (10%), and renal (4%) complications are the most frequent. Patients with severe malnutrition require perioperative nutritional support. Prolonged ileus occurs in 8%.[17] Meticulous wound closure is important, particularly in the

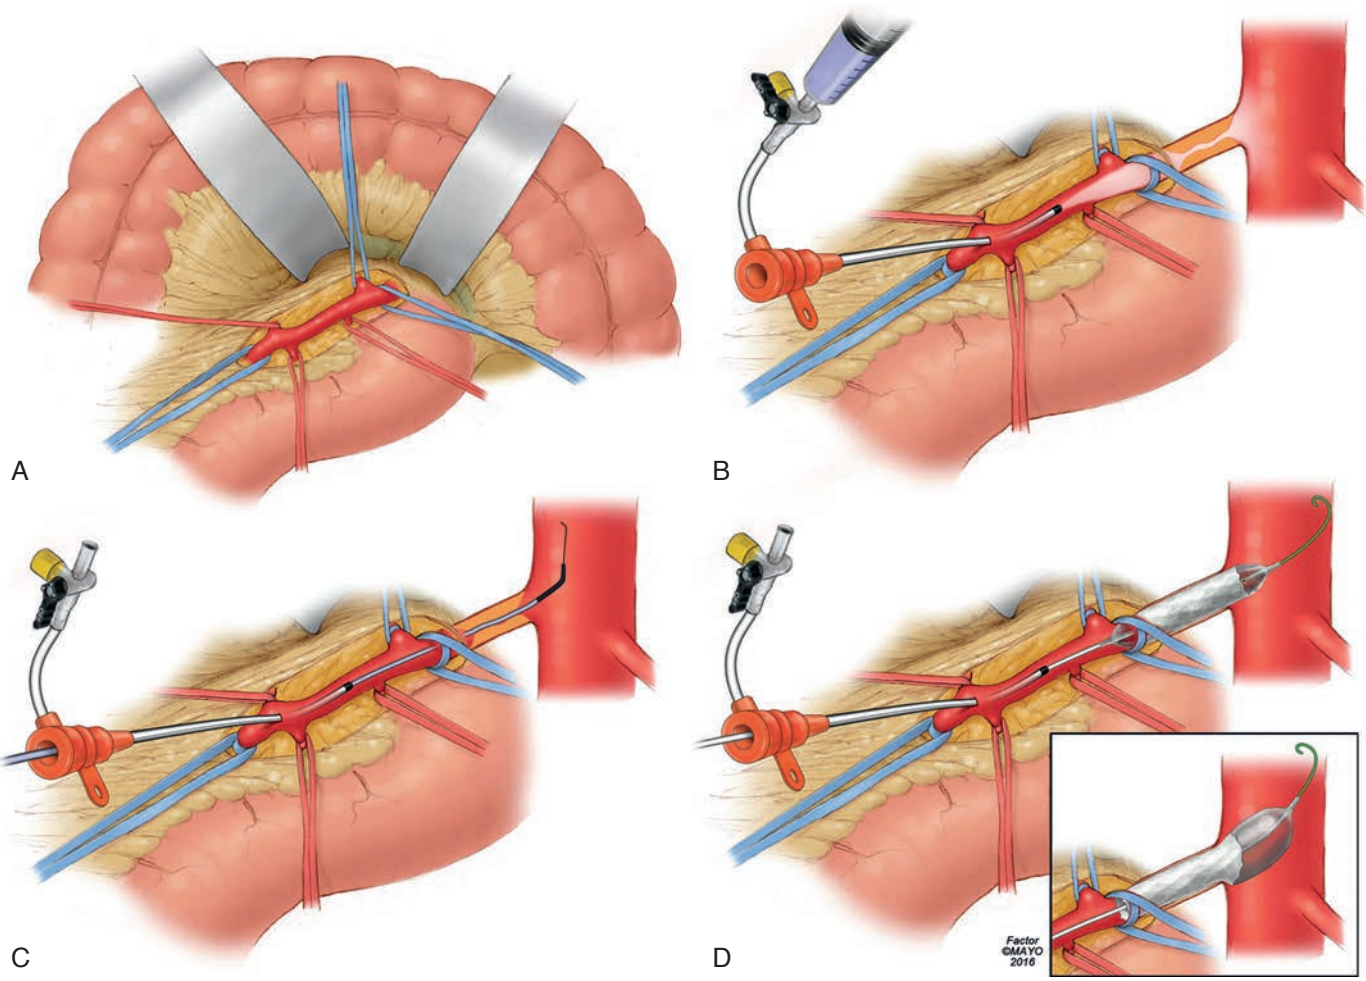

Figure 132.13 Technique of retrograde open mesenteric stenting requires open surgical exposure of the superior mesenteric artery (SMA) (A). Retrograde access is established using a 7 Fr sheath and catheter (B). After retrograde angiography, the occluded SMA is crossed using a glide wire (C). Stenting is performed using a covered stent or bare metal stent (D).

patient with malnutrition or severe ascites, due to risk of wound related complications (4%-8%).[15,72,76,77,79-81] Early graft thrombosis is uncommon (<2%) and indicates a technical problem (e.g., kink, intimal flap, dissection, thrombus), poor runoff, or hypercoagulable state.[17] If not recognized, early graft thrombosis is a lethal complication.

Postoperative Management

Patients undergoing open mesenteric reconstruction are admitted for 1 to 3 days to the intensive care unit for monitoring. The average length of hospital stay is 12 days.[17] Patients with severe ischemia typically experience major fluid shifts and have a high volume requirement over the first 48 hours because of the loss of autoregulation of the mesenteric arterioles and the systemic inflammatory response. Persistent hypotension, tachycardia, leukocytosis, reduction in urinary output with elevated bladder pressures, or increase in abdominal pain may indicate graft occlusion, ischemic bowel, or abdominal compartment syndrome. CT, abdominal reexploration, or both are needed to exclude these problems.

Return of oral intake varies, but many patients develop prolonged postoperative ileus and may need enteral or parenteral nutritional support. Total parenteral nutrition is started early after the operation once fluid requirements diminish if an ileus is anticipated in the malnourished patient. The "food fear" many patients have preoperatively does not resolve quickly after the operation, as it is often a "learned behavior." Furthermore, absorptive capacity of the gut changes, and patients often experience diarrhea over the first few postoperative weeks. Postoperative medical therapy includes ongoing recommendations for smoking cessation, antiplatelet, and cholesterol-lowering agents. Imaging surveillance is recommended using duplex ultrasound, which is obtained every 6 months during the first year and annually thereafter.

RESULTS

Despite the lack of prospective randomized comparisons between open surgery and endovascular treatment, mesenteric angioplasty and stenting have been widely adopted in most centers, resulting in a decline in the number of open surgical reconstructions. Endovascular revascularization has been associated with decreased

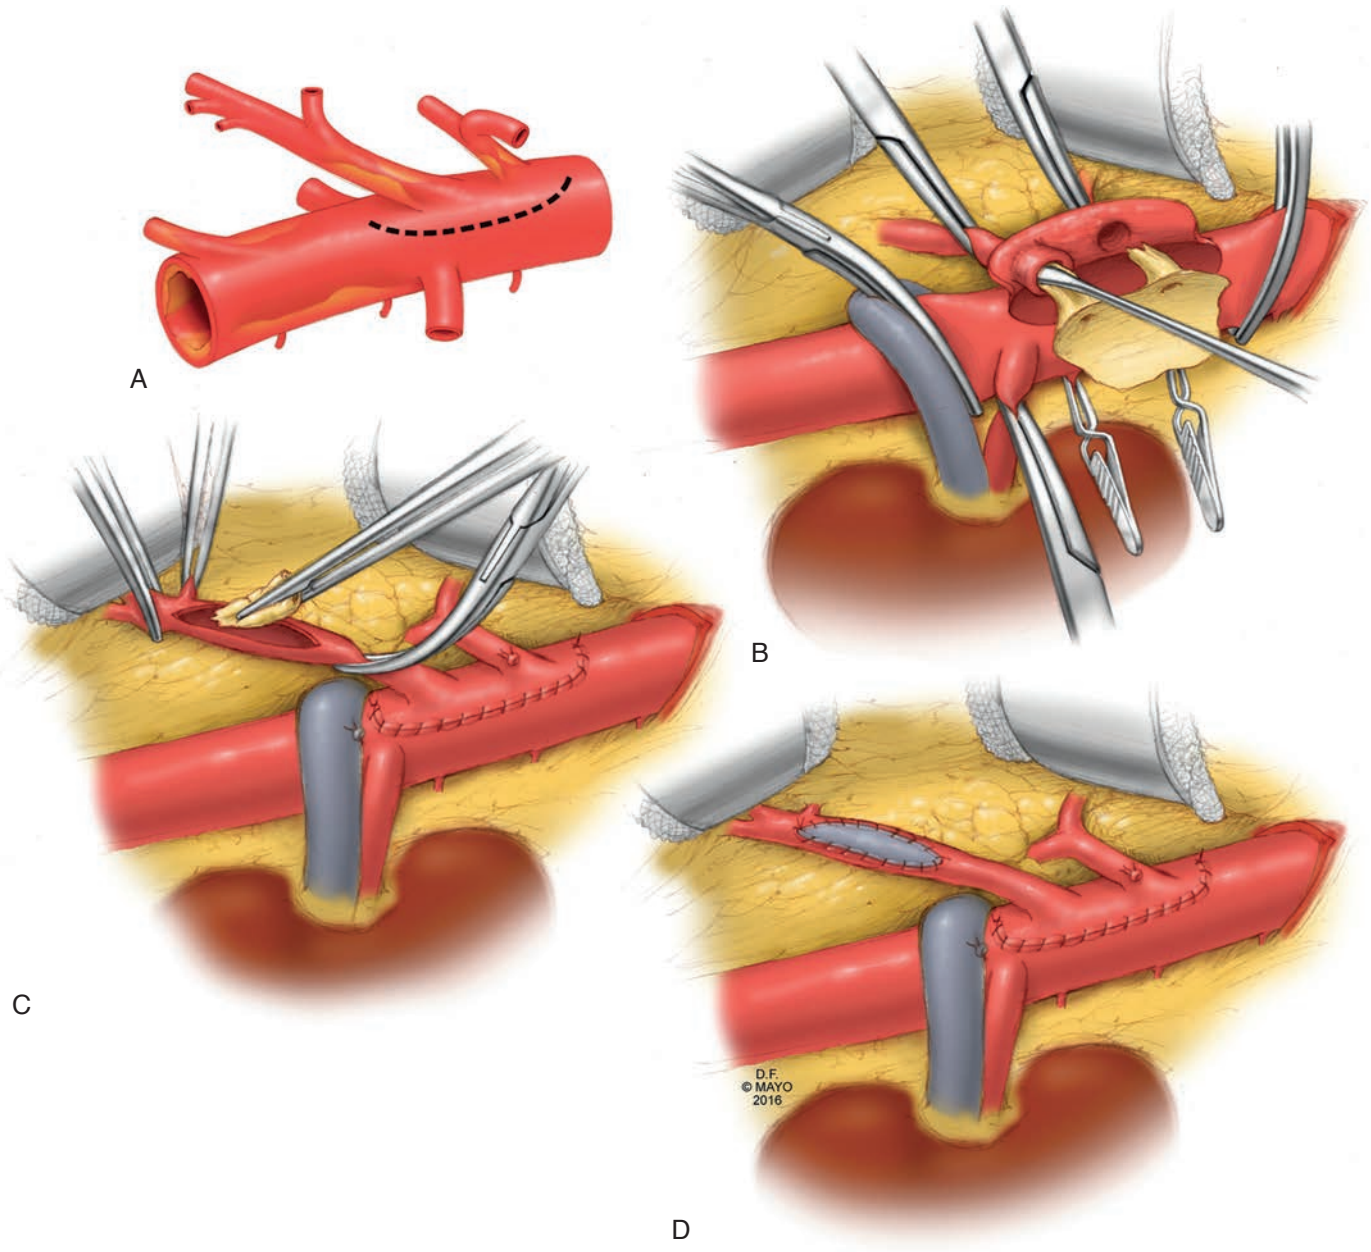

Figure 132.14 Technique of transaortic mesenteric endarterectomy using medial visceral rotation and a trapdoor aortotomy (A). The endarterectomy includes the origins of the celiac axis and superior mesenteric artery (B). The aortotomy is closed and the end point of the superior mesenteric artery is revised if needed (C). This is closed using vein patch angioplasty (D).

morbidity, length of stay, and convalescence time, but similar mortality compared with open repair.[17,82] Mesenteric bypass offers improved patency, with lower rates of reinterventions and better freedom from recurrent symptoms.[5,17,21,57,58,82-90]

Morbidity and Mortality

Based on a review of single-center reports and a systematic review, endovascular revascularization has been associated with decreased morbidity, length of stay, and convalescence time (Tables 132.1 and 132.2).[82] Morbidity and length of stay averages 11% and 3 days with endovascular, compared with 33% and 14 days with open surgery.[82] Mortality rates are similar, with average 30-day mortality of 6% (0%-15%) for open and 5% (0%-21%) for endovascular revascularization.[82] Open surgical bypass can be performed with low mortality in good risk patients operated on referral centers.[5,86] The Mayo Clinic group[17] reported a 2.7% mortality for open and 2.4% for endovascular revascularization. Mortality was 1% for low-risk and 6.7% for high-risk patients treated by open bypass, with the highest mortality rate (8.9%) in those patients who had a concomitant aortic reconstruction. Nonetheless, these operations carry high mortality in the community, reaching 20% in the state of New York and 13% in the United States.[5,86]

a. Considering only occluded SMA. In one case was used covered stent and, in other ones, bare metal stent.

Symptom Relief

Both methods of revascularization are highly effective in patients who have the correct diagnosis of CMI. In a systematic review, symptom improvement averaged 88% with endovascular and 93% with open revascularization.[82] Single-center reports indicate symptom improvement in greater than 90% of patients treated by stents. Angioplasty alone may be associated with lower rates of technical success (78%) compared with stenting (>95%).[86] Symptom improvement is noted immediately after revascularization, but it is not uncommon for patients to experience modest bloating and worsening diarrhea. The presence of persistent abdominal pain may suggest another diagnosis.

Restenosis, Symptom Recurrence, and Reintervention

Most single-center reports and a systematic review indicate that open reconstructions are more durable (see Table 132.2).[17,57,58,68,76,78,87,89,91-96] Bypass is associated with lower rates of restenosis, better patency, and higher freedom from recurrent symptoms or reinterventions compared with mesenteric angioplasty and stenting. Primary patency of open bypass averaged 89% at 5 years in a recent review of the pooled literature (57%-92%), with freedom from reinterventions of 93%.[86] Ryer and colleagues indicated that open bypass has been increasingly performed in patients with more comorbidities and worse anatomy. Despite these adverse characteristics, open surgery had excellent primary patency of 76% at 5 years.[78] In the systematic review of van Petersen and associates,[82] endovascular treatment was associated with more restenosis (37% vs. 15%), symptom recurrences (30% vs. 13%), and reinterventions (20% vs. 9%). Primary patency was lower for mesenteric stenting (51% vs. 86%), with similar secondary patency rates (83% vs. 87%).

Endovascular treatment has been plagued by high rates of restenosis, affecting as much as 20% to 66% of the patients, not matching the excellent patency rates reported for open reconstructions (see Table 132.1).[17,21,52,56-68,89,90,92,96-100] Contemporary reports of primary stenting indicate that restenosis occurs in 40% of patients and that half of these require reintervention.[47] The average 3-year primary patency rate for bare metal stents is 52% (range, 30%-81%), calculated from pooled literature.[86] The secondary patency rate is better than 90%, as evidenced by reports of mesenteric reinterventions.[47,86] Oderich and associates recently reported a nonrandomized comparison of covered versus bare metal stents in 225 patients treated for CMI.[54] In that study, covered stents had 92 ± 6% primary and 100% secondary patency rates at 3 years, rivaling the results of open bypass. Covered stents outperformed bare metal stents, with less restenosis, symptom recurrences, reinterventions, and better patency rates. These observations held true both in primary interventions for native artery lesions and in reinterventions for in-stent or native artery restenosis after endovascular procedure. Independent predictors of restenosis were use of bare metal stents, cigarette smoking, advanced age, and female gender.

Patient Survival

Poor prognostic indicators for long-term patient survival after mesenteric revascularization include advanced age and presence

of severe cardiac, pulmonary, or renal disease.[17,101] The type of revascularization has not been shown to affect survival, but comparative analysis is limited by selection bias, favoring open bypass for good risk and endovascular revascularization for higher risk patients. Tallarita and associates reported long-term survival in a cohort of 343 patients treated for CMI, with nearly identical 5-year survival rates using propensity matched scores for patients treated by open (57%) or endovascular (60%) revascularization.[101] Five-year patient survival averaged 71 ± 4% for low-risk, 49 ± 6% for intermediate-risk, and 38 ± 7% for high-risk patients. Freedom from mesenteric-related death was 91 ± 2% after open and 93 ± 4% after endovascular revascularization at 5 years. Independent predictors of any cause mortality were age greater than 80 years (OR 3.3, CI 1.03-1.06, $P = < .001$), chronic kidney disease stage IV or V (OR 5.5, CI 1.4-16.6, $P < .01$), diabetes (OR 1.7, CI 1.2-2.6, $P < .01$), and home oxygen therapy (OR 3.7, CI 1.2-9.1, $P < .001$). Chronic kidney disease stage IV or V (OR 3.4, CI 3.3-345, $P = .003$) and diabetes (OR 4.2, CI 1.7-10.5, $P = .005$) were independently associated with mesenteric related death. In that study, the most common causes of late death were cardiac events, followed by cancer, respiratory complications, and mesenteric-related complications. The combined rate of early and late mesenteric-related death was 8% for patients treated by open and 6% for those who underwent endovascular revascularization.

Acute arterial mesenteric ischemia (AMI) is a diagnostically and technically challenging disease process with three distinct subtypes—embolic, thrombo-occlusive, and nonocclusive. The first superior mesenteric artery (SMA) embolectomy for AMI was reported by Klass in 1951, who was the first surgeon to focus on the restoration of arterial blood supply in an attempt to salvage acutely ischemic bowel.[1] Several reports were produced over the next two decades, demonstrated increasing success with SMA thromboembolectomy and thromboendarterectomy[2] for the treatment of acute embolic SMA occlusion. Unfortunately, successful outcomes after the treatment of acute thrombotic SMA occlusion remained elusive, with mortality rates as high as 70% to 90%. Early and liberal use of angiography was championed by Boley[3,4] and Clark[5,6] in the early 1970s. With an aggressive approach, including the use of vasodilators, they demonstrated a reduction in the AMI mortality rate to approximately 50%. Mortality has not been significantly improved upon despite major advances in the subsequent years. Most contemporary reviews still report mortality rates between 60% and 80%.[7,8] However, a review of the Nationwide Inpatient Sample (NIS) data from 1988 to 2006 did show an apparent reduction in in-hospital mortality for AMI after 2000, when endovascular techniques became more commonplace.[9] Overall, the treatment for acute mesenteric arterial occlusions still remains traditionally surgical, with intensive medical support, and the addition of limited interventional options for nonocclusive mesenteric ischemia (NOMI). However, there are recent reports of endovascular or hybrid endovascular-surgical treatments for all forms of AMI that can be applied to the treatment of well-selected patients.

INCIDENCE AND RISK FACTORS

AMI is uncommon, accounting for less than 1 of every 1000 hospital admissions.[10] Females are affected up to three times as frequently as males,[9] typically presenting in their 60s to 70s, and often have a number of medical comorbidities. Clinical risk factors often provide clues to the specific pathophysiology. Patients at risk for an SMA embolus include those with a history of atrial fibrillation/flutter, recent myocardial infarction, congestive heart failure, or peripheral arterial emboli. Alternatively, a history consistent with chronic mesenteric ischemia—such as postprandial abdominal pain, weight loss, and food

Abstract

This chapter focuses on the arterial forms of acute mesenteric ischemia (AMI) - embolus, acute thrombotic occlusion and non-occlusive mesenteric ischemia. Diagnosis of AMI can be challenging but must be recognized early and treated aggressively in order to improve patient survival. Dedicated mesenteric CT angiography is the most important imaging modality to confirm the diagnosis and to plan the best revascularization strategy. There are limited percutaneous endovascular approaches that may apply in highly selected patients but more traditional operative exploration with mesenteric embolectomy or bypass is more often required. Retrograde open mesenteric stenting (ROMS) to revascularize the SMA is effective, quick and avoids the need for bypass conduit in the setting of peritoneal soilage.

intolerance—should raise the suspicion of an acute on chronic thrombosis of an SMA stenosis (see Chapter 132). In a national database review, it was found that patients who underwent angioplasty/stenting for AMI had higher rates of comorbidities than those who underwent open surgical repair, including those with hypertension, peripheral vascular disease, coronary artery disease, atrial fibrillation/flutter, and chronic renal failure.[9] In contrast, patients with NOMI are likely to be critically ill, having suffered significant hemodynamic insults in the preceding hours to days. Cardiac surgery and hemodialysis patients are classically at highest risk for NOMI. Overall, the diagnostic algorithm should be tailored to the suspected cause—arterial embolization, arterial thrombosis, or nonocclusive ischemia.

PATHOPHYSIOLOGIC CLASSIFICATION

Arterial Embolism

Arterial embolism is the most common pathophysiology of AMI, accounting for 40% to 50% of cases.[11] Nearly one-third of patients with an SMA embolus have had an antecedent embolic event, most commonly arising from a cardiac source. Atrial tachyarrhythmia, low ejection fraction (congestive heart failure, cardiomyopathy), recent myocardial ischemia or infarction, and ventricular aneurysm are elements that place a patient at risk for a thromboembolic event. There is some speculation, however, that the overall incidence of thromboembolism in patients with atrial fibrillation is declining secondary to better guidelines for and compliance with anticoagulation.[12]

Although less common than a cardiac source, additional consideration should be given to atheroembolic material from a proximal arterial source, such as in instances of a cardiac valvular disease, endocarditis, proximal aneurysm, aortic mural thrombi, or recent catheter-based angiography.[13]

Because of its oblique origin from the visceral aortic segment, the SMA is the most common mesenteric vessel to undergo thromboembolism. Thromboemboli tend to lodge in the proximal SMA, just beyond the first few jejunal branches as the SMA tapers. A minority (15%) may lodge at the SMA origin, but 50% lodge distal to the middle colic artery,[14] creating a classic pattern of ischemia that spares the first portion of the small intestine and the ascending colon (Fig. 133.1). Atheroembolic emboli, in contrast, tend to be smaller and therefore lodge in the more distal mesenteric circulation; as a result, they affect bowel perfusion less often and in more localized areas.

Arterial Thrombosis

Acute arterial thrombosis superimposed on preexisting severe atherosclerotic disease is the next most common cause of AMI, accounting for 25% to 30% of cases.[11,15] Many patients with visceral atherosclerotic disease are asymptomatic prior to a thrombotic event. Autopsy studies have shown that 6% to 10% of people have a greater than 50% stenosis in at least one mesenteric artery; in those with peripheral vascular disease, the incidence may be as high as 27%.[16,17] In these instances, bowel infarction is more insidious in onset because extensive collaterals are able to maintain viability until there is final closure of a critically stenotic vessel or collateral. Consideration must also be given to how vascular collaterals, interrupted by previous abdominal surgery or bowel resection, may affect the region or extent of bowel involvement. Overall, the pattern of infarction, due to the involvement of the SMA from its origin, is more confluent without sparing of the proximal jejunum or right colon.[18,19]

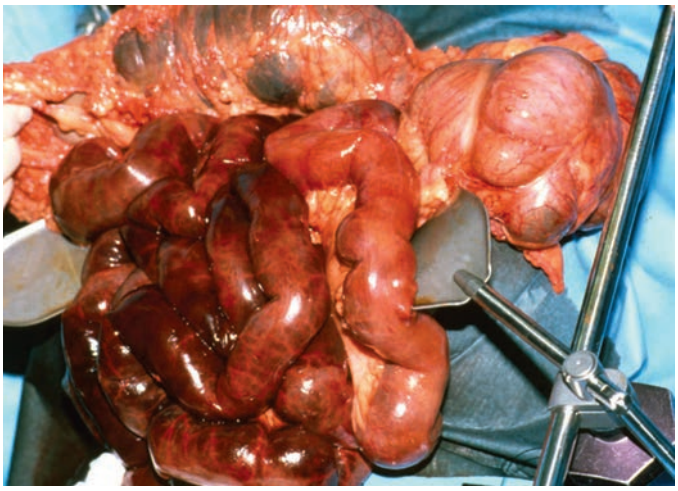

Figure 133.1 Intraoperative photograph of a patient with a superior mesenteric artery embolus. Note the relative sparing of the proximal jejunum and proximal transverse colon. (Courtesy of R. M. Zwolak.)

Acute-on-chronic presentations are not uncommon. Up to 20% of AMI patients have demonstrated a history of chronic mesenteric ischemia, with symptoms of abdominal pain, food avoidance, or weight loss.[17] Even for patients with asymptomatic mesenteric arterial lesions, the natural history of mesenteric occlusive disease is progressive and potentially morbid. In one report, 86% of patients with advanced asymptomatic three-vessel mesenteric atherosclerosis eventually developed abdominal discomfort, frank mesenteric ischemia, or died during a 2.6-year mean follow-up interval.[20] Therefore it is critical to elicit a history of symptoms of chronic mesenteric ischemia to determine if AMI has an acute-on-chronic etiology.

Complications of mesenteric revascularization can also lead to acute mesenteric ischemia. Immediate endovascular failures—including distal embolization, vessel perforation, dissection, stent migration, and thrombosis—result in higher mortality, morbidity, and longer hospital length of stay.[21] In addition, owing to high recurrence rates, both short and long-term follow-up is critical for maintaining the patency of open and especially endovascular revascularized vessels.[9,22,23]

Nonocclusive Mesenteric Ischemia

Mesenteric vasospasm, usually in the distribution of the SMA, is the sine qua non of NOMI. This form of AMI accounts for approximately 20% of presentations and carries the highest mortality rates because of its frequent association with multisystem organ failure.[24,25] Initial descriptions were in postmortem

observations of small intestinal gangrene in patients who had shown no evidence of arterial or venous occlusive disease.[26] Several reports have described this diagnosis in patients with severe cardiac failure, sometimes but not always with concomitant visceral atherosclerosis.[3,14,27-31] These observations formed the basis for the hypothesis that cardiac failure, peripheral hypoxemia, paradoxical splanchnic vasospasm, and reperfusion injury may all contribute to the development of NOMI. Perhaps resulting from excessive sympathetic activity during cardiogenic shock or hypovolemia, the vasospasm represents a homeostatic mechanism that attempts to maintain cardiac and cerebral perfusion at the expense of visceral and peripheral organs. Vasopressin and angiotensin are the likely neurohormonal mediators of this process.[32,33] In the current era, vasoactive medications such as epinephrine, norepinephrine, and vasopressin have also been associated with the development of NOMI.[31-34] Once mesenteric vasospasm is initiated, it may persist even after correction of the initiating event. Although intestinal autoregulation may initially offset reductions in blood flow, the autoregulatory capacity is exceeded after several hours.[30]

The exact mechanism of persistence of vasospasm is unknown, but it plays an important role in the development and maintenance of occlusive and nonocclusive mesenteric ischemia as well as reperfusion phenomena complicating mesenteric revascularization.[35] The degree of ischemia-reperfusion injury appears to be related to the frequency as well as the duration of ischemic episodes. Clark and Gewertz demonstrated that two 15-minute periods of low flow followed by reperfusion resulted in more severe histologic injury than a single 30-minute period of ischemia.[36] NOMI results in an analogous scenario, whereby hypoperfusion may be partial and occasionally repetitive. Episodic reperfusion is thought to prime the ischemic tissue with leukocytes that are attracted to and produce reactive oxygen species.[37] This concept is supported by studies demonstrating attenuation of ischemia-reperfusion injury by reperfusion with leukopenic blood or blockade of endothelial cell surface receptors for leukocyte adherence.[38,39] Reports of NOMI after elective mesenteric revascularization further support reperfusion injury in the pathogenesis of NOMI.[35]

FINAL COMMON PATHWAY OF BOWEL ISCHEMIA

The degree of reduction in blood flow that the bowel can tolerate without permanent cellular damage is remarkable. Only one-fifth of the mesenteric capillaries are open at any given time, and normal oxygen consumption can be maintained with only 20% of maximal blood flow.[40] Proposed mechanisms that result in the preservation of splanchnic tissue perfusion include direct arteriolar smooth muscle relaxation and a metabolic response to adenosine and other metabolites of mucosal ischemia.[41] In addition, the intestinal mucosa is able to extract increasing amounts of oxygen during hypoperfusion[42] to preserve mucosal integrity during periods of metabolic insult. Prolonged ischemia, whatever the pathophysiologic cause, leads to disruption of the intestinal mucosal barrier, primarily through the actions of reactive oxygen metabolites and polymorphonuclear neutrophils.[8] The mucosal surfaces are affected first because the mucosal metabolic demand is much higher than that of the serosa. Clinically, this may present with malabsorption and heme-positive diarrhea before the onset of other symptoms.

DIAGNOSTIC EVALUATION

The pathologic causes of abdominal pain and tenderness in the elderly population fluctuate; all too frequently, AMI is not included in the initial differential diagnosis. Delays in diagnosis and treatment remain the greatest challenge to reducing morbidity and mortality for all forms of AMI.[43] It has been shown that survival decreases from approximately 50% to 30% when the diagnosis of SMA embolism is made more than 24 hours after the onset of symptoms.[14] More recent reviews suggested that only one-third of AMI patients were correctly identified before surgical exploration or death.[44,45] Bowel necrosis is probably the best indicator that there has been a delay in diagnosis; together with advanced patient age, this has been linked to higher mortality rates.[9,43] A high index of suspicion in the setting of a compatible history and physical examination serves as a cornerstone of prompt treatment. Once AMI is suspected, the clinician should quickly move to appropriate testing to confirm the diagnosis, keeping in mind that the best first "test" may be an operation.

There has been a developing paradigm shift in the diagnostic algorithm for AMI. Older models[4,46] advocated early and aggressive use of diagnostic arteriography, although computed tomographic angiography (CTA) has supplanted this when AMI is suspected. With nearly universal 24-hour access to high-resolution CTA, the diagnosis of SMA embolus or thrombotic occlusion can be confirmed, with a simultaneous evaluation of the intestine that may help support or refute the diagnosis. Nevertheless, angiography still plays an important role in the diagnosis and treatment of AMI, especially with the growing number of endovascular treatments or adjuncts now available. Streamlined diagnosis and treatment are now increasingly performed in an operating room environment, allowing general and vascular surgeons to work together to provide definitive treatment while saving precious time.

Clinical Presentation

The signs and symptoms of AMI can easily be mistaken for other, more common intra-abdominal pathologies such as pancreatitis, cholecystitis, appendicitis, diverticulitis, or bowel obstruction. The classic symptomology of "pain of out proportion to exam" for early mesenteric ischemia may be absent in 20% to 25% of cases, depending on the cause and timing of presentation.[24] Until transmural ischemia has developed, there is relatively little peritoneal irritation, thus minimizing tenderness to palpation. For patients who present with SMA embolism, the onset is more abrupt and without a prodrome, progressing rapidly with clinical decline because of the lack of established collateral circulation. Occasionally, there may be a sudden and forceful bowel evacuation shortly after the onset of pain.[1]

In contrast, with SMA thrombosis there can be a more intermediate rate of progression as a result of developed collaterals. The subacute presentation may start weeks or days before the final acute insult that prompts the patient to seek medical attention. Patients may have abdominal pain, distention, diarrhea, acidosis, sepsis, or gastrointestinal bleeding singly or in combination.

NOMI patients can have the most insidious onset, with a protracted clinical course. Because they are already critically ill and frequently in a hospital critical care setting, they are least able to offer any history. The pain associated with NOMI can be variable in location as well as in character and often difficult to ascertain based on sedation related to their critical illness.

Laboratory Evaluation

The most useful laboratory studies for mesenteric ischemia are those that assess fluid status, electrolyte and acid-base imbalances, as well as signs of infection. Due to poor oral intake and fluid sequestration, patients are often acidotic and dehydrated on presentation, reflected by laboratory abnormalities such as hemoconcentration, leukocytosis, and a high anion gap. Lactic acidosis demonstrates severe and sometimes irreversible bowel injury; ideally identification and intervention will have occurred before this develops. High amylase, aspartate aminotransferase, and lactate dehydrogenase can also be observed, yet all are insensitive and nonspecific for the diagnosis of mesenteric ischemia.[47,48] Elevated D-dimer levels have been shown in rat models of AMI as well as in AMI patients who presented within 24 hours of the onset of symptoms, in contrast to patients with inflammatory conditions or bowel obstruction.[44,49] No patient with a D-dimer concentration of 0.3 μg/mL (1.6 nmol/L) or less had acute SMA occlusion, suggesting this as a possible exclusionary test.[44] More recent investigations of urinary and plasma intestinal fatty acid–binding protein (iFABP) levels holds promise as a diagnostic test for AMI.[50-52] First discovered in rodents, the human homologue was found to be elevated in cases of documented bowel infarction.[53,54] Elevated plasma and especially urinary levels of intestinal FABP, liver FABP, and ileal bile acid binding protein (I-BABP) were demonstrated in patients diagnosed with intestinal ischemia. In a small series of 50 consecutive patients suspected of AMI, Acosta[50] correlated intestinal FABP, liver FABP, and I-BABP levels with clinical findings. Of the 50 patients, 22 were confirmed to have AMI; in these patients, all three levels were elevated. Furthermore, urinary I-BABP was elevated specifically when the ileum was involved, allowing for localization. Overall, the test was rapid and potentially useful for early diagnosis of intestinal ischemia.[50] However, it has yet to be routinely used in clinical practice as a diagnostic tool for AMI.

Diagnostic Imaging

Abdominal Plain Radiographs

Abdominal plain radiographs are normal in up to 25% of patients with AMI.[55] However, ileus may be an early finding consistent with mesenteric ischemia, and advanced cases of intestinal ischemia may show evidence of bowel wall edema ("thumbprinting") or pneumatosis. Plain abdominal radiography is most useful in excluding other causes of abdominal pain such as bowel obstruction or perforation.

Duplex Ultrasonography

Duplex ultrasonography accurately identifies high-grade stenoses of the celiac artery and SMA but may miss an SMA embolus that is lodged beyond the proximal segment. It is the noninvasive diagnostic study of choice in the workup of chronic mesenteric ischemia. However, it has little to no role in the diagnosis of AMI and can delay treatment. Many hospitals do not have ready access to such specialized vascular laboratory testing, especially during off hours, and it is highly technologist-dependent. In addition, the presence of intestinal gas—which is the rule in any nonfasting patient and especially someone suspected of having AMI—can easily obscure visualization of the mesenteric vessels. Finally, any abdominal tenderness compromises the study and only adds to the patient's discomfort.

Computed Tomography

The use of ultrafast multidetector CTA (MDCTA) for the evaluation of both acute and chronic mesenteric ischemia is well described.[56-59] The widespread availability of the newest generation of CT scanners has advanced the diagnostic algorithm for AMI, providing a significant amount of information about the central arterial and venous circulations. Accurate timing of contrast injection and fine slices through the upper abdomen usually provide excellent visualization of the celiac artery and SMA (Figs. 133.2A-E and 133.3). Main branches of the celiac artery and SMA are also seen remarkably well using MDCTA because of thinner collimation (0.5-1.5 mm) and overlapping data acquisition. This reduces the amount of volume averaging and creates higher-quality three-dimensional (3D) volume sets for reformatting and interpretation.

CT also excludes or identifies alternate causes of abdominal pain and can assess bowel perfusion to some extent. The timing of intravenous contrast administration is tailored to the specific clinical question but most often is ordered as early arterial phase, as would be any CT angiographic protocol. The use of traditional oral "positive" contrast agents detracts from image quality; instead, a visceral CTA protocol should include the use of a "negative" oral contrast agent such as water (500-750 mL) given immediately before the scan. This prevents image artifact from pooled areas of high opacification within the intestinal tract and also enhances the ability to see bowel wall enhancement (or the lack thereof) in the late arterial phase of the arterial contrast bolus.[55] Biphasic CT, which includes an arterial phase and a delayed phase, can improve sensitivity in order to detect early findings of AMI by allowing time-based visualization of the portal venous system and bowel wall perfusion. Therefore a single scan can identify arterial occlusions as well as findings that support the diagnosis of AMI, such as changes in bowel wall thickness, pneumatosis, and mucosal or bowel wall enhancement patterns (Fig. 133.4A-C). Kirkpatrick and coworkers[60] sought to improve on a previous retrospective report that used single-detector

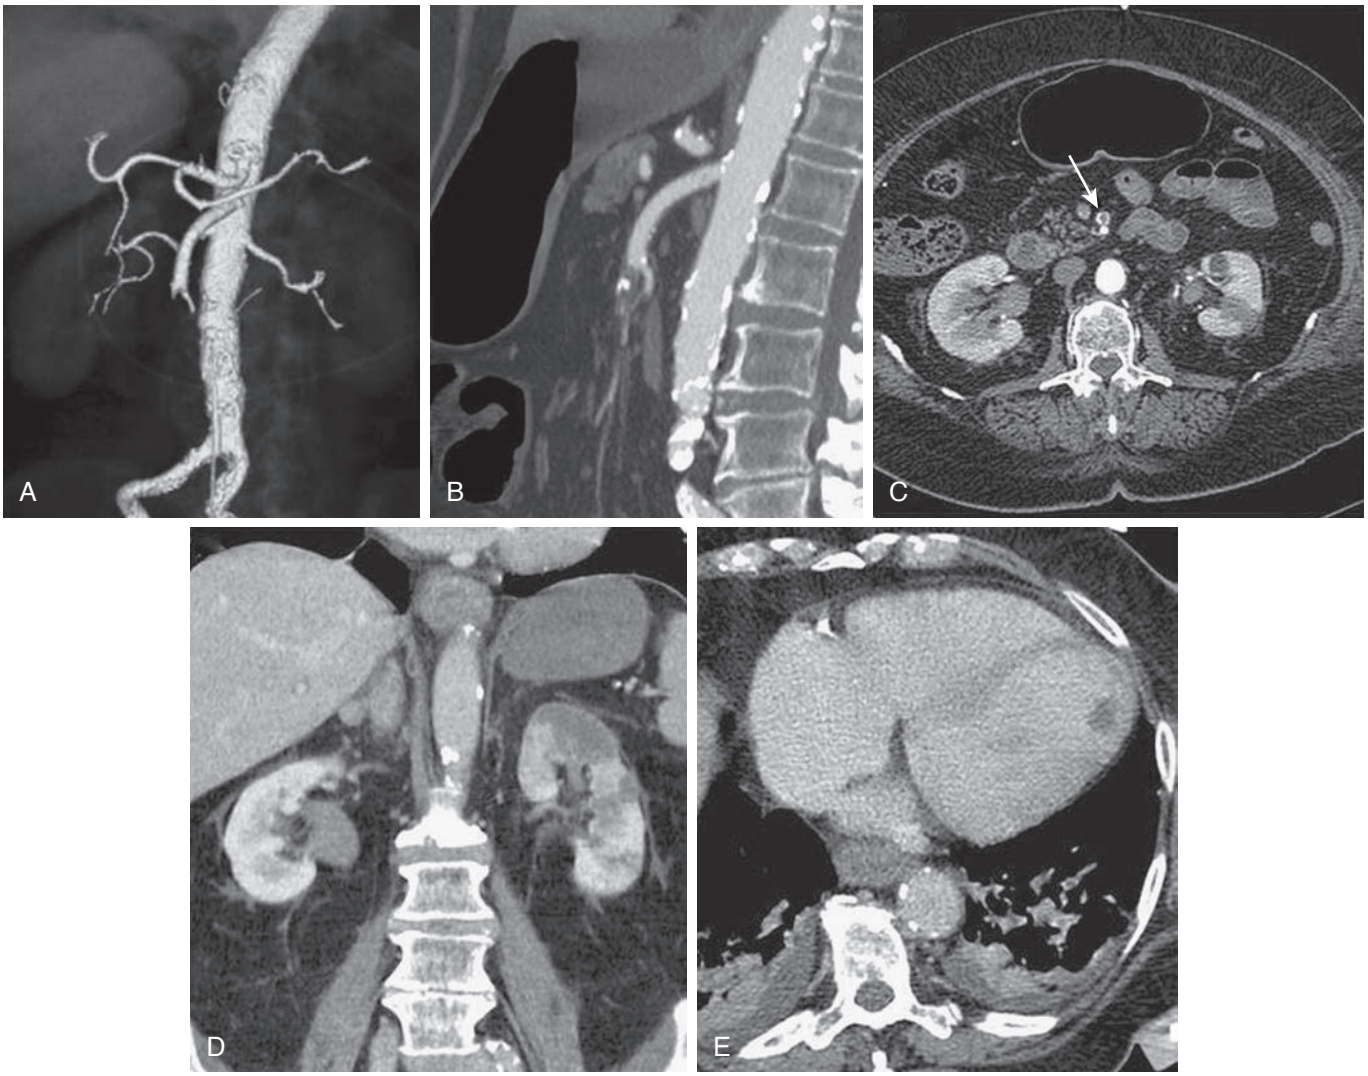

Figure 133.2 (A) Three-dimensional volume rendering of arterial-phase multidetector computed tomographic angiography (MDCTA) shows an abrupt mid-superior mesenteric artery (SMA) occlusion consistent with embolus. (B) Sagittal multiplanar reformat shows the same occlusion. (C) SMA occlusion seen on an axial CTA slice *(arrow)*. (D) Coronal multiplanar reformat reveals left kidney infarction. (E) Transverse portal venous-phase MDCTA depicts thrombus in the left ventricle as the likely embolic source. (From Aschoff AJ, Stuber G, Becker BW, et al. Evaluation of acute mesenteric ischemia: accuracy of biphasic mesenteric multi-detector CT angiography. *Abdom Imaging*. 2009;34:345–357.)

helical CT.[61] A total of 62 patients suspected of having AMI underwent biphasic MDCTA and were evaluated prospectively. As in the previous study, no single CT finding was both sensitive and specific (Table 133.1). However, 26 patients had AMI confirmed at surgical exploration or based on pathologic examination, and all of these had been correctly identified by the interpreting radiologist as having AMI. An additional four scans interpreted as demonstrating AMI turned out to be false-positives, with the ultimate diagnosis of Crohn disease (2), neutropenic enterocolitis (1), and infectious enterocolitis (1). Thus, the initial interpretation had a sensitivity of 100% and a specificity of 89% for the diagnosis of AMI. In the same study, CTA visualization was judged to be satisfactory in all cases up to second-order branches of both the celiac artery and the SMA. Angiography was available in only three patients but correlated well with the CTA findings. In a more recent retrospective chart review using similar MDCTA protocols and even higher-resolution CT, Aschoff and associates were able to duplicate Kirkpatrick's findings in terms of overall accuracy.[62] Again, no one CT finding was perfectly sensitive or specific for AMI, but using a combination of CT criteria (pneumatosis, bowel edema, other solid-organ infarction) to generate an overall impression, these authors were able to achieve positive and negative predictive values of 100% and 96%, respectively.

Arteriography

Although traditional catheter-based arteriography (Fig. 133.5) has been replaced by MDCTA as the definitive diagnostic study for occlusive forms of AMI, patients with strongly suspected NOMI may still benefit from a more traditional angiographic approach as long as there is no immediate need for exploration

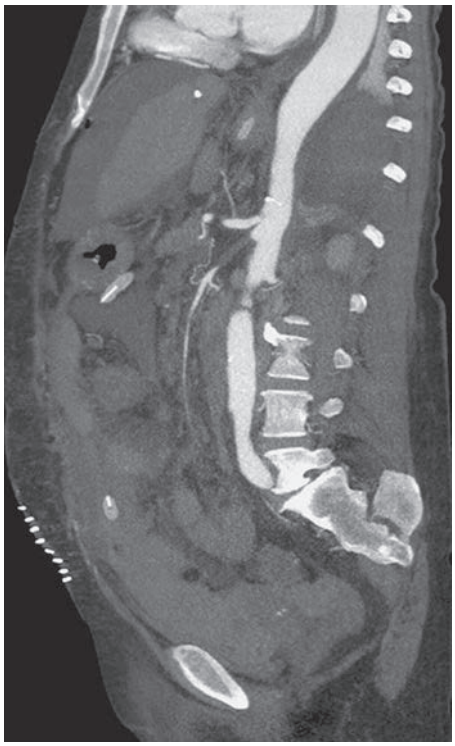

Figure 133.3 Computed tomographic angiography sagittal multiplanar reformat shows an acute thrombotic occlusion of the proximal superior mesenteric artery. Bowel resection was performed 3 days before this image was obtained. The concomitant celiac stenosis suggests an acute-on-chronic presentation of acute mesenteric ischemia. (From Aschoff AJ, Stuber G, Becker BW, et al. Evaluation of acute mesenteric ischemia: accuracy of biphasic mesenteric multi-detector CT angiography. *Abdom Imaging*. 2009;34:345–357.)

based on the overall clinical presentation. Arteriography's role in the therapy of all forms of AMI, however, has been strengthened. It offers several complementary or stand-alone treatment options depending on the specific pathology, including injection of intra-arterial vasodilators,[63] thrombolysis,[64] and angioplasty with or without stenting (see further on).[65] As vascular surgeons become accomplished interventionalists with better intraoperative imaging options, the confirmatory diagnostic arteriogram can be followed immediately by the most appropriate and definitive revascularization option (bypass, endovascular, or hybrid approach) combined with abdominal exploration if required by the patient's clinical presentation.

Magnetic Resonance Angiography

MRI can incorporate both functional and anatomic evaluations of the mesenteric vasculature, which holds promise for the diagnosis of chronic mesenteric ischemia.[66,67] Gadolinium-enhanced magnetic resonance angiography (MRA) is theoretically appealing because it is noninvasive and avoids the risk of allergic reaction and nephrotoxicity associated with iodinated contrast agents. However, MRA is too lengthy a study, requires too much postprocessing, and is not as readily available for the emergency evaluation of these critically ill patients. In addition, the secondary signs of AMI, such as indurated fat or bowel wall thickening, which are routinely delineated by CT, are more difficult to assess with MRA.

Diagnostic Laparoscopy

Laparoscopy in the setting of AMI has limited ability to assess bowel viability. Serosal color can be difficult to judge, and segmental ischemia can be missed because of the difficulty in "running" the bowel along its entire length and over all surfaces. To increase the sensitivity of diagnostic laparoscopy, some authors have successfully used fluorescein with a laparoscopic ultraviolet light.[68-70] Nevertheless, diagnostic laparoscopy for this indication has not been widely accepted[71] because it may still miss areas of nonviable bowel.

TREATMENT

Initial Resuscitation and Critical Care

Fluid resuscitation of a patient with AMI should begin immediately with isotonic crystalloid solution and then continue with blood, if necessary. Electrolyte imbalances should be monitored and corrected. Invasive monitoring (hourly urine output, continuous central pressure, and arterial pressure monitoring) is indicated to ensure that all parameters are optimized before intravenous contrast administration or operative exploration. Broad-spectrum antibiotics should be given to guard against translocated bacteria and sepsis. If there are no contraindications, intravenous heparin should also be administered to maintain a partial thromboplastin time greater than twice normal.

The presentation of sepsis and organ dysfunction in these patients is common; for the most part, these disorders are managed as they would be in other situations. Vasopressors, however, may worsen ischemia in marginally viable bowel and exacerbate visceral

vasospasm. Before the initiation of any vasopressor, volume resuscitation must be confirmed by the presence of adequate right heart filling pressures. Because of the large and ongoing fluid sequestration in these patients, massive 24-hour crystalloid requirements are not uncommon. When necessary, better vasopressor options include low- to mid-dose dopamine (3-8 μg/kg per minute) and epinephrine (0.05-0.10 μg/kg per minute). Pure alpha-adrenergic agents should be avoided if possible, even after successful revascularization.[8]

Treatment of Nonocclusive Mesenteric Ischemia

NOMI accounts for more than 10% to 20% of cases of acute mesenteric circulatory disorders and leads to extensive irreversible intestinal necrosis. The prognosis is poor despite the absence of organic obstruction in the principal arteries. The primary treatment for NOMI is medical, with extensive critical care support and prompt arteriography. Operative exploration is reserved for signs of peritonitis that suggest the presence of gangrenous bowel that requires resection.

Boley and coworkers reported favorable mortality rates of 40% to 50% with the aggressive use of intra-arterial vasodilators; they suggested that the extent of bowel resection during laparotomy (whatever the cause of ischemia) could be significantly reduced if vasodilation were performed preoperatively.[4] Interventional therapies are targeted at relieving vasospasm using intra-arterial infusions of vasodilator medications (Fig. 133.6A and B). The angiographic appearance of NOMI can be subtle, but four reliable arteriographic criteria have been described for the diagnosis of mesenteric vasospasm: (1) narrowing of the origins of multiple branches of the SMA, (2) alternate dilation and narrowing of the intestinal branches—the "string of sausages" sign (Fig. 133.7), (3) spasm of the mesenteric arcades, and (4) impaired filling of the intramural vessels (Fig. 133.8A and B).[72] Once the angiographic diagnosis of NOMI is made and other causes of acute abdomen are excluded, directed intra-arterial vasodilators are infused and often continued for several days as long as the patient's condition remains stable or until there is improvement. The most common intra-arterial agent used in the majority of reports is the phosphodiesterase inhibitor papaverine[19,73,74] initiated at a dose of 30 to 60 mg/h, but there are reports of prostaglandin analogues[75] that also lead to improvement. Because papaverine is metabolized primarily in the liver, hypotension is uncommon as long as the catheter remains in the SMA; but careful monitoring of the blood pressure, heart rate, and rhythm is appropriate. If a sudden decrease in blood pressure is noted, saline should be substituted for the papaverine infusion and a plain abdominal radiograph should be obtained to confirm the position of the catheter. Finally, heparin sodium is chemically incompatible with papaverine and should not be infused simultaneously through the same catheter. In the case of resolved abdominal symptoms, a second arteriogram is advisable before the cessation of papaverine unless the risk of contrast nephropathy precludes it (see Fig. 133.6B).

Surgical Treatment

Surgical exploration is required for all patients who have evidence of any threatened bowel regardless of the underlying cause. The

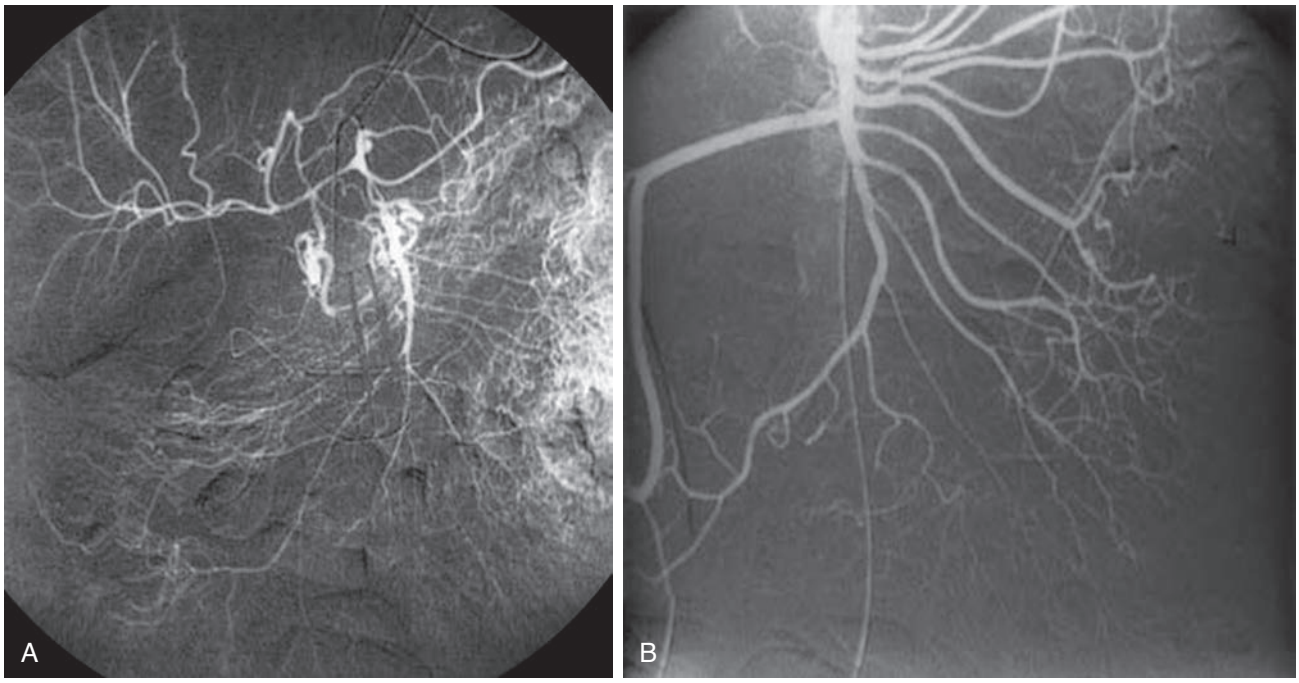

Figure 133.6 Arteriogram With Selective Superior Mesenteric Artery (SMA) Injections. (A) Severe SMA vasospasm with narrowing of all SMA branches. Intramural vessels are not seen owing to severe ischemia. (B) There is significant improvement after several hours of vasodilator administration. (From Trompeter M. Non-occlusive mesenteric ischemia: etiology, diagnosis, and interventional therapy. *Eur Radiol.* 2002;12:1179–1187.)

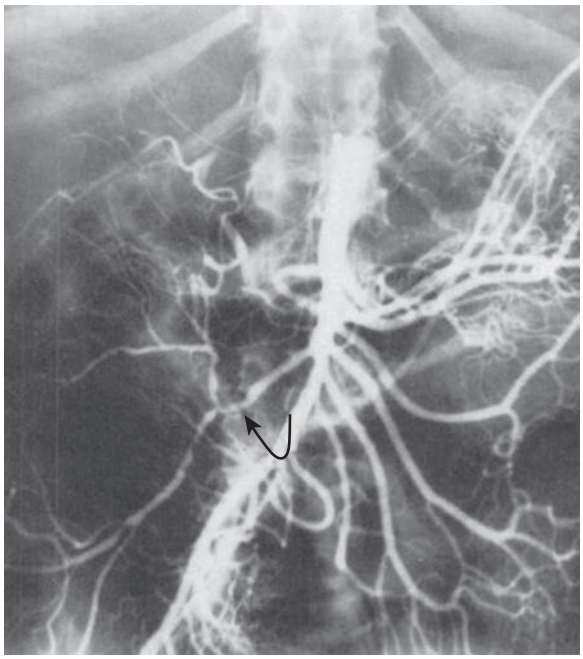

Figure 133.7 Selective superior mesenteric artery arteriogram in a patient with nonocclusive mesenteric ischemia. Note the "string of sausages" appearance of some of the ileocolic branches *(arrow)*. (From Clark RA, Colley DP, Jacobson ED, et al. Superior mesenteric angiography and blood flow measurement following intra-arterial injection of prostaglandin E1. *Radiology*. 1980;134:327–333.)

intraoperative appearance of the bowel can be deceiving. Bowel that is nearing irreversible necrosis can be deceptively normal in appearance; conversely, bowel that appears severely ischemic may be viable after revascularization. Thus the surgeon should in all cases proceed with revascularization before resecting any intestine unless faced with an area of frank necrosis or perforation and peritoneal soilage. In this case, resection of the affected bowel without reanastomosis and with containment of the spillage should be achieved rapidly before revascularization. Only in a very few patients—those who are already in extremis and present with massive bowel necrosis—can revascularization ethically be withheld. Preparation and draping of all patients undergoing laparotomy for presumed AMI should include both lower extremities at least to the knee to allow the harvest of saphenous or femoral vein for bypass.

The abdomen is best explored via a vertical midline incision (Fig. 133.9A and B). There are two variations in the technique for exposing the SMA below the pancreas. Selection between the two is based on the surgeon's level of confidence regarding the need for simple embolectomy or more complex arterial repair with or without bypass. In the case of a confirmed embolus and a more normal-appearing SMA, the artery can be approached anteriorly at the base of the transverse mesocolon without formal mobilization of the fourth portion of the duodenum or ligament of Treitz. If the SMA is diseased or thrombosis is the cause, a more lateral approach to the SMA above the fourth portion of the duodenum is preferred so as to facilitate a retrograde bypass

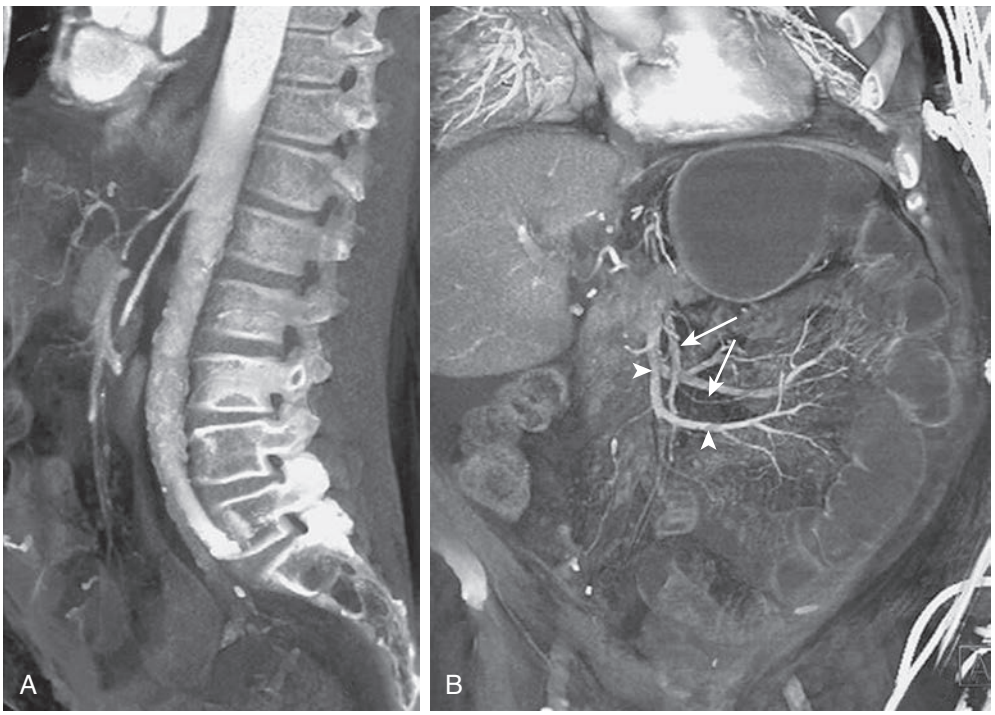

Figure 133.8 Computed Tomographic Angiography Appearance of Nonocclusive Mesenteric Ischemia. if necessary (see Figs. 133.9A and B and 133.10A-F) (see Chapter 54).

Superior Mesenteric Artery Embolectomy

Anterior exposure of the SMA for straightforward embolectomy is achieved by elevating the omentum and transverse colon; the small intestine is wrapped in moist laparotomy pads and retracted to the right. A horizontal incision is made in the peritoneum at the base of the transverse mesocolon (see Fig. 133.9B, *dotted line*). Careful dissection in the mesentery initially uncovers venous tributaries of the superior mesenteric vein, autonomic nerve fibers, and small lymphatics that are divided to gain exposure of the SMA. The SMA lies to the left of the superior mesenteric vein and can be fragile. Exposure of the more proximal segments is possible by judicious mobilization of the inferior pancreatic border (exercising caution to minimize trauma to the pancreas), the nearby splenic vein, and its tributaries from the pancreas.

A segment of the proximal SMA between the middle and right colic branches is isolated. Near circumferential dissection is frequently required to isolate and control any of the jejunal branches in this segment. After systemic heparinization, the artery is opened transversely (Fig. 133.11) in a segment of sufficient diameter to allow direct repair. For diminutive vessels, a short longitudinal arteriotomy with patch closure may be considered. The proximal SMA is vented to allow any clot to be expelled without the use of an embolectomy catheter if possible. When necessary, catheter embolectomy is typically performed with a 3- or 4-Fr balloon catheter. With extraction of the embolus, torrential, pulsatile inflow should be expected.

Distally, a smaller embolectomy catheter, typically 2 or 3 Fr, is employed. Great care must be taken to avoid damaging or rupturing the fragile ileocolic and jejunal arteries. Difficulty passing a catheter down multiple small branches adds to the complexity of the distal embolectomy. An alternative or adjunct to balloon embolectomy of the distal mesenteric vessels is for the surgeon to place a hand on either side of the mesentery and "milk" thrombotic material out of the vessels. After all macroscopic clot is cleared, consideration can also be given to the administration of a small one-time dose of a thrombolytic agent (recombinant tissue plasminogen activator or urokinase) into the distal vessels. When all thrombus has been removed, the arteriotomy is closed primarily with interrupted sutures or with a vein patch and flow is reestablished.

Superior Mesenteric Artery Bypass

As mentioned previously, when bypass is considered, the lateral portion of the SMA is exposed, rather than the more limited exposure provided by a strictly anterior approach. The peritoneum is opened lateral to the duodenum, down over the aorta, and onto the left or right common iliac artery (see Fig. 133.9B, *dashed line*). Several combinations of graft orientation and conduit are available. The decision is influenced largely by the suitability of potential inflow vessels for a proximal anastomosis and by the presence or absence of peritoneal soilage, respectively. In the emergent setting, a single bypass to the SMA is all that is required. The preference for two-vessel revascularization,[76] which most surgeons espouse in the performance of elective bypass for chronic symptoms, does not apply.

Graft orientation is influenced mainly by the degree of atherosclerosis and occlusive disease present in the inflow vessels and by the overall lie of the graft. Given the choice, most surgeons prefer a retrograde graft orientation with its origin from the right common iliac artery in a "lazy C" configuration (Fig. 133.12A-C). This avoids any aortic clamping and usually provides a good lie to prevent kinking. Second-choice inflow sources for retrograde bypasses involve similar lazy-C grafts from the left iliac artery or distal infrarenal aorta. With any of these configurations the graft lie tends to be improved by increasing the graft length slightly and performing an end-to-end graft-to-SMA anastomosis, as pictured in Fig. 133.10C to E. Alternatively, a very short retrograde bypass using a larger-diameter graft (8-10 mm) can be configured from the immediately infrarenal aorta (Fig. 133.13), but the potential for kinking with shorter grafts can be more difficult to anticipate until all the retractors are removed. When distal inflow sources are unclampable, heavily diseased, or aneurysmal, an antegrade bypass can be considered. Advantages of the antegrade bypass include the fact that the supraceliac aorta is often relatively free of disease and that the straighter graft orientation is less prone to kinking. Dissection of the supraceliac aorta is technically more demanding, however; it requires more time and adds a hemodynamically and physiologically stressful aortic cross-clamp if a partially occluding clamp is not possible.

(F) Patch closure of the SMA. (From Kazmers A. Operative management of acute mesenteric ischemia. *Ann Vasc Surg*. 1998;12:187–197.)

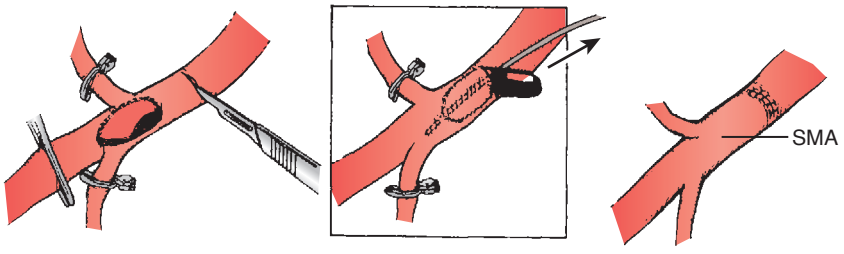

Figure 133.11 Traditional transverse arteriotomy for superior mesenteric artery (SMA) embolectomy. (From Kazmers A. Operative management of acute mesenteric ischemia. *Ann Vasc Surg*. 1998;12:187–197.)

Synthetic bypass grafts of 6- to 8-mm Dacron or externally supported polytetrafluoroethylene are preferred because of the better size match, ease of handling, availability, kink resistance, and general perception that long-term patency is better. The superior patency of prosthetic mesenteric bypasses, however, is not well documented. Therefore the choice of conduit is heavily influenced by the degree of abdominal contamination and the perceived risk of subsequent graft infection. The actual rate of mesenteric graft infection is not known with certainty, but when present, it is potentially catastrophic and likely to involve virulent organisms. Therefore rifampin-soaked Dacron could be used. However, if good-quality vein is available, it is preferred in the presence of significant peritoneal soilage. Great saphenous vein and thigh femoral vein are the primary options. Modrall and colleagues have reported that symptomatic recurrences were less common in patients bypassed with femoral vein compared with great saphenous vein conduit.[77] In practice, however, the additional time and expertise required to harvest a deep leg vein is too much to consider in such critically ill patients. Great caution must be used in fashioning vein grafts because their smaller diameter and thin-walled nature make them more prone to kinking and external compression than synthetic grafts. When

the use of a prosthetic graft is unavoidable, Kazmers and colleagues illustrate a useful technique to provide coverage of a retrograde bypass by bringing an omental flap through the transverse mesocolon (Fig. 133.14A-C).[78]

Assessment of Bowel Viability

After revascularization has been accomplished, the viability of the bowel must be reassessed. If possible, before making a decision about viability, 20 to 30 minutes of reperfusion time should be permitted while retractors are being repositioned.[78] The initial clinical evaluation of the bowel consists of assessment for visible and palpable pulsations in the mesenteric arcade, normal color and appearance of the bowel serosa, peristalsis, and bleeding from cut surfaces. Each of these is subjective and prone to inaccuracy; with the use of clinical criteria alone, bowel viability can be successfully determined with a sensitivity of only 82% and a specificity of 91%.[79]

Wright and Hobson reported that absence of pulsatile signals on the antimesenteric border of the intestine as detected with a continuous wave 9- to 10-MHz Doppler ultrasound probe implies a nonviable segment.[80] The clinical practicality of this technique combined with surgical judgment has been demonstrated in multiple studies.[79,81,82] As a stand-alone method of determining intestinal viability, however, Doppler assessment has limitations because it may miss weak signals in small vasoconstricted vessels in otherwise viable bowel.[83] Other adjunctive methods of assessing bowel viability have been proposed. Highly accurate quantification of perfusion is possible using fluorescein and a perfusion fluorometer[84] or a laser Doppler flowmeter,[85] but special equipment requirements and technical considerations make this less practical for routine clinical use. Whitehill and associates found that Doppler ultrasound evaluation, photoplethysmography, and fluorescein injection may be too sensitive in some cases for an accurate determination of bowel viability, yielding false-positive results by detecting levels of flow below those needed to sustain tissue viability.[86]

Ultimately, accurate determination of intestinal viability is the product of clinical judgment and timely reevaluation, with the goal of preserving as much bowel length as possible. The option of deferring extensive bowel resection and reanastomosis underscores the fundamental importance of a mandatory second-look procedure.

Endovascular Treatment

Superior Mesenteric Artery Embolization

As acute arterial occlusion caused by thromboembolization rapidly progresses to bowel necrosis and the incipient downward spiral that frequently results in death, restoration of flow must be accomplished within a few hours. Based on this, one would suspect that thrombolysis takes too long to achieve timely revascularization. Nevertheless, there are increasing numbers of reports of successful percutaneous endovascular procedures using mechanical and chemical thrombectomies.[87-97] However, these reports should be interpreted with caution, as it is difficult to determine technical failure rates from single-center case reports, which by their nature focus on positive results.

In the case of an SMA embolus, if endovascular lysis was more broadly applied, the failure rate would not compare favorably with open mesenteric thrombectomy. Wang and coworkers have offered a retrospective report of 7 patients with SMA emboli who were treated with catheter-based thrombolysis, which was successful in only 4 cases.[98] Despite a shorter time to diagnosis and initiation of treatment in the lysis group compared with a similar cohort of 9 surgically treated patients, there was no survival difference. However, even when technically successful, percutaneous catheter thrombectomy and certainly chemical thrombolysis can be very time-consuming compared with a straightforward open embolectomy.

Raupach et al. recently reported a retrospective single-center 12-year experience of 37 patients who all underwent primary endovascular therapy for acute SMA embolism with subsequent on-demand laparotomy (73%). With a 92% technical success rate, they reported that 40% required bowel resection and there was an overall 27% in-hospital mortality.[89]

A review of 20 case reports and 7 small series published over a 47-year span for a total of 48 patients[10] reported that only 33% of patients demonstrated total or near-total arteriographic occlusion of the SMA before treatment. Technical resolution of thrombus was achieved in 43 patients, but 18 still required operative exploration for bowel resection, with only one surgical embolectomy required. This review does not give any credence to the use of percutaneous thrombolysis as an efficacious or even safe mode of therapy for acute SMA embolism. It only serves to magnify the enormous publication bias inherent in the literature on this topic.

Another shortcoming of a purely endovascular approach to SMA embolism is the lack of a built-in assessment of bowel viability, which is routine with open embolectomy. Patient mortality is closely associated with bowel necrosis, and when resection is necessary, it cannot be delayed. Therefore a significant weakness of a less invasive intervention is that there is no direct intestinal evaluation. In avoiding abdominal exploration, close monitoring of the patient's overall clinical condition, laboratory markers, and occasionally laparoscopy are substituted. However, these modalities are known to be unreliable.[71]

Superior Mesenteric Artery Thrombosis

Endovascular treatment for mesenteric ischemia has been well described for subacute or chronic presentations, especially in patients at high operative risk or as a bridge to elective surgical bypass after the acute illness has resolved.[99-102] However, it not generally applied to patients with AMI who require emergent revascularization with the potential need for bowel resection. Terminal thrombosis of an atherosclerotic SMA is perhaps the most challenging AMI cohort to treat in endovascular fashion. As described previously, operative bypass to the SMA is traditionally required owing to the extent of disease. A less invasive option for SMA revascularization in these critically ill patients has appeal. But in order to be successful, a percutaneous recanalization is needed of a long-segment occlusion that, unlike with embolic presentations, typically occupies the origin and initial 3 to 6 cm of the SMA.

Therefore endovascular treatments necessitate advanced endovascular skills and, even in the most experienced hands, can take substantial time, which might actually delay revascularization. Nevertheless, a few case reports of percutaneous interventional treatment for AMI have been published.[90-93,95,103] Widespread experience is lacking, and this approach has shortcomings similar to those discussed for the endovascular treatment of SMA embolism. Indeed, our own experience with percutaneous stenting in acutely ischemic patients has been very disappointing in terms of both technical success and patient outcome.[104] This experience led directly to a more efficacious hybrid technique. In our practice, we now reserve percutaneous mesenteric stenting for patients with chronic or subacute presentations who do not require a detailed assessment of bowel viability.

Hybrid Procedure: Retrograde Open Mesenteric Stenting

Wyers et al. have reported a hybrid open-interventional approach for the treatment of acute atherosclerotic SMA thrombosis that involves an efficient, less invasive mesenteric revascularization without compromising important general surgical principles.[104] In fact, the general surgical principles of thorough abdominal exploration, sepsis control, and a low threshold for second-look operations must be honored in order to increase the chances of a favorable outcome. Similar to a technique in an earlier case report by Milner and associates,[105] the authors described retrograde open mesenteric stenting (ROMS) of the SMA in 6 patients. In this ROMS approach, the visceral peritoneum is incised horizontally or longitudinally at the base of the transverse mesocolon, the SMA is controlled, and a local thromboendarterectomy of the SMA is performed if necessary (Fig. 133.15A and B). Placement of a patch angioplasty then facilitates retrograde cannulation of the SMA with a long flexible sheath directed toward the aorta (Fig. 133.16). Because of the superior pushability with sheath access so close to the obstruction, technical success was 100%, even in the five patients who had previous unsuccessful attempts to cross the SMA from a percutaneous antegrade approach. Often, more than one balloon-expandable stent is required to fully treat these SMA lesions, which are typically 3 cm long or longer (Fig. 133.17A-C).

Although derived from a small series with no statistically significant results, the ROMS outcomes were promising. The

ROMS group suffered only 17% in-hospital mortality, compared with 80% among five patients treated with conventional mesenteric bypass. Recurrent stenosis after ROMS, as with all forms of mesenteric stenting,[65,100] occurs frequently and relatively early; therefore, close duplex surveillance for the first month and every 3 months thereafter is recommended. Most patients with recurrent stenosis can be retreated with a percutaneous approach as outpatients. Many of these patients remain poor operative candidates and have limited life expectancies because of comorbidities.[106] In this situation, even repeated SMA dilations are a viable, safe option. For patients who make a good recovery and are nutritionally sound, a more durable operative bypass may be considered.[99] ROMS during emergent laparotomy for AMI is a promising technique and an attractive alternative to emergent surgical bypass.[107]

OTHER CONSIDERATIONS

Spontaneous Visceral Dissection

Spontaneous visceral dissection is a rare vascular pathology. Usually patients present with acute abdominal pain, but there are reports of intestinal angina with weight loss from a chronic dissection, causing lumen compromise. However, with the increasing popularity of CT scans for the investigating abdominal pain combined with technical advances in MDCTA, spontaneous isolated celiac and SMA dissection (SIDSMA) has been reported more frequently in recent years as an incidental finding. Most commonly identified by CT, it can be diagnosed by duplex ultrasound, MRI, and angiography.[108,109] Reported risk factors include hypertension, male gender, atherosclerosis, pregnancy, connective tissue disorders, fibromuscular dysplasia, vasculitis, and trauma; however, a definitive pathologic cause is rarely identified.[110] Spontaneous dissections of the SMA are associated with a broad spectrum of clinical pictures, from asymptomatic incidental findings to acute catastrophic bowel ischemia/infarction or rupture of an aneurysmal SMA. Treatment options

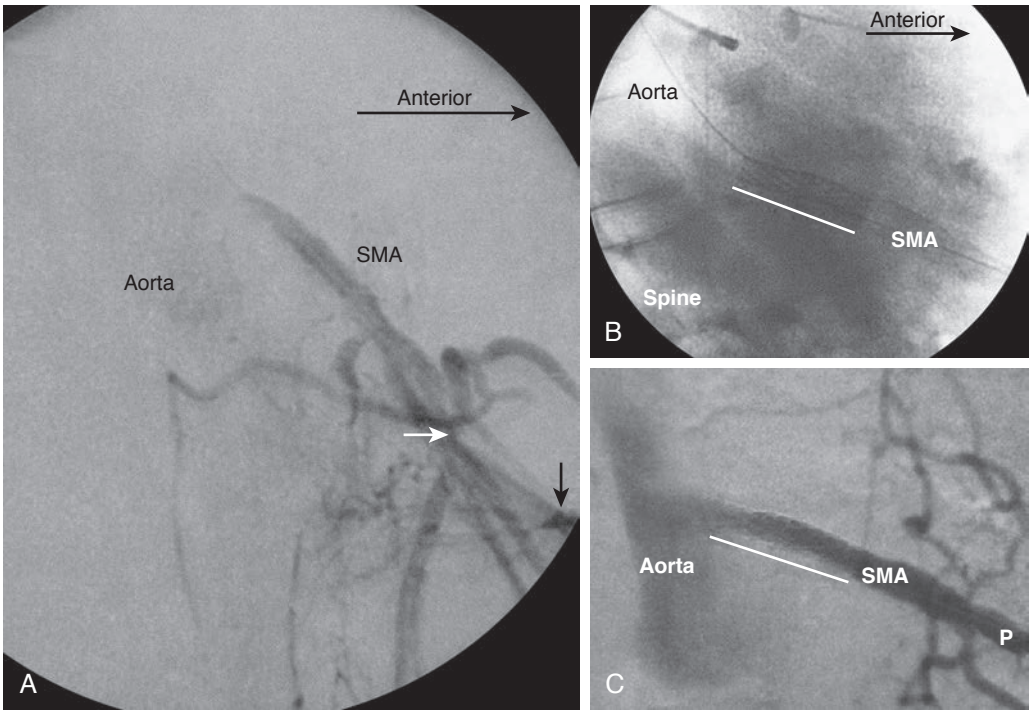

Figure 133.17 Retrograde Open Mesenteric Stenting. (A) Intraoperative arteriogram during retrograde superior mesenteric artery (SMA) injection. Note the proximity of the sheath's point of entry *(black arrow)* and the sheath's tip *(white arrow)* to the proximal SMA occlusion. There is no reflux of contrast material into the aorta. (B) Intraoperative lateral fluoroscopic image of two stents (underscored by a *white line*) deployed in the SMA origin with the 0.018-in wire still in place. range from conservative management, anticoagulation, endovascular stenting, and open surgical repair, although no consensus guidelines exist for management.[111]

Many studies suggest operative intervention for all symptomatic patients, although there are numerous case reports describing successful nonoperative management for both symptomatic and asymptomatic patients.[111,112] Gobble et al.[113] identified 106 articles on SIDSMA and found only 55% (31 of 56) success with expectant management (bowel rest and observation), with an almost 50% mortality identified in those who failed expectant management. This extensive literature search identified the average age at presentation as 54 years, four times more prevalent in men, with approximately half of the patients presenting with aneurysmal degeneration of the SMA. Anticoagulation therapy was successful in 65% of cases (15 of 23), with 7 of the 8 failures salvaged with surgery. Rescue stenting and primary surgical treatment had a 100% success rate, and primary endovascular stenting had 80% success (4 of 5), with rescue stent success for the one case of delayed aneurysmal degeneration. The authors proposed treating symptomatic patients with primary endovascular stenting, the use of anticoagulation for failed stenting, and open surgery for unsuccessful anticoagulation (Fig. 133.18).

Similarly, Min et al.[111] demonstrated only 50% success with expectant management without anticoagulation or antiplatelet therapy, with two failures successfully rescued with endovascular stenting, and 100% successful primary endovascular stenting. The authors recommended endovascular treatment for aneurysms greater than 2.0 cm, concern for bowel ischemia, stenosis greater than 80%, and patients with recurrent or nonresolving abdominal pain.[111]

Finally, a recent retrospective review from our institution, one of the largest patient cohorts in the literature on spontaneous visceral dissection, suggests an overall relatively benign clinical course despite persistent CT findings and supports a nonoperative approach with a short course or anticoagulation followed by lifelong antiplatelet therapy (aspirin) and surveillance for both symptomatic and asymptomatic patients without evidence of mesenteric ischemia or aneurysm (>2.0 cm).[112]

Second-Look Surgery

Even after reperfusion and careful assessment, bowel viability cannot be determined with certainty at the time of initial exploration. The frequency of bowel resection is routinely higher during second-look surgery (53%) compared with the initial exploration and revascularization procedure (31%).[43] The decision to perform this second-look surgery is made at the time of initial operation. This plan is essentially inviolate regardless of the clinical status of the patient. Typically, at the conclusion of the initial procedure, the surgeon leaves transected ends of the intestine stapled shut without reanastomosis. Likewise, if bowel edema is significant,

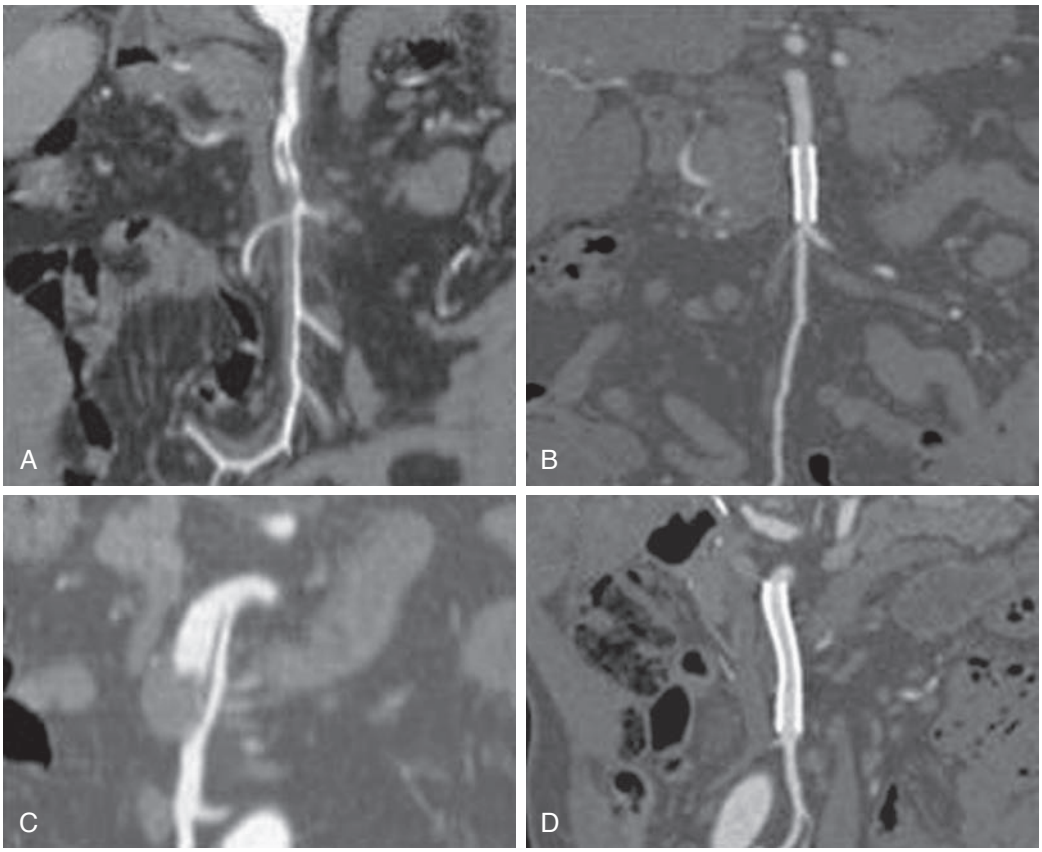

Figure 133.18 Reconstructed Computed Tomography Angiography (CTA) Findings Indicated for Primary Endovascular Stenting. (A) Severe compression of the true lumen and (B) a patent superior mesenteric artery stent and complete obliteration of the false lumen at 60-month follow-up CTA in patient no. 12. (C) Large dissecting aneurysm (20.0 mm in diameter) and (D) near complete disappearance of the aneurysm at 36-month follow-up CT in patient no. 13. (From Min SI, Yoon KC, Min SK, et al. Current strategy for the treatment of symptomatic spontaneous isolated dissection of superior mesenteric artery. *J Vasc Surg*. 2011;54(2):461–466.)

the abdominal fascia can be left open in anticipation of a return to the operating room within the next 48 hours. Certainly if the patient's clinical condition deteriorates at any point, reoperation is immediate. This strategy allows the preservation of as much bowel as possible, resecting only areas of bowel that are clearly nonviable at each procedure. The patient is returned to the operating room 12 to 48 hours later, and the abdomen is reexplored. By this time, the viability of the bowel has usually declared itself, but occasionally a third look is required. This mandatory return protects the patient from ongoing bowel necrosis before irreversible physiologic changes develop and before perforation, which would risk further sepsis, abscess, or graft infection. Mesenteric blood flow is reassessed, and the bowel anastomoses are performed if the condition of the bowel is satisfactory.

Intraoperative Vasodilators

Splanchnic vasospasm may persist for variable periods of time, causing continued bowel ischemia after a successful revascularization.[14,114] Low flow after ischemia can also result from relative hypovolemia, myocardial depression, and sepsis. To treat local vasospasm in the mesenteric arcades, papaverine can be administered selectively in the SMA. Alternatively, intravenous glucagon administration increases cardiac output and flow to all layers of the small and large intestine as well as the liver while inhibiting gastrointestinal motility and secretory function. This has been shown to improve survival in an animal model[115,116] but has not been tested extensively in humans. Glucagon administration should be coupled with additional volume resuscitation to avoid vasodilation-mediated hypotension.

Duplex Follow-Up

Visceral duplex remains technologist-dependent and may not be universally available. However, duplex ultrasound appears to be the most reasonable, cost-effective way to obtain objective data for clinical decision making after various forms of mesenteric revascularization. Large series reports of its use after mesenteric bypass have been lacking. However, Liem and coworkers characterized duplex-derived flow velocities in mesenteric artery bypass grafts for the first time.[117] Postprandial scans demonstrated higher midgraft flows in smaller-diameter (6 mm) grafts and saphenous vein grafts compared with larger-diameter (7 mm) grafts without being affected by graft orientation or inflow source. No duplex scan characteristics were found to predict graft thrombosis.

Restenosis is common and happens early after mesenteric stenting,[65,100] including ROMS patients. Therefore frequent duplex surveillance is required to judge the need for reintervention. Although the published data on Doppler ultrasound of native (unstented) mesenteric arteries is very good,[118-120] the literature that focuses on stented mesenteric vessels is limited. Mesenteric duplex following interventional visceral artery therapy is promising but still empiric, based on an anticipated high rate of restenosis. Absolute velocity thresholds that indicate the need for prompt reintervention have yet to be identified. However, the traditional velocity criteria for native vessels seem to provide reasonably accurate information to guide clinical decision making.

SUMMARY 1778

Spontaneous isolated arterial dissection within the splanchnic circulation without associated aortic dissection is a rare entity, but is being reported with increasing frequency. This most likely reflects improved imaging modalities (particularly abdominal computed tomography [CT]) and increasing awareness of this condition rather than an increasing prevalence. Spontaneous isolated superior mesenteric artery dissection (SISMAD) was first reported by Bauersfeld in 1947.[1] There are currently greater than 622 cases of SISMAD reported in the literature as well as more than 100 cases of spontaneous isolated celiac artery dissection (SICAD) and an assortment of other splanchnic artery dissections.[2,3] Due to the low prevalence of spontaneous isolated visceral artery dissection and the variety of clinical presentations, there is a lack of consensus regarding treatment guidelines.[4] The goal of this chapter is to review the current literature on visceral dissection and help establish the best treatment guidelines for the contemporary vascular surgeon.

INCIDENCE

Spontaneous isolated dissection of the splanchnic arteries is a rare condition. The superior mesenteric artery (SMA) is the most common visceral artery affected, followed by the celiac artery.[5,6] In 1959, Foord reported an incidence 0.06% SISMAD from a cohort of 6666 autopsies.[7] Prior to 2001, only 46 cases of SISMAD were reported. As of 2016, that number has increased to more than 622 cases.[2,8] There is a lower incidence of SICAD with approximately 100 cases reported to date.[9] There are even fewer reports of concomitant SISMAD and SICAD. Garrett et al. reviewed the literature through 2008 and reported 13 concomitant spontaneous isolated visceral artery dissections (SIVADs).[4] Spontaneous isolated dissection of the splenic, hepatic, middle colic, and inferior mesenteric arteries have also been reported.[10–13] Sixty-seven percent to 88% of isolated splanchnic artery dissection have been observed in males.[2,4,10,14–16] Typically, patients present in the fifth to sixth decade of life.[2,4,17,18] Sixty percent to 70% of patients with an aortic dissection present with hypertension; in contrast, only 30% to 40% of patients with isolated splanchnic dissections present with hypertension.[2,4,14,19,20] Although isolated splanchnic dissections have been reported on all continents, the majority of cases have been reported in Korea, China, and Japan, suggesting a genetic predisposition.[4]

ETIOLOGY

There are multiple theories on the etiology of isolated splanchnic artery dissections and the cause may vary between different visceral vessels. Proposed etiologies of SIVAD include connective tissue diseases (Marfan's syndrome, Ehlers-Danlos syndrome, Loeys-Diez syndrome), cystic medial necrosis, segmental arteriole mediolysis, Bechet disease, and fibromuscular dysplasia.[2,4,21–24]

Abstract

Spontaneous isolated arterial dissection within the splanchnic circulation unassociated with aortic dissection is a rare entity, but is being reported with increasing frequency. This most likely reflects improved imaging modalities (particularly abdominal computed tomography) and increasing awareness of this condition rather than an increasing prevalence. Due to the low prevalence of spontaneous isolated visceral artery dissection and the variety of clinical presentations, there is a lack of consensus regarding treatment guidelines. The goal of this chapter is to review the current literature on visceral dissection and help establish the best treatment guidelines for the contemporary vascular surgeon.

Keywords

Spontaneous isolated arterial dissection
Splanchnic artery dissections
Mesenteric artery dissections
Celiac artery dissection
Superior mesenteric artery dissection
Segmental arterial mediolysis

However, the majority of patients with SIVAD do not have any of these arteriopathies. Tobacco use, atherosclerosis, alcohol abuse, obesity, heavy weight lifting, and pregnancy have also been suggested as risk factors for SIVAD.[7,19,25–27]

In the majority of SISMADs, the dissection originates 1 to 3 cm from the SMA ostium.[2,4,6,28–32] At this position, the SMA transitions from a fixed retropancreatic position with an acute turn into a mobile mesenteric root. Hyperdynamic forces occurring at this transition point most likely result in this zone's becoming the origin for most SISMADs.[14] Park et al. conducted flow dynamic studies using computational fluid dynamic models that showed greater shear stress on the anterior convex portion of the SMA just distal to the ostium. These authors suggested that the etiology of SISMAD is more likely due to elevated shear stress at this location in the SMA rather than an underlying connective tissue disease or uncontrolled hypertension.[19] Solies et al. also suggested high shear stress as the etiology of SISMAD due to the 1- to 3-cm origin of SISMAD.[33,34] This theory is analogous to type II aortic dissections originating at the ligamentum arteriosum due to luminal stress at the transition from a fixed to an unfixed point. Another proposed hypothesis is development of primary hemorrhage in the media due to a rupture of the vasa vasorum, which then leads to dissection.[10] Jia et al. have linked chromosome locus 5q13-14, which is associated with familial ascending aortic aneurysms and dissections, with SISMAD.[35]

There is no clear etiology for SICAD.[9,36–38] In theory, the median arcuate ligament may represent a fixed transition point for the origin of celiac dissection. However, DiMusto et al. did not find any evidence of SICAD originating from the median arcuate ligament in their reported series of 19 SICAD.[5]

There are several case reports describing the histologic findings of SIVAD. Common features include fragmentation of elastic fibers, loss of smooth muscle cells, myxoid degeneration, and atheromatous changes. No definitive correlation to arteritis, cystic medial necrosis, or other arteriopathies was identified.[2,14,19] Since most patients with SIVAD are not currently treated with open surgery, fewer specimens are available for histologic examination. However, it appears that only a minority of SIVAD cases are associated with other arteriopathies.

The majority of current published literature on SIVADs comes from east Asian countries. Corrected for population, Korea appears to have the highest number of reports per capita, followed by Japan and then China.[2,19] This suggests, but does not prove, a higher prevalence of SIVAD in Asian populations.

CLINICAL PRESENTATION

SIVAD has a wide range of presentations including an incidental finding, an association with bowel ischemia, or aneurysmal formation with or without rupture. With modern CT and computed tomography angiography (CTA), a larger number of incidental SIVADs have been identified. In some series, as many as one-third of SIVADs are found incidentally.[31,39] Symptomatic SIVAD presents with abdominal pain in 90% of cases. Pain is described as severe and tearing in the mid-epigastric area with occasional radiation to the back. Other potential SIVAD symptoms may include nausea, emesis, melena, and diarrhea.

Abdominal pain out of proportion to physical findings suggests the diagnosis of mesenteric ischemia, which may be a clue to the diagnosis of SIVAD. Without the presence of bowel ischemia, abdominal pain is believed to originate from the visceral nerve plexus due to inflammation from the arterial dissection. It has been suggested that increased length of a SISMAD causes more periarterial inflammation and more severe pain.[14,40,41] Persistent abdominal pain that does not resolve is more likely due to mesenteric ischemia rather than inflammation of neural tissue.[20] Patients with SIVAD have a wide variety of clinical presentations and, thus, multiple treatment algorithms have been proposed. This creates diagnostic and therapeutic management challenges for the clinician.

DIAGNOSIS

There are no specific laboratory tests for SIVAD; however, elevated lactate levels correlate with end organ malperfusion. In patients with SIVAD without mesenteric ischemia, leukocytosis as well as elevated C-reactive protein and/or erythrocyte sedimentation rate may be present.[2]

Prior to 1975, all SIVAD cases were diagnosed by autopsy. The first case of SISMAD was reported in 1947. This patient had a SISMAD originating 2 cm from the SMA ostium that led to bowel infarction and death.[1] The first documented survivor after treatment of SISMAD was reported in 1992, wherein angiography demonstrated the lesion after laparotomy for ischemic bowel.[42] Digital subtraction angiography (DSA) supplanted conventional arteriography by minimizing contrast exposure and providing improved definition of distal mesenteric branch vessels compared to other imaging modalities. However, DSA is a more invasive test with limited ability to identify end organ malperfusion when compared with contrast-enhanced CT.[10]

CTA and contrasted-enhanced CT are now used to diagnose more than 95% of contemporary cases of SIVAD. Less commonly used are duplex ultrasonography (DU), DSA, and magnetic resonance imaging (MRI), repectively.[2] Although DU is a reliable, inexpensive, and noninvasive modality for diagnosis and surveillance of mesenteric vascular disease, in some cases it has low diagnostic sensitivity. Subhas et al. reported that DU only identified 56% of SISMADs.[10] An intimal flap may be difficult to visualize sonographically and acute thrombosis of the false lumen may hinder discrimination of the false channel. Bowel gas and obesity also render DU studies difficult to perform successfully even with experienced technologists. MRI may demonstrate similar evidence of disease, but is both less efficient and less commonly available in the acute setting compared to CT.

Contrasted-enhanced CT is capable of identifying dissection flaps, false lumens, re-entry tears, thrombus, intramural hematomas, aneurysm formation, and rupture of splanchnic arteries. When visualization of the dissection itself is limited, increased attenuation of the mesenteric fat may suggest the diagnosis.[10,43,44] CT not only identifies the SIVAD, but also demonstrates the characteristics of the dissection such as its origin, length, and

concomitant lesions.[32] CT is also able to identify other markers of end organ malperfusion. CTA should now be considered the gold standard for diagnosis of SIVAD.[10]

CLASSIFICATION SYSTEM

A number of classification systems have been developed for SISMAD. The goals of a classification system are to assist with risk assessment and determination of the best treatment algorithm for different types, extent, and characteristics of SISMADs. In 2007, Sakamoto et al. reported the first classification system for SISMAD. This group characterized SMA dissections based on CT appearance: Type I, patent false lumen with both entry and re-entry; Type II, a "cul-de-sac" shaped false lumen without re-entry; Type III, thrombosed false lumen with ulcer defect; and Type IV, a completely thrombosed false lumen without ulcer (Fig. 134.1). In Sakamato's series, all Type 1 SISMAD were treated successfully with conservative measures such as anticoagulation and medical management. In patients with Type II SISMAD, the true lumen may be compromised by false lumen compression. They recommended that these patients be followed very closely for signs of mesenteric ischemia. Type III SISMADs had the highest rate of intervention in contrast to Type IV SISMADs that did not require any intervention. Although this series only included 12 patients, it was the first classification system that attempted to determine best treatment using image classification.[45] A criticism of this system is the exclusion of patients with total thrombotic occlusion.[46]

Yun et al. reported a classification system with 3 types of SISMADs. Type I, patent true and false lumen revealing entry and re-entry sites; Type IIa, patent true lumen but no re-entry of the patent false lumen; Type IIb, patent true lumen but no re-entry of thrombosed false lumen; and Type III, dissection with occlusion of SMA (Fig. 134.2). This classification system was based on a clinical series of 32 patients. The authors were able to correlate pain severity with length of dissection, but could not predict outcome or recommend treatment guidelines based on the classification system due to small sample size. Four of the 32 patients underwent intervention (one endovascular and three open surgeries) for persistent pain due to bowel ischemia, but the type of SISMADs in these patients was not described.[40] Notably, due to the simplicity of Yun's classification system, it has become the most commonly used.

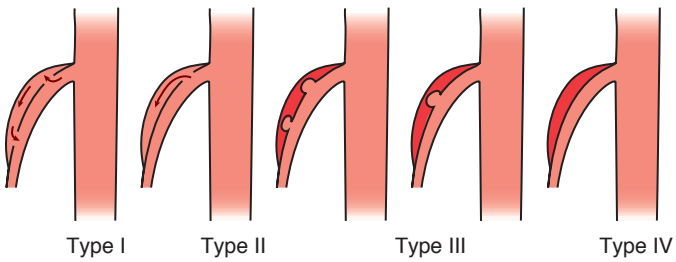

Figure 134.1 Spontaneous isolated superior mesenteric artery dissection classification system proposed by Sakamoto et al: Type I, patent false lumen with both entry and re-entry; Type II, a "cul-de-sac" shaped false lumen without re-entry; Type III, thrombosed false lumen with ulcer defect; and Type IV, a completely thrombosed false lumen without ulcer. (From Sakamoto I, Ogawa Y, Sueyoshi E, et al. Imaging appearances and management of isolated spontaneous dissection of the superior mesenteric artery. *Eur J Radiol.* 2007;64:103–110.)

Zerbib et al. described a more complex classification system by adding more categories to Sakamato's scheme. Type V is aneurysmal dissection with stenosis of the distal segment of the SMA. Type Va is total thrombosis of SMA and Type VIb shows partial SMA thrombosis. These authors compared outcomes of reported cases in the literature using their classification system. Their results showed that Types II and III lesions required more interventions in contrast to Types I and IV. Unfortunately, they were unable to predict clinical outcome based on this classification system.[47]

Luan et al. described a classification system based on the location and extent of the SMA dissection rather than luminal patency. These authors suggest four types of dissection. Type A is described as a dissection at the curve of the SMA and extending proximally to the SMA ostium. Type B is described as a dissection limited to the curve of the SMA. Type C is described as extending from the curve of the SMA distally, but not involving the ileocolic or distal ileal artery. Type D is described as extending toward the ileocolic and/or ileal artery (Fig. 134.3). In this series, patients with Type B dissection were symptomatic less often in contrast to patients with Type D dissection who presented with more severe pain. Unfortunately, management strategies are difficult to assess due to a sample size of only 20 patients. Type B patients were more likely to have successful treatment with conservative treatment compared with Type C and D patients.[32]

Other classification systems have been proposed, but unfortunately have not added to improvement of clinical management strategies.[30] Dissections of other visceral vessels have not been included in these systems. There is lack of wide acceptance of any one algorithm at this point in time.

TREATMENT

Management of SISMAD or other visceral vessel dissection depends on the clinical circumstances including morphology of the dissection, resultant symptoms, and the patient's clinical course. Little can be stated with authority at this time due to the low prevalence of reported SISMAD cases in the English medical literature worldwide and fewer cases including vessels other than the SMA. The majority of these cases have been reported within the last 2 decades, a time period with major advances in diagnostic imaging and therapeutic interventions.

Asymptomatic Patients

Technical improvements in multi-helical CT in the last decade, as well as increasing frequency of the use of CT in evaluating patients with various conditions, have led to an increase in the reported incidence of SIVAD. As a result, SIVAD has been observed in a number of asymptomatic patients. There is consensus that these patients should be managed medically.[7,20,40,48–53] However, the role of antiplatelet agents and anticoagulants is not well defined in either asymptomatic or symptomatic patients.

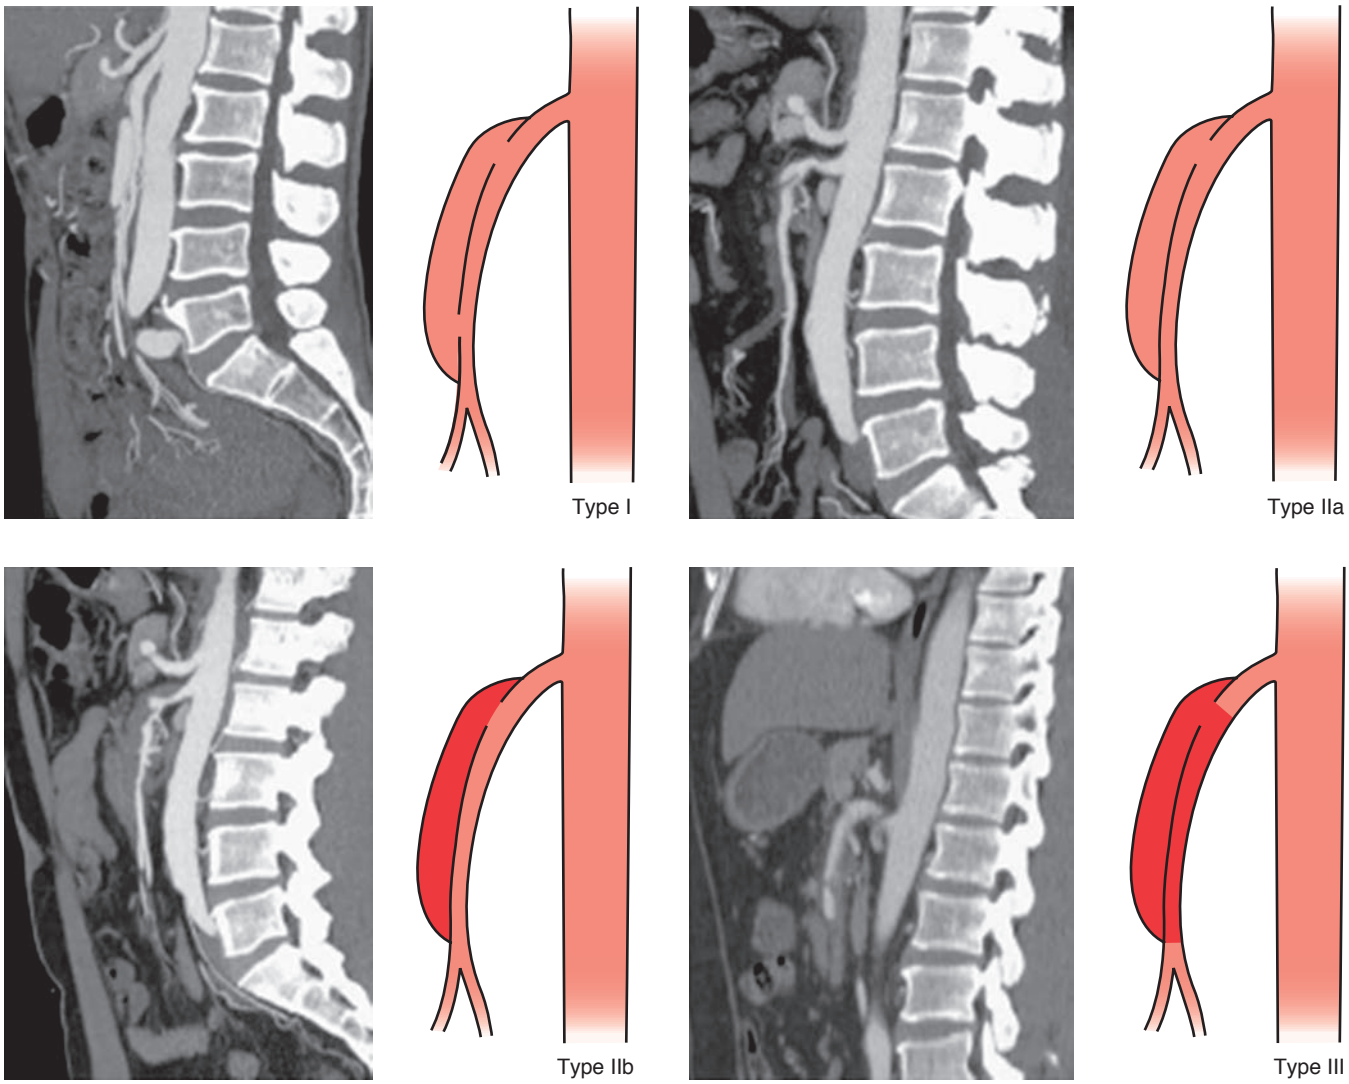

Figure 134.2 Yun et al. classification system for spontaneous isolated superior mesenteric artery dissection: Type I, patent true and false lumen revealing entry and re-entry sites; Type IIa, patent true lumen but no re-entry of the patent false lumen; Type IIb, patent true lumen but no re-entry of thrombosed false lumen; and Type III, dissection with occlusion of superior mesenteric artery. (From Yun WS, Kim YW, Park KB, et al. Clinical and angiographic follow-up of spontaneous isolated superior mesenteric artery dissection. *Eur J Vasc Endovasc Surg*. 2009; 37(5):572–577.)

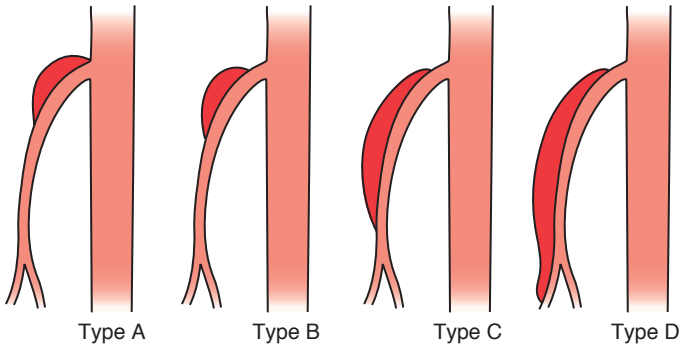

Figure 134.3 Classification system by Laun et al: Type A dissection at the curve of the superior mesenteric artery (SMA) and extending proximally to the SMA ostium; Type B dissection limited to the curve of the SMA; Type C extending from the curve of the SMA distally, but not involving the ileocolic or distal ileal artery; Type D extending toward the ileocolic and/or ileal artery. (From Luan JY, Li X. Computed tomography imaging features and classification of isolated dissection of the superior mesenteric artery. *Eur J Vasc Endovasc Surg*. 2013;46(2):232–235.)

Symptomatic Patients

As previously noted, a minority of patients that present with acute symptoms of SIVAD have vessel perforation and/or hemorrhage. Most patients report abdominal pain. The pain may be due to the dissection itself or to visceral malperfusion with end organ ischemia.

Most would agree that an incidental finding of a SIVAD without significant aneurysmal dilation or symptoms does not require intervention. However, there is controversy regarding management of patients presenting with symptoms of abdominal pain. The variability of collateral networks to maintain intestinal perfusion creates unpredictability regarding the persistence or resolution of ischemic symptoms.

Initial treatment is typically bowel rest and observation, particularly for patients with normal serum lactate level and lack of leukocytosis. Patients with persistent pain may be treated

with parenteral nutrition to reduced visceral "demand ischemia." Recruitment of collateral flow pathways or resolution of dynamic obstruction with dissection stabilization may explain resolution of ischemic pain. Pain secondary to the inflammatory process created by the dissection itself may persist for days. The role of anticoagulation is not well defined. Most authors have utilized at least short-term anticoagulation, but the benefit of this treatment has been questioned in recent reports.[5,40]

Some patients found to have SIVAD who present with abdominal pain and without bleeding may be managed medically. Ambo et al. was the first to report this treatment approach in 1994.[54] Yang et al. reported a series of 46 SIVAD patients with CTA surveillance for a mean of 23 months.[14] These authors observed remodeling and improvement of the dissection in a majority of patients (Fig. 134.4). More importantly, none of these patients developed extension of the dissection, bowel ischemia, or arterial rupture. However, in a different series by Li et al., 3 of 24 patients initially managed conservatively developed progression, including one patient with a fatal bowel infarction.[30] Overall, a majority of patients with SIVAD reported in the last two decades have undergone successful medical management.[20,30,55–57] There is a small number of patients with SICAD that have also undergone successful medical manangement.[5,36,52,58,59] In patients whose symptoms resolved with conservative management involving gradual return to enteric nutrition, radiographic follow-up is recommended.[8] There is no well-defined role for long-term anticoagulation or antiplatelet therapy.[60] A majority of patients treated expectantly in recent reports have not been treated with oral anticoagulation, and some authors do not utilize antiplatelet therapy in patients who do not undergo intervention.[40,46]

Surgical Treatment

A majority of early publications regarding treatment of SIVAD, mostly SISMAD, reported surgical treatment. The first documented successful surgery for SIVAD was reported in 1992. This patient was diagnosed with SISMAD via arteriography after laparotomy for mesenteric ischemia. The patient underwent a right gastroepiploic-to-SMA bypass.[42] In most patients

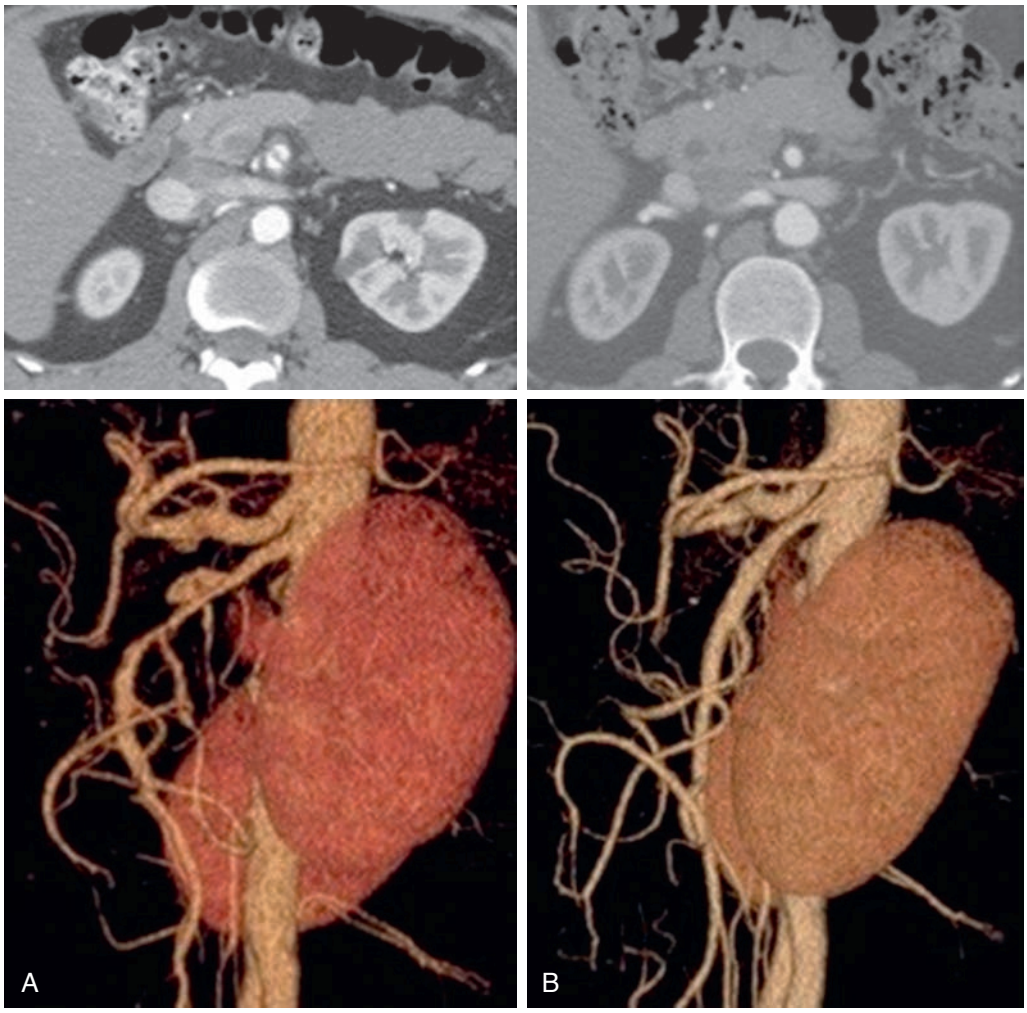

Figure 134.4 Computed tomography angiography demonstrating remodeling of spontaneous isolated superior mesenteric artery dissection before (A) and after (B) without intervention. (From Park YJ, Park KB, Kim DI, et al. Natural history of spontaneous isolated superior mesenteric artery dissection derived from follow-up after conservative treatment. *J Vasc Surg*. 2011;54:1727–1733.)

presenting with intra-abdominal hemorrhage or advanced bowel ischemia, open surgery remains the preferred option. Aside from resecting necrotic bowel when necessary, direct treatment of the arterial dissection can be accomplished by direct arterial repair. When operating for bleeding, ligation alone is appropriate if collateral flow appears sufficient.[61] When bowel is threatened, surgery may include aorto-visceral bypass, extra-anatomic bypass (with gastroepiploic or hepatic artery inflow for SMA dissection), and intimectomy/fenestration often combined with vein patch repair. Autogenous graft material, most commonly the greater saphenous vein, has been utilized in most reports.[42]

Endovascular Treatment

Thrombolysis

Thrombolytic therapy has rarely been employed in the setting of visceral vessel thromboembolism. There are few reports of its utilization in the setting of SIVAD, usually in combination with stenting. Mixed results have been observed.[62–64]

Embolization

Occasionally patients present with aneurysm formation or vessel perforation by the false channel as the primary concern. Endovascular coil embolization has been utilized in this setting (Fig. 134.5).[30,64,65]

Stenting

The first report of endovascular stenting to treat a SISMAD was published in 2000 by Leung et al.[66] Cumulative experience with stenting in the published English literature totals only a few dozen cases; thus it is difficult to make broad conclusions regarding indications, technique, and efficacy.[31,67] The majority of patients treated with stents had ongoing abdominal pain as the primary indication for treatment.[68,69] Many theorize that

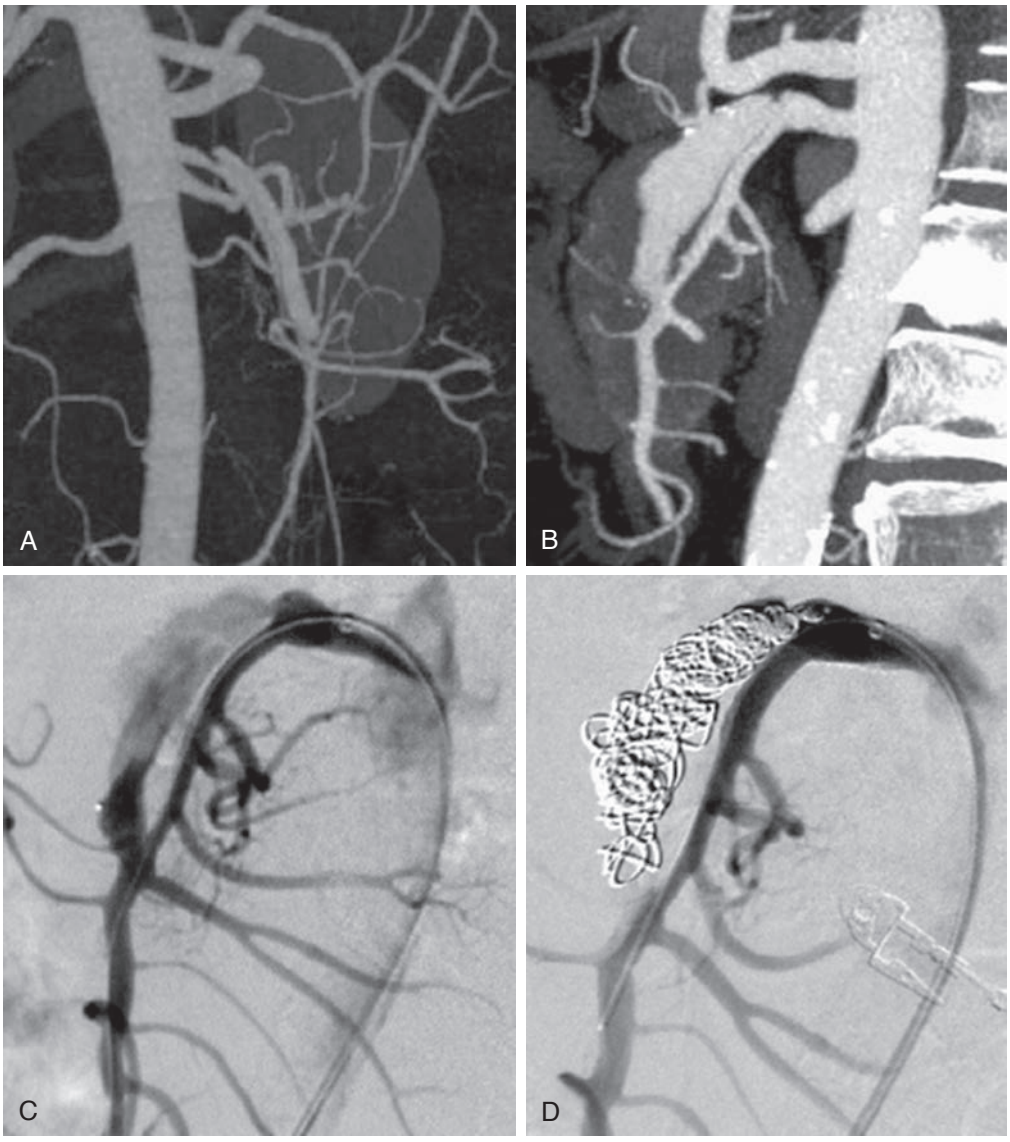

Figure 134.5 Imaging of superior mesenteric artery dissection (A), with pseudoaneurysm (B), treated with coil embolization of false lumen and pseudoaneurysm (C and D). (From Ozaki T, Kimura M, Yoshimura N, et al. Endovascular treatment of spontaneous isolated dissecting aneurysm of the superior mesenteric artery using stent-assisted coil embolization. *Cardiovasc Intervent Radiol.* 2006;29:435–437.)

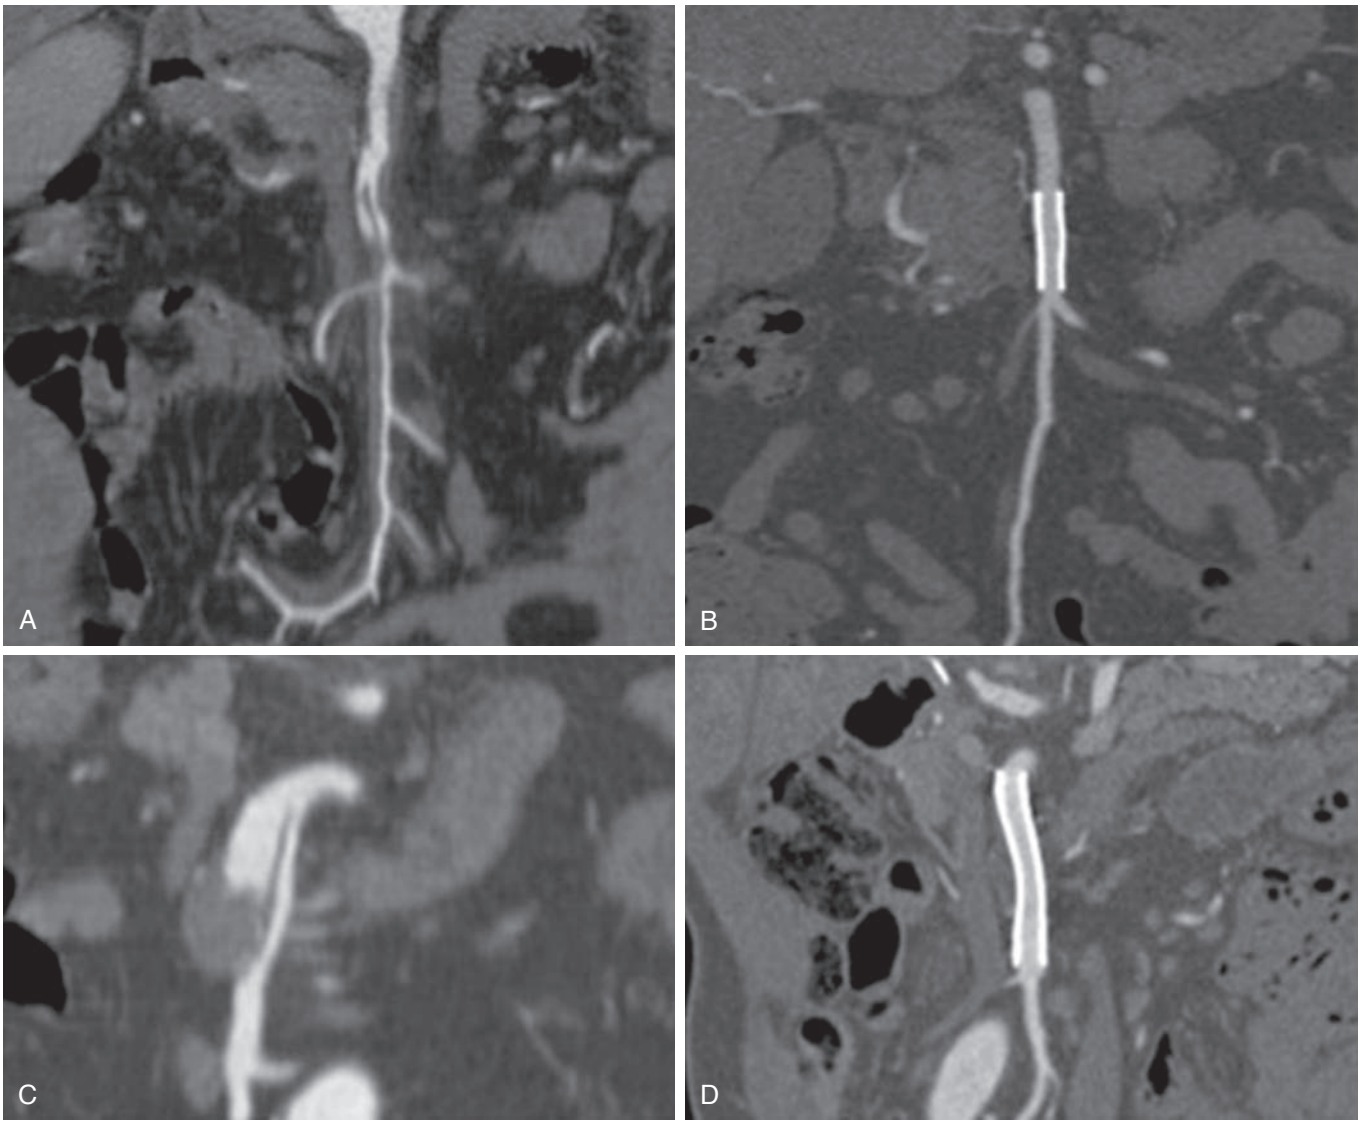

Figure 134.6 Superior mesenteric artery dissection (A and C), and successfully treated with endovascular stenting (B and D). (From Min SI, Yoon KC, Min SK, et al. Current strategy for the treatment of symptomatic spontaneous isolated dissection of superior mesenteric artery. *J Vasc Surg*. 2011;54:461–466.)

the symptom of pain is more commonly due to the dissection itself with an inflammatory response to the vessel injury rather than from mesenteric malperfusion and ischemia. A disadvantage of endovascular treatment compared to surgery is the inability to inspect the bowel for evidence of ischemia or necrosis. Accordingly, almost all patients treated with endovascular stents had variable symptoms of abdominal pain, rather than advanced ischemia or bowel necrosis.

The goal of endovascular treatment is elimination of stenosis caused by false lumen encroachment, as well as stabilization of vessel integrity to avoid late degeneration and aneurysm formation. According to the limited available natural history data, aneurysm formation appears to be a relatively rare occurrence; thus stenting should be primarily used for the former indication. Persistent pain is considered an indication for intervention in several series, analogous to the treatment of aortic dissection. Some authors have noted that patients having intervention with stenting have had an accelerated return to normal dietary intake and hospital discharge.[28,70] Others advocate a more selective application of stenting. Min et al. suggest that SMA stenosis of greater than 80% or dilation to more than 2 cm are indications for primary stenting (Fig. 134.6).[28] However, other authors have observed radiographic improvement in the degree of stenosis with conservative management in the large majority of patients.[57,63]

Visceral vessel stenting via transfemoral artery access has been reported most commonly. However, left brachial artery access provides significant advantage because it allows antegrade tracking of the acutely angulated proximal vessel, particularly the SMA. Caution must be taken to gain wire access to the true lumen, which may be challenging.[71] As the entry point for SMA dissection is rarely ostial, self-expanding stents are preferred over the balloon expandable design for most lesions. Nitinol bare metal stents have been utilized in most reports.[72]

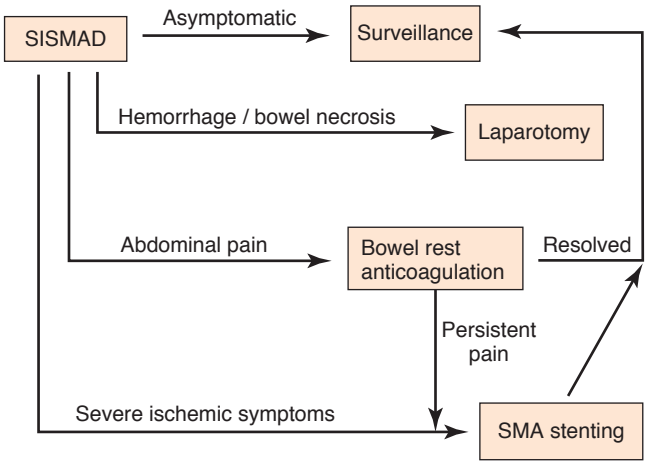

Figure 134.7 Suggested treatment algorithm for spontaneous isolated superior mesenteric artery dissection (SISMAD). *SMA*, Superior mesenteric artery.

Covered stents may have occasional utility, particularly when excluding aneurysmal vessels.[73–75] However, in most situations, preservation of flow to the remaining patent SMA branches is the priority and bare stents are preferred. Most authors have utilized stents long enough to treat the entire length of the dissection rather than only the entry tear. Multiple stents have been reported in about one third of patients.[76] Published long-term results with stenting are limited, but few failures have been reported to date.[30,77–80] Intermediate-term patency appears to be high and late recurrent dissection or arterial degeneration appears to be very low. Most authors recommend long-term antiplatelet therapy as adjunctive therapy.

In comparison with medical management, the majority of the current literature available on endovascular management of SIVAD pertains to lesions of the SMA. However, there are a few reports of successful surgical and endovascular management of SICAD. Similar to SISMAD, recognizing which branch of the celiac artery has the dissection is more challenging than the technical aspects of the treatment.[5,36,59]

Fig. 134.7 demonstrates a suggested treatment algorithm we endorse based upon the available data.

OTHER CONSIDERATIONS

Segmental Arterial Mediolysis

Segmental arterial mediolysis (SAM) has recently gained recognition as a distinct pathologic entity. Although dissections may occur with this non-inflammatory arteriopathy, aneurysms are more common and multiple lesions in various vessels are often present at the time of diagnosis (Fig. 134.8). Visceral vessels are at highest risk for SAM, often with multiple areas of aneurysmal dilation and occasionally dissections. Intra-abdominal hemorrhage is more common than thrombotic or ischemic complications. Open surgical treatment has often been utilized on an emergent basis; however, endovascular management with coil embolization has played an increasing role in more recent reports.[21,22]

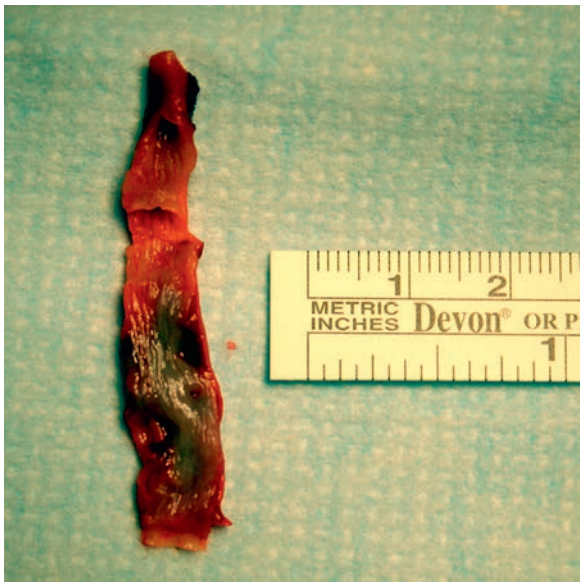

Figure 134.8 Segmental arterial mediolysis affecting the superior mesenteric artery in a patient presenting with rupture—distal superior mesenteric artery specimen opened, revealing dissection. (From Tameo MN, Dougherty MJ, Calligaro KD. Spontaneous dissection with rupture of the superior mesenteric artery from segmental arterial mediolysis. *J Vasc Surg*. 2011;53:1107–1112.)

SURVEILLANCE

There is no consensus on surveillance of patients with SIVAD; however, most clinicians suggest some type of routine follow-up.[10,14,81] CTA is the surveillance study of choice; however, DU may also be used. The rationale for surveillance is the potential for SIVAD to form a splanchnic aneurysm.[82] The true incidence of aneurysm formation is unknown, but this has been reported.[67] Imaging at 1 month post initial SIVAD, every 6 months for the first year, then annual surveillance has been proposed. This is a reasonable approach until the natural history of this disease entity is better defined.[4,14]

REMODELING

Surveillance of SIVAD has shown that more arteries remodel than form aneurysms. Park et al. showed that 41% of SISMAD treated medically had improvement on surveillance CTA and 15% of patients had complete remodeling of the SMA. Positive predictors for complete remodeling included type II lesions from the Yun classification system. These are SISMADs that had a single tear and no re-entry tear. This leads to false lumen thrombosis and more complete remodeling of the SMA. It is unclear if remodeling leads to better clinical outcomes, but there is no report to date of late morbidity in a patient whose dissection was described as improving.[14]

SUMMARY

Isolated visceral artery dissections are rare, but have been increasingly recognized with advanced imaging techniques in recent years. No single etiologic factor has been identified, but

a higher prevalence is observed in the east Asian population. Although bowel ischemia and hemorrhage can complicate these SIVADs, the majority can be managed medically. Endovascular treatment has played a growing role in management of symptomatic lesions with high procedural and intermediate-term success. Radiographic surveillance is recommended in patients regardless of initial treatment.

INTRODUCTION

"Compression of the celiac artery by the median arcuate ligament is well-documented."[1] Stanley and Fry published this statement in 1971 after reviewing "provocative xylose absorption tests" in ten female and five male patients over a 3.5-year period. After transecting the median arcuate ligament in these 15 patients, they concluded that intestinal ischemia was the underlying disorder in median arcuate ligament syndrome (MALS). However, 45 years later, MALS continues to be difficult to qualify, quantify, and diagnose. MALS (also known as celiac artery compression syndrome and Dunbar syndrome) is an anatomic and clinical illness resulting from extrinsic compression on the celiac axis. Clinical manifestations include postprandial and exercise induced epigastric abdominal pain, nausea, vomiting, weight loss, and "food fear," or fear of pain triggered by eating. Lipshutz[2] offered the first anatomic description of the celiac artery in 1917, and Harjola performed the first surgical release in 1963.[3] In 1967 Dunbar et al.[4] reported a larger case series in which operative division of the MAL resulted in clinical improvement in 13 of 15 patients. Anatomically, up to 24% of the population may have MAL compression; however, less than 1% of these patients are symptomatic.[5] Over the last several years, the etiology of MALS has shifted from a vascular disease to a neurogenic illness with compression of the surrounding celiac plexus and ganglion. Presently, patient selection remains critically important in order to obtain optimal clinical outcomes following treatment.[6]

Anatomy

Embryologically, the diaphragm is derived from the septum transversum and descends from the neck toward the celiac axis between weeks 9 and 12 and ultimately forms the MAL. Typically the diaphragmatic crura arise from the anterior aspect of L1 to L4 and project cephalad to join the anterior longitudinal ligament of the spine overlying the celiac axis. The MAL is composed of the fibrous edge of the diaphragmatic crura that crosses the aorta at the level of the celiac artery. These fibers splay over the aorta and extend laterally toward the suspensory ligament of the fourth portion of the duodenum (Fig. 135.1). In the majority of the population, the ligament does not encroach on the celiac artery and causes no compression (Fig. 135.2). As noted previously, as much as 10% to 24% of the population may have MAL compression without symptoms.[5] The celiac nerve plexus branches across the abdominal aorta between vertebral levels T11 to L1.

Pathophysiology

Multiple theories exist regarding the pathophysiology of the epigastric pain associated with MALS. One theory hypothesizes

that increased blood demand through a compressed celiac artery leads to foregut ischemia and pain. However, collateral blood flow between the mesenteric vessels compensates for either subtotal or intermittent occlusion of the celiac artery. Also, studies performed using gastric exercise tonometry document that mucosal oxygen delivery does not correlate with celiac artery compression or clinical symptoms.[7] Similar findings exist with gastric perfusion studies.[8] In addition, MAL compression has never been reported as a cause of gastric necrosis or even gastric ischemia on endoscopic evaluation.[6] Another theory states that midgut ischemia induces abdominal pain through a vascular steal syndrome. In theory, blood flow from the superior mesenteric artery may be diverted through collaterals to compensate for inefficient delivery through a stenotic celiac artery, and this mechanism results in small bowel ischemia and pain. This mechanism would be difficult to document with retrograde flow studies. Others suggest that the epigastric pain is caused by overstimulation of the celiac plexus with subsequent splanchnic vasoconstriction and ischemia (Fig. 135.3).[9] Other authors favor a neurogenic hypothesis for symptoms of MALS. Histologic analysis of the celiac plexus shows that the nerves consist of pain fibers and inhibitory motor fibers to the stomach. Thus entrapment of the ganglion by the MAL may alter gastric myoelectrical activity and impair antral motility,[10] and the compression may induce pain.[11] Since the underlying pathophysiology of MALS is unknown, the diagnosis of MALS is difficult. Consequently, to enhance the benefit of surgical intervention, efforts aimed at improving the ability to reliably diagnose MALS are required.

DIAGNOSIS

History and Physical Exam

The ultimate goal of surgical intervention begins with accurately identifying patients with symptomatic MALS and those patients who would benefit from surgery. Initially the workup includes consultation with a vascular and general surgeon for a detailed history and physical examination. Overall, history and physical often prove nondiagnostic or equivocal. The history may yield previous surgical interventions, including cholecystectomy and/or diagnostic laparoscopy. The most common presenting symptom is abdominal pain, and an overwhelming majority of symptoms are classified as postprandial. Other symptoms include weight loss, bloating, nausea, vomiting, and exercise-induced pain (Box 135.1; Fig. 135.4). Recently, patients with autonomic neuropathy, including postural orthostatic tachycardia

- Nausea
- Vomiting
- Unintentional weight loss
- Exercise induced pain

Less Common

Autonomic dysfunction
- Fibromyalgia
- Postural
- Orthostatic tachycardia syndrome

syndrome (POTS), have been diagnosed with MALS.[12] Physical examination typically reveals a thin, flat, nontender abdomen. Despite the suspected underlying pathology, an abdominal bruit is usually not detected with auscultation.

There is a female predilection at 2:1 to 3:1, and typical ages range in the fourth and fifth decade. Some recent literature challenges the classic age range and shifts the disease onset to the second and third decades.[13] However, there are many cases where the diagnosis is delayed, with patients complaining of several years of symptoms prior to diagnosis.

Often patients have had multiple evaluations regarding their abdominal symptoms. Many patients face an inherent bias from their physicians following an initial negative workup, and many of these patients frequently carry a "psychiatric" or noncompliant diagnosis. Anecdotally, fibromyalgia, autonomic dysfunction, and pain medication–seeking behavior may be included in these patients' charts. Most patients have already had an extensive gastrointestinal workup, including gallbladder ultrasounds, esophagogastroduodenoscopy, colonoscopy, enteric motility studies, computed tomography (CT), and magnetic resonance imaging (MRI). In one series, 54% of patients had undergone a prior abdominal procedure, including cholecystectomy, exploratory laparoscopy/laparotomy, and/or biliary and pancreatic sphincterotomy.[14]

RADIOLOGIC STUDIES

During the 1960s and 1970s, lateral aortography was the most reliable and objective means of documenting the presence and extent of celiac artery compression. Using inspiratory and expiratory images, this invasive test was considered pathognomonic for MALS. Today, CT angiography (CTA) and magnetic resonance arteriography (MRA) have emerged as the two most common diagnostic studies for MALS. CTA and MRA can

evaluate the structural elements of the celiac artery, the MAL, and the surrounding viscera, in addition to providing aortic and celiac branch anatomy. CTA and MRA may also identify concomitant abdominal disease such as a co-existing neoplasm, mesenteric thromboses, or atherosclerosis. Although CTA and MRA provide information about the relationship of the celiac artery with the diaphragm and help visualize the compressed artery from various angles, they are not dynamic and therefore do not provide information during the respiratory cycle (see Fig. 135.4).

At some institutions, MALS is now diagnosed initially with transabdominal duplex ultrasound scanning of the celiac artery. Several studies have demonstrated varying degrees of compression of the celiac artery during the respiratory cycle. Normally the distance between the celiac artery and MAL increases during inspiration and decreases with expiration.[15] During expiration, the aorta moves in a cephalad direction and may subject the celiac artery and its surrounding celiac plexus to compression by the MAL. During inspiration, the celiac artery moves away from the MAL as the aorta moves caudally.[15] These distinct anatomic findings during normal breathing induce dynamic celiac artery velocities during inspiration and expiration. However, diagnostic ultrasound is technician-dependent and requires a high degree of expertise to reliably assess the mesenteric vessels.

Ultrasound scanning is performed during inspiration and expiration by using 3.5 to 5.0 MHz probes with linear array or convex sector probes. Arterial inflow is based on B-mode and the peak systolic velocity (PSV). Ultrasound measurements focus on the proximal portion of the celiac artery just distal to the ostia. According to criteria published by Moneta et al.,[16] a PSV greater than 200 cm/s, no flow, or retrograde common hepatic arterial flow during inspiration or expiration were consistent with a significant (>70%) stenosis of the celiac artery (Fig. 135.5). Turbulent flow with elevated peak systolic velocities on expiration, which normalize or decrease with inspiration and standing erect, are suggestive of MALS (see Fig. 135.5). The ultrasound findings should document a peak expiratory velocity of greater than 200 cm/s to entertain a diagnosis of MALS and should be greater than resting and inspiratory velocities. Peak expiratory velocities of greater than 500 cm/s have been reported.[13] Other ultrasound findings associated with MALS include abnormal origins of the celiac and superior mesenteric arteries, poststenotic bulbar dilation, and reverse flow in the hepatic artery.[17] Gruber et al. were able to correlate a diagnosis of MALS with celiac artery end diastolic velocity of 350 cm/s or greater, a 210% change in pulse volume amplitude with inspiration and expiration, and a celiac artery deflection angle of 50 degrees. These findings by Gruber showed a sensitivity of 83% and specificity of 100% compared with angiographic evidence of MALS.[18] A combination of ultrasound, CTA, and MRA usually provides enough information, coupled with the patient's symptoms, to confirm or exclude a diagnosis of MALS (see Fig. 135.4).[13]

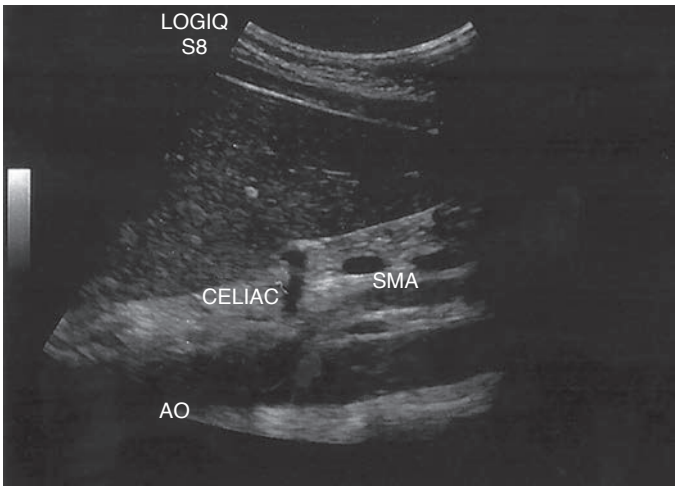

Figure 135.5 Doppler ultrasound image representation of normal findings and positioning during dynamic studies for median arcuate ligament syndrome.

Aortic angiography may reveal an asymmetric focal narrowing of the proximal celiac axis with poststenotic dilation. Narrowing is accentuated on expiration and relieved on inspiration. Increased collateral vessels in the celiac artery distribution may be evident and is indicative of significant stenosis.

Gastric exercise tonometry has been used as well to diagnose MALS. This test uses arterial blood gases and nasogastric fluid with a standardized protocol to measure arterial and gastric carbon dioxide levels before, during, and after 10 minutes of submaximal exercise. After acid suppression with a proton pump inhibitor or H2 blocker, baseline measurements of gastric PCO2 and arterial blood gases are obtained. Following a 10-minute bicycle test and a 20-minute recovery period, blood gases and gastric PCO_2 are measured during peak exercise and recovery. A positive pathologic test consists of (1) a gastric-arterial PCO_2 gradient greater than 0.8 kPa after exercise, (2) an increase in gastric PCO_2 from baseline to peak exercise, and (3) an arterial lactate level less than 8 mmol/L.[7]

MANAGEMENT

Percutaneous celiac ganglion block has been used for decades to control intractable pain from intraabdominal cancer or chronic pancreatitis.[14] In a series of 36 patients from the Mayo Clinic, preoperative celiac ganglion block was successfully performed on nine patients diagnosed with MALS, and all nine improved after surgery.[19] Theoretically, a visceral block could be used as a preoperative diagnostic and potentially therapeutic test. However, there is limited data to support this algorithm.

Endovascular treatment alone does not benefit patients with MAL compression of the celiac axis. Matsumoto et al. reported immediate failure after performing five percutaneous transluminal angioplasty (PTA) procedures for symptomatic visceral artery stenosis, secondary to extrinsic compression by the MAL or occult malignancy.[20] In 2002 Matsumoto also described patients who immediately failed PTA in the setting of mesenteric ischemia but had immediate relief of symptoms after surgical release of the MAL.[21] It is not uncommon to find patients with celiac artery stenosis who have had PTA attempted and subsequently required open or laparoscopic release of the MAL. Due to the angulation and compression of the celiac artery, PTA in patients

with MALS may be associated with fractured stents and stent migration into various visceral arteries. Although data is limited to case reports, PTA alone is not successful without removal of the extrinsic compression of the MAL. PTA or stenting are now relatively contraindicated in the setting of MALS, as the extrinsic compression of the ligament would only obstruct or crush the stent and result in early restenosis.[22] Thus purely endovascular treatment of MALS is not recommended.[14]

Currently most surgeons agree that laparoscopic division of the MAL and the associated celiac ganglion tissue are critical for a successful treatment.[13] In addition to sympathetic pain fibers, the celiac ganglion contains inhibitory sympathetic motor fibers, which modulate the intrinsic neural circuit of the stomach.[23] As noted earlier, decompressing or dividing the neural fibers would therefore decrease pain and improve gastric motility.[10,13]

Laparoscopic Technique

A laparoscopic MAL release typically uses a standard five-port laparoscopic technique with the patient in the supine position (Fig. 135.6). The midline port is placed slightly more cephalad to visualize the aorta and celiac artery over the pancreatic body during the dissection. The ultrasonic scalpel is used to enter the lesser sac after the liver is retracted cephalad. A window is created to circumferentially expose the left gastric artery and coronary vein. With gentle retraction, the artery and vein are retracted from left to right to obtain an optimal view of the left and right borders of the aorta as it approaches the origin of the celiac artery. An extensive dissection of the common hepatic, left gastric, and splenic arteries is performed.[1] Typically the dissection extends 4 cm distal to the celiac artery bifurcation in order to divide all the neurovascular bundles surrounding the three associate vessels. The crural and MAL fibers are then divided from the overlying aorta using the hook cautery (Video 135.1). The aortic dissection extends 5 cm proximal to the origin of the celiac artery to ensure a complete division of the celiac plexus (Video 135.2; Figs. 135.7-135.9). The dissection extends to the prevertebral fascia on the right of the aorta and to the suspensory ligament of the fourth portion of the duodenum on Fig left. All ganglionic fibers that are visualized are divided with the electrocautery or ultrasonic scalpel.

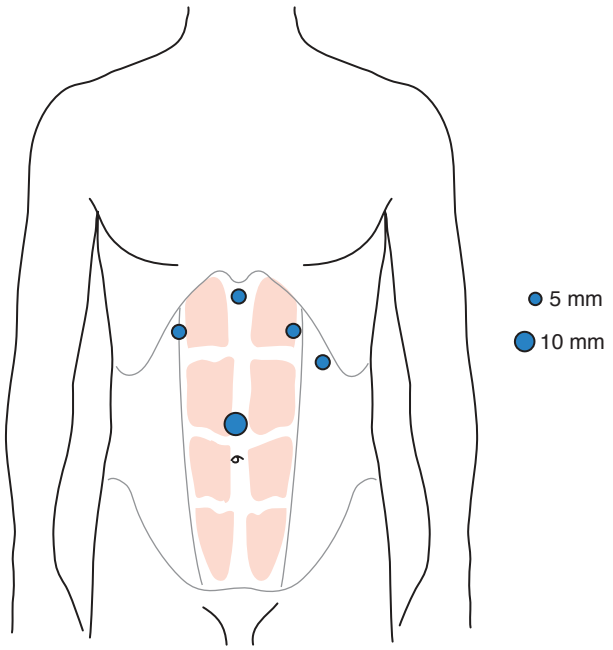

Figure 135.6 Port placement.

Results

Prior to laparoscopic release, open surgical treatment of MALS was described by a number of authors. Harjola[3] and Dunbar et al.[4] performed a midline laparotomy with decompression or division of the MAL and the associated celiac plexus. Reilly reported 51 patients with 9 years follow-up (1964–1980) who

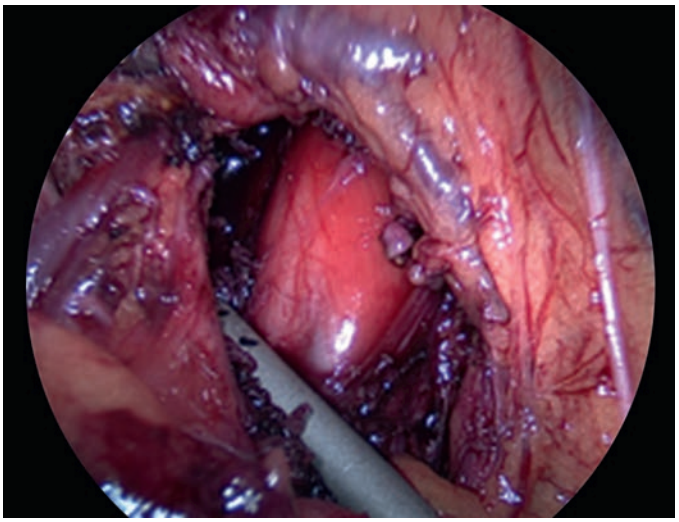

Figure 135.7 Midline view following aortic dissection during median arcuate ligament release. The released celiac origin can be appreciated as it branches from the aorta.

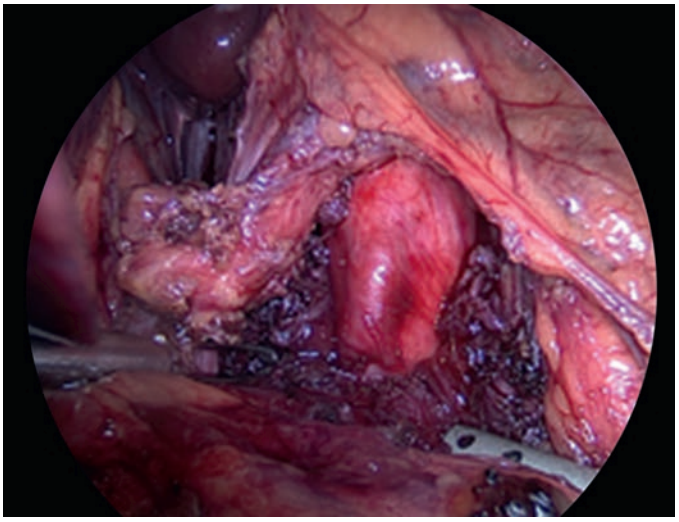

Figure 135.8 Further imaging showing release of median arcuate ligament and decompression of the celiac plexus

underwent a combination of decompression alone, decompression with graduated celiac artery dilation through a celiac or splenic arteriotomy, or decompression with reconstruction and bypass of the stenotic arterial segments.[24] Of those 16 patients who underwent MAL decompression alone, 9 (56%) achieved symptom relief. Of 35 patients who underwent decompression and reconstruction, 27 (77%) achieved symptom relief. Ten (40%) of 25 patients who received postoperative arteriograms remained symptomatic, and seven of those patients (70%) showed persistent celiac stenosis. In 2009, Grotemeyer et al. reported a case series of 18 patients, with three patients lost to follow-up, who underwent open decompression, and 11 of which (73%) had good resolution of their symptoms. However, five of the 11 patients (45%) required additional interventions on the celiac trunk prior to pain resolution.[25] Major postoperative complications following the open approach included a thrombosed bypass graft (2%), cerebrovascular accidents (1.4%), gastroesophageal reflux disease (1%), pancreatitis (1%), hemothorax (0.3%), and splenic infarction (0.3%).[26,27]

Several series have demonstrated successful laparoscopic treatment of MALS. In a single center report of data from 1999 to 2009 including 14 patients, 10 patients underwent a laparoscopic MAL release and two patients were converted to a laparotomy for bleeding from either the celiac or left gastric artery. An additional four open MAL divisions were included. Median follow-up was 14 months, and 38% of the laparoscopic group and 50% of the open group had persistent pain at last follow-up.[28] The authors concluded that late recurrence was frequent but seemed to be milder than the initial clinical presentation. Laparoscopy was associated with a shorter hospital stay and decreased time to feeding. The authors also concluded that optimal patient selection, as a predictor of clinical response, remains a challenge.

A retrospective review was published in 2012, which encompassed 20 studies; 13 studies reported open MAL division and seven studies reported laparoscopic MAL division. Nearly 25% of patients in the open series underwent concomitant arterial reconstruction. Of those in the laparoscopic group, 9% underwent celiac artery angioplasty and stenting after laparoscopic division of MAL. Follow-up in the open group extended as far as 229 months, and laparoscopic follow-up extended to 44 months. Laparoscopic conversion to a laparotomy was 9.1%. Intraoperative complications included visceral bleeding, pneumothorax, aortic bleeding, and phrenic artery laceration. All of these complications occurred at a rate of less than 4%. The authors documented immediate postoperative symptom relief in 85% of patients, with a recurrence rate of 6.8% in the open group and 5.7% in the laparoscopic group.[27]

In 2013, El-Hayek et al. reviewed their treatment of 15 patients from 2007 to 2012, including one procedure performed with robotic assistance. They reviewed postoperative celiac velocities in 12 of the 15 patients. Ten patients showed a statistically significant decrease in celiac artery velocity. Of note, two patients showed celiac occlusion, but all but one patient reported the resolution of preoperative pain.[29]

Recently the two largest laparoscopic series to date have been published. Weber et al. reported on 39 patients, of whom 70% reported symptom relief following laparoscopic treatment of MALS despite persistent celiac artery stenosis on postoperative duplex ultrasound. In the same study, all nonresponders with regard to symptom improvement had normal celiac artery velocities after surgery.[6] Brody reported that 33/38 patients had complete resolution of preoperative pain at follow-up, ranging from 6 months to 3 years.[13] In this study, a short form (SF) 36 question survey was used pre- and postoperatively in addition to pre- and postoperative dynamic Doppler ultrasound. The reported postoperative complications from this study included pancreatitis and dehydration.[13] Based on this experience, Brody and his group recommend a predictive formula utilizing SF-36 questionnaire values and celiac artery ultrasound values to identify patients for operative success.[13] Such a formula may enhance preoperative patient counseling with regard to symptom improvement. This series also reported several patients that required supplemental nutrition through enteric tubes or total parenteral nutrition before surgery. Following the laparoscopic MAL release, oral nutrition was restored in all patients, and two patients on TPN were transitioned to intermittent fluids on a weekly basis.[13] There appears to be a scale of improvement based on symptom resolution that does not directly correlate with ultrasound velocity or other imaging changes.

With the adoption of the robotic platform, a few cases have been reported using a robotic-assisted laparoscopic MAL release. In 2013, Do et al. reviewed 16 patients, four of which were completed with robotic assistance. The only significant difference found between laparoscopic and robotic approaches was a shorter operative time for laparoscopy (101.7 min vs. 148.8 min).[22] Thus far no clear advantage for a robotic-assisted MAL release has been demonstrated.

Van Peterson et al. reported their experience using an endoscopic retroperitoneal approach to divide the MAL in 46 patients. Complications included a 2% conversion rate to a laparotomy and a pneumothorax in 4% of patients. Overall, 78% (36/46) of patients had postoperative angiography confirming normal vessel anatomy. Six of the remaining 10 patients underwent endovascular treatment; five patients had a successful dilation with resolution of the celiac artery stenosis. Symptoms were

based on three responses: free of symptoms, improved, or persistent symptoms. In this group, 41/46 (89%) patients reported improvement of symptoms and 65% reported resolution of symptoms with surgical intervention. The authors did not mention whether persistent symptom complaints resulted in endovascular intervention. But no patient who reported persistent symptoms received endovascular intervention. This further supports the theory that MALS is a neurogenic disease, and the vascular abnormalities are only a physiologic marker for ligamentous compression on the artery and nerve plexus. Their median follow-up of 20 months gave sufficient evidence to suggest comparable results to open procedures available at that time.[30]

Based on a literature review and institutional experience, Kim et al. recently proposed an algorithm for diagnostic evaluation and intervention in patients with MAL syndrome.[31] As previously mentioned, patients begin with a workup for abdominal pain, including right upper quadrant ultrasound, abdominal CT, upper endoscopy, and/or HIDA scan. Abnormal findings on these studies result in appropriate treatment for the diagnosed pathology. Normal findings in these studies lead to a duplex ultrasound of the celiac artery. Findings suggestive of MALS or equivocal ultrasound findings may be supplemented with CTA or MRA of the abdomen, or angiography of the celiac artery with pressure gradient measurements for confirmation. Evidence of celiac artery compression is an indication for laparoscopic or robotic MAL release, including celiac ganglionectomy. Follow-up included postoperative celiac artery duplex ultrasound and assessment of symptom resolution. If symptoms persist, angiography of the celiac artery with pressure gradient measurement is used to diagnose residual stenosis. If stenosis remains, angioplasty or stenting of the celiac artery is recommended. If symptoms still persist, vascular reconstruction should be considered if ischemia is felt to contribute to the patient's pain.[31]

CONCLUSION

MALS can be a difficult disease to diagnose, but recent publications document an increasing incidence of surgical treatment for this apparently rare disease. Compression of the proximal celiac artery by the MAL results in image-apparent stenosis, with detectable changes in dynamic ultrasound velocities. However, celiac compression and change in arterial velocity are only markers for neural compression. The true pathophysiologic dysfunction lies within the neural network of the celiac ganglion, which is subjected to the same compression as the celiac artery by the MAL. The celiac plexus is composed of pain fibers and inhibitory motor fibers to the stomach. The rationale for MAL release rests on the theory that MAL syndrome results from compression of the celiac plexus. The compression creates a variety of symptoms, including nausea, vomiting, and gastric dysmotility. Furthermore, the neural compression may contribute to other neurogenic diseases, such as POTS.[12]

As more patients are accurately diagnosed, treated, and followed, the true parameters that mark a successful treatment will continue to change. To date, case series remain small, with both open and laparoscopic approaches and follow-up remains limited to less than 3 years. The complex nature of the disease process requires subjective and objective data to create an algorithm to identify patients who may benefit from surgical intervention.

The common definition of mesenteric venous thrombosis (MVT) refers to a single entity involving thrombosis within the superior mesenteric vein with or without extension to the portal or splenic vein. Recovery following resection of infarcted intestine secondary to mesenteric vessel occlusion was first reported by Elliot in 1895.[1] MVT was recognized as an entity distinct from mesenteric arterial occlusion by Warren and Eberhard in 1935.[2]

EPIDEMIOLOGY

MVT is most commonly encountered in middle-aged and older adult patients, with an equal gender distribution when age differences between genders are taken into account.[3,4] In a population-based study with an average autopsy rate of 87%, MVT was found to be present in 63 of 402 patients (16%) with acute mesenteric ischemia (Fig. 136.1).[5,6] Additionally, the overall incidence of MVT with transmural intestinal infarction was estimated to be 1.8 per 100,000 person-years in Malmö, Sweden, between 1970 and 1982, and the cause-specific mortality ratio was 0.9 per 1000 autopsies.[5] The overall incidence of MVT increased to 2.7 per 100,000 person-years in the same city between 2000 and 2006.[4] An important factor contributing to an underestimation of the latter incidence estimate was the declining autopsy rate, from 87% to 10%, between the two periods. In contrast, factors increasing the incidence estimate over time were the growing proportion of older adults in the population and the greater amount of diagnostic activity and its higher quality. Patients with MVT were diagnosed at autopsy, at operation, or with computed tomography (CT) in 12% (6 of 51), 19% (10 of 51), and 69% (35 of 51) of cases, respectively,[4] during the latter period.

PATHOGENESIS

Etiology

Primary MVT is defined as spontaneous, idiopathic thrombosis of the mesenteric veins not associated with any other disease or etiologic factor. Patients with any condition known to predispose to MVT (Box 136.1) are considered to have secondary MVT.[7] Approximately 90% of MVTs are secondary.[8]

Risk Factors

Several conditions are associated with MVT (see Box 136.1); these can be divided into three main categories: direct injury, local venous congestion or stasis, and thrombophilia (i.e., the classical three factors identified by Virchow: vessel wall, flow, and blood). Splenectomy is a risk factor for the development of thrombus propagation from the ligated splenic vein to the

Abstract

Mesenteric venous thrombosis is a very difficult disease to diagnose on clinical grounds. However, owing to the increased availability and evolution of computed tomography in developed countries, early diagnosis prior to the development of peritonitis is often possible. First-line therapy is full-dose anticoagulation, whereas endovascular therapy including thrombolysis may be considered in cases refractory to anticoagulation therapy. Exploratory laparotomy and bowel resection for this disease will always be a treatment option in patients developing peritonitis or not responding to anticoagulation in a clinically favorable way. At present, it is recommended that risk-factor evaluation for mesenteric venous thrombosis should include screening for inherited disorders such as factor V Leiden mutation, prothrombin gene mutation, protein C deficiency, protein S deficiency, and antithrombin III deficiency as well as acquired disorders such as *JAK2* V617F mutation, lupus anticoagulant, and cardiolipin antibodies.

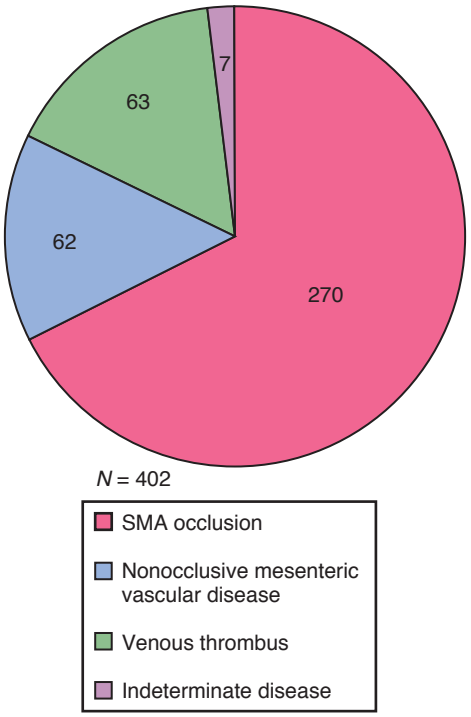

Figure 136.1 Acute mesenteric ischemia: distribution of etiologies in 402 patients in Malmö, Sweden, between 1970 and 1982.[4,5] Mesenteric venous thrombosis, acute SMA occlusion (embolus/thrombus ratio = 1.4), and nonocclusive mesenteric ischemia were found in 16%, 68%, and 16%, respectively. *SMA*, Superior mesenteric artery.

BOX 136.1 Conditions Associated With Mesenteric Venous Thrombosis

Direct Injury

- Abdominal trauma (blunt and penetrating)
- Postsurgical (particularly postsplenectomy)
- Intra-abdominal inflammatory states (pancreatitis, inflammatory bowel disease)
- Peritonitis and abdominal abscess

Local Venous Congestion or Stasis

- Portal hypertension; cirrhosis of the liver
- Congestive heart failure
- Hypersplenism
- Obesity
- Increased abdominal pressure; abdominal compartment syndrome

Thrombophilia

- Protein C and protein S deficiency
- Antithrombin III deficiency
- Activated protein C resistance (factor V Leiden gene mutation)
- Presence of 20210 A allele of prothrombin gene
- Methylenetetrahydrofolate reductase mutations
- *JAK2* V617F gene mutation
- Neoplasms (particularly pancreatic and colonic)
- Oral contraceptive use
- Polycythemia vera
- Essential thrombocytosis
- Heparin-induced thrombocytopenia
- Lupus anticoagulant–antiphospholipid syndrome
- Cytomegalovirus infection
- Extramesenteric venous thromboembolism

portomesenteric venous system.[9] In retrospect, after scrutinizing the multidetector computed tomography (MDCT) images, the prevalence of incidental, probably asymptomatic, nonanticoagulated MVT in patients with inflammatory bowel disease was reported to be as high as 27%[10] and was located at the periphery, limited to the territory of inflammatory bowel disease. The detection of MVT was associated with disease severity and factors such as bowel wall thickening, ascites, bowel stenosis, and intestinal surgery.[10] Severe acute pancreatitis may lead to MVT but more frequently to splenic vein thrombosis due to its very close proximity to the inflamed pancreas.[11,12] In a case-control study, obesity was found to be a risk factor.[5] Inherited thrombophilia[13-15] was reported in 42%[3] to 55%[4] of patients with MVT. Factor V Leiden mutation (activated protein C resistance) was present in 45% of the patients with MVT in Malmö, Sweden[4]; this was considerably higher than the known prevalence rate of 7% in the background population.[16] Although factor V Leiden mutation is a genetic defect, peripheral venous thrombotic manifestations are frequently delayed until adulthood, even in homozygotes.[16,17] Case-control studies suggest that factor V Leiden[18] and prothrombin G20210A gene mutations[18,19] are overrepresented in patients with MVT. MVT has been reported to be a common first clinical manifestation of patients with newly diagnosed myeloproliferative disorders such as polycythemia vera or essential thrombocytosis and often occurs before a rise in peripheral blood counts. The *JAK2* V617F (Janus-activated kinase gain-of-function substitute of valine to phenylalanine at position 617) mutation is diagnostic of myeloproliferative disorders[20]; in a meta-analysis of four case-control studies it was—in contrast to patients with other venous thromboembolisms—found to be strongly associated with thrombosis within the mesenteric, portal, and hepatic veins (splanchnic venous thrombosis).[21] Primary cytomegalovirus infection has also been associated with MVT.[22] Neither liver cirrhosis nor abdominal cancer was a risk factor in a population-based case-control study based on autopsies.[5] Synchronous venous thromboembolism in the systemic circulation frequently occurs in patients with MVT, especially pulmonary embolism.[5] There may be an increased risk of MVT following laparoscopic surgery because of venous stasis from increased intra-abdominal pressure, especially in obese patients undergoing Roux-en-Y bypasses, or when there is a more extensive intraoperative mobilization of the mesenteric, portal, or splenic vein. Together with the presence of any systemic thrombophilic state, development of MVT seems to be more likely.[23,24]

NATURAL HISTORY

It is difficult to pinpoint the natural history of MVT. The disease is uncommon, patients often have diffuse symptoms, and the condition is not always detected, even with contemporary diagnostic routines. Thus we have no absolute knowledge of the total number of patients with symptomatic and asymptomatic disease. However, in a population-based study with a high autopsy rate (87%), it was found that 35 of 31,015 patients (0.1%) examined postmortem had MVT.[5] The majority of

patients with MVT at autopsy (27 of 35, or 77%) had a transmural intestinal infarction, judged to be the cause of death. The patients diagnosed at exploratory laparotomy all had transmural intestinal infarction and required bowel resection for survival. The mortality rate among those undergoing exploratory laparotomy was 30% (12 of 40). Portal venous thrombosis (PVT) was studied in the same cohort, and there were some interesting differences: PVT was 10 times more common than MVT at autopsy, patients with PVT more often had asymptomatic disease, and PVT was seldom considered the cause of death.[25] Two studies[26,27] suggest that superior MVT, in contrast to isolated PVT, is associated with symptoms in the overwhelming majority (92%[26]) of cases and also often results in bowel gangrene (33%[27]-45%[26]), depending on diagnostic and therapeutic activity. On the other hand, recent MDCT imaging studies have reported that one-fourth of the patients with inflammatory bowel disease have thromboses in the peripheral mesenteric veins and that most of these thromboses are probably asymptomatic.[10]

PATHOLOGY AND MANIFESTATIONS

The degree of intestinal ischemia that develops depends on the extent of venous thrombosis within the splanchnic venous circulation and whether there is occlusion and collateral flow. Patients with isolated PVT without peripheral propagation to the superior mesenteric vein are asymptomatic in the majority of cases (61%[26]) and almost never experience intestinal infarction (0%[26]-10%[27]). In 270 patients with porto-MVT found at autopsy, 29 of 31 (94%) patients with MVT had intestinal infarction and 0 of 239 (0%) with isolated PVT had intestinal infarction.[27]

At operation, MVT is characterized by a limited segment of intestinal ischemia, with edema, swelling, and reddish discoloration of the affected small bowel and its adjacent mesentery and a palpable pulse in the superior mesenteric artery (SMA) and its branches.[28] In contrast, intestinal ischemia due to arterial occlusive or nonocclusive disease is often characterized by extensive ischemia that includes the jejunum, ileum, and colon,[29] with patchy cyanosis, reddish black discoloration, and no palpable pulsations. MVT can be confirmed during surgery if an infarcted bowel segment is removed. Division of a small part of the adjacent mesentery, without previous vessel ligation, reveals thrombosis within the veins, whereas a pulsatile hemorrhage arises from the arteries. The extent of intestinal infarction is often limited to the jejunum or the ileum (Fig. 136.2).[5]

DIAGNOSIS

Patients with symptoms of less than 4 weeks' duration are classified as having acute MVT. Those with symptoms lasting longer than 4 weeks but without bowel infarction or those with clinically insignificant MVT diagnosed incidentally on abdominal imaging are classified as having chronic MVT. The majority of patients—71% and 74% in two large clinical series[4,7]—have acute MVT.

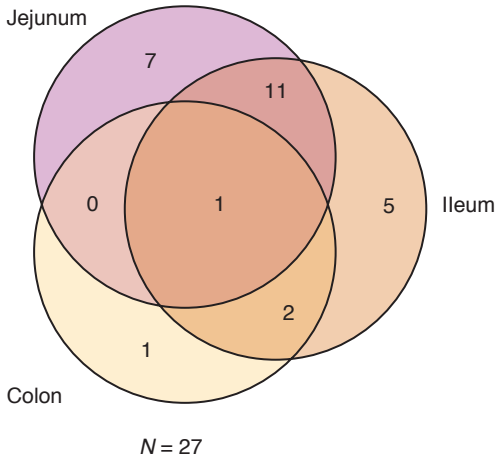

Figure 136.2 Venn diagram showing the extent of intestinal infarction in 27 patients with mesenteric venous thrombosis and transmural intestinal infarction.

Recognition by History and Physical Examination

Acute and particularly chronic MVT is a difficult diagnosis among patients presenting with acute or subacute abdominal pain. Awareness of the disease, a careful risk factor evaluation, and positive findings at physical examination may lead the clinician to the diagnosis. The onset of acute MVT is often insidious, and diffuse abdominal pain may be present for days or weeks. Abdominal pain is often[7,8] but not always present at admission. The second most common symptom is nausea/vomiting, whereas diarrhea and lower gastrointestinal bleeding are present in less than 20% of cases.[30,31] Typically a middle-aged patient with a personal or a family history of deep venous thrombosis presents with abdominal pain of a few days' duration, vomiting, and abdominal distention as well as a clearly raised C-reactive protein (CRP) level. The patient may develop localized peritonitis. With progression to transmural intestinal infarction, peristalsis ceases and signs of generalized peritonitis appear.

Laboratory Testing

There are no accurate plasma biomarkers for diagnosing intestinal ischemia. D-dimer has been reported to be a sensitive but not specific marker of acute thromboembolic occlusion of the SMA.[32] From a theoretical point of view, we have reason to believe that a normal D-dimer level may be useful to exclude MVT as well. This view is supported by experience from a small series of patients.[4]

Further, because inherited thrombophilic factors are common in MVT, it is recommended for risk factor evaluation that all patients with MVT should be screened for the following inherited disorders: factor V Leiden mutation, prothrombin gene mutation, protein C deficiency, protein S deficiency, and antithrombin III deficiency. Simultaneously, the patient should be checked for acquired disorders such as *JAK2* V617F mutation,[20,21] lupus anticoagulant, and cardiolipin antibodies. Whether the presence of these thrombophilic factors influences recurrence rates and/or duration of anticoagulation treatment or not is unclear.

Since MVT may be diagnosed before a rise in peripheral blood counts in myeloproliferative disorders,[20] it may be wise to obtain a full blood count with white blood cell differentiation at follow-up.

Noninvasive and Invasive Testing

MDCT of the abdomen, with intravenous contrast injection and imaging in the portal venous phase, is the most important, available, and accurate diagnostic tool.[33-35] The protocol for acute CT of the abdomen varies with the clinical history provided by the referring physician who requests the examination. Of note, MVT is seldom suspected by the clinician before ordering CT; in fact, the diagnosis is often first made by the radiologist.[36] In one series, MVT or intestinal ischemia was suspected before CT in only 1 patient with congenital portal vein occlusion out of 20 with verified MVT (5%).[36] Optimally, the CT protocol would include biphasic imaging in the arterial and portal phases with 1-mm thin slices and reconstructions in the coronal and sagittal planes.

The vascular and intestinal findings of MVT on MDCT (Figs. 136.3-136.5) are summarized in Table 136.1.[36] MDCT often demonstrates extensive thrombosis of the portomesenteric system, with extension of thrombosis to at least the extrahepatic portal and splenic veins. Intestinal findings are less common and more subtle. Hence the radiologist should always examine the mesenteric vessels in cases of an acute or unclear abdomen. An optimized CT protocol should be used in MVT patients in whom the discontinuation of oral vitamin K antagonist (VKA) treatment is being considered or when patients on anticoagulation treatment are suffering from abdominal pain or experiencing a general deterioration in their condition.

Exploratory laparoscopy or laparotomy will continue to be a necessary diagnostic tool for some patients, even after CT, especially those presenting with peritonitis. In experienced hands, laparoscopy (see film sequence) can be the preferred method to assess intestinal viability.[37,38] Major obstacles for

full visualization and macroscopic evaluation of the small intestines are extensive paralysis with bowel dilatation and prior adhesions.

TREATMENT AND RESULTS

The first-line treatment option is conservative with anticoagulation, fasting, nasogastric tube, fluid and electrolyte replacement, analgesics, and administration of total parenteral nutrition. The use of antibiotics directed toward intestinal flora is logical in cases of advanced MVT with risk of sepsis secondary to bacterial translocation or bowel perforation.[39] A few patients will undergo laparotomy and bowel resection at three different time points: at admission due to late presentation or diagnosis, after some weeks due to failure of anticoagulation therapy to reverse the condition, and after some months due to late bowel stricture. Systemic thrombolysis in MVT has not been evaluated systematically, but extensive MVT can be successfully treated with recombinant tissue plasminogen activator (rt-PA; total dose of approximately 100 mg for 48 hours).[40] Endovascular treatment in combination with heparin infusion, with or without bowel resection, is an additional treatment tool in those few patients who do not respond satisfactorily to heparin infusion alone. A multidisciplinary stepwise management strategy involves modern surgical and endovascular treatments that focus on early mesenteric recanalization and bowel viability salvage. This is best done in an integrated intestinal stroke center composed primarily of gastroenterologist and gastrointestinal and vascular surgeons. Such a center seems to be able to generate favorable outcomes, with overall recanalization rate of 91% and 30-day mortality rate of 12% or lower in acute superior MVT.[41]

Medical Treatment

Immediate full anticoagulation with a continuous infusion of unfractionated heparin is used in surgical as well as nonsurgical cases to obtain an activated partial thromboplastin time of 50 to 70 seconds monitored at 4-hour intervals. In the early phase, unfractionated heparin offers two advantages over LMWH: the anti-inflammatory effect is greater and it can be reversed with protamine if laparotomy becomes necessary. Every patient should initially be closely observed, with repeated abdominal evaluations and body temperature readings as well as daily CRP and leukocyte measurements. In the absence of recovery, with rising CRP values, or in the case of any clinical deterioration, repeat CT examinations with intravenous contrast can show changes such as extension of venous thrombosis and can evaluate the severity of ischemic bowel lesions, providing help in the often difficult decision-making process of when to proceed to laparotomy.[42]

When gastrointestinal function has normalized, LMWH or oral VKA or new direct oral anticoagulants (DOAC) are advocated. The anti-inflammatory effects of LMWH (compared with VKA or DOAC) may be advantageous in the early follow-up period.[43] The thrombotic status within the splanchnic venous system after VKA treatment has not been evaluated systematically with repeated CT scans, but it seems that most thrombosis shows either no change or regression after a short period (3 months) of VKA treatment.[36] Lifelong treatment with VKA is recommended[44] owing to the high recurrence rate of MVT, up to 36%, without anticoagulation.[7] Long-term treatment with LMWH is reserved for patients with liver dysfunction or other conditions in which oral VKA treatment is contraindicated, inappropriate, or a less reliable treatment option. Most patients can be treated conservatively if they are diagnosed in a timely manner.[8] One series showed that MDCT in the portal venous phase was diagnostic in all 20 investigated patients, and conservative management was possible in 19 (95%).[36] The duration of anticoagulation therapy must be carefully balanced against risk factors for bleeding, such as the presence of varices, low platelet count and previous bleeding, risk for recurrence due to persisting risk factors, previous venous thromboembolism, and consequences of recurrence or progression due to extensive bowel involvement.[45] An alternative medical option is the use of a fixed dose of DOAC. The advantages include fewer interactions with other medications and lack of need of frequent monitoring; the disadvantages include the present lack of antagonists to factor Xa inhibitors and lack of specific safety data in patients with MVT. However, the effects of another DOAC, dabigatran, a thrombin inhibitor, can instantly be reversed with idarucizumab.[46,47]

In-hospital mortality among identified and actively treated patients has decreased to 20%, probably because of earlier detection with CT and identification of a higher proportion of patients without peritonitis and not requiring laparotomy.[3,8]

Anticoagulation with or without bowel resection in patients with acute MVT has also improved survival in comparison with observation alone.[7] The overall 30-day survival in a contemporary series was 80% (41 of 51), and the estimated 5-year survival for the 51 patients was 70%.[4] Prognosis of patients with MVT after hospital discharge seems to be highly associated with the underlying disease, and cancer patients have the poorest survival.[4] Gastrointestinal bleeding,[7] late small bowel perforation, and intestinal stricture[8] have been described as specific gastrointestinal complications.

Endovascular Treatment

A number of endovascular procedures for the treatment of MVT have been developed in recent years, including percutaneous transjugular intrahepatic portosystemic shunting (TIPS) with mechanical aspiration thrombectomy[48] and direct thrombolysis,[49,50] percutaneous transhepatic mechanical thrombectomy,[51] percutaneous transhepatic thrombolysis,[52,53] thrombolysis via the SMA,[54] and thrombolysis via an operatively placed mesenteric vein catheter.[55] Rapid thrombus removal or dissolution can be achieved through these techniques, especially after TIPS and stent placement to create a low-pressure runoff.[56] Mechanical thrombectomy is performed using a variety of thrombectomy devices and is most effective in cases of acute rather than chronic thrombus. Before considering thrombolysis, checking for relative and absolute contraindications such as recent cerebral infarction (within 6 weeks), history of cerebral hemorrhage, malignant tumor, arteriovenous malformation in the brain, severe diabetic retinopathy, gastrointestinal hemorrhage, or esophageal varices should be performed. Local direct thrombolysis into the portomesenteric circulation through the transjugular or transhepatic route is useful for clearing residual clots and restoring venous flow. Indirect thrombolytic therapy via the SMA is less effective and more time-consuming, may require longer infusion times and higher doses of thrombolytic agent, and is also associated with an increased bleeding risk. There is some experience with both rt-PA and urokinase as thrombolytic agents.[54] Balloon angioplasty is an alternative technique of clot fragmentation in cases of refractory thrombus and fixed venous stenosis. Aspiration thrombectomy is performed with a stiff, large-diameter (at least 8F), angled catheter connected to a Luer-Lok syringe to create a vacuum effect.[49] A potential drawback of thrombectomy and angioplasty is intimal trauma that can promote rethrombosis.

Endovascular techniques have been successful in terms of survival, patency of the portomesenteric veins, lower rates of portal hypertension,[53] low complication rates, and avoidance of bowel resection[53] in selected patients. However, in a larger series of 16 patients with MVT treated with local thrombolysis, 1 had complete lysis, 11 had partial lysis, and 4 had no lysis of the superior mesenteric vein.[54] Local thrombolysis was associated with significant bleeding complications in 60% of patients, including intra-abdominal bleeding, bleeding from the access site, perihepatic hematoma, nosebleed, and hematuria.[54] Accumulation of blood from the portal vein in the right pleural space, causing right-sided hemothorax, has been reported during percutaneous transhepatic thrombectomy and thrombolysis,[57] as have deaths due to gastrointestinal hemorrhage and sepsis.[54,57]

Patients should be anticoagulated with unfractionated heparin following endovascular treatment, and the bowel should be rested. VKA or DOAC replaces heparin when gastrointestinal function is normalized. Patency of the portal system after TIPS can be evaluated by follow-up Doppler ultrasound at 1 and 3 months and then again at 6 months to check the portal system and shunt function.[49] Clearance of thrombus can be evaluated with CT, but a clear correlation between radiologic findings and clinical symptoms does not appear to exist.

There are no comparative studies between anticoagulation alone and endovascular treatment to help establish the indication for endovascular treatment. Most patients are treated successfully with medical treatment only, but a small proportion (5%[4]) of patients deteriorate during medical treatment. In those situations, clinical practice in some centers during the last decade has been to initiate endovascular treatment.

Surgical Treatment

The indications for surgery are peritonitis, severe gastrointestinal bleeding, small bowel perforation, and intestinal stricture; the last is often associated with chronic diarrhea. When a clear clinical deterioration or peritonitis develops in a patient with MVT, laparotomy is indicated. In very select cases, open surgical thrombectomy may be considered worthwhile.[58] When an emergency laparotomy must be performed, endovascular treatment with thrombolysis is contraindicated. If there are signs of extensive intestinal ischemia, which is rare, one possible strategy may be surgical thrombectomy combined with bowel resection of the gangrenous bowel, heparinization, and second-look laparotomy. Bowel resection should be performed in cases of frank transmural intestinal necrosis, uncertain bowel viability, or severe ischemic bowel lesions (Fig. 136.6). However, signs of peritonitis are not always associated with transmural intestinal infarction, and some patients with rebound tenderness can still be treated conservatively.[8] Primary bowel anastomosis after resection is recommended. This is a straightforward treatment in the typical patient in whom a short segment of the small bowel is affected. In the less common situation, in which a longer segment of the intestines is threatened, an alternative is to staple off the infarcted intestine, perform skin-only closure rather than fascial closure, and delay reconstruction until a second-look laparotomy, when the viability of the remaining small intestine can be evaluated. At the second look, areas of intestinal ischemia with doubtful viability may have recovered, and there is usually a clearer demarcation of the infarcted segments. The purpose of the second-look laparotomy is to reduce unnecessary bowel resections at the primary exploration, thus permitting salvage of segments of bowel with doubtful viability.

Immediately after surgery, a heparin infusion is administered. The patient should be on bowel rest and receive total parenteral nutrition for a few days until the return of

Figure 136.6 Ischemic bowel due to mesenteric venous thrombosis (see also film sequence). A 47-year-old man with a history of deep venous thrombosis and pulmonary embolism treated with a vena cava filter and a vitamin K antagonist (VKA) presented with a 3-day history of lower abdominal pain and obstipation. He had discontinued VKA treatment 4 days previously. At admission, plasma D-dimer was 9.6 mg/L (reference value, <0.2 mg/L), and plasma lactate was normal. He developed signs of generalized peritonitis with rebound tenderness in the abdomen 12 hours after admission. Laparoscopy showed signs of ischemia in the proximal ileum. At laparotomy, 1.2 m of the small bowel was ischemic. It was decided to remove the two most reddish, discolored, severely ischemic segments *(arrows)* by resecting a total length of 0.4 m, followed by one small bowel anastomosis. Note the edema of the affected small bowel loops and their adjacent mesentery. Treatment with a full dose of low-molecular-weight heparin was started at the end of surgery. Second-look laparotomy was performed after 30 hours. Reassessment of bowel viability showed that the intestines had normal turgor and color and the anastomosis was intact. Recovery thereafter was uneventful, and lifelong treatment with VKA was prescribed. Histopathology of the resected bowel did not show transmural infarction but did show infarcted mucosa and venous thrombosis.

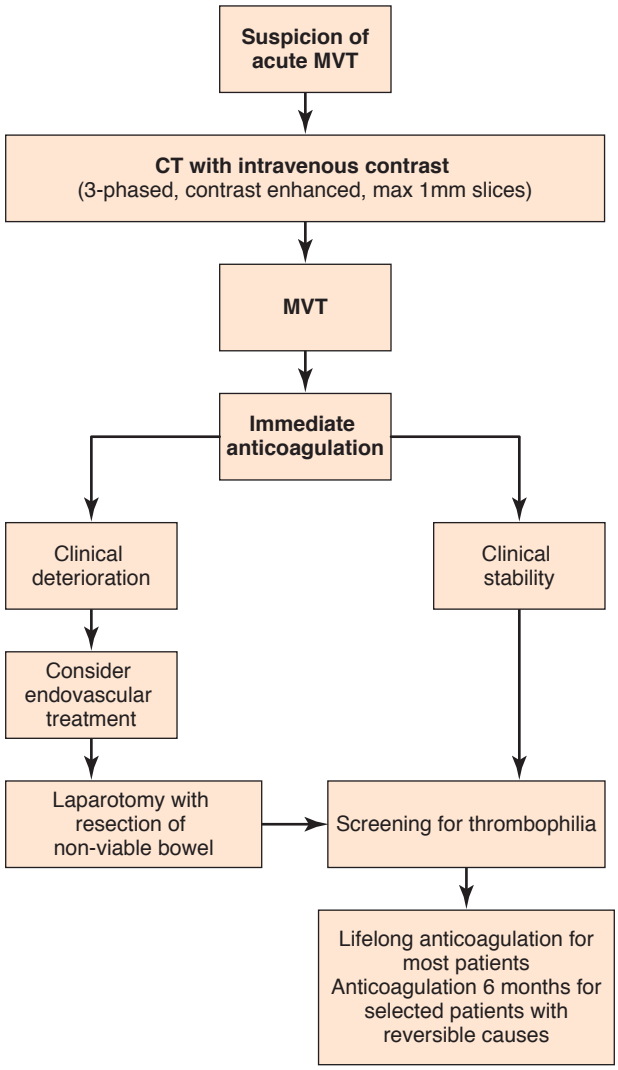

Figure 136.7 Management algorithm for patients with acute mesenteric venous thrombosis (MVT). *CT*, Computed tomography.

gastrointestinal function. All patients should then receive anticoagulation with either LMWH or VKA. Lifelong treatment should be considered for most patients owing to the high recurrence rate and the often fatal outcome in case of recurrence. The value of a postoperative CT scan to evaluate the extension of thrombosis and the frequency of thrombus recanalization is unclear. However, a repeat CT scan after 6 months of anticoagulation therapy may be helpful in determining the duration of treatment if lifelong treatment is not being considered.

Morbidity rates in cases managed with and without surgery are similar,[8] although it must be recognized that these are different groups of patients, and no randomized studies exist. The short-term[3] and 2-year[8] survival rates are comparable between groups undergoing surgery and medical treatment. The survival rate after bowel resection is around 80%.[3,7] The most common complications following surgery are pneumonia, wound infection, renal failure, sepsis, and gastrointestinal bleeding.[7,8] Fortunately the occurrence of short-bowel syndrome after bowel resection for MVT is rare.[2,7] In a recent series, none of the 12 patients who underwent bowel resection developed short-bowel syndrome.[4] The median length of the resected intestinal segment in that series was 0.6 m (range, 0.1-2.2 m). The relatively high frequency (23%) of short-bowel syndrome in patients with acute MVT in an older study might be attributable to unnecessarily extensive bowel resections or suboptimal pharmacologic therapy.[7] Among patients with MVT, bowel resections should always be conservative. A pragmatic management algorithm for patients with acute MVT is shown in Fig. 136.7.[59]

Vasculitis refers to a group of inflammatory disorders that result in inflammation and necrosis of blood vessels with subsequent impairment of flow resulting in ischemia and infarction of distal tissues.[1,2] Often, vascular surgeons are the first physicians consulted in cases of vasculitis, and vasculitis should be considered in patients with ischemic occlusive disease or aneurysmal disease in the absence of traditional risk factors and in association with features of a systemic inflammatory process. Prompt involvement of a rheumatologist can expedite diagnostic testing and treatment. Vessels of any location may be affected by vasculitis, and the classification nomenclature has been defined by the International Chapel Hill Consensus Conference,[3] as outlined in Table 137.1

VASCULITIS PRESENTATION

There is no single presentation of vasculitis, but clinical manifestations often suggest the size of vessel affected and thus can help guide the likely diagnosis and necessary work-up. For example, patients with large-vessel vasculitis often present with limb

TABLE 137.1 International Chapel Hill Consensus Conference Nomenclature[3]

Nomenclature		Vasculitis
Large-vessel vasculitis		Giant cell arteritis (also known as temporal arteritis) Takayasu's arteritis
Medium-vessel vasculitis		Polyarteritis nodosa Kawasaki disease
Small-vessel vasculitis	Immune complex-mediated	Antiglomerular basement membrane (anti-GBM) disease Cryoglobulinemic vasculitis IgA vasculitis (Henoch-Schönlein purpura) Hypocomplementemic urticarial vasculitis (anti-C1q vasculitis)
	Antineutrophil cytoplasmic antibody-mediated (ANCA-associated pauci-immune)	Granulomatosis with polyangiitis (previously known as Wegener's granulomatosis) Microscopic polyangiitis Eosinophilic granulomatosis with polyangiitis (previously known as Churg-Strauss syndrome)
Variable-vessel vasculitis		Behçet's disease Cogan syndrome Thromboangiitis obliterans (Buerger's disease).
Single-organ vasculitis		Cutaneous leukocytoclastic vasculitis Cutaneous arteritis Primary central nervous system (CNS) vasculitis (isolated angiitis of the CNS) Isolated aortitis Others
Vasculitis associated with systemic disease		Lupus vasculitis Rheumatoid vasculitis Sarcoid vasculitis Others
Vasculitis secondary to other etiology		Hepatitis C-associated cryoglobulinemic vasculitis Hepatitis B-associated vasculitis Syphilis-associated vasculitis Drug-associated immune complex vasculitis (hypersensitivity vasculitis) Cancer-associated vasculitis Others

Thromboangiitis obliterans (Buerger's disease) was not classified at the Chapel Hill conference but fits best in to the variable-vessel vasculitis group.

claudication, vascular bruits, asymmetric blood pressures, or absence of pulses. The medium vessel vasculitides often present with cutaneous nodules and ulcers, livedo reticularis, digital gangrene, mononeuritis multiplex, and renovascular hypertension. In contrast, patients with small vessel vasculitis tend to present with palpable purpura, pulmonary-renal syndromes (glomerulonephritis and alveolar hemorrhage), urticarial skin rashes, and scleritis.

Histologic Characteristics of Vasculitis

The vasculitides typically cause characteristic histologic features, including infiltration of the vessel wall by neutrophils, mononuclear cells, and/or giant cells. Fibrinoid necrosis is seen with pan-mural destruction of the vessel wall and evidence of leukocytoclasis (disruption of leukocytes resulting in the histologic finding of "nuclear dust"). It should be noted that perivascular infiltration alone is a nonspecific histologic finding, which is not diagnostic of vasculitis.

Histologic findings in the specific diseases are dependent on the vessel size affected and the underlying disease physiology. Giant cell arteritis (GCA), Takayasu's arteritis, and primary central nervous system (CNS) vasculitis are cell mediated, whereas polyarteritis nodosa (PAN), Henoch-Schonlein purpura, cryoglobulinemic vasculitis, and cutaneous leukocytoclastic angiitis are immune complex mediated. The ANCA-associated vasculitides (AAV) involve both cellular and humoral immune responses and often involve granulomatous tissue injury without immune complex formation.

Angiography

When tissue biopsy is not feasible, angiography imaging can be helpful for assessing specific types of arteritis. For example, angiography of the celiac trunk, superior mesenteric, and renal arteries can be diagnostic of PAN; imaging of the aortic arch is essential for the diagnosis of Takayasu's arteritis and GCA with large-vessel involvement; angiography of the extremities can be helpful in the diagnosis of thromboangiitis obliterans (TO); and angiography of the cerebral circulation is essential for the diagnosis of primary CNS vasculitis. Angiographic findings that are characteristic of vasculitis include irregular asymmetrical tapering and narrowing as well as "beading" with segmental stenosis and aneurysm formation.

Noninvasive Vascular Imaging

Noninvasive vascular imaging is used to evaluate some vascular beds, although it is somewhat controversial. In GCA, Doppler ultrasound of the temporal arteries has been shown to demonstrate inflammatory changes and can be used to assist with biopsy site selection; however, utility as a diagnostic tool is highly dependent on the experience of the sonographer; thus it should not replace temporal artery biopsy as a diagnostic tool.[4] Magnetic resonance angiography of the aorta has utility in larger vascular beds and can be used to image the aorta in Takayasu's arteritis and GCA. Aortic wall enhancement with gadolinium indicates active inflammation.[5] Positron emission tomography (PET) has also been used to demonstrate enhancement in the aortic and subclavian vascular beds in Takayasu's and GCA[6] but has not gained widespread use as a diagnostic tool.

LARGE-VESSEL VASCULITIS

Takayasu's Arteritis

Takayasu's arteritis is a cause of large-vessel vasculitis affecting the aorta and its branches that presents in younger individuals. It is discussed in Chapter 139.

Giant Cell Arteritis (Temporal Arteritis)

Epidemiology

GCA primarily affects patients over 50 years of age and is more common in Caucasian patients of Northern European descent. While relatively rare in African Americans, GCA has been reported in all racial groups; thus patients of other races presenting with a consistent history should be fully evaluated.[7] The incidence of GCA increases dramatically with age and is approximately 10 times more common in patients in their 80s than in patients aged 50 to 60.[8] GCA is more common in women than men with a lifetime risk of 1% in women and 0.5% in men.[9]

Pathogenesis

The exact cause of GCA is unknown. Genetic polymorphisms of the human leukocyte antigen class II region, specifically HLA-DRB1*04 and DRB1*01, are associated with susceptibility to GCA.[10] Notably, the T-cell cytokine IFN-gamma is abundantly expressed in GCA but absent from arteries of polymyalgia rheumatica (PMR) patients without GCA.[11] It is thought that in response to immunologic injury, the artery releases growth and angiogenic factors that induce proliferation of myofibroblasts, new vessel formation, and marked thickening of the arterial intima. This leads to vessel narrowing and occlusion resulting in symptoms of ischemia including jaw claudication, visual loss, and stroke.

Clinical Characteristics

GCA should be suspected in individuals over the age of 50 presenting with new-onset headache and evidence of systemic inflammation. Approximately 20% of GCA patients present with cranial symptoms, including headache, scalp tenderness, jaw and tongue claudication, diplopia, and blindness. New onset of diplopia in an elderly patient is highly suggestive of GCA.[12] Jaw claudication is also a very specific symptom.[13] PMR is also a common presentation with 40% of cases presenting with complaints of symmetric pain and stiffness of the shoulder and thigh girdle muscles. It should be noted that some patients develop PMR without GCA and only 10% to 20% of patients presenting with PMR go on to develop GCA. In 20% of GCA cases, symptoms of both cranial GCA and PMR are present at presentation. GCA may also have a more indolent presentation

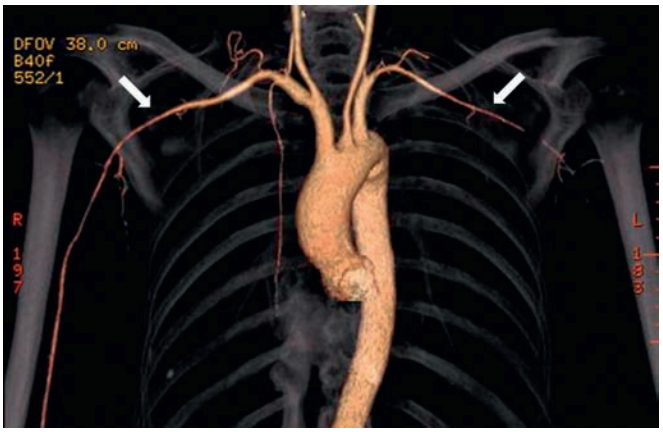

Figure 137.1 Computed tomography angiography with 3D reconstruction images reveals bilateral subclavian, axillary, and proximal brachial artery stenoses in a patient with giant cell arteritis. Moderate narrowing of both proximal common carotid arteries is also noted.

with 15% of cases exhibiting fever and systemic symptoms with no other localizing symptoms. GCA is the cause in 15% of elderly patients with an FUO. Finally, around 5% of GCA cases present with claudication symptoms, cough, tenosynovitis, and the syndrome of relapsing seronegative symmetric synovitis with pitting edema can also occur.

Physical findings in GCA include scalp tenderness and reduced pulse and tenderness of the temporal artery. Of GCA patients presenting with cranial and/or PMR symptoms, approximately 20% have clinical evidence of large-vessel vasculitis impacting subclavian arteries and other vascular territories (Fig. 137.1); thus it is important to check for discrepancies in blood pressure between the extremities, and the carotid and subclavian arteries should be auscultated for bruits. GCA patients have a 17-fold increased risk of development of thoracic aortic aneurysms and a 2.4-fold increased risk of developing abdominal aortic aneurysm compared to controls. Long-term monitoring with periodic imaging of the aorta is recommended.[14]

Abrupt onset of painless blindness may occur as a result of ischemic optic neuritis in 15% of patients and this is usually related to arteritis of the posterior ciliary branches of the ophthalmic arteries. Amaurosis fugax is the strongest predictor for future blindness with a relative risk of 6.3.[15] Thrombocytosis is also associated with visual loss. Patients may additionally complain of blurring of vision, iritis, conjunctivitis, scintillating scotoma, photophobia, glaucoma, and opthalmoplegia from ischemia of extraocular muscles. Retinal and ophthalmic artery thromboses and occipital strokes are less common. It should be noted that risk of visual loss also drops significantly once steroids have been commenced, with less than 10% of patients developing blindness after steroids have been initiated.[16]

Involvement of the intracranial vasculature in GCA is relatively rare, because these vessels lack an internal elastic lamina; however, involvement of internal carotids and vertebral arteries can occur and lead to strokes, seizures, acute hearing loss, vertigo, cerebral dysfunction, and depression.

TABLE 137.2 American College of Rheumatology Criteria for Diagnosis of Giant Cell Arteritis (1990)

Criterion	Definition
Age at disease onset > 50 years	Development of symptoms or findings beginning at age 50 or older
New headache	New onset headache
Temporal artery abnormality	Temporal artery tenderness to palpation or decreased pulsation without evidence of arteriosclerosis of cervical arteries
Elevated erythrocyte sedimentation rate (ESR)	ESR > 50 mm/h by Westergren method
Abnormal artery biopsy	Biopsy specimen showing vasculitis characterized by predominance of mononuclear cell infiltration or granulomatous inflammation, usually with multinucleated giant cells

To meet criteria for a diagnosis of giant cell arteritis, at least three out of the five criteria should be present.[17]

Diagnostic Criteria

The 1990 American College of Rheumatology criteria for the diagnosis of GCA[17] are listed in Table 137.2. For diagnosis of GCA, at least three out of five criteria must be present. The presence of three or more criteria yields a sensitivity of 93.5% and specificity of 91.2% for distinguishing GCA from other forms of vasculitis. While the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are often markedly elevated in GCA, only a minority of patients have a normal ESR. Often, patients will have other evidence of systemic immune response, including normocytic anemia and elevated platelet count (see Table 137.2).

The gold standard diagnostic test for GCA is temporal artery biopsy. An adequate length of temporal artery (2-3 cm) should be obtained at biopsy, and bilateral biopsies (particularly if the first is negative) are recommended by some groups.[18] Up to 50% of biopsies show diffuse lymphocytic infiltrate without evidence of granulomatous inflammation or giant cells. Fragmentation and fraying of the internal elastic lamina can be seen in normal aging, so in the absence of inflammation, this finding is not diagnostic of GCA. Ideally, biopsy specimens should be obtained prior to or within 7 days of starting corticosteroids. However, corticosteroid therapy does not normalize the affected artery; it simply reduces the inflammatory infiltrate, so "healed temporal arteritis" can still be diagnosed by the presence of intimal fibrosis, medial scarring, and asymmetric destruction of the internal elastic lamina.[19]

Large-vessel involvement may be assessed using conventional angiography, magnetic resonance angiography, or computed

tomography (CT) angiography.[5,6,12] Newer imaging modalities including ultrasound and PET are being evaluated as diagnostic tools in GCA.[6]

Medical Treatment of Giant Cell Arteritis

Corticosteroid therapy is standard of care in the management of GCA, and the initial dosing should be 40 to 60 mg daily. In patients with incipient visual loss, intravenous methylprednisolone (1000 mg per day for 3 days) may be considered. The initial prednisone dose should be maintained until inflammatory markers normalize (usually at least 1 month). Various tapering methods are used, but a rule of thumb is to reduce the prednisone by 5 mg every 1 to 2 weeks until 30 mg per day is reached and then to reduce the amount by 2.5 mg every 1 to 2 weeks until 15 mg per day. The subsequent taper should be 2.5 mg every 4 weeks until 10 mg and then 1 mg every 4 weeks until the patient is off prednisone. Alternate-day steroid dosing regimens are not effective. Clinical symptoms, ESR, and CRP should be monitored for every change in dose, and it should be noted that spontaneous recurrence may occur in as many as 50% of cases. Up to 40% of cases (especially women) need long-term corticosteroid therapy for several years. All patients are recommended to also receive low-dose aspirin 81 mg per day to reduce the risk of cardiovascular events and blindness. It was recently shown that methotrexate is an effective steroid-sparing agent and may allow more rapid steroid tapering. Tumor necrosis factor (TNF)-α inhibitors were ineffective, but the anti-IL6 antibody Tocilizumab was effective for steroid-dependent, treatment-resistant GCA. Other trials of biologic and nonbiologic disease-modifying antirheumatic drugs (DMARDs) are ongoing. Fig. 137.2 shows marked improvement in diffuse arterial wall thickening caused by GCA in response to steroids.

Role for Vascular Surgical Intervention in Giant Cell Arteritis

Revascularization procedures are rarely required in GCA due to development of collaterals. Balloon angioplasty in combination with immunosuppressive treatment has been tried in small case series, but unless the inflammatory process is well controlled, the risk of restenosis is high. For patients with aortic aneurysms, surgery is indicated with surgical results similar to those seen in patients with aneurysms from other etiologies.[20]

Idiopathic Aortitis

Inflammation of the aorta discovered incidentally on histology is seen in 3% to 10% of surgical aortic aneurysm repairs. Miller et al. recorded 45 cases of incidental aortitis in a retrospective review of 514 ascending aortic specimens (frequency 8.8%). In the thoracic aorta, some of these lesions are histologically indistinguishable from GCA, but others demonstrate

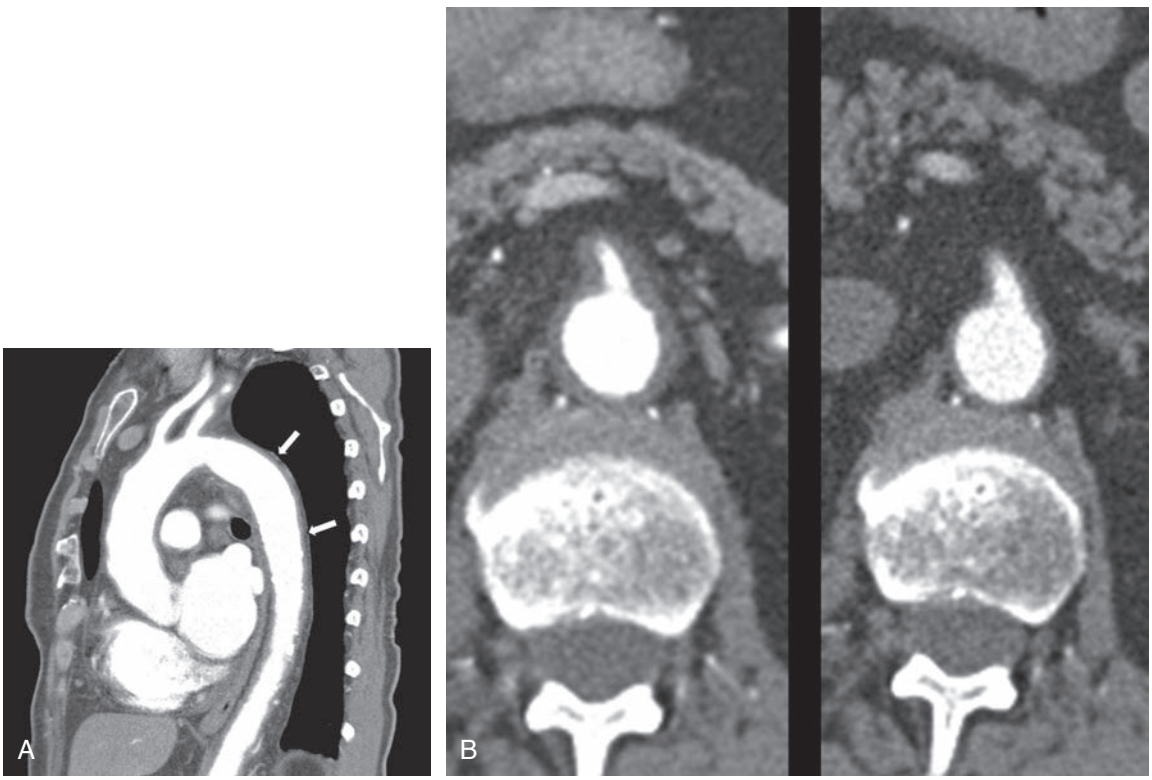

Figure 137.2 Computed tomography angiogram of a patient with giant cell arteritis and involvement of the aorta. (A) This sagittal image demonstrates thickened arterial walls, most prominent in the great vessels, and throughout the entire descending thoracic aorta. (B) Arterial wall thickening extended into the upper abdominal aorta and superior mesenteric artery (SMA), which was stenosed *(left panel)*. Reimaging after 6 months of treatment with corticosteroids revealed marked improvement in the diffuse arterial wall thickening and SMA stenosis *(right panel)*.

lymphoplasmacytic infiltrate, and 75% of these are due to IgG4-related disease. In the abdominal aortal, lesions can be grouped into idiopathic retroperitoneal fibrosis (Ormond Disease) and inflammatory aortic aneurysms that are often associated with smoking and a family history of aortic aneurysm, which some of these lesions are due to IgG4 related systemic disease. The syndrome of idiopathic abdominal peri-aortitis has also been described without associated aneurysm or retroperitoneal fibrosis. In these patients, rarer etiologies including Erdheim-Chester disease should be considered.

Idiopathic Retroperitoneal Fibrosis (Ormond Disease)

Idiopathic retroperitoneal fibrosis is rare, affects men more than women (3:1), and presents in patients in middle age (40-60 years old). Typically, patients present with pain in the lower back, abdomen, flank, and scrotum. Some patients also demonstrate systemic symptoms including fever, anorexia, and malaise. Patients have hypertension in 75% of cases and lower extremity edema and phlebitis can be seen. Serologic work-up is usually negative, but inflammatory markers are elevated in 75% of cases. Classic CT findings include presence of a homogeneous mass around the aorta following the iliac bifurcation with associated medial deviation of the mid-part of the ureter and secondary hydronephrosis. Usually, lymphadenopathy is absent. Biopsy may be performed laparoscopically or through open procedure, and histology shows sclerosis with infiltration of mononuclear cells. The pathophysiology of this process is unknown, but an exaggerated local inflammatory response to oxidized low-density lipoprotein in aortic plaque has been postulated. Treatment with high-dose prednisone is recommended (60 mg daily for 1 month followed by tapering off to 10 mg/day by 3-6 months). Maintenance therapy with prednisone is recommended for 1 to 3 years. The disease recurs in 10% to 30%, and use of mycophenolate mofetil, tamoxifen, or methotrexate should be considered for these patients. Monitoring with inflammatory markers and CT scan should be continued every 3 months while on treatment and every 6 months when off treatment.

IgG4-Related Systemic Disease

IgG4-related systemic disease affects older males with 60% to 80% of cases affecting patients older than 50 years. Often, there is a past medical history of allergic diseases and atopy (eczema and asthma). Patients develop tumor-like lesions in one or more organs and on biopsy-dense lymphoplasmacytic infiltrates with storiform fibrosis and obliterative phlebitis.[21] Lesions should be stained to demonstrate IgG4 positive cells (with >30 per high-powered field and IgG4/IgG positive ratio >50% confirming the diagnosis). Elevated serum IgG4 is seen in 60% to 80% of cases but is not always detected. Serologic work-up is usually negative. Several organs may be affected simultaneously with the most common presentations being type I autoimmune pancreatitis, sclerosing cholangitis, salivary gland involvement (Mikulicz disease), and sclerosing sialadenitis (Kuttner tumor). The disease may be associated with chronic lymphoplasmacytic aortitis and aneurysm formation. This more commonly affects the thoracic than abdominal aorta and can be mistaken for idiopathic retroperitoneal fibrosis. Treatment for IgG4-related disease includes high-dose steroids along with DMARDs; in recent years, rituximab (a monoclonal antibody targeting B cells) has been shown to be effective.[22]

Erdheim-Chester Disease

Erdheim-Chester disease is a rare histiocytic disease that is associated with periaortic fibrosis (referred to as "coated aorta"), periarterial infiltration of coronary arteries, and pericardial thickening and effusion. Retroperitoneal involvement may also manifest with mass-like infiltrative lesion or with perinephric changes known as "hairy kidney."[23] It may be confused with idiopathic retroperitoneal fibrosis and IgG4-related disease,[24] but the distinguishing feature is that most patients also have bone lesions, often in the lower extremities that present with juxtaarticular pain. Biopsy of involved tissue reveals tissue infiltration by sheets of foamy histiocytes interspersed with inflammatory and multinucleated giant cells. In recent years, it has become clear that the disease is associated with gain-of-function mutations in the proto-oncogene BRAF (the BRAFV600E mutation), and treatment with BRAF inhibitors has been found to be effective with less toxicity than prior treatment options such as interferon.[25]

MEDIUM-SIZED VESSEL VASCULITIS

Polyarteritis Nodosa

PAN is a necrotizing vasculitis of small and medium arteries and is characterized by the absence of glomerulonephritis and anti-neutrophil cytoplasmic (ANCA) antibodies.[26] Diagnosis is based on presence of 3 out of the 10 American College of Rheumatology criteria (Table 137.3).

Pathogenesis

PAN may be idiopathic or secondary to hepatitis B infection. In hepatitis B associated PAN, the mean time between hepatitis diagnosis and PAN is 7 months. PAN may also be associated with other viral infections including HIV and has been seen as a paraneoplastic manifestation of hematology malignancy (particularly, hairy-cell leukemia).

Histology

The histologic lesion in PAN is a focal, segmental necrotizing vasculitis affecting medium-sized arteries. It commonly affects arterioles with sparing of large vessels and veins. The arterial wall inflammation is characterized by fibrinoid necrosis of the media along with neutrophilic and lymphocytic infiltrate. Active necrotizing lesions are often seen alongside healed and fibrotic lesions. Localized thromboses may occur at the site of inflammatory injury, and arterial aneurysms may form as a result of weakening of the vessel wall by the inflammatory process, ultimately leading to end organ injury from ischemia, infarct, and hemorrhage.

TABLE 137.3 American College of Rheumatology Diagnostic Criteria for Polyarteritis Nodosa

Criterion	Definition
Weight loss >4 kg	Loss of at least 4 kg since illness began without dieting or other confounding factors
Livedo reticularis	Mottled reticular pattern over the skin of extremities or torso
Testicular pain or tenderness	Pain or tenderness of the testicles not due to infection, trauma, or other causes.
Myalgias, weakness or leg tenderness	Diffuse myalgias or weakness of muscles, tenderness of leg muscles.
Mononeuropathy or polyneuropathy	Development of mononeuropathy, multiple mononeuropathies, or polyneuropathy
Diastolic BP > 90	Development of hypertension with diastolic BP >90 mm Hg
Elevated BUN or creatinine	Elevation of BUN > 40 mg/dL or creatinine >1.5 mg/dL
Hepatitis B infection	Presence of Hepatitis B Surface antigen or antibody in serum
Arteriographic abnormality	Arteriogram showing aneurysms or occlusions of visceral arteries not due to arteriosclerosis, fibromuscular dysplasia, or noninflammatory causes.
Biopsy of small or medium-sized artery demonstrating polymorphonuclear neutrophils	Histologic changes showing presence of granulocytes, and or mononuclear leukocytes in vessel wall.

Epidemiology

BP, Blood pressure; *BUN*, blood urea nitrogen.

Polyarteritis nodosa (PAN) is rare, with annual incidence 2 to 9 cases per million and is declining likely related to reduction in prevalence of hepatitis B infection as vaccination has been more consistent. It may present at any age and in any racial group but is more common in men aged 40 to 60 years. To meet criteria for a diagnosis of PAN, 3 out of the 10 criteria need to be present.[26]

Laboratory Testing

There are no diagnostic serologic tests for PAN. Elevated systemic inflammatory markers are common, and patients may also exhibit normocytic anemic and thrombocytosis. Usually, complement levels are normal. Hepatitis B serology should be tested, and patients with hepatitis-B associated PAN demonstrate hepatitis B surface antigen positivity, HBeAg, and positive PCR for hepatitis B virus DNA. ANCA testing, rheumatoid factor (RF), cryoglobulins, and antinuclear antibodies (ANA) should be negative.

Clinical Features

Patients with PAN present with constitutional symptoms (fever and weight loss) in the setting of organ dysfunction. Commonly seen manifestations include skin lesions—including palpable purpura, livedo, necrotic lesions, and digital infarcts; peripheral neuropathy and mononeuritis multiplex; abdominal pain due to mesenteric vasculitis; and hypertension with microscopic hematuria or proteinuria. Biopsy of affected tissue is crucial for establishing the diagnosis. If the presenting symptoms are related to mesenteric ischemia or renal involvement, then visceral angiogram can be helpful confirming the diagnosis. Angiographic findings include presence of saccular aneurysms, microaneurysms, occlusions and cutoffs with luminal irregularity, and stenosis of small and medium vessels of abdominal viscera. Severe gastrointestinal (GI) involvement is a major cause of morbidity in PAN. Renal biopsy is usually unhelpful, since the renal injury is not glomerular in nature. Microaneurysms of renal artery branches can occasionally rupture and cause renal hematomas. Myalgias due to skeletal muscle involvement and large joint arthralgias are common. Importantly, PAN does not affect the lungs or upper respiratory tract, which is an important feature in distinguishing this disease from the ANCA-associated vasculitides.

Treatment

In patients with hepatitis B associated PAN, antiviral therapy should be initiated prior to immunosuppression. Some patients with severe manifestations of hepatitis virus-associated PAN benefit from short-term treatment with glucocorticoids and plasma exchange until the antiviral therapy becomes effective.[27] Plasma exchange has not been shown to be effective in PAN that is not associated with hepatitis B. Prolonged immunosuppression should be avoided to facilitate immunologic clearance of hepatitis B infected hepatocytes.

In patients with PAN not associated with viral disease, excellent 5-year survival rates of over 80% can be achieved with appropriate immunosuppressive therapy and use of steroids improves survival.[28] For mild and isolated cutaneous disease, initial monotherapy with daily oral prednisone (1 mg/kg ideal body weight up to a maximum of 60 mg per day) is recommended. The initial dose should be continued for 4 weeks, and the taper should be guided by clinical improvement, tapering below 20 mg per day should be done slowly, not faster than by 2.5 mg every 14 days. Most patients remain on prednisone for approximately 6 to 8 months. Many patients with mild disease respond to glucocorticoid monotherapy, but for those patients who do not achieve remission with glucocorticoids alone, addition of a DMARD agent, such as azathioprine (2 mg/kg per day) or methotrexate (20-25 mg weekly) is recommended, with monitoring through rheumatology to allow prednisone to be weaned. Methotrexate should not be used in patients with renal disease or hepatitis.

For patients with moderate to severe disease, data from long-term follow-up studies in several cohorts of patients with PAN shows improved outcomes from induction therapy with steroids and cyclophosphamide[27,29,30] followed by either azathioprine or methotrexate for remission maintenance. There has been no comparison of oral versus IV cyclophosphamide use in PAN; however, one small randomized controlled trial of 18 patients with PAN and 47 with microscopic polyangiitis (MPA) demonstrated that use of steroids with 12 monthly pulses of IV cyclophosphamide had a lower risk of relapse and higher event-free survival than patients receiving only 6 monthly pulses of IV cyclophosphamide. Mortality did not differ, and

this study did not investigate remission maintenance regimens. Some investigators also extrapolate use of the "CYCLOPS" cyclophosphamide dosing regimen that was shown to be comparable to oral cyclophosphamide for induction and remission of ANCA-associated vasculitis, but this has not been studied in PAN. It should be noted that in the management of other forms of vasculitis, the IV dosing of cyclophosphamide often allows effective disease control with lower cumulative dose and potentially reduced bone marrow, bladder, ovarian, and testicular toxicity; but many of the original studies of cyclophosphamide use for vasculitis used the daily oral dosing regimen that is preferred by some due to a higher effective dose and better long-term response rates. In addition, cyclophosphamide should not be dosed without involvement of rheumatology, because this drug carries several adverse effects including cytopenias, gonadal failure, and risk for hemorrhagic cystitis and increased risk of malignancy. Dose reduction is necessary for renal insufficiency and advanced age, and the dose should be adjusted based on the nadir white blood count to minimize bone marrow toxicity. In addition, prophylaxis for pneumocystis jirovecii (PJP) infection should be employed in patients receiving high-dose steroids in combination with DMARDs.

Prognosis

Untreated PAN is associated with poor prognosis (13% 5-year survival, but with treatment the 5-year survival improves to ~80%).[31,32] Age greater than 65, cardiac symptoms, GI involvement, and renal insufficiency (creatinine >1.7 mg/dL) are associated with higher mortality. Renal transplant has been performed in patients with PAN and end-stage renal disease. Of the 112 cases reported in the European Renal Association-European Dialysis and Transplant Association, registry transplantation was associated with significantly lower patient and allograft survival compared to those with renal disease from other causes.[33] Approximately 13% of graft failures were due to disease recurrence.

Other Diseases Showing Aneurysms on Abdominal Visceral Angiography

Several other diseases may demonstrate aneurysms on abdominal angiography. Segmental arterial mediolysis (SAM) is a rare, nonatherosclerotic, noninflammatory disease that affects muscular arteries and can mimic PAN. Classically, this involves the splanchnic arteries in middle aged and elderly patients, the basilar cerebral arteries in adults, and coronary arteries in children and young adults, but the aorta is spared. Patients present with life-threatening hemorrhage due to aneurysm rupture, and histologically, there is lysis and loss of the muscular layer of the media, resulting in arterial dilatation and aneurysm formation. It is thought that this is a variant of fibromuscular dysplasia. Other diseases that can mimic PAN include pseudoxanthoma elasticum, neurofibromatosis, and vascular type Ehlers-Danlos syndrome in which a defect in type III collagen results in vascular wall weakening and aneurysm formation. Finally, a newly described syndrome associated with genetic deficiencies in adenosine deaminase-2 can present with a phenotype similar to PAN, with fever, systemic symptoms, livedoid rash, and early-onset stroke.[34]

Thromboangiitis Obliterans (Buerger's Disease)

TO is an inflammatory obliterative nonatheromatous vascular disease that affects the small and medium-sized arteries, veins, and nerves.[35] While it is only associated with mild inflammatory changes, the presence of inflammation means that this disease is considered to be a vasculitis.

Epidemiology

TO is predominantly a disease of young men, most commonly affecting individuals between the ages of 18 and 50 years; and men are more commonly affected than women. The disease is also more common in the Middle and Far East than in North America and Western Europe.[35]

There is a strong association with tobacco exposure, although TO has been reported even in individuals who only smoke small amounts, and it has also been seen in pipe smokers, marijuana users, and tobacco chewers.[36]

Clinical Presentation

The initial manifestation of TO is lower extremity claudication, and this sometimes progresses to digital ischemia. Pedal, instep claudication is also a very specific symptom and patients often present initially to podiatrists for initial evaluation. Gangrene, ulceration, or rest pain is the presenting complaint in one-third of patients; often, this can be triggered by minimal trauma such as nail trimming or pressure from tight shoes. Superficial thrombophlebitis and Raynaud's syndrome are also described.[37]

Diagnostic Testing

TO is a diagnosis of exclusion, prothrombotic states, diabetes, and other autoimmune diseases; especially scleroderma should be excluded before attributing digital gangrene to TO. Patients should also undergo echocardiogram to rule out infectious endocarditis and arteriogram to rule out atherosclerosis. Arteriographic features of TO include bilateral focal segmental stenosis and occlusion with relatively normal intervening vessels. Collateral development around areas of occlusion lead to the appearance of "tree-root," "spiders web," or "corkscrew" collaterals. The most important finding is that proximal arteries are normal without evidence of atherosclerosis or emboli.[35]

Pathologic Findings

Most pathologic specimens come from amputated limbs and show panvasculitis with highly cellular thrombosis and microabscesses in the thrombus and vessel wall. In the subacute phase, the thrombus is less cellular and may recanalize. Unlike most other forms of vasculitis, the internal elastic lamina is preserved, and venulitis is often seen.

Treatment

Treatment of TO involves total cessation of tobacco, and nicotine replacement products. Calcium channel blockers and pentoxifylline are sometimes helpful. Intravenous iloprost can assist with

the period of critical ischemia.[38] Sympathectomy can also be tried.[35] Approximately 50% of patients who continue to smoke will require amputation.[39] Surgical recanalization and bypass grafting is challenging, but several groups are now reporting promising results in patients who remain abstinent from nicotine.[39-41]

Kawasaki Disease

Kawasaki disease is an acute vasculitis typically seen in children, in which there is involvement of small and medium-sized arteries, especially the coronary arteries.[42] Most patients are under the age of 5 years, and boys are more commonly affected than girls (1.5 : 1), and high-grade fever is one of the cardinal presenting signs in Kawasaki disease. Coronary artery dilatation and aneurysm formation can occur in up to 20% to 29% of patients,[43] and the main cause of death is myocardial infarction. Treatment with high-dose aspirin and IV immunoglobulin is effective and reduces the incidence of coronary artery aneurysms.[44]

SMALL-VESSEL VASCULITIS

Antineutrophil Cytoplasmic Antibody-Associated Vasculitides

The AAV primarily affect small arteries, and their cardinal finding is the presence of ANCA. ANCAs are antibodies directed against specific proteins in granules in the cytoplasm of neutrophils and lysosomal proteins in monocytes. Classification of the diseases associated with ANCA was recently revised to granulomatosis with polyangiitis (GPA, previously known as Wegener's syndrome), MPA, and sosinophilic granulomatosis with polyangiitis (EGPA, previously known as Churg-Strauss syndrome).

Granulomatosis With Polyangiitis (Previously Known as Wegener's Granulomatosis)

GPA is a granulomatous vasculitis of the upper and lower respiratory tract that also causes pauci-immune focal, segmental, cresentic glomerulonephritis. There is a strong association with cANCA antibodies with proteinase-3 specificity (PR-3). Patients may be classified by organ involvement into generalized GPA, where there is involvement of upper and lower respiratory tract and kidney, and limited GPA, where there is only respiratory tract involvement with sparing of the kidney.

Epidemiology

GPA is rare, affecting 8 to 10 patients per million per year. The mean age at diagnosis is 41 years, although it has been reported in children as young as 5 years old and in elderly patients. Only 16% of cases present in childhood. The disease is more common in Caucasians than in African Americans (7 : 1).

Clinical Presentation

Patients present with chronic sinusitis, epistaxis, and chronic purulent nasal drainage along with chronic inflammation of the auditory canal causing acute suppurative otitis media and chronic serous otitis media. New onset of otitis media in an adult should prompt rheumatologic evaluation for GPA. Chronic inflammation of the laryngeal and tracheal mucosa can lead to hoarseness and subglottic stenosis. The peripheral nervous system may also be involved with development of mononeuritis multiplex. CNS involvement includes chronic pachymeningitis, cranial neuropathies, pituitary involvement, brainstem, and spinal cord lesions.

Pulmonary involvement is seen at presentation in 50% of cases and ultimately affects almost 90% of patients. Some patients may be only mildly symptomatic, but pulmonary imaging should be completed. Nodules and fixed infiltrates are often seen. During the acute phase, pulmonary capillaritis develops with infiltration of neutrophils, and other inflammatory cells in the alveolar septa. As lesions become chronic, granulomas develop in the alveolar septa and within vessels and airway walls. These nodules may cavitate and sometimes become secondarily infected.

Renal involvement is present at presentation in 15% to 30% of cases and ultimately affects 50% to 80%. Renal pathology shows pauci-immune, focal, segmental, crescentic, necrotizing glomerulonephritis. Immunofluorescence demonstrates absence of immunoglobulin, immune complex, and complement deposition.

Laboratory Testing

ANCA positivity is seen in 90% of patients with generalized GPA and approximately 60% of limited cases. Of the patients with positive ANCA 80% to 90% have cANCA positivity with PR-3 specificity. The overall specificity of PR3-ANCA for generalized GPA is thus 98%. All patients with possible GPA should have screening urinalysis to check for evidence of active urinary sediment (hematuria, pyuria, proteinuria, or casts).

Often, ANCA titers correlate with GPA disease activity, and rising ANCA titer may herald a flare, a feature that is helpful in distinguishing flare from infection in patients with chronic disease.[45] Patients on maintenance therapy with PR-3 positivity have an increased risk of flare if therapy is stopped; thus current recommendations are for this group of patients to remain on maintenance immunosuppression.[46]

Treatment

Patients with severe GPA should receive induction therapy with IV steroids (methylprednisolone 1000 mg daily for 3-5 days) followed by daily oral steroids. If alveolar hemorrhage is present, plasmapheresis is also used acutely. Therapy with monthly IV cyclophosphamide or rituximab should be used for induction of remission. Rituximab is as effective as cyclophosphamide and is particularly useful for patients who have relapsed and those who do not respond to cyclophosphamide.[47-49] In addition, rituximab is removed by plasmapheresis but not hemodialysis. In limited GPA, prednisone plus methotrexate has been used if the renal function is normal.

During the remission maintenance phase, clinical trials show that azathioprine is equally as cytoxan at maintaining remission[50] but carries fewer side effects. The MAINRITSAN study recently showed that rituximab every 6 months was further

superior to azathioprine in maintaining remission and preventing relapse.[51]

The relapse rate of GPA is high. Patients who have been in complete remission for 12 to 18 months have a 50% risk of relapse when therapy is weaned. Maintenance therapy for more than 36 months is associated with lower relapse rate; however, many rheumatologists continue patients on long-term maintenance therapy due to the known high relapse rate in this disease.

All patients receiving immunosuppression with steroids and biologic or nonbiologic DMARDs should also receive prophylactic therapy for PJP[52] and therapy to reduce osteoporosis.[53] Patients receiving cyclophosphamide are at risk for gonadal failure and should be monitored for hemorrhagic cystitis and secondary malignancy.

Microscopic Polyangiitis

MPA is a systemic necrotizing vasculitis of small vessels (capillaries, venules, and arterioles) that is associated with ANCA formation but classically on histology has few or no immune deposits (pauci-immune) and in which there is no granuloma formation.[54]

Epidemiology

MPA can affect men and women and may occur at any age, although it is most common between the ages of 30 to 50 years.

Clinical Presentation

Patients present with pulmonary-renal syndrome with almost all patients developing a rapidly progressive pauci-immune glomerulonephritis and approximately 30% of patients developing pulmonary capillaritis with diffuse alveolar hemorrhage.

Laboratory Testing

pANCA with myeloperoxidase specificity (MPO) is seen in 60% of patients, although some patients have evidence of cANCA with specificity against PR-3. In the presence of PR-3, patients with MPA can distinguished from GPA by the absence of upper-respiratory tract involvement.

Renal Histopathology

Renal histopathology shows focal, segmental necrotizing glomerulonephritis with crescent formation, but on immunofluorescence and electron microscopy, no immune deposits are seen (pauci-immune). Lung biopsy shows pulmonary capillaritis with negative immunofluorescence, and biopsy of involved skin usually reveals leukocytoclastic vasculitis.[54,55]

Treatment

Treatment for MPA is similar to that for GPA and EGPA with induction therapy with IV steroids followed by oral daily prednisone and either cyclophosphamide or rituximab. During the acute phase of pulmonary hemorrhage, plasmapheresis with IVIG has been used. Maintenance therapy is similar to that for GPA.[56,57] The prognosis for MPA is guarded,[58] with 33% of patients relapsing and 20% of patients requiring dialysis. The overall 5-year survival rate is 70% to 75%.

Eosinophilic Granulomatosis With Polyangiitis (Previously Known as Churg-Strauss Syndrome)

Epidemiology

EGPA is a rare (1-4 patients per million) granulomatous vasculitis of the small and medium-sized vessels associated with eosinophilia. Patients with EGPA often have a prior history of allergic disease with 70% having a history of rhinitis often with nasal polyps and greater than 95% having a history of adult-onset asthma.[59,60] The ACR criteria for EGPA include asthma, eosinophilia greater than 10%, mono- or poly-neuropathy, nonfixed pulmonary infiltrates, paranasal sinus abnormalities, and biopsy showing eosinophilic infiltrate. The presence of more than four of these six criteria carries sensitivity of 85% and specificity 99.7% for the diagnosis.[60]

Pathophysiology

Characteristic histopathologic changes in EGPA include extravascular small necrotizing granulomas near small arteries and veins. In contrast to other granulomatous lesions that have a basophilic core, the granulomas in EGPA have a central eosinophilic core surrounded radially by macrophages and giant cells.[59] It is thought that the disease is driven by cytokine pathways that stimulate eosinophils including IL-5. There have been suggestions that leukotriene inhibitors such as montelukast (singulair) may contribute to the pathogenesis of this disease, since it often becomes clinically apparent when a patient with chronic asthma is started on a leukotriene inhibitor and systemic corticosteroids are weaned. This co-temporal relationship is well recognized, but it remains unclear whether it is causative.[59]

Clinical Presentation

The clinical presentation of EGPA is often a triphasic process, although it should be noted that these phases are not always sequential and may present simultaneously. The prodromal phase lasts on average 28 months but may persist for 2 to 7 years. Patients present with symptoms of allergic rhinitis, asthma, and nasal polyposis. In 50% of cases, there are symptoms of recurrent fevers. In addition, during the second phase, peripheral blood and tissue eosinophilia develop with shifting pulmonary infiltrates, chronic eosinophilic pneumonia, and eosinophilic gastroenteritis. Flares during this phase are associated with fever, and myocarditis may also develop during this phase. Life-threatening systemic vasculitis develops on average 3 years after the onset of the prodromal phase, and at this time, the asthma dramatically resolves.[61] Patients develop myocarditis, valvular insufficiency, vasculitic peripheral neuropathy, eosinophilic gastroenteritis, purpura, and testicular pain.

Laboratory Findings

The cardinal laboratory finding in EGPA is eosinophilia (>1500 cells/μL).[60] Serologic testing reveals pANCA pattern with anti-MPO specificity, and patients also sometimes have a positive RF. Patients who are ANCA positive have a higher risk of renal disease, alveolar hemorrhage, mononeuritis multiplex, and purpura.

Treatment

Treatment of EGPA involves induction therapy with IV glucocorticoids followed by daily oral prednisone with either monthly IV cyclophosphamide, or more recently, rituximab has been shown to be beneficial.[62] Some EGPA patients may respond to steroid monotherapy.[63]

VASCULITIS SECONDARY TO CONNECTIVE TISSUE DISEASES

Vascular Manifestations of Behçet's Disease

Behçet's disease (BD) is a systemic vasculitis of unknown etiology that classically presents with oral and genital ulcers (Fig. 137.3), uveitis, skin lesions, and vascular manifestations. Vascular issues were seen in up to 50% of patients in a large study in Turkey,[64] and vascular complications are more common in men who develop the disease at a young age. Vascular manifestations include arterial and venous thrombosis and unusual aneurysms, particularly affecting the pulmonary arteries.[65] Patients are at high risk for thrombotic complications and may develop superficial and deep vein thrombosis, as well as thrombosis of the large central veins, especially the superior and inferior vena cava. Other recognized manifestations include development of hepatic vein thrombosis causing Budd-Chiari syndrome, mesenteric vein thrombosis, renal vein thrombosis, and intracranial thrombosis involving the dural sinus. In BD, thrombus is adherent to the vessel wall and thrombosis may progress despite anticoagulation. Arterial complications are less common than venous problems, occurring in 1% to 7% of patients. Occlusive arterial disease can involve both upper and lower extremities resulting in ischemic symptoms. The aorta is the most common site of aneurysm formation, with pulmonary, femora, popliteal, brachial, and iliac arteries also reported in descending order of frequency. Patients often have multiple arterial aneurysms with a saccular configuration, and there is a high risk of rupture, thrombosis, and aneurysm recurrence. Pulmonary artery aneurysms, in particular, can lead to massive and fatal hemoptysis.[66] Intracranial aneurysms can occur in BD, and successful endovascular treatment has been reported. Care should be taken with line insertion in these patients, since arterial puncture for angiography can result in aneurysm rupture.

Figure 137.3 Large, painful, oral ulcers in a patient with Behçet's disease.

Epidemiology

BD is seen worldwide but it is more common in Turkey, the Mediterranean basin, and the Middle and Far East along the historic Silk Road trade route. Typically, the disease presents in young adults aged 20 to 40 years. The pathogenesis of BD is unknown but genetic, infectious, and immunologic factors have been implicated. There is a high prevalence of disease in patients with HLA-B51 genotype, and it is thought that polymorphisms in genes for several proinflammatory cytokines might play a role in disease susceptibility.[67]

Treatment

Treatment of BD involves systemic immunosuppression with glucocorticoids and steroid-sparing DMARD agents, and mucocutaneous lesions often respond to colchicine.[68] Thalidomide has been used for refractory oral and genital ulcers, and high-dose steroids and cytotoxic agents are used in patients with vasculitis. Relapses are frequent and patients should be closely monitored.[68]

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a chronic multisystem autoimmune disease characterized by autoantibodies to various nuclear antigens. Vasculitis may occur in up to one-third of SLE patients[69] and most commonly affects the small vessels of the skin (leukocytoclastic vasculitis). Patients often present with tender punctate lesions on the fingertips and palms, but ischemic lesions nodules and ulcers may also occur. Vasculitis of medium-sized vessels can result in mononeuritis multiplex and lesions in the abdominal viscera, and large-vessel vasculitis with a similar distribution to Takayasu's arteritis has also been described. Pulmonary capillaritis in SLE may present with alveolar hemorrhage and carries a high risk of mortality. Inflammatory vasculitis in SLE merits escalation of therapy with steroids and DMARD agents.

Ischemic events related to the antiphospholipid syndrome may mimic vasculitis in SLE and should be considered in the differential diagnosis in lupus patients presenting with digital and skin ulcerations.[70,71] If antiphospholipid antibodies are present, then anticoagulant therapy and therapy with the antimalarial agent hydroxychloroquine can be of benefit.

Rheumatoid Vasculitis

Rheumatoid arthritis vasculitis is a known complication of longstanding rheumatoid arthritis (RA), and RA is an inflammatory symmetric polyarthritis. Vasculitis occurs in 10% to 15% of cases, which is usually those with more aggressive disease and high-titer RF. Patients may develop cutaneous ulcers,[72] peripheral neuropathy, and scleritis, and mesenteric vasculitis and aortitis may also occur but is rare. Rheumatoid vasculitis

is associated with significant morbidity and mortality and should be treated aggressively with high-dose steroids and biologic DMARDs.[73-76]

Relapsing Polychondritis

Relapsing polychondritis is a rare autoimmune disease manifested with recurrent inflammation of cartilaginous tissues. This disease can also be complicated by large-vessel involvement with aortitis leading to thoracic and abdominal aortic aneurysms.[77]

Cogan's Syndrome

Cogan's syndrome may present with large and medium-sized vasculitis in a Takayasu's like distribution.[78] Cogan's syndrome is an immune-mediated disorder characterized by interstitial keratitis, vestibular dysfunction, and sensorineural hearing loss. Keratitis symptoms include bilateral redness, pain, and photophobia with increased lacrimation. Other forms of ocular inflammation, including uveitis, scleritis, choroiditis, and retinal artery occlusion, may also occur with or without concomitant keratitis. Vestibular dysfunction presents with tinnitus, vertigo, and sensorineural hearing loss, which may be fluctuating but leads to deafness in more than 50% of cases. Eye and ear involvement usually develop within 1 to 6 months of each other. The mean age of onset is around 30 years, although it has been reported in children and in the elderly. The syndrome is equally distributed in men and women, and there is no racial predilection. Typically at presentation, patients are systemically unwell with constitutional symptoms, fever, athralgias, serositis, mononeuritis, hepatomegaly, and splenomegaly. Laboratory work-up reveals elevated inflammatory markers but negative autoantibodies, and keratitis usually responds to topical steroids. Vestibular dysfunction merits oral prednisone, and if systemic manifestations are also present, then a steroid-sparing agent such as azathioprine, methotrexate, mycophenolate, or cyclosporine should be added.[79,80]

Pseudoxanthoma Elasticum

Pseudoxanthoma elasticum is an inherited systemic disease that can cause early and diffuse arteriopathy in the absence of traditional risk factors.[81] Small and medium-sized arteries are affected more commonly than the aorta, and patients often present with symptoms of claudication in the lower extremities. Both traditional surgical bypass and percutaneous angioplasty have been used successfully in the management of claudication due to pseudoxanthoma elasticum. In patients with pseudoxanthoma presenting with peripheral vascular symptoms, screening for coronary disease is advised since equally severe coronary disease can be identified and can manifest with heart failure due to widespread coronary ischemia or restrictive cardiomyopathy. Because pseudoxanthoma can affect the internal mammary arteries, vein conduits are recommended for coronary bypass. In addition, arterial rupture can occur in the GI and genitourinary tracts, resulting in a higher risk of bleeding with antiplatelet and anticoagulant therapy.

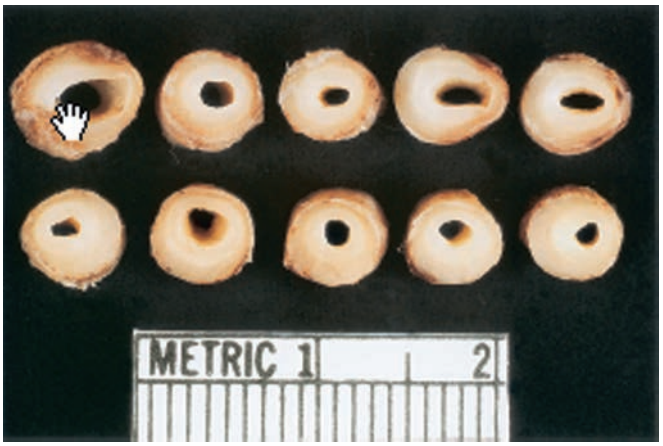

Figure 137.4 Exercise-related external iliac arteriopathy. Photograph of resected external iliac artery, cut in cross-sections, showing luminal stenosis.

Exercise-Related External Iliac Arteriopathy

Exercise-related external iliac arteriopathy is a syndrome seen in competitive bicyclists and those cycling on average 8000 to 33,000 km/year. The condition occurs in both men and women, and both external iliac arteries may be affected. Repetitive bending and compression of the external iliac artery between the psoas branch, circumflex iliac, and internal epigastric arteries lead to fibrosis and thickening of the arterial wall. Smooth muscle proliferation and intimal thickening is seen (Fig. 137.4), and some cases report complete occlusion as well as spontaneous dissection of the external iliac artery. Typically affected patients report claudication with exercise and diagnosis can be confirmed with resting and exertional ABI following an exercise that is known to induce symptoms. Treatment includes bypass with prosthetic grafts, endarterectomy with patch, angioplasty, and bare metal stenting. Patch angioplasty results in better reoperation rates and higher patient satisfaction than balloon angioplasty.

VASCULITIS MIMICS

Several disorders can mimic vasculitis and should be considered in the differential diagnosis when evaluating a patient. Typically, these syndromes do not require long-term immunosuppressant therapy.

Fibromuscular Dysplasia

Fibromuscular dysplasia is a noninflammatory vascular disease that most commonly affects the renal and carotid arteries but may also affect any vascular bed.[82] It should be considered in the differential diagnosis of a patient presenting with noninflammatory vascular lesions and is well reviewed in Chapter 142.

Radiation Arteritis

Epidemiology

External beam radiation for malignancies may cause inflammation and fibrosis in adjacent large arteries and lead to clinically

significant stenosis and aneurysm formation. The prevalence of stenosis following radiotherapy can be as high as 30% in the carotid arteries.[83] In the early phase after irradiation, pathologic changes include endothelial damage, intimal thickening, and smooth muscle loss with fibrosis; over time, calcification and more typical atherosclerosis develop, in some cases, leading to bulky stenosis. Radiation-related vasculopathy has been described in many vascular beds, including cervicocranial stenosis following radiotherapy for esophageal squamous cell carcinoma, the visceral vessels following treatment for lymphoma, and in the iliac arteries after treatment for cervical cancer. There may be a delay of decades between the initial radiation exposure and the presentation with vascular insufficiency.[84]

Pathogenesis

Radiation arteritis results in damage to all layers of the arterial wall, and endothelial cell injury with resultant inflammation predisposes to thrombus formation. Medial necrosis has been described with late fibrosis, and the vasa vasorum may be obliterated as a result of adventitial scarring. Structural injury further predisposes to atherogenesis with lipid deposition and atheroma formation in the region of the prior scar. The result is stenotic lesions similar to those seen in atherosclerosis but in the region of prior radiation exposure rather than a typical location (Fig. 137.5).

Clinical Presentation

Presentation of radiation-induced arteritis is similar to vascular insufficiency from atherosclerotic disease. Carotid lesions may present with transient ischemic attacks, amaurosis fugax, or stroke. Visceral involvement presents with mesenteric angina, and irradiation of iliac and pelvic vasculature can result in lower extremity intermittent claudication. Embolization with acute vascular ischemia has also been described. Aneurysm formation and rupture are rare but may occur spontaneously or following surgical repair or stenting.

Diagnostic Evaluation

Angiography is the mainstay of work-up with lesions appearing similar to the tapered narrowing of extracranial GCA. The development of accelerated atherosclerosis in regions of previous radiation-induced vascular damage may also lead to the angiographic appearance of friable, typical atheromatous lesions.

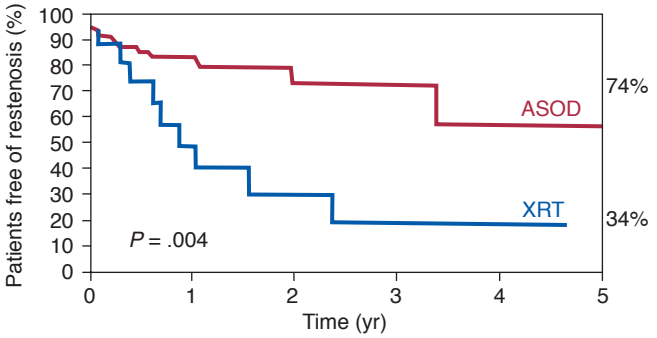

Figure 137.5 Rates of restenosis following carotid artery stenting for radiation-induced carotid artery stenosis. *ASOD,* Atherosclerotic occlusive disease; *XRT,* radiation induced occlusive disease. (From Protack CD, Bakken AM, Saad WE, Illig KA, Waldman DL, Davies MG. Radiation arteritis: a contraindication to carotid stenting? *J Vasc Surg.* 2007;45:110–117.)

Treatment

Because of the risks of postoperative wound infection and poor wound healing associated with open surgical procedures, the use of endovascular techniques to manage radiation-induced arterial stenosis is growing. The most prominent example is carotid stenting (CAS) for symptomatic, and sometimes asymptomatic, radiation-induced carotid stenoses.[85] In a recent series of 23 patients treated with primary CAS, the 30-day survival and 3-year neurologic-event–free survival rates were similar, but the risk of restenosis was greater compared with 127 patients treated with CAS for atherosclerotic carotid disease (Fig. 137.6).[86] In this series, late restenosis occurred up to about 2.5 years following the procedure. Case series also describe good results from endovascular treatment of renal artery stenosis related to radiation for Hodgkin lymphoma and iliofemoral stenosis related to radiation for genitourinary malignancies.[87]

Neurofibromatosis Type-1

Neurofibromatosis type-1 is an autosomal dominant disorder that results in a loss-of-function mutation of the tumor suppressor gene NF-1. The disease affects 1:3000 individuals. Patients develop neurofibromas along with other tumors including schwannomas and pheochromocytomas. Vascular manifestations are a known complication of NF-1 but are rare,[88] affecting only 0.4% to 6.4% of NF-1 patients. In young patients, the vascular lesions resemble fibromuscular dysplasia with development of saccular and fusiform aneurysms, stenotic lesions, arteriovenous malformations, and extrinsic compression from

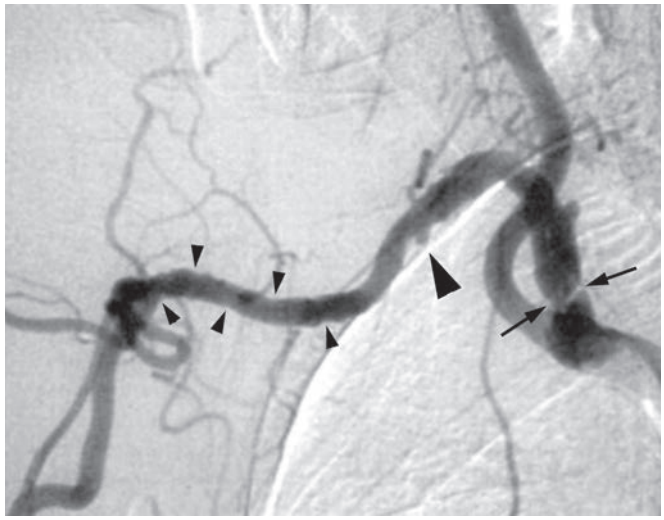

Figure 137.6 Angiogram of a 66-year-old patient presenting with acrocyanosis of the fingers and livedo of the skin occurring 21 years after local adjuvant radiation therapy for breast adenocarcinoma. This view of the aortic arch and right upper extremity demonstrates radiation-induced atherosclerosis with an ulcerated plaque at the origin of the subclavian artery *(arrows)* with diffuse atheromatous changes in the area of prior radiation *(arrowheads).* (From Rubin DI, Schomberg PJ, Shepherd RF, Panneton JM. Arteritis and brachial plexus neuropathy as delayed complications of radiation therapy. *Mayo Clin Proc.* 2001;76:849–852.)

neurofibromas. The average age for vasculopathy diagnosis is 38 years. Spontaneous aneurysm rupture can result in life-threatening hemorrhage, and rupture of vertebral artery aneurysms may lead to cervical vertebral arteriovenous malformations. Surgical intervention for vascular lesions in NF-1 is safe and has been determined to be effective and durable.[88]

Drug-Induced Vasculitis

Several drugs are known to result in hypersensitivity vasculitis[89] including chemotherapeutic agents, growth factors, interferons, antithyroid drugs,[90,91] hydrochlorthiazide,[92,93] hydralazine,[94] minocycline, penicillamine, and vaccines.

Beta-blockers can cause a milder form of vasospasm and exacerbate Raynaud's phenomenon. Ergot preparations used to treat migraine headaches can cause a diverse spectrum of vascular syndromes including acute arterial thromboembolism, dissection, and severe vasospasm that angiographically resemble Takayasu's arteritis.

Cocaine has been associated with venous and arterial thrombosis, aortic dissection, and hemispheric and lacunar stroke. Cocaine adulterated with levamisole causes a dramatic small vessel cutaneous vasculitis that results in skin necrosis and cause tissue loss in the nose, ears, breasts, and digits.[95] Lesions classically begin as palpable purpura, but as they enlarge, they develop a "cookie cutter" edge. Typically, these lesions are multicentric, do not conform to typical vascular territories, and they are extremely painful. The pain is worse with elevation and improves with dependency. Unless concomitant atherosclerosis is present, patients should have normal pulses. Lesions typically respond to withdrawal of the offending agent, and aggressive wound care and immunosuppressive therapy, occasionally, is warranted.

INTRODUCTION

Definition

Thromboangiitis obliterans (TAO), also known as Buerger disease (BD) or von Winiwarter-Buerger syndrome, is a chronic, non-atherosclerotic, segmental, obliterative, inflammatory vasculopathy primarily involving infrapopliteal and infrabrachial medium and small-sized arteries and veins.[1-5] It is predominantly a disease of young men, with onset typically before the age of 45 to 50 years.[1,4-6] The prevalence in women, however, has been increasing likely related to increased tobacco use.[1,7,8] The disease is more common among people of Middle East, Asia, Mediterranean region, and Eastern Europe but is rare in Africa, central Europe,

Abstract

Buerger disease (BD) is a chronic, inflammatory vasculopathy primarily involving infrapopliteal or infrabrachial medium and small-sized arteries and veins typically detected in men before the age of 50 years. Features of advanced BD include ischemic ulcerations and digital gangrene as a result of critical limb ischema. Smoking cessation is the first line therapy for BD, and revascularization is often not feasible. Intravenous iloprost is an effective treatment option for patients with critical limb ischemia. Endothelin receptor antagonists, immunoadsorption, growth factors, and gene and stem cell-based therapies may have a role for the treatment of patients with BD and critical limb ischemia.

and America. TAO is typically manifested by distal extremity ischemia involving the feet, legs, or hands as a result of infrapopliteal or infrabrachial occlusive disease leading to critical limb ischemia (CLI). Advanced TAO features are rest pain, ischemic ulcerations, and digital gangrene.

TAO develops as response to environmental factors primarily with smoking resulting in major and minor amputations with high degree of morbidity and disability resulting in unemployment, psychological, behavioral, social, and financial costs. Pathologically, TAO is characterized by a highly cellular arterial thrombus, extensive intimal inflammation, and preserved all layers of the arterial wall including internal elastic lamina.[9] The disease frequently involves adjacent or superficial veins and nerves. TAO is classified under nonnecrotizing, nongranulomatous medium and small vessel vasculitis.[7] However, TAO has not been included in the revised 2012 Chapel Hill consensus conference nomenclature of vasculitides.[10,11] Absence of markers of inflammation and autoantibodies is unique for TAO in comparison to other types of vasculitis.[1,12] Patients experience periods of acute exacerbation leading to CLI associated with smoking. Remissions follow abstinence from tobacco or occur in the fifth to sixth decades of life. Rare reports of cerebral, coronary, visceral, ophthalmic, and multiorgan involvements have also been described. Reduction in extremity amputation rate can be achieved by smoking cessation. For optimal outcome, multidisciplinary approach is required for the management of TAO patients including vascular surgery, rheumatology, hematology, dermatology, smoking cessation counseling, dental care, rehabilitation medicine, analgesia, and wound care specialists.

Brief Historical Review

Reports resembling TAO have appeared in medical writings since the mid-1800s, but the cases were labeled arteriosclerosis obliterans (ASO) or frostbite because of the lack of pathologic confirmation.[13] In 1879, Felix von Winiwarter described a 57-year-old man with a prolonged history of foot pain that eventually progressed to gangrene and limb loss, which is now recognized as the first published case of a patient with CLI.[1,13,14] In 1898, Haga reported similar clinical features resulting in spontaneous gangrene.[15] In 1908, Leo Buerger described a new and unusual form of progressive vaso-occlusion in Polish and Russian immigrants with who underwent amputation for "*Spontan-gangrän*."[16] Based on his findings, Buerger called the disease "*thromboangiitis obliterans*" to distinguish it from ASO. Subsequently, Buerger emphasized the association of migrating thrombophlebitis with thromboangeitis.[17] Buerger's 32-chapter, 628-page monograph entitled "The Circulatory Disturbances of the Extremities" was published in 1924.[18] Allen and Brown reviewed 200 patients diagnosed with TAO who were evaluated at the Mayo clinic from 1922 to 1926.[19] However, between the 1930s and 1960s, numerous investigators expressed skepticism concerning the identity of TAO.[20-22] In the early 1960s, several authorities considered TAO a distinct diagnosis that should be separated from ASO.[23-27] Today, TAO is accepted as a definite medium and small vessel vasculitis with a typical clinical picture, natural history, and histopathology.[1,4,8,28-30]

TABLE 138.1 Proportion of Thromboangiitis Obliterans Patients Within Peripheral Vascular Disease Throughout the World

Region/Country	%	Reference
North America	0.75	42, 48-51

Japan	16	138, 371, 372
Korea	66	1
India	45-63	1

EPIDEMIOLOGY

Population Affected

TAO is found worldwide, and it affects both sexes and all races.[1,7,12,29,31] However, the incidence varies by geographic location (Table 138.1) and with uneven gender distribution.[1,32-35] Buerger's view of the disease as being largely restricted to the Jewish race is no longer valid.[18,36] TAO is more common among people of the Middle East, Asia, the Mediterranean, and Eastern Europe but is rare in Africa, central Europe, and America. TAO has a striking predominance in men, especially in series reported before 1960. The reported incidence of TAO in women was less than 1% in most published series in that era.[37] Indeed, only 2 of Buerger's 500 reported cases were women.[18] However, TAO is no longer exclusively seen in male population.[7,38-41] Over the last three decades, this apparent gender discrimination for TAO is disappearing, probably as a result of the rising use of tobacco products by young women.[3,39,42] In recent series, 9.8% to 23% of patients were women.[3,8,33,43,44] Currently, TAO affects men at a 5-fold to 10-fold higher rate than women.[3,29,33,38,44,45] A limited number of pregnancies among patients with active TAO have also been reported.[46-49]

There was an eightfold decrease in the annual incidence of TAO at the Mayo Clinic, which has steadily declined from 104 per 100,000 patient registrations in 1947 to 12.6 per 100,000 patient registrations in 1986.[8,50] The number of new patients with TAO in Japan has also been decreasing,[51] the ratio of TAO to ASO patients has declined from 1:3 in 1990s to 1:10 after 2000 in Japan.[51] Currently, TAO affects approximately 10 in 100,000 people in the European Union (estimated from the applications to the Committee for Orphan Medicinal Products). The number of patients affected by TAO is estimated about 51,000 in European Union, and 4000 in Japan.[52] Pooled characteristics of patients with TAO are listed in Table 138.2.

TABLE 138.2 Pooled Characteristics of Patients With Thromboangiitis Obliterans From Different Regions Globally

Prevalence	Uncommon
Prevalence in woman	Increasing
Incidence	Declining
Involved arterial size	Small and medium
Age at diagnosis (years)	29-42
Age at hospital admission (years)	42.5 ± 8.4
Male, %	77-98
Female, %	2-23
History of smoking, %	93-94
Intermittent claudication, %	17-62
Rest pain, %	13-89
Ischemic ulcers and gangrene, %	38-85
Upper extremity	2-28
Lower extremity	35-100

Risk Factors

The only risk factor consistently reported is smoking. The strong correlation between tobacco use and the pathogenesis, initiation, and progression of the disease is well established.[3,6,28,29,31,53-55] There is also a higher incidence of TAO among individuals with cigar and pipe smoking; habitual home-made cigarette smoking such as "*bidi*" smoking in India, Bangladesh, and Ceylon;[56] "*kawung*" smoking in Indonesia;[57,58] and chewed "*miang*" (steamed tea leaves) or "*khiyo*" (the home-made raw tobacco in handrolled banana leaves) smoking in Thailand, as well as in users of smokeless tobacco and marijuana.[29,59-61] Higher rate of tobacco consumption and higher carboxyhemoglobin levels were detected in patients with TAO than ASO patients and control subjects.[62] Lower socioeconomic status, poor oral hygiene, nutritional deficits, a history of viral or fungal infection, cold injury, abuse of sympathomimetic drugs, and arsenic intoxication are reported as other possible risk factors.[9,57,62-67] An emerging body of evidence demonstrates that ischemia induced by cocaine, amphetamines, and cannabis addiction can closely mimic TAO symptoms[68-73] or may accelerate TAO onset and presentation.[73] Furthermore, a close relation between long-term arsenic exposure from artesian well water and endemic blackfoot disease has been reported in Taiwan.[74,75] In fact, arsenic adulteration of tobacco as a causative agent for TAO has been suggested in populations smoking bidis or kawung.[66,76-78]

Etiology

The etiology of BD is unknown; however, the close association between disease activity and use of tobacco in any form is beyond any debate.[1,8,34,55,79-81] Genetic predisposition, immune-mediated mechanisms, hypercoagulable states, endothelial dysfunction, and an oral infection-inflammatory pathway have been implicated as potential etiologic factors.[44,82-84]

Immune-Mediated Injury

Several observations implicate an immunologic phenomenon and hypersensitivity to tobacco antigens in the etiology of TAO.[85] It is clearly demonstrated that there is a close relationship between active smoking (high levels of urinary cotinine) and the aggravation of TAO.[86,87] Increased cellular sensitivity to collagen type I,[88-90] type III,[89] and type IV[91] has been reported in patients with TAO compared to ASO patients and healthy male controls. Circulating immune complexes have been reported in the peripheral arteries of some patients with TAO.[92-94] It has been suggested that an unidentified antigen possibly related to a constituent of tobacco smoke triggers immunologic damage to the arterial intima.[95] Recent research has shown that T-cell–mediated cellular and B-cell–mediated humoral immunity associated with the activation of macrophages or dendritic cells in the intima play a key role in TAO.[9]

Previous studies showed activation of endothelial cells associated with TNF-alpha secretion by tissue-infiltrating mononuclear inflammatory cells and expression of intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), and E-selectin on endothelial cells in TAO patients.[96] Increased levels of TNF-alpha, IL-1beta, IL-4, IL-6, IL-12, IL-17, and IL-23 and reduced expression of IL-10 were reported in patients with TAO compared to the controls suggesting the involvement of autoimmune pathology.[97,98] An experimental study further reported the key role of high-mobility-group box protein 1 (HMGB1) which may contribute to the pathogenesis of TAO by binding its receptor RAGE in sodium laurate-induced TAO rats.[99] HMGB1 not only induces the production of inflammatory mediators by mononuclear cells, but also activates endothelial cells, leading to the upregulation of the adhesion molecules. rA box, the antagonist of HMGB1, improved the pathologic condition by inhibiting the release and injury of inflammatory mediators and improving the hypercoagulable state of blood.[99] Furthermore, a recent clinical study confirmed significant increases in HMGB-1, MMP-9 and ICAM-1 levels compared with controls in patients with TAO.[100] Thus, immunologically mediated inflammation of the vessels is thought to be the cause of arterial or venous thrombosis and vascular occlusions in TAO.

The clinical picture of antiphospholipid syndrome in young smokers may mimic TAO symptoms.[101] The prevalence of anticardiolipin antibodies was significantly higher in patients with TAO (36%) than in those with premature atherosclerosis (8%; $P = .01$) and in healthy individuals (2%; $P = .001$).[102] Patients with TAO and high anticardiolipin antibodies tended to be younger and to have a significantly higher rate of major amputations and poor prognosis than did those without the antibody.[103,104] Antineutrophil cytoplasmic antibodies (ANCAs)[105] and anti-endothelial cell antibodies[106] were also reported in small series of TAO; however, in another study from Germany, ANCA was not detected in any of the active or inactive TAO patients.[107]

Genetic Predisposition

The importance of a genetic predisposition to tobacco sensitivity is debatable.[89,95,108] One percent of TAO cases in Japan consisted of members of the same family.[109] Genes of the major histocompatibility complex, particularly HLA-A9 and HLA-B5, have been linked to TAO in a study from England.[110] In Israel, a higher frequency of HLA-DR4 and a significantly lower frequency of HLA-DRW6 antigen were reported.[95] However, in the Japanese population, haplotypes of various HLA groups were associated with TAO.[111,112] These haplotypes are rare among Caucasians. In North Indian patients, there was a strong positive association between HLA-DRB1*1501 and TAO.[113] Current concepts suggest that the arterial vasospasm of TAO may be caused by an interaction between smoking and several gene polymorphisms that reduce endogenous nitric oxide, an endothelium-derived vasodilator. Recently, higher incidence of mutations associated with arterial vasospasm; 5A/6A stromelysin-1, also called matrix metalloproteinase-3; and homozygosity were reported in TAO cases compared to controls.[114] Findings regarding genetic predisposition of TAO should be confirmed in larger studies. A recent case-control study from China reported three single-nucleotide polymorphisms, namely rs376511 (OR = 24.4, 95% CI: 8.68-68.62, $P < .0001$), rs7632505 (OR = 29.47, 95% CI: 7.16-121.3, $P < .0001$), and rs10178082 (OR = 18.09, 95% CI: 6.56-49.92, $P < .0001$), are associated with TAO in the Uyghur population.[115,116]

Hypercoagulability

The role of thrombotic risk factors including factor V Leiden and prothrombin 20210G/A mutations, antithrombin, protein C and S deficiency, hyperhomocysteinemia, and platelet aggregation responses in the etiology of TAO remains controversial.[117-126] Most authorities have failed to identify a specific hypercoagulable state in patients with TAO,[29,117] while others have shown one or more abnormalities.[117,118] In one study, the level of urokinase-plasminogen activator was twofold higher and the level of free plasminogen activator inhibitor 1 was 40% lower in patients with TAO than in healthy volunteers.[127] Some authors suggest that hyperhomocysteinemia may have a role in the pathogenesis of TAO.[120-123] Elevated platelet contractile force values were reported in two patients with TAO despite the use of anticoagulation drugs and the suppression of adenosine diphosphate–mediated platelet aggregation.[125] Whether high platelet contractile force plays a role in the pathogenesis of TAO or simply serves as a marker of enhanced platelet function, endothelial dysfunction, or both remains to be elucidated.

Oral Infection-Inflammatory Pathway

Historically, Buerger and then Allen and Brown suspected that infectious foci, including oral and throat infections, might serve as contributory factors in TAO.[19] Higher prevalence of severe periodontal disease in TAO patients is well documented,[82,128,129] suggesting oral infection-inflammatory pathway as a possible etiologic link in TAO.[82] Elevated immunoglobulin G titers against *Treponema denticola*, *Porphyromonas gingivalis*, and *Actinobacillus actinomycetemcomitans* were detected in patients with TAO.[128] Furthermore, several bacterial DNAs of periodontal pathogens were identified in the biopsies from the arterial samples and samples of phlebitis migrans in patients with TAO.[82,130,131]

Vascular Endothelium and Circulating Progenitor Cells

Endothelium-dependent vasorelaxation was impaired even in the nondiseased limbs of patients with TAO.[132] TAO during the exacerbation phase is associated with diffuse increase in vasomotor tone in the conduit arteries that aggravates ischemia.[133] In another study, similar to ASO patients, flow-mediated vasodilation was impaired compared to normal control subjects; however, the number and function of circulating progenitor cells (CPCs) were restored despite endothelial dysfunction in patients with TAO.[134] Increased levels of plasma endothelin-1 were also reported during the exacerbation periods of TAO.[135]

Pathology

The specific pathologic mechanisms in TAO are still unknown.[83] BD is characterized by segmental inflammatory cell infiltration of the vessel wall and arterial or venous thrombotic occlusions.[9,31,136] Hypercellular thrombus formation and preserved architecture of vessel walls is well established in TAO.[137] Earlier studies suggested TAO as a thrombotic disorder complicated by vasculitis, namely transmural neutrophilic infiltration.[36,138] Today, there are compelling reasons to believe that the primary event is the activation of antigen-presenting cells following endothelial cell damage induced by an unidentified antigen, possibly tobacco glycoproteins.[9,51,95,137] Cellular and humoral inflammation, which leads to thrombotic occlusion of the blood vessels, is restricted to the intima of the artery, which defines TAO as an endarteritis.[9,51] Intimal inflammation followed by T-cell infiltrations might result in early arterial occlusion, which is the pathognomonic finding in TAO.[139] Regardless of the pathologic stage, the internal elastic lamina and the architecture of the vascular walls are well preserved in TAO, which is in contrast with atherosclerosis and systemic vasculitis.[1,9,36,54,137,140] Inflammatory cell infiltration is found in the intimal layer and the thrombus.[9,141]

The evolution of TAO is often categorized into three stages.[36] In the acute phase, inflammation affecting the small-caliber and medium-caliber (1- to 5-mm diameter) arteries and veins is observed (Fig. 138.1). The primary features of TAO during

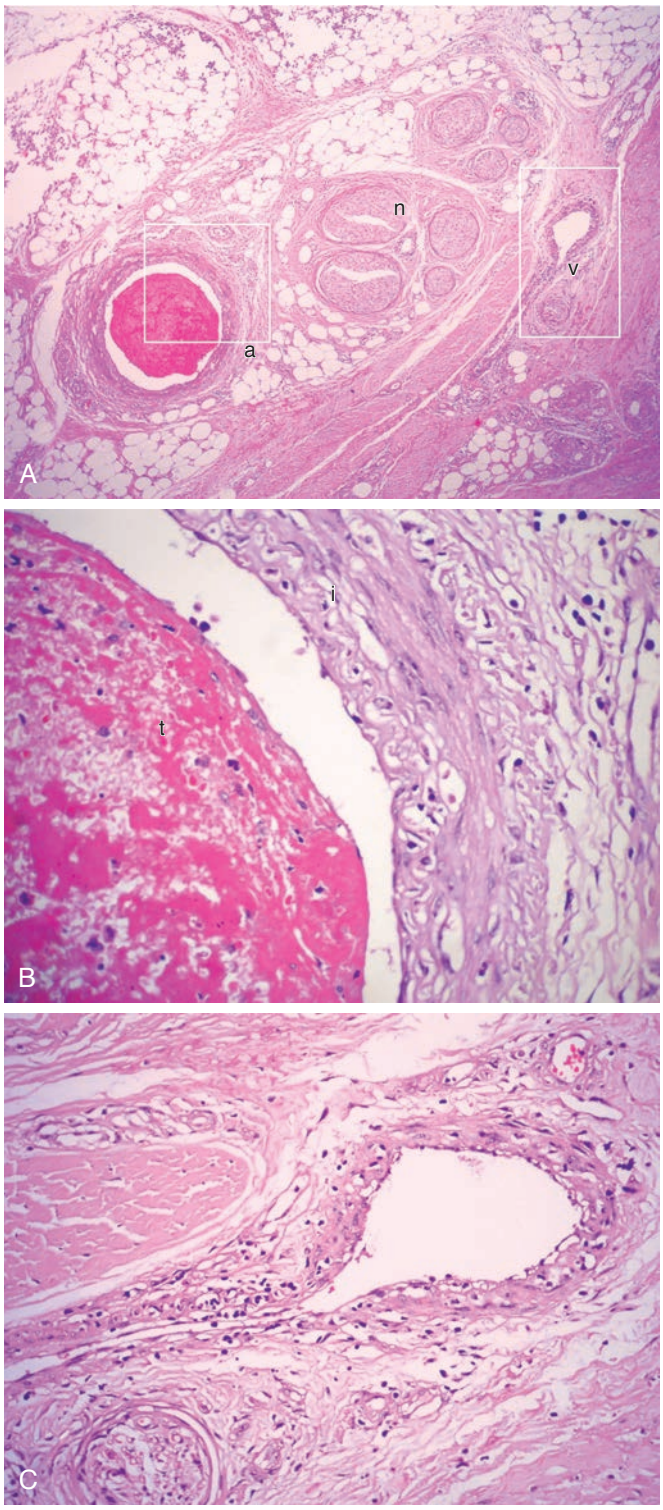

Figure 138.1 (A) Typical subacute thrombotic occlusion of the right digital artery in a 37-year-old male smoker with Buerger disease (H&E, ×64). (B) High-power view of area *a* in A demonstrating the digital artery with cellular arterial thrombus *(t)* and remarkable inflammation in the intima *(i)* (H&E, ×400). (C) High-power view of area *v* in A demonstrating the adjacent digital vein with phlebitis (H&E, ×400). *n*, Nerve.

the acute phase include an occlusive, highly cellular arterial thrombus, polymorphonuclear cell infiltrate with leukocytoclasis, giant cells, and microabscess formation; marked inflammation of the entire vessel wall; and neurovascular bundle.[24,50,54] However, most of the infiltrating cells are detected in the intima.[51] The intense inflammatory infiltration and cellular proliferation seen in acute lesions are distinctive, especially when veins are involved. Multinucleated giant cells can be seen, but fibrinoid necrosis and granuloma are not observed.[9] During the intermediate or subacute phase, there is progressive organization of the occlusive thrombus, with partial recanalization and disappearance of the microabscesses.[9] An inflammatory response, including CD3+ pan–T cells, CD4+ T helper-inducer cells, and CD20+ pan–B cells, against the internal elastic lamina of the affected vessels has been shown in detail (Fig. 138.2).[9,139,141] In addition, CD68+ macrophages or S-100+ dendritic cells are found in the intima during both the acute and subacute stages.[51] IgG, IgM, and IgA and complement factors 3d and 4c are deposited along the inner aspect of the internal elastic lamina.[9] The chronic phase or end-stage lesion is characterized by thrombus organization followed by recanalization, prominent vascularization of the media, and perivascular fibrosis.[36,54,136] Regardless of the pathologic stage, the internal elastic lamina and the architecture of the vascular walls are well preserved in TAO, in contrast with atherosclerosis and other types of systemic vasculitis (Fig. 138.3).[1,9,36,54,140]

CLINICAL PRESENTATION

TAO usually presents with distal extremity ischemia in a smoker younger than 50 years old,[4,142] and the median age at diagnosis is 34 years.[29,143] Characteristically, distal extremity ischemia involves the feet, legs, hands, or arms (Fig. 138.4A and B); and as the disease progresses, it may involve more proximal arteries.[54] Frequently identified signs and symptoms of TAO are listed in Table 138.2, and the most common symptoms are forefoot arch or lower calf claudication as a manifestation of infrapopliteal occlusive disease.[54] Foot claudication is particularly characteristic,[144] but foot or arch claudication may be misattributed to orthopedic problems. Early symptoms may include coldness or burning pain in the feet and hands, associated findings of dependent rubor,[145] cyanosis, migratory superficial thrombophlebitis (see Fig. 138.4C),[130,146] and Raynaud phenomenon.[3,57,147,148] Patients with TAO commonly report cold sensitivity, and sensory findings may be one of the earliest manifestations. In the Cleveland Clinic series reported by Olin and colleagues, 69% of cases revealed sensory findings.[3] Ischemic neuritis or superficial thrombophlebitis may also produce severe pain.[149] In addition, migrating phlebitis (phlebitis saltans) may occur as an early sign and has been reported in 40% to 65% of TAO patients during the course of the disease.[146,150,151] Ascending venography and histologic investigations suggest that 60% of the cases have venous involvement.[152] Occasionally, superficial thrombophlebitis may extend into the deep venous system; however, deep venous thrombosis in BD is unusual[151] In the acute phase of the disease, involved vessels are tender and indurated and reflect the local inflammatory reaction.

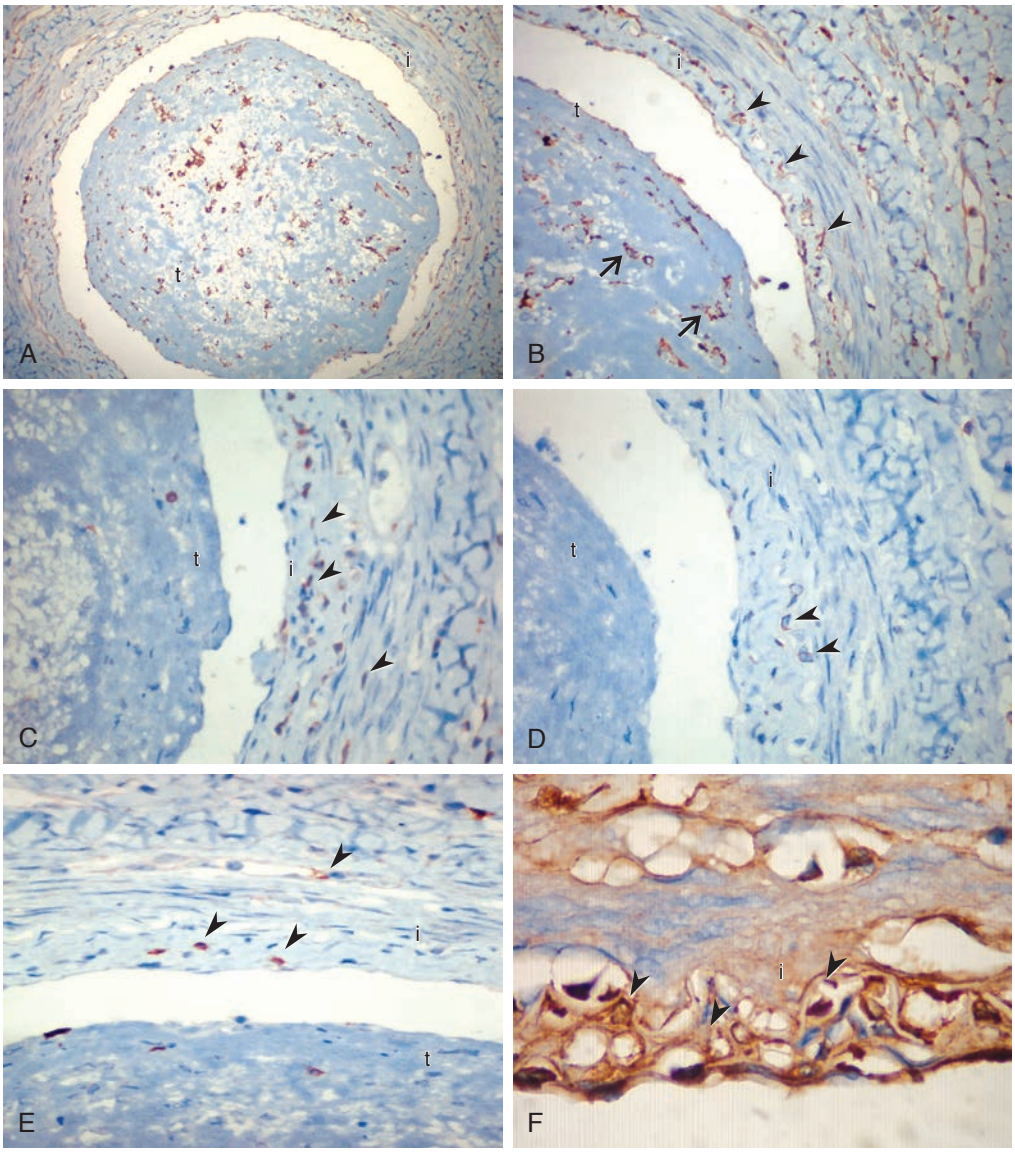

Figure 138.2 (A) Microphotograph of an acute-stage lesion with highly cellular thrombus *(t)* and inflammatory infiltration along the vessel wall with increased anti-CD68$^+$ (clone: KP1) histiocytes. (B) High-power view showing highly cellular thrombus *(arrows)* and abundant histiocytes in the intimal layer *(arrowheads)*. (C to E) Anti-CD3$^+$ (rabbit polyclonal) stained T cells (C), anti-CD4$^+$ (clone: 1F6) T-helper cells (D), and anti-CD8$^+$ (clone: C8/144B) cytotoxic T cells (E) in the intimal layer (*arrowheads;* brown membrane staining, ×400). (F) Deposition of immunoglobulin G (brown, *arrowheads*) within the interstitial intimal tissue (×600). Immunohistochemistry was performed with a Ventana iVIEW DAB detection system. *i,* Intima.

Late findings may present as trophic nail changes, ischemic ulcerations, and digital gangrene,[29,35,54,150,153-155] and almost all ulcers occur in patients between 20 and 50 years of age.[156] Superinfection commonly develops, and the ischemic ulcerations progress toward necrosis and distal gangrene. At this stage, the pain is often excruciating. Ischemic ulcerations often appear dry and irregular with a pale base and various shapes.[40,157] Joint manifestations, mainly transient, migratory episodes of large joint arthritis involving wrist and knees, may occur in approximately 12.5% of patients before the onset of digital ischemia.[12,151,158,159] Subungual splinter hemorrhages may also be detected as an early sign.[151,160,161] Coexisting psychological conditions are also common and mainly are anxiety, depression, amputation, and unemployment-related fears.[162] No difference in clinical presentation in women compared with men has been observed.[3,163]

TAO does not occur in only one limb.[151] Multiple limb involvement is a common feature of TAO.[1,54,60,164,165] In the series reported by Shionoya, two limbs were affected in 16% of patients, three limbs in 41%, and all four limbs in 43% of patients.[164] The Intractable Vasculitis Syndromes Research Group of Japan reported isolated lower extremity involvement in 75%, only upper extremity involvement in 5%, and both upper and lower extremity involvement in 20% of patients with TAO (Table 138.3).[166] Therefore, it is recommended that noninvasive imaging of all extremities be performed in patients with suspected

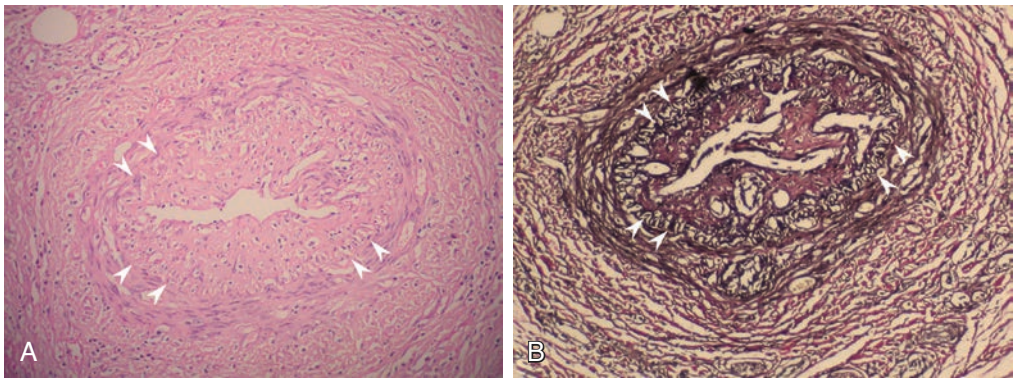

Figure 138.3 (A) Microphotograph of a chronic-stage lesion of Buerger disease, with recanalized arterial thrombus and striking intimal thickening (H&E, ×200). The internal elastic lamina *(arrowheads)* and the architecture of the vascular wall are well preserved. (B) The same vessel stained with elastic van Gieson (×200).

(B) Necrosis of the ends of almost all fingers led to autoamputation in the same patient after continued smoking. (C) One of the cardinal signs of thromboangiitis obliterans is superficial thrombophlebitis, seen here on the left leg of a 28-year-old smoker. Note the hairless skin distally. (D) Infected left metatarsal ulceration with osteomyelitis untreated for several weeks in a 32-year-old male patient with previous great and 5th toe amputations.

TAO.[1,167] It is common to see angiographic abnormalities consistent with TAO in limbs that are not yet clinically involved. Rarely, TAO has been associated with visceral,[168-188] cerebral,[189-193] coronary,[194-203] internal thoracic artery,[196,197] and multiorgan involvement.[204,205] Involvement of the cerebral vessels may result in progressive cognitive decline and migraine,[206] transient ischemic attack, ischemic stroke, or schizophrenia-like symptoms.[189-193] Coronary artery involvement may result in myocardial ischemia or infarction.[194-202] Visceral vessel involvement may manifest as abdominal pain, nausea, vomiting, fever, diarrhea, melena, weight loss, and anorexia and result in ileus, ischemic colitis, mesenteric infarction, intestinal perforation, or liver hypoxia.[169-174,178,180,185-187] Involved vascular beds exhibit similar pathologic characteristics as vessels in the extremities. Even rarer are instances of TAO in saphenous vein arterial grafts,[207] the temporal arteries,[208] the ophthalmic circulation,[209-211] and intrarenal arterial branches[212] of smokers. Also uncommon is the occurrence of TAO in pudendal,[213,214] testicular and spermatic arteries and veins, as was originally described by Buerger.[18] Rare cases of nephropathy as a result of mesangial immunoglobulin A deposition,[215] or renal artery thrombosis; cutaneous manifestations presenting as painful nodular erythema with livedo

TABLE 138.3 Distribution of Arterial Involvement in 825 Patients With Thromboangiitis Obliterans (1650 Upper and 1650 Lower Extremities)

Lower extremity involvement only	616 (74.7%)
Upper and lower extremity arteries	167 (20.2%)
Upper extremity involvement only	42 (5.1%)
Lower Extremity ($n = 783$)	
Anterior tibial artery	683 (41.4%)
Posterior tibial artery	667 (40.4%)
Dorsalis pedis artery	349 (21.2%)
Peroneal artery	304 (18.4%)
Popliteal artery	301 (18.2%)
Digital arteries	180 (10.9%)
Plantar arteries	149 (9.0%)
Other	296 (19.8%)
Upper Extremity ($n = 209$)	
Ulnar artery	189 (11.5%)
Digital arteries	133 (8.1%)
Radial artery	115 (7.0%)
Superficial or deep palmar arch	75 (4.5%)
Brachial artery	13 (0.8%)
Other	26 (1.6%)

Modified from Sasaki S, Sakuma M, Kunihara T, et al. Distribution of arterial involvement in thromboangiitis obliterans (Buerger's disease): results of a study conducted by the Intractable Vasculitis Syndromes Research Group in Japan. *Surg Today*. 2000;30:600–605.

reticularis,[216] and avascular necrosis of femoral heads[217] have also been reported. TAO in unusual locations should be diagnosed only when the histopathologic findings are classic for the acute-phase lesion and the clinical presentation is consistent with the diagnosis of BD.[167]

DIAGNOSIS

A century after its first description, the major clinical challenge in TAO is the absence of universally accepted diagnostic criteria.[1,28,218-220] Shionoya has identified five major criteria for the diagnosis of TAO: (1) smoking history, (2) onset before age 50, (3) infrapopliteal arterial occlusive lesions, (4) either upper limb involvement or phlebitis migrans, and (5) an absence of atherosclerotic risk factors other than smoking.[28] In 1992, Papa and Adar proposed various clinical, angiographic, histopathologic positive and negative criteria, and in a second report, they proposed a point-based scoring system to improve the diagnostic certainty.[55,221] More stringent major and minor supportive criteria were developed by Mills and Porter, based on a cohort of patients in Oregon.[222] Olin's criteria include (1) age less than 45 years; (2) current (or recent) history of tobacco use; (3) the presence of distal-extremity ischemia (indicated by claudication, pain at rest, ischemic ulcers, or gangrene) documented by noninvasive vascular testing; (4) exclusion of autoimmune diseases, hypercoagulable states, and diabetes mellitus by laboratory tests; (5) exclusion of a proximal source of emboli by echocardiography and arteriography; and (6) consistent arteriographic findings in the clinically involved and noninvolved limbs.[1,3] All investigators accepted the exclusion of atherosclerotic risk factors other than smoking. Therefore, TAO is a clinical diagnosis, and the diagnosis requires investigations aimed at excluding other possible diagnoses.

Vascular Evaluation

A complete vascular examination is critical for the diagnosis. Physical examination reveals involvement of small and medium-sized arteries with normal brachial and femoral pulses. The radial, ulnar, dorsalis pedis, or posterior tibial pulses may be absent. Digital arteries may be occluded. An abnormal Allen test, which suggests ulnar artery occlusion in a young smoker with lower extremity ulcerations, is highly suggestive of TAO, since abnormal Allen tests occurred in 63% of cases in the Cleveland Clinic series.[3] Superficial phlebitis may be another clue to the diagnosis. Neurologic examination may document peripheral nerve involvement, with sensory findings in up to 70% of patients.[1] Calculation of the ankle-brachial index, toe-brachial index, and wrist-brachial index at rest and after *exercise* is recommended as the initial screening test. Seasonal variation, with exacerbation of TAO occurring more frequently in the winter, has been reported;[223,224] this may be attributed to cold weather and the stimulation of vasospasm and Raynaud phenomenon.[223]

Noninvasive Testing

Four-limb segmental arterial pressure measurements and pulse volume recordings are usually normal above the knee and markedly reduced distally.[80] Abnormal digital plethysmographic patterns in both lower and upper extremities would objectively document distal occlusive disease in a patient meeting the clinical criteria for TAO.[29,55,65,79,225] Calcification of the involved arterial wall is almost always absent on plain radiography,[31] and arterial duplex scanning is used not only to exclude proximal atherosclerotic lesions and to demonstrate distal arterial occlusive disease, but also to visualize and functionally evaluate the corkscrew shaped collaterals. Using continuous wave Doppler ultrasound monophasic waveform pattern within the corkscrew-shaped collaterals is also known as Martorell sign ("snake" or "dot" sign) (Fig. 138.5).[226,227] In a recent study from Poland, Doppler spectral waveform analysis in 40 TAO patients and 40 healthy subjects revealed a reduction of reversed diastolic flow amplitude with no significant decrease in peak systolic amplitude in patients with TAO.[228] The authors concluded that decreased vascular resistance may develop as a result of increased collateral blood flow and low-resistance cutaneous arteries; thus, resistance index can be a useful Doppler parameter in the early diagnosis of TAO and probably in monitoring disease progression. Another study confirmed augmented flow-mediated

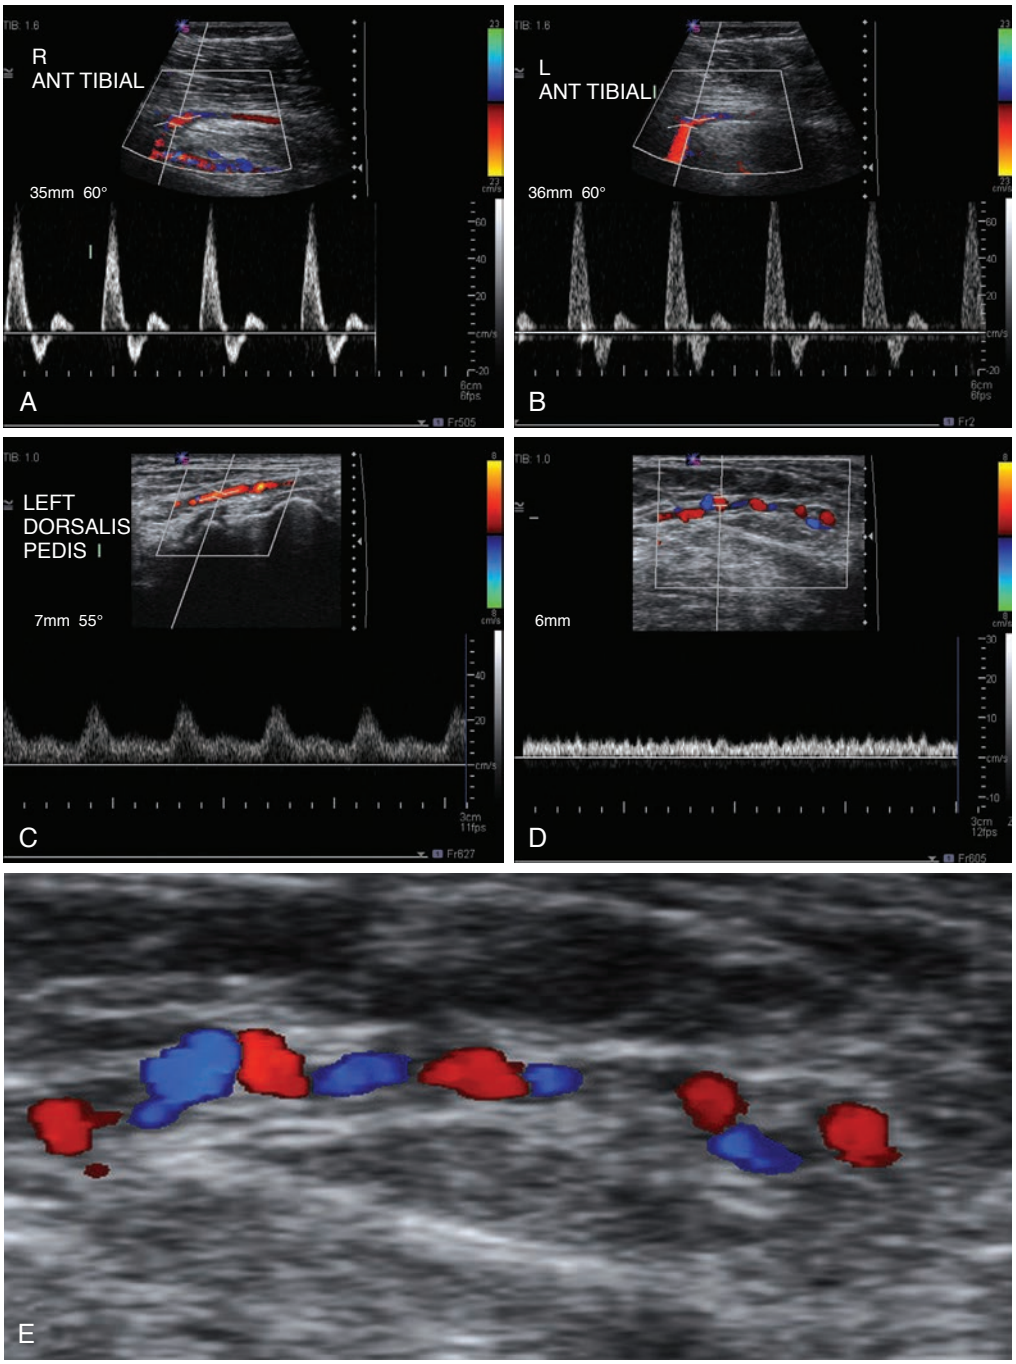

Figure 138.5 Color-flow Doppler studies demonstrating triphasic flow within the right (A) and left (B) anterior tibial arteries, monophasic flow within the left dorsalis pedis artery (C), and the "dot" sign because of continuous flow within corkscrew collaterals at the toe level (D and E).

vasodilation in a corkscrew collateral artery but impaired flow-mediated vasodilation in a native artery in patients with TAO.[229] These findings indicate selective impairment of vascular endothelium, but not smooth muscle cells in native arteries in patients with BD.[229] Laser Doppler flowmetry, transcutaneous oxygen, and carbon dioxide pressures can help evaluate the severity of ischemia and the effectiveness of treatment.[230]

Emboli as a cause of distal ischemia should be ruled out, as the signs and symptoms of embolic occlusions can mimic those of TAO. Cardiac investigations, including electrocardiography, rhythm monitoring, and echocardiography, are recommended to rule out cardiac and thoracic aortic sources of emboli to the involved extremity.[231] In addition, abdominal ultrasonography may be considered to rule out a proximal source of emboli from an abdominal aortic aneurysm or atherosclerotic aorta.

Gadolinium-enhanced magnetic resonance angiography and multidetector computed tomographic angiography (Fig. 138.6) may be useful diagnostic alternatives in patients with TAO. Furthermore, ischemic ulcerations with signs and symptoms of secondary infection should be evaluated using conventional

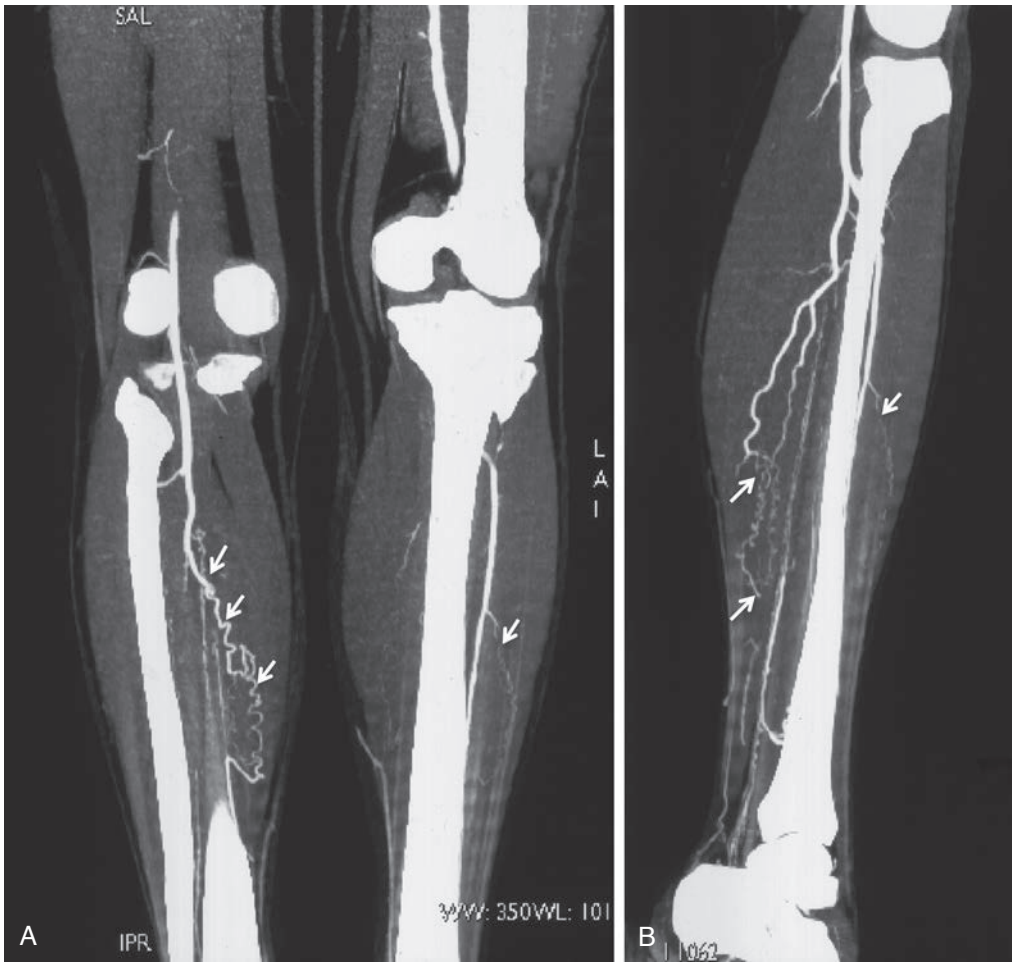

Figure 138.6 (A and B) Abrupt right tibial vessel occlusion with corkscrew collaterals *(arrows)* in a 34-year-old man detected with 64-slice multidetector computed tomographic angiography.

radiography and magnetic resonance imaging to determine the presence of osteomyelitis.[232] Recently, 18F-flourodeoxyglucose positron emission tomography has been investigated in TAO case series but have been found to be unsuitable investigative procedure for the diagnosis of TAO.[233]

Laboratory Testing

There are no specific laboratory tests for the diagnosis of TAO; however, serologic testing for autoimmune antibodies, thrombophilia, and vasculitides should be included in the screening process. Acute-phase reactants, erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) are typically normal or slightly elevated in the absence of extensive trophic lesions. Absence of immunologic markers including complement levels, rheumatoid factor (RF), antinuclear antibodies (ANA), anticentromere antibodies, anti–SCL-70 antibodies, ANCAs, and cryoglobulins are characteristic for TAO. However, anticardiolipin antibodies may be present in patients with TAO, and the toxicology panel should include cocaine, amphetamines, and cannabis. A suggested diagnostic algorithm for the diagnosis of TAO is summarized in Table 138.4.

Angiography

Thoracoabdominal digital subtraction angiography plays an important role in both supporting the diagnosis of TAO and ruling out other causes of ischemia. Arteriographic findings in TAO may be suggestive but not pathognomonic. Thus, this method is not a "gold standard" for diagnosis. Segmental occlusive lesions (diseased arteries interspersed with normal-appearing arteries), more severe disease distally, involvement of digital arteries,[65] normal proximal arteries without evidence of atherosclerosis, and collateralization around areas of occlusion with corkscrew shape (Martonell sign) also known as "tree root" or "spider's leg" collaterals are the common features of TAO (Fig. 138.7).[44,234] The infrapopliteal or infrabrachial arteries are the most common sites of occlusion. In addition, small corkscrew patterns (types III and IV) are associated with higher prevalence of ischemic ulcers compared to large corkscrew collaterals (types I and II).[235] Although corkscrew collaterals, which represent widened vasa vasorum, suggest TAO to many clinicians,[44] this finding is not pathognomonic. In one study, 27% of 144 limbs affected by TAO had a corkscrew appearance.[236] Corkscrew-shaped collaterals can also be seen in connective tissue diseases

TABLE 138.4 Suggested Diagnostic Algorithm for the Diagnosis of Thromboangiitis Obliterans

1. Young smoker (confirm tobacco, bidi, kawung, cannabis, or cocaine use)
2. Document distal lower or upper extremity ischemic symptoms and signs (claudication, ischemic rest pain, ulcerations, and gangrene)
3. Note the maximal pain-free walking distance, and pain scale (0-10 scale)
4. Document distal nature of disease
   - Blood pressure measurements, ankle-brachial and/or ankle-toe pressure indices
   - Transcutaneous oxygen tensions
   - Arterial duplex scanning
   - Intraarterial digital-subtraction angiography (IA-DSA)
   - Computed tomographic angiography (CTA)
   - Magnetic resonance angiography (MRA)
5. Laboratory tests to exclude connective tissue diseases and hypercoagulable states
   - Routine complete blood count and biochemistry including fasting blood glucose, renal function, and liver enzymes
   - Thyroid function tests
   - Urinalysis
   - Lipid profile
   - Serum homocysteine, vitamin B12, red blood cell folate
   - Coagulation profile: prothrombin time, activated partial thromboplastin time, protein C, protein S, antithrombin III, factor V Leiden, prothrombin gene mutation 20210, antiphospholipid antibodies, anticardiolipin antibodies
   - Autoimmune screen: erythrocyte sedimentation rate, C-reactive protein, complement measurements, antinuclear antibody, antineutrophil cytoplasm antibody, rheumatoid factor, cryoglobulins, scleroderma-specific antibodies (antibodies SCL-70)
   - Measurements of serologic markers for the CREST syndrome (calcinosis, Raynaud phenomenon, esophageal disease, sclerodactyly, telangiectasia)—Anticentromere antibodies
   - Hand radiographs (to exclude calcinosis)
   - Hepatitis B, C serology
   - Venereal Disease Research Laboratory test
6. Exclusion of proximal sources of emboli
   - Electrocardiography, rhythm monitoring
   - Echocardiography (transthoracic, transesophageal if necessary)
   - Abdominal ultrasonography
   - Arteriography (IA-DSA, CTA, MRA)
7. Nielsen digital hypothermic challenge test (Raynaud evaluation)
8. Toxicology screen for cocaine, amphetamine, and cannabis
9. Biopsy indicated only for unusual features
   Age >45 years at onset
   Documented disease in unusual locations (proximal disease, central nervous system disease)

Modified from Lazarides MK, Georgiadis GS, Papas TT, et al. Diagnostic criteria and treatment of Buerger's disease: a review. *Int J Low Extrem Wounds*. 2006; 5:89–95; Mills JL, Sr. Buerger's disease in the 21st century: diagnosis, clinical features, and therapy. *Semin Vasc Surg*. 2003;16:179–189; and Olin JW. Thromboangiitis obliterans (Buerger's disease). In: Rutherford RB, ed. *Vascular Surgery*. 6th ed. Philadelphia: Elsevier Saunders; 2005:404–419.

such as scleroderma, CREST syndrome (calcinosis, Raynaud phenomenon, esophageal disease, sclerodactyly, telangiectasia), systemic lupus erythematosus, rheumatoid vasculitis, and the antiphospholipid-antibody syndrome.[1] Furthermore, cocaine, amphetamine, or cannabis addiction can cause BD-like clinical and angiographic signs.[69-72,77,151,237] The angiographic features that support a diagnosis of TAO are listed in Table 138.5, and a study from Japan determined the distribution of arterial involvement in TAO on the basis of a nationwide survey in 1993 by the Intractable Vasculitis Syndromes Research Group (see Table 138.3).[166]

Biopsy

A biopsy is rarely needed unless the patient presents with atypical features, such as large-artery involvement or age older than 50 years.[1] Biopsy of an acute superficial thrombophlebitis often demonstrates the typical histopathologic lesions of acute TAO.[50] Kroger suggested that the possibility of arteriosclerosis should be discounted only in young patients aged 20 to 30 years.[220]

TABLE 138.5 Angiographic Findings in Thromboangiitis Obliterans

- Involvement of small and medium-sized arteries
  Digital arteries of fingers and toes
  Palmar, plantar, tibial, peroneal, radial, and ulnar arteries
- Segmental occlusive lesions: diseased arterial segments interspersed with normal-appearing segments
- More severe disease distally
- Tapering or abrupt arterial occlusions with collateralization around areas of occlusion: described as "corkscrew collaterals," "spider leg" or "tree root appearance" (not pathognomonic)
- Normal proximal arteries free of atherosclerosis, aneurysms, or other sources of emboli

Differential Diagnosis

Differential diagnosis of TAO includes a broad range of disorders, and diagnostic evaluations should exclude ASO, thromboembolism, and other vasculitides.[7,54,220] TAO differs from ASO with infrapopliteal or infrabrachial arterial involvement and

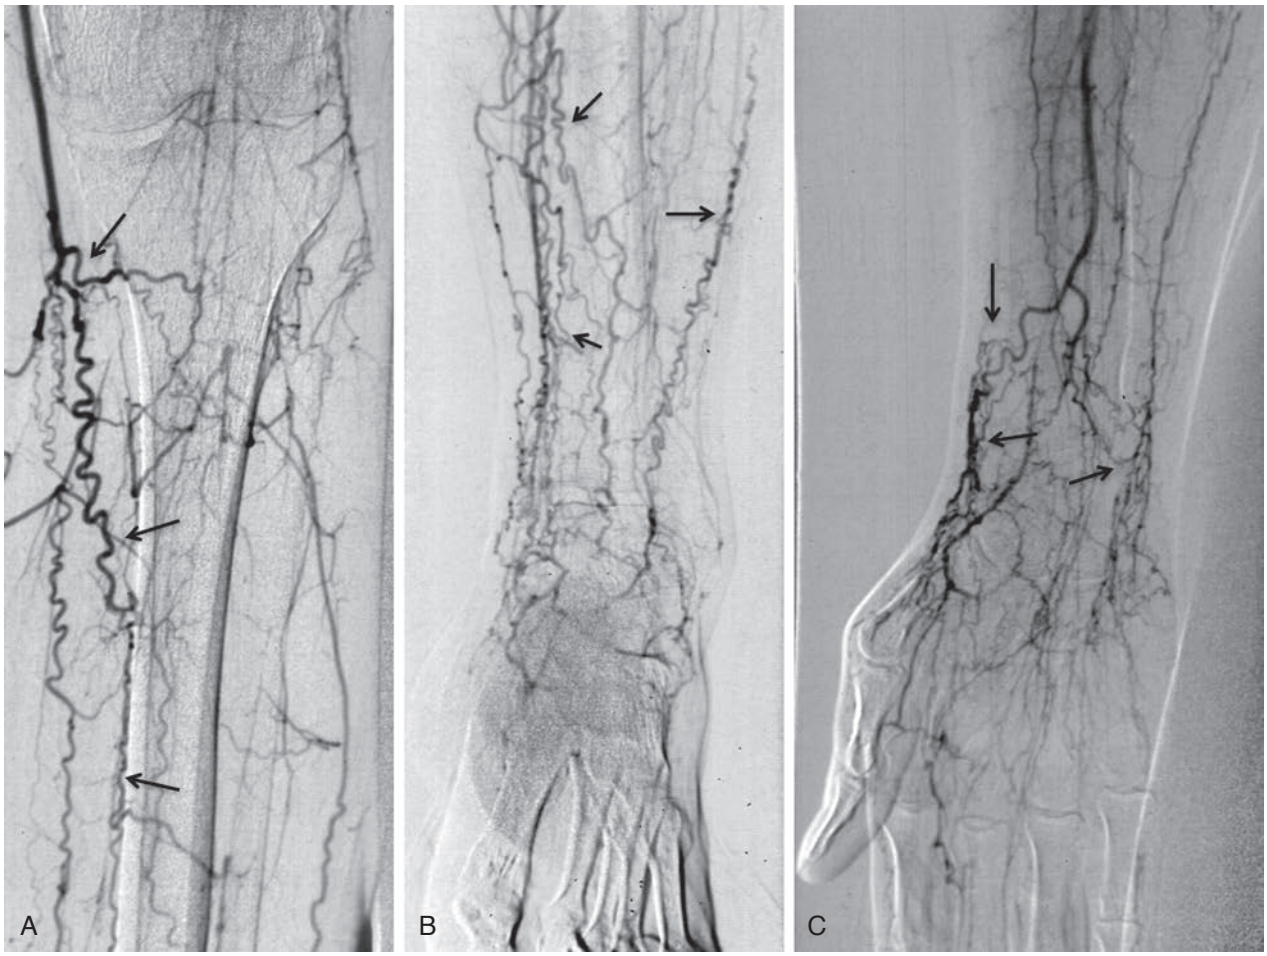

Figure 138.7 Digital subtraction angiography reveals left popliteal and tibial vessel occlusions with corkscrew collaterals *(arrows)* proximally (A) and distally (B) and right radial and ulnar artery involvement (C) in a 32-year-old man with a nonhealing left toe ulceration.

associated migratory thrombophlebitis. TAO differs from most other types of vasculitis with nonnecrotizing, nongranulomatous inflammation of medium and small size arteries; preserved internal elastic lamina; and media; and serologic markers (elevated acute phase reactants such as ESR and CRP, presence of circulating immune complexes, and presence of autoantibodies such as antinuclear antibody, RF, and complement levels) are usually normal or negative.[12,54] Causes of distal arterial ischemia, including scleroderma, CREST syndrome, systemic lupus erythematosus, Takayasu arteritis, polyarteritis nodosa, giant cell arteritis, rheumatoid vasculitis, mixed connective-tissue disorders, antiphospholipid syndrome, vascular compression syndromes (thoracic outlet syndrome, hypothenar hammer syndrome, repetitive vibratory injury, popliteal artery entrapment, carpal tunnel syndrome), malignancies, hematologic thrombophilia disorders (lupus anticoagulant, anticardiolipin antibody syndrome), drug-induced hypersensitivity, ergot abuse, cannabis arteritis, and microbial infection, should also be considered in the differential diagnosis. If TAO and ASO or other vasculitides cannot be differentiated, the diagnosis can be confirmed by biopsy of a subcutaneous nodule or involved vein, which may show the characteristic acute-phase lesion.[54,151] TAO has important features that are distinguishable from other forms of vasculitis,[167] such as a highly inflammatory thrombus with relative sparing of the blood vessel wall. Preservation of the internal elastic lamina distinguishes TAO from the true necrotizing forms of vasculitis.[238-240] Kimura disease presenting with Raynaud phenomenon and digital infarcts, and marked eosinophilia may mimic TAO symptoms.[241]

Natural History

Exacerbations and remissions are characteristic features of TAO. In one study, at a mean follow-up of 10.7 (range: 2-30) years, patients experienced an average of 5.4 (range: 1-20) acute episodes with severe symptoms.[143] Patients have a significantly diminished quality of life compared with age- and sex-matched controls.[242,243] TAO population and a matched coronary artery disease population had similar degrees of tobacco dependence and Fagerström scores.[244] In one study, the life expectancy of patients with TAO was comparable to that of the normal population.[25] In contrast, Cooper and colleagues reported that survival among the TAO cohort was significantly lower than that in the matched US population in the TAO group, and the

average age at death was 52.2 ± 8.9 years.[242] The risk of any amputation during mean follow-up of 15.6 years was 25% at 5 years, 38% at 10 years, and 46% at 20 years.[242] The risk of major amputation, defined as above-knee, below-knee, or hand amputation, was 11% at 5 years, 21% at 10 years, and 23% at 20 years.[242] In this analysis, the amputation rate was significantly reduced in those who discontinued tobacco use. The authors concluded that the risk of amputation in previous smokers is eliminated 8 years after smoking cessation.[242] Cumulative survival rates in the series reported by Ohta and colleagues were 97.0% at 5 years, 94.4% at 10 years, 92.4% at 20 years, and 83.8% at 25 years (mean follow-up, 10.6 years).[243] These investigators also demonstrated that the occurrence or recurrence of necrotic lesions was usually arrested in patients older than 60 years. There was a strong correlation between continued smoking and limb amputation leading to poor quality of life and job loss.[243] Another study from Turkey reported similar survival rates: 95.0% at 2 years, 92.4% at 5 years, and 88.4% at 10 years (mean follow-up, 11.6 years).[154] A study from Japan confirmed that failure to cease smoking was the most significant factor affecting the risk of ulcer formation (OR: 1.71) and risk for amputation (OR: 2.73; 95% CI: 1.86-4.01).[150]

TREATMENT

Lifestyle Changes

Smoking Cessation

The first step in management of TAO is complete and permanent discontinuation of smoking in any form,[29,54,81,167,245] including passive smoking.[87] The hazards of continued smoking in patients with TAO seems to be independent of factors such as the number of cigarettes smoked per day[167]; whether the tobacco product is in the form of cigarettes, bidis, cigars, chewing tobacco, or snuff;[56,60,246] cigarette characteristics; and smoking behavior, including degree of inhalation. Counseling, smoking-cessation programs, pharmacotherapy using bupropion or varenicline, and exercise training form the cornerstone of treatment.[45] Nicotine replacement therapy may result in disease progression, thus this should be avoided;[1,247] however, in terms of limb salvage in a stage of CLI in patients with TAO, smoking cessation may not be sufficient.[248]

Exercise Training

Benefits of exercise training in claudication are well established.[249] Regular exercise training (sessions lasted more than 30 minutes and 3-5 times per week) improves pain-free walking time by an average of 180% and maximal walking time by an average of 120% in patients with claudication.[250] Randomized trials confirmed that ischemic exercise training triggers the release of CPCs from the bone marrow and promotes homing of CPCs into vascular networks.[251]

Foot, Hand, and Dental Care

Daily foot and hand hygiene as well as avoidance of trauma, thermal injury, vibration, chemicals, and cold are easily applied measures to prevent ischemic ulcers.[252] Any injury to the involved extremity should be treated promptly. Adequate oral hygiene, controlling the bacterial biofilm, and periodontal treatment might be useful measures preventing the recurrence of the disease.[130,253]

Pharmacologic Treatment

Treatment must be tailored to the individual and is often based on the patient's clinical presentation. TAO has conventionally been treated with antiplatelet agents including oral anticoagulants, clopidogrel, dextran, pentoxifylline, phenylbutazone, pyridinolcarbamate, inositol niacinate, nonsteroidal antiinflammatory agents, and immunosuppressive drugs including cyclophosphamide[254] and corticosteroids.[255] However, no randomized controlled trials have been reported assessing the efficacy of previously mentioned agents in TAO.[256,257] Reported two cases of steroid-responsive TAO[255] with remarkable eosinophilia is controversial.[241] Appropriate antibiotics and nonsteroidal antiinflammatory agents should be used in patients with complicated phlebitis, cellulitis, or osteomyelitis.

Calcium Channel Blockers

Calcium channel blockers have been used for TAO patients associated with the Raynaud phenomenon. Nifedipine, nicardipine, or amlodipine may similarly be used in patients with significant vasospasm.[1]

Prostacyclin Analogs

Prostaglandin I2 (Prostacyclin), a main product of arachidonic acid metabolism by endothelial cells, is a potent vasodilator through vascular smooth cell relaxation, and it inhibits platelet aggregation, chemotaxis, and cell proliferation.[258,259] Epoprostenol is a freeze-dried preparation of prostacyclin for intravenous administration.[260] Iloprost is a stable and synthetic analogue of epoprostenol with a plasma half-life of 20 to 30 minutes. It is commonly used in the treatment of peripheral vascular disease because of its vasodilating and platelet inhibitory effects. Iloprost also downregulates the expression of intercellular adhesion molecule-1 and endothelial leukocyte adhesion molecule-1 on interleukin-1β–stimulated endothelial cells and inhibits lymphocyte adhesion to endothelial cells.[261]

Iloprost Infusion

Moderate quality of evidence exists with limited number of randomized trials in pharmacologic treatment of TAO with CLI.[257] In a European multicenter, randomized, double-blinded trial involving patients with TAO and CLI, Fiessinger and Schafer compared 6-hour infusion of iloprost (0.5-2.0 ng/kg per minute) and oral aspirin (100 mg/day) for a 28-day trial period.[262] Among 152 patients, 133 patients fulfilled the entry criteria of rest pain, ischemic ulceration, or gangrane.[262] At 28 days of treatment, iloprost was superior to aspirin at achieving ulcer healing or relief of ischemic pain; 85% of patients in the iloprost group improved versus 17% in the aspirin group. Furthermore, at 6 months, the response rate was 45 of 51 (88%) patients treated with iloprost compared with 12 of 44 (21%) patients treated with aspirin. Only 6% of patients in the iloprost group ultimately

required amputation compared with 18% in the aspirin group.[262] In a randomized, multicenter study, the Turkish Buerger's Disease Research Group compared the results of lumbar sympathectomy ($n = 78$) to 28 days of intravenous iloprost ($n = 84$) in 162 patients with CLI and TAO.[263] The primary endpoint of the study was complete healing without pain or major amputation at 4 and 24 weeks. Complete healing was achieved in 61.9% of the iloprost group and 41% of the lumbar sympathectomy group at 4 weeks ($P = .012$) and in 85.3% versus 52.3%, respectively, at 24 weeks ($P < .001$).[263] The risk of amputation is also reduced with combination of iv iloprost infusion and supervised smoking cessation in TAO patients with CLI.[264] Thus, reported evidence suggests that intravenous iloprost is effective pharmacologic treatment option in healing ulcers and relieving rest pain in patients with TAO and CLI.[257] Iloprost has been authorized in some European Union Member States for the treatment of TAO.

Oral Iloprost

The European TAO Study Group conducted a double-blinded, randomized, placebo-controlled trial comparing oral iloprost (100 or 200 mcg) with placebo for 8 weeks among 319 patients with ischemic rest pain or ulcerations recruited from 22 centers in six countries in Europe,[258] and the duration of treatment was 6 weeks. The primary endpoint was total healing of the most important lesion, and the secondary endpoint was total relief of pain at rest without the need for analgesics at six months. The combined endpoint consisted of the patient's being alive with no major amputation, no lesions, no rest pain, and no analgesic use. After 6 months of therapy, low-dose iloprost was significantly better than placebo at relieving rest pain without the use of analgesics, and for achieving the combined endpoint.[258] However, neither dose of oral iloprost showed a significant effect on the total healing of lesions compared with placebo.

Prostaglandin E1 Analogs

Limaprost alfadex, a prostaglandin E1 analogue, was developed in Japan to treat ischemic symptoms of TAO also has strong vasodilatory and antiplatelet activity similar to Prostacyclin. In a randomized, double-blinded trial in 136 Japanese patients primarily with TAO, there was no significant difference in the improvement of ischemic symptoms between patients receiving limaprost 30 μg/day and those receiving oral ticlopidine 500 μg/day.[265]

Phosphodiesterase Inhibitors

Phosphodiesterase 3 Inhibitors (Cilastazol)

Phosphodiesterase 3 (PDE3) isoenzyme is found in vascular smooth muscle and platelets. Inhibition of PDE3 isoenzyme increases intracellular cyclic adenosine monophosphate (cAMP) results in smooth muscle relaxation and decreases platelet aggregation. In one small study, cilastazol was effective at improving ischemic ulcerations in patients with refractory digital ischemia.[239] The role of cilostazol in TAO is, however, still not clear.

Phosphodiesterase 5 Inhibitors (Sildenafil, Tadalafil)

PDE5 isoenzyme is found in the corpus cavernosum of the penis and vascular smooth muscle. Inhibition of PDE5, a cyclic guanosine monophosphate (cGMP)-dependent phosphodiesterase increase intracellular cGMP, results in decreased intracellular calcium and increased nitric oxide leading to vascular smooth muscle relaxation and vasodilation. There are few reported cases of TAO with digital symptoms successfully treated with off-label use of PDE5 inhibitors, namely sildefanil (20 mg tid) or tadalafil (40 mg every other day).[266-268]

Endothelin Receptor Antagonists

Bosentan, an oral dual endothelin-1 receptor antagonist targeting two transmembrane receptors, namely ETA and ETB, has been useful in patients with TAO and ischemic lesions.[268-271] Bosentan has selective vasodilatory, antiinflammatory, and antifibrotic properties. Previous case series showed clinical and angiographic improvement in 10 out of 12 patients with ulcers and/or pain at rest.[272] De Haro et al. reported that Bosentan therapy (125 mg/12 h) maintained for four months resulted in clinical improvement and complete healing of the ulcers in a single-center prospective study with 48 months follow-up data in patients with TAO and ischemic ulcers unresponsive to conventional therapies.[273] Only 2 out of 22 extremities (9%) underwent major amputation. Well-conducted randomized clinical trials are, however, still needed, especially in patients with pain at rest and ischemic ulcers.

Thrombolytics

Selective intraarterial infusion of urokinase and streptokinase as a treatment option for TAO has been reported.[274-278] However, in the series of Hussein et al., limb salvage rate was 33%, and bleeding complications occurred in 17% of the patients treated with intraarterial streptokinase.[275] Matsushita and associates administered a continuous intraarterial infusion of urokinase (20,000 U/h) and heparin (800 U/h) in a 19-year-old woman with CLI and TAO.[39] Although her symptoms improved temporarily, thrombolytic therapy did not enable recanalization of the occluded popliteal artery. High-quality trials assessing the effectiveness of thrombolytics in patients with TAO are needed.

Folate Supplementation

Folate therapy in TAO patients with increased homocysteine levels has been investigated in one randomized trial from Iran.[279] Single dose of folic acid (5 mg) and placebo were compared in 30 patients with TAO.[279] The authors concluded that single dose folic acid has homocysteine lowering effect but did not inhibit the risk of minor or major amputation rate.[279] Further clinical evidence about folate therapy for TAO patients is required.

Statins

There is increasing experimental evidence that the pleiotropic effects of statins may improve or restore endothelial function and decrease oxidative stress and vascular inflammation.[280-282]

However, the therapeutic role of statins in inflammation-induced thrombosis is still an unresolved issue.[283]

Analgesia

Analgesia is often required in patients with rest pain and ischemic ulcers. Opioids, nonsteroidal antiinflammatory drugs, antidepressants, and neuronal block may relieve symptoms.

Regional Sympathetic Blockade

Guanethidine, an adrenergic neuron blocker that inhibits the presynaptic release and subsequent reuptake of noradrenaline from postganglionic sympathetic nerve endings, has been proposed for the treatment of TAO.[284-287] Intravenous regional sympathetic blockade with guanethidine has been described by Hannington-Kiff.[288] This "chemical sympathectomy" is based on multiple sessions of intravenous regional sympathetic blockage with lidocaine and guanethidine using Bier's arterial arrest.[289,290] However, despite promising case reports in patients with ischemic rest pain and nonhealing ulcerations, limitations regarding the use of this therapy still exist.[284]

Spinal Cord Stimulation

There are increasing reports in the literature regarding the use of implantable spinal cord stimulators in patients with TAO.[291-296] Electrical spinal cord stimulation relieves pain through several mechanisms, including preventing transmission of painful stimuli through the corresponding dermatomes, stimulation of the production of inhibitory neurotransmitters in the spinal cord, and inhibition of sympathetic vasoconstriction with consequent improvement in peripheral microcirculation.[291,294,296] Spinal cord stimulation successfully addresses the neurogenic, but not the somatic, aspects of pain in patients with TAO.[287] Spinal cord stimulation can be attempted when other forms of therapy are ineffective.[167]

Surgery

Lumbar or Thoracic Sympathectomy

In a randomized, multicenter study, the Turkish Buerger's Disease Research Group compared the results of lumbar sympathectomy ($n = 78$) to 28 days of intravenous iloprost ($n = 84$) in 162 patients with CLI and TAO.[263] The primary endpoint of the study was complete healing without major amputations or pain at 4 and 24 weeks. Complete healing was achieved in 61.9% of the iloprost group and 41% of the lumbar sympathectomy group at 4 weeks ($P = .012$) and in 85.3% versus 52.3%, respectively, at 24 weeks ($P < .001$).[263] Kothari et al. recently reported that thoracoscopic dorsal sympathectomy reduces pain in patients with upper limb involvement in a recent case series of 25 TAO patients from India.[297]

Distal Surgical Revascularization

The role of surgical revascularization in TAO is not clear. Revascularization is often not feasible because of the distribution of diffuse, segmental arterial involvement, and the distal nature of the disease.[54] Distal arterial spasm during dissection and poor-quality veins owing to phlebitis are other disease-specific handicaps. The arterial circulation of the lower extremity generally cannot serve as the distal anastomotic site for bypass surgery, resulting in suboptimal patency rates. However, if the patient has CLI and a distal target vessel is present, bypass surgery using autologous vein should be considered.[298,299] Arterial bypass of the larger vessels may be used in selected cases. In 1974, Inada and associates demonstrated that of their 236 patients with TAO, only 11 (4.6%) had lesions that were amenable to surgical revascularization,[300] whereas a vasculitis database from Japan revealed that 15.5% of TAO patients underwent surgical revascularization.[150] Dilege and associates reported that 36 of their 94 patients with TAO (38.3%) were deemed eligible for revascularization, but only 27 patients (28.7%) actually underwent revascularization procedures.[301] In this study, any crural vessel with at least 10 cm of patency, preferably in continuation with the pedal arch or draining with a good collateral network, was considered appropriate for revascularization. The patency rates at 12, 24, and 36 months were 59.2%, 48%, and 33.3%, respectively. The limb salvage rate was, however, 92.5%. Bypass surgery was most frequently required below the trifurcation segment of the knee joint, with a cumulative patency rate of 54.6% at 5 years.[302] In a retrospective review of 216 patients with TAO over a 10-year period, Sayin and colleagues reported that lumbar sympathectomy was performed in 85% and thoracic sympathectomy in 9.3% of TAO patients.[303] Twenty-one patients (9.7%) underwent direct arterial reconstruction of varying types. The investigators noted that four of the five endarterectomized segments had occluded by the 7-year follow-up.[303] Sasajima and associates showed that a strategy of aggressive distal bypass surgery using autologous disease-free vein grafts for TAO may provide acceptable primary and secondary patency rates.[298] The patency rates in the postoperative nonsmoking group were significantly higher than in the smoking group (66.8% vs. 34.7%; $P < .05$).[298] Predictors of early graft failure were poor quality vein, inadequate technique for anastomosis, inadequate tunneling, anastomosis to a diseased artery, arterial spasm, and vein graft intimal hyperplasia.[298] Late failures were due to disease progression, especially in smokers, vein graft intimal hyperplasia or aneurysm, atherosclerosis, and competition with collateral flow.[298] Bozkurt and colleagues reported cumulative secondary patency rates of 57.9% for bypass grafts at a mean follow-up of 5.4 years in 19 patients with BD.[304] Cumulative patency was 70% (7 of 10) for saphenous vein grafts, 50% (3 of 6) for polytetrafluoroethylene grafts, and 33.3% (1 of 3) for composite grafts. Different distal bypass techniques and routes have been described to obtain better anatomic orientation and patency rates in patients with TAO.[305-307] Collateral artery bypass is an option when the main arteries are affected by TAO,[308] and successful local flap transfers after distal bypass surgeries have been reported in selected cases.[309-312] The prevalence of amputation and the primary and secondary patency rates after revascularization in patients with TAO are summarized in Table 138.6.

Pedicled Omental Graft

For foot salvage, paramalleolar arterial bypass grafts may be combined with microvascular free tissue transfer.[309] Successful

TABLE 138.6 Prevalence of Amputations, Primary and Secondary Patency Rates After Arterial Revascularization in Patients With Thromboangiitis Obliterans

Authors	Year	Study Type	Number of Patients	Number of Bypasses	Primary Patency	Secondary Patency	Limb Salvage	Amputations

local flap transfers after distal bypass surgery has been reported in selected cases,[309-312] and omental transfer to areas not amenable to arterial reconstruction has been proposed as a therapeutic option in TAO.[313-319] In two retrospective series from India, complete healing was achieved in more than 80% of the patients, and limb salvage was 100% with pedicled omental graft.[314,317] This surgical technique, however, has not been used in Europe or the United States.

Distal Venous Arterialization

Distal venous arterialization may be offered as a last surgical resort for limb salvage in the absence of graftable distal arteries.[320-324] Distal venous arterialization can successfully salvage the critically ischemic lower limb with few serious complications. A recent meta-analysis showed that overall 1-year foot preservation was 71% (95% CI: 64%-77%), and 1-year secondary patency was 46% (95% CI: 39%-53%) after distal venous arterialization.[321]

Local Wound Care

In clinical practice, wound toilette, including limited surgical or ultrasound debridement and appropriate antibiotics, is often useful in the treatment of infected ischemic ulcerations.[29] Caution is advised for excessive local debridement, which may widen ulcers.[325] Topical agents for elimination of necrotic tissue and infection, maintaining a moist environment, and management of wound margin are the hallmarks for the treatment of ischemic ulcers associated any vasculitis.[325] Given the absence of a proven benefit and its high cost, hyperbaric oxygen therapy should be considered only in selected patients with ischemic ulcers, osteomyelitis, or necrotizing fasciitis who have not responded to other forms of treatment.[40,72,326-331] Negative-pressure wound therapy may be helpful, as continuous or intermittent vacuum-assisted settings may have a role in the treatment of debilitating complex chronic ulcers in patients with TAO.[332-334]

Endovascular Treatment

Percutaneous subintimal angioplasty for limb salvage in patients with nonhealing ulcers has been proposed,[335-338] but it would be premature to claim that this method might provide new opportunities for patients with TAO. However, extended endovascular management for tibial or foot artery obstruction was recently achieved in 17 patients with TAO and CLI with a technical success rate of 95%.[339] Successful use of Silver-Hawk directional atherectomy in two TAO patients with popliteal occlusions was recently reported; however, this endovascular procedure requires further validation by larger studies.[340]

Other Interventional Procedures

Immunoadsorption

Recent pilot studies demonstrated near complete pain relief, increased maximum walking distance, and tissue perfusion after selective removal of circulating immunoglobulins and antibodies from patient's plasma using immunoadsorption techniques.[341,342] In one study, agonistic autoantibodies directed against G-protein coupled receptors were identified in 9 out of 11 patients. The

Figure 138.8 Limb salvage after autologous bone marrow–derived mononuclear cell therapy. Preoperatively *(left)*, this patient had a nonhealing ischemic wound of the great toe and required high doses of narcotic analgesics. After surgical débridement *(right)*, complete healing was achieved at 3 weeks and maintained at 24 months.

authors concluded that elimination of agonistic autoantibodies by immunoabsorption may relieve immune-mediated vasospasm and improve microcirculation.[343]

Growth Factors

Basic fibroblast growth factor and vascular endothelial growth factor (VEGF) may play a role in patients with CLI due to BD. Isner and colleagues treated seven limbs in six patients with TAO (three men, three women; mean age, 33 years) in an open-label, dose-escalating, phase 1 clinical trial to document the efficacy and safety of gene transfer of naked plasmid DNA encoding VEGF (phVEGF165) via intramuscular injection in the treatment of CLI.[344] Ulcers, which had not healed for more than 1 month before therapy, healed completely in 3 of 5 limbs after intramuscular phVEGF165 gene therapy. Nocturnal pain at rest was relieved in the remaining two patients, although both continued to have claudication. Two patients with advanced distal forefoot gangrene ultimately required below-knee amputation despite evidence of improved perfusion. This report suggests that angiogenesis induced by phVEGF165 gene transfer may provide an effective therapy for patients with advanced TAO that is unresponsive to standard interventions.[344] Another study demonstrated higher VEGF plasma levels in patients with TAO compared with controls ($P = .008$), showing the existence of a natural defense mechanism for ischemia and new collateral formation.[345] A recent Phase I/IIa open-label four dose-escalation clinical study assessing the safety, tolerability, and efficacy of a single intramuscular administration of DVC1-0101 in patients with PAD also involved two patients with TAO.[346] DVC1-0101 is a new gene transfer vector based on a nontransmissible recombinant Sendai virus (rSeV) expressing the human fibroblast growth factor-2 (FGF-2) gene (rSeV/dF-hFGF2). The investigators concluded that DVC1-0101 was safe, effective, and resulted in significant improvements of limb function.[346]

Stem Cell-Based Therapeutic Angiogenesis

Angioblasts isolated from peripheral blood or bone marrow–derived CPCs can be incorporated into sites of active angiogenesis, providing a key factor in re-endothelialization.[347] Culture-expanded CPC transplantation in an animal model of limb ischemia improved neovascularization and blood flow recovery and reduced limb necrosis and autoamputation by 50% compared with controls.[348] Preclinical,[349] and clinical studies in patients with peripheral artery disease and CLI,[350] including TAO, suggest that the implantation of autologous bone marrow mononuclear cells,[351-354] autologous peripheral blood stem cells,[355,356] mesenchymal stem cells derived from human umbilical cord blood,[357] autologous adipose tissue-derived stem cells,[358] and autologous whole bone marrow stem cells[359] into ischemic limbs can restore limb function by increasing new collateral vessel formation.[360] We and our colleagues have also demonstrated that the implantation of autologous bone marrow mononuclear cells in the ischemic limbs of patients with TAO is associated with improved rest pain scores ($P < .0001$), peak walking time ($P < .0001$), quality of life ($P < .0083$), and augmentation of collateral formation at 24 weeks in 78% of patients.[352,361,362] Healing of ischemic ulcers was achieved in 83% of the study group (Fig. 138.8). Subsequent studies and meta-analysis supported intramuscular bone marrow cell administration as a relatively safe, feasible, and potentially effective therapy in patients with CLI and TAO.[360,363] Bone marrow-derived mononuclear cell therapy induced long-term improvement leading to an amputation-free rate of 91% (95% CI: 82%-100%) at 3 years in the Therapeutic Angiogenesis by Cell Transplantation (TACT) Trial.[364] A combined approach of intraarterial and intramuscular injections may maximize the chances of local deposition of stem cells in the ischemic limb.[365]

Another method of stimulating angiogenesis by inserting intramedullary K-wires has been suggested by Inan and associates.[366] Fenestration of the tibia at six sites with EPC mobilization from bone marrow using recombinant human granulocyte colony-stimulating factor was also reported recently by Kim and associates in 27 patients (34 lower limbs) with BD.[367] Over a mean follow-up period of 19 months, 13 of 17 limbs with nonhealing ulcers healed. This technique resulted in a similar degree of new vascular collateral network development[367] compared with autologous bone marrow mononuclear cells aspirated from the iliac crest and implanted into the intermetatarsal region, the gastrocnemius muscle, and the dorsum of the foot or forearm.[352] Recently, functional impairment of endothelial progenitor cells was confirmed in TAO patients compared to healthy nonsmokers and smokers.[368] Ongoing work is focused on understanding the mechanisms of therapeutic angiogenesis, including vascular stem cell niches, mobilization, homing, and vascular repair.[369]

ACKNOWLEDGMENTS

We sincerely thank Drs. Shigehiko Shionoya and Jeffrey W.Olin, the authors of this chapter in previous editions, for their

outstanding work, which has provided invaluable insights into Buerger disease, and Drs. Isinsu Kuzu and Suat Aytac of the Ankara University School of Medicine for their scientific assistance and the provision of pathology and radiology illustrations.

SELECTED KEY REFERENCES

Cacione DG, Baptista-Silva JC, Macedo CR. Pharmacological treatment for Buerger's disease. *Cochrane Database Syst Rev*. 2016;(2):CD011033.

This is an important update assessing the effectiveness of any pharmacologic agent (intravenous or oral) compared with placebo or any other pharmacologic agent in patients with Buerger disease. In this review, five randomized controlled trials were identified (n = 602) comparing prostacyclin analogue with placebo, aspirin, or a prostaglandin analogue, and folic acid with placebo.

Cooper LT, Tse TS, Mikhail MA, McBane RD, Stanson AW, Ballman KV. Long-term survival and amputation risk in thromboangiitis obliterans (Buerger's disease). *J Am Coll Cardiol*. 2004;44:2410–2411.

This study describes the time-dependent event rates for major or any amputation and death in a cohort of patients with TAO. In contrast with previous studies, the investigators report an excessive late mortality in patients with TAO compared with the US population. However, the risk of amputation in previous smokers is eliminated by 8 years after smoking cessation.

Durdu S, Akar AR, Arat M, Sancak T, Eren NT, Ozyurda U. Autologous bone-marrow mononuclear cell implantation for patients with Rutharderford grade II-III thromboangiitis obliterans. *J Vasc Surg*. 2006;44:732–739.

This is the first study investigating the use of autologous bone marrow mononuclear cell implantation for patients with Rutherford grade II-III thromboangiitis obliterans resulting in new vascular collateral networks across the affected arteries in 78.5% of the patients. Total healing of the most important lesion was achieved in 83% of patients with ischemic ulcers. Relief of rest pain without the need of narcotic analgesics improved in all patients.

Isner JM, Baumgartner I, Rauh G, et al. Treatment of thromboangiitis obliterans (Buerger's disease) by intramuscular gene transfer of vascular endothelial growth factor: preliminary clinical results. *J Vasc Surg*. 1998;28:964–973.

The first report that documents the results of six patients with Buerger disease who were treated with gene therapy as part of a larger phase-I clinical trial to document the safety and efficacy of intramuscular gene transfer of naked plasmid DNA-encoding vascular endothelial growth factor (phVEGF165) in the treatment of critical limb ischemia.

Kim DI, Kim MJ, Joh JH, et al. Angiogenesis facilitated by autologous whole bone marrow stem cell transplantation for Buerger's disease. *Stem Cells*. 2006;24:1194–1200.

This intriguing study documents the angiogenesis facilitated by fenestration of the tibia bone and autologous whole bone marrow stem cell transplantation for Buerger disease.

Kobayashi M, Ito M, Nakagawa A, Nishikimi N, Nimura Y. Immunohistochemical analysis of arterial wall cellular infiltration in Buerger's disease (endarteritis obliterans). *J Vasc Surg*. 1999;29:451–458.

This original study describes important histologic observations from 33 specimens of nine patients with Buerger disease. The investigators concluded that Buerger disease was a vasculitis (endarteritis) induced by an antigen in the intimal layer and subsequent activation of T-cell mediated cellular immunity and B-cell-mediated humoral immunity associated with activation of macrophages or dendritic cells in the intima.

Kobayashi M, Sugimoto M, Komori K. Endarteritis obliterans in the pathogenesis of Buerger's disease from the pathological and immunohistochemical points of view. *Circ J*. 2014;78:2819–2826.

This review demonstrates important pathologic characteristics of arteries affected with Buerger disease. The authors' observations support activation of antigen-presenting cells by an unidentified antigen in the blood, resulting in an immunoreaction closely linked to Notch signaling pathway. The authors conclude that restriction of cellular and humoral immune reaction to the arterial intima defines Buerger disease as an endarteritis.

Mills JL Sr. Buerger's disease in the 21st century: diagnosis, clinical features, and therapy. *Semin Vasc Surg*. 2003;16:179–189.

This is another important update on the clinical features and fundamental management principles of Buerger disease. The concept "No tobacco, no Buerger disease" is reintroduced.

Ohta T, Ishioashi H, Hosaka M, Sugimoto I. Clinical and social consequences of Buerger disease. *J Vasc Surg*. 2004;39:176–180.

This original investigation documents the natural course of TAO in Japan. The investigators report that occurrence or recurrence of necrotic lesions usually subsides after the age of 60, and arterial reconstruction is associated with poor long-term results although it shortens the healing process of ischemic ulcers.

Olin JW. Thromboangiitis obliterans (Buerger's disease). *N Engl J Med*. 2000;343:864–869.

This landmark review summarizes the clinical features, pathogenesis, diagnostic criteria, and recommendations for the treatment of thromboangiitis obliterans and currently is still relevant.

Shionoya S. Diagnostic criteria of Buerger's disease. *Int J Cardiol*. 1998;66(suppl 1):S243–S245.

The article outlines the current need for well-defined clinical diagnostic criteria for Buerger disease and important hallmarks of the clinical picture.

The European TAO Study Group. Oral iloprost in the treatment of thromboangiitis obliterans (Buerger's disease): a double-blind, randomized, placebo-controlled trial. *Eur J Vasc Endovasc Surg*. 1998;15:300–307.

The first randomized trial comparing oral iloprost with placebo conducted in 22 centers in six European countries.

INTRODUCTION

Takayasu disease is an immune arteritis causing inflammation of the aorta, its major branches, and pulmonary arteries. It is predominantly a disease of young women, with onset typically in the second or third decade of life.[1] The disease is more common among Asians, although all ethnicities can be affected. The annual incidence in North America is approximately 2.6 per million people.[2]

The first description of a patient with Takayasu arteritis (TA) may have occurred as early as the 18th century. Morgagni found large-vessel aneurysms and stenoses at autopsy in a 40-year-old woman in 1761.[3] In 1830 Yamamoto described a 45-year-old man who originally presented with complaints of fever and developed pulselessness in the radial arteries 1 year later.[4] TA is named after Japanese ophthalmologist Mikito Takayasu, who presented his findings of arteriovenous anastomoses of the ocular papilla in a 21-year-old woman with sudden vision loss in 1908.[4] Two other ophthalmologists at the same meeting presented similar findings in patients with absent radial pulses.[5] The term *Takayasu arteritis* was first coined in 1939 by Yasuzo Shinmi when reporting on a patient with comparable symptoms and physical findings.[6] In 1975 the research committee of the Japanese Department of Health and Welfare officially proposed adopting the term *Takayasu arteritis* for the disease.

Although TA is a chronic disease, it is characterized by a waxing and waning course. Symptoms range from fever, myalgias, and loss of appetite to cerebral, visceral, and extremity ischemia.[7] This variation in presentation frequently leads to a delay in diagnosis.

EPIDEMIOLOGY

TA most commonly affects patients from East Asia, and the incidence varies by geographic location. The estimated incidence in Japan is approximately 150 new cases per year,[7] and postmortem studies reveal a prevalence of 1 in 3000 patients.[8] The incidence in India is 200 to 300 per million,[9] whereas the incidence in Sweden is 0.8 per million, with a prevalence of 0.64 per 100,000.[10] In Birmingham, England, the incidence is 0.2 per million.[9] Finally, a population-based study in Olmstead County, Minnesota, found an incidence of 2.6 per million.[2]

TA affects women 6 to 8 times more frequently than men, although this distribution may depend on the region being studied. Authors from India have found female to male ratios of 4:1,[11] whereas others from China have reported ratios of 3:1.[12] The median age at diagnosis in a cohort of 60 patients from the National Institutes of Health (NIH) was 25 years.[13] Although the detection of TA in some patients after age 40

Abstract

Takayasu disease is an immune arteritis predominantly affecting the aorta, its major branches and the pulmonary arteries of young women. The disease is most prevalent in Asians, with an annual incidence in North America of approximately 2.6 per million people. It is characterized by a waxing and waning clinical course with symptoms from fever, myalgias, and loss of appetite to cerebral, visceral and extremity ischemia. Both genetic predispositions and immune-mediated mechanisms have been implicated as etiologies for the disease.

Patients often present at varying courses of the disease process, including constitutional symptoms of fever, headache, myalgia, or weight loss; or, symptoms of vessel inflammation such as carotidynia. Patients may also be diagnosed with advanced stages of disease where the vessel fibrosis or aneurysmal degeneration has occurred. There is no global consensus for diagnostic criteria, and other vasculitides must be ruled out prior to a final diagnosis. Furthermore, no single serologic test has been identified for the diagnosis of Takayasu's. Advancements in radiological imaging, such as computed tomography angiography, magnetic resonance angiography and duplex ultrasound have allowed for better evaluation of vessel wall changes consistent with Takayasu disease. Positron emission tomography has also been integral to evaluate responses to medical therapy.

Treatment is aimed at immunosuppressive therapy with glucocorticoids in the active phase or additional immune-modulators for patients who relapse. Revascularization may need to be performed in select patients with refractory disease suffering from cerebral, visceral or extremity ischemia or aneurysmal degeneration. Such procedures should be performed when disease activity is minimal. Open revascularization has been the gold standard therapy, and while some have seen success with endovascular therapies, there is not enough data available to suggest this is superior to open bypass grafting.

aortic fibrosis

years may be related to delays in diagnosis, it is now understood that a significant number of patients do not develop symptoms until later in life. When the results from most major studies are examined, the majority of patients develop symptoms between the ages of 20 and 40 years, with no trend by region.[13–19]

PATHOGENESIS

Etiology

A genetic predisposition to the disease has been suggested because of the predilection for patients of Asian descent, especially those with a Japanese background,[20] and the occasional familial clustering of the disease.[21] HLA-Bw52 occurs in approximately 44% of Japanese patients with TA, compared with 13% in the general Japanese population.[22] Furthermore, the haplotype of Bw52-Dw12 confers a greater likelihood of an active inflammatory state and rapid disease progression.[23] Other studies have found increased susceptibility in patients with gene mutations in the HLA-A, -D, and -DR regions.[24,25] In a group of North American patients with TA, there was no significant association between any HLA antigen and disease severity or complications.[26] In fact, there was a negative association between TA and the HLA-DR1 antigen, suggesting a possible protection against disease development. Further studies examining the genetic factors associated with TA must be performed because consistent associations are lacking.[27]

Immune-mediated mechanisms, including both antibody- and cell-mediated mechanisms, have also been suggested as a cause of TA. TA has been associated with rheumatoid arthritis,[28] systemic lupus erythematosus,[29] inflammatory bowel disease,[30] and glomerulonephritis.[31] All these conditions have autoimmune mechanisms associated with their pathology, which suggests a common mechanism with TA.

Cell-mediated mechanisms of endothelial damage have been implicated in TA. Gamma/delta T cells in patients with TA are reactive to Hsp60 and exhibit cytotoxicity to aortic endothelial cells, suggesting a role in the pathogenesis of TA.[32] This mechanism occurs via increased production of interferon gamma and is distinct from other similar rheumatologic disorders.[33]

Antibody-mediated mechanisms of TA have been advocated based on elevated levels of antiaortic endothelial cell antibodies. These lead to the induction of endothelial adhesion molecules, cytokines, and apoptosis.[34] Levels of antiaortic endothelial cell antibodies are 20 times greater in patients with TA compared with healthy controls[35] and with patients with other autoimmune disorders.[36]

The fact that TA is commonly found in women of childbearing age suggests that sex hormones may play a role in its development. Studies of patients with TA compared with healthy controls have shown elevated urinary estrogens.[37] Furthermore, the association of Klinefelter syndrome in patients with TA may implicate elevated estrogens in the disease.[38]

Many causative factors have been implicated in TA, but none is found consistently. The cause of TA is likely multifactorial, and further studies are necessary to elucidate the associations among the various suggested mechanisms.

Pathology

Histologic examination of inflammatory lesions of TA reveals a panarteritis of all three layers of the vessel wall, with skip areas along the length of the vessel (Fig. 139.1).[39] These lesions can range from acute exudative inflammation to chronic, nonspecific productive inflammation to various types of granulomatous inflammation.[40] Active inflammatory lesions begin in the vasa vasorum, extend through the media and adventitia, and terminate in a diffuse or nodular fibrosis. Smooth muscle cells and fibroblasts invade the intima and produce excessive ground substance. Occasionally, intimal thickening of the peripheral branches of inflamed arteries may lead to end-organ ischemia.

Immunohistochemical examination of postoperative aortic specimens with active inflammation has shown replacement of the muscular and elastic layers of the media and adventitia by dense fibrous tissue.[41] In certain patients, inflammatory nodules of numerous T cells and B cells colocalized with dendritic cells have been observed in the deep portion of the intima and adventitia. This colocalization suggests that interactions between dendritic cells and lymphocytes may be important in the pathogenesis of TA.

In the chronic phase of TA, inflammation leads to thickening of the entire vessel wall. The vessel lumen narrows owing to proliferation of the intima, destruction of the elastic fibers of the media, and fibrosis of the adventitia.[42]

Aneurysmal disease may also be associated with TA, although it is less frequent than stenotic disease. It has been hypothesized that aneurysmal disease occurs when destruction of the elastic component of the media occurs before fibrosis of the adventitia, leading to a weakened vessel wall.[43]

CLINICAL PRESENTATION

TA was first thought to progress in three phases. The first phase was characterized by an inflammatory period with constitutional symptoms such as fever, headache, weight loss, myalgia, and arthralgia. The second phase was characterized by vessel inflammation with symptoms of vessel pain and tenderness, or carotodynia. The third and final phase, called the "burned-out" phase, was characterized by vessel fibrosis or aneurysmal degeneration. In this phase, patients presented with the classic signs of ischemia or aneurysm. It is now understood that although most patients with TA experience these three phases, many do not; and patients with TA can endure very diverse courses. In a group of North American patients, 10% were asymptomatic at presentation, 57% never had any constitutional symptoms, and only 33% developed systemic symptoms.[13] Some TA patients present with inflammatory and fibrotic changes simultaneously, further emphasizing the diverse nature of this disease.[7]

It is likely that the nonspecific nature of constitutional complaints leads to the delay in diagnosis that is common in patients with TA. We reported a median delay of 1 year before diagnosis in a group of North American patients, similar to the 10 to 15.5 months reported in other studies.[13,20] Approximately 90% of patients see more than one medical doctor, with

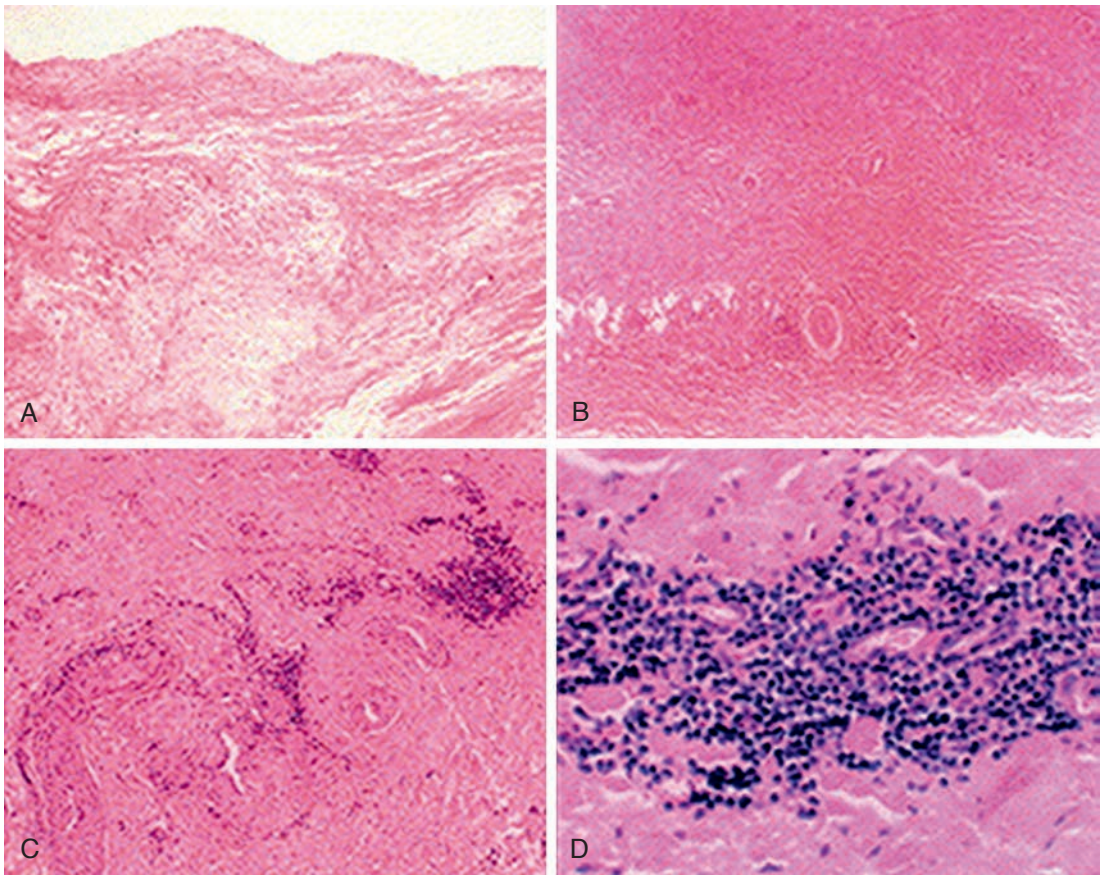

Figure 139.1 Histologic Findings in Takayasu Arteritis. (A) Aortic cusp with intimal fibrosis and myxoid degenerative changes in media without inflammatory cells. (B) Aortic wall with fibrosis of media and infiltration of inflammatory cells around vasa vasorum. (C and D) Inflammatory cell infiltrate consists of predominantly mononuclear lymphocytes. (From Song JK, et al. Echocardiographic and clinical characteristics of aortic regurgitation because of systemic vasculitis. *J Am Soc Echocardiogr*. 2003;16:850–857.)

a mean of five doctors, before obtaining the correct diagnosis of TA.[42]

Physical examination may help in diagnosis but is not particularly sensitive. However, normal physical exam findings should not be thought to exclude the presence of arterial disease.

The clinical presentation of patients with TA varies by geographic region (Table 78.1).[7] The most frequent finding in patients from North America and Italy were carotid bruits,[13,20] versus absent pulses in Mexico[44] and hypertension in India.[45]

Overall, arterial involvement is often symmetric in paired arteries and contiguous in the aorta.[46] Cerebrovascular signs and symptoms are common because of the frequency of aortic arch and branch involvement. Approximately 32% of patients present with carotodynia.[13] Many patients report syncope or presyncope at some point during the disease course. Ischemic symptoms of stroke, transient ischemic attack, or amaurosis fugax occur in 5% to 20% of patients.[47] Visual disturbances occur in up to 30% of patients and are statistically associated with vertebral and common carotid artery involvement (Fig. 139.2).[13] The retinal disease pattern described by Takayasu also leads to visual disturbances due to central retinal hypoperfusion.[48]

Upper extremity involvement is common in patients with TA. Diminished or absent pulses occurs in 53% to 98% of patients.[13,49] Claudication is more frequent in the upper extremities than the lower extremities and occurs in approximately 62% of patients.[13] This may be because the left subclavian artery is more commonly affected by TA than other arteries (Fig. 139.3).[13,20] It has been hypothesized that subclavian steal syndrome is rare in patients with TA because the subclavian artery is involved both proximal and distal to the origin of the vertebral artery. More recent studies have shown that this may not always be true, with angiography demonstrating isolated disease in the proximal subclavian artery 80% of the time.[46]

Cardiac manifestations of TA are common. Coronary artery involvement occurs in 6% to 16% of patients with TA and may lead to ischemic symptoms or congestive heart failure.[49] Aortic valve regurgitation occurs in 12% to 24% of patients and is generally caused by dilation of the aortic root.[20] Aortic valve regurgitation seems to be more common in TA patients from India.[22] Mitral valve regurgitation occurs in 3% to 11% of patients.[7,50] The cause of mitral valve regurgitation is unclear but is thought to be independent of aortic regurgitation.[51] Pulmonary artery involvement with TA may be underdiagnosed. In studies in which pulmonary angiography was performed, up to 70% of patients had evidence of disease.[52,53] These patients most often present with symptoms of pulmonary hypertension. Finally, diffuse vascular involvement of the myocardium has been reported in the absence of coronary stenosis or aortic valve

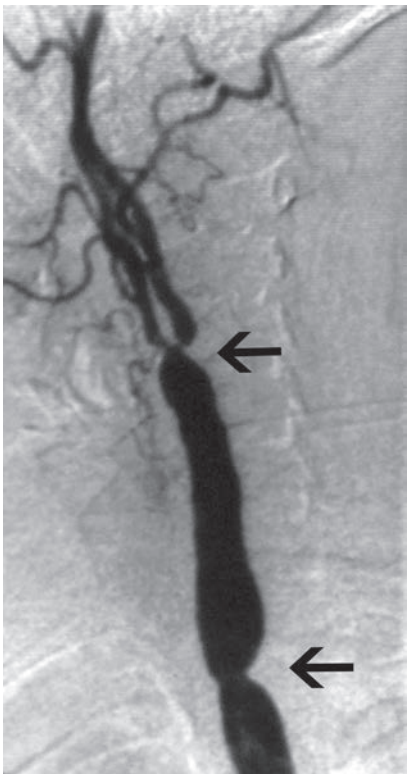

Figure 139.2 Selective carotid angiogram of a 34-year-old woman with symptoms of cerebral ischemia. Note the stenoses of both the common carotid artery and the carotid bifurcation *(arrows)*.

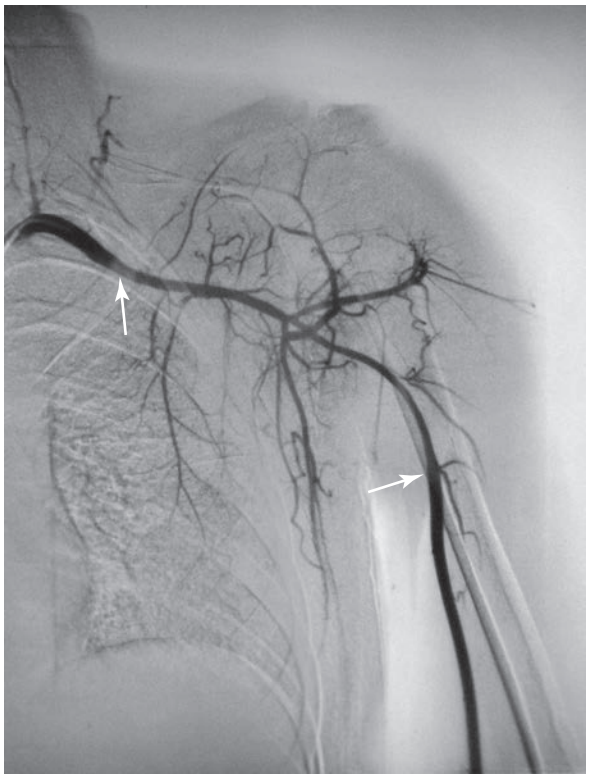

Figure 139.3 Selective left subclavian angiogram of a 26-year-old woman with claudication of the left upper extremity. Note the long, tapered stenosis of the left subclavian and axillary arteries.

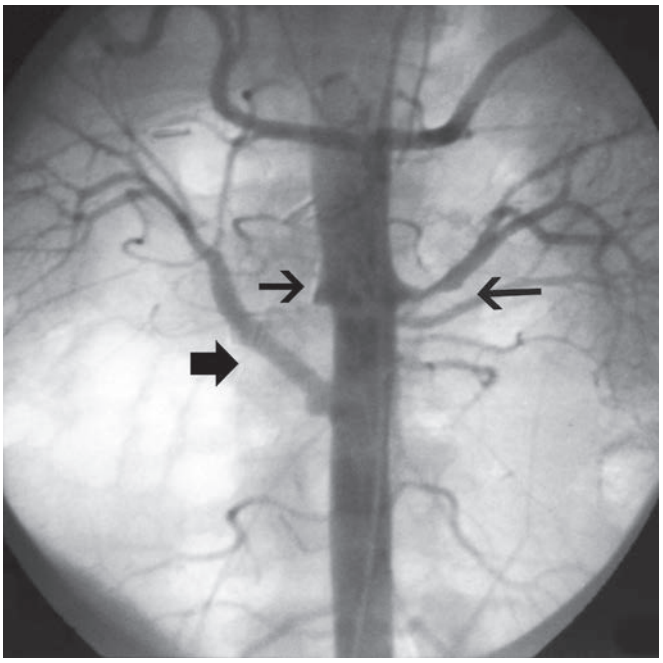

Figure 139.4 Abdominal aortogram of a 48-year-old hypertensive woman with known Takayasu arteritis. Note the short-segment left renal artery stenosis *(long arrow)*, right renal artery occlusion *(small arrow)*, and right aortorenal artery bypass *(broad arrow)*.

regurgitation. Patients present with symptoms of congestive heart failure, and biopsies of the myocardium show diffuse myocarditis.[54]

Hypertension is one of the most common presenting signs in patients with TA and occurs in 33% to 60% of patients.[12,13] Bilateral stenosis of the subclavian arteries occurs in up to 92% of patients with TA and can mask hypertension.[13] Therefore blood pressure measurements of both upper and lower extremities should be performed in any patient suspected of having TA. Renal artery stenosis is a significant cause of hypertension in patients with TA. Involvement of the renal arteries occurs in approximately 20% to 50% of patients.[50,55] The stenoses are frequently bilateral and involve the ostia of the vessels (Fig. 139.4).[50] Hypertension in the absence of renal artery stenosis occurs in 5% to 30% of patients.[13,20] Causes of hypertension in this group of patients include middle aortic syndrome, reduced compliance of the aorta, and dysfunction of the carotid baroceptors (Fig. 139.5).[56,57] Sen and colleagues first reported on 16 patients with middle aortic syndrome in 1963.[58] All patients presented with hypertension, and more than half of them had decreased or absent lower extremity pulses. In a 1991 report from the Japanese Ministry of Health and Welfare, middle aortic syndrome occurred in 16% of surgically treated patients with TA.[59] Long-segment narrowing of the descending thoracic or abdominal aorta is characteristic, and interscapular or abdominal bruits are frequently heard on auscultation. According to one report, the majority of patients with middle aortic syndrome die by age 35 if left untreated.[60] Middle aortic syndrome is not unique to TA and may be due to congenital hypoplasia, von Recklinghausen disease, fibromuscular dysplasia, and tuberculosis.[61–63]

Figure 139.5 Abdominal aortogram of a 37-year-old hypertensive woman. Note the long, tapered stenosis of the infrarenal aorta *(arrow)* and sparing of the distal aorta and iliac arteries.

Figure 139.6 Aortic arch angiogram depicting extensive aneurysmal disease of the arch vessels of a 54-year-old man.

Visceral arterial involvement occurs in 3% to 31% of patients with TA.[20,50] Despite these findings, symptoms of mesenteric ischemia are rare. Aortic endarterectomy for visceral ischemia has been performed, with mixed results. It is controversial in patients with TA because the inflammatory lesions typically involve all three layers of the arterial wall, making the procedure difficult.[64,65]

Lower extremity ischemic symptoms occur in 24% to 32% of patients and, as stated previously, are less common than upper extremity symptoms.[13,49] Iliac artery disease is seen in approximately 20% of patients undergoing angiography.[13,20] Angiographic data suggest that claudication of the lower extremities may be related to abdominal aortic involvement because stenotic disease of the femoral, popliteal, and tibial arteries is rare.[20]

Aneurysmal disease in patients with TA varies by geographic location. In South Africa, up to 71% of patients underwent surgery for aneurysmal disease.[66] In a study of Thai patients, 60% of patients had aneurysms, with the abdominal aorta being the most common location, followed by the subclavian artery and the thoracic aorta.[60] In North America, 27% of patients had aneurysms, with the aortic arch being the most common site, followed by the abdominal aorta (Fig. 139.6).[13] Elsewhere, 13.7% of patients in India and 7% of patients in Italy had aneurysms on angiography.[20,50] A study from Japan reported 32% of patients with aneurysmal disease and noted that the aneurysms were frequently multiple and associated with stenotic lesions (Fig. 139.7).[67] In most series the incidence of aneurysm

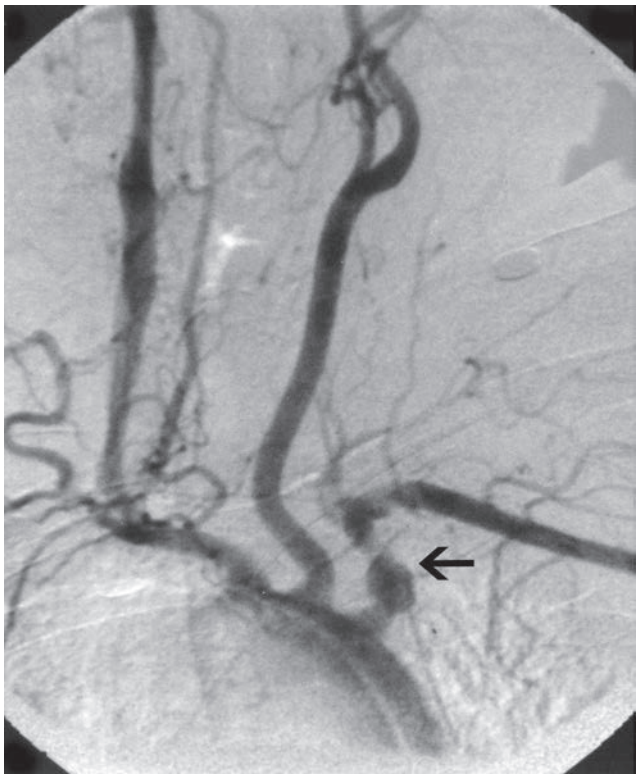

Figure 139.7 Aortic arch angiogram of a 33-year-old woman with left upper extremity claudication. Note the left subclavian aneurysm and concomitant distal stenosis *(arrow)*.

rupture is low compared with that of noninflammatory aneurysms.[68]

Patients with TA may present with nonischemic symptoms. Raynaud phenomenon has been reported in approximately 8% to 14% of patients.[20] Skin changes have been reported in 8% to 25% of patients.[13,49] These cutaneous manifestations of TA range from erythema nodosum to pyoderma gangrenosum to a lupuslike malar flush.[69,70]

DIAGNOSTIC EVALUATION

Diagnostic Criteria

Because TA affects patients in myriad ways, there have been many proposed diagnostic criteria. The first diagnostic criteria were set forth by Ishikawa, based on a cohort of 96 Japanese patients with TA and 12 patients with other diseases of the aorta.[16] These criteria included an obligatory age less than 40 years. The Ishikawa criteria identified 96% of young patients and 80% of older patients with active disease but, unfortunately, only 67% of young patients and 64% of older patients with inactive disease.

In 1990 the American College of Rheumatology created new diagnostic criteria based on a North American group of patients with TA (Table 78.2).[71] It removed Ishikawa age criterion because 13% of patients developed the disease after age 40.[13] The presence of at least three of the six criteria from the traditional classification demonstrated a sensitivity of 90.5% and a specificity of 97.8%. The same group also created a classification tree with five of these six criteria, omitting claudication of an extremity. The classification tree demonstrated a sensitivity of 92.1% and a specificity of 97.0%.

In 1996 Sharma and associates devised a third set of diagnostic criteria. The Ishikawa criteria were modified in an effort to improve early diagnosis and to take into account geographic and racial variations (Table 78.3).[72,73] The presence of two major criteria, one major criterion and two minor criteria, or four minor criteria was found to have a sensitivity of 92.5% and a specificity of 95% in a group of Indian patients and 96% sensitivity and 96% specificity in a group of Japanese patients.

Although there is no global consensus on the best diagnostic criteria, it is generally agreed that the diagnosis of TA should not be made without ruling out all other vasculitides, vascular infections, fibromuscular dysplasia, and idiopathic inflammatory syndromes.[74]

Laboratory Markers

TA is not associated with any specific laboratory abnormality but is characterized by generalized inflammatory markers. Patients are frequently anemic, with hematocrits in the 20s or 30s.[42] The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are the most common markers used. At presentation, approximately 72% of patients with TA have an elevated ESR.[7] However, the ESR is very nonspecific; 56% of patients have an elevated ESR with disease remission, and 28% have a normal ESR with clinically active disease.

Investigators have begun to examine the role of other laboratory markers in TA, including serum interleukin-6 (IL-6) and regulated upon activation, normal T-cell expressed, and presumably secreted (RANTES). IL-6 enhances T-cell cytotoxicity and natural killer cell activity,[75,76] whereas RANTES is a selective chemoattractant for most mononuclear cell types implicated in TA.[77] A recent study showed increased levels of IL-6 and RANTES in patients with TA.[78] Furthermore, both IL-6 and RANTES paralleled disease activity.

Other investigators have examined matrix metalloproteinases (MMPs) in patients with TA.[79] MMP-2 levels were elevated in patients with TA compared with controls, although no correlation was found between serum MMP-2 and disease activity. MMP-3 and MMP-9 levels in patients with active disease were elevated compared with those in controls and patients in disease remission, and a positive correlation was found between MMP-3 or MMP-9 level and disease activity.

At present there is no single serologic test for TA, and the role of specific serum markers is still being delineated.

Radiologic Evaluation

Although histopathologic examination of arterial specimens provides the most accurate determination of disease, radiologic evaluation can provide a more extensive assessment of pathology. In the past, digital subtraction angiography of all possibly affected arteries was considered the only reliable radiologic method of evaluating patients with TA.[80]

More recently, noninvasive methods such as ultrasound, computed tomographic angiography (CTA), and magnetic resonance angiography (MRA) have been used to assess the mural changes of the arterial wall seen in TA before the development of stenotic or aneurysmal disease.[81] Duplex ultrasound has been useful for evaluating the carotid arteries in patients with TA. Active disease is characterized by prominent wall thickening with a maintained outer diameter, whereas inactive disease is characterized by mild wall thickening with a decreased outer diameter (Fig. 139.8).[82] A comparison of duplex ultrasound and arteriography of the carotid arteries reveals that the two closely correlate in terms of disease assessment and that ultrasonographic mural thickness is a more sensitive indicator of early, latent inflammation.[83]

Findings on CTA may include high density and calcifications of the aortic wall on precontrast images, a thickened wall with enhancements in the arterial and venous phases, and a low-attenuation ring in the venous phase (Fig. 139.9).[84] CTA is also useful to assess the extent of disease involvement. In one study the extent assessed by mural change was wider than that assessed by luminal change in 61% of patients.[85] Skip lesions were seen in 16% of patients, although contiguous arterial involvement was more common (81%). Finally, CTA revealed the coexistence of active and inactive lesions in 11% of patients. A comparison of CTA with conventional angiography showed that the two correlated in 71% of patients, but CTA

(C) Angiography of the branches of the aortic arch, confirming the ultrasound diagnosis and revealing narrowing of up to 40% as well as post-stenotic dilations at the right common carotid artery, the left proximal common carotid artery, the proximal right subclavian artery, and the proximal right vertebral artery. (From Schmidt WA, et al. Diagnosis of early Takayasu arteritis with sonography. *Rheumatology (Oxford)*. 2002;41:496-502.)

depicted more extensive disease, owing to its ability to assess mural inflammation.[86]

MRA is also useful for the noninvasive assessment of patients with TA. Spin-echo MRA depicts early arterial wall thickening similar to CTA.[87] Significant enhancement of the aorta and carotid arteries may be seen before the development of stenoses, and greater contrast enhancement in the aortic wall as compared with myocardium correlates positively with disease activity (Fig. 139.10). T2-weighted images may show bright signal correlating with vessel wall inflammation and edema.[88] MR does have limitations: although MRA accurately depicts approximately 98% of arterial involvement in TA, 2% of stenotic arteries are overestimated as occluded.[89] Furthermore, vessel wall edema can be found in up to 56% of patients who are in clinical remission.[90] The new intravascular contrast agent gadofosveset trisodium (MS-325) shows promise in the use of MR for the detection of TA, and more specifically for differentiation between active and inactive disease.[91]

The inflammation associated with TA has led investigators to evaluate the role of positron emission tomography (PET). Quantification of ^{18}F-fluorodeoxyglucose (^{18}F-FDG) uptake can be used to evaluate active vascular inflammation before the development of hemodynamically significant stenoses.[92] It may be useful not only in identifying disease activity but also in accurately monitoring treatment efficacy (Fig. 139.11). In one study, ^{18}F-FDG PET had a 92% sensitivity, 100% specificity, and negative and positive predictive values of 85% and 100%, respectively, in disease activity assessment.[93]

Overall, ^{18}F-FDG PET strongly correlates with the response to medical therapy and may prove useful for managing patients whose serum inflammatory markers remain elevated despite inactive disease.

Despite the development of these noninvasive imaging modalities, digital subtraction angiography remains the "gold standard" for evaluation of vascular lesions associated with TA (see Figs. 139.2–139.7). Panangiography depicts the extent of

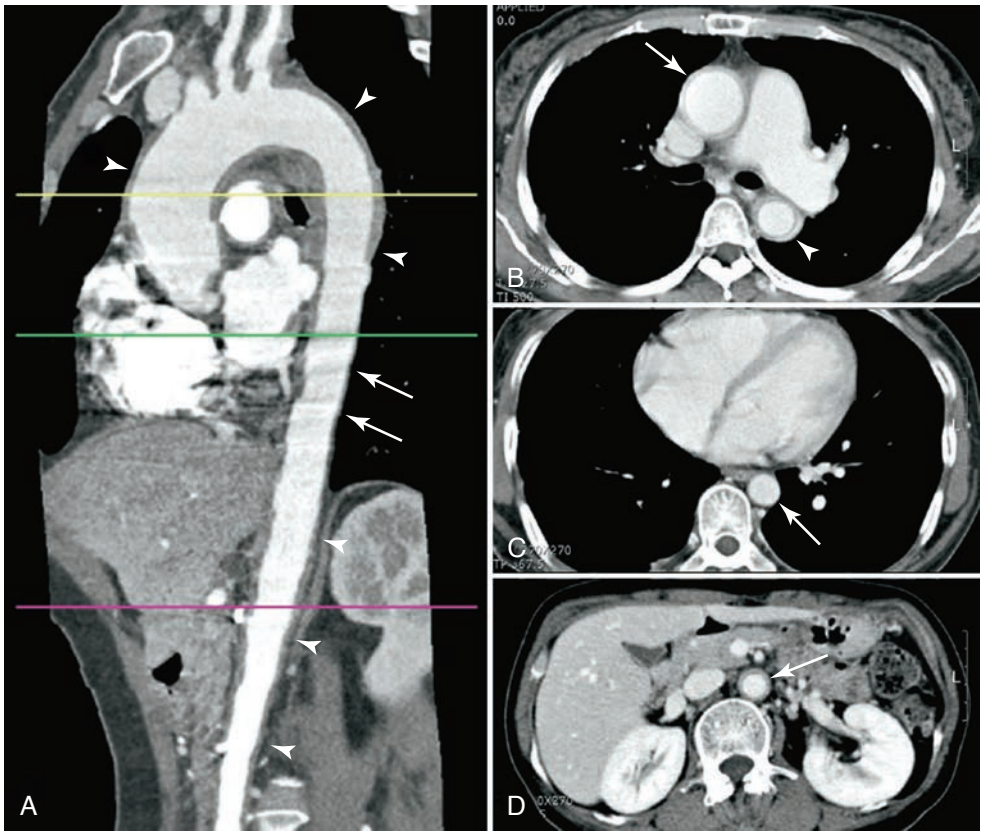

Figure 139.9 Takayasu Arteritis Involving the Aorta With a Skipped Segment in a 50-Year-Old Woman. (A) Multiplanar reformation image shows wall thickening *(arrowheads)* of ascending thoracic aorta, aortic arch, proximal descending thoracic aorta, and abdominal aorta. No wall thickening of distal descending thoracic aorta is noted. Motion artifact (pulsation artifact) was not observed in the thickened segment, such as the aortic arch and abdominal aorta, because of stiffness of the involved aorta but was observed in the distal descending thoracic aorta *(arrows)* owing to pulsation of the noninvolved segment. (B) Computed tomography (CT) scan at the proximal descending thoracic aorta shows diffuse wall thickening and inner low-attenuation ring of ascending *(arrow)* and descending thoracic aorta *(arrowhead)*. (C) CT scan at the distal descending thoracic aorta *(arrow)* shows no wall thickening of aorta. (D) CT scan at the abdominal aorta shows diffuse wall thickening and inner low-attenuation ring of abdominal aorta *(arrow)*. (From Chung JW, et al. Patterns of aortic involvement in Takayasu arteritis and its clinical implications: evaluation with spiral computed tomography angiography. *J Vasc Surg*. 2007;45:906-914.)

disease, which ultimately correlates with disease severity, and is useful in preoperative planning. Lesions characteristic of TA include stenoses, either short and segmental or long and diffuse; aneurysmal dilation, either fusiform or saccular; or a combination of the two.[94] Serial angiographic examinations may be useful in tracking disease activity and response to therapy.[95] Comparison of direct aortic blood pressure measurement at the time of angiography to measurements in the upper and lower extremities is important considering the nature of stenotic lesions and their interference with extremity cuff pressures. Finally, the classification of TA is based on arteriographic findings and correlates with clinical manifestations and prognosis.[42]

CLASSIFICATION

The classification of TA was originally proposed by Ueno in 1967.[96] He divided TA into three types based on aortic involvement (Table 78.4). Type I disease was confined to the aortic arch and its branches, type II involved the descending and abdominal aortas and their branches, and type III was a combination of types I and II. Lupi-Herrera added a type IV to this classification for pulmonary artery involvement.[23] Nasu and others described a variation on Ueno's classification based on the distribution of aortic disease.[8,15,97] In 1994 a new classification was proposed at the Tokyo International Conference on Takayasu Arteritis that divided TA into six patterns of disease.[98] Type I disease was limited to the aortic arch branches. Type IIa disease involved the aortic arch and its branches, and type IIb disease the aortic arch, its branches, and the descending thoracic aorta. Type III disease involved the descending thoracic and abdominal aorta and its branches. Type IV disease involved the abdominal aorta and its branches. Type V disease involved the entire aorta and its branches. A "C" or "P" was added if a patient had coronary or pulmonary artery involvement, respectively.

Classification of disease activity is important in determining response to treatment but has not been uniform throughout the literature. Because steroids play a major role in the treatment of TA, certain authors have relied on steroid use as the sole determinant of active disease. This definition is ultimately too

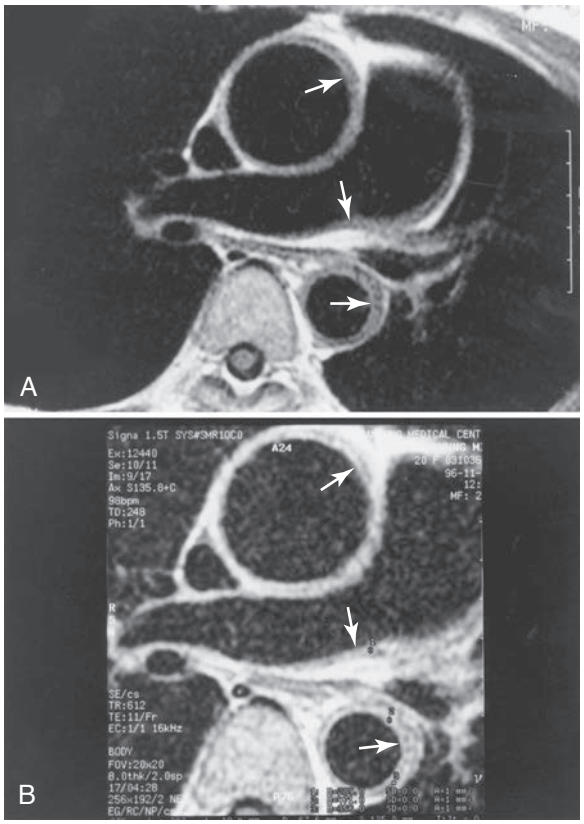

Figure 139.10 **Clinically Active Takayasu Arteritis in a 25-Year-Old Woman.** (A) A T1-weighted axial magnetic resonance image before contrast media injection shows diffuse and concentric mural thickening of the thoracic aorta *(arrows)* and mild mural thickening of the right pulmonary artery *(arrow)*. (B) Immediately after contrast media injection, a T1-weighted axial image shows enhancement in the thickened aortic and pulmonary arterial walls *(arrows)*, which suggests increased vascularization in the inflamed vessel walls. (From Choe YH, et al. Magnetic resonance imaging diagnosis of Takayasu arteritis. *Int J Cardiol.* 1998;66(Suppl 1): S175-S179.)

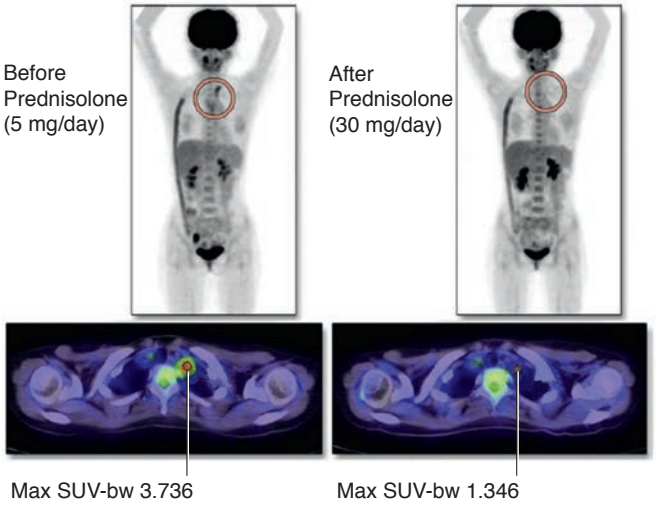

Figure 139.11 A 23-year-old woman with Takayasu arteritis was taking corticosteroids at a dose of 5 mg/day. The erythrocyte sedimentation rate was 18 mm/h, but she had left arm pain with slight elevation of the C-reactive protein level up to 1.1 mg/dL. The ^{18}F-fluorodeoxyglucose positron emission tomography/computed tomography imaging showed uptake in the left subclavian artery, and the maximum standardized uptake value (max SUV) was elevated *(left)*. After the dose of prednisolone was increased to 30 mg/day, the uptake disappeared, and max SUV decreased *(right)*. Strong ^{18}F-fluorodeoxyglucose uptake on her right side is uptake due to an artificial graft from the right axial artery to the right external iliac artery. (From Tezuka D, et al. Role of FDG PET-CT in Takayasu arteritis: sensitive detection of recurrences. *JACC Cardiovasc Imaging.* 2012;5:422-429.)

narrow and may equate patients in remission and off steroids with patients acutely presenting with active disease and not yet on steroids.[99] The NIH followed 60 patients between 1970 and 1990, with an average age at disease onset of 25 years.[13] Active disease was defined as new onset or worsening of two or more features of TA (Box 78.1). These included systemic manifestations, elevated ESR, signs of vascular disease, and typical angiographic findings. Researchers at the Mayo Clinic have used a similar definition of two or more features of TA but have substituted elevated CRP and active inflammation at the time of operation and in the pathologic specimen.[100] These criteria may be more stringent, but they make the diagnosis of active disease difficult without open surgical operation.

MEDICAL TREATMENT

Approximately 12% to 20% of patients diagnosed with TA have a self-limited, monophasic illness and may not need immunosuppressive therapy.[20,79] All other patients typically require some regimen of immunosuppression to control disease activity. Glucocorticoids are the first line agents for patients with TA and are begun at a dose of 1 mg/kg per day for 1 to 3 months. If there is improvement in disease activity, the prednisone dose may be tapered and ultimately discontinued. The clinical response to oral glucocorticoids is varied and ranges from 20% to 100%.[23,101] Determining clinical response is complicated by the difficulty of assessing disease activity based on laboratory markers and symptoms alone. In the NIH cohort, oral glucocorticoids induced remission in 60% of patients at least once.[13] In the 40% who did not achieve disease remission with oral glucocorticoids, the addition of other cytotoxic agents induced remission in another 40%.

Relapse is common even in patients who achieve remission on oral glucocorticoids and is seen in 45% to 96% of patients.[13,51] Alternative immunosuppressive agents are typically added in 40% to 73% of patients who relapse or who never achieve remission.[19,51] These regimens may include oral glucocorticoids with the addition of methotrexate, cyclophosphamide, azathioprine, or mycophenolate mofetil.

Although the results of immunosuppressive regimens are promising, limitations of therapy still exist in larger series of patients. In the Cleveland Clinic cohort, only 28% of patients had sustained remission,[51] and 23% of patients in the NIH cohort had continuous disease regardless of therapy.[13] These results, along with the hypothesis that autoimmunity contributes to the disease, have led investigators to examine the role of immunomodulating medications for the treatment of TA.

REFRACTORY THERAPY

Immunomodulating medications have been used with some success in patients unable to achieve remission on standard

drug therapies. Long-term data from the Cleveland Clinic on patients treated with anti-TNF therapy found that remission was achieved and prednisone was discontinued in 60% of patients and tapered to less than 10 mg/day in an additional 28%.[102]

Anti-IL-6 therapy (tocilizumab) has also been used successfully to induce remission and decrease the need for steroid therapy.[103,104] When comparing anti-TNF agents to tocilizumab, there were no significant differences in efficacy between therapies. More recently, B-cell depletion strategies using rituximab have also been used successfully in patients refractory to other immunosuppressive therapies.[105]

INDICATIONS FOR AND RESULTS OF REVASCULARIZATION PROCEDURES

The need for surgical procedures in patients with TA varies by geographic region. Approximately 50% of patients from the United States and Italy need surgery,[7,20,51] whereas only 10% to 12% of patients in Japan and India undergo surgical intervention.[21,50] If possible, surgery should be performed when disease activity is minimal.[53] In fact, one study showed a decrease in the 5-year patency rate from 88% to 53% when bypass was performed in patients with active disease.[106] Another study found that patients with active disease were more likely to require revision or develop progressive symptomatic disease at another site.[100] In a group of 42 patients with TA, the rate of bypass revision or disease progression at 5 years was 0% in patients with quiescent disease not on steroids, 10% in patients with quiescent disease on steroids, 57% in patients with active disease on steroids, and 67% in patients with active disease not on steroids. Again, disease activity assessment is not perfect, and surgical specimens show active disease in up to 44% of patients who were thought to be in remission.[7]

General indications for surgical revascularization include hypertension in the setting of renal artery stenosis, lifestyle-limiting extremity ischemia, cerebral ischemia or greater than 70% symptomatic stenosis of cerebral vessels, moderate (grade II New York Heart Association) aortic regurgitation, cardiac ischemia in the setting of proven coronary artery stenosis, severe aortic coarctation, or progressive aneurysmal enlargement and dissecting aneurysm.[18]

Endovascular Treatment

Initial reports of percutaneous vascular interventions in patients with TA were promising. Sharma reported 1-year success rates for percutaneous transluminal angioplasty (PTA) of the renal arteries and the abdominal aorta of 80% and 100%, respectively.[107] Others reported initial success rates in 74% of patients.[108] In a report of subclavian artery PTA, initial success rates were 88% for stenotic lesions and 67% for total occlusions. On mean 4-year follow-up, restenosis occurred in 20% of patients.[109]

Despite these results, long-term evaluation of percutaneous interventions is less encouraging. In a study of 20 patients treated with PTA, the initial success rates of PTA for renal artery stenosis and middle aortic syndrome were 83% and 100%, respectively, but the 5-year patency rate was 33.3% for each.[110] In a study of Korean patients, patency rates decreased from 90% at 1 year to 50% at 10 years.[111] Stable disease activity and treatment with glucocorticoids and immunosuppressive agents were found to aid in the maintenance of arterial patency.

In the NIH cohort, 11 patients underwent a total of 20 endovascular interventions: 8 subclavian, 7 renal, 4 iliofemoral, and 1 thoracic aorta angioplasty.[13] The initial success rate was 56%; it was only 33% on the second attempt. Restenosis was frequent and occurred within 3 to 13 months. In the Cleveland Clinic cohort, 20 patients underwent PTA: 8 renal, 4 subclavian, 2 iliofemoral, 2 carotid, 2 axillary, 1 abdominal aorta, and 1 coronary angioplasty.[51] Restenosis was common and occurred in 78% of patients. Thirteen of those patients required reintervention, and 6 required subsequent bypass.

PTA's poor long-term results in patients with TA may be explained by the fibrotic and noncompliant nature of diseased vessels. Many authors have reported the need for higher balloon pressures to achieve success.[112] Other impediments to successful angioplasty include the fact that stenoses in TA are often long, and PTA results have been poor for eccentric stenoses and diffuse aortic disease.[100]

With developments in the technology of endovascular devices, the long-term results of percutaneous interventions in TA are beginning to show some improvement. Although the number of patients reported is small, stent-grafts have been found to have better patency rates in the treatment of TA than PTA or bare metal stents.[113] In this retrospective study, none of the stent-grafts occluded or became severely stenosed during follow-up ranging from 2 to 6 years, as compared with bare metal stents that had a higher rate of in-stent restenosis.

The poor results of endovascular treatment of TA have led some to use drug-eluting technology for the treatment of restenoses. Spacek et al. reported restenosis within a bare metal carotid stent 1 year from the index procedure.[114] This was treated using an off-label coronary drug-eluting stent. Six months after drug-eluting stent placement, the patient developed restenosis within the bare metal stent, but outside the drug-eluting stent. This second restenosis was treated with a drug-eluting balloon. At 30-month follow-up, the patient did not develop restenosis.

Open Surgical Treatment

Open vascular surgical intervention has been a mainstay in the treatment of complications associated with TA. The majority of vascular lesions associated with TA cause ischemic symptoms and are best managed with bypass grafts.

Common carotid bypass is typically performed for stroke prevention and is one of the most common procedures performed for ischemic disease.[13] Unlike atherosclerotic carotid disease, the lesions of TA are longer, poorly amenable to endarterectomy, and cause symptoms through thrombosis rather than embolism. Endarterectomy in patients with TA is more difficult because of the transmural nature of the inflammation and the difficulty in determining the correct plane of dissection.[115,116] In the

Cleveland Clinic cohort, two-thirds of endarterectomy and patch angioplasty procedures failed.[52] Carotid bypass in patients with TA should originate from the aortic arch rather than an aortic branch artery because the arch is typically less involved with disease compared with its branches.[1]

Upper extremity bypass for subclavian and axillary lesions is one of the most common surgical procedures performed in patients with TA. In the NIH and Cleveland Clinic cohorts, upper extremity bypass was performed in 17% and 11%, respectively.[13,51] Again, the aortic arch may be preferred for inflow, owing to its less common involvement.

Coronary artery revascularization is frequently necessary because of ostial narrowing and subsequent ischemia. Excellent results have been obtained with bypass surgery. Aortic regurgitation may present along with coronary artery disease in up to 45% of patients, necessitating concomitant aortic valve replacement.[117]

Renal artery revascularization is commonly performed after failed endovascular therapy and may be more beneficial as a first-line therapy in patients who have disease beyond the ostia.[118] Inflow is typically taken from the aorta but may be limited to the visceral vessels if the abdominal aorta is significantly diseased. An autologous conduit is preferred, owing to the lower complication rate.[13] In one of the largest series of renal revascularization for TA-induced renal artery stenosis, 27 patients underwent 40 interventions: 32 aortorenal bypasses, 2 repeat implantations, 4 nephrectomies, and 2 transluminal angioplasties.[119] These interventions significantly decreased both the mean arterial blood pressure and the number of antihypertensive medications, and they increased the mean glomerular filtration rate. The 5-year primary and secondary patency rates were 79% and 89%, respectively.

Open surgical treatment remains the gold standard for the treatment of middle aortic syndrome. Endovascular repair of middle aortic syndrome has been attempted, with successful initial results, but 5-year patency rates were approximately 33%.[120] This has led other investigators to examine aortic stenting. Again, initial success rates were excellent, but long-term results are lacking.[121,122] Patch aortoplasty has been performed in the past, but it has the same complications related to endarterectomy for carotid revascularization. Definitive repair typically consists of aorto-aortic bypass, owing to the long length and calcification of the affected segment.[123] Inflow should be taken from the suprarenal aorta because the infrarenal aorta is frequently involved with disease (Fig. 139.12). The iliac arteries are commonly used as a distal target because the distal aorta is usually spared. Open surgical revascularization can lead to a greater than 75% improvement in hypertension, with 50% of patients no longer requiring antihypertensive medications.[124] Postoperative event-free survival is greatest in those who experience resolution of hypertension.

Revascularization of the visceral arteries may occasionally be necessary in patients with chronic mesenteric ischemia. Although some reports have recommended bypass or endarterectomy even in asymptomatic patients,[125] reports from North America suggest that only the rare patient with TA and symptoms of chronic mesenteric ischemia should undergo mesenteric bypass.[13,51]

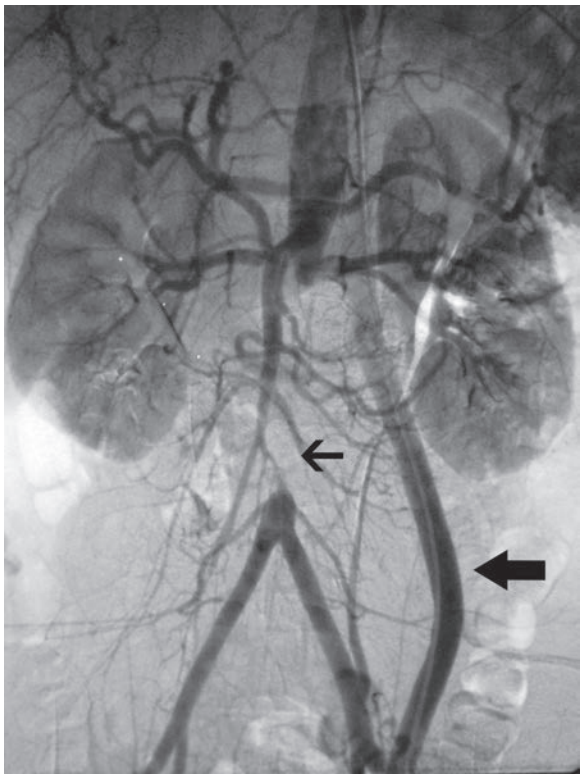

Figure 139.12 Angiogram of a 46-year-old woman who originally presented with hypertension and lower extremity claudication. Note the occlusion of the infrarenal aorta consistent with middle aortic syndrome *(small arrow)* and the bypass from the thoracic aorta to the left external iliac artery *(large arrow)*.

As stated previously, symptoms of lower extremity ischemia are much less common than upper extremity ischemia. Lower extremity ischemia is frequently caused by middle aortic syndrome (see earlier for details of its treatment), but it may also be due to involvement of iliac and femoral vessels. In these cases, standard bypass may be performed, with reasonable success.[1]

Few reports of endovascular aneurysm repair exist in the literature, and the majority of patients have undergone open aneurysm repair. The fact that the incidence of rupture is lower for TA-related aneurysms must be weighed against the fact that these patients develop aneurysms at such a young age.[1] Therefore aneurysm repair is typically performed for the same indications as in patients with non-TA aneurysms.

Certain authors have hypothesized that patients with TA are at increased risk for anastomotic aneurysms due to vessel wall inflammation. In a large study of 103 patients with TA treated surgically, over 40 years with 259 anastomoses, the anastomotic aneurysm rate was 12%.[126] The investigators found that the incidence of anastomotic aneurysms was increased only after operations for aneurysmal lesions and not in patients with systemic inflammation or on steroids.

Overall results suggest that open surgical treatment of TA can be performed with minimal morbidity and mortality.[100] In the NIH cohort, 30% of the bypasses resulted in complications, including 24% restenosis and 4% thrombosis,[13] whereas 36%

of the bypasses in the Cleveland Clinic cohort had restenosis or occlusion.[51] Reports from Japan have shown similar results. In a series of 106 patients followed up to 40 years, the 10-year cumulative patency rates of carotid, subclavian, aorto-aortic, renal, and mesenteric revascularizations were 88%, 64%, 100%, 68%, and 67%, respectively.[127] Overall 20-year survival was 74%. Early death occurred in 12% of patients (0% after 1980). Late death occurred in 31% of patients and was most frequently due to congestive heart failure.

Direct Comparison of Endovascular and Open Surgical Treatment

Due to the low incidence of TA, few studies have compared endovascular therapy and open surgery. However, one large retrospective multicenter study examined the outcomes of 79 patients with TA, of whom 63% were treated with an open surgical procedure and 34% with endovascular intervention, including angioplasty and/or stenting.[128] Follow-up ranged from 2 to 11 years. Surgical intervention was associated with a 38% vascular complication rate compared with 50% for endovascular intervention. Biologic inflammation, as manifested by elevated ESR, CRP, and serum fibrinogen levels at the time of intervention, was independently associated with complications after intervention.

Analysis of outcomes in patients with symptomatic supraaortic arterial occlusive disease has also shown the superiority of open surgical treatment in long-term outcomes. Kim et al. compared endovascular intervention with angioplasty and bare metal stent placement to open surgical treatment with bypass for short (<5 cm) occlusive lesions.[129] Restenosis was observed in 53% of patients in the endovascular group and 13% of patients in the bypass group. However, serious early postoperative complications, such as intracerebral hemorrhage or cardiac tamponade, were more common in the surgical bypass group.

Patients who undergo revascularization for symptomatic TA lesions should be carefully followed because they are likely to develop symptoms requiring intervention in another vascular bed or revision of the original procedure. A study from UCLA of 40 patients with TA who underwent revascularization from 1980 to 2009 (60 bypass procedures and 4 endovascular interventions) showed that during a mean follow-up of 6.4 years, 40% of patients exhibited progression of TA requiring intervention.[105]

SPECIAL CONSIDERATIONS

Pregnant Patients

Because TA is most commonly a disease of women of childbearing age, many authors have examined the effects of TA on pregnancy. In the NIH cohort, five women became pregnant, and all delivered healthy children without complications related to the delivery.[13] One patient in this group had an exacerbation of TA-related symptoms. Similarly, the Cleveland Clinic cohort reported one spontaneous abortion in four pregnancies. All three children brought to term were healthy.

Overall, prognostic indicators of poor maternal and fetal outcome include hypertension, aneurysmal disease, cardiac failure, and extent of disease.[7] Interestingly, the state of pregnancy may alter TA physiology, as evidenced by improvement in inflammatory markers and hemodynamic parameters.[130] Pregnancy itself has not been found to have an adverse effect on the state of TA.[131]

Pediatric Patients

The youngest patient ever diagnosed with TA was 7 months old.[116] This patient presented with an aneurysm of the right common iliac artery and an iliocaval fistula. Overall, patients presenting with TA before age 20 years represent approximately 13% to 77% of reported cases.[13,23,52] The propensity for nonspecific systemic symptoms makes diagnosis difficult, although it is unclear whether the development of TA before age 20 actually leads to a delay in diagnosis. The thoracic and abdominal aorta are most commonly involved, and ischemic symptoms are less frequent.[7]

One of the largest series of children diagnosed with TA comes from China and reviews the presenting signs and symptoms, and outcomes of treatment of pediatric patients with TA.[132] Fourteen children, with a mean age of 10, were diagnosed with TA in the 12-year-long review. Median time to diagnosis after onset of symptoms was 2 months. The most common presenting symptom was hypertension (in 93%), and most patients had an abnormal pulse exam. Medical treatment was successful in 50% of patients. Imaging may show arterial stenosis, dissection, or aneurysm.[133]

Quality of Life

Recent studies suggest that the impact of systemic vasculitis may be far more significant than previously thought. An estimate of expenditures for vasculitis-related hospitalizations for polyarteritis nodosa, hypersensitivity vasculitis, Wegener granulomatosis, giant cell arteritis, and TA amounted to $150 million per year.[112] Beyond monetary concerns, quality of life (QoL) issues are central to patient well-being.[120]

We examined QoL in a group of 158 patients with TA using the Short Form (36) Health Survey, a validated health-related QoL questionnaire, and found that the effect of TA on physical and mental health was more extensive than expected.[48] More than half the patients reported a worsening in their mood, happiness, and energy level; almost half reported a change in work duties or hours, and a quarter resigned their jobs as a direct result of TA. Younger age and freedom from immunomodulating medications were associated with superior physical QoL, and disease remission was associated with superior physical and mental QoL. Similar studies from Italy and Turkey have reported impaired QoL in patients with TA.[134,135] As diagnostic capabilities and therapeutic options develop, the prognosis of patients with TA continues to improve.[136] Future advances in imaging and biochemical methods of diagnosis, as well as immunomodulatory approaches to treatment will continue to improve the QoL of patients with TA.

PROGNOSIS

The overall prognosis of patients with TA is guarded. The effects of TA extend into all aspects of patients' lives, especially given the fact that the disease develops at such an early age and progresses despite both medical and surgical therapy. Relapse is common and occurs in 29% to 90% of patients.[19,51]

A study from Japan found that the presence of a major complication (retinopathy, hypertension, aortic regurgitation, aneurysmal disease), progressive disease course, and elevated ESR were poor prognostic indicators for survival in patients with TA.[21] The overall survival rate in 120 patients 15 years after the diagnosis of TA was 83%. For patients with both a major complication and a progressive disease course, survival decreased to 43% at 15 years. Congestive heart failure is the most common cause of death in patients with TA across geographic regions.[21–23]

The primary structural proteins of connective tissue are composed of collagen and elastin, which vary in type and amount within each of the body's tissues; those constitutive of blood vessels are listed in Table 140.1. A *connective tissue disease* is a genetic disease in which the primary target is either collagen or elastin protein assembly, disruption of which leads to an inherent predisposition to degeneration, loss of structural integrity, and consequent aneurysm formation or spontaneous vascular dissection and rupture. Although inflammation may affect these proteins and induce structural damage in some patients, such conditions often imply some element of autoimmune disorder and are termed *collagen vascular diseases* or *mixed connective tissue diseases*. Such conditions and arteritides related to the vascular tree, which are considered in Chapter 137, may have genetic profiles that predispose to their development. Although clustering of aneurysms in multiply affected family members within these arteritides may indicate some element of an inheritance pattern, there are often greatly varying levels of expression and penetrance, and no defined genetic test is available to assist treatment. Herein we seek to define the common

Abstract

A connective tissue disorder is a genetic disease in which the primary target is either collagen or elastin protein assembly, disruption of which leads to an inherent predisposition to degeneration, loss of structural integrity, and consequent aneurysm formation or spontaneous vascular dissection and rupture. These "heritable disorders of connective tissue" can have severe vascular manifestations and most commonly include Marfan syndrome, the vascular type of Ehlers-Danlos syndrome (EDS IV or VEDS), Loeys-Dietz syndrome (LDS), and familial thoracic aortic aneurysm and dissection (TAAD).

connective tissue diseases affecting the arterial tree, which have a studied natural history, a defined basis for genetic inheritance, and sufficiently understood pathophysiologic mechanisms to guide treatment paradigms. These "heritable disorders of connective tissue"[1] have severe vascular manifestations, and most commonly include Marfan syndrome (MFS), the vascular type of Ehlers-Danlos syndrome (EDS IV), Loeys-Dietz syndrome (LDS), and familial thoracic aortic aneurysm and dissection (TAAD).

MARFAN SYNDROME

Antonin-Bernard Marfan, a professor of pediatrics in Paris, in 1896 encountered a 5-year-old girl with congenital deformation of all four limbs.[2] By the time she was 11 years old, thoracolumbar kyphoscoliosis, pectus carinatum, and signs of tuberculosis had developed.[3] She died at age 16 from infection, and no autopsy was performed to document any vascular involvement. The first description of aortic pathology in MFS was published in 1943, a year after Marfan's death.[4] Although he correctly identified the many mendelian features of the condition that would eventually bear his name, the pleiotropic disorder has benefited from decades of further description of clinical manifestations, molecular pathogenesis, and emerging therapeutic options.

Epidemiology and Natural History

The incidence of MFS is about 2 to 3 per 10,000 individuals, but this estimate relies on proper recognition of all affected and genetically predisposed individuals.[5] A population-based study in Scotland found an incidence of 1 in 9,802 live births,[6] although this number would underestimate the true incidence inasmuch as the features of MFS, particularly the skeletal ones, become more apparent with growth. Furthermore, even though the disorder is passed as a dominant Mendelian trait, about 25% of cases are due to sporadic de novo mutations.[7] The disease has no gender predisposition. Its incidence is increased in athletes, particularly in basketball and volleyball players, because the characteristic tall stature with long-bone overgrowth (dolichostenomelia) confers a competitive advantage. In a screening study of 415 high-school basketball and volleyball athletes performed with standard echocardiography, 4 (1%) of these subjects exhibited aortic root enlargement greater than 4.6 cm, and MFS was diagnosed in 2.[8]

The life span of individuals with MFS was significantly shortened before the widespread use and successful refinement of aortic root surgery. Before the adoption of thresholds for aortic root replacement, the cause of death was cardiovascular (aortic rupture, aortic dissection, or valvular disease) in 90% of cases at a mean of 38 years old.[9] A report in the 1970s on the life expectancy of patients with MFS described longevity as only two-thirds that of unaffected individuals, with life-table mortality curves deviating in infancy.[9] However, a later assessment of longevity in patients with MFS describes a nearly normal life expectancy as a result of improvement and refinement in diagnosis and treatment, particularly of the cardiovascular manifestations of the disorder.[10]

Pathogenesis

As early as 1955 it was suggested that the basic structural defect in MFS was localized to the elastic fiber,[11] with skin and aorta from affected patients showing decreased elastin content and fragmentation of elastic fibers.[12,13] Yet the elastin gene and molecule were poor targets to explain the clinical manifestations of MFS in tissues that are devoid of elastin, such as bone and the ciliary zonules in the eye. Further histochemical analysis demonstrated that the amorphous fragmented elastin tissues were surrounded by a rod-like material with a distinct staining pattern and distinguishable susceptibility to enzymatic digestion.[14,15] These so-called microfibrils are 10 to 14 nm in diameter and are constituents of all connective tissue.[15] Sakai et al.[16] first identified fibrillin-1 (FBN1) as the principal component of the extracellular matrix microfibril, present in all tissues with the phenotypic manifestations of MFS. Additional linkage analysis mapped the MFS locus to 15q21.1.[17] The mutation is passed in an autosomal dominant manner with complete penetrance, so 50% of the offspring of an affected individual can inherit a genetic predisposition to the disorder.[5]

Role of Fibrillin

The *FBN1* gene contains 65 exons spanning 235 kilobases of genomic DNA.[18,19] The gene encodes a 350-kD glycoprotein that is highly conserved among different species, thus suggesting its critical homeostatic importance.[19] These models demonstrated that normal FBN1 molecules are not needed to assemble an elastic fiber; rather, microfibrils are required to maintain normal elastic fibers during postnatal life. If proper connections among elastic fibers and vascular smooth muscle cells are not suitably maintained, cells adopt matrix-degrading enzymes such as matrix metalloproteinase types 2 and 9. Thereafter, aortic wall homeostasis is perturbed, and inflammation as well as calcification and structural weakening of elastic fibers may ensue. This pathology has been observed in large muscular arteries from patients with MFS,[20] leading to appreciation of the classic lesion of cystic medial necrosis in large arteries of individuals with MFS. Verhoeff–van Gieson staining of elastic fibers in the aorta

demonstrates classic lamellar disorganization in MFS secondary to errant elastic fiber maintenance (Fig. 140.1).

Interaction With Transforming Growth Factor

The discovery of the role of microfibrils in regulating cytokines has further advanced our understanding of the pathogenesis of MFS and raised the possibility of a new treatment paradigm. FBN1 shares a high degree of homology with the latent transforming growth factor-β (TGF-β)–binding proteins. The TGF-β cytokines are secreted as large latent complexes consisting of TGF-β, a latency-associated peptide, and one of three latent TGF-β-binding proteins (Fig. 140.2).[21] In normal trafficking, the large latent complex is sequestered and bound to microfibrils, and TGF-β cytokine signaling is prevented. As depicted in Figure 140.2, without proper microfibrils, the TGF-β complex cannot form, thereby leaving TGF-β in the milieu to incite excess signaling. This pathogenetic mechanism of dysregulated TGF-β activity seems more plausible in explaining the clinical features of MFS that are poorly reconciled with structural failure, such as long-bone overgrowth, craniofacial abnormalities, and muscle hypoplasia.[22,23]

Clinical Manifestations and Diagnostic Evaluation

MFS is a multisystem disorder with manifestations principally within the cardiovascular, ocular, and skeletal systems. The disorder occurs worldwide, with no gender or race predilection.

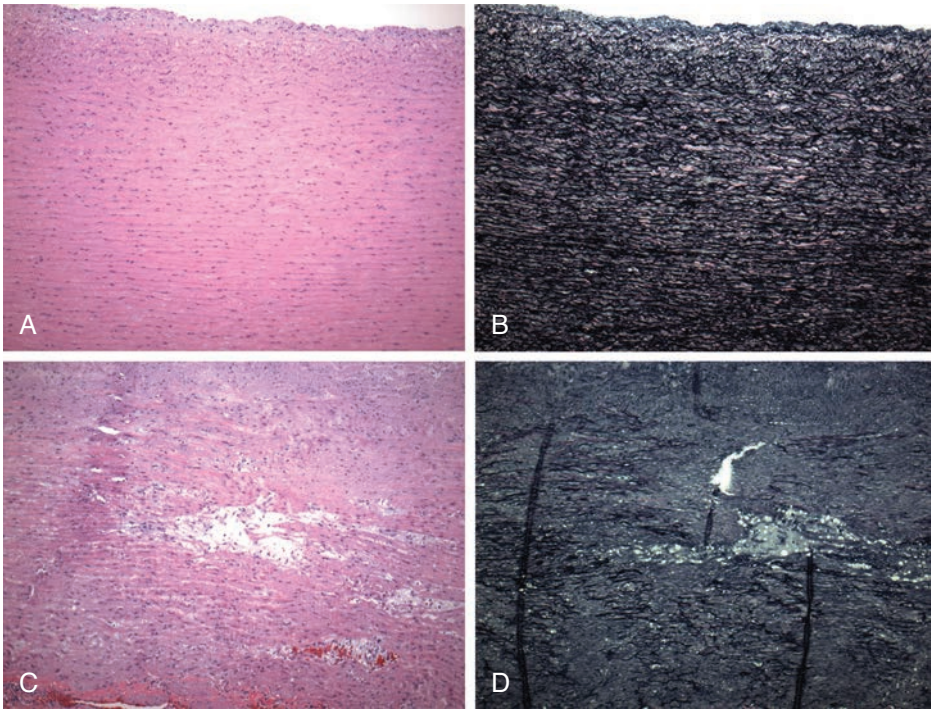

Figure 140.1 (A and B) Photomicrographs illustrating the regular and parallel nature of the elastic lamellae found within the media of the normal ascending aorta. The lamellae are composed of elastic fibers running in parallel with intervening smooth muscle, ground substance, and collagen. The Verhoeff–van Gieson (VVG) stain highlights these major elastic fibers *(black)* (A, hematoxylin-eosin [H&E], ×100; B, VVG, ×100). (C and D) Photomicrographs showing profound fragmentation of the elastic fibers, with spaces left within the media of the ascending aorta. Though often referred to as cystic medial degeneration, the spaces created by this fragmentation lack a lining and hence are not truly "cysts." These spaces often contain increased amounts of glycoproteins. The VVG stain further highlights the severe elastic fiber *(black)* fragmentation. The *vertical black lines* are fixation artifacts from folding of the elastic sheet (C, H&E; D, VVG). (Plates courtesy Joseph Maleszewski, MD, Johns Hopkins Hospital Department of Pathology.)

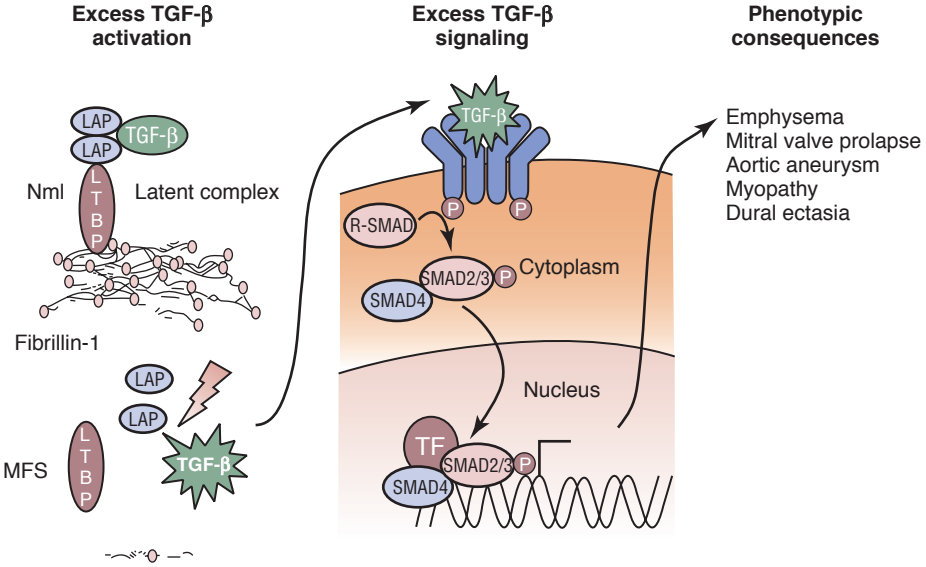

Figure 140.2 Excess activation of transforming growth factor-β (TGF-β) causes many of the features of Marfan syndrome. Normal TGF-β metabolism requires binding of the cytokine to several proteins, including microfibrils, to prevent excess signaling. In Marfan syndrome, lack of normal microfibrillar assembly allows TGF-β to remain unsequestered in the extracellular space. As a consequence, excess TGF-β signaling can occur on the cell surfaces of TGF-β receptors. Once the TGF-β binds to its receptor, downstream receptor–associated SMAD proteins translocate to the nucleus to modulate transcriptional activity, alter protein expression, and yield phenotypic change. *LAP,* Latency-associated peptide; *LTBP,* latent TGF-β binding protein; *MFS,* Marfan syndrome; *Nml,* normal; *TF,* tissue factor.

However, the cardinal manifestation of aortic root aneurysm and its risk of life-threatening aortic dissection or rupture can lead to a shortened life expectancy. Consequently the leading cause of mortality has been cardiovascular in more than 90% of cases (aortic dissection, valve disease, or congestive heart failure), which decreased life expectancy to approximately two-thirds that of unaffected individuals.[5] Improvements in the recognition of MFS and surgical advances have returned life expectancy to the nearly normal range by addressing the most threatening manifestations of MFS—aortic catastrophe in the form of dissection or rupture of the ascending aorta.

Diagnostic Criteria

Ghent Criteria

Clinical diagnostic criteria for MFS were outlined at the International Nosology of Heritable Connective Tissue Disorders in 1986 during the Connective Tissue Meeting in Berlin.[24] Thereafter, the recognition that many individuals diagnosed by means of these original criteria did not have the *FBN1* mutation (genetic testing became possible after 1986) led to a focused revision in 1996 and another in 2010.[25,26] Termed the *Ghent criteria,* the current nosology places emphasis on the cardinal manifestations of the syndrome, namely aortic root aneurysm, ectopia lentis, and *genetic testing*, versus the less predictive skeletal findings (Box 140.1). Once MFS is diagnosed in an individual, all first-degree relatives should be evaluated for the presence of the condition. In children, repeated evaluations may be required to avoid missing the disorder in its evolution.

BOX 140.1 2010 Revised Ghent Criteria for the Diagnosis of Marfan Syndrome and Related Disorders

In the absence of family history:

1. Ao (Z >2) AND EL = MFS
2. AO (Z >2) and FBN1 = MFS
3. AO (Z >2) and systemic score (>7 pts) = MFS
4. EL and FBN1 with known Ao = MFS
   EL with or without systemic *and* with an FBN1 not known with Ao or no FBN1 = ELS
   Ao (Z <2) *and* systemic (>5 with at least one skeletal feature) without EL + MASS
   MVP *and* Ao (Z > 2) *and* systemic (<5) without EL = MVPS

In the presence of family history:

1. EL and FH of MFS (as defined above) = MFS
2. Systemic (>7) and FH of MFS (as defined above) = MFS
3. Ao (Z >2) above 20 years old, >3 below 20 years old + FH of MFS (as defined above) = MFS Caveat: without discriminating features of SGS, LDS, VEDS (as defined in Table 140.1) *and* TGFBR1/2, collagen biochemistry, COL 3A1 testing as indicated. Other conditions/genes will emerge over time.

Ao, Aortic diameter at the sinuses of Valsalva above indicated Z-score or aortic root dissection; *EL,* ectopia lentis; *ELS,* ectopia lentis syndrome; *FBN1,* fibrillin-1 mutation (as defined in Box 140.2); *FBN1 not known with Ao,* FBN1 mutation that has not previously been associated with aortic root aneurysm dissection; *FBN1 with known Ao,* FBN1 mutation that has been identified in an individual with aortic aneurysm; *MASS,* myopia, mitral valve prolapsed, borderline Z-score (<2) aortic root dilatation, striae, skeletal findings; *MFS,* Marfan syndrome; *MVPS,* mitral valve prolapsed syndrome; *Systemic,* systemic score (see Box 140.2); and *Z,* Z-score.

Differential Diagnosis

Other conditions also associated with *FBN1* mutations may be considered in the differential diagnosis of MFS. The MASS phenotype is based on the association of *m*itral valve prolapse, myopia, mild *a*ortic root dilatation, *s*triae, and mild *s*keletal changes.[27] The skeletal features of MASS often include the mild manifestations of tall stature, mild dolichostenomelia (long-bone growth), and scoliosis. Occasionally, a major Ghent criterion from the skeletal system may be met but no other major criteria are noted. For patients with MASS, mutations in the *FBN1* gene have generally created premature termination codons, and the mutant transcript can be easily and rapidly degraded.[28]

Shprintzen-Goldberg syndrome is characterized by craniosynostosis, facial hypoplasia, anterior chest deformity, arachnodactyly (long, spider-like fingers), and aortic root dilatation. Developmental delay is also common. Point mutations in *FBN1* have been found in some affected individuals, but phenotypic heterogeneity—specifically regarding development, retardation, and aortic root involvement—probably indicates substantial genotypic variation.[29] The aortic root enlargement in Shprintzen-Goldberg syndrome is similar to that in MFS.

Homocystinuria is caused by a deficiency of cystathionine β-synthase. Patients with homocystinuria often have tall stature, long-bone overgrowth, and ectopia lentis but no aortic enlargement. The inheritance is autosomal recessive, and affected individuals often have mental retardation, a history of thromboembolism, and coronary artery disease. Plasma homocysteine values are typically markedly elevated, easily distinguishing this disease from MFS.[5]

Congenital contractural arachnodactyly (CCA) shares many skeletal features with MFS but without the ocular and cardiovascular manifestations. The mutation in the few patients reported in the literature is located in the *FBN2* gene,[30] and physical therapy is key to maintaining joint range of motion. It has been suggested that President Abraham Lincoln had MFS, but pictures of him in his later years suggest large joint contractures, which are more typical of CCA.

The overlap of LDS and MFS is considered later in this chapter.

BOX 140.2 Criteria for Causal *FBN1* Mutation

- Mutation previously shown to segregate in Marfan family
- De novo (with proven paternity and absence of disease in parents) mutation (one of the five following categories):
- Nonsense mutation
- In-frame and out-of-frame deletion/insertion
- Splice-site mutations affecting canonical splice sequence or shown to alter splicing on messenger RNA/complementary DNA level
- Missense mutation affecting/creating cysteine residues
- Missense mutation affecting conserved residues of epidermal growth factor consensus sequence
- Other missense mutations: segregation in family if possible + absence in 400 ethnically matched control chromosomes; if no family history, absence in 400 ethnically matched control chromosomes
- Linkage of haplotype for n > 6 meioses to the *FBN1* locus.

Surveillance

MFS is a pleiotropic disorder, and surveillance of the many systems at risk for abnormality is prudent. The cardinal manifestations are ocular, skeletal, and cardiovascular. Regular examinations by an ophthalmologist for slit-lamp testing, a cardiologist for imaging of the aortic root, and an orthopedist for the development of scoliosis should be performed on an annual basis. In this section, focus is placed on aortic and vascular pathology. For recommendations with regard to the other body systems, the reader may find useful information at the National Marfan Foundation website (www.marfan.org). The clinical manifestations within the cardiovascular system that require preventive attention involve the atrioventricular valves, the annuloaortic valve mechanism, and the aortic root and ascending aorta.

Aortic Disease

Aortic aneurysm and dissection are the most life-threatening manifestations of MFS. The threat depends on age, with rupture and dissection rates increasing as the aortic root dilates.[31,32] Because root dilatation at the sinuses of Valsalva can begin in utero, lifelong transthoracic echocardiographic monitoring is needed. For patients in whom the aortic root and ascending aorta are poorly visualized as a result of anterior chest deformity, computed tomographic angiography or magnetic resonance angiography (to avoid radiation exposure) is a viable substitute. Absolute thresholds for replacement of the aortic root in children have not been established, given the observation that dissection is very rare in the young.[5] However, if the aortic root is noted to grow more than 1 cm over consecutive annual assessments or if significant aortic regurgitation is present, early surgery may be necessary.[26] In children and teenagers, a nomogram reflects the number of standard deviations of the patient's aortic root from the mean aortic root diameter in the population and is termed a *Z-score*. If the child's Z-score deviates rapidly from that of the population (>2 to 3 SD) under surveillance, aortic root repair may be justified to prevent rupture. In adults, surgical repair of the aortic root and ascending aorta to prevent aortic rupture and dissection is recommended when its greatest diameter exceeds 50 mm.[26,32] Earlier intervention may be warranted with a family history of aortic dissection at lesser diameters.

Prevention

Lifestyle modifications are routinely recommended once the diagnosis of MFS is established. On the basis of data from the United States, genetic cardiovascular diseases account for 40% of deaths in young athletes.[33,34] A consensus document states that "burst" exertions such as sprinting, weightlifting, basketball, and soccer should generally be avoided. Favored are recreational sports in which energy expenditure is stable and consistent over long periods, such as informal jogging, biking, and lap swimming.[35] Importantly, litigation results suggest that physician reliance on consensus statements to determine medically reasonable levels of activity in patients with cardiovascular abnormalities is appropriate.[36]

Medical Treatment

Medical treatment with β-adrenergic receptor blockade to delay aortic root growth or prevent aortic dissection in patients with MFS is currently considered a standard of care.[5,26] General recommendations are a resting heart rate lower than 70 beats per minute and a heart rate less than 100 beats per minute with submaximal exercise. The rationale for this treatment paradigm is focused on decreasing proximal aortic shear stress and dP/dt. The only randomized trial assessing the effect of beta blockade studied 70 patients, 32 of whom received propranolol.[37] Treated patients received titrated dosages via an open-label approach to keep the heart rate at 100 beats per minute during exercise or a 30% rise in the systolic time interval. Serial echocardiograms were performed and correlated with age, height, and weight over a mean follow-up of 7 years. Fewer patients in the propranolol-treated group reached the primary endpoint of aortic regurgitation, aortic dissection, surgery, heart failure, or death (5 in the treatment group and 9 in the control group). Aortic growth after normalization was lower in the propranolol-treated group (0.023 cm/year) than in the control group (0.084 cm/year, $P < .001$).[37] For patients with increased body weight or an end-diastolic aortic diameter greater than 40 mm, the response to beta blockade was worse, thus suggesting that beta-blockers must be given at an adequate doses and early in the course of the disorder to optimize benefit.[26,37]

The 2006 publication of the ability of losartan, a US Food and Drug Administration–approved antihypertensive medication and selective angiotensin II receptor antagonist, to inhibit aortic aneurysm in murine models of MFS[38] has opened a potential new medical treatment paradigm. The exact mechanisms by which losartan inhibits TGF-β in the aortic wall are not completely understood, but a variety of feedback mechanisms are likely.[39] A multicenter trial comparing beta blockade and losartan therapy for the control of aortic root growth in children and young adults with MFS has been initiated through the National Institutes of Health and was reported in 2014.[40] In comparison of Marfan patients taking atenolol or losartan, both were equally effective at controlling aortic root dilatation.[40] Currently, losartan dosing is titrated to maximum 2 mg/kg, or 100 mg for adults. In a study of 600 Marfan patients followed for a median of 6 years, angiotensin II receptor blocker therapy was associated with reduced risk for type b dissection.[41]

Surgical Treatment

The traditional threshold for prophylactic surgical repair of the aortic root is 5 cm in patients with MFS. Operations on the arterial tree outside the ascending aorta have been reported (Fig. 140.3) and can have acceptable outcomes.[42] Indeed, as the life expectancy of individuals affected by MFS has increased with prophylactic root replacement, it is plausible that the remaining aorta or other large arteries may progress to require repair in the absence of antecedent dissection. For aortic arch and descending thoracic or thoracoabdominal aneurysms, standard criteria for repair generally follow that of atherosclerotic aneurysms—a threshold of 5.5 to 6.0 cm.[26]

Descending Thoracic and Thoracoabdominal Aorta

The first successful replacement of the thoracoabdominal aorta in a patient with MFS was performed by Crawford[43] in the 1980s. Elective surgical repair of descending thoracic aortic aneurysm and thoracoabdominal aortic aneurysms (TAAAs) in MFS has benefited from the general refinements and the introduction of adjuncts to reduce spinal cord injury and other major complications in a manner similar to standard atherosclerotic aneurysms (see Chapter 77). Prophylactic aortic replacement is indicated when the aortic diameter reaches 5.5 to 6.0 cm or if symptoms related to the aneurysm occur. Because of the frequent involvement of the descending and thoracoabdominal aorta with aneurysms of chronic dissection etiology, the extent of repairs in MFS tend to be greater, with 42% to 78% of all TAAAs being DeBakey type II.[44] Paraparesis and paraplegia rates after TAAA repair in MFS compare favorably with those for nonconnective tissue disease when matched for the extent of repair required.[44] Because of the very young mean age of patients with MFS undergoing TAAA repair versus the older mean age of patients with degenerative TAAA, overall long-term survival was better for those with MFS.[44]

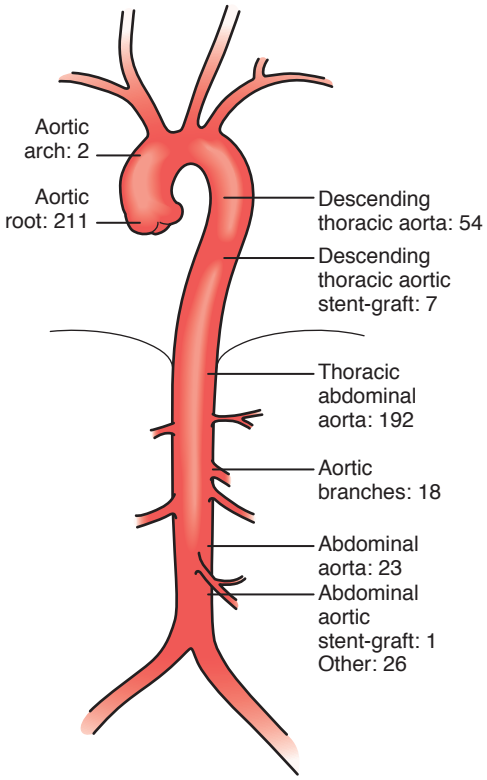

Figure 140.3 Distribution of vascular repairs in 300 patients with Marfan syndrome. (From Lemaire SA, Carter SA, Volguina IV, et al. Spectrum of aortic operations in 300 patients with confirmed or suspected Marfan syndrome. *Ann Thorac Surg.* 2006;81:2063–2078.)

Given the preponderance of type II TAAA repairs in the available series, the rate of freedom from further aortic repair is high because little aorta remains to degenerate. However, secondary aortic procedures after TAAA repair in patients with MFS are often performed for pseudoaneurysm or for aneurysmal degeneration of the inclusion or Carrel patch (Fig. 140.4). Indeed, in the series reported by Lemaire et al.,[42] 95% of reoperations (19 of 20) after previous TAAA repair ($n = 178$) in patients with MFS were performed for visceral patch aneurysm.[42] In our series of 107 patients who underwent TAAA repair, including creation of visceral patches, 17 were known to have a connective tissue disease.[45] With a mean time to diagnosis of 6.5 years, 3 of these 17 patients (17.6%) were found to have aneurysmal degeneration of the visceral patch. By comparison, visceral patch aneurysms were noted after only 5.6% of atherosclerotic TAAA repairs.[45] All of these patients with MFS had inclusion patches that encompassed the celiac axis, superior mesenteric artery, and both renal arteries, thus suggesting that the visceral patch should have been much smaller in all patients with connective tissue diseases to prevent late degeneration.[46] I, along with many surgeons, avoid patch inclusion entirely and use a prefabricated four-branch graft to perform individual bypasses to the renal and visceral aortic branches.[47] Intercostal inclusion patches can be limited also,

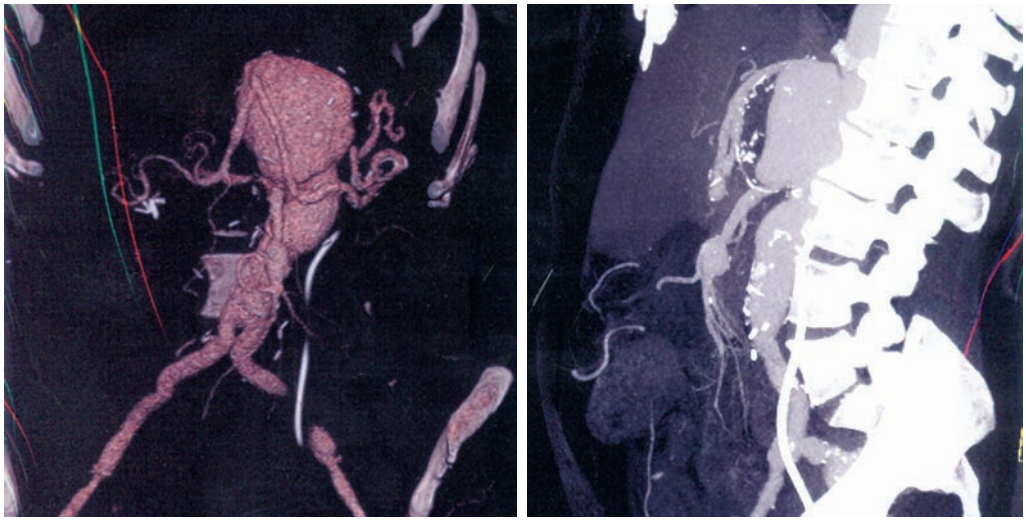

Figure 140.4 Ten-centimeter visceral patch aneurysm 7.5 years after a type II thoracoabdominal aortic aneurysm repair in a 48-year-old woman with Marfan syndrome. A hybrid open/endovascular stent-graft approach was used to repair the region. VRT reconstruction *(left)*; lateral view demonstrating effacement of distance between superior mesenteric artery and celiac axis *(right)*.

but those that degenerate to aneurysm may be treated with stent-graft therapy, although paraplegia concerns are paramount. Given the morbidity associated with repair of the patch aneurysm (2 intraoperative deaths in 5 of our patients taken to the operating room), Dardik et al.[45] recommend maintaining an indication for repair of 6.0 cm or larger.

Endovascular Treatment

In general, aortic stent-grafts should not be used in the thoracic or abdominal aorta or in patients with other connective tissue diseases. The currently approved devices have never been studied in the fragile milieu of the MFS aorta (connective tissue disorder was an exclusion criteria during pivotal trials), and the question of physical damage to the aorta from the persistent radial force of the stent-graft (Fig. 140.5) remains unanswered. A summary publication recommends endovascular repair only in instances of late localized pseudoaneurysm and stenting across native tissue aneurysm from "graft to graft" (see Fig. 140.5).[48,49,50]

Series of patients with MFS who were treated with endovascular therapy with reasonable follow-up periods to determine clinical effectiveness are now emerging. Botta et al.[51] examined 12 patients treated for dissection of the descending thoracic aorta after previous open aortic root/arch surgery. Five procedures were performed urgently and seven electively. In the immediate postoperative period, no paraplegia was encountered. However, after a mean follow-up period of 31 months, 25% of the patients had new dissection, either retrograde into arch or distal into the abdominal aorta. Waterman et al.[52] have published the largest series of patients with MFS undergoing endovascular therapy, and the results are sobering. Forty-four percent of patients experienced primary failure of the stent-grafts, many of which were converted to conventional surgical repairs. Among the primary treatment failures (7 of 16 patients), the mortality was 42%.

Indeed the issue of stent-graft–induced new entry (SINE) tears seems a persistent theme in patients with MFS.[53] The investigator concludes that the stress-induced injury of the stent-graft against the fragile aortic wall should be accounted for during design and placement of the endograft (Fig. 140.6). Although excessive oversizing should also be avoided, it is important to note that the extent of oversizing in this series was within the instructions for use for the available devices to date. Reported experiences with stent-graft therapy in MFS, stating that after stent grafting, retrograde type A dissection was the most common complication among patients with MFS after TEVAR.[54]

VASCULAR-TYPE EHLERS-DANLOS SYNDROME

EDS is a heterogeneous group of heritable disorders of connective tissue characterized by joint hypermobility, skin hyperextensibility, and tissue fragility affecting the skin, ligaments, joints, blood vessels, and internal organs. There are many subtypes of the disorder (Table 140.2 or www.ednf.org), with classic EDS (types I and II) being the most common.[55] The importance of identifying the correct type cannot be overstated, because the natural history and modes of inheritance differ among the subtypes. Historically, the older literature did not clearly differentiate among the types, and the severe complications of the vascular type of EDS were cited as being representative of the whole syndrome, thereby creating unnecessary anxiety. The current nomenclature (i.e., naming the vascular phenotype as vascular

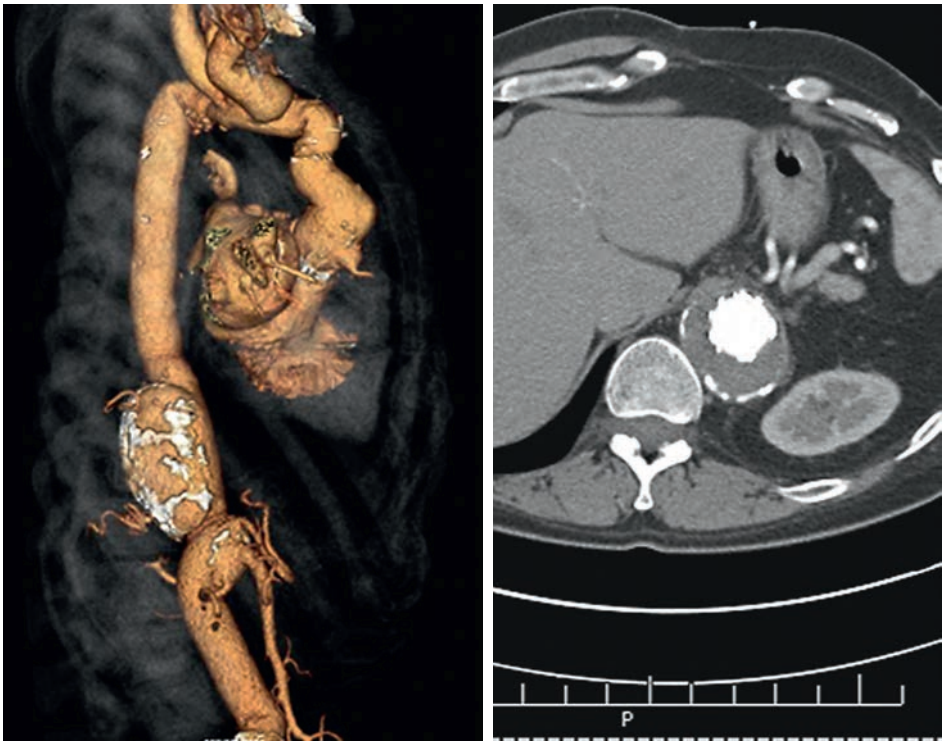

Figure 140.5 Intercostal patch aneurysm after thoracoabdominal aortic aneurysms repair. In this clinical scenario, the stent-graft has "graft-graft" fixation proximally and distally *(left)* in surgical graft material. Notably, intercostal patch aneurysms that are opposite the visceral patch may contraindicate stent-graft placement. Stent graft in position with thrombosis of intercostal patch aneurysm *(right)*.

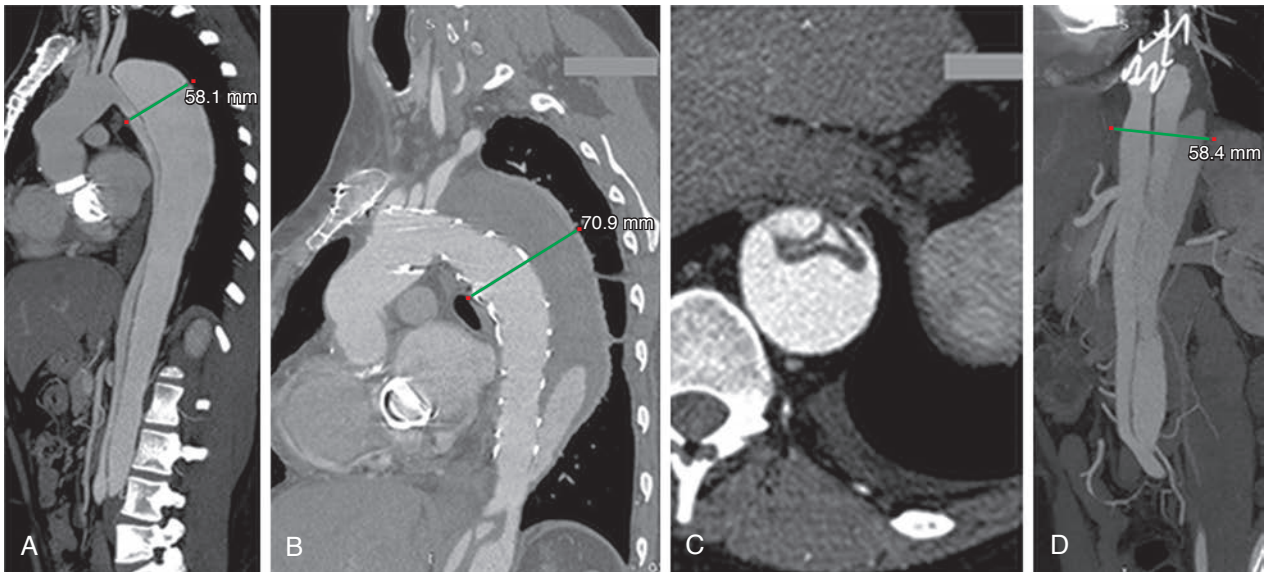

Figure 140.6 Progression of aneurysm in a patient with Marfan syndrome after thoracic endovascular aortic repair. (A) Initial stent-graft placement. (B) New distal entry tear caused by stent-graft edge seen on 1-month CT scan. (C) New presentation at 4 months with acute back pain and near-circumferential dehiscence of the intimomedia. The patient was treated medically until 6-month CT scan revealed (D) new progression to thoracoabdominal aortic aneurysms, which led to referral to the author for repair.

TABLE 140.2 Subtypes of Ehlers-Danlos Syndrome

Nomenclature (New Terms)	Type	Skin (0 to 4+) (Elastic-Fragile)	Joint Laxity (0 to 3+)	Features	Inheritance
Classic	I, II	+++/+++	+++	Vascular complications rarely	AD
Hypermobile	III	+/+	+++	Arthritis	AR
Vascular	IV	−/++++	+	Rupture of arteries, uterus, intestine; thin skin	AD
Kyphoscoliotic	VIA, VIB	+++/++	+++	Hypotonia, osteoporosis, Kyphoscoliosis; rupture of arteries, globe of eye	AR
Arthrochalasic	VIIA, VIIB	++/+	+++	Hip subluxation, osteoporosis	AD

Other	V	++/++		Skin lax	X-linked
	VIII	+/++	++	Periodontal disease	AD
	IX	+/−	+	Lax skin, osteoporosis, bladder diverticula, retardation	X-linked
	X	+/+	++	Petechiae	?

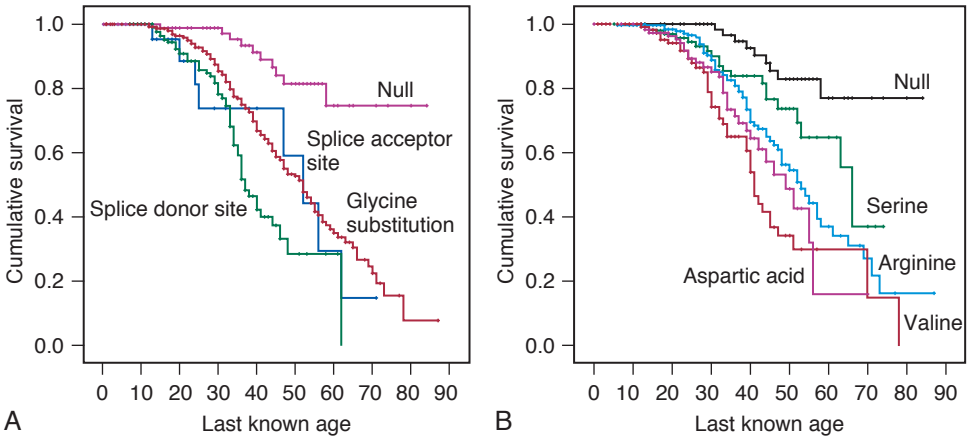
AD, Autosomal dominant; *AR,* autosomal recessive.

EDS) attempts to reinforce this important separation from other subtypes. This section focuses on the vascular type (EDS IV), its pathogenesis (defective type III procollagen encoded by the *COL3A1* gene leading to extreme vascular fragility), and its management.

Epidemiology and Natural History

The prevalence of EDS IV is currently estimated to be 1 in 50,000 to 90,000, and it is inherited in an autosomal dominant manner.[55,56] Approximately 50% of cases represent new mutations that occur sporadically and without an antecedent family history. As a rule, each patient or family carries a unique mutation in the *COL3A1* gene, which codes for type III procollagen.[57,58]

The overall life expectancy of patients with EDS IV is dramatically shortened, largely as a result of vascular rupture, with a median life span of 48 years (range, 6-73 years).[59] In a study of 220 patients with EDS IV confirmed by abnormal type III procollagen molecules and 199 relatives with a clinical diagnosis of EDS IV, major complications in childhood were rare, but 25% of the subjects suffered medical or surgical complications by the age of 20. By 40 years of age, major complications in



Substitution	Median survival in years	Estimated hazard ratio	95% CI
Null		(ref)	(ref)

(From Pepin MG, Schwarze U, Rice KM, Liu M, Leistritz D, Byers PH. Survival is affected by mutation type and molecular mechanism in vascular Ehlers-Danlos syndrome (EDS type IV). *Genet Med.* 2014;16(12):881–888.)

the vascular or gastrointestinal systems (men and women) or reproductive system (women, e.g., uterine rupture in pregnancy) had developed in 89%.[59] Death had occurred in 131 subjects, with rupture of thoracic or abdominal vessels in 78 (60%), central nervous system hemorrhage in 9 (7%), and an unspecified bleeding source in 16 (12%). Organ rupture (heart, uterus, spleen, liver) caused death in 13 (10%) of the patients, and intestinal rupture led to death in 10 (8%).[59]

Pathogenesis

EDS IV is due to mutations in the *COL3A1* gene, which encodes a protein for type III collagen assembly. Because most arteries and arterioles have significant amounts of type III collagen, defects in *COL3A1* lead to inherent weakness of these vessels.[59] The gene encodes a procollagen molecule, proa1(III), and basic collagen synthesis requires three polypeptide procollagen chains, referred to as α chains, to be folded tightly into a triple helix.[55] The abnormal collagen III molecule cannot fold stably into a triple helix, is slowly degraded in the rough endoplasmic reticulum of the fibroblast, and is never secreted extracellularly.[55]

The central concept of heterozygous mutations leading to structural defects of collagen α chains and instability or nonsecretion of the mutant protein has proved correct in several collagen disorders and has been termed "protein suicide."[60] A study by Pepin et al. recently demonstrated that different types of mutations may be associated with different overall survival. This genotype/phenotype correlation may have a basis in the high prevalence of glycine substitutions or deletions, as the very small molecular size of glycine is critical for proper folding of the collagen triple helix (Fig. 140.7).[61]

Clinical Evaluation

Common Manifestations

EDS IV has the worst prognosis among the types of EDS; for this reason, proper diagnosis is essential, because the physical findings may mimic those of other EDS subtypes or other connective tissue diseases (Box 140.3).[62] The presence of any two or more of the major criteria (easy bruising, translucent skin, facial features, and history of arterial, uterine, or intestinal rupture) is highly indicative of the diagnosis, and collagen testing

BOX 140.3 Diagnostic Criteria for Ehlers-Danlos Syndrome, Vascular Type

Major Diagnostic Criteria

- Thin, translucent skin
- Arterial/intestinal/uterine fragility or rupture
- Extensive bruising
- Characteristic facial appearance (thin delicate nose, thin lips, hollow cheeks)

Minor Diagnostic Criteria

- Acrogeria (taut, thin skin)
- Hypermobility of small joints
- Tendon and muscle rupture
- Talipes equinovarus (clubfoot)
- Early-onset varicose veins
- Arteriovenous carotid–cavernous sinus fistula
- Pneumothorax/pneumohemothorax
- Gingival recession
- Positive family history, sudden death in one or more close relatives

Data from Beighton P, De Paepe A, Steinmann B, Tsipouras P, Wenstrup RJ. Ehlers-Danlos syndromes: revised nosology, Villefranche, 1997. Ehlers-Danlos National Foundation (USA) and Ehlers-Danlos Support Group (UK). *Am J Med Genet*. 1997;77:31–37.

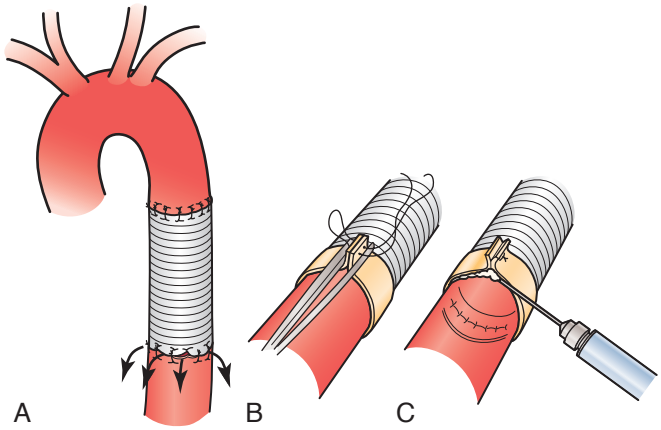

Figure 140.8 (A) Lack of adventitial and medial thickness in type IV Ehlers-Danlos syndrome promotes suture-line bleeding. Buttressing with felt (B) and the application of BioGlue (C) may reduce suture-line tension and promote hemostasis.

is strongly recommended. Such testing is both labor- and time-intensive but should strongly be considered before any treatment course is chosen for the suspected affected individual. The diagnosis of EDS IV is most commonly confirmed by demonstration of structurally abnormal collagen III.[63] Direct molecular genetic analysis of the *COL3A1* gene is also possible from a blood or serum sample.

Differential Diagnosis

The differential diagnosis of EDS IV includes disorders of bruisability and wound healing such as von Willebrand disease, platelet disorders, and scurvy. Bruisability is often elicited in children and may mimic nonaccidental injury ("battered child").[64] Indeed, excessive bruising with hematoma formation is a common first manifestation. In EDS IV, rupture or dissection of arteries occurs most often in medium-sized vessels, as opposed to the predominant occurrence of rupture and dissection in the aortas of patients with MFS. The vessel's tortuosity and elongation may be similar to findings in the arterial tortuosity syndrome or LDS, but vascular surgery is often much better tolerated in the latter. Multiple aneurysms through the visceral vessels may also be noted in polycystic kidney disease and hereditary forms of cerebral cavernous malformations.[65] Varicose veins and venous aneurysms are commonly seen in EDS IV but have little clinical or diagnostic significance versus nonsyndromic venous disease unless stripped, at which point bruising and skin injury can be extensive.

Selection of Treatment

Although no specific medical therapies exist for EDS IV, knowledge of the diagnosis can influence management strategies, assist in reproductive counseling, and direct the treatment of major complications. All patients with a confirmed diagnosis of EDS IV should carry medical attention bracelets as well as papers noting information on the condition and their blood groups. General recommendations for anesthesia also exist, including cross-matching of adequate blood, avoidance of intramuscular injection, adequate peripheral access, avoidance of arterial lines and central venous catheters, and gentle intubation maneuvers.[66] If central access is required, the use of ultrasound guidance for access is mandatory.

True Aneurysms

True aneurysms in EDS IV are rare and occurred in only 14% of patients in one series.[67] Given the difficulty of handling the fragile tissues and vessels, management of spontaneous bleeding should be conservative as long as possible, especially in the interstitial (muscular, retroperitoneal) spaces.[67,68] Bleeding within the peritoneal cavity usually requires immediate transfusion; if surgery is required, vessel ligation with umbilical tape appears to be the safest course, as opposed to direct repair.[67] Direct reconstructions must be tensionless, often pledgetted to reduce suture trauma, and reinforced circumferentially (Fig. 140.8). Angiography should be avoided because of severe morbidity and the risk of vessel dissection or perforation (or both) during selective catheterization or from the puncture site itself. In one study, the major complication rate from arteriography was 67% with 12% mortality,[69] although the benefit of more contemporary, lower-profile catheter and endovascular devices may have a favorable impact on this historically high percentage.

Vascular Complications

When there was bleeding from vascular rupture, the recommendation of avoiding any operation until faced with imminent risk of death remained axiomatic for many decades. This axiom further complicated the condition of patients with known aneurysms, whose vessels were allowed to dilate progressively under regular surveillance, which caused much angst for the surgeon and patient. For the individual patient, elective aneurysm

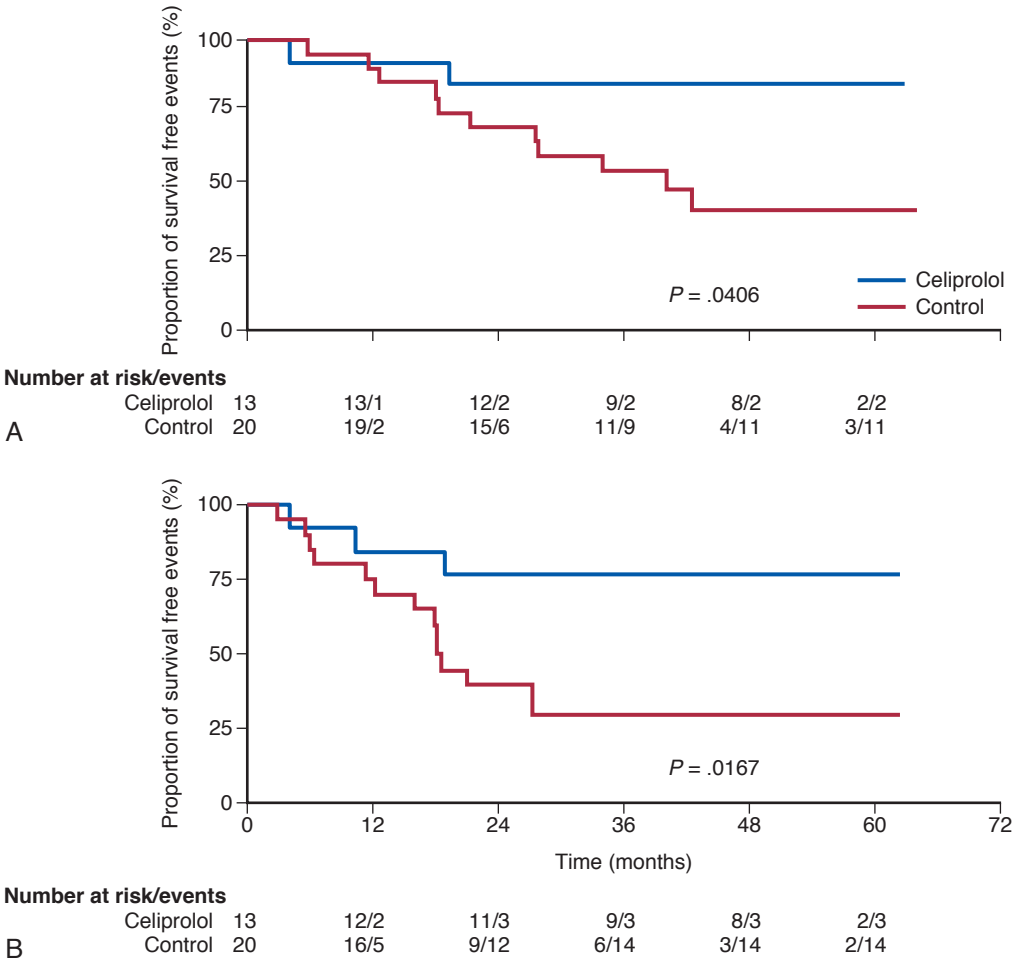

Figure 140.9 Kaplan-Meier survival curves in celiprolol study. Vascular event–free survival was improved in patients taking celiprolol who had a *COL3A1* mutation. (From Ong KT, Perdu J, De Backer J, et al. Effect of celiprolol on prevention of cardiovascular events in vascular Ehlers-Danlos syndrome: a prospective, randomized, open, blinded endpoints trial. *Lancet*. 2010;376(9751):1476–1484.)

repair must be considered, especially if previous operative therapies did not report excessive fragility. Patients with EDS IV at highest risk of inoperable tissue fragility can be identified if seen at a very early age (<20 years) or multiple asymptomatic dissections or aneurysms apart from the index vascular lesion are noted.[70]

Nonvascular Complications

Gastrointestinal perforations account for 25% of all EDS IV complications.[59] The sigmoid colon is the location of most perforations, and prompt diagnosis and immediate colostomy are favored.[59] For small bowel intestinal rupture, ostomy is also preferred, and most patients undergo restoration of bowel continuity in a staged fashion without complication.[59] Recurrent bowel perforation is always a risk, occurring between 2 weeks and 26 years after the first event in 17% of patients in one study.[59]

Uterine and pregnancy-related complications are discussed under "Pregnancy in Patients with Type IV Ehlers-Danlos Syndrome."

Medical Treatment

Celiprolol has been advanced as a treatment of choice to reduce the incidence of vascular ruptures in patients with EDS IV.[71] In a 5-year randomized study of 53 patients with suspected or proven EDS IV, celiprolol therapy reduced the incidence of vascular rupture to 20%, compared with 50% in control subjects (Fig. 140.9). The trial has been criticized for the lack of uniform genetic testing to prove that all subjects had the disorder (only 33 of 53 had a *COL3A1* mutation) and the fact that mean heart rate and blood pressure were actually higher than in the control patients. This last finding would suggest a mechanism for the drug other than simple dP/dT effects. Therefore prophylactic measures to control blood pressure and reduce atherosclerotic risk factors are recommended. Lifestyle modifications for EDS IV follow the general recommendations for other genetic diseases, as reviewed in the earlier discussion of MFS.[35]

Spontaneous abdominal bleeding without identifiable source (by CTA or angiography) is associated with an advanced stage of the disorder. Factor VII transfusion may be an acceptable

option, as surgical exploration should be deferred unless compartment syndrome develops.

Surgical Treatment

Surgical management of EDS IV is a formidable challenge. The traditional risk assessment paradigm cites invasive procedures so fraught with complications that intervention should be performed only for imminent risk of death.[67,68] The findings in patients with EDS IV can include arterial manifestations throughout the entire vascular tree (Fig. 140.10).

A report of patients treated at Johns Hopkins Hospital from 1994 to 2009 reveals some very important distinctions regarding the triage of patients with EDS IV.[70] Unlike in the Mayo Clinic series, in which the preponderance of patients were treated emergently, most of the patients in the Hopkins series were treated electively. Overall perioperative bleeding rate and mortality were greatly reduced by comparison (Table 140.3). Given the success of elective procedures, it may be worthwhile to consider elective intervention in patients with EDS IV, before rupture and the ensuing stress compound operative repair. Furthermore, it is also likely that some improvement in the Hopkins series rests in its more contemporary time period. Undoubtedly operative techniques have improved, and the researchers offer several methods to explain their admirable results:

1. Liberal use of adjunctive techniques to reduce operative trauma in both the endovascular and operative setting
2. Padded surgical clamps
3. Permissive hypotension (systolic blood pressure between 70 and 80 mm Hg) during vascular clamping and suture line testing

Patients with EDS IV have been found to have unique iliac aneurysms. The configuration usually spares the aortic bifurcation, and the common iliac arteries "balloon" in a bell-bottom fashion (Fig. 140.11). In such instances, repair should be entertained in young patients electively, with emphasis on adjunctive measures to secure anastomoses as described earlier.

Ultimately, patient risk-to-benefit assessment compels any decision to proceed with a major surgical intervention. It is worthwhile to note that genetic analysis of specific mutations and collagen III biochemical assay may not predict clinical

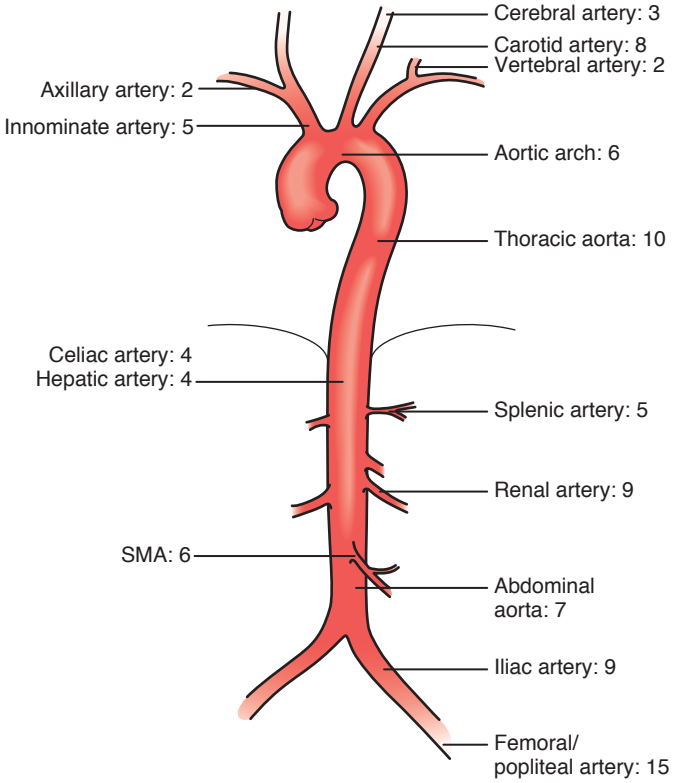

Figure 140.10 Arterial distribution of vascular complications in 24 patients with a clinical diagnosis of type IV Ehlers-Danlos syndrome. *SMA,* Superior mesenteric artery. Figure 140.11 "Bell-bottom" configuration iliac aneurysms in vascular Ehlers-Danlos syndrome. In my experience, this is a typical aneurysmal configuration. The aortic bifurcation is preserved, and adjunctive felt reinforcement secures hemostasis.

TABLE 140.3 Outcomes of Endovascular and Open Procedures in Ehlers-Danlos Syndrome Type IV

Procedure	Operative Death, No (%)	In-Hospital Death, No (%)	Length of Stay (Days), Median (*Interquartile Range*)	Any Complication, No (%)
Endovascular (n = 11)	0 (0)	0 (0)	3 (1-6)	0 (0)
Open (n = 9)	1 (11)	1 (13)	7 (6-8)	3 (38)

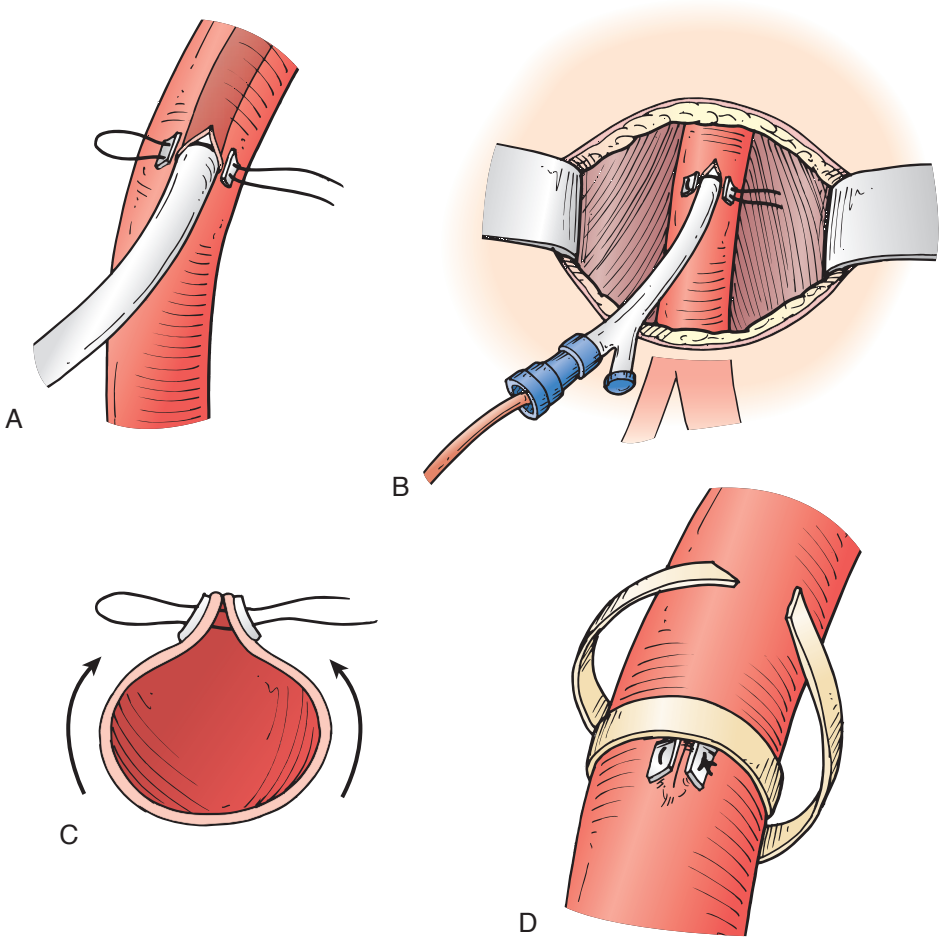

Figure 140.12 Techniques for access in severe fragility of VEDS without femoral clamp. The initial small bore sheath access through pledgetted "U" stitch **(A)** can be upsized to a large bore sheath **(B)**. The initial stitch can be tied down **(C)** for hemostasis and the vessel circumferentially reinforced **(D)** to prevent a late pseudoaneurysm.

course. However, those patients with "null" mutations have been appreciated to have a higher incidence of aortic and iliac pathology and are associated with better surgical handling.[72] But as with most connective tissue disorders, clinical history can be informative. For patients with severe phenotypic features (such as very affected skin or facial morphology), those with early-age onset, and those with prior complicated courses, complications can be expected. Furthermore, as median survival is 48 to 54 years, older patients may develop intolerance to procedural manipulations versus prior uncomplicated medical or surgical events, assuming a higher risk profile as vessel fragility worsens over a lifetime of EDS IV.

Endovascular Treatment

Endovascular approaches for coil embolization of aortic branch vessels and other medium-sized arteries have been successful in patients with hemorrhage.[67,70] Such approaches should be strongly considered for spontaneous splenic and hepatic arterial tears, many of which occur without previous trauma and may be imparted by relatively routine activities of daily living. Indeed, a report of endovascular interventions in a spectrum of patients with EDS revealed a very favorable safety profile.[73] Arterial access can precipitate femoral rupture and pseudoaneurysm formation, especially when large devices are necessary. Consideration should be given to open repair of any access puncture (Fig. 140.12), particularly when a larger French size is introduced, given the rate of complications reported.[73] Accordingly, stent-graft therapy for aortic aneurysms has not been reported in a significant sample, and long-term durability and threat to the fixation zones in the setting of chronic outward radial force may increase the frequency of secondary interventions. Consequently it is generally agreed that stent-graft therapy for EDS IV (and other connective tissue diseases) should be avoided.[50] Carotid–cavernous sinus fistula is a classic complication of EDS IV that is amenable to coil embolization in selected patients. It may manifest as subtle, progressive proptosis or headache, and high-quality imaging is key to determining whether the fistula can be addressed without risk of internal carotid sacrifice and resultant major stroke (Fig. 140.13).

Pregnancy in Patients With Type IV Ehlers-Danlos Syndrome

Pregnancy in women in EDS IV should be closely monitored. Whether elective cesarean section is warranted before labor or spontaneous vaginal delivery should be allowed is not known.[74] In the largest study of 220 patients with EDS IV, 81 women had 183 deliveries; 12 women (15%) died during the peripartum period or within 2 weeks after delivery.[59] The cause of death

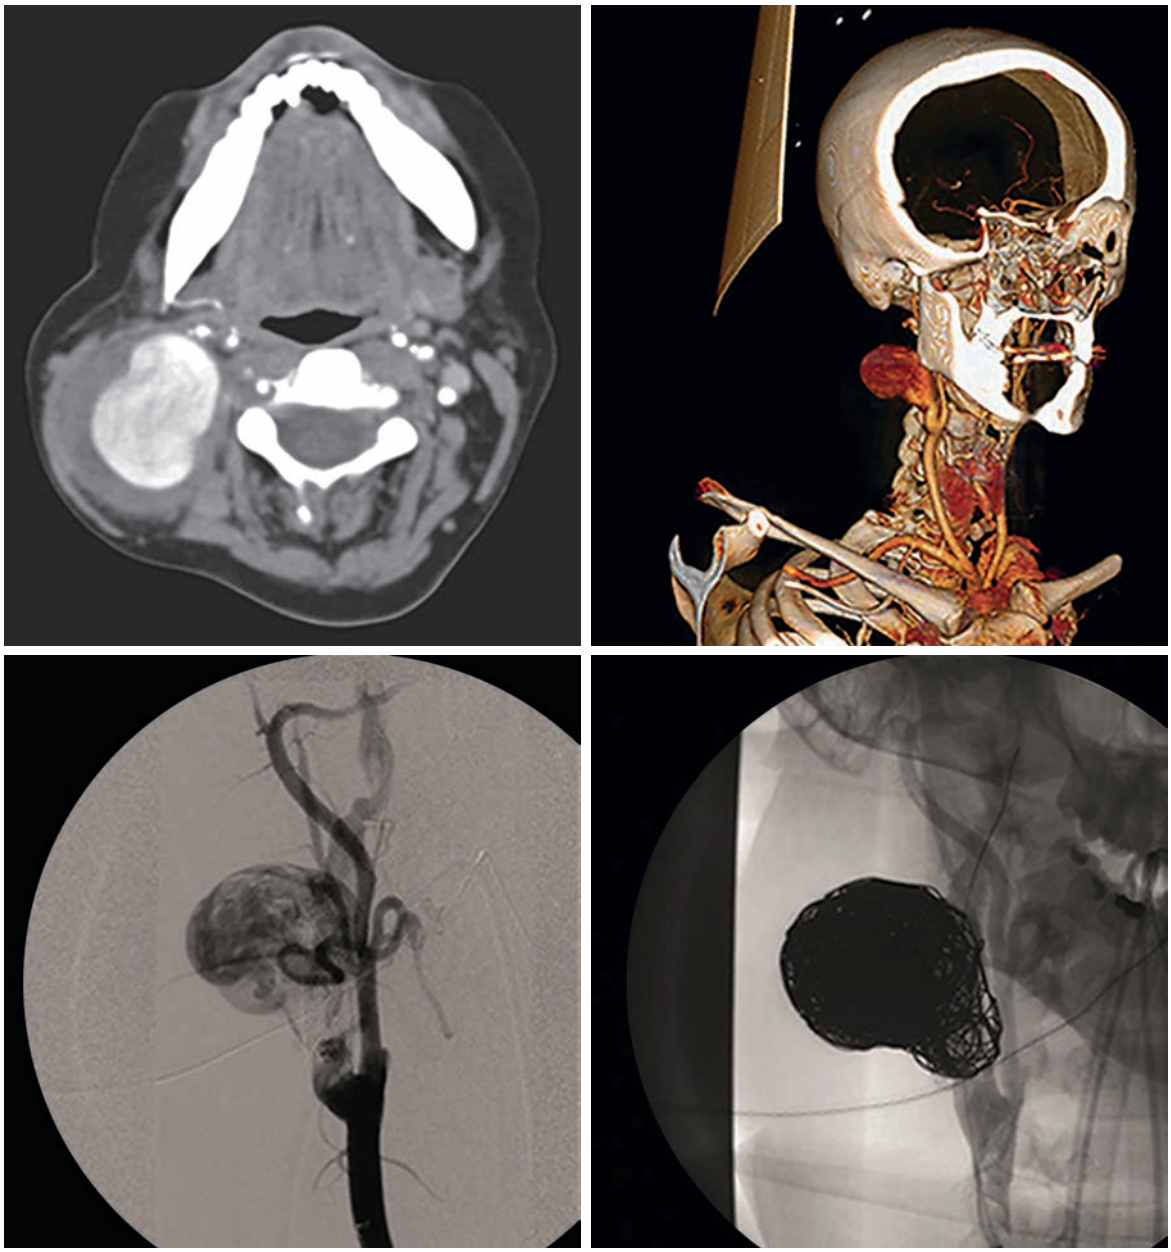

Figure 140.13 Acute development of internal carotid artery aneurysm in a woman with vascular Ehlers-Danlos syndrome 10 days postpartum, which caused significant dysphonia, dysphagia, and pain. Stent-assisted endovascular embolization was performed, and the aneurysm decreased by 50% at 3 months after the procedure.

in these women was uterine rupture in 5, vessel rupture during labor in 2, and death in the postpartum period from vessel rupture in 5. Women with EDS who become pregnant should be considered high-risk patients and managed at high-risk centers. Genetic counseling is also mandatory, because the disorder is inherited as an autosomal dominant trait and 50% of offspring of an affected individual would be expected to manifest the disorder in their lifetimes.

LOEYS-DIETZ SYNDROME

LDS is a newly described aortic syndrome typified by aortic aneurysm and vascular tortuosity, the characteristic craniofacial abnormality of a bifid uvula or cleft palate, and, finally, hypertelorism (Box 140.4).[75] The disease is caused by heterozygous mutations in the genes encoding TGF-β receptors 1 and 2 (*TGFBR1* and *TGFBR2*), SMAD3 genes, and TGF-B 2 receptors.[76,77] Since the original report, four subtypes of LDS have been proposed. LDS type I has both severe craniofacial features and aortic aneurysms.[77] LDS type II is characterized by less severe craniofacial abnormality, usually only a bifid uvula or high palate, and aortic aneurysms. LDS type III is characterized by aneurysms and early-onset osteoarthritis. LDS type IV includes aneurysm of the aorta and cerebral with arterial tortuosity. The cardinal manifestation involves the aortic root, but the aggressive nature of the root aneurysm to dissect or rupture (or

BOX 140.4 Scoring of Systemic Features

- Wrist *and* thumb sign: 3 (wrist *or* thumb sign: 1)
- Pectus carinatum deformity: 2 (pectus excavatum or chest asymmetry: 1)

- Skin striae: 1
- Myopia >3 diopters: 1
- Mitral valve prolapse (all types): 1
- Maximum total: 20 points; score ≥7 indicates systemic involvement.

both) at small diameter and in childhood separates this condition from MFS and EDS IV. Identification of affected patients and testing of all first-degree relatives are of paramount importance to motivate individuals for prophylactic surgery.

Epidemiology

Comparison of survival in the two subtypes of LDS was also reported.[76] In LDS type I, the mean age at death was lower (22.6 years) than in LDS type II (31.8 years, $P = .06$). The mean age at the first surgery was 10 years younger in patients with LDS type I than in those with type II (16.9 years versus 26.9 years, $P = .03$). Craniofacial abnormalities, when scored according to a craniofacial severity index, correlated inversely with the time of first surgery (more severe craniofacial abnormality indicated more aggressive aortic pathology).[76] LDS type III and LDS type IV may have a later onset of disease.

Clinical Evaluation

LDS is a multisystem disorder with a classic triad consisting of craniofacial abnormality (90%), hypertelorism (wide-set eyes, 90%), and arterial tortuosity/aneurysm (98%). In 40 patients with LDS who underwent anthropometric evaluation, there were findings additional to the classic triad throughout the craniofacial, skeletal, and cutaneous systems.[77] Developmental delay was infrequent (15%) and was occasionally associated with craniosynostosis, hydrocephalus, or Arnold–Chiari malformation, thus suggesting that learning disability is a rare primary manifestation of LDS.[77] A recent series had demonstrated peripheral vascular involvement is not predicted by prior aortic root repair. Thus, some LDS patients may present with nonaortic root aneurysm as their index aneurysm, in which case full body imaging is required.

Common Manifestations

The craniofacial manifestations encountered are most commonly hypertelorism and cleft palate or bifid uvula (Fig. 140.14).

Figure 140.14 Hypertelorism is noted in 90% of patients with Loeys-Dietz syndrome. In addition, this patient demonstrates malar hypoplasia (underdeveloped and flattened midface/zygomatic arches) and retrognathia (the mandible recedes under the maxilla). (From Williams JA, Loeys BL, Nwakanma LU, et al. Early surgical experience with Loeys-Dietz: a new syndrome of aggressive thoracic aortic aneurysm disease. *Ann Thorac Surg.* 2007;83:S757–S763.)

Craniosynostosis was present in 48%, malar hypoplasia (flat midface) in 60%, and blue sclerae in 40% in the first study describing the syndrome. In distinction to MFS, lens dislocation (ectopia lentis) was not recorded in any patient with LDS.[76,77]

Cardiovascular involvement is a hallmark of LDS, but aneurysms are not limited to the aortic root and can occur throughout the vascular tree. Arterial tortuosity, particular of the supra-aortic vessels, should prompt consideration of the disease, especially for LDS type III and IV.[77] Vessel elongation within tortuous segments can be difficult to diagnose without three-dimensional imaging (Fig. 140.15) and centerline measurement.

Differential Diagnosis

Because of the early age of appearance of dramatic pathology, vascular-type EDS is often considered along with LDS. It could not be more critical to differentiate the two, either by clinical examination to determine the LDS triad or by biochemical testing to confirm EDS IV, because surgical management and tissue fragility are dramatically more challenging in patients with EDS IV than in those with LDS.

Selection of Treatment

Risk assessment for prophylactic repair in patients with LDS must account for the aggressive nature of the aneurysms in this disorder. In adults, aneurysms of the thoracoabdominal and infrarenal aorta are repaired when they are 4.0 cm or greater. A new diagnosis of LDS should prompt a head-to-toe computed tomography or magnetic resonance imaging study to determine the presence of arterial pathology outside the aortic root (Fig. 140.16).[77] Because involvement of the supra-aortic trunks and vertebral vessels is not uncommon, surgical exposure may be difficult, and embolization approaches should be considered.

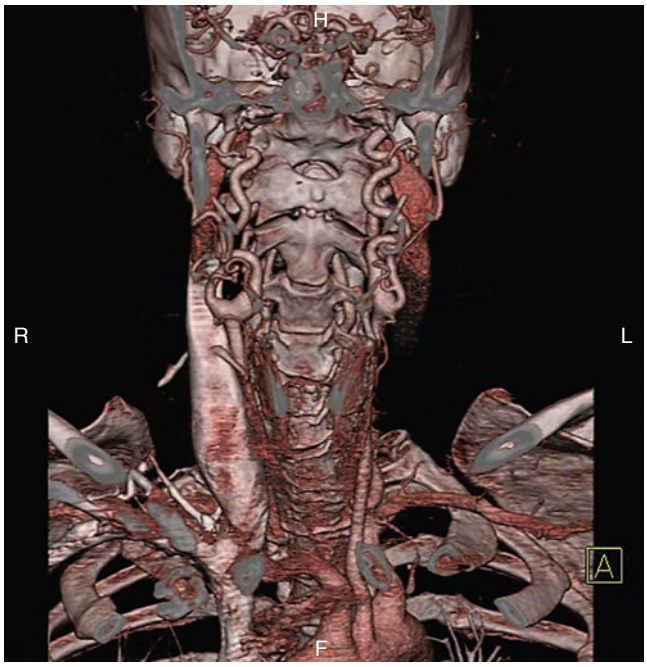

Figure 140.15 Bilateral carotid and vertebral arterial tortuosity is a common peripheral vascular finding in patients with Loeys-Dietz syndrome.

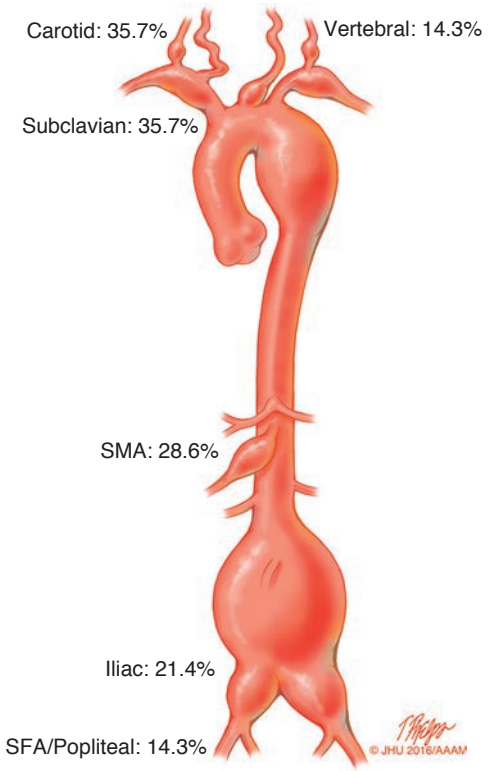

Figure 140.16 Vascular involvement of the supra-aortic branches and entire aorta is common in patients with Loeys-Dietz syndrome. *SMA,* Superior mesenteric artery. (From Beaulieu R, Lue J, Ehlert BA, Grimm JC, Hicks CW, Black JH. Surgical management of peripheral vascular manifestations of Loeys-Dietz syndrome. *Ann Vasc Surg.* 2016;38:10–16.)

Given the widespread involvement of the arterial pathology in this disorder, multiple operations or interventions in a single patient are not uncommon.[78,79]

Medical Treatment

Current recommendations for medical management and surveillance in LDS are predicated on the beta-blockade regimen recommended for patients with MFS, with the threshold for repair being more aggressive in LDS. Nonetheless, the pathophysiologic mechanism of increased TGF-β activity in the vessel wall compels some clinicians to initiate losartan therapy for the disease on the basis of the mechanisms demonstrated in the pathophysiology of MFS. However, randomized trials for this therapy are lacking, and preliminary data for losartan therapy are not conclusive to date. Lifestyle modifications should also restrict "burst" activity, as in MFS restrictions.[35]

Surgical Treatment

Early results after surgical treatment of aneurysm in LDS are now emerging because of the characterization of clinical and genetic features specific to the disease. Tissue handling and aortic anastomoses are favorable, and a small series of aortic root replacement in adults and children demonstrated no operative mortality, although 3 of 21 patients died in follow-up of thoracic aortic (n = 2) and abdominal aortic (n = 1) rupture.[78,79] In the accumulated experience at Johns Hopkins, patients returned to surgery for descending thoracic aortic replacement after previous ascending aortic aneurysm repair or valve-sparing aortic root aneurysm repair. Three of these patients returned thereafter with patch aneurysms after previous thoracoabdominal repairs and were confirmed as having LDS on subsequent *TGFBR* testing. As in MFS, this limited experience suggests that inclusion patch size should be limited or preferably avoided by direct anastomosis to the renal and visceral origins with prefabricated, branched Dacron grafts (Fig. 140.17) to the renal and visceral vessels.[78] On the basis of experience in the aortic root with premature rupture at small diameters, a general recommendation for repair of any aortic segment in adults would be 4 to 5 cm or growth of the aneurysm more than 0.5 cm in 1 year.[79] Recommendations for repair of peripheral aneurysms in LDS may be dependent on the patient's age, body size, and history, with rate of growth factoring into the decision, thus making regular surveillance with high-quality imaging critical.[79] Vessel tortuosity may also be progressive, even though arterial dissection or degeneration in the vascular "hairpins" has not been seen.

FAMILIAL THORACIC AORTIC ANEURYSM AND DISSECTION

Although it has been recognized that TAAD occurs in individuals with known genetic syndromes, a genetic basis for patients with TAAD who do not have a defined connective tissue disease has been investigated. These patients typically exhibit minimal or no outward anthropometric evidence of MFS, EDS IV, or LDS

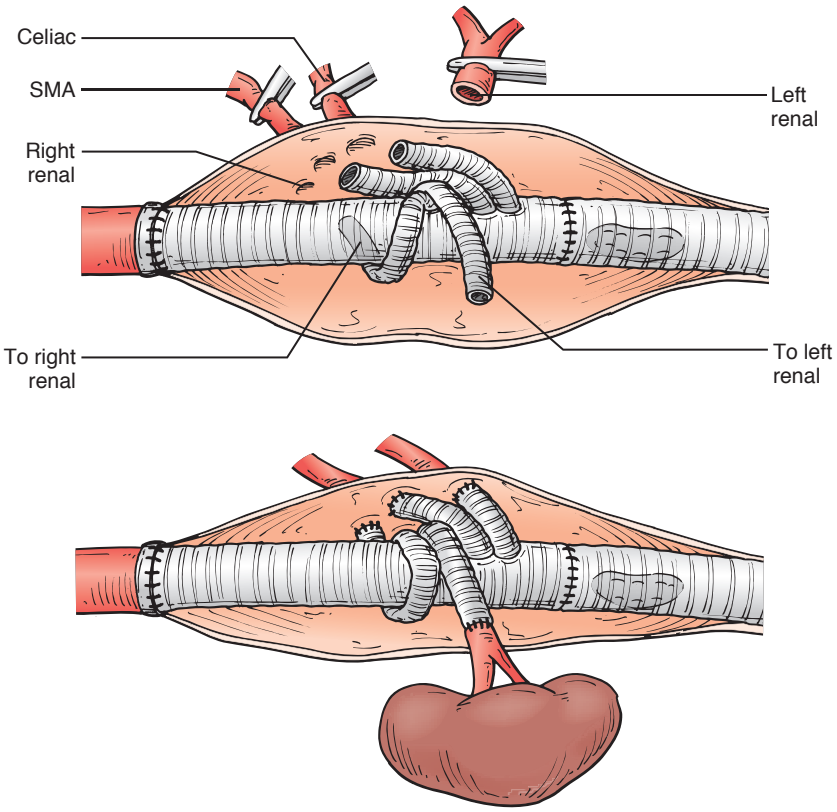

Figure 140.17 Technique for thoracoabdominal aortic reconstruction in patients with connective tissue disorder. Individual branch grafts are anastomosed in the visceral and renal origins, thus avoiding any late inclusion patch aneurysms. The 360-degree wrap helps reduce kinking of short direct branches as the retroperitoneum is closed. *SMA,* Superior mesenteric artery.

yet often relate an impressive history of aortic catastrophe in antecedents. Familial studies suggest that 11% to 19% of all nonsyndromic patients with TAAD have a first-degree relative with the disorder.[80,81] Pedigree analysis suggests that familial TAAD is inherited as a predominantly autosomal dominant disorder with decreased penetrance and variable expression that yields considerable clinical heterogeneity.[82] Genetic mapping of loci in familial TAAD has provided new insight into the pathogenesis of aneurysms throughout the aorta.

Pathogenesis

Five loci have been mapped for familial TAAD to date, including three identified genes. Despite locus heterogeneity, the final common pathologic change in the aortic wall is medial degeneration.[83,84] Disarray of smooth muscle cells and the accumulation of proteoglycan are also typically present. The first locus mapped for familial TAAD was the *TAAD1* locus at 5q13-14.[84] The initial genetic screen identified the location of the defective gene by using two families with similar phenotype for mapping. Subsequent to this mapping, 15 other families with familial TAAD patterning were found to carry the same genetic defect, which was segregated as an autosomal dominant disease. In families with this gene, women seemed to be less affected, thus suggesting reduced penetrance of expresssion.[85] Involvement of the ascending aorta is the primary finding.[84]

Alpha-actin mutations have been discovered to cause 14% of cases of familial TAAD.[86] The actin proteins are highly conserved and are critical cytoskeletal elements. Aortic tissue demonstrates cystic medial degeneration with focal areas of marked vascular smooth muscle proliferation. Interestingly, familial TAAD patients with *ACTA2* mutations are also noted to have significant livedo reticularis, a physical finding not encountered in the other connective tissue diseases. The overall penetrance to express aneurysm or dissection in individuals with familial TAAD and *ACTA2* mutations was low (0.48) and did not change with age. This fact distinguishes *ACTA2* mutations from other genes in familial TAAD, in which penetrance is clearly age-related.[86]

Fundamentally, the recognition of these local proteins and the critical role of maintenance of the extracellular matrix highlights the fact that aortic disease is a very local, not global issue. Research into defective mechanosensing by these contractile elements may provide valuable insight into why the aortic wall becomes vulnerable to aneurysm and dissection.[87,88]

Clinical Manifestations

Patients with familial TAAD are seen at a younger age than those with sporadic thoracic aortic aneurysms (mean age, 58.2 vs. 65.7 years), thus suggesting a more aggressive clinical entity.[80] In familial TAAD, thoracic aneurysms are the most common

(66%), followed by AAAs (25%) and cerebral aneurysms (8% to 10%).[80] Although the ascending aorta is more commonly affected by aneurysm (82%) than by dissection (18%), an equal distribution of aortic dissections and aneurysms is observed in the descending thoracic aorta (50% each) in affected individuals.

Selection of Treatment

Selection of treatment for patients with familial TAAD is complicated by the variable penetrance and expressivity of the disorder and the lack of an established genotype-phenotype correlation. In some families, the clinical history may suggest aortic catastrophe at very minimal aortic diameter dilatation, and treatment thresholds should be considered in the context of the pedigree history. For patients with a minimal contributory family history, treatment recommendations should follow typical sporadic thresholds—of 6.0 cm for thoracic aortic aneurysms and 5.5 cm for AAAs. Thoracic aortic growth rates in familial TAAD are comparatively higher than those of sporadic aneurysms, on average 0.21 versus 0.16 cm per year, respectively.[80] Endovascular stent-grafting approaches have not been reported in familial TAAD, but as in other connective tissue diseases, concerns about the inherent weakness and fragility of the aortic wall are paramount. Consensus on stent-graft therapy for patients with familial TAAD is not available, but one should follow the previous documents advising against such approaches for connective tissue diseases.[50]

Raynaud's phenomenon (RP) was first described by Maurice Raynaud (1834–1881) in 1862 when he reported 25 patients with intermittent digital ischemia and recognized the relationship of local cold and emotional stress in the causation of the episodes.[1] Raynaud's is an exaggeration of the normal physiologic response, which is defined as episodic pallor or cyanosis of the fingers caused by vasoconstriction of small digital arteries or arterioles occurring in response to cold or emotional stress. Although this term typically applies to the fingers, the toes can also be affected. The hallmark of RP is the change in skin temperature and color brought on by exposure to cold. A typical vasospastic attack is characterized by the sudden onset of pallor of part or all of one or more digits. Cyanosis follows as static blood in the capillaries becomes desaturated. The attack subsides with the return of arterial inflow, and postischemic vasodilatation results in hyperemia and rubor of the skin (Figs. 141.1 and 141.2).

Raynaud's through the years has been described as both a disease and phenomenon. Early literature referred to Raynaud's as "Raynaud's disease" almost exclusively until the 1940s. The nomenclature "Raynaud's phenomenon" started appearing in the literature soon thereafter. People have differentiated Raynaud disease, which is primary Raynaud's, versus Raynaud phenomenon, which is secondary or associated with other diseases. This nomenclature can be confusing, as many patients who start out with primary Raynaud's will develop associated connective tissue disorders over time. We have preferred to refer to all people with this condition as having Raynaud's syndrome.

RP consists of two sub-types: primary and secondary RP. Primary Raynaud's phenomenon (PRP) is the most common and is the idiopathic form. Secondary Raynaud's phenomenon (SRP) is associated with an underlying disease process, such as systemic sclerosis, rheumatoid arthritis, or other connective tissue disease (CTDs). Primary Raynaud's is considered to be a benign process and is not associated with structural vascular change. In contrast, patients with secondary Raynaud's have some degree of fixed vascular obstruction to blood flow, which decreases the threshold for cold-induced vasospasm. This can progress to digital ulceration, scarring, or gangrene.

Figure 141.1 Palmer view of the hands of a patient with a typical example of Raynaud's phenomenon. Note that attacks of digital vasospasm cause well-demarcated pallor affecting one or more fingers brought on by exposure to cold or emotional stress.

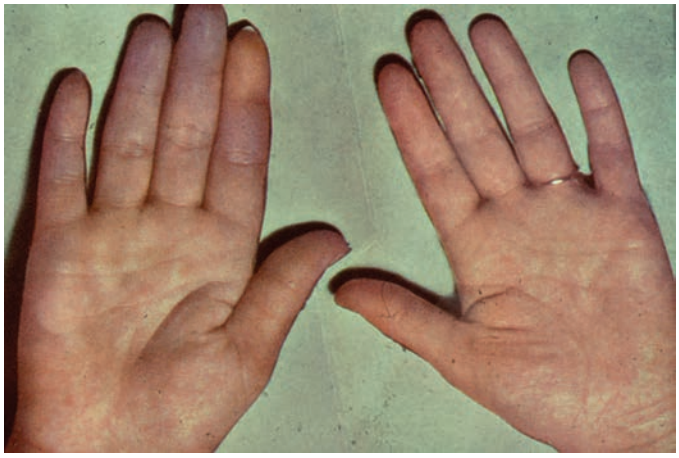

Figure 141.2 Palmer view of the hands of a patient with Raynaud's phenomenon demonstrating both pallor and cyanosis in multiple fingers.

EPIDEMIOLOGY

Prevalence of RP in the general population varies greatly with climate and ethnic origin. Several epidemiologic studies investigating disease prevalence have been performed, primarily in populations in colder climates. Overall estimates of disease prevalence in the general population range from 3.3% to 22%. Women are also more commonly affected than men, with a prevalence of 0.5% to 8.3% in men and 2.5% to 21% in women.[2-6] Two longitudinal population based studies have been performed to determine the incidence of PRP. In a 14-year study in a community in southern France, the annual incidence of new case of PRP was 0.25%.[2] In addition, similar findings were noted in the epidemiologic analysis of the Framingham off-spring study cohort. Over a 7-year period, the incidence of RP was 2.2% in women and 1.5% in men.[6]

Figure 141.3 Normal hand arterial anatomy. *1*, radial artery; *2*, Ulnar artery; *3*, deep palmer arch; *4*, common digital (metacarpal) artery; *5*, proper digital artery.

NORMAL ARTERIAL FLOW TO THE HAND

Circulation in the hand is complex with frequent anatomic variants. The deep and superficial arches supply the metacarpal arteries and in turn the proper digital arteries (Fig. 141.3). In most patients, branches of both the deep and superficial arches provide blood flow to all five fingers, and the two palmar arches provide important collateral flow between the radial and ulnar systems.[7] The superficial arch is incomplete in 21.5% of people.[8,9] Severe digital ischemia can occur with occlusion of the radial or ulnar artery and an incomplete superficial arch.

The metacarpal arteries in the palm originate from the superficial arch and provide blood flow to the digits. At the web space, the common digital (metacarpal) arteries branch to supply the proper digital arteries that run the length of each finger. In at least 86% of extremities, all five digits are supplied by arteries from both the deep and superficial arches.[7] Each finger has two digital arteries, which is important in preventing critical ischemia if one digital artery becomes occluded. The end of the finger is highly vascular with a dense network of blood vessels in the pulp of the fingers.

REGULATION OF BLOOD FLOW IN THE DIGITS

Blood flow in the digits is highly variable and can range from less than 1 mL/min per 100 L of tissue to 180 mL/min.[10] Blood flow to the skin of the digits has two functions, nutritional and thermoregulatory. Approximately 80% to 90% of blood flow through the digits is controlled by thermoregulatory mechanisms and serves an important role in controlling body temperature.[11] Blood vessels that are superficially located in the skin dilate to radiate excess heat to the environment, and this reduces body core temperature. In response to cold, these arteries constrict to decrease blood flow and conserve body heat.

Maximum vasoconstriction in response to cold occurs at 10°C to 20°C. At lower temperatures, cold-induced vasodilatation results in slight reopening of arteries to allow a trickle of blood

into the digits.[12] With cold exposure, there is a regular rhythmic fluctuation in finger flow caused by periods of vasoconstriction and vasodilatation in the fingers every 30 seconds to 2 minutes.[13] Other investigators have found similar rhythmic fluctuations in finger flow with a frequency of 5 to 10 per minute.[14] These alternating periods of vasoconstriction and dilatation have been called the hunting response.[15] This cold induced vasodilatation, which protects the fingers from freezing in a cold environment, is impaired in those with SRP because of the presence of occlusive arterial disease.

PATHOGENESIS

The exact pathogenesis of RP is unknown. Originally, Raynaud proposed that hyperactivity of the sympathetic nervous system was the cause. Lewis in 1929, disproved this theory by demonstrating that blockade of digital nerve conduction did not prevent vasospasm. Lewis in turn, theorized that "local vascular fault" in the digital arteries causing increased sensitivity of the blood vessel to cold led RP.[16] It is most likely a multifactorial problem involving a combination of vascular, neural, and humoral factors (Fig. 141.4).[17]

Vascular

Impaired Vasodilatation

Vascular endothelial cells synthesize several vasodilating and vasoconstricting substances.[18-21] Endothelial-derived relaxing factors include nitric oxide (NO), prostacyclin, adenosine triphosphate (ATP), and bradykinin. NO is a potent vasodilator synthesized from amino acid L-arginine by the activity of the enzyme NO synthase. NO diffuses from the endothelium into smooth muscle, where it activates guanylate cyclase to increase intracellular guanosine monophosphate (cGMP), which leads to vascular relaxation. Decreased NO formation can be found in patients with both systemic sclerosis and RP.[22-25] S-nitrosothiols are bioactive forms of NO that are involved in cell signaling and have been shown to be decreased in patients with systemic sclerosis and RP.[26] Additionally, decreased levels of asymmetric dimethyl-arginine, an inhibitor of endothelial NO synthase, has also been demonstrated in patients with SRP. A deficiency of one or more of these factors could potentially increase responsiveness of digital arteries to vasoconstrictive influences and increase the likelihood of vasospasm.

Endothelial dysfunction has been shown to be an important cause of RP in numerous studies. In one study, patients underwent a series of sequential infusions with acetylcholine, prostacyclin, glyceryl trinitrate, and L-arginine. Patients with a history of RP had a greater digital artery vasodilator response to intra-arterial glyceryl trinitrate (an endothelium-independent vasodilator), whereas in control patients, the difference in response was less pronounced.[27]

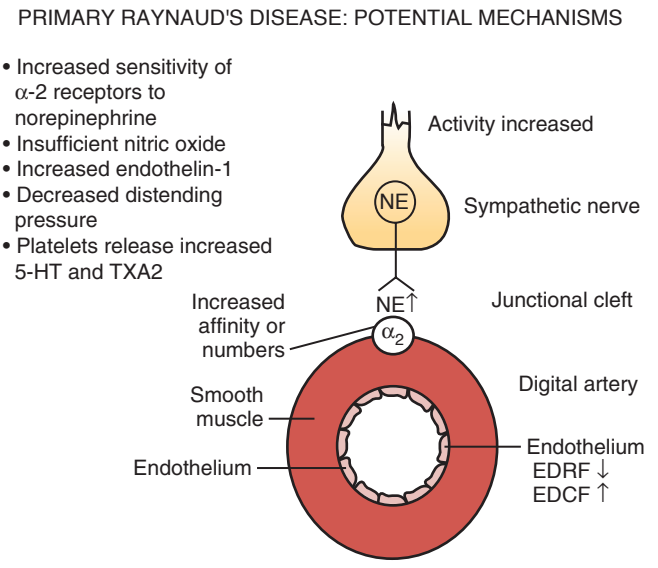

Figure 141.4 There are many potential causes of vasospastic attacks in primary Raynaud's phenomenon. Norepinephrine *(NE)* released from the sympathetic nerve ending acts on the post junctional α-2 receptor located on vascular smooth muscle. Local cooling enhances the response of the α-2 receptor, thereby causing increased arterial contraction. Endothelial dysfunction may lead to insufficient nitric oxide or increased endothelin-1, which changes the balance toward arterial constriction. Activated platelets release thromboxane A2 *(TXA2)* and serotonin (5-hydroxytryptamine *[5-HT]*), which may aggravate arterial vasospasm. A decrease in intraluminal distending pressure may decrease the "critical dosing pressure" threshold and result in a vasospastic attack. *EDCF*, Endothelium-derived contracting factor; *EDRF*, endothelium-derived relaxing factor.

Increased Vasoconstriction

The endothelial cell also produces factors that cause vessel contraction, such as endothelin-1 (ET-1), which is a potent vasoconstrictor, as well as a promoter of fibroblast and smooth muscle proliferation. Plasma ET-1 levels become elevated in response to cold, which may suggest an association between the rise in ET-1 levels and cold induced vasoconstriction.[28] A threefold rise in ET-1 concentration has been reported in subjects with PRP. However, more recent literature has challenged the relationship of ET-1 and RP. Smyth and colleagues found that increases in ET-1 levels in patient with both primary RP and scleroderma were similar to control subjects with cooling induced vasospasm.[29]

Angiotensin is another endogenous peptide with vasoconstrictive effects that has been implicated in the mechanism of vasospasm. The exact mechanism of involvement of angiotensin in RP remains unclear. Increased levels of angiotensin II have been shown in patients with scleroderma.[30] However, activation of the renin-angiotensin system has not been demonstrated in PRP.[31]

Neural Factors

More recently, the focus of RP pathophysiology has been on alterations in peripheral adrenoceptor activity. Early laboratory studies showed a marked reduction in cold-induced digital arterial vasospasm after the intra-arterial administration of reserpine.[32] This suggested that patients with RP may possess abnormal adrenergic receptors that become increasingly sensitive to stimulation after exposure to cold.

Characterization of α1- and α2-adrenoceptors has led to an improved understanding of the mechanisms of RP. Sympathetic nerves can respond to cold and emotional stress by releasing

neurotransmitters such as norepinephrine, which act on the postsynaptic α2-receptor and cause vascular smooth muscle contraction. Cold also causes increased affinity of the α2 receptor for norepinephrine, which results in enhanced smooth muscle contraction in the cold.[33-37] The initiation of the α2 adrenoceptor to cold is due to the activation of Rho-protein kinase signaling.[36,38,39]

Freedman and colleagues studied the effects of brachial artery infusions of an alpha-1, an alpha-2 antagonist, or both while vasospastic attacks were induced by cooling in 23 patients with idiopathic Raynaud's.[40] They found that in patients who were infused with yohimbine (α2 antagonist), there were significantly fewer attacks compared to the non-infused hand and compared to the group receiving prazosin (α1 antagonist) alone, demonstrating the importance of a2 adrenoceptors. However, in another randomized, controlled trial to evaluate the efficacy of a high potency α2c-adrenoceptor antagonist (ORM-12741) in patients with systemic sclerosis, subjects randomized to ORM-12741 had a longer time to temperature recovery time. These mixed results show continued investigations regarding the effect of α-adrenoceptors in the pathophysiology of Raynaud's and the therapeutic potential of adrenoceptor antagonist are needed.

Humoral Factors

Many circulating humoral factors have been implicated in the pathogenesis of RS. These include hormonal, genetic, platelet activation, and fibrinolysis. RP is more frequent in women than men and tends to be more frequent and severe between menarche and menopause. Investigators have demonstrated elevated sympathetic tone and decreased basal cutaneous circulation in women in comparison to men.[41] The role of estrogen is less clear. In human cell culture and in mouse models, estrogen has been demonstrated to increase expression of α-2 adrenoceptors.[42] Approximately one-quarter of patients with PRP have a family history of Raynaud's in a first-degree relative.[43] However, it has been difficult to differentiate genetic factors from shared environmental causes. Although a number of chromosomal regions have been evaluated in genomic studies, no significant differences in allelic frequency have been directed between patients with RP and normal controls.

Activation of platelets and increased levels of serotonin in the plasma have been detected in patients with RP.[44] Elevated circulating levels of activated platelet products, such as thromboxane and B-thromboglobulin, have been induced by cooling of subjects with RP. The relationship between serotonin elevations in the pathogenesis of RP is less clear and remains to be defined.

Abnormalities of fibrinolysis have been primarily implicated in patients with SRP, and elevated levels of tissue plasminogen activator inhibitor have been shown in patients with scleroderma.[45] Impairment in thrombolysis is also thought to predispose to fibrin deposition and vascular obstruction.[22]

Risk Factors

Many factors have been found to be associated with RP. These include genetic factors, such as gender; occupational; and drug exposure. RP predominantly affects young women, and has a male-female ratio close to 1:1.6.[46] The usual age of onset ranges from 11 to 45, while older patients with RP are more likely to have a contributing underlying arterial disease. The relationship between smoking and RP is less clear. In a study of the Framingham heart study offspring cohort, no association was found between smoking and RS in women; however, there was a significant association in men, particularly in those with other cardiovascular risk factors, with an odds ratio of 2.6.[47] Similar to smoking, the relationship between alcohol and RP remains to be clarified. A recent systematic review and meta-analysis of observational studies reported smoking as a major risk factor with an odds ratio of 1.27, while alcohol had an odds ratio of 0.33.[4]

Vibration-induced RP was first recognized in 1918 by Hamilton,[48] and it has been estimated that as many as 1.2 million American workers involved in a variety of occupations using vibrating tools are now at risk.[49] Chronic vibration appears to cause structural damage to the arterial wall with hypertrophy of the intima and media. Vibration is believed to cause sympathetic overactivity, endothelial damage, and smooth muscle hypertrophy, leading to vibration-induced vasospasm.[50-52] The prognosis may be poor because of the development of digital artery obstruction after prolonged exposure to vibration.

Several drugs have been implicated in the development of RP. For example, the incidence of RP in hypertensive patients taking beta blockers was 40% in a Scandinavian study in which patients responded to a questionnaire.[53] Vasospasm occurs with both selective and nonselective beta-blockers. Despite this, many patients with RP tolerate beta blockers, and many studies show no adverse effects on digital blood flow. Therefore, beta blockers are not contraindicated in patients with RP. Other drugs associated with RP include chemotherapeutic agents such as vinblastine and bleomycin,[54] bromocriptine, amphetamine, cocaine, and ergot preparations used for migraine headaches, which are a well-known cause of severe extremity vasospasm and ischemia.[55]

Associated Diseases

Secondary causes of RP are typically associated with some degree of fixed digital arterial obstruction. When the artery is narrowed because of preexisting large- or small-vessel disease, there is a lower "critical closing pressure," and a relatively normal vasoconstrictor response to cold or other stimuli will result in temporary closure of the vessel. RP is common in CTDs such as scleroderma, where intimal hyperplasia, thrombosis, and fibrosis result in luminal narrowing of the digital arteries, but this process may also involve the more proximal arteries of the hand and forearm.

The list of secondary causes of RP is extensive (Box 141.1). In a large series of 1,039 patients with RP referred to the Oregon Health and Science University from 1970 to 1995, more than half had primary vasospasm with no identifiable disease.[56] In those with associated abnormalities, the most common underlying disorder was CTD, which accounted for 27% of cases of RP. Scleroderma was the most likely CTD, followed

BOX 141.1 Conditions Associated With Secondary Raynaud's Phenomenon

Connective Tissue Diseases

- Progressive systemic sclerosis (scleroderma)
- Systemic lupus erythematosus
- Rheumatoid arthritis
- Sjögren's syndrome
- Mixed connective tissue disease
- Overlap connective tissue disease
- Dermatomyositis and polymyositis
- Vasculitis (small, medium-sized vessels)

Occlusive Arterial Disease

- Atherosclerosis
- Thromboangiitis obliterans (Buerger's disease)
- Giant cell arteritis
- Arterial emboli (cardiac and peripheral)
- Thoracic outlet syndrome

Occupational Arterial Disease

- Hypothenar hammer syndrome
- Vibration induced

Drug-Induced Vasospasm

- β-Adrenergic blocking drugs
- Vasopressors
- Ergot
- Cocaine
- Amphetamines
- Vinblastine/bleomycin

Myeloproliferative and Hematologic Disease

- Polycythemia rubra vera
- Thrombocytosis
- Cold agglutinins
- Cryoglobulinemia
- Paraproteinemia

Malignancy

- Multiple myeloma
- Leukemia
- Adenocarcinoma
- Astrocytoma

Infection

- Hepatitis B and C antigenemia
- Parvovirus
- Purpura fulminans

by undifferentiated and mixed CTD. Atherosclerosis was less common, followed by "hypersensitivity angitis," Buerger's disease, cancer, and vibration-induced white finger. A wide range of cancers have been associated with SRP. The most common associated malignancies are adenocarcinomas and hematologic malignancies, and possible mechanisms of arterial disease caused by malignancy include coagulopathy, cryoglobulinemia, or small-vessel vasculitis (Fig. 141.5).

CLINICAL FINDINGS

The diagnosis of RP is made mainly by clinical findings. The typical patient describes attacks of pallor involving part or all

Figure 141.5 Paraneoplastic vasculitis with gangrene of several digits in a patient in whom small cell lung cancer was recently diagnosed. The digital ischemia improved with chemotherapy.

of one or many fingers brought on by cold exposure with full and rapid recovery on rewarming of the digits. The episodes are self-limited and may last from less than a minute to generally not more than 10 to 20 minutes. Pallor may involve part of the digit or the entire finger. Vasospastic attacks most commonly involve the fingers but can affect both the fingers and toes in up to a third of patients. For reasons that have never been clarified, the thumbs are frequently spared. Thumb involvement generally portends secondary RP.

Attacks may occur several times a day to several times a week. In addition, episodes of vasospasm are more common in the cooler winter months, and some patients have few or no attacks during the summer. Pain is not usually a feature during the pallor or cyanotic phase of PRP. The absence of pain and lack of tissue damage during arterial vasospasm may be due to concomitant cold-induced intermittent vasodilatation allowing just enough blood flow to protect the fingers from severe ischemia or freezing. Other vascular beds prone to vasospasm include coronary and cerebral vessels. Patients with Prinzmetal's angina and migraine are more likely to have RP, suggesting a common factor causing generalized vasospasm.[57]

In contrast, patients with underlying occlusive disease have little or no reserve and cannot increase digital blood flow, with the result that ischemic damage can occur during exposure to cold. Patients with SRP are more likely to complain of digital pain on rewarming of cold fingers, because the blood flow cannot increase to match the increased metabolic activity of the finger.

DIAGNOSIS

Although many tests have been used for the diagnosis of RP, no consensus exists on the optimal battery of clinical and diagnostic tests. A suggested list of criteria for the diagnosis of primary RP and differentiation of primary from SRP is as follows: (1) vasospastic attacks precipitated by cold or emotional stress, (2) attacks involving both hands, asynchronous and/or asymmetric, (3) absence of tissue necrosis or gangrene, (4) no history

or physical findings suggestive of a secondary cause, (5) normal nail fold capillaries, and (6) negative serologic findings, particularly a negative test or low titer antinuclear antibodies (ANA).[58-61]

Physical Examination

The diagnosis of RP is primarily made by history and physical examination. The physical examination in patients with suspected RP is often normal. Nonetheless, determination of primary or secondary disease is aided by a focused physical examination. The vascular examination should determine the presence of large-, medium-, or small-vessel occlusive disease and should detect signs of a CTD.

The hand and fingers should be examined for evidence of skin thinning, tightening, sclerodactyly, or telangiectasia's, all of which may suggest associated autoimmune disease (Fig. 141.6). The skin of the hand and fingers should be inspected for ulceration or hyperkeratotic areas on the fingertips suggestive of healed ulceration (Fig. 141.7). Splinter hemorrhages under the nails may be an indicator of distal atheroemboli, although this finding may be a normal finding in manual workers (Fig. 141.8).

Pulse examination should include palpation of the subclavian, brachial, radial, and ulnar arteries. However, a palpable radial or ulnar pulse at the wrist does not mean that arteries are patent into the hand. The most common site of blockage of the ulnar artery is at the hypothenar eminence where it crosses the hook of hamate. The Allen test should be performed in every patient with suspected RP to detect the presence of radial or ulnar artery occlusion and to test for completeness of the ulnar arch.

Vascular Laboratory Evaluation

The noninvasive vascular laboratory is an important adjunct to the office-based clinical assessment of patients with RP.[62] Vascular laboratory testing can assist in differentiating between fixed arterial obstruction and pure vasospasm and can provide assessment of the location and severity of the circulatory impairment. However, the diagnosis of RP should not be made based on any laboratory test,[63] and the vascular laboratory should not take the place of a good history and physical examination.[7]

The most useful noninvasive laboratory tests for RS include room-temperature evaluation of arm, hand, and digital arterial perfusion, supplemented by measurement of digital temperature, systolic blood pressure, and laser Doppler flow of the fingers before and after local digital cooling.

Figure 141.6 Raynaud's phenomenon secondary to limited systemic sclerosis in a young male patient. Cyanotic discoloration is apparent on the left second and third fingers, and the diagnosis of scleroderma can be made by physical examination. There is resorption with healed ulcerations of several fingertips.

Figure 141.7 Advanced scleroderma with flexion contracture of the fingers and ulceration of multiple fingertips. Even with the best wound care, these ulcers can be difficult to heal.

Figure 141.8 Splinter hemorrhages under the nails may be a normal finding with local trauma but can also be an important indicator of distal atheroembolism, as seen in the patient. Note the splinter hemorrhages under the nail and subtle skin mottling consistent with microembolization.

Segmental Pressure Measurements and Duplex Ultrasonography

To evaluate for large-vessel occlusive arterial disease, segmental blood pressure measurements in the upper extremity can be obtained. Pneumatic cuffs are placed on the brachial, upper elbow, and wrist levels, and systolic blood pressure is measured. A pressure differential exceeding 10 mm Hg between levels may be significant and indicative of proximal occlusive disease.

Duplex scanning is useful for evaluation of proximal upper extremity arterial obstruction and aneurysmal disease. Traditionally, its role in the diagnosis of RP has been limited; however, power Doppler has emerged as a means of evaluating the digital arteries for the diagnosis of RP. Lee and colleagues compared power Doppler with a 10-MHz scan head focused at 5 mm with nail fold capillaroscopy for the diagnosis of primary and secondary RP.[64] The investigators could correctly diagnose RP in all cases and were able to correctly classify patients as having primary or secondary RP in 89% of cases.

Finger Systolic Blood Pressure

Finger systolic pressure is measured by applying small digital cuffs to the proximal part of the finger. The cuff is inflated above systolic blood pressure to occlude the digital artery. As the cuff is slowly deflated, the pulse returns to the distal part of the finger, and systolic blood pressure can be assessed by pulse-volume recording, strain-gauge plethysmography, or photo-plethysmography.[65,66] Decreased systolic pressure usually indicates fixed arterial occlusive disease in that finger; however, the range of normal digital pressure is variable and is influenced by temperature. A difference of more than 15 mm Hg between fingers or an absolute finger systolic blood pressure of less than 70 mm Hg may indicate occlusive disease.[67]

Evaluation of digital plethysmographic waveforms is also useful, particularly identifying obstructive RP. For example, patients with obstructive RP have blunted waveforms, whereas patients with vasospastic RP have either normal waveforms or a "peaked pulse." The peaked pulse pattern, first described by Sumner and Strandness, appears to reflect increased vasospastic arterial resistance (Fig. 141.9A and B).[68]

Cold Challenge Testing

The first vascular laboratory test used widely for the objective diagnosis of RP was the measurement of recovery in fingertip temperature after digital exposure to ice water.[69] There are many variations of the cold immersion test with various immersion times and temperatures. Baseline digital temperatures are recorded with a temperature probe at the end of the finger pulp. The hands are then immersed in cold water at 4°C for 20 seconds. The hands are dried, and digital skin temperature is recorded for each finger as the hands and fingers gradually warm to ambient room temperature. The length of time that it takes for the hands to rewarm to baseline is noted by recording finger temperatures or laser Doppler flux at 5-minute intervals until recovery of pre-immersion temperatures. A delay in rewarming suggests a tendency for vasospasm. Patients with RP typically take more than 10 minutes and sometimes 30 minutes or longer. However, although the ice water immersion test is 100% specific, it is only 50% sensitive and therefore is neither sufficiently accurate nor reproducible for routine clinical use.[70,71]

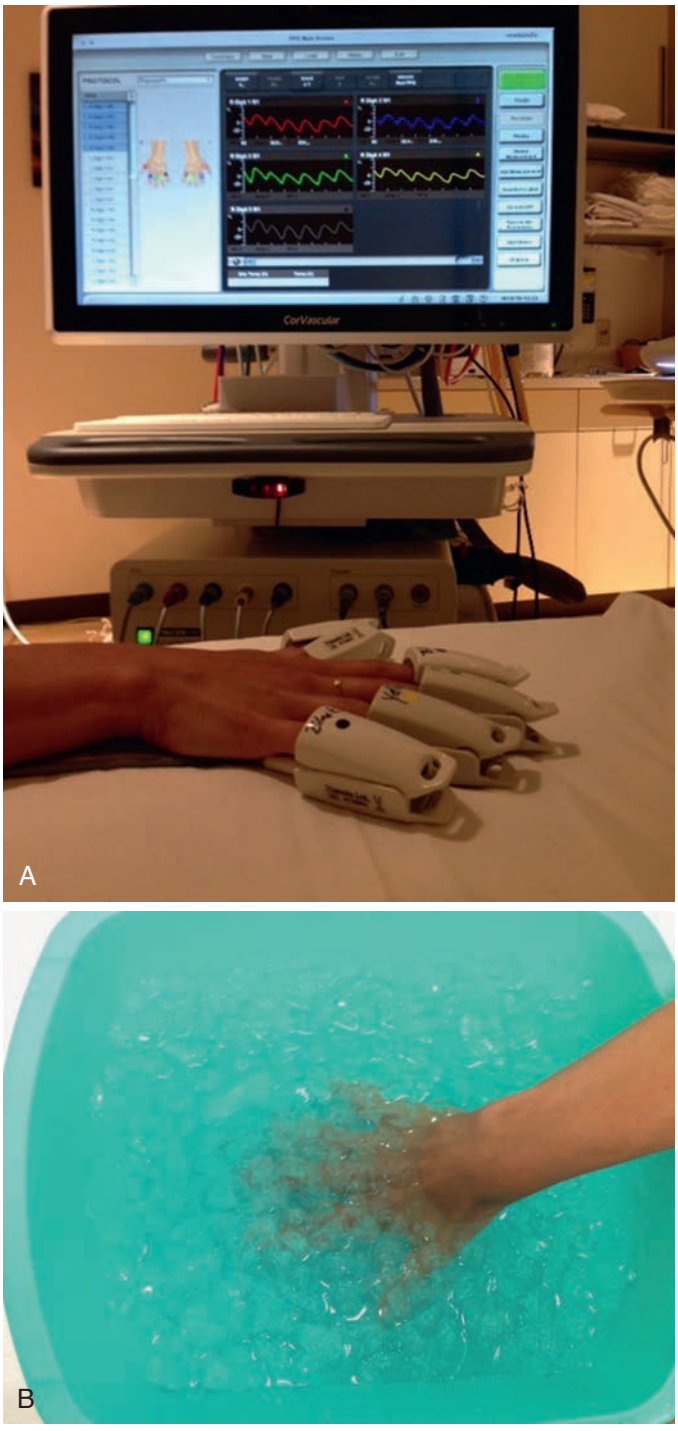

Figure 141.9 (A and B) Photoplethysmogram (PPG) may be completed as part of the work up for Raynaud's phenomenon. PPG's may be combined with a cold challenge. When completed together, a room temperature PPG is done, followed by submersion of the hands in ice cold water for 1 minute or as long as tolerated, then PPG's are done and recorded every minute thereafter until recovery is complete.

Nail Fold Capillary Microscopy

The superficial capillaries in the nail fold can be visualized with a low powered microscope or an ophthalmoscope at 40 diopters by applying a drop of immersion oil over the cuticle of the finger to make it translucent. Normal capillaries are seen as regularly spaced hairpin loops with a venous limb and an arterial limb. The arterial limb has a narrower diameter with more rapid flow, and the venous limb has a larger diameter with slower capillary flow.[7]

Abnormal capillaries are seen in scleroderma and mixed CTDs as enlarged, tortuous, and deformed or as loop dropout causing avascular areas.[72,73] The presence of abnormal nail folds in patients without CTD is a strong predictor of the subsequent development of CTD. With a mean follow-up of 6.5 years, Meli and colleagues demonstrated that 80% of patients with abnormal nail fold findings at the time of initial diagnosis of RS eventually developed CTD, primarily scleroderma, CREST, and mixed CTD. Thus, there may be significant prognostic utility in the use of nail fold capillaroscopy in the early phases of RS.[74]

Figure 141.10 A vascular mitten protects and maintains warmth of the hands. Patients with critical hand and finger ischemia can have further compromise in distal perfusion because of cool ambient room temperature causing vasoconstriction. A vascular mitten keeps the hands at body temperature and maximizes distal finger blood flow by avoiding cold-induced vasoconstriction.

Serologic Evaluation

Serologic studies may help confirm the diagnosis of CTD and are useful in screening for occult underlying CTD. Several screening tests can be done, and the most useful include ANA and rheumatoid factor (RF). ANA is present in 95% of patients with systemic sclerosis,[75] but they are not specific for scleroderma and can be present in several other CTDs. A positive ANA raises the suspicion for CTD but does not make the diagnosis. RF is a commonly used diagnostic marker for rheumatoid arthritis.[76]

TREATMENT

Treatment for RP varies greatly, and the natural history differs greatly between primary vasospastic and secondary obstructive causes. The approach to therapy must be individualized according to the patient's symptoms, the frequency of vasospastic attacks, the underlying disease, and the risk for development of ischemic ulceration, gangrene, or digital loss. For most patients with primary RP, there is no cure; however, several simple measures can be effective in reducing the frequency and duration of attacks.

Preventive measures consisting of education, reassurance, and avoidance of exposure to cold constitute the basis for most patients. Management principles can generally be considered in three groups: nonpharmacologic behavioral therapy, pharmacologic treatment, and interventional-surgical procedures. Connective tissue disorders associated with SRP are frequently managed with immunosuppression or immunomodulation.

Preventive Measures

Most patients with primary RP have only mild symptoms that do not require the use of vasodilatory medications. Primary RP is a benign disease, with few patients progressing to digital ulcers or tissue loss. In a longitudinal study from Oregon, digital ulcers occurred in 5% of patients in whom vasospastic RP was initially diagnosed when observed for more than 10 years.[56] These patients are best managed with a conservative program involving preventive measures, and education and reassurance is the mainstay of therapy.

Simple measures to maintain warmth and avoid cold are effective (Fig. 141.10). Ceramic-impregnated gloves that absorb ambient infrared light to generate heat resulted in significantly improved hand function and visual analog pain scores when compared with a placebo group wearing cotton gloves.[77] Situations likely to cause vasospasm should be avoided or minimized. Finally, avoiding agents that cause vasoconstriction, such as nicotine and vasoconstricting medications, is also an important aspect of therapy.[78,79]

Behavioral Therapies and Maneuvers

Temperature biofeedback is a type of mind/body therapy whereby patients are taught methods of self-regulation of skin temperature.[80] The primary goal is to teach methods of avoiding RP attacks; however, with training, individuals can learn to reverse the existing vasospasm. Temperature biofeedback has been studied in randomized trials with variable results. A recent meta-analysis suggests that biofeedback is not superior to placebo.[81] However, they also concluded that the literature is inconclusive, and more robust trials are needed to further evaluate complementary and alternative therapies.

Pharmacologic Therapy

Pharmacologic therapy is indicated in patients who have failed conservative therapy. Some patients will require medications only during the colder winter months. The goal of pharmacologic therapy is to decrease the frequency and severity of attacks

rather than cure the underlying disease, and medications may be useful for both primary and secondary RP. However, patients with secondary RP often have fixed obstructive arterial disease, and vasodilators are less effective or at times have no benefit at all.

A number of medications have been used for RP (Table 141.1). Choosing the best medication is difficult given the lack of large prospective, randomized, double-blind studies comparing the efficacy of different medications. There is also a significant placebo effect in published clinical trials ranging from 20% to 40%,[82] which needs to be considered when interpreting the results of uncontrolled trials. Additionally, most clinical trials rely on the patient's self-assessment of the frequency and severity of RP.

Calcium-Channel Blockers

Calcium-channel blockers are the most extensively researched medications and remain first-line therapy for RP. Nifedipine is considered by many to be the drug of first choice for RP. One multicenter, randomized controlled trial of 313 patients with primary RP treated with sustained-release nifedipine compared with placebo showed a 66% reduction in frequency in attacks.[83] In addition, a meta-analysis of 12 randomized, controlled trials demonstrated an overall reduction in severity of attacks graded on visual analog scale of 33%, with an average of 2.8 to 5.0 fever attacks per week in patients treated with nifedipine.[84] However, a recent Cochrane review found only moderate quality evidence showing that oral calcium channel blockers are minimally effective in the treatment of PRP as measured by frequency of attacks. Participants experienced 1.72 fewer attacks per week on calcium channel blockers compared to placebo,[85] but other calcium channel blockers may be used. Drugs in the dihydropyridine class are more potent vasodilators than the nondihydropyridine class, but they are more frequently associated with side effects.

Alpha Adrenergic Blockers

Sympathetic nerve simulation results in norepinephrine release, which acts on the α1 receptor located on vascular smooth muscle, causing vasoconstriction. This action is completely inhibited by α1-selective blockers. Prazosin is a selective α1 adrenergic antagonist that significantly reduces the number of attacks in both primary and secondary RP.[86] In a double-blind, placebo-controlled, crossover study of 24 patients, prazosin was reported superior to placebo in the treatment of RP. In contrast, the results for α-2 antagonist have been mixed. OPC-28326, a selective α2-antagonist, improved skin temperature recovery in patients with scleroderma compared to placebo.[87] However, more recently, ORM-12741, a α2c-adrenoceptor antagonist, was found to increase skin temperature recovery time.[88]

Prostaglandins and Analogues

Prostacyclins are vasodilators that have been used to treat critical digital ischemia secondary to fixed occlusive disease. Iloprost is a prostacyclin analogue reported to reduce the severity, frequency, and duration of RP attacks and promote healing of ischemic ulcers. Intravenous iloprost was directly compared with oral nifedipine in two randomized controlled trials. Forty-six patients with systemic sclerosis were randomized in one and 12 patients with systemic sclerosis in the other. Although medication regimen differed, both showed reduced mean number, duration, severity of RP attacks, and improved ulcer healing.[89,90] Hand temperature and blood flow increased with iloprost but not nifedipine.[89]

Phosphodiesterase Inhibitors

The phosphodiesterase type 5 (PDE5) inhibitors are selective inhibitors of cGMP-specific PDE5, which increase cGMP, resulting in enhanced cGMP-dependent micro- and macrovascular dilatation. In a placebo-controlled, double blind crossover trial comparing 4 weeks of therapy with sildenafil, 50 mg twice daily, versus placebo in 16 patients, the frequency of RP attacks was reduced by 33%, and the duration of attacks were reduced by 44% in the sildenafil group. Tadalafil and vardenafil have longer half-lives than sildenafil but have been less well studied in RP. Tadalafil has been shown to be efficacious in case series and small open-label pilot studies, randomized trials using tadalafil as monotherapy have not shown significant benefits in patients with SRP.[91] However, as combination therapy with other vasodilators, tadalafil use resulted in improved frequency and duration of attacks and ulcer healing.[92]

Endothelin Inhibitors

Endothelin is a potent endogenous vasoconstrictor. Bosentan is an endothelin receptor antagonist currently used to treat pulmonary hypertension. In the RAPIDS-2 trial, bosentan was shown to significantly decrease the incidence of new digital ulcers in patients with scleroderma, although there was no change in rates of ulcer healing, in pain, or in disability.[93]

Other Medications

Numerous other medications have been used in the treatment of RP with various results. Nitrates have been used in the treatment of RP as oral, topical, or intravenous preparations, but, in general, they are not first-line therapy. All forms are limited by side effects, particularly headaches and hypotension.

ACE inhibitors, angiotensin II receptor blockers, and serotonin reuptake inhibitors have all been used to treat RP. Captopril has been the most extensively used ACE inhibitor. A randomized controlled crossover trial of 15 subjects with primary RP, captopril caused a significant increase in cutaneous blood flow, but there was no change in frequency or severity of RP attacks.[94] Losartan, a angiotensin II receptor blocker, was found to be more effective than nifedipine in reducing the frequency and severity of vasospastic episodes in a randomized controlled trial in patients with PRP and those with SRP due to systemic sclerosis following 12 weeks of therapy.[95] Fluoxetine, a serotonin reuptake inhibitor, was shown to reduce the frequency and severity of attacks in both primary and secondary RP in a randomized cross-over trial with nifedipine (Fig. 141.11).[96]

Surgical Therapy

Surgical intervention tends to be reserved for patients who have failed conservative and pharmacologic therapy. Surgical therapies

TABLE 141.1 Medical Therapy for Raynaud's Phenomenon

Drug Class	Drug Names	Dosage	Results	Most Frequent Side Effects
Calcium channel blockers (dihydropyridine)	Nifedipine	10-30 mg PO qd-tid	33%-66% reduction in frequency and severity of attacks; most extensively studied medication	Hypotension, flushing, edema, palpitations, dizziness (similar for entire class of drugs)
	Nicardipine	20-50 mg PO bid	Mixed results compared with placebo	
	Amlodipine	10 mg PO qd	27% reduction in frequency of attacks	
	Felodipine	5-20 mg PO qd	Similar to nifedipine	
	Nisoldipine	5-10 mg PO qd	Mixed results improving severity and frequency of attacks	
Calcium channel blockers (non-dihydropyridine)	Diltiazem	30-120 mg PO tid	Some improvement but less efficacious than dihydropyridine class	Fewer side effects than dihydropyridine class
	Verapamil		No proven benefit	
Alpha 1 receptor antagonists	Prazosin	1 mg PO tid	1-2 fewer attacks per day, decreased duration; modest benefit in secondary RP	
	Terazosin	1 mg PO qhs	Not systematically studied	Orthostatic hypotension; palpitations
	Doxazosin	1 mg PO qhs		
Renin-angiotensin system mediators (ACE inhibitors)	Captopril	12.5-25 mg PO bid-tid	Improved finger blood flow; symptom relief mixed	Dry cough, headaches, fatigue, dizziness (similar for entire drug class)
	Enalopril	20 mg PO qd	Mixed results in clinical trials	
	Quinapril	80 mg PO qd	No clinical benefit	
Renin-angiotensin system mediators (angiotensin II receptor blockers)	Losartan	12.5-50 mg PO qd	Up to 50% reduction in severity and frequency of attacks	Dizziness
Serotonin reuptake inhibitors	Fluoxetine	20-40 mg PO qd	Significant decrease in severity and frequency of attacks vs. nifedipine	Headaches, nausea, palpitations, lethargy
Phosphodiesterase V inhibitors	Sildenafil	50 mg PO qd-bid Extended release 100-200 mg qd	Decreased duration and frequency of attacks; improvement of capillary blood flow; benefit primarily in secondary RP	Headache, flushing, nausea, muscle pain, dyspepsia, dizziness (similar for all drugs in this class)
	Tadalafil	20 mg every other day	Decreased frequency and duration of attacks and improved ulcer healing as add on therapy; less beneficial as monotherapy	
	Vardenafil	10 mg PO bid	Improved digital blood flow and symptoms in secondary RP	
Nitrates	Topical nitroglycerin (MQX-503)	0.5 gm of gel up to four times a day	Improved Raynaud Condition Score, no change in duration or frequency of attacks	Headache, upper respiratory tract infection; dizziness
Prostaglandins	Epoprostenol	1-2 ng/kg/min IV	Decreased severity of symptoms in patients with scleroderma and pulmonary hypertension	Flushing, headache, nausea, vomiting, hypotension
	Iloprost	0.5-2 ng/kg/min IV or 50 µm PO bid	IV form effective in ulcer healing and reducing symptoms; PO form not more effective than placebo	Headache, nausea, vomiting
Endothelin receptor antagonist	Bosentan	62.5 mg PO bid	Decreased new ulcer formation in patients with scleroderma. No effect on healing of existing ulcers	Elevated hepatic transaminases, peripheral edema

ACE, Angiotensin-converting enzyme; *bid*, twice a day; *IV*, intravenous; *PO*, orally; *qd*, once a day; *qhs*, every evening; *tid*, three times a day.

Figure 141.11 This patient was evaluated for acute ischemia of the fingertip. She was found to have positive antinuclear antibody and anticentromere antibody. An angiogram showed severe digital artery occlusive disease consistent with a connective tissue disease. Topical nitroglycerin ointment often fails to improve blood flow in the setting of critical ischemia because of severe underlying fixed small-vessel disease. The patient was treated with multiple agents, including oral, topical, and intravenous vasodilators; antiplatelet therapy; doxazosin; and nifedipine.

TABLE 141.2 Surgical and Other Invasive Therapy for Raynaud's Phenomenon

Invasive Therapy	Results
Botulinum Toxin	Improved pain and ulcer healing in small case series
Sympathetic block	Improved ulcer healing in small case series
Thoracoscopic symphathectomy	High recurrence rate in primary RP; improved ulcer healing and pain control in selected patients with secondary RP
Digital sympathectomy	Anecdotal reports of improved pain and ulcer healing
Spinal cord stimulators	Reduced pain and improved ulcer healing in small case series

RP, Raynaud's phenomenon.
From Landry G. Current medical and surgical management of Raynaud's syndrome. *J Vasc Surg*. 2013;57:1710–1716.

include botulinum toxin injection, sympathetic block, thoracoscopic sympathectomy, digital sympathectomy, and spinal cord stimulator (Table 141.2). Local debridement of dead tissue or removal of the fingernail is sometimes necessary. Partial or complete phalangectomy may be necessary in 10% to 20% of patients with digital ulcers or gangrene.

Sympathectomy

Sympathectomy is rarely if ever indicated in patients with primary RP, in which recurrence rates are high, but it may be effective in some patients who have critical ischemia of the digits. The evidence regarding thoracic sympathectomy was summarized by Coveliers and associates,[97] who found thoracic sympathectomy, may maximize tissue preservation or prevent amputation. Currently, thoracoscopic sympathectomy has supplanted open cervicothoracic sympathectomy as a technique of choice. Coveliers, more recently, showed moderate long-term efficacy of thoracoscopic sympathectomy in thirty-five patients with both PRP and secondary systemic disorders.[98]

More favorable results have been seen in lumbar sympathectomy, with long-term symptomatic relief noted in more than 90% of patients undergoing this procedure.[99] Lumbar sympathectomy remains a viable option in the rare patient with severely symptomatic lower extremity vasospasm.

Adventitial stripping of hand and digital arteries has been successful in healing ulcers and improving ischemic pain.[100,101] Results are anecdotal with no controlled trials comparing digital arterial sympathectomy with other less invasive treatment modalities, and in general, arterial sympathectomy should be reserved for refractory cases with risk for tissue loss.

Botulinum toxin is a commonly used medication that primarily inhibits muscle contraction. Botulinum toxin-A (BoNT-A) is injected into the interstitial space around the digital neurovascular bundles causing a chemical sympathectomy. Recently, increased use of botulinum toxin in the treatment of RP has been reported. A recent review of current literature found that BoNT-A injection is a valid therapeutic modality for both primary and secondary RP. It has been shown to reduce pain, promote ulcer healing, and increase blood flow.[102,103] More robust evidence is needed, but thus far, the limited evidence available is encouraging.

Nerve Stimulation

Transcutaneous nerve stimulation has been used in some patients to induce vasodilatation with varying results.[104] In addition, spinal cord stimulators are occasionally indicated for the treatment of various intractable pain syndromes of the upper extremities. A spinal cord stimulator may reduce pain and promote ulcer healing in severe cases of secondary RP with trophic lesions.

Alternative Therapies

Acupuncture may be of benefit in some patients. In a small, randomized trial, acupuncture was found to be effective in reducing the frequency and severity of attacks in patients with PRP. The mechanism of action is believed to be stimulation of sensory nerves, causing release of vasodilators such as substance P and calcitonin gene-related peptide.[105]

Seredine, a high-potency extract of Ginkgo biloba, has had mixed results in the treatment of PRP. A randomized placebo-controlled trial in patients with PRP showed a 56% drop in event rates in the group treated with ginkgo compared to placebo.[106] However, more recently, a placebo-controlled, double-blind, pilot study of 41 patients randomized to either ginkgo biloba special extract EGb 761 versus placebo for 10 weeks found no statistically significant reduction in clinically relevant symptoms.[107]

Fish oil and arginine have also been investigated. Fish oil failed to demonstrate any benefit in patients with SRP in a

small controlled trial.[108] Arginine, which is a substrate for NO synthesis and has a theoretical benefit of improving endothelial dysfunction, has failed to show benefit in patients with both primary and secondary RP.[109,110]

Laser therapy has been investigated as a potential treatment for a variety of vascular and rheumatologic disorders including RP. A randomized controlled trial evaluated low-level laser therapy with 685-nm wavelength diode laser versus sham in forty-eight patients with PRP.[111] They found the frequency and intensity of RP attacks were significantly reduced in the laser treated group. More recently, a group in Poland studied the effects of multiwave locked system (MLS) laser therapy on clinical features, microvascular changes in nailfold videocapillaroscopy (NVC), and circulating modulators, such as vascular endothelial growth factor (VEGF), and angiopoietin 2 (Ang-2) in patients with primary and secondary RP.[112] All patients with RP received MLS laser irradiation for 3 weeks. After 3 weeks, patients with RP reported a decrease in the number, mean duration, and pain intensity of attacks. In addition, 65% of patient with primary and 35% of patient with secondary RP were noted to have an increase in the loop number and/or a reduction in avascular areas in NVC. Patients with RP had higher levels of both VEGF, and Ang-2 compared to matched controls prior to laser therapy; however, post therapy Ang-2 levels were found to be reduced in patients with RP. The authors concluded that Ang-2 may be a useful marker of microvascular abnormalities in RP patients treated with laser therapy.

FIBROMUSCULAR DYSPLASIA IN OTHER ARTERIAL BEDS 1890

INTRODUCTION

Fibromuscular dysplasia (FMD) is a nonatheromatous, noninflammatory, proliferative process first described in 1938 as a rare cause of renovascular hypertension with a "string-of-beads" appearance. The pathogenesis is still unknown, but up to 10% of cases are familial. Its principal pathologic form involves primarily the media; it affects long, unbranched segments of medium-sized conduit arteries such as the renal artery and the internal carotid artery but has been observed in almost every artery in the body (Table 142.1).[1,2]

FMD occurs most frequently (>90%) in women between 20 and 60 years of age but may also be seen in men, older persons, or pediatric individuals. Although many clinicians believe that FMD is a rare disease, its prevalence in the general population is not known. There is evidence to suggest that FMD may be more common than previously thought.[3]

Abstract

Fibromuscular dysplasia (FMD) is a nonatheromatous, noninflammatory proliferative process affecting long unbranched segments of medium-sized conduit arteries such as the renal artery and the internal carotid artery; however, it has been observed in almost every artery in the body. It typically affects women. The clinical manifestations involve the spectrum of arterial obstruction and/or aneurysmal degeneration and depend on the arterial bed involved. Based on angiographic criteria, it can be be multifocal, characterized by the "string-of-beads" appearance, or focal, with a single area of stenosis. FMD is the second most frequent cause of renal artery stenosis after atherosclerosis and the most common cause of renal hypertension in young individuals. Carotid FMD is less frequent and may most often be related to cerebrovascular symptoms, although it remains asymptomatic and has a benign natural history. Treatment options can be medical/conservative, endovascular, and/or surgical depending on the patient's comorbidities and the severity and anatomy of the lesions.

[b]Data shown in parentheses are based on results in various published studies.

Although FMD is a systemic process, it is usually described in terms of the artery in which it occurs; its principal clinical manifestations involve the spectrum of arterial obstruction and/or aneurysmal degeneration and depend on the arterial bed involved: the renal arteries are often associated with hypertension and the extracranial carotid or vertebral arteries with headache (migraine-type), pulsatile tinnitus, transient ischemic attack (TIA), or stroke.[3-6]

PATHOGENESIS OF FIBROMUSCULAR DYSPLASIA

Etiology

Several theories have been proposed as to the etiology of FMD, including environmental and genetic factors, each with partial supporting evidence.

The fact that FMD is more common among women suggests that hormonal factors may be important. Of the 57 women in one study, 9, or 16%, had a previous diagnosis of hypertension during pregnancy, compared with 4% to 5% of pregnancies affected by hypertension in the general population.[7] The number of pregnancies and the frequency of oral contraceptive use or hormonal therapy did not differ between patients with FMD and the general population, however.[8]

Vessel wall ischemia may also be important for the development of FMD. The vasa vasorum of muscular arteries, which supply oxygen and nutrients to the arterial wall, originate from branch points of the parent arteries. Occlusion of the vasa vasorum induces the formation of dysplastic lesions in animal studies.[8] The vessels most commonly affected by FMD—such as the renal, internal carotid, and vertebral arteries—have long segments that lack branches and thus have fewer vasa vasorum. These arteries are subjected to repeated stretching during motion and respiration, which may injure the sparse vasa vasorum, causing arterial wall ischemia and subsequent development of FMD. This hypothesis is supported by the observation that FMD is more common in the right renal artery,[9] which is longer than the left. Its greater length makes the right kidney more susceptible to renal ptosis, which is also common among patients with renal FMD.[10] Vasospasm in the vessel wall might also induce ischemia in the vasa vasorum, and cases of FMD combined with Raynaud disease have been reported.[11] In vitro studies have also demonstrated increased production of collagen, hyaluronan, and chondroitin sulfate in arteries exposed to cyclic stretching.[12] Mural ischemia due to functional defects in the vasa vasorum, possibly in association with developmental renal malposition, has also been postulated as a cause of FMD.[13] However, these theories do not explain the gender difference.

FMD is associated with cigarette smoking. The prevalence of smoking is higher among patients with FMD than in matched controls, and patients with FMD who smoke have more severe arterial disease than nonsmokers.[14] In the US Registry for Fibromuscular Dysplasia, 37% of patients were current or former smokers compared with 18% reported for US women.[15] The mechanisms by which smoking contributes to FMD have not been elucidated.

The occurrence of renal FMD in siblings and identical twins suggests possible inheritance of the disease.[16] Rushton suggested that FMD is transmitted in an autosomal dominant manner, with incomplete penetrance and variable clinical symptoms.[17] A French study of renal FMD showed that 11% of patients had at least one sibling with renal FMD.[18] The US Registry study reported a 7% incidence in relatives; however, it also reported that stroke (54%), aneurysm (24%), and sudden death (20%) were common in first- or second-degree relatives.[15] The presence of FMD can be easily overlooked in relatives because it may be associated with only mild hypertension or may be asymptomatic. Subclinical dysplasia of the carotid artery also occurs in patients with renal FMD, in accordance with a possible autosomal dominant transmission.[19]

Associations with polymorphisms in the angiotensin-converting enzyme (ACE) insertion allele ACE-I have been reported, and an autoimmune origin of FMD has been suggested by genetic associations with HLA-Drw6.[20] Currently several groups are trying to delineate further gene patterns predisposing individuals for the development of FMD.[21]

FMD might coexist with other diseases of the vessel wall and endocrine system. Ehlers-Danlos syndrome type IV has been associated with medial fibroplasias and should be suspected in patients with multiple aneurysms and FMD.[22] FMD has also been reported in association with pheochromocytoma, Marfan syndrome, Alport syndrome, and Takayasu arteritis.[23-25]

Differential Diagnosis

Important differential diagnoses for FMD are type 1 neurofibromatosis, vascular Ehlers-Danlos syndrome, Williams syndrome, and vasculitis.[23,26] The diagnoses of these conditions rely on associated phenotypic traits: characteristic skin lesions in type 1 neurofibromatosis[27]; acrogeric dysmorphism, skin elasticity, and distal joint laxity in vascular Ehlers-Danlos syndrome[28]; and facial dysmorphism, supra-aortic stenosis, and particular behavior in Williams syndrome.[29] Genetic tests can also be used to rule out these conditions as alternative diagnoses.

Because FMD is a noninflammatory process, it is not associated with anemia, thrombocytopenia, or the increased acute-phase reactants that often occur in patients with vasculitis. Large-vessel vasculitis sometimes occurs in the absence of changes in acute-phase reactants, however. It might therefore be difficult to distinguish FMD from inflammatory vessel disease in the absence of tissue samples and without laboratory markers confirming inflammation.

Classification

Traditionally a histopathologic scheme was used to classify FMD, but in the current era fewer patients are undergoing surgical procedures to obtain specimens. The classification now uses an angiographic systems, the most common of which is the American Heart Association system adopted in 2014 that distinguishes between multifocal, characterized by the string-of-beads appearance, and focal FMD, with a single area of stenosis.[6] Unifocal FMD has less female predominance, is diagnosed in younger individuals, and is treated with better short- and long-term results than multifocal FMD.[30] This classification has not been applied to FMD in children.

The histopathologic scheme classified FMD into three categories related to the pathologic layer of the arterial wall affected— fibroplasia of the intima, media, or adventitia (periarterial fibroplasia) (Table 142.2; Figs. 142.1–142.4). FMD

TABLE 142.2 Classification of Dysplasias

Classification	Gender/Age	Cases (%)	Pathologic Features	Angiographic Appearance
Intimal fibroplasia	Often young; no gender difference	5–10	Collagen deposition within the intima internal elastic lamina may be disrupted	Unifocal—Ring-like focal stenosis or a long, irregular tubular stenosis
Medial Dysplasias				
Medial fibroplasia	Adolescents and females 20–70 years of age; female-to-male ratio 5–9:1	80	Areas of thinned media alternating with thickened fibromuscular ridges containing collagen Advanced medial dysplasia, especially in children, also shows secondary intimal hyperplasia (see Figs. 142.1 and 142.2)	Multifocal—"String of beads" appearance, with the "bead" larger than the proximal vessel Normally involves distal two-thirds of main renal artery but can also extend into branches (25%) (see Fig. 142.3)
Perimedial fibroplasia	Young girls and women up to 50 years of age	1–5	Patchy collagen deposition between media and adventitia External elastic lamina intact	Multifocal or unifocal—Can also result in "string of beads" appearance, but diameter of "beads" does not exceed diameter of proximal artery (see Fig. 142.4)
Adventitial fibroplasia	No gender difference	<1	Dense collagen replaces normally loose connective tissue of adventitia and may extend into surrounding tissue	Unifocal—Long stenosis

affecting the media is by far the most common type and is further subdivided into medial fibroplasia, perimedial fibroplasia, and medial hyperplasia. Although this classification was initially proposed for the renal arteries, it is also applicable to other arterial beds and has been angiographically correlated with FMD elsewhere. Complications of arterial dysplasia—such as aneurysm formation (in 17% of patients with FMD, one-third in the renal artery) and dissection (in 20% of patients with FMD, more common in carotid and vertebral arteries, one-fifth in the renal artery)[15]—should be classified as secondary events and differentiated from primary dysplastic lesions.

RENAL ARTERY FIBROMUSCULAR DYSPLASIA

FMD is the second most frequent cause of renal artery stenosis (RAS), after atherosclerosis, and the most common cause of renal hypertension in young individuals, predominantly Caucasian women in their 20s to 40s with normal kidney function.

Epidemiology

Symptomatic fibrodysplastic RAS occurs in 0.4% of the population,[3] but the prevalence of asymptomatic FMD in potential renal donors is around 4%.[19,31-33] The true prevalence is difficult to ascertain because there are no easily applicable screening tests. FMD is most often diagnosed in patients 15 to 70 years of age but it has been reported from infancy to age 89.[1,15,34,35] The medial type of FMD is most common and is more than four times more prevalent in females than in males.[15,19,31] In contrast, the less common intimal type is more prevalent in men.[18,19] Lesions may be bilateral, but in unilateral disease the right renal artery is affected more often than the left.

FMD is more likely to manifest in patients with treatment-resistant or malignant hypertension than in the general hypertensive population and accounts for up to 10% of all cases of renovascular hypertension[36-39]; the remaining cases of renovascular hypertension are caused mainly by atherosclerosis. Compared with patients with atherosclerotic RAS, patients with FMD are younger and have both fewer risk factors for atherosclerosis and a lower occurrence of atherosclerosis in other vessels.

FMD is diagnosed most often in whites and is reported less frequently in Hispanic and Asian populations. Few reports have

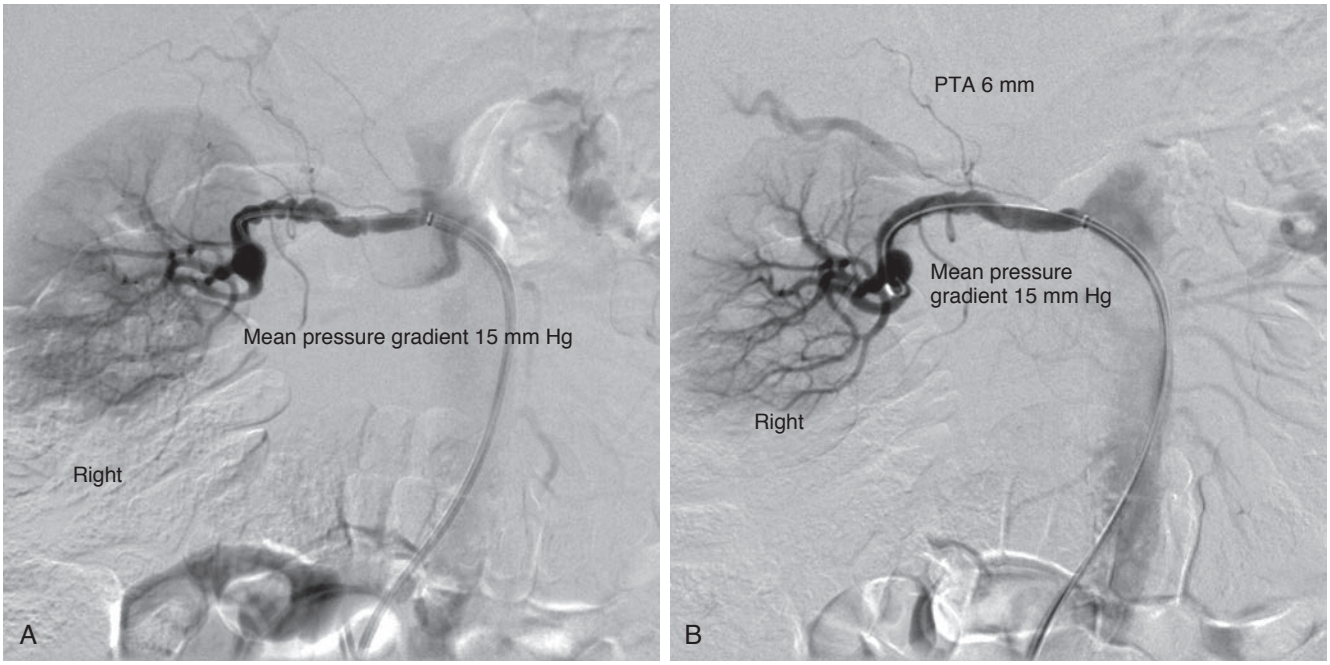

Figure 142.3 Typical selective angiographic multifocal appearance of medial fibrodysplasia with the "string of beads" in the distal main artery before (A) and after (B) percutaneous transluminal angioplasty dilation (PTA).

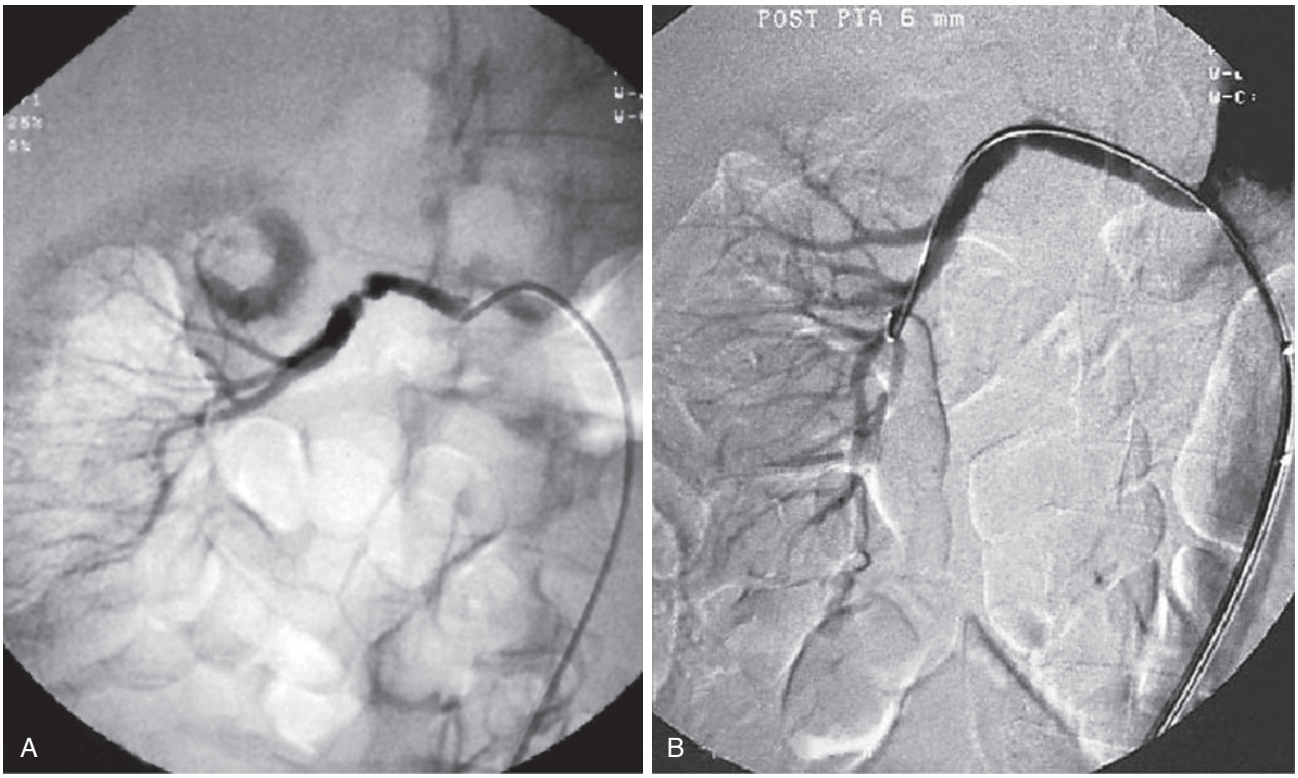

Figure 142.4 Short unifocal stenosis of the distal main artery, perhaps of the perimedial dysplastic type, before (A) and after (B) balloon dilation.

been published from Africa and South America. In the U.S. Registry, which contains data for 447 patients, 95% are white, 2% are African American, and 1% are Hispanic and Asian.[15] Diagnostic criteria vary and prevalence data are often derived from selected cohorts or autopsy studies, so the prevalence of FMD might be overestimated because of the difficulty of estimating the clinical significance of a morphologic stenosis.

Multiple arterial involvements have been reported in 8 of 34 and 9 of 102 renovascular patients with FMD in earlier series; in the U.S. Registry report, two vascular beds were affected in 35% and three in 22%.[9,15,40] This new information reinforces the need for a good clinical examination and at least a carotid artery investigation if FMD is found in other vascular beds.

In childhood, renovascular hypertension is a more important cause of hypertension. It is found in 8% to 10% of all hypertensive children and in up to 25% of those with secondary hypertension. The causes of pediatric RAS differ in different populations.[34,41] FMD is the most common cause of pediatric renovascular hypertension in North America and western Europe, whereas Takayasu arteritis dominates in Asia and Africa.[42]

Pathophysiology

Multiple septa in the renal arteries may together induce a significant reduction in renal perfusion in patients with FMD, resulting in renovascular hypertension, but the degree of RAS is often difficult to evaluate from imaging.

Subsequent reduction of arterial perfusion pressure leads to activation of the renin-angiotensin-aldosterone (RAA) system, resulting in volume expansion and hypertension. Several mechanisms—including increased endothelin-1 (ET-1) production, local RAA activation, arterial wall remodeling, and oxidative stress—help to sustain the hypertension, which now depends not only on the RAA system but also on local vasoconstrictive proliferative effects in the arterial wall, gradually leading to resistance to therapy.[43] Inflammatory mediators such as high-sensitivity C-reactive protein, tumor necrosis factor-α, interleukin-6, and neopterin and vasoconstrictive mediators such as ET-1 are increased in patients with renovascular hypertension. A separate analysis of patients with FMD, however, showed that neopterin and ET-1 were lower in patients with renovascular hypertension due to FMD than in those with RAS of atherosclerotic origin.[7,44] This finding suggests that inflammatory activation might be less important for the pathophysiology of renovascular hypertension caused by FMD than for that caused by atherosclerosis.

Luminal narrowing leads to renal parenchymal damage and ischemic nephropathy in patients with FMD.[45] However, this seems to be less important in patients with FMD than in those with atherosclerotic RAS; the latter show more pronounced reductions of total kidney and cortical perfusion. In addition, renal perfusion correlates inversely with the degree of stenosis in FMD but not in atherosclerotic RAS, further emphasizing that FMD hypertension is more truly renin-dependent than hypertension due to atherosclerosis.[46]

The contralateral kidney may be damaged by exposure to hypertension in FMD.[45] Deterioration of renal function in a patient with FMD affecting one renal artery suggests the development of bilateral stenosis, parenchymal disease, or both.

NATURAL HISTORY

Data with regard to stenosis progression and risk of deteriorating renal function in patients with FMD do exist, but they are not as robust as in patients with atherosclerotic RAS. Progression is less severe in FMD than in atherosclerotic stenosis.[19] About one-fourth of subjects with asymptomatic FMD demonstrate hypertension within 4 years of diagnosis,[31,32] and serial angiograms confirm FMD progression in up to 40% of cases.[47] Because angiography is not routinely performed in patients with FMD who have favorable clinical outcomes, these progression rates may be overestimated. FMD might also result in decreasing renal size and deterioration of renal function, although less often than in patients with atherosclerotic RAS. Aneurysms and dissection are fairly frequent, but complete vessel occlusion, renal infarction, and severe renal insufficiency as well as regression of stenosis have been reported only infrequently in patients with FMD.[5,15,48-50]

CLINICAL PRESENTATION

History and Physical Examination

Arterial hypertension of acute onset or that is increasingly difficult to treat suggests the presence of secondary hypertension—that is, a specific cause of blood pressure elevation, which can be identified in about 5% of adult hypertensive patients.[36] Renovascular hypertension caused by one or more stenoses of the extrarenal arteries is the second most common cause of secondary hypertension (after renal parenchymal disease) and occurs in approximately 2% of adult patients with blood pressure elevation assessed in specialized centers.[51] A physical sign suggesting RAS is abdominal bruit with lateralization. In patients with either high-grade stenosis of a single kidney or bilateral disease, often with one renal artery occluded and the other stenosed, acute pulmonary edema may occur, with or without renal failure. Typically, these patients present with severe and rapid-onset "flash" pulmonary edema, which can also occur in FMD and may be confused with coronary syndromes.[15] Among patients with RAS, the absence of general atherosclerosis suggests that the stenosis is caused by FMD, whereas signs of atherosclerotic disease in other vessels indicate a greater possibility of an atherosclerotic cause.

Screening for Secondary Hypertension

The patient's history can reveal acute-onset hypertension, concomitant flushing, or other paroxysmal symptoms. Physical examination may reveal abdominal bruits, and routine laboratory investigations may show signs of renal disease, hypokalemia, or hyperthyroidism. Secondary hypertension is also suggested by a severe blood pressure elevation, a sudden onset or worsening of hypertension, and blood pressure that responds poorly to appropriate doses of at least three drugs, including a diuretic. In these cases, specific diagnostic procedures for the evaluation of potential secondary hypertension should be considered, as outlined in Box 142.1.

BOX 142.1 Indications for the Evaluation of Secondary Hypertension

Secondary hypertension should be considered in hypertensive patients with the following characteristics:

- Requirement of more than three antihypertensive drugs to control hypertension
- Sudden acceleration of serum creatinine and hypertension
- Young age (<50 years)
- Worsening of previously well-controlled hypertension
- Spontaneous hypokalemia
- Bruit
- Unexplained (flash) pulmonary edema

DIAGNOSTIC EVALUATION

In patients with suspected renovascular hypertension due to FMD, the same diagnostic tools as for arteriosclerotic RAS are used. A limitation of renal artery duplex ultrasonography (DUS), magnetic resonance angiography (MRA), and computed tomographic angiography (CTA) is their unreliability to exclude FMD, because 20% to 25% of patients with FMD have branch lesions. Because MRA and CTA can identify vessels as small as 2 mm but have limited resolution for distal and intrarenal arteries, these techniques can be used to screen for possible FMD but not to exclude FMD. In terms of specificity and sensitivity, gadolinium-enhanced MRA and CTA are better than ultrasound for the detection of RAS, but intra-arterial digital subtraction angiography is most accurate for confirmation or exclusion of an FMD diagnosis.[30,52] This is still the "gold standard" for the detection of renal artery FMD (Fig. 142.5), and is especially useful in the evaluation of branch vessel disease. Intra-arterial measurement of the pressure gradient across the stenosis may be performed before treatment of RAS. Different methods have been used for such assessments, and there is no consensus regarding what level of mean or systolic pressure gradient indicates a hemodynamically significant RAS.[1,30,52] A renal-to-aortic pressure ratio less than 0.90 has been correlated with increased renin levels in the renal vein, suggesting a physiologically relevant stenosis.[53] A mean pressure gradient across the stenosis of more than 10 mm Hg predicts a favorable response to dilation.

TREATMENT SELECTION

The treatment options in renal artery FMD are medical, endovascular, and surgical. Treatment of patients with all forms of renovascular hypertension is controversial owing to the limited number of randomized long-term-outcome trials comparing

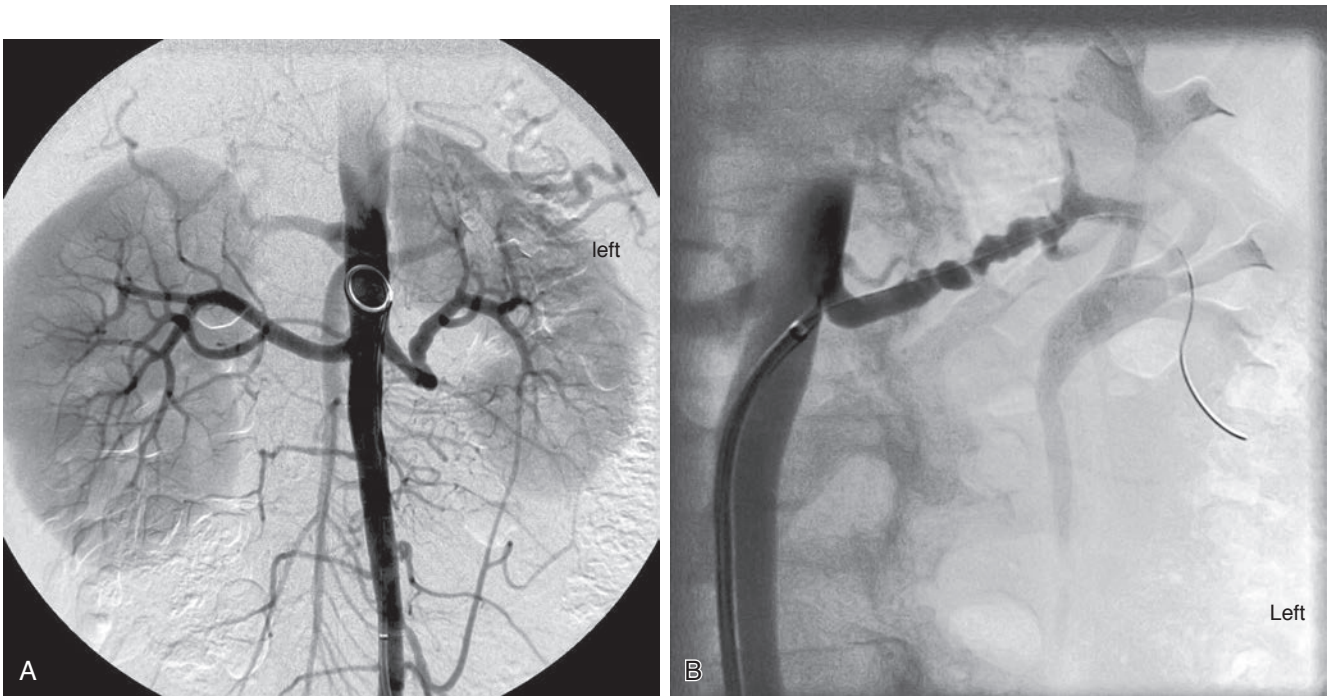

Figure 142.5 (A) Aortogram in a hypertensive young man reveals only minor findings in the left renal artery. (B) Selective angiogram from another angle shows the multifocal fibromuscular dysplastic lesion, across which a pressure gradient of 60 mm Hg was noted. The patient's hypertension was cured by percutaneous transluminal renal angioplasty.

different therapeutic approaches as well as to the difficulty of predicting the blood pressure response to renal revascularization procedures in individual patients.[3] In patients with FMD, endovascular or surgical treatment should be considered in those whose hypertension cannot be controlled with antihypertensive drugs, who are intolerant of or noncompliant with medication, and those with impaired renal function or ischemic nephropathy.[1] To identify progressive disease in patients undergoing medical therapy only, blood pressure and renal function should be monitored regularly. Some authors have also recommended that renal size be monitored by regular ultrasound examinations and that revascularization be recommended if that size decreases by 1 cm or more.[19]

MEDICAL TREATMENT

Many controlled trials have convincingly shown that lowering blood pressure reduces cardiovascular morbidity and mortality. All patients with renovascular hypertension caused by FMD are therefore candidates for antihypertensive treatment in accordance with current guidelines.[36,54,55] Blood pressure should be reduced to 130 to 139 mm Hg systolic and 90 mm Hg diastolic (130 to 139/80) in hypertensive patients and further to less than 130/80 mm Hg in patients with diabetes. These guidelines specify five different groups of first-line antihypertensive treatment: ACE inhibitors, angiotensin II receptor blockers (ARBs), beta blockers, calcium channel blockers, and diuretics. Single or combined, all of these drugs can be used in the treatment of renovascular hypertension due to FMD.

ENDOVASCULAR TREATMENT IN ADULTS

Percutaneous transluminal renal angioplasty (PTRA) has become the treatment of choice for renovascular hypertension due to FMD. Unlike the case in patients with atherosclerotic renovascular hypertension, progressive loss of renal function is uncommon in patients with FMD. Thus the main reason for treating FMD is unsatisfactorily controlled hypertension, and treatment often leads to cure or improvement.

Technical Considerations

The technique for PTRA in FMD is similar to that used to treat atherosclerotic renal artery lesions (see Chapter 127). Most operators are using guidewire systems based on 0.014- or 0.018-in guidewires to reduce vasospasm. All the components in such systems have low profiles. In patients with FMD, the right renal artery often takes off from the aorta proximally. Even in the right renal artery, which is often longer than normal in patients with FMD, the diversity of available guiding catheters usually allows catheterization from a femoral puncture. A brachial approach is seldom needed to get a better angle and/or "pushability" for renal catheterization.

Heparinization is the same as for other endovascular procedures. However, patients with FMD are often younger and have more pronounced vasoreactivity than those with atherosclerotic RAS. Many patients with FMD are already receiving antihypertensive treatment with calcium channel blockers; if

not, premedication with a short-acting dihydropyridine such as nifedipine can be used to reduce the risk of vasospasm. Even so, vasospasm in the kidney vasculature is so frequent in patients with FMD that some operators infuse 0.15 mg nitroglycerin into the renal artery just after catheterization in hemodynamically stable patients. If required, this dose can be repeated during the procedure.

A diagnostic aortogram and selective renal angiograms at different angles are obtained (see Fig. 142.5). In addition, many centers routinely measure pressure gradients. Because there is no optimal tip-pressure catheter, pressure measurements are usually made through a 4-Fr catheter.

In patients with FMD, the stenotic lesion is most often located in the middle part of the main renal artery. The diameter of the selected balloon is normally the same as the diameter of the unaffected proximal part of the renal artery. If the distal parts of the renal artery or its branches are affected, the use of multiple guidewires may be necessary. A kissing balloon technique can be used in branches. However, multiple guidewires or kissing balloons are normally not required; inserting a balloon into the main artery first, followed by the branches, often achieves good results.

The use of cutting balloons is not a first choice in patients with FMD, because ruptures have been reported with their use.[56,57] Before a cutting balloon is used in a procedure, CTA, MRA, or intravascular ultrasound (IVUS) may yield information about whether the lesion is dysplastic or hypoplastic. A hypoplastic lesion is a narrowing of the entire vessel with thin walls, which implies a higher risk of rupture. IVUS may add information on wall thickness. If cutting balloons are required, it is wise to start with an undersized balloon. Good results have been reported with the use of cutting balloons in complex lesions.[56]

Stenting

In FMD the stenotic lesion is normally highly amenable to PTRA. Balloon angioplasty enlarges the arterial lumen in FMD by breaking the septa and stretching the arterial wall, leading to separation of the intima from the media, fracture of the media, and stretch of the adventitia beyond its elastic recoil. Subsequent changes include smooth muscle cell necrosis, fibrosis, and some degree of neointimal formation. In the vast majority of cases, PTRA provides good results; pressure gradients are completely abolished, and there is no indication for stent placement. Also, given the relative youth of patients with FMD, stenting should be avoided; it is also reported to give a high rate of restenosis.[58] Surgical intervention may be more appropriate in cases of complex stenosis and should not be made more difficult with stent placement.

Indications for stenting of FMD lesions include severe procedural complications and perhaps suboptimal results with persistent pressure gradients after repeated angioplasty attempts or small aneurysms in the renal artery.

Procedure-Related Complications

Puncture-site hematoma is the most common complication of PTRA in FMD, reported in 3% to 26% of cases.[59,60] The trend toward using micropuncture to optimize puncture-site location and the fact that smaller introducers can be used further reduce this risk.

Renal artery dissection occurs rarely (1.4%-6.7%) if the balloons are not too oversized.[7,59-61] The majority of these dissections are small, and few require treatment. Repeated and prolonged balloon treatment is recommended, and dissections that are not hemodynamically significant can be left alone without jeopardizing the kidney. However, an extensive dissection that is limiting flow should be treated with stent deployment.

Rupture of the renal artery is uncommon in medial or perimedial dysplasia. Rupture is reported to occur in 2% to 6% of cases and is more common in patients with FMD who have complex stenoses.[7] Some small ruptures stop leaking after prolonged balloon treatment; others require stents, covered stents, or emergency open surgery after the balloon provides initial hemostasis. Both endovascular rescue equipment and resources for emergency operative repair must be available if complex stenoses are being treated.

Branch occlusion can be caused by guidewire misadventures or by dissection during balloon treatment close to a branch takeoff. Branch occlusion is seen in 1% to 5% of patients with FMD after PTRA procedures.[7,59] Still, most of these patients seem to have a favorable outcome.

Thrombosis of the renal artery after endovascular reconstruction in adults is very rare. Main artery occlusions have not been reported.

Early and Late Outcomes

The favorable results of endovascular treatment of main artery FMD lesions are obvious in most reports, even though follow-up information varies from less than 1 year up to 9 years in the different series.[57-59,62-64] PTRA can today be performed with good results even when branch arteries are affected. However, patients with branch artery involvement show less pronounced blood pressure responses and less optimal long-term effects after PTRA.[7]

Comparisons of published series are difficult because of the large variation in selection criteria and length of follow-up. Further, "cure," "improvement," and "benefit" are not always defined according to current guidelines. In a systematic review by Trinquart et al., the cure rate was around 65% for 30-year-old patients while 55-year-old patients had only about a 20% cure rate.[62] This striking decline in cure rate with age is also reported by others.[64] The review also reports a decline in cure rate from about 60% in series from 1980 to 1985, to about 30% in more recent series.[62] Another limitation in comparing series is that it may be unclear whether diuretics and nitrates were considered to be blood pressure–lowering drugs. When evaluating treatment, attention to 24-hour blood pressure measurements is essential because effects on nocturnal blood pressure are important.

Alhadad and coworkers found that 34% of their patients required a second PTRA procedure; however, the majority of these were either planned contralateral PTRAs or redo operations within 6 months of an initial suboptimal PTRA.[7] In the majority of cases, the restenosis lacks clinical significance. Savard and coworkers analyzed 1-year cure rates depending on the

angiographic type of FMD and found that 15 of 28 (54%) patients with unifocal FMD versus only 13 of 50 (26%) with multifocal FMD were cured.[30] Today most centers perform control angiography only if the initial PTRA procedure was suboptimal or if branches were treated.[7,59] In summary, in patients with a main-artery string-of-beads appearance and a good initial effect after PTRA, the long-term durability is good; for more complex lesions and branch vessel lesions, results are acceptable but reinterventions are needed more frequently.

SURGICAL MANAGEMENT

Patient Selection

Surgical revascularization in patients with FMD is currently reserved for patients with severe PTRA complications such as thrombosis, perforation, or dissection that cannot be handled with endovascular techniques. Another option in most of these cases is the use of a stent or a stent graft; the choice of treatment depends on the extension of the lesion and the current renal flow situation. It is therefore important that PTRA procedures be performed only in institutions where such complications can be handled. Open surgery should also be considered after repeated failure or restenosis of PTRA. In a series of 19 patients with FMD and failed PTRA, Wong and associates reported one emergent surgical revascularization due to thrombosis.[65] Among the remaining patients, two underwent nephrectomy and one was revascularized with aortorenal bypass. Among groups experienced with operative treatment after PTRA failure, the results are favorable.[34,65-68] Patients with FMD and large aneurysms should also be considered for open surgery; in cases of pediatric RAS (see the section titled Pediatric RAS and Arterial Dysplasia, further on, and Chapters 126 and 128), a careful choice between open and endovascular treatment should be made.

Techniques

Aortorenal Bypass

Ostial lesions are normally seen in atherosclerotic disease; the technique for the operative repair of these lesions is covered elsewhere (see Chapter 126). In patients with FMD requiring open surgery, lesions are most commonly located in the distal portion of the main artery, often combined with branch artery stenosis, and are normally repaired with in situ techniques. Many institutions use transverse, subcostal incisions and expose the kidney retroperitoneally or transperitoneally, depending on how much exposure of the aorta is required (Fig. 142.6). In most patients with FMD the aorta or iliac arteries can be used for proximal anastomosis without atherosclerosis limiting its placement.

Graft material for the reconstruction may be either saphenous vein or arterial homograft. In the treatment of FMD, autologous vein grafts are usually preferred for reconstructions in adults, and autologous hypogastric artery grafts are favored for bypass in children.[34,69] The hypogastric artery may also be used in adults, especially if several branches must be reconstructed.[67] Dacron or expanded polytetrafluoroethylene grafts can be used in renal artery lesions but are not the first choice. After resection even of a short part of a renal artery, direct anastomosis is often not possible in adult patients with FMD.

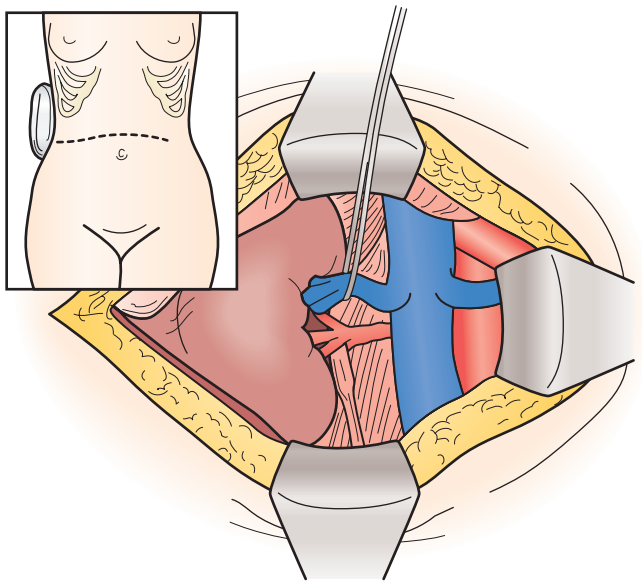

Figure 142.6 Operative approach through a transverse supraumbilical abdominal incision, with an extraperitoneal dissection and reflection of the colon and foregut structures providing exposure of the renal and great vessels.

Before renal circulation is clamped proximally, adequate diuresis must be established. Mannitol 12.5 to 20 g is administered intravenously before renal ischemia to optimize diuresis. Mannitol also acts as a specific hydroxyl free radical scavenger. A generous anastomotic circumference of the saphenous vein can be achieved by using a branch to widen the anastomotic area (Fig. 142.7). The choice of retrocaval or antecaval positioning of the right renal bypass should be made on a case-by-case basis. Some authors prefer not to pressurize the proximal anastomosis until reconstruction is complete. In patients undergoing in situ reconstructions, some surgeons use cool perfusion during renal ischemia. However, it is challenging to maintain cooling intra-abdominally, and such an effort does not convincingly optimize the outcome for the kidney. If cooling is used, clamping of the renal vein and a small venous incision prevent the cool perfusate from having systemic effects. Thereafter the renal anastomosis is made. Intraoperative assessment of the reconstruction is imperative; DUS is reported to be valuable.[67] Most centers do not routinely perform an early postreconstruction angiography.

In hypertensive patients with FMD in whom an aneurysm constitutes part of the indication for surgery, suturing of the aneurysm (aneurysmorrhaphy) is normally not adequate. A saphenous vein graft interposition is usually required.

Autotransplantation

Autotransplantation and renal repair in patients with FMD should be considered in the following situations: reoperation for failed renal artery repair, failed complex endovascular reconstruction after several attempts, multisegmental arterial dysplasia, and a single kidney and stenosis in several renal arteries.

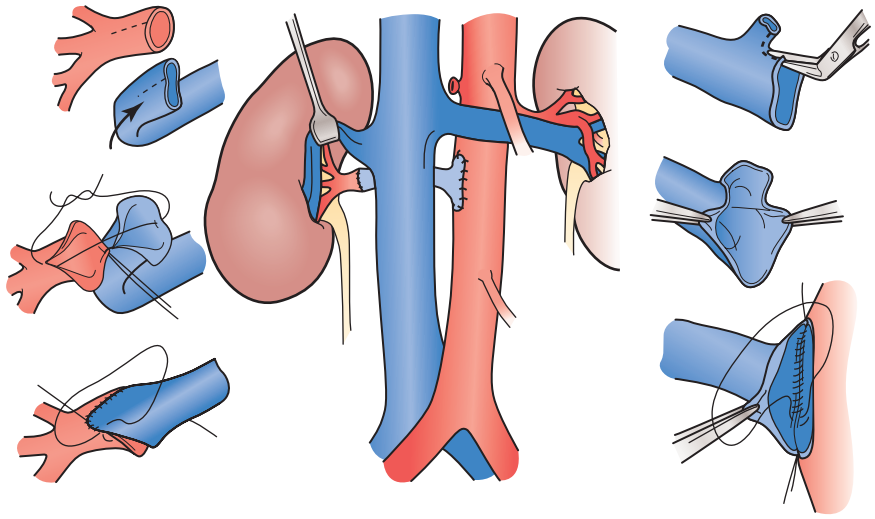

Figure 142.7 Techniques of an end-to-end spatulated renal artery anastomosis and retrocaval placement of the vein graft, with use of a branch of the vein graft to create a wide posteriorly oriented aortic anastomosis.

Current indications for autotransplantation and ex vivo repair have changed somewhat owing to refinements in endovascular techniques. PTRA has shown acceptable results in branch artery stenoses. Autotransplantation of the kidney was originally devised as a method for managing patients with high ureteric injury, and it was first used in renovascular hypertension in 1964. Today when renal FMD is treated surgically, it is usually for very complex disease, with a multisegmental distribution in not only first-order but also second-order branches. Ex vivo repair and autotransplantation, placing the kidney in the iliac fossa, are often required in the same manner as in renal homotransplantation.[66,70,71]

Many institutions preferentially use transverse left or right subcostal retroperitoneal exposure for mobilization of the kidneys. Adequate access may also be obtained with a median or paramedian incision. The renal vasculature is exposed, and the ureter with its surrounding small vessels is freed to at least the level of the iliac vessels. The ureter can be divided and reimplanted in the bladder. This allows optimal separate benchwork after the renal vessels are divided and the kidney is cooled with perfusate. The right kidney has a shorter vein, and a small patch of surrounding vena cava facilitates later vein anastomosis without causing any significant stenosis of the vena cava. The right renal artery is exposed on the back side of the vena cava as long as required. The artery is ligated first; thereafter, the vein is controlled.

The kidney is perfused with saline, Ringer solution, or Wisconsin solution, normally at a temperature of 4°C, until the venous effluent is clear. This normally requires 300 to 500 mL of perfusate. All renal arteries should be perfused. The kidney is kept in Ringer solution at 4°C and some ice slush; thereafter, further meticulous dissection can be undertaken.

Dissection into the renal hilum should be avoided if possible, because the numerous small veins may constitute a challenge. Depending on the type of repair that is planned, further autologous material for vessel repair must be harvested: parts of the proximal "healthy" renal artery, saphenous vein with or without branches, or internal iliac artery with several branches. The risk of unidentified renal arteries is reduced today with better imaging, but during cool perfusion of the kidney especially, the renal poles should be controlled so that blanching of the entire kidney is achieved.

After reconstruction of the renal vessels, reimplantation of the kidney in the left or right iliac fossa is performed. If the ureter has not been divided, it is important to avoid rotating the kidney while positioning it in the iliac fossa. Normally the vein anastomosis is performed first; the reconstructed renal artery is then anastomosed either end to side to the external or common iliac artery or end to end to the internal iliac artery (Fig. 142.8).

Results of Open Surgery

The published series on open surgery include various reports on aortorenal bypass, branch artery reconstructions, and autotransplantation. With each of these different techniques, the early outcome is excellent.

The proportion of cured patients has been somewhat lower during the last 10 years, however, owing to older patients, longer duration of hypertension before surgery, and more complex lesions, because PTRA is now used for main artery lesions. A recent review reported a reduction in cure rate with the increasing age of patients with FMD and also with open surgery.[62] Likewise, cure rate has decreased in recent publications probably due to more refined definitions of cure. The different failure rates among series can be explained by the varying complexity of the cases reported, but it may also reflect an overly optimistic expectation that reconstruction should be successful in patients with small kidneys with branch artery or multisegmental lesions. The number of nephrectomies required is low, however.[68,72]

Complications of Open Surgery

Only a few fatal outcomes have been reported after FMD surgery in adults. Overall morbidity from surgery is between 19% and 28%, mainly caused by minor complications such as urinary tract infection and postoperative pneumonia.[40,68]

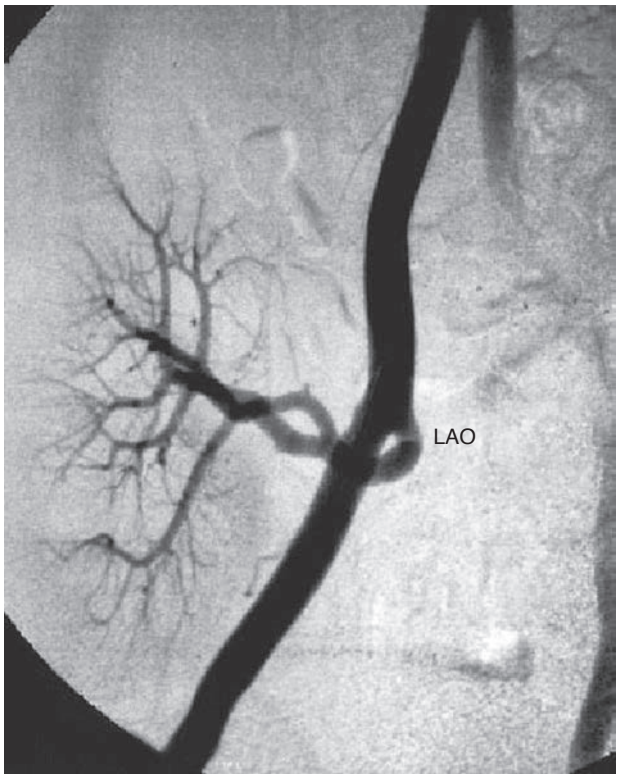

Figure 142.8 Control angiogram after autotransplantation with an arterial allograft (internal iliac artery) and three-branch reconstruction. Slight, insignificant hemodynamic stenosis is seen at the proximal reanastomosis of the internal iliac artery.

Figure 142.9 Ectatic vein bypass after an aortorenal bypass 6 years earlier. No further dilation has occurred during the 10-year follow-up.

Early postoperative occlusion after FMD reconstructions is seen in 3.8% to 13% of cases, and it occurs more often with venous grafts than with arterial autografts.[40,68,69,72] It is more frequent after the repair of renal arteries with small dimensions or branches with low flow. Optimal intraoperative assessment of the reconstruction is of the utmost importance to ensure that no technical defects will induce graft thrombosis.[67]

If pain over the kidney increases postoperatively, diuresis is reduced (which is often hard to evaluate because mannitol has been given and ischemia time differs), or episodic hypertension occurs during the postoperative course, graft occlusion should be ruled out. This can be achieved with ultrasound, conventional angiography, contrast CTA or MRA. Symptoms may be minor, however, which is reflected by the fact that Reiher and coworkers found 9 unsuspected thromboses in 90 reconstructed patients on routine postoperative angiography.[68] If occlusion is found, reestablishment of the renal circulation should be attempted, depending on both the time elapsed between the supposed occlusion and its diagnosis and the collateral circulation, which often helps in delaying irreversible ischemia. Rescue surgery can be considered several days after an occlusion if the renal parenchyma is enhanced by contrast examinations.

Late restenosis has become less common because most anastomoses are now made in an ovoid shape. Restenosis has been reported in 0% to 16% of patients[40,68,69] and in less than 8% of vein graft bypasses.[73] It is even rarer in arterial allografts; branch artery reconstructions also show low rates of restenosis.

The need for redo procedures in patients with FMD differs depending on the technique used and the complexity of the initial lesion.[40,68,69] Secondary treatment using endovascular technology has shown good results, perhaps because a restenosis treated by a redo is more fibrotic.[7,67,68]

Late vein graft dilations were documented in 20% to 44% of patients in early series of aortorenal bypasses in adults.[73,74] Normally a nonprogressive increase in vein diameter is seen (Fig. 142.9). Vein graft dilation has not been reported in series from the last decade, perhaps reflecting the fact that patients with FMD are now older and have a longer duration of hypertension before diagnosis and treatment than in early series.

Renal failure is very uncommon after surgery in patients with FMD.

FIBROMUSCULAR DYSPLASIA AND ANEURYSM

A large proportion of patients with FMD exhibit the string-of-beads appearance, with small aneurysmal areas interspaced by webs in the renal artery. "Macroaneurysms" with obvious aneurysmal development are not infrequent, however; in the U.S. Registry, 25 of 294 patients with renal artery FMD had aneurysmal changes.[15] The University of Düsseldorf group reported on 11 cases of renal artery aneurysm among 101 patients with FMD with renovascular hypertension and treated 48

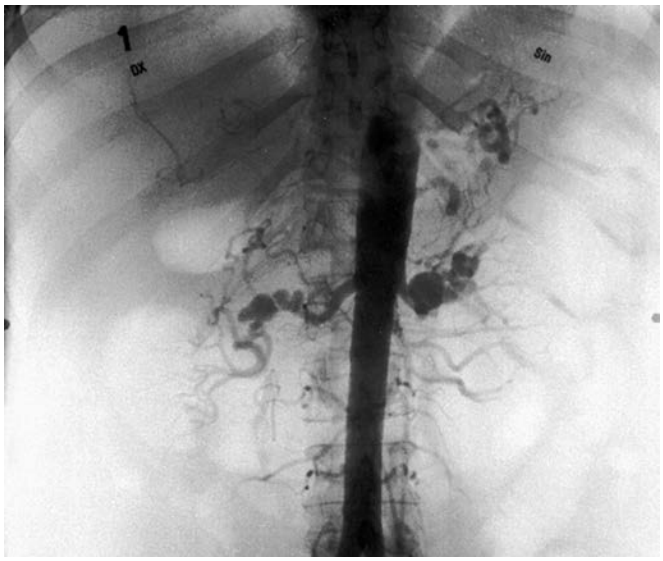

Figure 142.10 Bilateral fibromuscular multifocal dysplasia and aneurysm formation in both renal arteries. Hypertension was fairly well controlled on two drugs. No progression of the aneurysms or hypertension has been seen during 18 years of conservative treatment.

Figure 142.11 Female patient with a fibromuscular dysplastic multifocal lesion treated with endovascular dilation. The medium-sized aneurysm at the branch site decreased in size during follow-up, and the hypertension has clearly improved.

patients with FMD for renal artery aneurysm. Vuong and associates found that of 131 histologically examined renal arteries in patients with FMD, 35 specimens showed aneurysms measuring 0.5 to 2 cm.[9] Most renal artery aneurysms have a low risk of rupture and only a few ruptured FMD lesions have been reported. How FMD-related aneurysms measuring 1 to 2 cm should be handled is uncertain. Conservative treatment may be successful (Fig. 142.10). If additional risk factors are present, treatment may be justified. Aneurysms larger than 2 cm should probably be excluded.[67,68] Among pediatric patients with FMD undergoing open surgery, renal artery aneurysms are reported in 5% to 12%.[34,75]

Endovascular experience is limited. In some patients with renovascular hypertension, small aneurysms may shrink after successful PTRA of stenotic areas (Fig. 142.11). Favorable outcomes have been reported with both embolization and the use of stent grafts.[76]

PEDIATRIC RENAL ARTERY STENOSIS AND ARTERIAL DYSPLASIA

Renovascular disease is among the most common causes of hypertension in children, after thoracic aortic coarctation and renal parenchymal disease (Fig. 142.12).[34] Approximately 8% to 10% of all pediatric cases of secondary hypertension are due to renovascular disease, and pediatric RAS may occur in many different conditions, including FMD, developmental RAS, vascular neurofibromatosis type 1, Moyamoya, vasculitis such as Takayasu disease, Alagille syndrome, and Williams syndrome.[34,77] Up to 40% of children with renovascular hypertension have developmental renal artery lesions with midaortic syndrome and coexisting lesions in both the mesenteric and carotid arteries (see Chapter 130).[77]

Endovascular Treatment in Children

Technical success rates are high in published series, with cure or improvement reported in about 90% of cases. Because children have a greater tendency than adults for vasospasm during endovascular procedures, many centers give small doses of nitroglycerin at every exchange of catheters or wires to minimize this problem.

The string-of-beads type of lesion is not frequent in children. After ballooning of a stenosis, the frequency of recoil is high. If this persists after more prolonged dilation, oversized or cutting balloons should not be used until it has been determined whether the artery is dysplastic or hypoplastic. Patients with a suspected hypoplastic renal artery or a complex stenosis should be considered for open surgical repair. Long-term data on PTRA in children demonstrate variations in outcome. Restenosis is reported in up to one-third of patients. Follow-up examinations are recommended, especially if the initial treatment was for a complex or branch stenosis. A high rate of failure is also reported after treatment of multisegmental stenosis. Overall, the results may be encouraging, but they must be weighed against the results of open surgical repair in children. Because series are small, centralization of treatment is recommended. Treatment of very young children to achieve a moderate improvement may allow open surgery to be delayed until they are older, when the procedure can be performed with better long-term results.

Open Surgery for Pediatric Renovascular Hypertension

A high proportion of pediatric patients with FMD have ostial lesions. In the University of Michigan Pediatric Renovascular Group's report, 12 of 97 children undergoing open operation had multisegmental disease, 6 had aneurysms, 70 had ostial lesions, 15 had main artery changes, and 18 had branch involvement.[34] Unilateral stenosis was seen in 65 children and bilateral

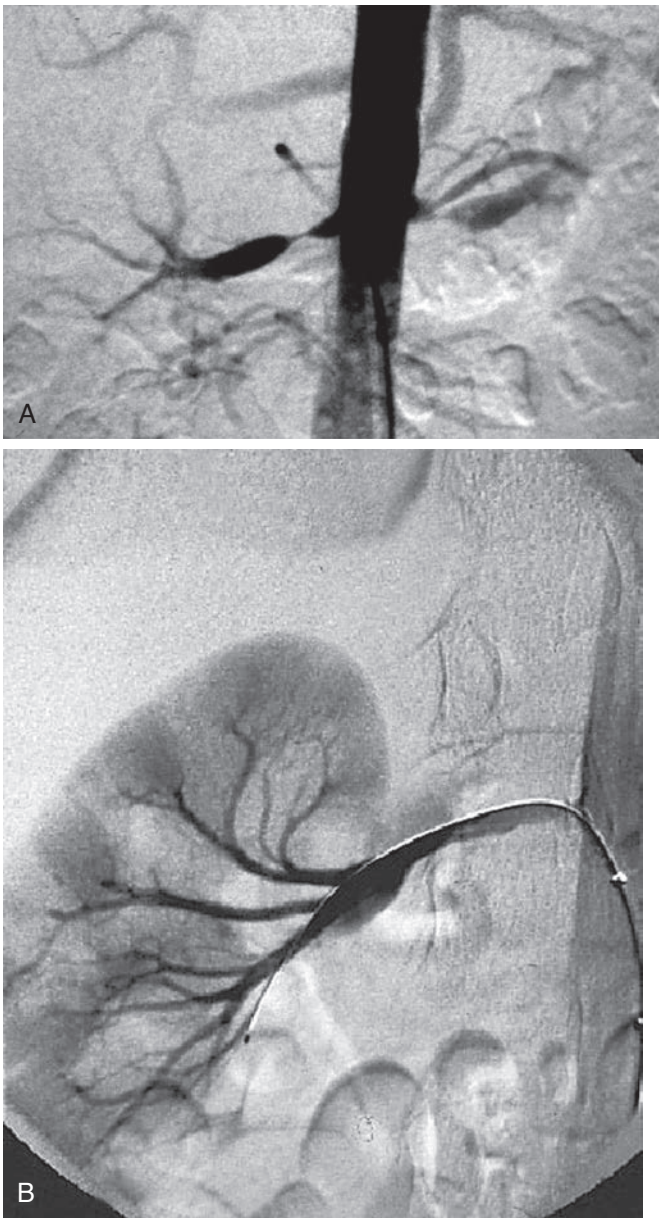

Figure 142.12 (A) Bilateral renal artery unifocal stenosis in a 6-year-old boy with tapered narrowings close to the takeoff from the aorta. Hypoplasia was ruled out. (B) He was treated first on the right side, after which the left stenosis was treated. He required a redo of the right lesion 4 years after the initial treatment.

stenosis in 47. Few girls younger than 10 years of age were treated; at that age, boys were three times more likely than girls to be affected. For children between the ages of 10 and 17, no gender difference was noted. Eleven children with irreparable renal disease required planned and one child unplanned nephrectomy due to technical failure of the reconstruction. The Michigan group has avoided aortorenal bypass with saphenous vein grafts owing to aneurysm formation in 6 of 25 pediatric vein bypasses.[74,77] Huang and colleagues reported on one case of aneurysm development among 12 pediatric venous bypasses requiring redo procedures.[78] Centers of excellence advocate direct aortorenal anastomosis if feasible, and the University of Michigan experience showed that direct anastomosis was possible in 41 of 58 recent reconstructions.[34] Arterial allograft is recommended, and the internal iliac artery is usually preferred over a saphenous vein bypass.

The procedural mortality after renal surgery in children is low, and few children develop renal impairment requiring dialysis. Long-term follow-up shows excellent results, with minimal restenosis and reintervention rates following reconstruction in spite of the children's growth. Centralization of the operative treatment of children is required.

EXTRACRANIAL CEREBROVASCULAR FIBROMUSCULAR DYSPLASIA

FMD is most commonly believed to affect the renal arteries and less frequently the carotid and vertebral arteries; however, data on the first 447 patients in the U.S. Registry show the extracranial carotid and vertebral arteries to be nearly as often involved as the renal arteries, primarily in middle-aged women.[15] Carotid FMD is associated with cerebral aneurysms and FMD involving the renal arteries.

Epidemiology

Although the prevalence in the general population is not well known, the incidence of carotid FMD was 0.42% in 3600 patients undergoing cerebral arteriographic examination in one study.[79] Many of these examinations were performed for suspected cerebrovascular disease, and thus the true frequency of carotid FMD in the general population is probably lower. In one series of 2000 carotid operations, FMD was the identified pathology in 3.4% of cases.[80] Carotid FMD is bilateral in 35% to 85% of reported cases.[1,2,80] Women 40 to 60 years of age predominate in most series, constituting 60% to 90% of patients.[1,2,80,81] This lesion is rare in African Americans. As described in the earlier section titled Renal Artery Fibromuscular Dysplasia, a patient may have evidence of FMD in a single artery or in multiple vascular beds; therefore, appropriate diagnostic evaluation is recommended.

Pathophysiology

This topic is discussed earlier in this chapter, under "Pathogenesis of Fibromuscular Dysplasia." Complications occurring with carotid FMD include encroachment on the arterial lumen, causing reduced perfusion, formation and brain embolization of thrombus, and dissection leading to aneurysmal dilation and possible rupture. These complications occur in less than 10% of cases.

Among the four types of FMD, the internal carotid artery is most often affected by medial fibroplasia, which results in an arteriographic appearance resembling a string of beads (Fig. 142.13), seen in 80% to 95% of the lesions.[1,2,80,81] The arterial segments involved tend to be more distal than in the case of arteriosclerosis; they are located in the middle and distal segments of the extracranial internal carotid artery without any appearance of disease at the carotid bifurcation. The serial stenoses are

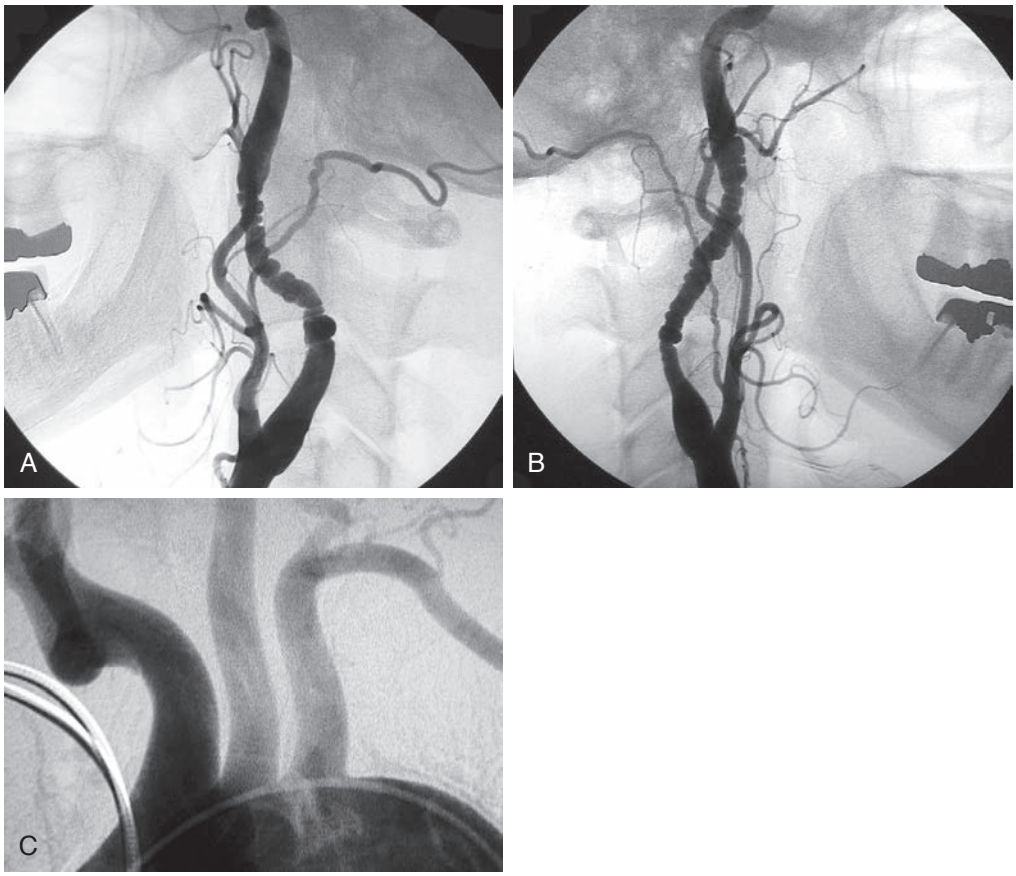

Figure 142.13 (A and B) Carotid arteriograms demonstrating the classic appearance of fibromuscular dysplasia in the usual location opposite the C1-C3 vertebral bodies and intervening disks. Note the low bifurcation and long internal carotid artery. The lesions are present bilaterally in this 43-year-old woman. (C) The aortic arch shows no evidence of disease.

frequently evident on examination of the external surface of the artery (Fig. 142.14). The artery is often elongated and tortuous, and kinking occurs in approximately 5% of cases (Fig. 142.15). Similar disease of the external carotid artery or the intracerebral arteries is rare.

Concurrent Pathology

Concurrent lesions that frequently complicate the management of carotid FMD include the following:

1. Atherosclerotic occlusive disease at the carotid bifurcation, which is seen in as many as 20% of individuals with carotid FMD.[80,82]
2. Extracranial carotid artery aneurysms. In the U.S. Registry, carotid aneurysms (including the extracranial and intracranial internal carotid artery and the ophthalmic artery) were reported in 16 (21.1%) of 76 patients with carotid FMD.[15]
3. Carotid artery dissection. In the U.S. Registry, carotid dissection was identified in 14.8% of 447 patients enrolled. Carotid artery dissection was prevalent in patients with carotid FMD and was seen in 68 of 88 (75.0%) patients.[15] The frequency of FMD in carotid dissection registries varies widely; however, in the most recent large multicenter series of 983 patients, its prevalence was 5.6%.[83]
4. Vertebral artery FMD. This is identified in 7% to 38% of patients with carotid lesions and is occasionally an isolated finding.[80,84] Vertebral artery disease is usually located at the level of the C2 vertebral body and does not extend intracranially.[81]
5. Intracranial aneurysms and occlusive disease. This is found in at least 10% of patients with FMD in general and as many as 51% of patients with internal carotid FMD in particular.[1,2,81,84] Solitary intracranial aneurysms are present in 80% of these patients, but multiple aneurysms occur in the remaining 20%. In the U.S. Registry, intracranial FMD, manifesting primarily as intracranial aneurysms, was reported in 8.3% of patients.[15] These aneurysms tend to be on the same side as the extracranial carotid FMD. They pose an independent threat of rupture and hemorrhage, and their natural history has the potential to be worsened by relief of a proximal stenosis.
6. Renal artery FMD coexists with carotid FMD in 8% to 40% of patients.[1,2,80]

Natural History

Our understanding of the natural history of FMD of the carotid circulation is not complete. Many series have documented the potential for carotid FMD to cause symptoms, as discussed

Figure 142.14 Medial fibrodysplasia of the extracranial internal carotid artery. Operative exposure of the artery reveals an external beaded appearance due to serial narrowing.

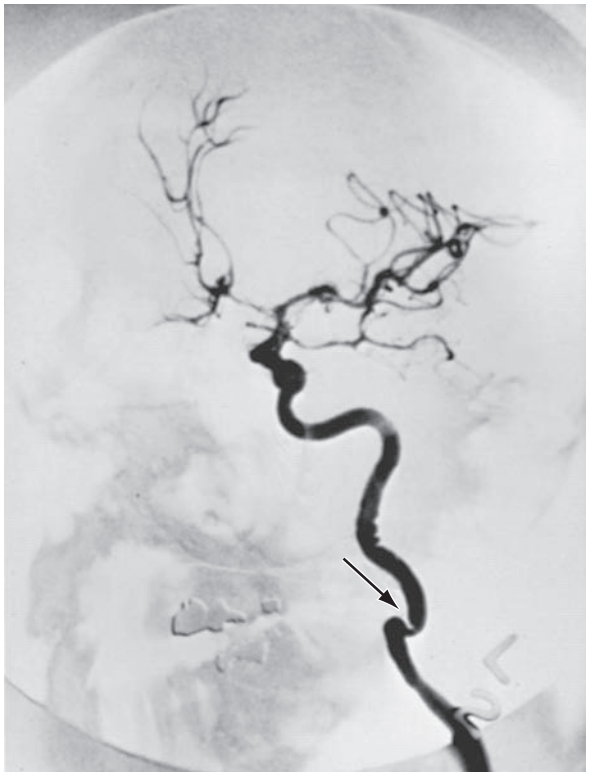

Figure 142.15 Medial fibrodysplasia of the extracranial internal carotid artery, with angulation and stenosis *(arrow)* affecting a tortuous elongated segment. (From Stanley JC, et al. Extracranial internal carotid and vertebral artery fibrodysplasia. *Arch Surg.* 1974;109:215-222.)

earlier, but the natural history of asymptomatic lesions is less well documented. In one series of 79 patients, most of whom were found to have carotid FMD incidentally on cerebral angiography (0.6% of the total), only 3 (4%) subsequently suffered a cerebral ischemic event during an average follow-up of 5 years.[85] When small groups of asymptomatic patients were studied prospectively, less than 10% went on to experience new neurologic symptoms. Roughly one-third of carotid FMD lesions demonstrate significant angiographic progression with time.[2,84,85] Most cases of asymptomatic carotid FMD are known to remain clinically silent, and there is no optimal method of noninvasive follow-up of these lesions to reliably grade progression. None of the existing studies has included a significant number of patients with high-grade asymptomatic stenoses, a group in which the risk for stroke would be expected to be higher.

Clinical Presentation

Extracranial cerebral artery FMD may be either an incidental finding without symptoms or the cause of neurologic events. Symptomatic manifestations in large, contemporary series of treated patients include TIA, stroke, and disability. Stroke is the initial finding in 12% to 27% of patients. Hemispheric TIA occurs in 31% to 42%, and amaurosis fugax in 22% to 28%.[80,84-86]

Physical examination findings at the time of enrollment were available for 414 patients (92.6%) in the U.S. Registry. Findings consistent with Horner syndrome (pupil abnormality or ptosis) were reported in 12.4% of patients. Cranial nerve abnormalities were reported in 9.4%, and other focal neurologic deficits in 13.6%. Bruits were reported over the carotid arteries (30.5%; 18.1% bilateral), epigastrium (17.5%), and flanks (6.1%). Among 306 patients with reported imaging of the extracranial circulation (carotid and vertebral) and a documented physical examination for carotid bruits, 227 (74.2%) had FMD. The sensitivity of a carotid bruit for extracranial FMD was 103 of 227 (45.4%), and the specificity was 74 of 79 (93.7%).[15]

Patients can also present with nonspecific symptoms or signs that frequently occur with carotid or vertebral artery FMD, such as dizziness, headache, altered mentation, pulsatile tinnitus, neck pain, headache, wooziness, and a swishing (swooshing, whooshing) sound in the ears. Such symptoms should trigger diagnostic evaluation for carotid FMD, especially in younger patients with no classic risk factors for atherosclerotic disease. Patients can report significant disability because of the constant noise in their ear and they seek support and help with others who are similarly afflicted.[3,87]

More focal and specific neurologic signs and symptoms may be related to one or more of the following mechanisms: (1) severe stenosis producing hypoperfusion, (2) embolization, (3) thrombosis, (4) dissection, and (5) aneurysm rupture.[88,89]

Other than this process occurring in a relatively young, mostly female population, the history and physical findings may be notable for the absence of additional identifying factors. There may be no particular history or inciting factors. The presence of atherosclerotic risk factors is variable. Physical examination may detect bruits in other locations.

Diagnostic Evaluation

Most asymptomatic patients with carotid bruit and those with hemispheric or nonfocal neurologic symptoms undergo carotid duplex ultrasound (DUS; see Chapter 88). DUS may reveal elevated velocity as a result of FMD, but the lesion may be missed because it is located more distally than the usual atherosclerotic plaque.[81,90] If the lesion is detected, the DUS study may not be able to evaluate the artery distal to the lesion because FMD may involve the artery all the way to base of the skull. Standard arteriography is excellent at delineating the anatomic features of FMD of the extracranial cerebral arteries. Many cases of carotid FMD are discovered during arteriography.[81] Severe tortuosity in the distal carotid arteries, an interesting finding, is seen in patients with FMD. This may occur in the absence of other findings such as beading. However, it is unclear whether this represents another manifestation of FMD.[3,87]

CTA may replace standard catheter-based arteriography in the evaluation of carotid FMD when enough experience has been gained for clinical and anatomic correlation, just as CTA has done in relation to other vascular beds and disease processes. When carotid FMD is identified, the intracranial vascular anatomy should be evaluated to check for the presence of intracranial aneurysms as well as contralateral carotid stenosis and vertebral artery disease. MRA has not been particularly useful in the diagnostic evaluation of carotid FMD because of the tendency for signal dropout with tight lesions and the propensity to produce a "beaded" appearance in normal conduit arteries, which may be confused with FMD. MRA may be beneficial in the follow-up of known FMD. Computed tomography or magnetic resonance imaging of the brain should be performed in patients with carotid FMD to look for evidence of infarction as well as for cerebral aneurysms.

Treatment Selection

Given the generally benign behavior of asymptomatic disease, patients with asymptomatic carotid FMD should be monitored and treated medically, with antiplatelet therapy for primary stroke prevention. There is no evidence to suggest a role for lipid-lowering therapy in patients with isolated FMD, although it should be considered as part of a primary prevention strategy in those with abnormal low-density lipoprotein cholesterol (LDL) levels and evidence of atherosclerotic occlusive disease.

Most reported cases of symptomatic carotid FMD have been treated with dilation of the responsible artery. There is no study in which a large number of patients with carotid FMD and focal cerebral ischemic events were treated medically. In a small series, 13 patients with either TIA (10 patients) or stroke (3 patients) did not undergo surgical intervention; only 1 patient remained symptomatic.[91]

Another rare potential indication for invasive therapy in patients with carotid FMD includes disabling intractable headaches. Percutaneous interventions have been offered to such patients, although the pathogenesis of headache in such patients is not known. The key lies in careful patient selection, reserving invasive therapy for patients with severe disabling symptoms after other common etiologies have been evaluated and ruled out and conservative therapies have been exhausted.[3,87]

At present we are left with a rare cause of focal cerebral ischemic events—extracranial carotid stenosis—which can be repaired with a fairly simple open operation or with percutaneous balloon dilatation.

Therapeutic Challenges

Because of the lack of sophisticated data on carotid FMD, the following challenges frequently arise in its management and must be considered during the treatment planning stage:

1. One of the key driving factors in the treatment of atherosclerosis of the carotid bifurcation, the degree of stenosis, cannot be determined with any reliability in carotid FMD. This problem makes the severity of the disease in a given patient extremely difficult to assess. The indication for mechanical treatment is driven primarily by the development of cerebral ischemia. The problem also compromises the follow-up of asymptomatic patients.
2. It is not always possible to determine which of two concurrent lesions is causing the cerebral symptoms, as is the case with coexistent carotid FMD and significant atherosclerotic disease of the carotid bifurcation. These lesions are usually treated simultaneously. Carotid FMD may also be associated with a coexistent cerebral aneurysm, presenting the same dilemma of competing suspected lesions.
3. When symptomatic carotid FMD is treated, it can be a challenge to decide how to manage a contralateral severe but asymptomatic lesion. Although asymptomatic lesions seem to have a generally benign course, such may not be the case in a patient who suffered a stroke on the contralateral side from the same pathology.
4. Patients with carotid FMD often have nonfocal symptoms, some of which may be due to global ischemia. The indications for intervention in this situation are ambiguous.
5. The presence of an intracranial aneurysm may alter the treatment sequence or the surgical approach.
6. The presence of hypertension secondary to renal artery FMD may complicate any procedure performed for carotid FMD.

Clinical Considerations

Because of the relative safety and effectiveness of mechanical intervention (see the section titled "Mechanical Repair," further on), dilation of the artery is appropriate for lesions causing focal ischemic events (hemispheric or ocular) or episodes of cerebral hypoperfusion. A lesion causing a focal cerebral ischemic event should be considered for treatment because it remains a significant threat. Hypoperfusion is rare but can occur in the setting of critical bilateral carotid FMD or even unilateral disease when there is a significant defect in the circle of Willis. Percutaneous transluminal angioplasty (PTA) has been successful in the treatment of renal artery FMD, and carotid angioplasty with stenting has a growing role in the management of carotid disease; however, the results and durability of balloon angioplasty for carotid FMD with or without stent placement are not known.

Symptomatic patients at high surgical risk should be considered for percutaneous balloon angioplasty, especially if the anatomy allows the use of cerebral protection devices.

Anatomic Considerations

Cerebral Protection

The lesion requiring treatment in carotid FMD is usually a series of webs with intervening pockets, in between which platelet thrombi and cellular debris have accumulated. Disruption of the webs, whether by balloon dilatation or rigid dilatation, produces potentially embolic debris. Some type of cerebral protection is warranted. Carotid FMD tends to involve the carotid artery for several centimeters distal to the bifurcation and may affect the length of the artery to the base of the skull, thus precluding a "landing zone" for an embolic filter to be placed during the procedure. Most distal filters require a few centimeters of straight, healthy artery proximal to the petrous portion of the carotid artery to be functional and safely placed. Cerebral protection using flow reversal devices and proximal occlusion of the common and external carotid arteries may be the best method of protection during percutaneous intervention because the safety and efficacy of these devices has been demonstrated in patients undergoing carotid angioplasty and stenting for atherosclerotic occlusive disease.

Stents

It is not clear whether carotid balloon angioplasty should be accompanied by stent placement in FMD. Stent placement is not usually required after PTA in renal artery FMD because the results are excellent without stents and the patients are usually otherwise young and healthy with good life expectancies. However, stents are routinely placed when atherosclerotic stenosis of the carotid bifurcation is treated percutaneously, and there is some likelihood that stent placement after PTA helps stabilize flaps and disrupted dysplastic tissue. Experience with PTA for carotid FMD is limited, and there are even fewer cases of carotid stent placement for FMD. In light of this paucity of cases, more time will be required to determine the role of PTA with or without stenting in the treatment of patients with carotid FMD.

Medical Management

Patients with asymptomatic carotid stenosis secondary to FMD should be started on a regimen of antiplatelet agents. Diagnostic evaluation should be undertaken to rule out other arterial pathology. If associated conditions are identified, either in the carotid circulation (e.g., carotid aneurysm) or in other vascular beds (e.g., RAS), they should be treated as needed.

Carotid FMD should be monitored at intervals of 6 months with a noninvasive study such as DUS, CTA, or MRA. If DUS follow-up is used, the internal carotid artery must be interrogated as distally as possible. If symptoms develop or there is a significant change in the pathologic lesion (e.g., dissection), mechanical repair of the artery should be considered. There is no established role for anticoagulation or for anti-inflammatory medications such as steroids in carotid FMD. Chiropractic manipulation of the neck should be avoided, as should sports that are likely to produce whiplash-type neck injuries.

Mechanical Repair

Methods of mechanical intervention for the treatment of carotid FMD include open surgical graduated rigid dilatation, open access for transluminal balloon dilation with proximal clamping and back-bleeding to avoid embolization, and PTA (with or without stent placement or cerebral protection devices). Although open surgical treatment has been successfully used in the past, percutaneous balloon therapy with flow reversal represents the optimal current approach, as discussed later. Surgical therapy or endovascular therapy with stents or coils may also be needed for patients with concomitant aneurysms or with aneurysmal complications.

Open Surgical Dilation

The usual fibrodysplastic lesion encountered in the internal carotid artery responds to mechanical dilation. Over the past several decades such treatment has been performed with relative success and safety by means of rigid dilators of progressively enlarging size passed antegrade into the internal carotid artery with arterial control.[1,7,26,30,31] This approach permits gentle disruption of the obstructive webs while allowing associated debris to be flushed out of the artery and has been shown over the years to have reasonable results.

The main disadvantage of this approach is that it is performed without imaging of the luminal surface. The length of the arterial segment to undergo treatment must be estimated. Kinks and coils must be managed by "feel" without direct guidance. There is no simple method of assessing the results of treatment in real time, the way interval arteriography can guide a procedure during percutaneous treatment. The other disadvantage is the need for a neck incision and arterial exposure.

Exposure for the open approach is similar to that for carotid endarterectomy except that higher internal carotid artery exposure is usually required to ensure that dilation is carried out under direct vision and that the extracranial carotid artery can be safely straightened during passage of the dilator (see Chapter 90). The posterior belly of the digastric muscle may be divided, but subluxation of the mandible is rarely required. If the distal internal carotid artery is not accessible, balloon angioplasty should be considered (see the section titled Open-Access Balloon Dilation, further on). The normal arterial segment above the highest point of involvement is apparent with direct inspection, and the internal carotid artery is encircled at this point.

The surgeon should take care to not manipulate the intervening segment of the internal carotid artery as it is gently exposed throughout its length. Determination of stump pressure or electroencephalographic monitoring is not ordinarily needed for this brief procedure but may be indicated if a more extensive procedure is planned (e.g., bifurcation endarterectomy, correction of redundancy, interposition grafting). Except in such unusual circumstances, a shunt is unnecessary.

Heparin is administered (75-100 U/kg) before flow is interrupted. Dextran 40, 25 mL/h beginning at the time of surgery and continued during the immediate postoperative period, may

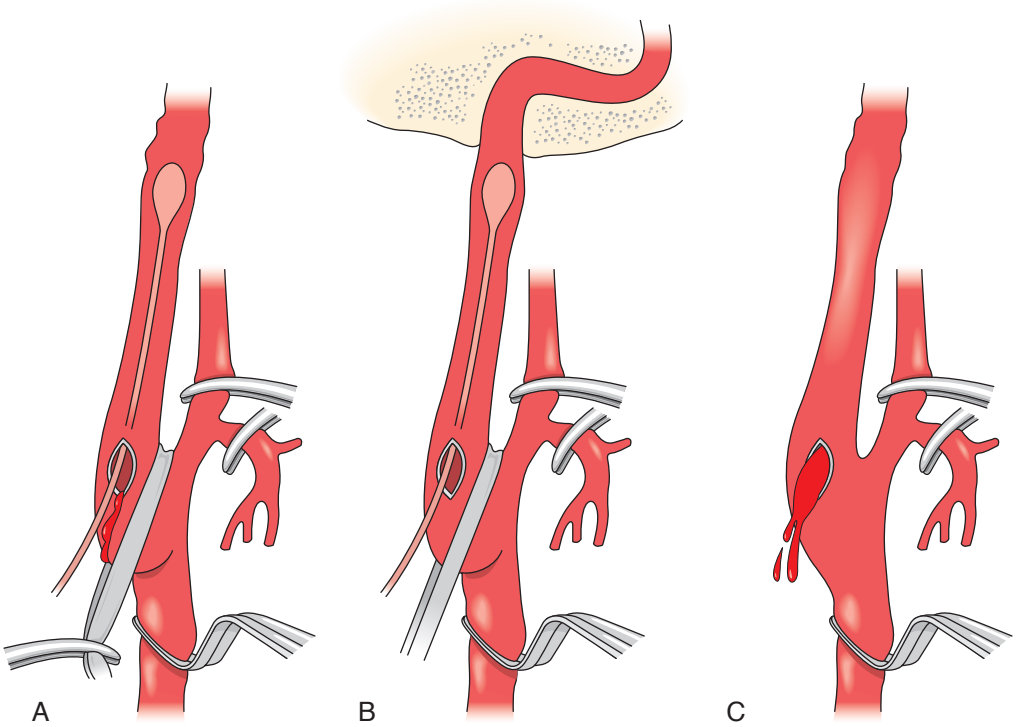

Figure 142.16 Drawings showing the main features of the open surgical technique. (A) Straightening of the carotid artery with downward traction on a polymeric silicone (Silastic) sling. (B) Gentle, graduated dilation of the internal carotid artery from 2 to 4 mm. Passage of the dilator to the bony canal at the base of the skull is shown. (C) Back-bleeding of the artery to remove dislodged debris. (From Wylie EJ, et al. Nonatherosclerotic diseases of the extracranial carotid arteries. In: Egdahl R, ed. *Manual of Vascular Surgery,* New York: Springer-Verlag; 1986: 184-185.)

help prevent early deposition of thrombotic material on the inner surfaces of the arteriotomy and the fractured septa. The common carotid artery is cross-clamped. Traction on a polymeric silicone (Silastic) sling placed around the internal carotid artery just above the bifurcation is performed to straighten the artery. A short arteriotomy is made in the internal carotid artery at the base of the bulb. Graduated metal dilators are then gently passed up the straightened internal carotid artery, beginning with a probe 1.5 mm in diameter probe and progressing up to a 3.5-mm diameter probe or, occasionally, one 4.0 mm in diameter (Fig. 142.16). A series of "giving" sensations is usually felt as each septal stenosis is gently fractured for the first time, but such sensations are not felt thereafter.

The procedure is terminated after the segment has been gently stretched to full diameter throughout its course. This step can usually be observed under direct vision. It is important not to exceed this gentle stretching and therefore not to proceed beyond a 4-mm diameter. Back-bleeding after passage of the dilators should be thorough because large debris is sometimes retrieved. The short arteriotomy is closed rapidly with a simple running suture of 6-0 polypropylene. Careful interrogation of the entire segment with a Doppler ultrasound probe or DUS scanner after restoration of flow ensures patency without turbulence and residual defect.

There are three large series of surgically managed patients.[18,92,93] These reports consist primarily of patients undergoing rigid carotid dilation but also include some instances of carotid replacement and vertebral revascularization. The incidence of perioperative stroke during surgical treatment in these series ranged from 1.4% to 2.6%. TIA occurred in 1.4% to 7.7%, and perforation occurred twice in 318 operations (0.6%). Cranial nerve injuries, most of which were transient, resulted from extensive distal operative exposure of the internal carotid artery and were reported to occur in 5.1% to 16.7% of cases.

Excellent long-term follow-up data are available. Late stroke developed in 1.2% to 3.8% of patients, and nearly all late deaths (up to 22 years) were due to nonneurologic causes. In one series, 94% of patients underwent DUS scanning (mean follow-up, 7 years).[92] Actuarial rates of primary patency, survival, and stroke-free survival were 94%, 96%, and 94%, respectively, at 5 years and 94%, 82%, and 88%, respectively, at 10 years. When follow-up angiography is performed, it usually demonstrates a normal-sized lumen (Fig. 142.17).

Despite the acceptable outcomes reported with surgery, most writers believe that similar outcomes can be achieved with percutaneous techniques and cerebral protection (see later).[3]

Open-Access Balloon Dilation

When the length of the diseased internal carotid artery extends too far distally to be dissected and adequate control of manual dilation is ensured, some writers have advised balloon angioplasty combined with open arterial control, as described under Open

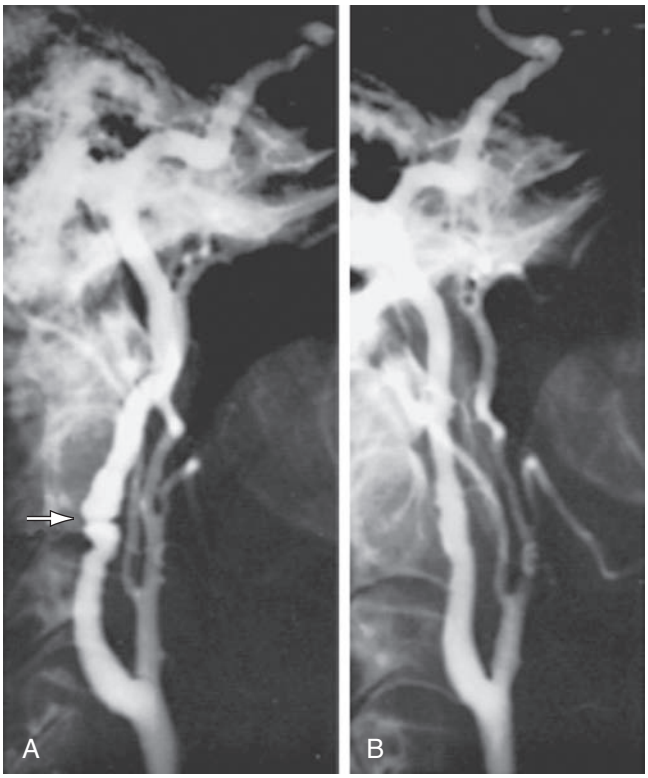

Figure 142.17 (A) Preoperative right carotid arteriogram showing a localized zone of fibromuscular dysplasia characterized by an intraluminal diaphragm *(arrow)*. (B) Postoperative right carotid arteriogram after graduated intraluminal dilatation. The carotid lumen is now widely patent.

Surgical Dilation.[94,95] The benefit of this approach is the opportunity for controlled dilation with interval arteriography while maintaining the ability to back-bleed the artery and avoid embolization of debris from the dilated lesion. Among a small number of patients in several reports, it appears that early results with this approach may be comparable to those of rigid dilation.

Percutaneous Transluminal Angioplasty

PTA has become the preferred approach for more proximal internal carotid artery FMD. The rationale for this approach is based on the success of PTA in the treatment of renal artery FMD and dramatic improvement in the technology, which supports balloon angioplasty and stenting of the atherosclerotic carotid bifurcation.

Diagnostic evaluation for carotid FMD is likely to include an arch aortogram and carotid and cerebral arteriograms, as noted earlier. These are valuable tools for planning carotid PTA. Arteriography provides important information with respect to the optimal strategy that should be pursued on the basis of the demonstrated anatomy. Lesions that have signs of aneurysm formation should not be considered for endovascular management; they may be better treated with open arterial replacement. On the other hand, lesions that show some evidence of dissection should be considered for stent placement, and care should be taken to avoid overdilation and possibly rupture.

If significant kinking of the distal artery at the diseased segment is noted, there are additional considerations for technique. Kinks are not favorable for stent placement because the stent can make them worse. During open, rigid dilation, the artery is dissected and straightened before treatment, and surgical shortening of the artery may be required. Such shortening obviously cannot be done during balloon angioplasty.

It is not always possible to tell where the lumen is located when angiography is used to help with passage of the guidewire, and patience and persistence may be required to safely cross the lesion. Having the sheath tip close by to use as a stable platform is helpful. In addition, an angled catheter may be used to support and direct the guidewire as it traverses the web-like internal carotid artery lesions, which sometimes have only pinhole openings. As the guidewire passes through each lesion, the responsiveness and directionality of the guidewire decrease.

Heparin is administered to provide an activated clotting time in excess of 250 seconds. Most patients with carotid FMD are young, and they are much more likely than other patients with vascular problems to have an arch favorable for percutaneous carotid artery access, one with less tortuosity and less ectopic vascular disease. The carotid arteries frequently arise from the superior aspect of the arch rather than on the upslope of the proximal arch (see Fig. 142.13). The carotid artery sheath may be placed in the distal common carotid artery because the bifurcation is not usually diseased (Fig. 142.18). The external carotid artery is generally normal in appearance and can be used as a place to anchor the stiff exchange guidewire for sheath placement.

After the stiff exchange guidewire is placed, the carotid sheath is advanced. Once the sheath is in place, its position is confirmed with an arteriogram and an arteriographic "road map" of the bifurcation is obtained. Because internal carotid artery lesions may extend to the base of the skull, the image intensifier must be placed so that the operator can observe the distance from the tip of the sheath inferiorly to the area distal to the lesion superiorly. Use of some type of cerebral protection is highly desirable but not always possible, as discussed previously. If there is no safe landing zone for a distal protection device, it is better to perform the procedure without it or, preferably, to use flow reversal techniques and devices. The distal filter or occlusion balloon may move slightly during the procedure, even when it is performed with meticulous technique. Therefore the distal protection device must be placed at least 1.5 to 2 cm distal to the lesion. If stent placement is anticipated, the nose cone on the stent delivery catheter typically requires at least 2 cm of clearance. Care must also be taken to avoid interactions of the guidewire with any associated intracranial pathology that may be present.

If a distal occlusion balloon or filter is used, placement is likely to be in the petrous carotid or above, so that the balloon is distal to the disease. This segment of the internal carotid artery is more prone to spasm and dissection than the extracranial segment, so caution should be exercised. The distal protection device with the shortest landing zone is the distal occlusion balloon. A proximal occlusion device, with or without flow

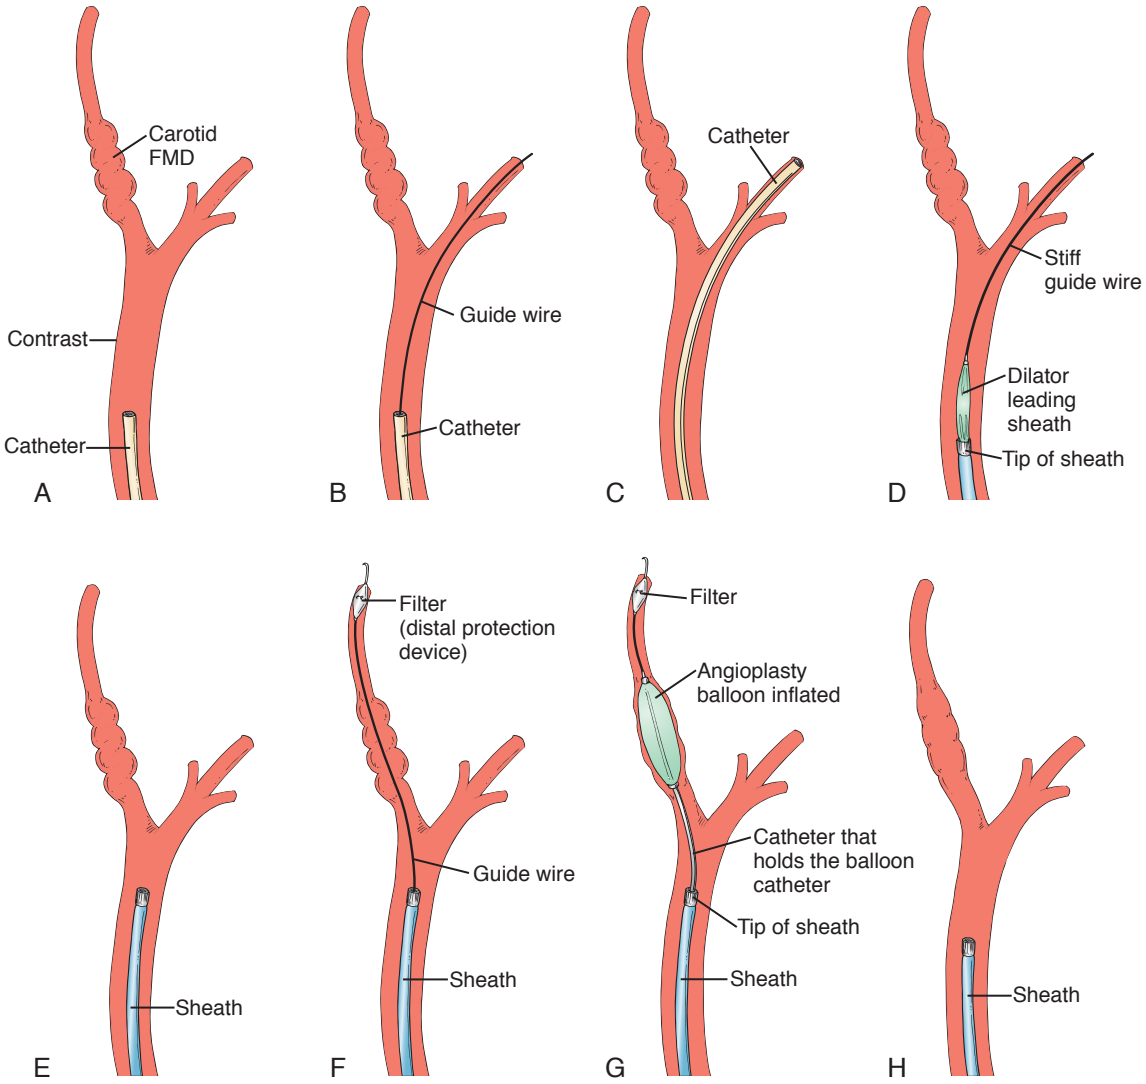

Figure 142.18 Endovascular Technique. (A) Internal carotid artery narrowed by fibromuscular dysplasia (FMD). An arteriogram was performed through a carotid catheter. (B) Guidewire placed in the external carotid artery through use of a road-map arteriogram of the carotid bifurcation. (C) Cerebral catheter advanced into the external carotid artery. (D) Stiff guidewire advanced into the external carotid artery. The carotid access sheath is advanced over this exchange guide wire. (E) Carotid sheath in place with the tip of the sheath in the distal common carotid artery. (F) Cerebral protection device in place in the distal internal carotid artery. (G) Balloon angioplasty of the fibromuscular lesion in the internal carotid artery. (H) After balloon angioplasty, the lumen improved significantly.

reversal, is a reasonable alternative for cerebral protection in the patient with distal internal carotid artery lesions and no safe filter landing zone; in fact, this may be a safer first-line choice for cerebral protection not only owing to the possibly compromised internal carotid landing zone but also because of the amount of debris that can be generated.

FMD generally covers a longer distance of the internal carotid artery than carotid atherosclerosis and may therefore require a longer balloon (4 cm). It is best to dilate the entire lesion with a single balloon inflation. The balloon should be slightly undersized with regard to the intended diameter of the artery to help avoid dissection or rupture.

Fortunately the most frequently encountered extracranial carotid FMD pathologic lesion is medial fibroplasia, which is amenable to dilation and less likely to include aneurysmal dilation. For FMD lesions that contain aneurysmal segments, PTA is probably not advisable.

Carotid stent placement may be challenging in patients with carotid FMD because many of them have redundancy, kinks, and coils of the cervical internal carotid artery. The segments involved by FMD tend to be longer than those involved by atherosclerosis, in which almost all lesions are shorter than 2 cm, and experience with stent placement near the base of the skull is limited. In addition, no one knows the implications of stent placement in patients with a life expectancy of many decades, as is the case with many FMD patients.

Given a track record of success with PTA of FMD lesions in other locations, primary stent placement is probably not

warranted, at least without more data. In addition, FMD tends to occur in a younger group of patients with a reasonably long life expectancy, and the performance of carotid stents over decades is not known. However, if dissection, residual stenosis, or flaps are evident on completion arteriography, a stent should be considered. Smaller stents are used than is normally the case with bifurcation disease because self-expanding stents are sized for the distal internal carotid artery (5 or 6 mm) rather than the common carotid artery (8 or 10 mm). The minimum length of artery required to cover the disease should be stented because stents confer stiffness and create compensatory bends or even kinks in the more relaxed, nonstented segment of artery. Preexisting kinks, coils, and redundancies are common in FMD. These configurations present unique challenges for stenting. Stent placement in a kink should be performed cautiously because the extra curvature is usually transferred to another segment of the artery and may exacerbate a kink in that area. Stent placement in a coil should be avoided altogether.

Unfortunately it is not possible at present to provide a comprehensive assessment of the results of PTA because few data are available regarding perioperative complications or longer-term success.[3] Since the 1980s, only a few dozen patients have been reported in the literature as having undergone PTA for carotid FMD, usually as part of larger series of those undergoing angioplasty. Periprocedural complications are very rare and may include dissection or stroke. No follow-up is available beyond the perioperative period.

FIBROMUSCULAR DYSPLASIA IN OTHER ARTERIAL BEDS

Fibrodysplasia is considered a systemic arteriopathy; although it may be clinically overt when it affects the renal and extracranial carotid, it can frequently be identified in lower limb vessels (mainly iliac arteries) and less frequently in the visceral and coronary arteries.[3,6,15,92]

Although fibrodysplasia is usually asymptomatic, presenting symptoms of lower extremity involvement include claudication or other atypical lower extremity symptoms.[96] In the viscera, FMD usually involves more than one vessel. Although typically asymptomatic, mesenteric ischemia can occur, but owing to extensive collateralization rarely results in infarction.[97] Epicardial coronary artery involvement has rarely been reported. Coronary FMD typically appears as a well-demarcated long smooth lesion in the distal portion of the artery. There is an abrupt transition from an angiographically normal coronary artery to the abnormal area. Rarely, the string-of-beads appearance will be noted in the coronary arteries.[3,98]

INTRODUCTION

Most lower extremity ischemic symptoms occur in patients with atherosclerotic occlusive disease. Nonatheromatous causes must be considered, however, in the absence of significant atherosclerotic risk factors, especially in younger and more active individuals. The two most common nonatheromatous causes of popliteal artery disease are popliteal artery entrapment syndrome (PAES) and adventitial cystic disease (ACD). Clinical symptoms associated with these pathologies range from claudication to critical limb ischemia (CLI). Given their rarity and the younger age of presentation, these conditions are often not diagnosed in a timely fashion, resulting in prolonged disability and occasional progression to CLI.

POPLITEAL ARTERY ENTRAPMENT SYNDROME

Epidemiology

PAES was first described in 1879 by University of Edinburgh medical student Anderson Stuart.[1] It was not until 1965, however, that Love and Whelan at the Walter Reed Army Medical Center in Washington, DC, coined the term "popliteal artery entrapment syndrome" to describe this clinical entity.[2,3] The anatomic abnormalities associated with PAES have been observed in 3.5% of individuals in a postmortem study,[4] and up to 60% of young individuals with claudication symptoms suffer from the syndrome.[5] Those affected tend to be active and otherwise healthy, which has led some clinicians to describe PAES as the "jogging disease."

The majority (up to 80%) of reported cases are in men, with a median age of 32 years (range, 20.7 to 41 years).[6] Cases of PAES have also been described in children and women, but are unusual.[7] While the anatomic variant in affected individuals is first developed in utero, several decades are sometimes necessary before the syndrome is detected. Bilateral lower-extremity symptoms in PAES have been described in approximately 30% of cases, and two thirds of patients with unilateral symptoms were found to have bilateral anatomic abnormalities.[8] Rare instances of bilateral popliteal artery occlusion secondary to popliteal artery entrapment have also been reported,[9] and concurrent entrapment of the popliteal and anterior tibial arteries has been described.[8,10]

Pathogenesis

Etiology

The anatomic variations observed in PAES are best understood by considering the embryologic development of the structures within the popliteal fossa.

The lower extremity arterial system arises from two arteries, the axial and external iliac arteries, which originate from the umbilical artery. The femoral artery originates from the external iliac artery and progresses distally in the anterior compartment, whereas the axial artery elongates distally in the posterior compartment. At around 42 days of intrauterine life, the axial artery is divided into three segments, depending on its relationship to the popliteus muscle: proximal, deep, and distal. A bridging artery, the ramus communicans superius, joins the femoral artery and the proximal segment of the axial artery through the adductor hiatus. During the following week of development, the proximal component of the axial artery gives rise to a branch that runs superficial to the popliteus muscle and joins with the distal segment of the axial artery. The deep segment of the axial artery involutes, and the fully developed popliteal artery results from the fusion of these arterial elements (Fig. 143.1).[2]

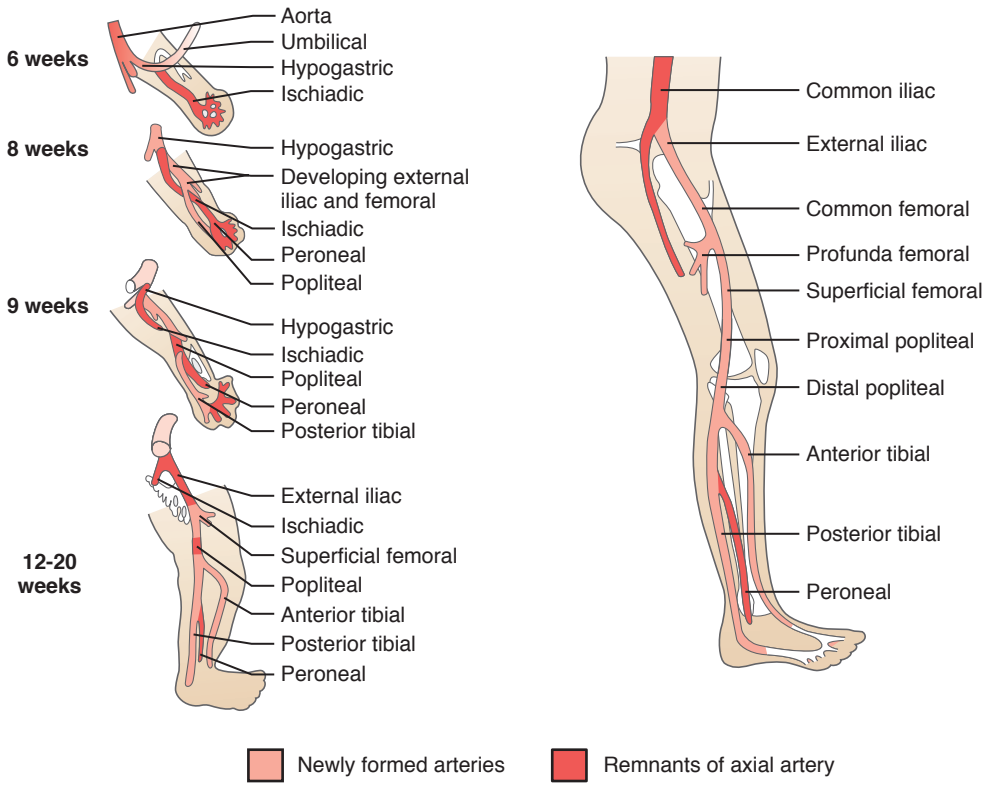

Figure 143.1 Embryologic derivation of the popliteal and other lower limb arteries. Remnants of the axial artery and arteries that develop with later differentiation are indicated. (From Levien LJ, Benn CA. Adventitial cystic disease: a unifying hypothesis. *J Vasc Surg.* 1998;28:193-205.)

Initially, both heads of the gastrocnemius muscle originate from the proximal tibia. With development, these migrate cranially along the femur to different extents. The final position of the medial head of the gastrocnemius muscle is more proximal to that of the lateral head and immediately caudal to the adductor hiatus, with the popliteal artery lying immediately lateral.[2] These dynamic processes of muscle and arterial development create the potential for various anatomic variations that may lead to popliteal artery entrapment (Fig. 143.2).

Classification

The current PAES classification system consists of six variants, types I to VI, and is based on the Heidelberg classification. It accounts for variations in the anatomy of the popliteal fossa (Fig. 143.3).[11]

Type I

The popliteal artery completes its development before migration of the medial head of the gastrocnemius muscle, which then pushes the artery medially during migration. This results in the popliteal artery's medial deviation to a normally situated gastrocnemius muscle.[8]

Type II

The artery is displaced medially, but the medial head of the gastrocnemius muscle has an abnormal attachment on the lateral aspect of the medial femoral condyle or intercondylar area. In this case, the artery forms prematurely and partially arrests the migration of the gastrocnemius muscle, resulting in the artery positioned medially to an abnormally attached muscle. In contrast to the normal position of gastrocnemius muscle insertion in type I entrapment, type II is defined by an abnormal femoral insertion site.

Type III

This type is caused by an abnormal muscle slip or fibrous band that arises from either the medial or lateral femoral condyle.[8] Type III entrapment occurs when embryologic remnants of the gastrocnemius muscle remain posterior to the popliteal artery or when the artery develops within this muscle mass. Occasionally a double origin of the gastrocnemius muscle can surround and compress the popliteal artery.

Types I to III represent the same anatomic variant, the degree of which depends on the temporal relationship between popliteal artery development and migration of the medial head of the gastrocnemius muscle.

Type IV

The mechanism resulting in type IV entrapment is fundamentally different from that causing types I to III. Type IV entrapment occurs with persistence of the axial artery as the mature distal popliteal artery. This artery remains in its embryologic position, deep to the popliteus muscle or fibrous bands.[8]

Type V

Both the popliteal artery and vein are involved or entrapped by any of the previously described mechanisms. This subtype has been estimated to occur in approximately 10% to 15% of cases.[12,13]

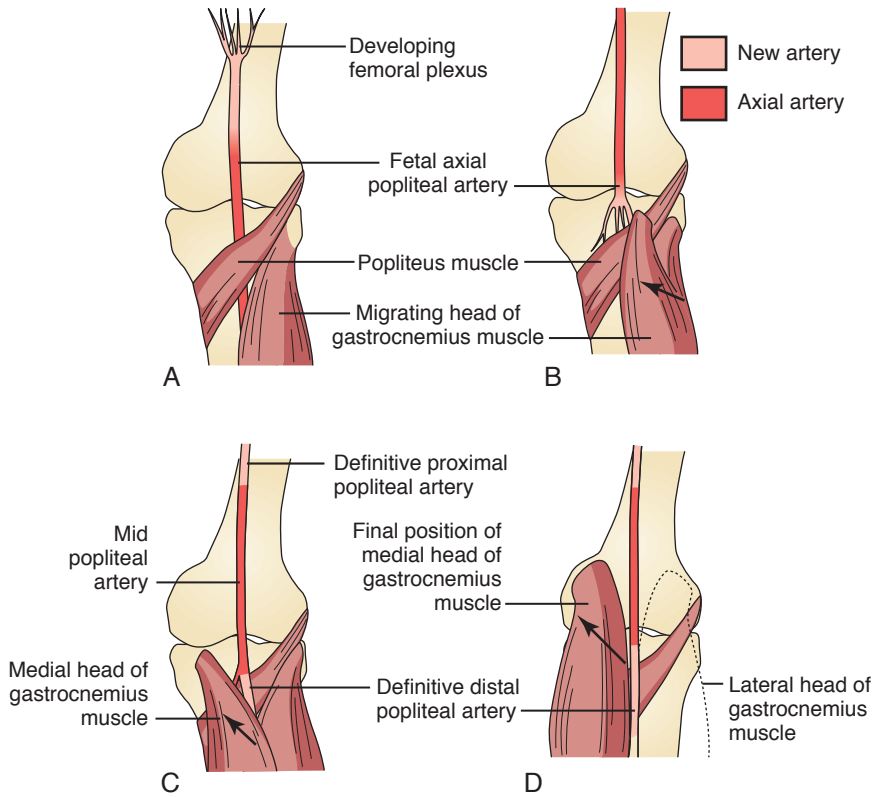

Figure 143.2 Migration of the medial head of the gastrocnemius muscle through the popliteal fossa during formation of the popliteal artery. **(A)** The medial head of the gastrocnemius muscle begins to migrate from the region of the fibula. At this stage, the axial distal popliteal artery lies deep to the popliteus muscle. **(B)** The distal portion of the popliteal artery involutes as the medial head of the gastrocnemius muscle passes from lateral to medial. The proximal popliteal artery is derived from fusion with the developing femoral plexus, whereas the midportion of the popliteal artery is formed from the persistent axial artery remnant. **(C)** A new or nonaxial distal popliteal artery now forms superficial to the popliteus muscle, after the medial head has migrated through the popliteal fossa. **(D)** Normal definitive popliteal anatomy. (From Levien LJ, Veller MG. Popliteal artery entrapment syndrome: more common than previously recognized. *J Vasc Surg*. 1999;30:587-598.)

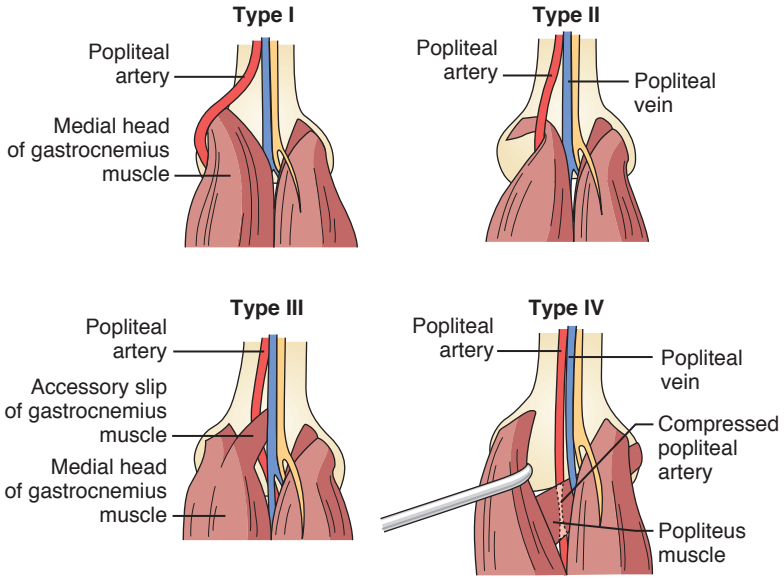

Figure 143.3 Types of popliteal artery entrapment syndromes. (From Levien LJ, et al: Popliteal artery entrapment syndrome: more common than previously recognized. *J Vasc Surg*. 30:587-598, 1999.)

Type VI

An additional type of entrapment—previously known as functional entrapment, or type F—is now commonly referred to as type VI entrapment. Patients present with the typical features of PAES in the absence of an explanatory anatomic abnormality.[8] It has been proposed that the anatomic abnormality in type VI entrapment is an especially lateral attachment of the medial head of the gastrocnemius muscle to the posterior aspect of the medial femoral condyle. Alternatively, hypertrophy of gastrocnemius following regular exercise is thought to result in compression of the posteromedial aspect of the popliteal artery. When subjected to MRI examination, individuals with type VI PAES and popliteal artery occlusion with stressor maneuvers tend to have a more extensive midline position of the medial head of the gastrocnemius muscle. When compared with normal controls, patients with type VI PAES have more of this muscle attached toward the supracondylar femoral midline, around the lateral border of the medial femoral condyle, and within the intercondylar fossa.[14]

Recent advancements in imaging technologies have led to the discovery of other etiologies for popliteal artery entrapment, such as anomalous slips of the lateral head of the gastrocnemius or plantaris muscles.[15–17] Such cases are extremely rare, however, and have not warranted a modification of the current classification system.

Pathology

The pathologic classification of PAES describes the continuum of histologic changes that result with chronic popliteal compression, from fibrosis of the various arterial layers to complete occlusion and thrombosis.[8] In stage 1, the fibrosis is confined to the adventitia. In stage 2, it extends into the media, which may result in poststenotic dilation or aneurysm formation. In stage 3, the artery may become thrombogenic as the fibrosis extends into the intimal layer.[13] However, the degree of arterial damage does not appear to be directly related to the duration of compression or popliteal entrapment.

Clinical Presentation

PAES patients are typically young, physically active men who present with lower-extremity claudication. However, a range in the severity of associated symptoms, along with a grading scale for their description, has been described (Table 143.1).[2]

Claudication symptoms may be atypical and paradoxical, worsening with standing or walking and improving with more vigorous exercise, or they may occur immediately, rather than after walking for a long distance. Patients occasionally describe symptoms of coldness, blanching, and numbness. All types of entrapment (except type VI) can involve the tibial nerves and result in paresthesia. A minority of patients (10%) present with signs and symptoms of chronic CLI, and even fewer present with acute limb ischemia. Venous entrapment (type V) is suggested by calf cramping or symptoms more typical of a compartment syndrome, including swelling and a feeling of fullness.[13]

Pedal pulses are typically palpable and normal at rest, but disappear with passive dorsiflexion or active plantar flexion of the foot. These maneuvers tense the gastrocnemius muscle against the entrapped artery, temporarily occluding the patent lumen. They should also be performed on the contralateral asymptomatic limb. If left untreated, chronic entrapment causes progressive fibrosis of the popliteal artery, resulting in a thrombogenic intimal surface and eventual arterial thrombosis and occlusion.[8] Occlusion of the popliteal artery can be heralded by the sudden onset of more severe calf claudication and absent pedal pulses. This can occur after an episode of strenuous exercise, and should result in a high degree of suspicion for PAES when it occurs in a young adult with no risk factors for atherosclerosis.

Poststenotic dilation or aneurysmal degeneration of the popliteal artery, when it occurs, can be a source of distal emboli.[8]

Diagnostic Evaluation

The differential diagnosis for nonatherosclerotic lower-extremity peripheral arterial disease is outlined in Table 143.2.[18]

Noninvasive Testing

Exercise treadmill testing is commonly performed as an initial investigation. The patient is instructed to walk or jog until symptoms develop. Ankle-brachial pressure measurements are obtained before and following the treadmill test, and should drop significantly. Subsequently, duplex segmental pressures are taken with the Doppler probe placed on the posterior tibial artery. Active plantar flexion and passive dorsiflexion of the ankle with the knee in full extension results in gastrocnemius muscle contraction.[12] Readings are repeated several times, and care should be taken to avoid moving the probe during muscle contractions. Similarly, duplex studies are performed with visualization of the popliteal artery during calf muscle contraction and relaxation. The duplex interrogation must be repeated several times, because the popliteal artery can be pushed deeper into the popliteal fossa during muscle contraction, negatively affecting visualization and volume recordings. A positive duplex test with provocative maneuvers should prompt further investigative studies. While some investigators have had excellent results with duplex ultrasound,[19] others have reported high (72%) false-positive studies, resulting in an overestimation of popliteal artery compression.[13]

TABLE 143.1 Classification of Popliteal Artery Entrapment Syndrome Symptoms

Class	Description
0	Asymptomatic
1	Pain, paresthesia, and cold feet after physical training (e.g., jogging, heavy work)
2	Claudication while walking (>100 m)
3	Claudication while walking (<100 m)
4	Rest pain
5	Necrosis

From di Marzo 2005.

Angiography

Angiography remains the mainstay of investigation at many centers, with a reported median sensitivity of 97% (range, 85% to 100%).[6] In general, the diagnosis of PAES should be considered when at least two of the following angiographic features are present:[2]

- Medial deviation of the proximal popliteal artery
- Focal occlusion of the mid-popliteal artery
- Poststenotic dilation of the distal popliteal artery

Angiography has the additional advantage of delineating tibial artery anatomy following embolization from a poststenotic dilation of an entrapped popliteal artery or a thrombogenic entrapped artery. Angiographic views should be obtained in the neutral position and during provocative maneuvers (Fig. 143.4). Angiography is useful to distinguish PAES from ACD of the popliteal artery. In contrast to PAES, the arterial stenosis

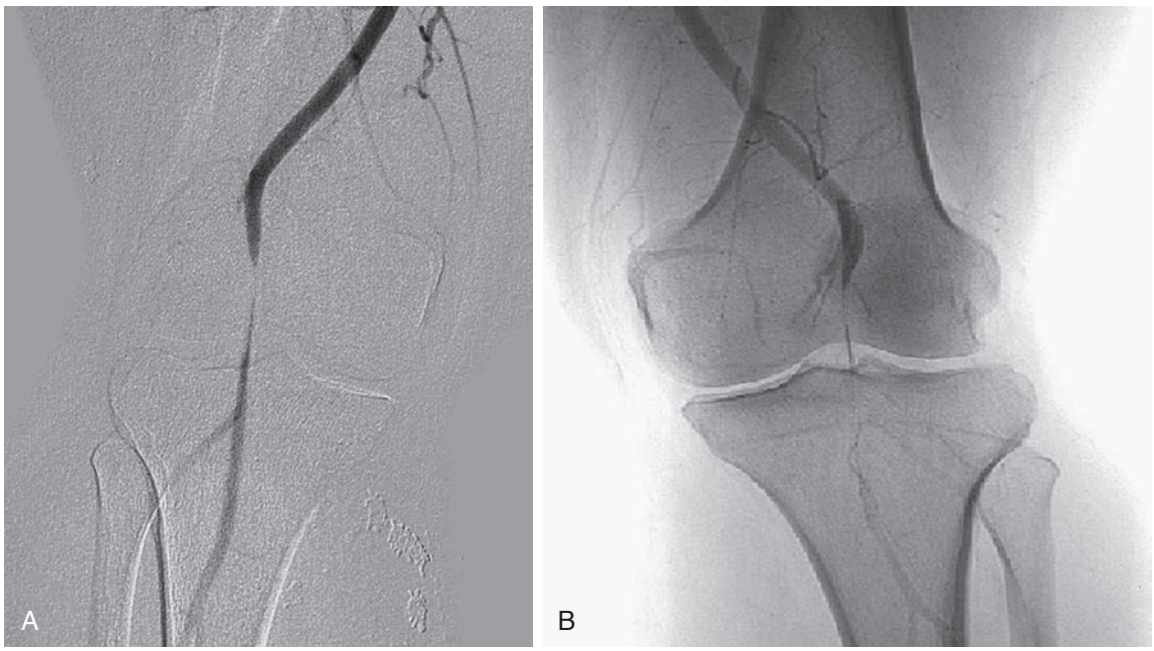

Figure 143.4 Angiogram reveals popliteal artery occlusion with plantar flexion of the foot. (From Causey MW, Singh N, Miller S, et al. Intraoperative duplex and functional popliteal entrapment syndrome: strategy for effective treatment. *Ann Vasc Surg*. 2010;24:556-561.)

TABLE 143.2 Differential Diagnosis of Nonatherosclerotic Peripheral Artery Disease

		Age	Sex	Key Features	Diagnosis
Popliteal artery entrapment syndrome		Young adults	M > F	Exertional claudication pain, paresthesias, and poikilothermia after exertion external compression of popliteal artery from muscles and ligaments in popliteal fossa	Loss of Doppler signaling with provocative maneuvers demonstration of compression on active pedal plantar flexion against resistance CT/MRI to demonstrate entrapment of vascular structures
Adventitial cystic disease		4th and 5th decades	M > F	Exertional claudication with extended recovery time compared to aPAD symptoms caused by compression of arterial lumen by mucinous containing cystic lesion within the adventia	Loss of pedal pulses with sharp knee flexion (Ishikawa sign) CT/MRI
Iliac artery endofibrosis		2nd and 3rd decades	M = F	Competitive athletes, common in cyclists intimal thickening by collagen fibers, fibrous tissue, and smooth muscle proliferation femoral bruit with hip flexion	Arterial duplex ultrasound and digital subtraction angiography with hip flexion and extension intravascular ultrasound with intraarterial translesional pressure gradients
Fibromuscular dysplasia		2nd to 5th decades	F > M	"String of bead" appearance symptoms based on vascular bed involved	Digital subtraction angiography with intravascular ultrasound
TAO (Buerger disease)		<50 years		Tobacco smokers intermittent claudication, Raynaud phenomena, superficial thrombophlebitis skipped lesions and corkscrew collaterals	CT/MRI digital subtraction angiography
Medium and large vessel vasculitis	TA	15–30 years	F > M	Asian and Latin decent pulseless upper extremity	Elevated inflammatory markers Duplex ultrasound CTA MRA temporal artery biopsy (GCA)
	GCA	>50 years	M = F	Headache, jaw claudication, visual disturbances	
	Behcet's	<30 years	M = F	Recurrent mucosal ulcers, uveitis, pathergy	
Chronic exertional compartment syndrome		>40	M = F	Athletes typically bilateral complete symptom resolution 10-20 min after rest	Imaging to rule out other causes elevated intra-compartment pressures before and after exercise

or compression from adventitial cysts is readily visible in the neutral position.

Computed Tomography and Magnetic Resonance Imaging

Less invasive imaging alternatives such as computed tomography (CT) or magnetic resonance imaging (MRI) can be particularly useful in cases of popliteal artery entrapment syndrome when the artery is occluded, because they illustrate the anatomic relationships between the vessels and muscles in the popliteal fossa and identify anomalous muscular insertions (Fig. 143.5). Some investigators believe that MRI is superior to CT in this regard, and should be the diagnostic test of choice in young patients presenting with intermittent claudication.[13]

Treatment

In most cases of symptomatic PAES, surgical intervention is indicated and should be offered. This is especially true for types I to V entrapment, and depends on the severity of symptoms in type VI entrapment. The approach to treatment is dictated by the patient's anatomy, clinical presentation, and the status of the popliteal artery (Table 143.3).

In general, early intervention allows for a more limited operation with myotomy alone, rather than arterial reconstruction. Because the natural history of PAES progresses from arterial fibrosis to thrombosis and eventual occlusion, most authors advocate surgical correction of types I to V PAES to prevent arterial degeneration. The principles of surgical treatment include release of arterial entrapment, restoration of normal anatomy, and restoration of arterial flow.[13]

Endovascular therapies are limited because they do not address the underlying muscular entrapment. There have been reports of small numbers of patients with occluded popliteal arteries undergoing endoluminal interventions and thrombolysis followed by myotomy several weeks later. These patients were anticoagulated for various periods.[20] However, anticoagulation and the preservation of a potentially thrombogenic popliteal artery are

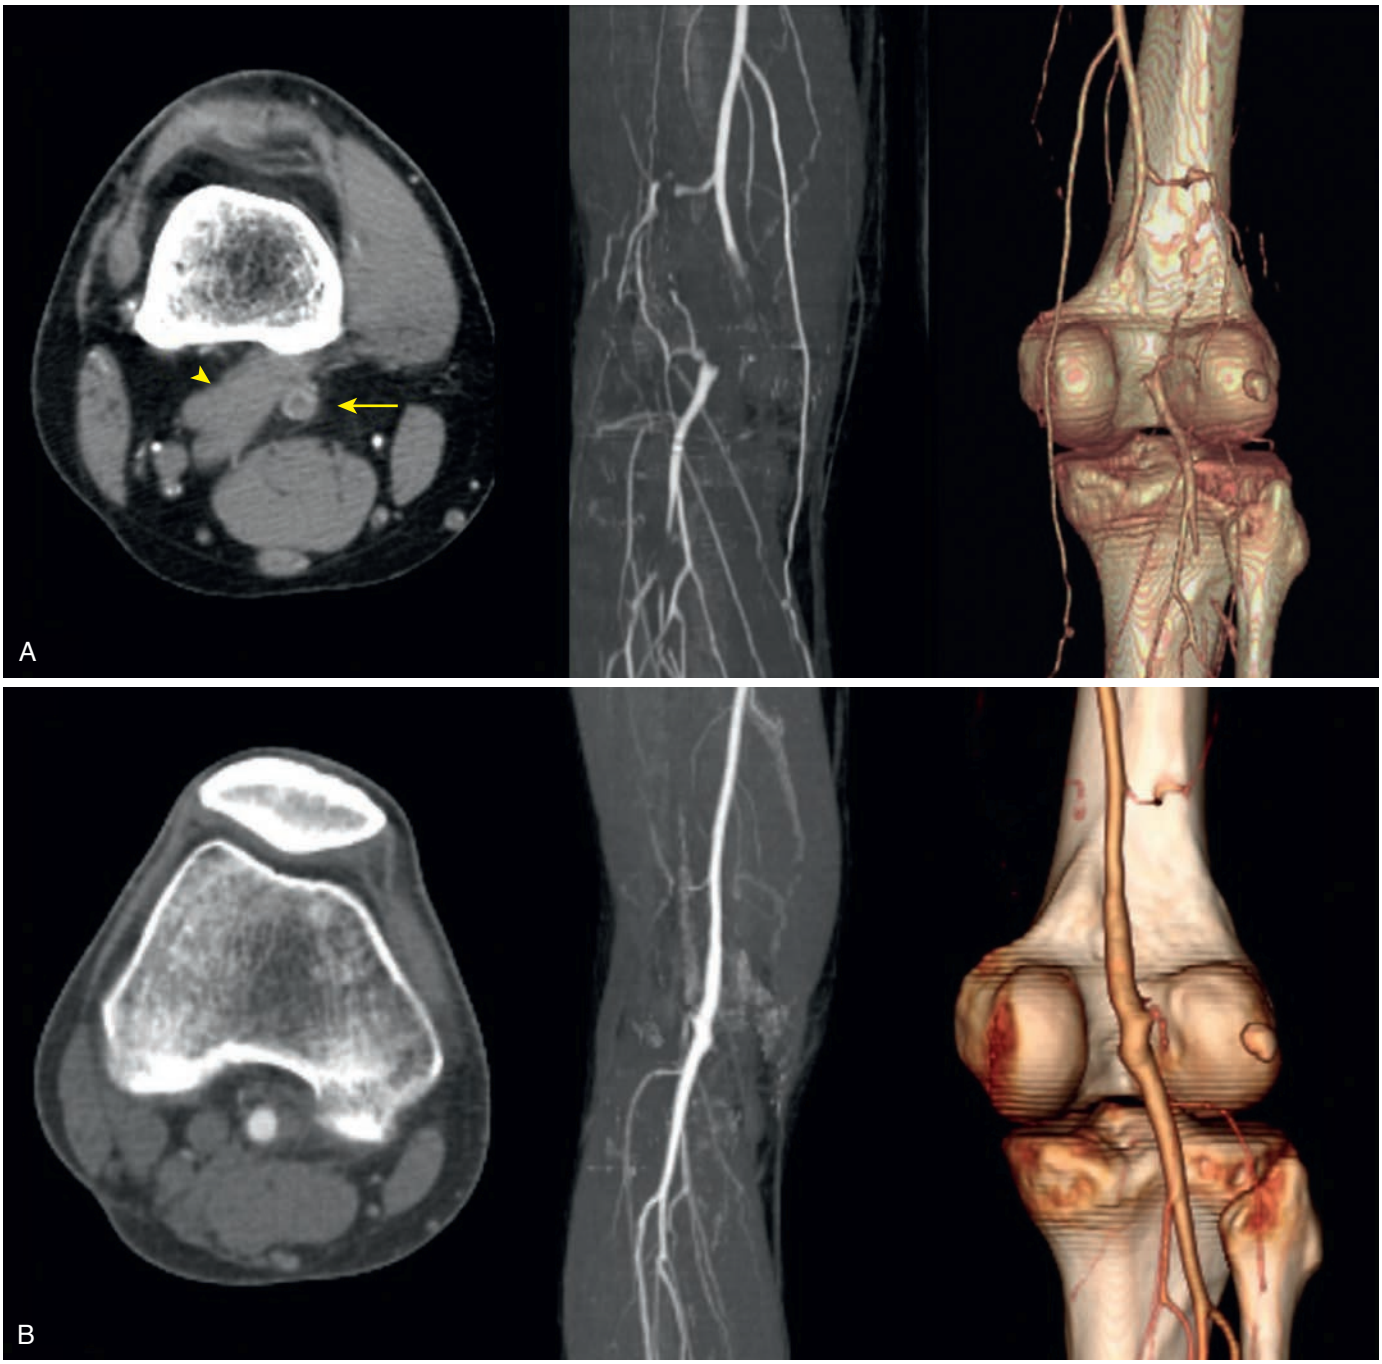

Figure 143.5 Popliteal entrapment syndrome type I **(A)** medial head of gastrocnemius muscle *(arrowhead)* occludes popliteal artery *(arrow)*. **(B)** Patent artery following musculotendinous resection and popliteal artery interposition venous graft. (From Kim SY, Min SK, Ahn S, et al. Long-term outcomes after revascularization for advanced popliteal artery entrapment syndrome with segmental arterial occlusion. *J Vasc Surg*. 2012;55:90-97.)

suboptimal treatment options in this young and active patient population.

Type I to V, Normal Popliteal Artery

In the absence of arterial fibrosis in an otherwise normal-appearing popliteal artery, musculotendinous release alone is sufficient to restore normal anatomy.[13] Musculotendinous release can be performed through either a posterior or a medial approach. Proponents of the posterior approach highlight the operative flexibility that it offers the surgeon, the wider degree of inspection possible, the greater ease of identifying and addressing the specific anatomic abnormality, and an adequate exposure to complete an arterial reconstruction if necessary.[13,21] Following an S- or Z-shaped incision, flaps are raised to expose the deep fascia, which is incised longitudinally, avoiding injury to the median cutaneous sural nerve. Sacrifice of the lesser saphenous vein

TABLE 143.3 Management Options for Popliteal Artery Entrapment Syndromes

Status of Artery	Entrapment Type	Operation	Surgical Approach
Normal	I and II	Myotomy	Medial
	III and IV	Myotomy	Posterior
	V	Myotomy	Medial or posterior
	VI	Myotomy if symptomatic	Medial or posterior
Abnormal (occluded, stenosed, or poststenotic dilatation or aneurysm)	I to VI	Decompression and arterial resection and replacement or exclusion and bypass	Medial or posterior

can facilitate exposure. As the vessels are approached, the tibial nerve is encountered and mobilized. The popliteal vein is identified, passing between the heads of the gastrocnemius muscle deep in the popliteal fossa. The popliteal artery, which is not in its normal position, is identified higher in the popliteal space and followed distally. The artery's abnormal course can be medial to the medial head of the gastrocnemius muscle or entrapped by anomalous muscular structures or tendinous tissue.[21]

Through this posterior exposure, the medial head of the gastrocnemius muscle or the entrapping musculotendinous bands are completely divided, with no adverse functional sequelae, even in these young, active patients.[22] In entrapment types III and IV, mobilization of the muscular portion of the medial head of the gastrocnemius off of the posterior aspect of the femoral condyles usually suffices to relieve compression of the artery.

The medial operative approach is most suited for PAES types I and II and is less appropriate for types III and IV, where it may be more difficult to delineate the arterial and muscular anatomy. Entrapment types III and IV may best be explored via the posterior approach. Type V entrapment can be explored through either route, depending on the underlying muscular abnormality. The medial approach seems to result in a quicker return to normal athletic activities in these active patients and less incision-related morbidity.[8] Similar to the posterior approach, the medial head of the gastrocnemius muscle is divided when approached from its medial aspect, permitting complete arterial decompression.

Types I to V, Abnormal Popliteal Artery

Arterial bypass or replacement is indicated in cases of complete thrombosis, arterial wall degeneration from the chronic entrapment, thrombus formation on the intimal surface, fibrotic narrowing of the artery, and poststenotic dilation or aneurysm formation. When the popliteal artery demonstrates evidence of chronic damage, even if the extent is only minimal fibrosis, it should be replaced or bypassed in its entirety. Early reports of this syndrome described numerous instances of thromboendarterectomy with or without vein patch angioplasty. This approach produced inferior results, with a higher incidence of arterial thrombosis and reocclusion compared with arterial replacement with an autogenous conduit.[13]

Intraoperative duplex ultrasound can be useful for determining the need for arterial bypass. White and colleagues recently proposed the following intraoperative duplex ultrasound criteria for performing an interposition graft bypass in PAES patients: peak systolic velocity of 250 to 275 cm/s or greater, velocity ratio of 2 or greater, arterial occlusion, or aneurysmal (poststenotic) degeneration.[23]

The entrapment is first relieved by dividing the muscle or tendinous segment causing the arterial compression. Resection of the thrombosed artery and a short interposition venous graft are then performed. Alternatively, a short venous bypass graft can be performed, with exclusion of the occluded artery to prevent distal thromboemboli. If poststenotic dilation or aneurysm formation has occurred, arterial resection and venous replacement are performed.

Arterial reconstruction can be performed through a posterior or a medial approach. The posterior approach permits use of the lesser small vein as the venous conduit, but it is less useful in cases requiring a more distal reconstruction. Conversely, the medial approach allows for the harvesting of the more proximal great saphenous vein if a conduit of larger caliber is required. In addition, it is much easier to expose the more distal popliteal artery, or tibial arteries, through a medial exposure if a more distal revascularization is required. This may be the case with extensive poststenotic dilatation or with tibial artery occlusion secondary to thromboemboli from the entrapped popliteal artery.

Type VI, Symptomatic

Most authors support surgical intervention for symptomatic type VI PAES. Hislop and colleagues in Australia have advocated for the injection of *Botulinum* toxin (Botox BTX-A) as an initial intervention in those patients.[24] Botox's proposed mechanism of action is through paralyzing the slip of muscle responsible for the dynamic arterial occlusion, inducing muscle atrophy that increases the space available for the popliteal artery, and relaxing the arterial smooth muscle, which results in popliteal vasodilation. However, this treatment remains untested in prospective studies.

Other authors have advocated for the use of surgical decompression for these patients, either through a medial or a posterior approach. Transection and resection of the muscular portion of the medial head of the gastrocnemius muscle, with preservation of the tendon, is usually sufficient to relieve symptoms.[13] To ensure adequate decompression, one must take care to completely transect the muscular fibers from the posterior aspect of the lateral femoral condyle and the intercondylar area. Adequacy of the extent of the myectomy can be determined with intraoperative duplex. Before resection, arterial systolic velocities are measured and compared with post myectomy velocities in

neutral, plantar, and dorsiflexion positions. Myectomy is continued until no further changes in velocity are observed.[25]

Type VI, Asymptomatic

Up to half the normal asymptomatic population may exhibit signs of popliteal artery compression, with provocative measures such as active plantar flexion and passive dorsiflexion of the foot. When these individuals are truly asymptomatic, little evidence supports prophylactic operative intervention, and these asymptomatic patients are best followed.[13]

Similarly, although bilateral popliteal artery entrapment is common, often only one extremity is symptomatic (43% of cases).[26] These asymptomatic contralateral extremities should be investigated, but surgical exploration is seldom indicated in the absence of symptoms.[4]

Treatment Outcomes

Myotomy alone for the management of PAES with a normal popliteal artery is associated with excellent results. In one large series, patients were able to return to their prior sports activities, did not require any further interventions, and maintained arterial patency at 10 years of follow-up.[8]

Bypass surgery with vein graft for PAES with an abnormal popliteal artery is associated with 65% to 100% graft patency at 10 years of follow-up.[27–29] Interposition grafts have better patency rates compared with long bypass grafts.[30] Reports of outcomes after hybrid procedures that combine angioplasty with musculotendinous resection and popliteal artery release are limited, but Ozkan and colleagues from Turkey reported primary and secondary patency rates of 60% at a median follow-up of 5 years.[31]

ADVENTITIAL CYSTIC DISEASE

Epidemiology

ACD was first reported in 1947 by Atkins and Key in London. The patient was a 40-year-old policeman with claudication and ACD of the external iliac artery.[32] It was not until 1954, however, that Ejrup and Hiertonn from Sweden described the first case involving the popliteal artery.[33] Since then, more than 700 cases have been reported, with the popliteal artery most commonly affected (80.5% of cases).[34]

ACD accounts for 0.1% of lower-extremity claudication.[35] In the majority of cases, popliteal artery involvement is unilateral, and only five cases of bilateral lesions have been reported.[34] The next most commonly involved arteries are the external iliac and femoral arteries,[36,37] but the disease has been reported in most of the arteries lying adjacent to joint spaces (Fig. 143.6).[38] Although it is most commonly a disorder of the arterial system, ACD of the iliofemoral and saphenous veins has also been described.[39]

ACD affects males predominantly, with a male to female ratio of 5 to 1, and patients are typically in their mid-40s.[34] Some investigators have reported a slightly older age at diagnosis in women.[40] Cases of pediatric patients (5 to 15 years old) have also been described.[34] It must be emphasized, however, that the diagnosis is often delayed because of the relatively young age of these patients and the absence of atherosclerotic risk factors. The prevalence of ACD has been variously reported as 1 in 1200 patients with claudication, regardless of age, and 1 in 1000 diagnostic angiograms.[41] These reports include predominantly symptomatic patients, so the incidence of ACD in the general asymptomatic population is unknown.

Pathogenesis

Etiology

The precise cause of ACD remains unclear and somewhat controversial. Five theories of etiology and pathogenesis have been proposed: the repetitive trauma, ganglion, systemic disorder, developmental, and articular theories.[40,41] Although convincing data to support the validity of the first three theories are scarce, they are briefly described as follows.

Repetitive Trauma Theory

Proponents of this theory suggest that repeated flexion and extension of the knee joint result in chronic injury of the popliteal artery that is characterized by cystic degeneration.[38,40,42] This repetitive distraction movement of the popliteal artery causes intramural hemorrhage between the adventitia and media. Subjecting the knee joint to repetitive movement and stress leads to joint degeneration and changes in the surrounding connective tissue, which in turn secrete hydroxyproline that acts on the intramural hemorrhage to result in adventitial cyst formation.[42]

Although this theory is simple and relatively intuitive, scientific data to support it are scarce. Repetitive trauma as a causative factor does not explain cases occurring in arteries that are not subjected to such stress or in younger patients who have not been subjected to the same duration of this stimulus. Furthermore, one would expect more cases of adventitial cystic disease in athletes, and there would be a positive correlation between age and incidence of the disease. Such trends, however, have not been observed.

Ganglion Theory

Proponents of this theory have been prompted by the similar content of simple ganglions and popliteal artery cysts.[38,40,43] Both types of cystic structures contain high levels of hyaluronic acid. In addition, there have been case reports of synovial cystic structures and Baker's cysts directly involving adjacent vascular structures.[44] Presumably, in the case of the popliteal artery, these synovial cysts enlarge and track along arterial branches, where they implant in the adventitia of the popliteal artery itself.[45] However, there is no evidence of histologic similarities between the lining and chemical content of the cystic fluid in the synovium and popliteal artery cysts. In fact, fluid from adventitial cysts has a much higher hyaluronic acid content than synovial cysts.[46]

Systemic Disorder Theory

This theory postulates that a systemic mucinous or myxomatous degenerative condition leads to development of ACD. Despite

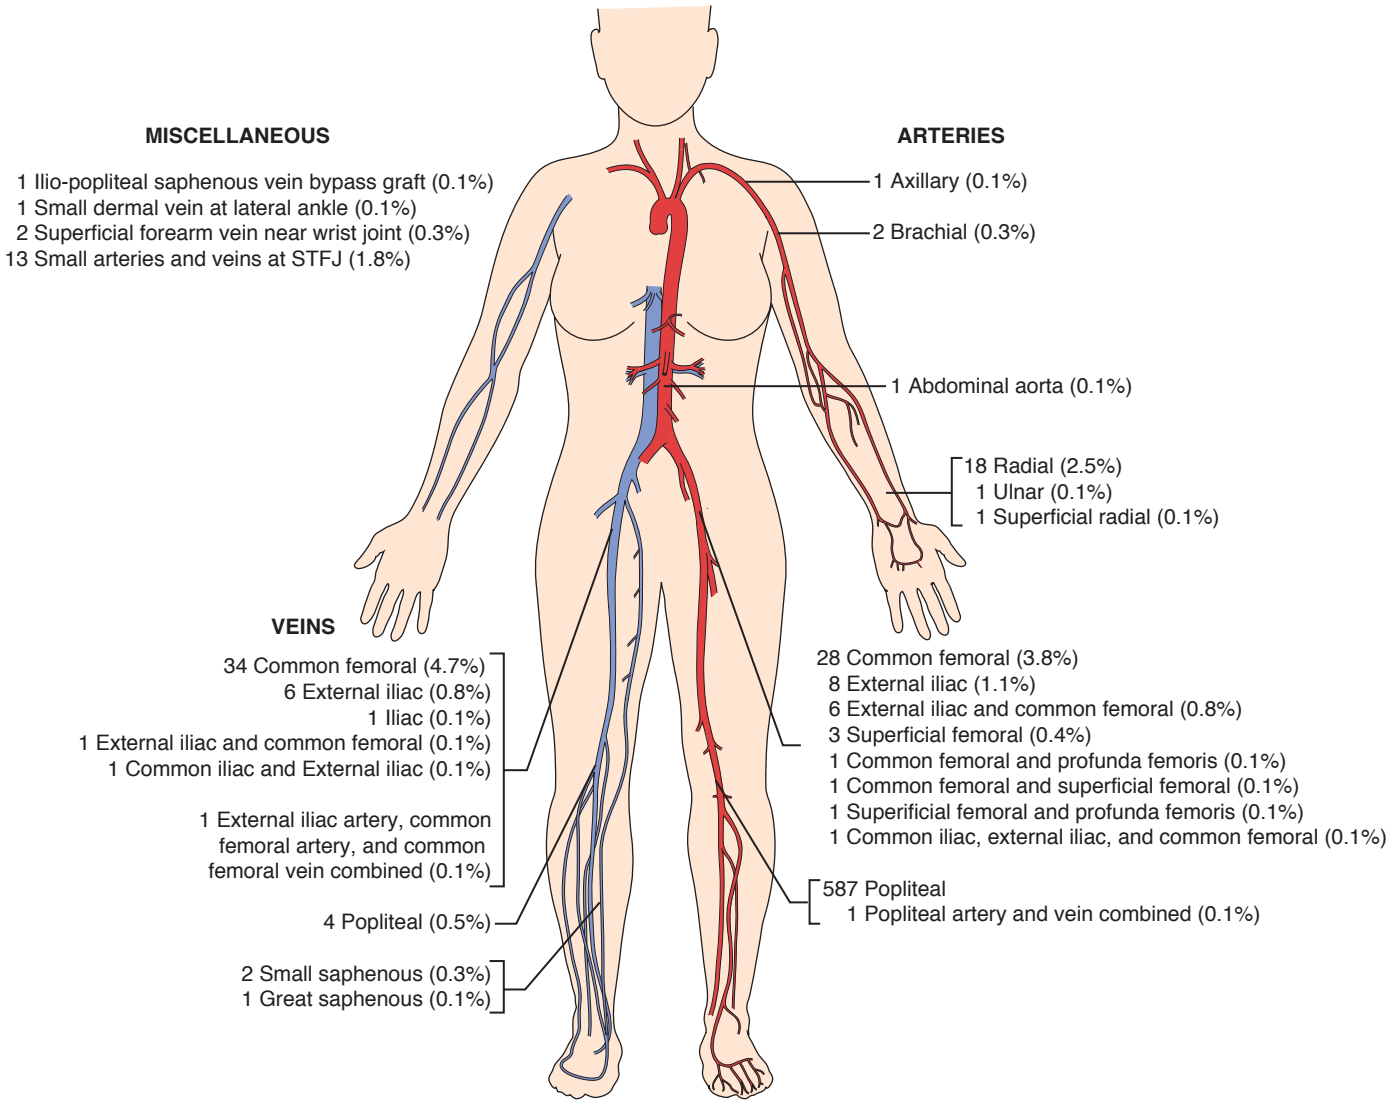

Figure 143.6 Artistic drawing demonstrating the various sites of adventitial cystic disease. *STFJ,* Superior tibiofibular joint. (From Desy 2014.)

being proposed in 1967,[47] no systemic disorder has ever been identified to support this theory. In addition, reports of bilateral disease are very rare,[48] as are cases of synchronous or metachronous cysts in different vascular locations that one would expect with a systemic disorder.

Developmental Theory

Also known as the cellular inclusion theory, this theory proposes that ACD occurs when mesenchymal mucin-secreting cells are implanted in the adventitia of the vessel during development. Levien and Benn noted that nonaxial arteries form from vascular plexuses between 15 and 22 weeks of embryologic development adjacent to developing joints.[38] During this time, mesenchymal cells that form these joints can be incorporated into closely adjacent vessels and may be responsible for subsequent cyst formation when these mesenchymal cells start to secrete mucoid material.

Articular (Synovial) Theory

Connections between the knee joint capsule and an adjacent popliteal artery adventitial cyst have been identified both intraoperatively and by preoperative imaging.[32,40,45,47,49–52] The articular (synovial) theory postulates that synovial fluid from a neighboring joint egresses and dissects along the adventitia of an articular (capsular) branch to the parent vessel.[52–54] Proponents of this theory argue that ligation of the joint connection along with simple cyst incision and drainage provides definitive treatment for this disease while decreasing the need for vein harvest.[34]

On the one hand, the presence of such a connection lends support to the ganglion theory of development, with the connection representing a direct communication between the joint capsule and the arterial adventitial layer through which synovial cysts can migrate.[45,49,51] Alternatively, proponents of the developmental theory claim that these communications represent a

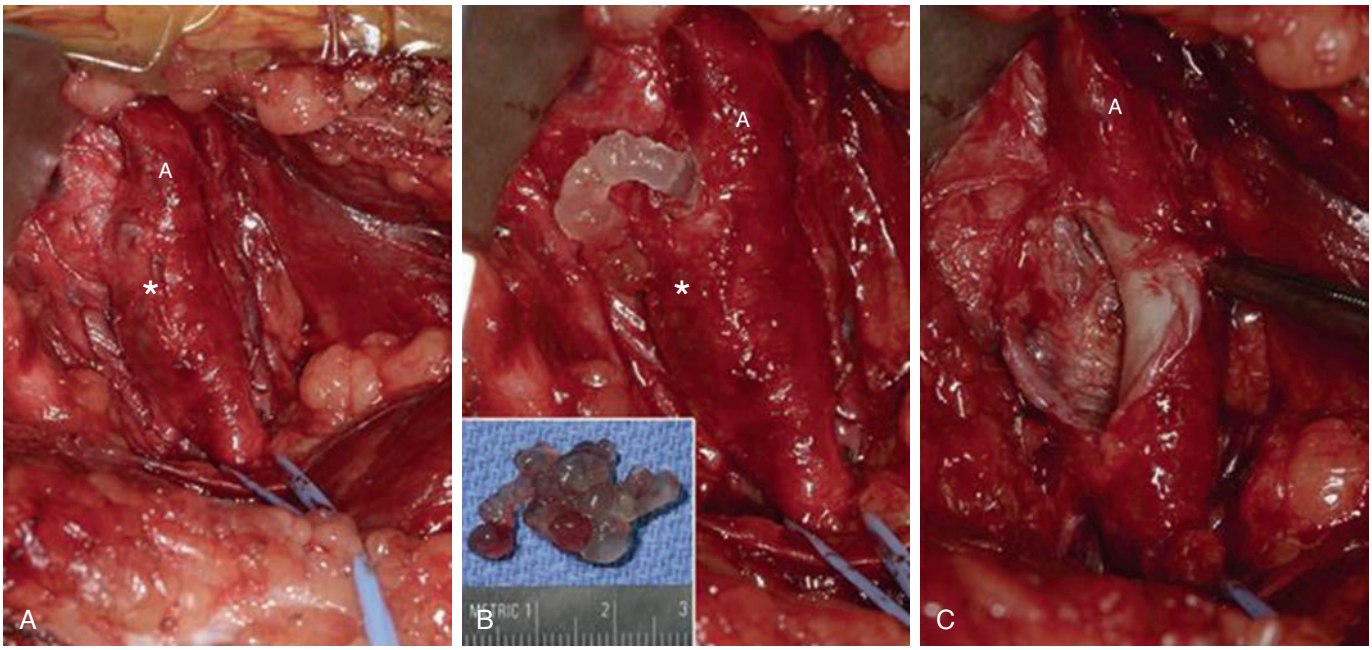

Figure 143.7 Adventitial cystic disease of the popliteal artery opened and evacuated. **A,** Cystic adventitial disease of the popliteal artery. **B,** Incision of adventitia with drainage of mucoid material (inset). **C,** The popliteal artery after evacuation of mucoid cyst. (From Spinner 2013.)

residuum of the embryologic process, when mesenchymal cells of the adjacent joint are included in the adventitia of the nearby developing artery.[38,45]

Pathology

Popliteal artery adventitial cysts are filled with a gelatinous mucoid material. Microscopic examination reveals a simple cuboid cell lining in the adventitial layer, with a notable absence of any coexisting microscopic features of atherosclerotic disease. Grossly, the popliteal artery may appear enlarged and sausage-like, connected by adhesions to adjacent structures (Fig. 143.7). The cyst is usually unilocular but can be multilocular. Cyst contents are usually clear or yellow, but can be dark red following hemorrhage. At the time of operation, these cysts are apparent following incision of the adventitial layer.

Clinical Presentation

Arterial

The typical patient with ACD of the popliteal artery is a young male who complains of sudden onset of short-distance calf claudication.[41] The disease can present in all ages, however, and has been described in young children.[55] The duration of symptoms is generally relatively short (weeks to a few months) and unilateral. Claudication symptoms may completely resolve for a period of time and then recur, or they may progress rapidly. Recovery time is often prolonged, up to 20 minutes, compared with that of typical claudicants.[56]

Given the focality of these cysts, the young age of patients, and the otherwise normal status of inflow and outflow vessels, progression to CLI is unusual with ACD, although the severity of claudication can progress and become disabling. It appears that the cysts need to be present and slowly enlarging for extended periods before patients enter the symptomatic phase. These enlarging cysts lead to progressive compression of the arterial lumen and can result in a "functional" occlusion of the artery without causing complete thrombosis. In cases of apparent arterial occlusion without thrombosis, evacuation of cyst contents can restore arterial patency. Nonetheless, prolonged compression of a compromised lumen can lead to popliteal artery thrombosis and a fixed occlusion.

Approximately two thirds of patients present with popliteal artery stenosis rather than occlusion. On physical examination, this may be demonstrated by normal or diminished pedal pulses and by an audible bruit in the popliteal fossa. Pedal pulses that are present at rest may disappear with flexion of the hip and knee (Ishikawa sign),[57] representing a functional stenosis that progresses to vessel occlusion with this physical manipulation. This is in contradistinction to popliteal artery entrapment, in which pedal pulses disappear with gastrocnemius muscle contraction caused by active plantar flexion or passive dorsiflexion of the foot.[41]

There have been case reports of spontaneous cyst resolution,[58–61] possibly because of cyst rupture into the popliteal fossa. However, this is extremely unusual and should not be considered a feature of this disorder. Furthermore, Zhang and colleagues from Manitoba described a recurrence of the disease after an apparent spontaneous cyst resolution in a female patient who eventually required surgery.[62]

Venous

Venous ACD of the lower extremities is very rare.[39,63] As with arterial ACD, it occurs predominantly in young males and has

been described in children.[64] However, it most commonly involves the iliofemoral rather than the popliteal segments. Typically the diagnosis is made when a young, previously healthy male presents with painless swelling of the lower extremity and is investigated for deep venous thrombosis. Venous ACD should be considered when there is evidence of extrinsic compression on venous duplex imaging or a filling defect on venography. The optimal method of management is not well defined, but most authors advocate operative exploration with venotomy and evacuation of the cyst contents, followed by cyst wall excision to minimize the risk of recurrence. A recurrence rate of 11.5% has been reported.[63]

Diagnostic Evaluation

Ankle-brachial indices in patients with ACD are unaffected at rest and drop following exercise. This pattern should raise the suspicion of an arterial cause of the patient's symptoms and prompt further investigation.

As with all other arterial pathologies, there has been a steady progression of diagnostic modalities from standard angiography and Doppler ultrasound technologies to cross-sectional imaging with CT and MRI. Although each method has advantages and disadvantages, current recommendations advocate the use of duplex ultrasound scanning followed by CT or MRI as the best diagnostic approach.[41]

Noninvasive Testing

Duplex ultrasound should be the initial diagnostic tool for this disorder.[65,66] The number of cysts and their dimensions can be easily evaluated. Elevated Doppler velocities and cystic extraluminal compression of the affected popliteal artery segment is considered diagnostic. The boundary between the cyst and the arterial lumen is depicted by a fine bright line that pulsates. Ultrasound can also differentiate these cysts from popliteal artery aneurysms by an absence of flow within the cysts. Following intervention, duplex scanning is a useful postoperative surveillance tool to exclude cyst recurrence and residual or recurrent stenosis.

Angiography

Traditionally, angiography was the gold standard for diagnosing ACD, but this has now been largely replaced by noninvasive methods. Complete popliteal artery occlusion is demonstrated with angiography in up to one third of cases, and the remaining studies demonstrate an eccentric compression of the popliteal artery lumen known as the "scimitar" sign, or an "hourglass" sign secondary to concentric compression (Figs. 143.8 and 143.9).[65] These imaging features can be detected with CT and MRI as well.

Angiography lacks sensitivity compared with other imaging modalities, because stenosis can be missed on anteroposterior views and may be evident only with lateral projections. Angiograms that demonstrate eccentric stenosis in the absence of thrombosis and poststenotic dilation are specific for ACD. However, the diagnostic capability of conventional angiography is limited in patients with arterial occlusion and provides little information about arterial wall pathology and the surrounding soft tissues.[41]

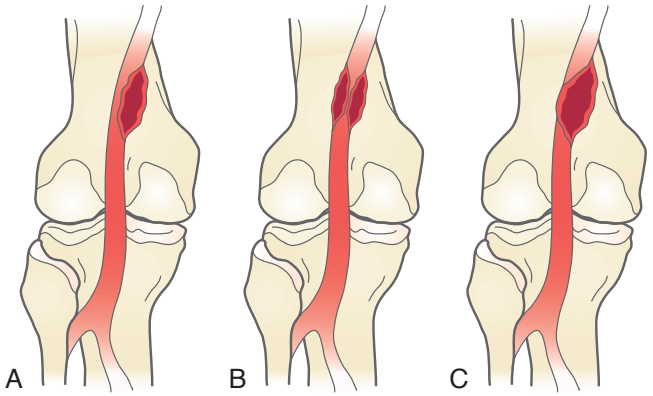

Figure 143.8 Adventitial cysts can occur in variable locations on the popliteal artery. The expanding cyst may indent the artery, resulting in the "scimitar" sign **(A)**; encircle the artery, resulting in the "hourglass" sign **(B)**; or completely occlude the vessel **(C)**.

Computed Tomography and Magnetic Resonance Imaging

CT is being used more extensively in cases of popliteal artery disease. It allows for the differentiation of ACD from PAES and aneurysmal disease, especially in cases of popliteal artery occlusion or thrombosis. CT also has the ability to demonstrate the size of the cysts and their relationship to surrounding structures (Fig. 143.10).[67]

At some institutions, MRI is frequently used for the workup of ACD (Fig. 143.11).[68] Advantages of MRI include the avoidance of ionizing radiation and intravascular contrast agents. MRI clearly depicts the extent of cystic involvement, and many authors consider it essential during the planning of surgical intervention.[34] Some authors recommend protocolling the MRI to include T2-weighted and gradient-echo sequences for suspected cases of ACD.[41] Others have described the use of T3 high spatial resolution MRI imaging, but there are concerns that significant increases in spatial resolution may adversely affect the image signal-to-noise ratio and limit the study's usefulness.[69,70]

Despite the lack of convincing evidence to support the use of MRI over CT, few investigators would argue against the use of cross-sectional imaging for the diagnosis of ACD and subsequent treatment planning. Duplex ultrasound remains useful as an initial diagnostic test and for postoperative surveillance. Emerging diagnostic technologies such as intravascular ultrasound and optical coherence tomography (Fig. 143.12) might also play an important role in the vascular surgeon's diagnostic toolbox as they become more widely available.[71]

Treatment

Given the rarity of ACD, treatment recommendations are mostly based on an evaluation of cumulative single-center experiences as opposed to randomized-controlled studies or prospectively maintained databases.

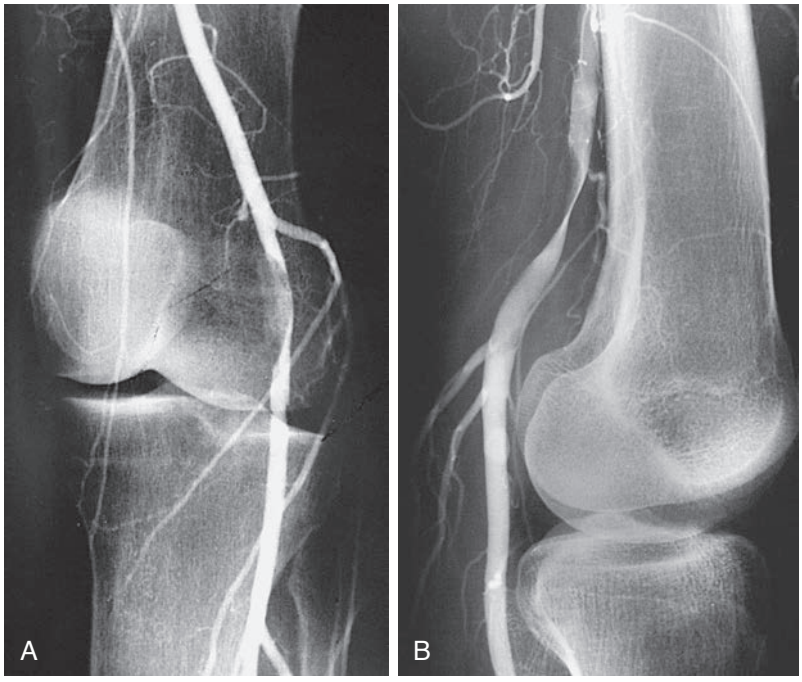

Figure 143.9 **(A)** Femoral angiogram shows compression of the right popliteal artery by an adventitial cyst. **(B)** Lateral view of another patient shows anterior compression of the popliteal artery above the knee.

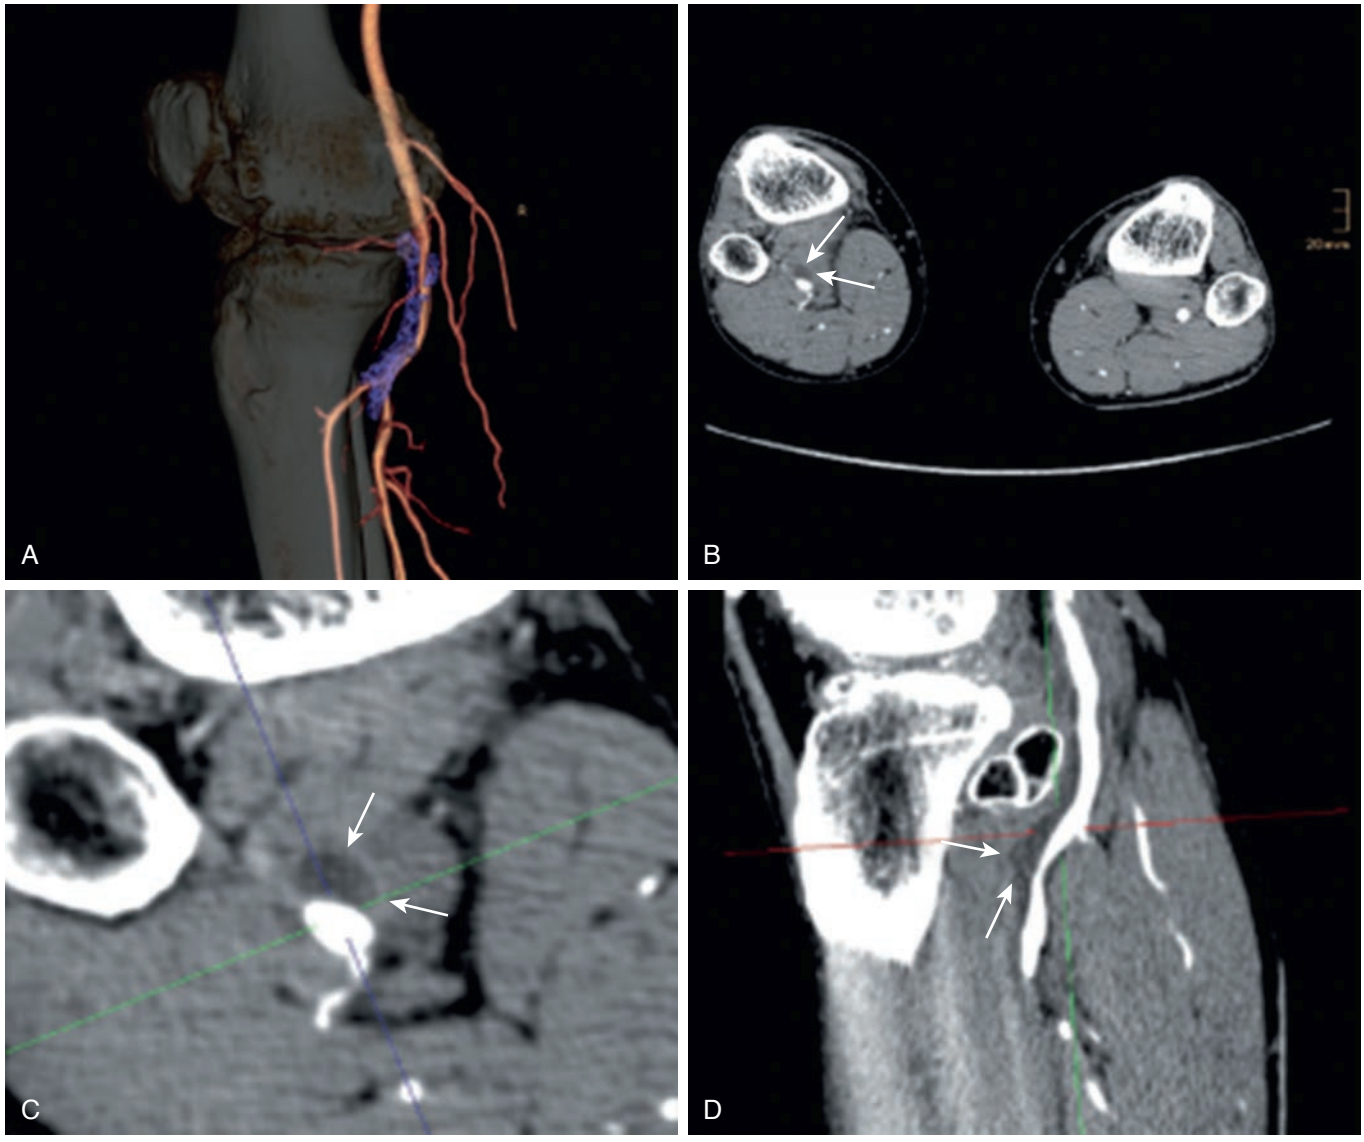

Figure 143.10 Contrast medium–enhanced CT angiography with three-dimensional reconstructions **(A)** shows a cystic extraluminal mass along and around the popliteal artery (**B** and **C,** *arrows*) extending to the tibiofibular trunk (**D,** *arrows*). (From Wick 2012.)

(From van Rutte PWJ, et al. In treatment of popliteal artery cystic adventitial disease, primary bypass.)

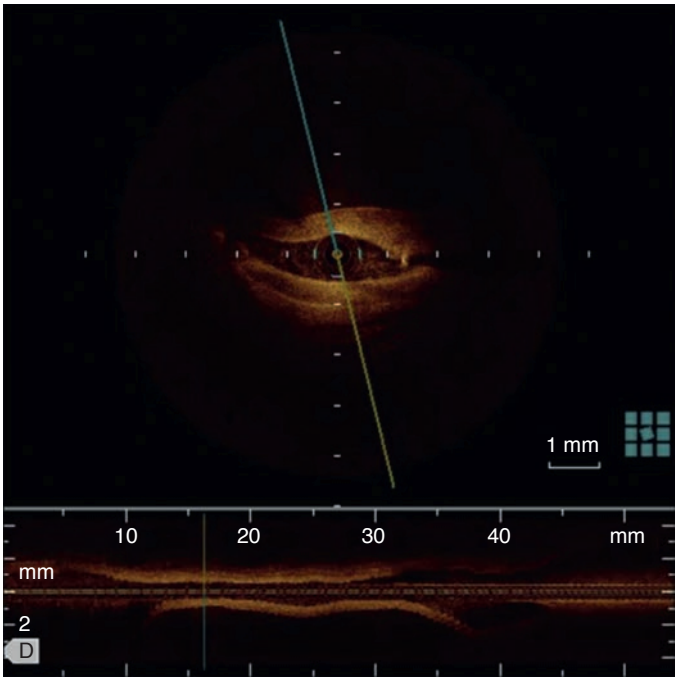

Figure 143.12 Optical coherence tomography cross-sectional images showing ACD of the popliteal artery extending from the 11 to 8 o'clock position. Multiloculated anechoic lesions around the stenosis area are more evident than by intravascular ultrasound. (From Takasawa 2016.)

Management options for ACD can be divided into nonresectional and resectional interventions.[34,41] In the majority of instances where nonocclusive stenoses are encountered, nonresectional methods are recommended. Resection, with subsequent arterial reconstruction, is more commonly used in cases of complete popliteal artery occlusion secondary to thrombosis or in the presence of extensive degeneration of the arterial wall.

Nonresectional Methods

Nonresectional methods of treatment include percutaneous transluminal angioplasty (with or without stenting), CT- or ultrasound-guided percutaneous cyst aspiration, and cyst evacuation (with or without cyst excision). These treatment methods are described as follows, in order of increasing chance of initial success and decreasing recurrence rate.

Transluminal Angioplasty

Angioplasty, with or without stenting, has been largely discarded as a treatment option. It is ineffective because the normal intimal layer of these arteries and the compliant arterial segment can recoil and restenose as early as 24 hours following balloon dilation.[72]

Cyst Aspiration

Promising short-term outcomes have been achieved with CT- or ultrasound-guided cyst aspiration. The technique is well-described, including the imperative for precise positioning of the needle tip in order to avoid the popliteal vein and the tibial and peroneal nerves.[41,73–75] Despite the simplicity of this treatment modality, failures are not unusual in cases of multiple loculations and highly viscous cyst fluid. Spontaneous cyst resolution has been described after an unsuccessful attempt at aspiration, highlighting a possible role for disrupting the cyst wall in cyst resolution.[76] Given the risk of incomplete evacuation and recurrence, cyst aspiration should be limited to patients

who refuse operative intervention and agree to close imaging surveillance and probable reintervention.

Cyst Excision and Evacuation

Operative exposure of the involved popliteal artery is best achieved via a posterior approach with the patient prone. In the case of a stenotic popliteal artery, incision into the cyst and evacuation of its contents is usually sufficient to restore arterial patency.

Resectional Methods

In instances of popliteal artery thrombosis or extensive arterial degeneration, a resectional treatment approach is preferred. The affected popliteal artery is explored through a posterior approach, and the extent of resection is determined by the length of arterial involvement on preoperative cross-sectional imaging and intraoperative findings. Arterial reconstruction is performed with an autogenous venous conduit or prosthetic graft of the surgeon's choice.

Choice of therapy is determined by the luminal status of the popliteal artery. In nonoccluded arteries, nonresectional methods, including imaging-guided cyst aspiration or operative cyst evacuation and excision, offer good short-term outcomes. In instances of popliteal artery thrombosis, resection is advocated, with excision of the involved artery and reconstruction with an autogenous conduit.

Treatment Outcomes

Recurrence of popliteal ACD has been described following all methods of therapy, although it is less likely with resection of the cyst or the involved artery.[77] Symptoms recur in 10% to 30% of patients undergoing cyst aspiration at a mean follow-up period of 15 months.[56,78] Treatment failure or recurrence has also been reported in 15% of patients undergoing cyst evacuation and 6% to 10% of those undergoing resection.[41,79] Arterial segment revascularization with autogenous venous conduit is associated with the highest success rate,[35] although disease recurrence has been reported in the vein graft after popliteal bypass surgery.[80,81] Conversely, short-term failure of treatment after endovascular therapy has been reported in 37.5% of patients undergoing percutaneous transluminal angioplasty and 50% of patients undergoing angioplasty and stenting.[82] Given the recurrence risk with all of these therapies, indefinite and periodic postoperative duplex surveillance is necessary.

Management of an infected arterial aneurysm remains a daunting surgical challenge. These infections occur in any named vessel and often affect elderly patients with multiple medical comorbidities. Medical treatment alone with culture directed antibiotics rarely eradicates the infection, and excision of the involved vessel with anatomic or extra-anatomic arterial reconstruction is usually required. Reports of using endovascular stent-grafts as the primary treatment or a bridging therapy to arterial reconstruction have been published; however, the specific role of endovascular devices in the treatment of this difficult problem remains to be defined.

HISTORY AND EPIDEMIOLOGY

Osler in 1885 was the first to publish a comprehensive discussion of infected aneurysm.[1] His series described infected peripheral arterial aneurysms in patients with endocarditis. In addition, his proposed pathogenesis included embolism of bacteria-laden material from infected heart valves to peripheral arteries resulting in destruction of the arterial wall. He termed the resulting aneurysm "mycotic," since the eccentric saccular configuration resembled a mushroom. Unfortunately, this term led to confusion, with some assuming that it applied only to infections caused by fungi, and others applied the term to all infected aneurysms rather than just those associated with bacterial endocarditis. For this reason, the term is best avoided.

In 1923, Stengel and Wolfert demonstrated that infected aneurysms could result from a variety of blood borne septic conditions, not just endocarditis.[2] Sommerville in 1959 reported a third type of arterial infection, one that occurred in preexisting atherosclerotic aneurysms.[3] Later, infected pseudoaneurysms due to illicit drug use or iatrogenic arterial trauma were described. The overall incidence of infected arterial aneurysms has risen in recent decades with the increasing prevalence of immunosuppressed patients, invasive hemodynamic monitoring, catheter-based procedures, and illicit drug abuse.[4-17]

PATHOGENESIS AND ETIOLOGY

Infected arterial aneurysms are classified into four types based on etiology: (1) microbial arteritis with aneurysm formation due to noncardiac origin bacteremia or contiguous spread of a localized infection; (2) post-traumatic infected pseudoaneurysms, most commonly related to illicit drug abuse; (3) infection of

TABLE 144.1 Clinical Characteristics of Infected Aneurysms

	Microbial Arteritis	Posttraumatic Infected Pseudoaneurysms	Infection of Preexisting Aneurysms	Infected Aneurysms From Cardiac Source
Etiology	Bacteremia, contiguous spread	Narcotic addiction, trauma	Bacteremia, contiguous spread	Endocarditis
Age	>50 years	<30 years	>50 years	30-50 years
Incidence	Common	Common	Unusual	Rare
Common location	Aorta Iliac artery Intimal defects	Femoral Carotid	Infrarenal Aorta	Aorta Visceral Intracranial Peripheral
Common bacteriology	*Salmonella* Others	*Staphylococcus aureus* Polymicrobial	*Staphylococcus* Others	Gram-positive cocci

Adapted from Wilson SE, Van Wagenen P, Passaro E Jr. Arterial infection. *Curr Probl Surg*. 1978;15:1–89.

a preexisting atherosclerotic aneurysm from bacteremia or contiguous spread; and (4) infected aneurysms from septic emboli, as classically described by Osler (Table 144.1).[1]

Microbial Arteritis

Bacterial seeding can occur in nonaneurysmal arteries with preexisting wall irregularities caused by atherosclerosis or congenital abnormalities (e.g., aortic coarctation, patent ductus arteriosus).[18,19] Additionally, normal arteries can be infected by a local invasive infection. Once established, suppuration, localized perforation, and pseudoaneurysm can result. Alternatively, more diffuse infection can result in rapid development of a true aneurysm, although often the aneurysm is saccular rather than a typical fusiform degenerative aneurysm. All named arteries are at risk, but the aorta is most commonly involved, likely due to its large intraluminal surface area and propensity for atherosclerotic involvement.[15,20-23]

Conditions associated with microbial arteritis include diabetes, cirrhosis, chronic hemodialysis, posttransplant immunosuppression, human immunodeficiency virus infection, alcoholism, chronic glucocorticoid therapy, chemotherapy, and malignancy.[11,16-19,24-29] In a study of 43 patients with infected aneurysms, Oderich et al.[7] found that 70% of patients had at least one of the aforementioned immunocompromised conditions.

Post-Traumatic Infected Pseudoaneurysms

Arterial trauma leading to direct bacterial inoculation of the arterial wall can result in an infected arterial aneurysm. Bacteria can be introduced at the time of endovascular access or during drug abuse with inadvertent or intentional intra-arterial injection (Fig. 144.1A and B). Notably, the use of percutaneous closure devices for endovascular procedures has been reported to be associated with infected pseudoaneurysms.[30,31] Not surprisingly, the common femoral artery is the most common location, but posttraumatic infected pseudoaneurysms involving the carotid, brachial, external iliac, and subclavian arteries have also been reported.[10,24,25]

Infection of Preexisting Aneurysms

Preexisting aneurysms can be secondarily infected by hematogenous or contiguous spread. Aneurysms are susceptible to infection, because the diseased intima or intraluminal thrombus permits bacterial seeding (Figs. 144.2A and B).[3] Of interest is that bacteria can be cultured from thrombus associated with asymptomatic degenerative aneurysms in up to 4% of patients,[3] and both Bennett[20] and Jarrett[19] demonstrated this finding and suggested that aneurysms associated with bacterial growth in the thrombus were more apt to rupture.[19,20] Furthermore, Ernst[32] showed that a greater number of positive cultures were found in those patients with ruptured aneurysms compared with asymptomatic and symptomatic aneurysms (38% vs. 9% and 13%, respectively). Recent research has suggested the possibility that multi-bacterial infection in the aortic wall may contribute to the development of degenerative aortic aneurysms.[33]

Infected Aneurysms Due to Endocarditis

Currently, less than 10% of infected arterial aneurysms originate as classically described by Osler.[15,34,35] Septic cardiac emboli may lodge in the lumen or occlude the vasa vasorum of the arterial wall, leading to ischemia and arterial wall infection. Once the artery is infected, rapid, focal, and progressive deterioration occurs and results in the characteristic saccular or multilobulated "mushroom-like" aneurysms. This process often leads to a locally contained rupture and formation of a false aneurysm.[14,21] Infected aneurysms associated with cardiac emboli are frequently multifocal, involving the aorta, intracranial circulation, and splanchnic and femoral arteries, typically at arterial bifurcations.[1,2,36]

MICROORGANISMS

The predominant microorganisms found in infected aneurysms depend on the type and etiology of the aneurysm, the patient's geographic location, and immune system. The bacteriologic spectrum is extensive and may be broader than was once

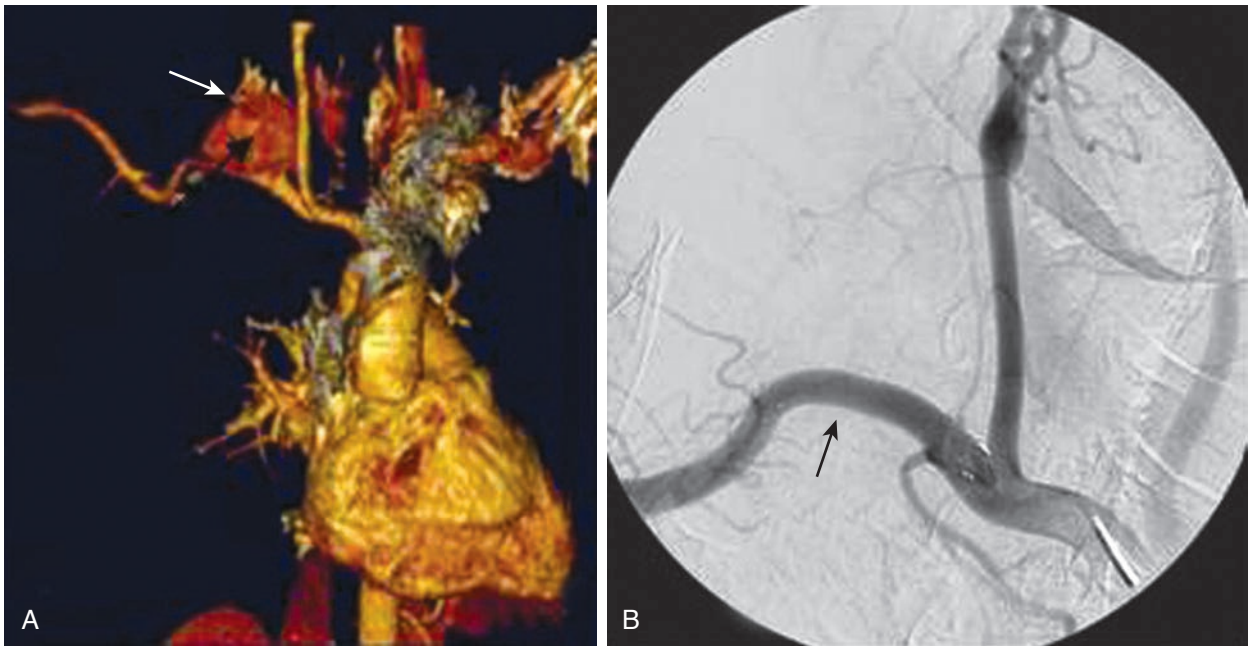

Figure 144.1 (A) Three-dimensional reconstruction computed tomographic angiography image in a patient with a polymicrobial posttraumatic false aneurysm of the right subclavian artery caused by repeated percutaneous cervical injection of illegal narcotics *(arrow)*. (B) Treatment with a covered stent-graft for control of hemorrhage *(arrow)*. Adjuvant therapy included open debridement and irrigation along with intravenous antimicrobial therapy.

believed.[37] *Staphylococcus* species, of which many are methicillin resistant, are the most common organisms and account for 28% to 71% of cases. *Salmonella* species are the second most common and have been reported in 15% to 24% of patients. *Streptococcus* species account for less than 10% of the cases in the postantibiotic era.[8,13,38] Overall, blood cultures are positive in 50% to 85% of infected aneurysm patients, and organisms have been isolated from aneurysmal tissue in up to 76% of patients with a suspected infected aneurysm.[7,15,39-43] As endoluminal device implantation has increased, infection in an existing aneurysm and microbial arteritis has also increased.[44,45]

Specific Organisms

Although less common, gram-negative infections are more virulent than gram-positive infections as demonstrated by rates of aneurysm rupture (84% vs. 10%) and patient mortality (84% vs. 50%).[19] The increased virulence is postulated to occur due to the ability of gram-negative organisms such as *Pseudomonas aeruginosa* to release alkaline proteinase along with a variety of elastases that cause vascular wall necrosis.[46] Furthermore, gram-negative organisms are commonly implicated in graft disruption and arterial stump hemorrhage after

reconstruction. Consequently, the presence of gram-negative organisms is an important consideration when contemplating repair strategies.

Methicillin-resistant *Staphylococcus aureus* (MRSA) has become an important public health problem. New strains of *S. aureus* with multiple resistant traits have been associated with high morbidity and mortality, and several recent series report MRSA as the predominant organism in infected aneurysms.[47-49] In particular, infected arterial aneurysms with MRSA have been reported as the primary organism found in patients due to illicit drug abuse.[50,51]

The diseased aorta appears to be particularly vulnerable to seeding by *Salmonella* species, and this pathogen is frequently found in infected preexisting aneurysms and in the infected atherosclerotic nonaneurysmal aorta. Specifically, *Salmonella choleraesuis* and *Salmonella enteritidis* account for more than half of reported cases of *Salmonella* aortitis.[34,52]

Clostridia infections of the aorta have been reported as well. One species, *Clostridium septicum*, has a propensity to cause fulminant infected aortic aneurysms. *C. septicum* aortitis is usually related to a gastrointestinal or hematological malignancy.[53] The proposed pathogenesis involves micro perforation of the gastrointestinal malignancy leading to hematogenous seeding in areas of the aorta with existing abnormalities, such as ulcerated plaques.[54,55] If not aggressively managed by wide debridement of involved aorta and reconstruction, the overall prognosis is poor with rapid deterioration of the aortic wall leading to rupture and death in 64% to 100% of patients (Fig. 144.3).[54-56]

Fungal infections, although rare, have been reported in patients with diabetes mellitus, immune suppression, and those with a history of systemic fungal disease.[4,57,58] Reported fungal pathogens include *Candida*, *Cryptococcus*, *Aspergillus*, and *Pseudallescheria boydii*.[59-62]

Treponema pallidum and *mycobacterium* species have also been found in infected aneurysms.[32,63-65] *T. pallidum* (syphilis) once caused up to 50% of infected aneurysms, but is much less common since the advent of penicillin. Finally, tuberculosis (TB) is a rare cause and is generally secondary to erosion of TB infected periaortic lymph nodes into the aortic wall.[66] More recently, it has been reported that the use of Bacillus Calmette-Guerin (attenuated bovine TB bacillus) as an intravesical treatment for superficial bladder cancer has led to remote arterial infections involving the infrarenal aorta and popliteal artery.[67,68]

DIAGNOSIS

Clinical Findings

The patient presentation of an infected aneurysm will depend on the anatomic location, the virulence of the organisms, and the duration of the infection. General symptoms can include malaise, fever, and/or chills. Although some patients can manifest more dramatic signs of overt sepsis, most have a nonspecific clinical picture that can be associated with back or abdominal pain, distal embolization, a pulsatile tender abdominal mass, or pulsatile peripheral mass with overlying cellulitis.[16,19,69-71] Hemodynamic instability due to rupture can be the initial clinical event.

Laboratory Studies

Leukocytosis and an elevated erythrocyte sedimentation rates are common, but nonspecific findings in patients with an infected aneurysm.[72] Positive blood cultures without an obvious source in patients with a known arterial aneurysm should raise diagnostic suspicion. Negative blood cultures are not sufficient to rule out the diagnosis of an infected aneurysm.[12] The diagnostic utility of blood cultures is limited if patients have been treated with antibiotics prior to the lab draw.[58]

Imaging

Radiologic studies are essential to establishing the diagnosis and determining surgical management. Ultrasonography and arterial duplex are helpful for initially assessing potentially infected peripheral aneurysms, but they are of limited value for infections of the aorta.[16] Computed tomographic angiography (CTA) is the imaging modality of choice when an infected aneurysm is suspected. Typical CTA findings include saccular, multi-lobulated, or eccentric true and false aneurysms; adjacent soft tissue inflammation and fluid; air within the aneurysm and in the aneurysm wall; or evidence of aneurysm rupture. Serial scans obtained days to weeks apart can be particularly valuable when the initial clinical and CTA findings are suspicious but not diagnostic. The findings of a rapidly enlarging aneurysm or the interval development of aneurysms in previously uninvolved aorta are highly suggestive of infection (see Fig. 144.3).[73-76]

Positron emission tomography (PET) alone or in combination with CTA has also been used effectively, given the often avid uptake of the radionuclide tracer by infected tissues.[77-79] Magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) are highly sensitive for inflammation and can also be helpful in patients with contraindications to iodinated contrast and when the CTA is equivocal.[80,81] Finally, indium 111–labeled white blood cell scanning has been used to identify prosthetic graft infections, but its use has not always been accurate in infected aneurysms.[82,83] Although not sensitive or specific, these studies can be of assistance when other imaging studies are equivocal.

MANAGEMENT

Antibiotics

Antibiotic therapy has a critical role in the treatment of all infected aneurysms and should be initiated immediately and continued for at least 6 weeks to indefinitely after surgical treatment. Pre- and postoperative antibiotic therapy should be broad spectrum, until organism-specific therapy can be instituted. Because of the importance of organism-specific therapy, obtaining a set of blood cultures before initiating antibiotics and obtaining tissue and fluid cultures at the time of operation is paramount. The actual duration of antibiotic therapy varies from weeks to lifelong and is guided by organism virulence and antibiotic sensitivity profile as well as the arterial segment involved and type of reconstruction.[84,85] At a minimum, 6 weeks of intravenous antibiotic therapy should be employed.[21,86] Especially in locations

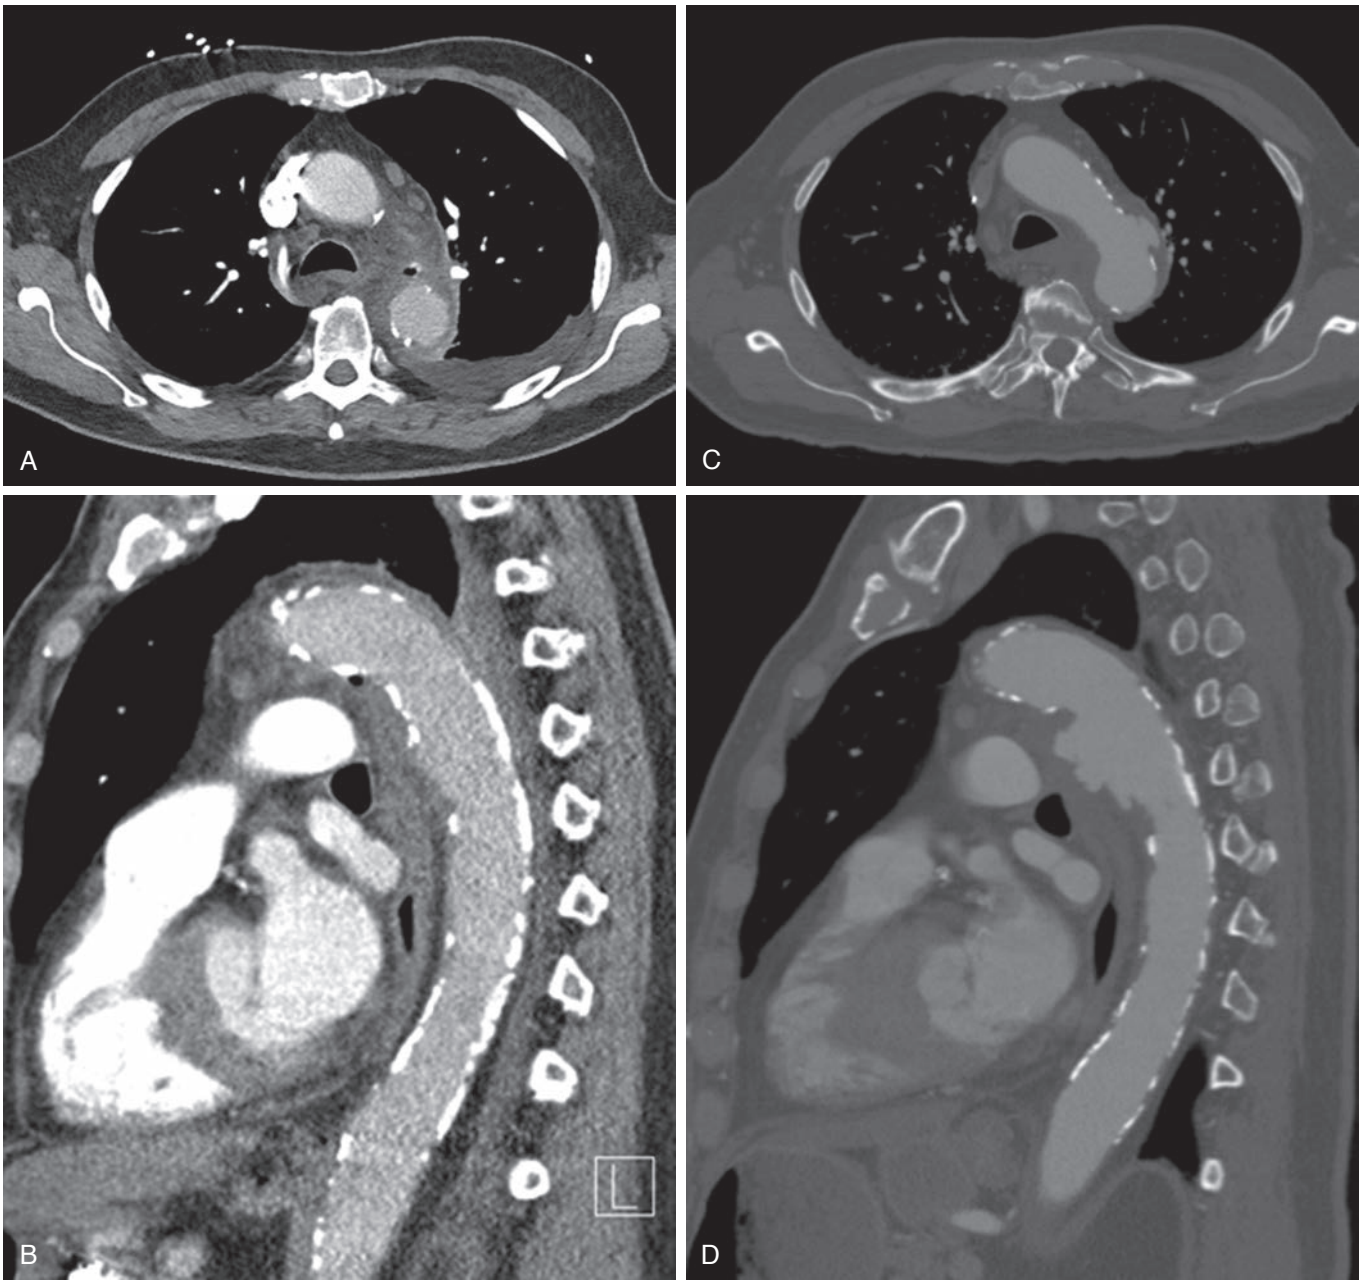

Figure 144.3 *Clostridium septicum* aortitis of the proximal descending thoracic aorta: (A and B) Proximal descending thoracic aorta with periaortic gas formation, and thickened wall. (C and D) Interval computed tomographic angiography in 10 days showing rapid enlargement of the aortic pseudoaneurysm. Patient underwent open aortic debridement via posterolateral thoracotomy, and in-situ reconstruction.

where recurrent infection is often lethal, such as aortic infections, most surgeons lean toward longer, even lifelong, suppressive antibiotic treatment.

Operative Treatment

While the nuances of the operative treatment depend on anatomic location, the following general principles apply to the treatment of all infected aneurysms.

1. To minimize excessive bleeding proximal and distal arterial control should be obtained early in the course of the operation.
2. Intraoperative cultures should be obtained in all patients. Intraoperative gram stain can be useful in certain patients to assist intraoperative decision making regarding arterial conduit and method of revascularization. Importantly, a negative intraoperative gram stain does not rule out infection.[87]
3. Infection control requires resection of the involved arterial segment and wide debridement of adjacent tissues, including all surrounding necrotic or infected tissues.
4. Either in-situ or extra-anatomic reconstruction can be used. Graft conduits for in-situ reconstruction include autogenous vein (saphenous, femoral), cryopreserved arterial allograft, or prosthetic graft that is either silver impregnated or soaked

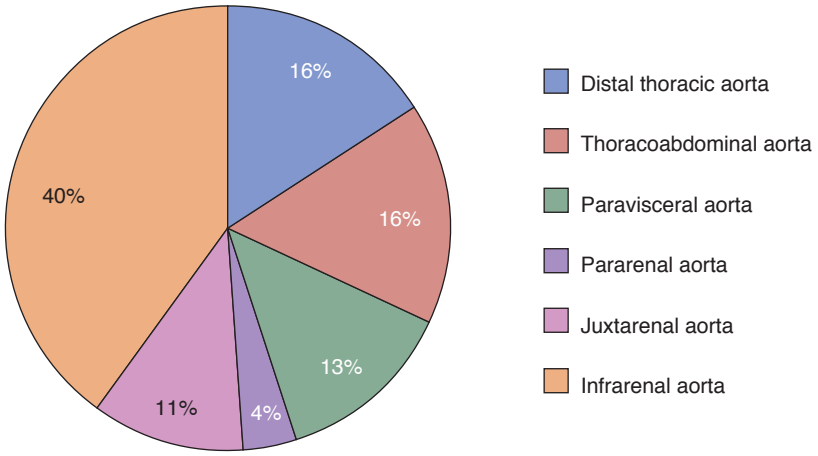

Figure 144.4 Distribution of infected aortic aneurysms in a report of 43 consecutive patients from the Mayo Clinic. (From Oderich GS, Panneton JM, Bower TC, et al. Infected aortic aneurysms: aggressive presentation, complicated early outcome, but durable results. *J Vasc Surg.* 2001;34:900–908.)

in antibiotics such as rifampin. The type of reconstruction used is guided by multiple factors, including the surgeon's experience, the patient's surgical risk, the anatomic location of the aneurysm, and the availability of autogenous conduit.

5. Following in-line reconstruction, the graft should be covered by well vascularized tissue such as omentum or muscle flaps. The use of antibiotic beads placed into the infected bed and/or surrounding the arterial reconstruction has also been reported to be of benefit.

AORTA

Infected aneurysms have been described in all segments of the aorta from the aortic root to the aortic bifurcation. Oderich reported the following distribution: infra-renal 40%, distal thoracic 16%, thoracoabdominal 16%, para-visceral 13%, and juxta-renal aorta and para-renal aorta 4% (Fig. 144.4).[7] The presence of a leukocytosis and positive blood culture have been reported in approximately 75% of patients.[7] CTA evidence of a peri-aortic mass or stranding is common and has been reported in 48% of patients.[88,89] Infected aortic aneurysms often involve parts of the aorta that are not commonly involved with atherosclerosis.[89] Despite the significant morbidity and mortality, outcomes have improved in the last 15 years, with the rupture status and expeditiousness of intervention impacting the outcome.[90]

Thoracic Aorta

Infected thoracic aortic aneurysms are highly lethal with a reported mortality of 30% to 50%. Gram-positive bacteria such as *Staphylococcal* species, *Enterococcal* species, and *Streptococcus pneumoniae* are the most common organisms.[91] *Salmonella* species infection does occur and is associated with a poor clinical outcome. Aneurysm formation can cause localized compressive symptoms such as dysphagia, dyspnea, hoarseness, cough, and superior vena cava compression.[91] However, the most common presentation is rupture.

Surgical excision of the infected segment, wide debridement, and long-term intravenous antibiotics remain the definitive treatment. Specific measures such as a spinal drain may be indicated to enhance spinal cord perfusion.[92] Depending on the aortic involvement, exposure may require a median sternotomy, left thoracotomy, or left thoracoabdominal incision. In-situ reconstruction is the most common approach, usually with a cryopreserved arterial allograft or rifampin soaked Dacron graft.

Another option for descending thoracic aorta infections is the ascending to infra-renal aortic reconstruction or "exclusion-bypass" first described by Kiefer.[93] A bypass from the ascending to infrarenal aorta is created through a median sternotomy and laparotomy. The ascending aorta is partially clamped, and an end-to-side proximal anastomosis is performed to a prosthetic graft, which is then tunneled through the right pleural cavity, across the diaphragm behind the left lobe the liver, through the lesser sac, and behind the pancreas to reach the infra-renal aorta. The distal anastomosis is performed to the infra-renal aorta with the cross-clamp applied below the renal arteries. The operation is generally well tolerated, since aortic clamping does not result in visceral or renal ischemia. Upon completion of the bypass, the distal aortic arch and supra-celiac aorta are stapled close, excluding the descending thoracic aorta. Complete debridement of the infected descending aorta is performed usually as a staged procedure through a posterior-lateral thoracotomy.

More recently, treatment using endovascular stent grafts combined with antibiotic therapy has been used as an alternative to conventional thoracotomy in managing infected aneurysms of the thoracic aorta. When combined with prolonged antibiotic therapy, this may be an especially attractive option in patients who are at high risk for open surgical repair.[94] Although published experience is limited, these grafts can serve as a bridge to definitive repair or as definitive palliation.[95,96]

Surgical complications are similar to those related to non-infected thoracic aneurysm repair. Infected Crawford type II thoracoabdominal aneurysms, age greater than 65, and contained rupture are associated with a 20% 30-day mortality.[97] Mortality of 85% has been reported in patients who were managed with antibiotic therapy only, with in-hospital rupture occurring in two-thirds of patients.[98]

Abdominal Aorta

Surgical intervention is dependent on the location and extent of the infection and associated patient comorbidities. Infection of the aorta without a preexisting aneurysm tends to affect the posterior wall of the supra-renal or supra-celiac segments. Infections of a preexisting aneurysm occur most commonly in the infra-renal location due to the frequency of aneurysms in this location.[99] Para-renal or para-visceral aortic infections are a greater surgical challenge, and the need to preserve the renal/visceral perfusion dictates that an in-situ reconstruction is preferred rather than over sewing of the aortic stump coupled with aortic based bypasses to maintain visceral and renal perfusion.[100-103] Overall, surgical mortality due to infected abdominal aortic aneurysms varies between 15% to 38%.[104]

Currently, an in-line reconstruction is preferred for most infected abdominal aortic aneurysms. Conduit options include cryopreserved arterial allografts, antibiotic treated Dacron grafts or creation of a "neo-aorta-iliac system" (NAIS) with the autogenous femoral-popliteal vein.[26,27,105-111] When an in-situ reconstruction is considered not possible or prudent, extra-anatomic reconstructions in a clean tissue plane with excision and debridement of the infected aneurysm and surrounding tissues may be employed. For all surgical reconstructions, liberal use of omental or rectus muscle flaps is important. Recently, endovascular approaches have been utilized as either a bridge or definitive therapy in selected patients.

Cryopreserved Arterial Allografts

Arterial allografts for in-situ aortic reconstruction have been shown to be quite resistant to re-infection by gram-negative organisms as well as other bacteria and microorganisms.[112] Allografts are procured from organ donors, processed using antimicrobial blends, and then cryopreserved using liquid nitrogen. When requested, the allografts can be thawed in under 45 minutes. They are surgically easy to handle and can be used in most infected fields without concern for re-infection. The main limitation to the use of arterial allografts is expense and availability. Grafts need to be ordered usually 24 hours in advance and supply may be limited. Depending on the number and segments of allograft needed, the cost can be more than $20,000. Nevertheless, cryopreserved arterial allografts are an excellent option and are our preferred option for in-situ revascularization, especially for those infections involving the para-renal and para-visceral aorta (Fig. 144.5A to D). A recent multicenter review demonstrates 75% 1-year survival and 51% at 5 years with freedom from graft explant of 99% at 1 year and 88% at 5 years.[113]

Complications associated with allograft reconstruction include peri-anastomotic hemorrhage, graft limb occlusion, and pseudo aneurysm. A higher rate of graft failure and hemorrhage has been associated with aorta-enteric fistulas, and this should be taken into consideration when planning repair.[114] In a recent series, allograft-related morbidity was 11.8% compared with 57.1% in patients who underwent extra-anatomic bypass or in-situ reconstruction with a prosthetic graft.[115]

Antibiotic Soaked Dacron Grafts

In-situ reconstruction with prosthetic grafts has reported re-infection rates as high as 20%.[116] For this reason, antibiotic, usually rifampin, soaked Dacron grafts are used for infected aneurysms with para-visceral and thoracoabdominal extension

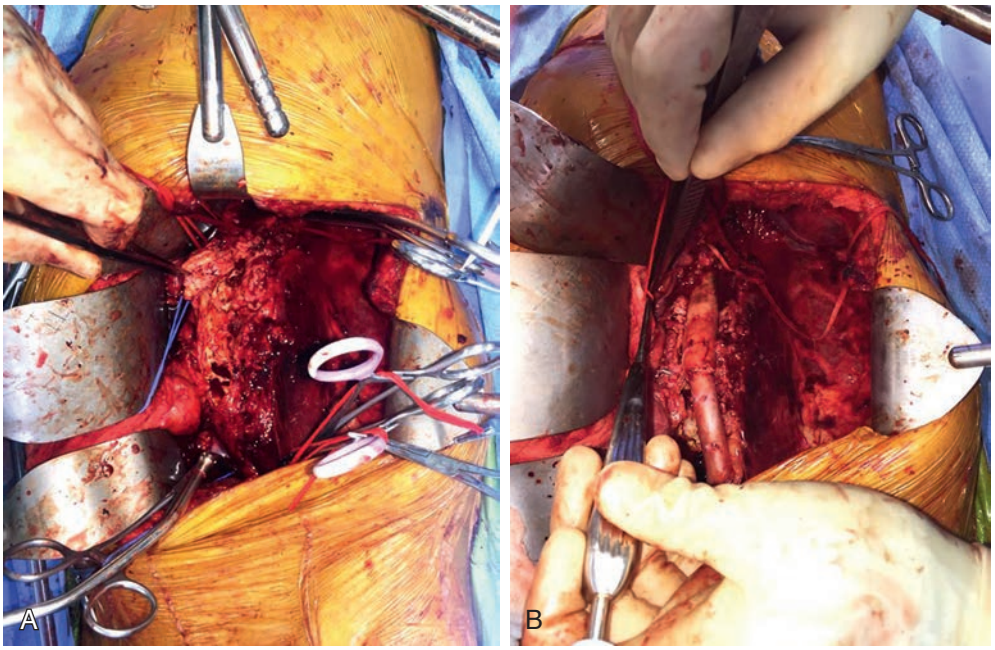

Figure 144.5 Paravisceral abdominal aortic pseudoaneurysm, caused by *methicillin resistant staphylococcus aureus* aortitis. (A) Debridement of the infected aorta revealed rupture of the posterior aortic wall as well as thickened inflammatory phlegmon surrounding the paravisceral aorta. (B) In-situ reconstruction using cryopreserved homograft. Celiac, superior mesenteric, and right renal arteries were incorporated with the beveled proximal anastomosis. The left renal artery was reimplanted.

and in patients who present in extremis and require rapid surgical management for control of hemorrhage and sepsis. Antibiotic soaked grafts maintain their bactericidal activity by being coated with collagen or gelatin to provide a bond between the graft and antibiotic.[117] Rifampin has been the agent of choice given that it has broad-spectrum activity against gram-positive and gram-negative organisms.[117]

A cumulative review of antibiotic soaked grafts found perioperative morbidity to occur in 20% to 60% of patients with a reported graft reinfection rate of 4% to 22%.[118] A series from the Mayo Clinic in patients who were treated with an in-situ rifampin soaked Dacron graft had an operative mortality of 20%, but no patients had a late graft reinfection.[119] Another series from the same group focused on 54 patients in whom in-situ rifampin soaked Dacron graft reconstruction was performed for aortic graft enteric erosion or fistula. The protocol was excision of the infected graft, intestinal repair, placement of in-situ rifampin-soaked Dacron graft with omental wrap and long term antibiotics.[120] Patient survival at 1 year, 5 years, and 10 years were 85%, 59%, and 40%, respectively, with no patients dying from graft-related complications.[120] Late graft-related complications occurred in 16% with 4% developing graft reinfection.[120] Another recent single center series reported a 30-day mortality of 18% and a 2-year survival of 73% with silver coated Dacron grafts bathed in 5000 IU neomycin/250 IU bacitracin solution.[121]

Small case series have reported high rates of graft reinfection in rifampin soaked Dacron grafts when used in patients with active MRSA infection at the time of implantation.[122] In vivo canine experiments comparing resistance to MRSA growth with rifampin soaked and silver impregnated Dacron grafts have found in both graft configurations diminishing levels of bacterial growth suppression after 7 days.[123] Consequently, some authors advocate limiting antibiotic soaked grafts to patients with low virulence organism infection.[124]

Neo-Aorta-Iliac System

Described by Clagett, the NAIS procedure utilizes deep femoropopliteal vein to create a neo-aorta-iliac conduit.[125] The procedure has a prolonged operative time, averaging 10 hours, and because of that, it may be of limited use in the patient with overt sepsis or the elderly with a multitude of comorbidities.[126]

The femoral-popliteal vein can be used in a number of different configurations to achieve in-line revascularization, depending on the extent of infection, the necessary reconstruction, and the availability of conduit. The most common configuration is demonstrated in Fig. 144.6, and an intraoperative picture is demonstrated in Fig. 144.7. Further details are provided in Chapter 47.

The femoral-popliteal veins provide a reasonably good size match for the aorta in most cases and are resistant to recurrent infection. Re-infection is rare, occurring in less than 2% of patients.[127] Primary patency rates are 87% and 82% at 2 and 5 years, respectively, along with primary assisted patency rates of 96% and 94% at 2 and 5 years, respectively.[128-130]

Despite the magnitude of the operation, the reported 30-day mortality rate is less than 10%, and the 5-year survival is 60%

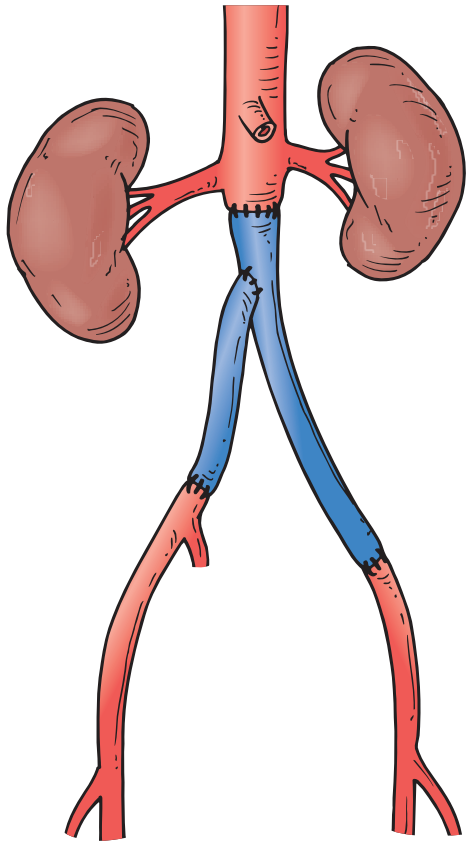

Figure 144.6 A common configuration of neo-aorto-iliac system reconstruction using an autogenous femoral vein. Various configurations can be used to accommodate more or less extensive infection or occlusive disease. (Courtesy G. Patrick Clagett, MD.)

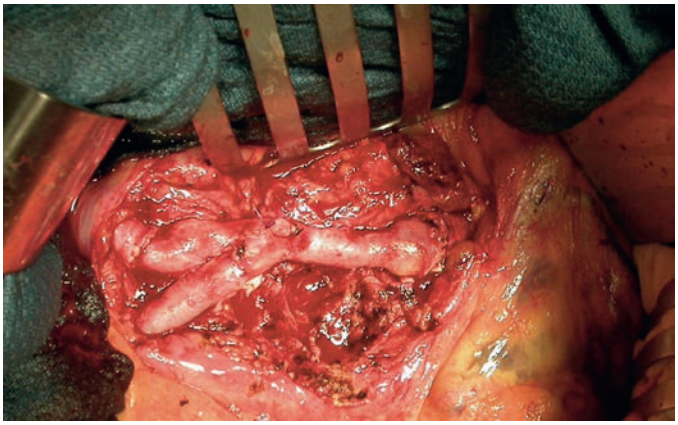

Figure 144.7 Neo-aorto-iliac system reconstruction with femoropopliteal vein in a patient with salmonella infected infrarenal aortic aneurysm. (Courtesy of G. Patrick Clagett, MD.)

when used for an infra-renal aortic graft infection.[130] As evidenced by the excellent patency, graft stenosis after NAIS reconstruction is uncommon. The risk factors for stenosis include small graft size (<7 mm), history of coronary artery disease, and smoking.[128] Patients should be monitored by duplex ultrasonography to promptly detect and treat graft stenosis.

Specific morbidity associated with femoral-popliteal vein harvest includes the need for fasciotomy in 12% of patients,

with a higher rate in patients with previous ipsilateral saphenous vein harvest. Compartment syndrome can also occur and is related to the compromised venous outflow following the vein harvest coupled with the large volume crystalloid resuscitation often required in these critically ill patients.[127] Late clinically significant chronic venous insufficiency develops in less than 15% of patients and is generally mild when it occurs.[131]

Extra-Anatomic Abdominal Aortic Reconstruction

The primary extra-anatomic approach is an axillary-femoral bypass in a clean operative field followed by aneurysm resection, debridement of surrounding tissues, and aortic stump closure. In stable patients, the procedure can be staged with the extra-anatomic bypass being performed first, followed in a day or so by the definitive resection of the aneurysm. The axillary artery with the highest brachial pressure should be selected for inflow. Generally, an 8-mm-ringed polytetrafluoroethylene graft is sufficient. Aortic stump closure can be difficult due to the limited and friable aorta available for closure. A two-layer closure is recommended buttressed with anterior spinal ligament and an omental pedicle when possible.

Although this method of reconstruction may seem like an attractive option in older, more debilitated patients, it is associated with significant perioperative morbidity and mortality. Because the infected aneurysm tissue must still be resected and the aorta closed, the added benefit of using an extra-anatomic bypass is less than would be expected. Furthermore, aortic stump disruption, which may occur late in the patient's course, has been reported in up to 12% of patients.[132] Five-year patency of the axillary-femoral graft is reasonably good at 70%.[133] However, infection of the extra-anatomic reconstruction can occur in 6% to 20% of cases, often necessitating a very difficult in-situ reconstruction.[19,71,134-137] In a contemporary series, Lee reported long term survival to be equal to in-situ reconstruction but with a higher rate of late complications, 33% versus 0%. This suggests that this approach should be limited to patients who are considered unsuitable for in-situ revascularization.[138]

Endovascular Aortic Repair

Endovascular aortic repair (EVAR) for infected abdominal aortic aneurysms has increased in recent years. A recent meta-analysis of 48 patients treated with EVAR found that a ruptured aneurysm and fever at time of operation were the two most significant predictors of persistent infection. Persistent infection after EVAR, in turn, had a poor outcome with 12-month survival of 39%. Persistent sepsis and re-bleeding were reported in 23% of the cases, but overall 30-day and 2-year survival were reasonable at 89.6 ± 4.4% and 82 ± 5.8%, respectively.[139] Another recent study found no significant difference between EVAR and open repair in the 24-month actuarial aneurysm-related event-free rate (78.3 ± 9.7% vs. 80.1 ± 8.9%).[140]

Salmonella, however, has been associated with persistent and extended infection, and the virulence of the organism involved is an important consideration when contemplating EVAR.[141] In addition, EVAR outcomes appear to be adversely impacted by the presence of aorta-aero-digestive fistulas with a reported 30-day mortality rate of 33% and overall mortality of 67%.[142,143] Finally, other authors have demonstrated that re-operation for these infected aneurysms, after initially treated by EVAR, is more likely to be unsuccessful or more complicated, leading to higher operative mortality (Fig. 144.8A and B).[139,141,144,145] Consequently, if EVAR is chosen as the initial approach, it should be considered only a bridge to more definitive therapy in the patient who can tolerate an open reconstruction.[143]

(B) Digital subtraction angiogram revealing exclusion of the pseudoaneurysm after emergency stent-graft *(arrow)* deployment for control of hemorrhage.

FEMORAL ARTERY

Infected femoral artery aneurysms are most commonly due to endovascular arterial access or illicit drug injection, and involve organisms that are highly resistant to conventional antibiotics. Clinically, these infections present with fevers, groin pain, cellulitis, and a pulsatile mass. Risk factors include obesity, diabetes mellitus, and groin hematomas after endovascular intervention. *S. aureus* and gram-negative organisms are commonly cultured.

The reported rate of infectious complications related to femoral percutaneous procedures is less than 1%, but the innumerable procedures performed through femoral artery access on a daily basis means that it is not an infrequent clinical problem. Notably, some authors have described an association between the use of percutaneous closure devices with braided nonabsorbable suture and infected femoral artery aneurysms.[31,146-150]

The development of an infected femoral aneurysm in the setting of illicit drug abuse is a particularly challenging problem due to the presence of highly resistant organisms. These patients have a high rate of limb loss, and aggressive definitive treatment should be quickly undertaken. Because of organism virulence, the method of revascularization should be carefully considered, and wide debridement of the infected tissue with tissue culture should always be performed to guide antibiotic therapy.

Options for revascularization are described in Fig. 144.9A and B and include an in-situ interposition graft with autogenous vein or cryopreserved arterial allograft covered with a sartorius or other rotational muscle flap. Extra-anatomic reconstructions include obturator bypass, lateral femoral bypass, and axillary-femoral bypass with distal target either the superficial femoral or profunda femoris artery. With the exception of the infected aneurysms due to illicit drug injection, an interposition graft using cryopreserved arterial allograft is in our practice the preferred option.[151,152] Due to the virulence of organisms associated with aneurysms due to illicit drug injection, ligation and an extra-anatomic method of revascularization or ligation alone is advisable.[153]

Ligation of the common femoral artery alone without reconstruction allows for limb preservation in cases in which the profunda-superficial femoral artery junction is maintained.[154] Collateral flow between the internal iliac artery and the distal extremity circulation, including the inferior gluteal artery, the obturator artery, and the inferior epigastric artery can provide sufficient perfusion for limb viability. However, the absence of a pedal artery Doppler signal during test occlusion of the distal iliac artery indicates inadequate collateral flow, thus precluding femoral artery ligation.[154,155] When ligation in the acute phase is performed, symptoms of ischemia can develop in up to 88% of patients, with disabling claudication the most common complaint (Fig. 144.10).[156-158] Finally, if ligation of the common femoral, superficial femoral, and profunda femoris arteries are required for control of the infectious process, the amputation rate has been reported to be as high as 33% in the absence of an extra-anatomic reconstruction (Table 144.2).[5,14,16,159]

POPLITEAL ARTERY

Infected popliteal artery aneurysms are rare, and the available data comes mostly from case reports. This condition usually presents as a tender pulsatile mass with associated cellulitis, deep vein thrombosis from compression, lower extremity edema, and fever. Acute lower extremity ischemia may be present due to thrombosis or rupture.[160,161] The most common etiology is septic embolization from endocarditis due to *Streptococcus* and *Staphylococcus* species.[162] *Salmonella* infections are associated with

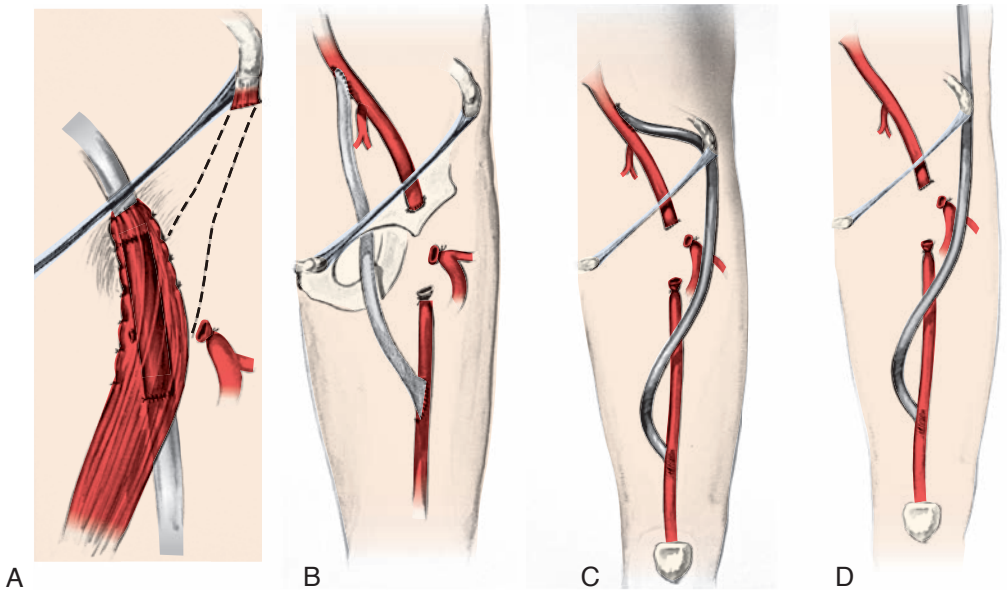

Figure 144.9 Methods of femoral artery reconstruction. (A) Interposition vein autograft covered by rotated sartorius muscle. (B) Obturator bypass. (C) Lateral femoral bypass. (D) Axillary-to-distal femoral bypass. (A, B, and D, From Reddy DJ, Smith RF, Elliott JP Jr, Haddad GK, Wanek EA. Infected femoral artery false aneurysms in drug addicts: evolution of selective vascular reconstruction. *J Vasc Surg.* 1986;3:718–724.)

microbial arteritis and spontaneous rupture of a nonaneurysmal popliteal artery. Antibiotics against suspected organisms should be instituted early, and the duration of therapy should be guided by the treatment of the causative endocarditis. Arterial duplex and CTA are used to confirm the diagnosis, define the extension of the infection, and plan revascularization.[163]

Figure 144.10 Arteriogram after ligation of the femoral artery bifurcation showing prompt reconstitution of the deep femoral artery by numerous collaterals *(large arrow)* with faint visualization of the slightly more distal superficial femoral artery *(small arrow)*.

Surgical treatment includes wide debridement and excision of all infected segments. In many patients, the popliteal vein is also involved, and this should be excised as well. Reconstruction with an autogenous saphenous vein bypass is the preferred option performed through a medial approach. Other reports have described the use of in-situ interposition cryopreserved arterial allografts with good results.[115,162]

CAROTID ARTERY

Historically, most primary carotid infected aneurysms were the result of pharyngeal infections. With the inception of antibiotics, carotid artery infections have become rare. Currently, as is the case with infected popliteal aneurysms, embolization due to endocarditis is the most common cause, and *S. aureus* and *Streptococcus pyogenes* are the most common organisms.[164-166]

Common clinical findings include fever, chills, and a pulsatile tender neck mass. The carotid mass is often medially deviated, leading to misdiagnosis as a pharyngeal mass. Patients can also present with dysphonia and dysphagia due to structural compression or with a neurologic deficit.[166] If left untreated, these aneurysms can shower septic emboli to the brain or rupture.[167] As in other arterial segments, diagnosis is confirmed by arterial duplex and CTA.

Because of the potential consequences of disruption and hemorrhage after in-situ reconstruction, some authors recommend ligation and excision alone.[168,169] Ehrenfeld demonstrated that ligation of the internal carotid artery is safe if the systolic carotid stump pressure exceeds 70 mm Hg and long-term anticoagulation is used.[170] However, some authors have reported late neurologic events after ligation in up to 20% to 60% of patients.[171,172] Extracranial-intracranial bypass has been utilized following ligation as has in-situ reconstruction of the carotid artery with an autogenous femoral or a saphenous vein.[25,165,173] Covered stents have been used to allow temporary exclusion of the aneurysm and control bleeding prior to definitive surgical

TABLE 144.2 Treatment Method and Results of Infected Femoral Artery False Aneurysms Secondary to Drug Addiction

Type of Aneurysm and Treatment	No. of Aneurysms	No. of Viable Limbs	Cases of Graft Sepsis (%)	No. of Amputations (%)
Common femoral artery: ligation-excision	14	14	–	0
Deep femoral artery: ligation-excision	11	11	–	0
Superficial femoral artery: ligation-excision	4	4	–	0
Common Femoral Bifurcation				
Ligation-excision	21	14	–	7 (33)
Reconstruction with autogenous vein	6	6	1	0

management.[174] The rarity and complexity of these patients with an infected carotid artery aneurysm emphasizes the need for individualized and creative patient management.[175-177]

UPPER EXTREMITY ARTERIES

Most infected aneurysms of the upper extremities are secondary to trauma and are occasionally the result of emboli from endocarditis. The use of percutaneous catheterizations and indwelling catheters for diagnostic procedures and arterial monitoring can lead to the development of infected brachial and radial artery aneurysms.[178] A tender mass with or without cellulitis is usually present, along with fever, chills, and leukocytosis. Infected radial artery aneurysms from indwelling catheters often have digital embolization as the first manifestation.[179] As with most pseudoaneurysms from direct arterial trauma, gram-positive bacteria are the most frequently isolated organisms. Intravenous drug users are a frequently affected population, and as with femoral artery infections, the arterial involvement is often extensive, making management difficult. Additionally, autogenous vein conduit may be limited in this patient population, and distal arterial runoff may also be compromised from long-term use of illicit drugs.[180]

Ligation and excision of the infected arterial segment with debridement of surrounding tissue followed by revascularization is required if the infectious process involves the brachial artery. If the radial or ulnar artery alone is involved, ligation and debridement is generally well tolerated. When revascularization is needed, the use of the greater saphenous vein is the preferred choice; however, in the case of patients who use illicit drugs, an autogenous conduit may not be available. In these patients, prosthetic graft tunneled in a clean tissue plane may be required. Six weeks of culture-directed intravenous antibiotic therapy is recommended.

VISCERAL ARTERIES

Visceral artery infected aneurysms are rare, with the superior mesenteric artery (SMA) being the most common site, followed by the celiac artery and its branches. These infected aneurysms usually result from an embolic event due to infectious endocarditis.[181] As reported in a recent series, intravenous drug abuse can also have an etiologic role.[181,182] When symptomatic, patients can have severe abdominal or back pain with a nonfixed tender pulsatile mass. Fever, nausea, gastrointestinal bleeding, and jaundice may also be present.[182,183] It is important to recognize that a significant percentage (19%) of patients have synchronous infected aneurysms at remote locations.[182] Diagnosis is confirmed by CTA, but in some patients, angiography may also be helpful. Location is usually within 5 cm of the SMA origin, and a single segment is affected. Rupture has been reported to occur in 38% to 50% of cases, and mortality after rupture approaches 30%.[182,184]

Surgical treatment includes ligation and excision of the affected segment; further revascularization is required in approximately 15% of patients, and is dependent on visceral collateral flow and the location of the aneurysm. An autogenous conduit, usually the greater saphenous vein, is the preferred conduit.[177,185,186] After open repair and prior to closure, careful examination of bowel perfusion and viability is of utmost importance.[182]

Geography and Ethnicity 1924
Inflammatory Bowel Disease 1924
Systemic Lupus Erythematosus 1924
Varicose Veins 1925
Iliac Vein Compression 1925
Popliteal Vein Entrapment 1925
Other Risk Factors 1925
NATURAL HISTORY 1926
Recanalization 1926
Recurrent Venous Thrombosis 1926
Mortality 1926

Acute venous thromboembolism (VTE), including deep venous thrombosis (DVT) and pulmonary embolism (PE), are the most common preventable cause of hospital death[1] and a source of substantial long-term morbidity.[2-4] The impact on health is so great that the Surgeon General of the United States issued a "Call to Action" to combat VTE.[5] An understanding of the risk factors and natural history of VTE is essential in guiding prophylaxis, diagnosis, and treatment. In addition, recognizing underlying risk factors and the multifactorial nature of VTE may aid in the identification of situations likely to provoke thrombosis in both high-risk individuals and those with unexplained thromboembolism. Furthermore, understanding the natural history of VTE is important in defining the relative risks and benefits of anticoagulation, as well as the duration of treatment in individual patients.

EPIDEMIOLOGY

Incidence

The incidence of recurrent, fatal, and nonfatal VTEs is estimated to exceed 900,000 cases annually in the United States alone.[6] A 35-year population-based study using the Rochester Epidemiology Project database of Olmsted County Minnesota demonstrated an overall average age- and sex-adjusted annual VTE incidence of 122 per 100,000 person-years (DVT, 56 per 100,000; PE, 66 per 100,000).[7] This study also demonstrated higher age-adjusted rates among men than women (134 vs. 115 per 100,000, respectively). First-time VTEs are approximated to occur in 250,000 US white individuals annually.[8] When compared with other racial populations, whites have a lower incidence of VTE than do African Americans (104 vs. 141 per

Abstract

The incidence of recurrent, fatal and nonfatal venous thromboembolism (VTE) is estimated to exceed 900,000 cases annually. VTE is associated with a number of risk factors. These include age, immobilization, travel, history of VTE, malignancy, surgery, trauma, pregnancy, oral contraceptives and hormonal therapy, blood group, geography and ethnicity, inflammatory bowel disease, systemic lupus erythematosus, varicose veins, iliac vein compression, popliteal vein entrapment, among others. The main complications of VTE include recurrent thrombosis and mortality, especially related to pulmonary embolism, along with post-thrombotic morbidity related to deep venous thrombosis.

100,000) and a higher incidence of VTE than do Hispanics and Asian/Pacific Islanders combined (104 vs. 21 per 100,000).[9] However, the problem of VTE is not just isolated to the United States; it is a global issue. The estimates of VTE across the European Union were 684,019 cases of DVT, 434,723 cases of PE, with 543,454 VTE-related fatalities.[10]

Populations Affected

The incidence of VTE varies with the population studied, use of thromboprophylaxis, the intensity of screening, and the accuracy of the diagnostic test employed. For example, individuals with acute spinal cord injury who were screened systematically with venography demonstrated DVT at a rate of 81%.[11] However, medical-surgical intensive care unit (ICU) patients who received thromboprophylaxis had a DVT rate reported at 10% to 18%,[12] compared with those who were not given DVT prophylaxis having a rate of 25% to 32%.[12,13] Interestingly, the risk of VTE in the critically ill is not limited to the time actually spent in the ICU. A single-center study showed that of the VTEs diagnosed in the critically ill, 64% were diagnosed with a VTE after discharge from the ICU. It is suggested that prolonged immobility after discharge from the ICU may have contributed to the high rate of DVT.[14] Similarly, prolonged immobility contributes to increased rates of VTE in nursing home residents.[15] In summary, it appears that medical-surgical ICU patients are at lower risk for DVT compared with acute spinal cord injury, trauma, or neurosurgery patients, but at a comparable risk to patients who have had major orthopedic surgery, and at higher risk than medical-surgical ward patients.[13,16] Furthermore, a more recent study noted a high (15.2%) rate of DVT in critically ill trauma patients within the first week that did not vary regardless of whether or not prophylaxis was used.[17]

TABLE 145.1 Risk Factors for Acute Deep Venous Thrombosis and Pulmonary Embolism

Risk Factor for DVT or PE	Odds Ratio	95% Confidence Interval
Hospitalization		
With recent surgery	21.72	9.44-49.93
Without recent surgery	7.98	4.49-14.18
Trauma	12.69	4.06-39.66
Malignant Neoplasm		
With chemotherapy	6.53	2.11-20.23
Without chemotherapy	4.05	1.93-8.52
Prior central venous catheter or pacemaker	5.55	1.57-19.58
Prior superficial vein thrombosis	4.32	1.76-10.61
Neurologic disease with extremity paresis	3.04	1.25-7.38
Varicose Veins		
Age 45 years	4.19	1.56-11.30
Age 60 years	1.93	1.03-3.61
Age 75 years	0.88	0.55-1.43
Congestive Heart Failure		
Thromboembolism not categorized as a cause of death at postmortem	9.64	2.44-38.10
Thromboembolism categorized as a cause of death at postmortem	1.36	0.69-2.68

DVT, Deep venous thrombosis; *PE,* pulmonary embolism.

Risk Factors

DVT occurring in the setting of a recognized risk factor is often defined as a secondary event, whereas those that occur in the absence of risk factors is termed primary or idiopathic.[18] Known risk factors for DVT are listed in Table 145.1.

The high incidence of acute DVT in hospitalized patients, the availability of objective diagnostic tests, and the existence of clinical trials evaluating prophylactic measures have helped to more readily identify high-risk groups in this population compared with the outpatient population. Malignancy, surgery, and trauma within the previous 3 months remain significant risk factors for outpatient thrombosis, whereas the prevalence of surgery and malignancy is higher among inpatients with DVT.[19,20] Approximately 47% of outpatients with a documented DVT have one or more recognized risk factors.[19] The incidence of VTE proportionally increases with the number of risk factors.[21] The 2005 Caprini score is currently the most used system in the country (Fig. 145.1).[12,22]

Age

VTE occurs in all ages, although a higher incidence has consistently been associated with advanced age. In a community-based study of phlebographically documented DVT, the yearly incidence of DVT was noted to increase progressively from almost 0 in childhood to 7.65 cases per 1000 in men and 8.22 cases per 1000 in women older than 80 years.[23] The incidence of DVT increased 30-fold from those age 30 years to those older than 80 years. Rosendaal[24] similarly noted an incidence of 0.006 per 1000 children younger than 14 years, which rose to 0.7 per 1000 among adults 40 to 54 years old. Furthermore, Hansson and colleagues[25] found the prevalence of objectively documented thromboembolic events among men increased from 0.5% at age 50 years to 3.8% at age 80 years.

The influence of age on the incidence of VTE is likely multifactorial. The number of thrombotic risk factors increases with age, with three or more risk factors being present in only 3% of hospitalized patients younger than 40 years but in 30% of those 40 years and older.[21] Interestingly, it also appears that the number of risk factors required to precipitate thrombosis decreases with age.[24] This may be related to an acquired prothrombotic state associated with aging because higher levels of thrombin activation markers are found among older people.[26] Advanced age also has been associated with anatomic changes in the soleal veins

Patient's name:_____ Age: ___ Sex: ___ Wgt: ___ lbs

Choose all that apply

Each risk factor represents 1 point
- Age 41–60 years
- Minor surgery planned
- History of prior major surgery
- Varicose veins
- History of inflammatory bowel disease
- Swollen legs (current)
- Obesity (BMI >30)
- Acute myocardial infarction (<1 month)
- Congestive heart failure (<1 month)
- Sepsis (<1 month)
- Serious lung disease incl. pneumonia (<1 month)
- Abnormal pulmonary function (COPD)
- Medical patient currently at bed rest
- Leg plaster cast or brace
- Other risk factors_____

Each risk factor represents 3 points
- Age over 75 years
- Major surgery lasting 2–3 hours
- BMI >50 (venous stasis syndrome)
- History of SVT, DVT/PE
- Family history of DVT/PE
- Present cancer or chemotherapy
- Positive factor V leiden
- Positive prothrombin 20210A
- Elevated serum homocysteine
- Positive lupus anticoagulant
- Elevated anticardiolipin antibodies
- Heparin-induced thrombocytopenia (HIT)
- Other thrombophilia
  Type_____

Each risk factor represents 2 points
- Age 60–74 years
- Major surgery (>60 minutes)
- Arthroscopic surgery (>60 minutes)
- Laparoscopic surgery (>60 minutes)
- Previous malignancy
- Central venous access
- Morbid obesity (BMI >40)

Each risk factor represents 5 points
- Elective major lower extremity arthroplasty
- Hip, pelvis or leg fracture (<1 month)
- Stroke (<1 month)
- Multiple trauma (<1 month)
- Acute spinal cord injury (paralysis) (<1 month)
- Major surgery lasting over 3 hours

For women only (each represents 1 point)
- Oral contraceptives or hormone replacement therapy
- Pregnancy or postpartum (<1 month)
- History of unexplained stillborn infant, recurrent spontaneous abortion (≥3), premature birth with toxemia or growth-restricted infant

Total risk factor score ☐

Please see following page for prophylaxis safety considerations
revised May 16, 2006

Prophylaxis regimen

Total risk factor score	Incidence of DVT	Risk level	Prophylaxis regimen
0–1	<10%	Low risk	No specific measures; early ambulation
2	10–20%	Moderate risk	ES or IPC or LDUH, or LWMH
3–4	20–40%	High risk	IPC or LDUH, or LMWH alone *or* in combination with ES or IPC
5 or more	40–80% 1–5% mortality	Highest risk	Pharmacological: LDUH, LMWH*, Warfarin*, or Fac Xa* alone *or* in combination with ES or IPC

Legend
ES — Elastic stockings
IPC — Intermittent pneumatic compression
LDUH — Low dose unfractionated heparin
LMWH — Low molecular weight heparin
Fac Xa — Factor X inhibitor

Prophylaxis safety considerations: Check box if answer is 'YES'

Anticoagulants: Factors associated with increased bleeding
☐ Is patient experiencing any active bleeding?
☐ Does patient have (or has had history of) heparin-induced thrombocytopenia?
☐ Is patient's platelet count <100,000/mm^3?
☐ Is patient taking oral anticoagulants, platelet inhibitors (e.g., NSAIDS, clopidigrel, salicylates)?
☐ Is patient's creatinine clearance abnormal? If yes, please indicate value ————————
If any of the above boxes are checked, the patient may not be a candidate for anticoagulant therapy and you should consider alternative prophylactic measures.

Intermittent pneumatic compression (IPC)
☐ Does patient have severe peripheral arterial disease?
☐ Does patient have congestive heart failure?
☐ Does patient have an acute superficial/deep vein thrombosis?
If any of the above boxes are checked, then patient may not be a candidate for intermittent compression therapy and you should consider alternative prophylactic measures.

Figure 145.1 The Caprini risk factor tool to predict the risk of venous thromboembolism. *DVT,* Deep venous thrombosis; *PE,* pulmonary embolism. (From Wakefield T, Henke P. *Complications in Surgery*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2011:353.)

and more pronounced stasis in the venous valve pockets.[27,28] We have also noted biologic changes with aging in our research laboratory, such as elevations in P-selectin, tissue factor (TF), antiphospholipid antibodies, and procoagulant microparticles, supporting the effect of age on venous thrombogenesis.

Venous diseases, including VTE, are usually regarded as rare in young children,[3] with an incidence of 0.006 per 1000 children younger than 14 years,[24] whereas the incidence in hospitalized children younger than 18 years has been estimated to be 0.05%.[29] Early mobilization and discharge may partially explain the lower incidence in children.[29] However, the diagnosis is often not considered in pediatric patients, and few studies have systematically evaluated children for DVT. Over time the number of recognized cases in hospitalized children has increased from 0.3 to 28.8 per 10,000 from 1992 to 2005.[30]

VTE in children is almost always associated with recognized thrombotic risk factors,[24,31-33] and multiple risk factors are often required to precipitate thrombosis.[24] DVT may occur in as many as 3.7% of pediatric patients immobilized in halo-femoral traction for preoperative treatment of scoliosis,[34] 4% of children hospitalized in the ICU,[35] and 10% of children with spinal cord injuries.[36,37] Symptomatic postoperative DVT is regarded as unusual in children, although there are few data from studies using routine surveillance,[38] and autopsy-identified PE is approximately four times more frequent in pediatric patients who have undergone surgery than in the general pediatric medical population.[31] Other thrombotic risk factors in hospitalized children are local infection and trauma, immobilization,[33] inherited hypercoagulable states,[24] oral contraceptive use,[39] lower limb paresis,[34] and the use of femoral venous catheters.[40] Outpatient DVT is often associated with a prior DVT and thrombophilia.[30]

Immobilization

Immobilization is a risk factor for VTE. Stasis in the soleal veins and behind the valve cusps is worsened by inactivity of the calf muscle pump,[28] which is associated with an increased risk of DVT. The prevalence of lower extremity DVT in autopsy studies also parallels the duration of bed rest, with an increase during the first 3 days of confinement and a rapid rise to very high levels after 2 weeks. DVT was found in 15% of patients dying after 0 to 7 days of bed rest, in comparison with 79% to 94% of those dying after 2 to 12 weeks.[27] Preoperative immobilization is also associated with a twofold increase in risk of postoperative DVT,[41] and DVT among stroke patients is significantly more common in paralyzed or paretic extremities (53% of limbs) than in nonparalyzed limbs (7%).[42] Patients with neurologic disease and extremity paresis or plegia have a threefold higher risk for DVT and PE, which appears to be independent of hospital confinement.[43]

Travel

Immobilization as a thrombotic risk factor extends to include prolonged travel, particularly the "economy class syndrome," which occurs in people who have sat in a cramped position during extended aircraft flights.[44] Several case series have reported the occurrence of PE in relation to extended travel,[44-49] although none has rigorously examined the prevalence relative to that of the general population, and few have thoroughly reported the presence of other risk factors. A high prevalence of preexisting venous disease and other thrombotic risk factors in this group of patients has sometimes been noted.[26,49] The question of prolonged travel as a risk factor is moderated by observations that extreme duration of venous stasis alone may fail to produce thrombosis[50] and that no consistent rheologic or prothrombotic changes have been demonstrated during prolonged travel.[26,51] However, PE is the second leading cause of travel-related death, accounting for 18% of 61 deaths, suggesting that a relationship cannot be excluded.[48]

More evidence that a connection between travel and DVT and PE has accumulated. In a case-control study, Ferrari and associates found[52] that long distance travel increased the risk of DVT, with an odds ratio (OR) of 4.0, and Samama[53] made similar observations (OR, 2.3). Scurr and colleagues[54] found a 10% risk of calf DVT in patients who traveled without compression stockings. Lapostolle and coworkers[55] observed that over an 86-month period, 56 of 135.3 million airline passengers had severe PE. The frequency among those who traveled more than 5000 km was 150 times as high as those who traveled less than 5000 km. In another case-control study, Paganin and associates[56] observed a high incidence of VTE in patients with risk factors for DVT who traveled long distances: in particular, history of previous VTE (OR, 63.3), recent trauma (OR, 13.6), presence of varicose veins (OR, 10), obesity (OR, 9.6), immobility during flight (OR, 9.3), and cardiac disease (OR, 8.9) increased the risk of DVT. These investigators concluded that low mobility during flight was a modifiable risk factor for development of PE and that travelers with risk factors should increase their mobility.[57]

After a consensus meeting, the World Health Organization published the following conclusions: an association probably exists between air travel and DVT; such an association is likely to be small and mainly affects passengers with additional risk factors for VTE; similar links may exist for other forms of travel.[58] The available evidence does not permit an estimation of actual risk.

History of Venous Thromboembolism

Approximately 23% to 26% of patients presenting with acute DVT have a previous history of thrombosis,[23,59] and histologic studies confirm that acute thrombi are often associated with fibrous remnants of previous thrombi in the same or nearby veins.[60] Depending on sex and age, population-based studies have demonstrated that recurrent VTE occurs in 2% to 9% of people.[3]

The risk of recurrent VTE is higher among patients with idiopathic DVT.[61] In addition, primary hypercoagulability appears to have a significant role in many recurrences. Simioni and associates[61] reported the cumulative incidence of recurrent thrombosis among patients who are heterozygous for the factor V Leiden mutation to be 40% at 8 years of follow-up, 2.4-fold higher than in patients without the mutation, although the importance of heterozygous factor V Leiden to recurrent thrombosis has been questioned.[62] den Heijer and colleagues[63] estimated that 17% of recurrent thromboembolic events may

be due to hyperhomocysteinemia. A similar relationship between impaired fibrinolysis and recurrent DVT has been suggested by several investigators, although the methodologic validity of these findings has been questioned.[64]

Malignancy

Approximately 20% of all first-time VTE events are associated with malignancy.[65] An estimated 1 in 200 individuals with malignancy will develop either DVT or PE, a fourfold higher risk than those without malignancy.[43] Considering all-cause mortality of in-hospital death for cancer patients, one in seven will die of PE.[66] Strikingly, the discovery of an occult malignancy associated with an otherwise first-time idiopathic VTE is as high as 12% to 17% in some series.[67,68] In another 5% to 11% of patients, malignancy appears within 1 to 2 years of presentation for DVT.[67-69] Several series have documented a significantly higher risk of malignancy in patients with presumed idiopathic DVT.[67,70] Among such patients, 7.6% have been noted to have a malignancy during follow-up, with an OR of 2.3 in comparison with those with secondary thrombosis.[68] The incidence of occult malignancy diagnosed within 6 to 12 months of an idiopathic DVT is 2.2 to 5.3 times higher than that expected from general population estimates.[71,72] The highest rates of VTE are associated with pancreatic malignancies, followed by kidney, ovary, lung, and stomach.[73]

The underlying mechanisms contributing to the hypercoagulable state in malignancy have been well studied and are multifactorial. Venous compression secondary to tumor growth, cancer-associated thrombocytosis, immobility, indwelling central lines, and chemotherapy or radiation therapy are all risk factors that increase the possibility of VTE.[74] However, the systemic prothrombotic response seen in malignancy is mediated by cytokines, inhibitors of fibrinolysis, and procoagulants.[75]

Tumor cells can directly initiate hemostasis through constitutive expression of TF. TF is not normally expressed on resting vascular endothelium but rather induced by chemical mediators during times of inflammation or vessel damage to bind factors VII and VIIa. This complex of TF and factor VII activates factors X and XI through proteolysis, leading to the generation of thrombin.[76] Another mediator in malignancy-associated VTE is cancer procoagulant (CP). The role of CP in coagulation is limited to its association with malignancy because it has not been identified in normal healthy tissue. CP serves as a direct activator of factor X, independent of the presence of factor VIIa. The platelet adhesion molecules glycoprotein Ib and glycoprotein IIb/IIIa (GPIIb/IIIa) have also been identified on tumor cells, allowing for platelet activation and aggregation.[77]

The prothrombotic contribution of cytokines such as vascular endothelial growth factor (VEGF), tumor necrosis factor-α (TNF-α), and interleukin-1 (IL-1) mediate their actions through induction of TF on vascular endothelium, monocytes, and leukocytes.[76,78] In addition, IL-1 and TNF-α downregulate the expression of thrombomodulin, the receptor for thrombin, on the endothelial surface. This results in a decrease in thrombin-thrombomodulin complexes, the activating complex of protein C, a natural anticoagulant.[76,78] Furthermore, IL-1 and TNF-α stimulate the production of plasminogen activator inhibitor 1 (PAI-1), the main physiologic inhibitor of fibrinolysis.[79]

As many as 90% of patients with cancer have abnormal coagulation parameters, including increased levels of coagulation factors, elevated fibrinogen or fibrin degradation products, and thrombocytosis.[80] Elevated fibrinogen and thrombocytosis are the most common abnormalities, perhaps reflecting an overcompensated form of intravascular coagulation.[80] Levels of the coagulation inhibitors antithrombin, protein C, and protein S also may be reduced in malignancy.[81]

Markers of activated coagulation are elevated in the majority of patients with solid tumors and leukemia.[80] Fibrinopeptide A levels reflect tumor activity, decreasing or increasing in response to treatment or progression of disease, suggesting that tumor growth and thrombin generation are intimately related.[80] Furthermore, these levels may fail to normalize after administration of heparin to patients with cancer and DVT, perhaps explaining why these DVTs may be refractory to anticoagulants.[80]

VTE is also associated with the treatment of some cancers. DVT complicates 29% of general surgical procedures for malignancy.[81] Preoperative activation of the coagulation system, as reflected by elevated thrombin-antithrombin complex values, is associated with a 7.5-fold increased risk of postoperative DVT.[80] Some chemotherapeutic regimens also predispose to DVT, and thrombotic complications may be as common as the more widely recognized infectious complications.[82] VTE has been reported in up to 6% of patients undergoing treatment for non-Hodgkin's lymphoma, and in 17.5% of those receiving therapy for breast cancer.[83] Among patients with stage II breast cancer, thrombosis was significantly more common in those randomly assigned to 36 weeks of chemotherapy (8.8%) than in those receiving only 12 weeks of treatment (4.9%).[82] Potential thrombogenic mechanisms associated with chemotherapy include direct endothelial toxicity, induction of a hypercoagulable state, reduced fibrinolytic activity, tumor cell lysis, and use of central venous catheters.[83,84] Some intravenous chemotherapeutic agents are associated with activation of coagulation and increased markers of thrombin generation, a response that is blocked by pretreatment with heparin.[85] An additional risk factor in some cancer patients is an elevated soluble P-selectin.[86]

Surgery

The high incidence of postoperative DVT, as well as the availability of easily repeatable, noninvasive diagnostic tests, has allowed a greater understanding of the risk factors associated with surgery than in other conditions. Surgery constitutes a spectrum of risk that is influenced by patient age, coexistent thrombotic risk factors, type of procedure, extent of surgical trauma, length of procedure, and duration of postoperative immobilization.[87] The type of surgical procedure is particularly important.[41] Historically, the overall incidence of DVT is approximately 19% in patients undergoing general surgical operations, 24% in those having elective neurosurgical procedures; and 48%, 51%, and 61% among those undergoing surgery for hip fracture, hip arthroplasty, and knee arthroplasty, respectively.[87] On the basis of these data, patients can be classified as being at low, moderate, or high risk for thromboembolic

complications. Approximately half of postoperative lower extremity thrombi develop in the operating room, with the remainder occurring over the next 3 to 5 days.[88] However, the risk for development of DVT does not end uniformly at hospital discharge. In one study, 51% of the thromboembolic events occurred after discharge from gynecologic surgical procedures.[89] Similarly, up to 25% of patients undergoing abdominal surgery have DVT within 6 weeks of discharge.[90] Heit and associates found a nearly 22-fold higher risk of DVT and PE among patients who were hospitalized following previous surgery.[89]

All components of the Virchow triad may be present in the surgical patient—perioperative immobilization, transient changes in coagulation and fibrinolysis, and the potential for gross venous injury. Immobilization is associated with a reduction in venous outflow and capacitance during the early postoperative period.[91] Surgery is also accompanied by a transient, low-level hypercoagulable state, presumably mediated by the release of TF, which is marked by a rise in thrombin activation markers shortly after the procedure begins.[91] The thrombogenic potential of different surgical procedures appears to differ, with greater rises in thrombin activation markers during hip arthroplasty than after laparotomy.[92] Increased levels of PAI–1 are also associated with a decrease in fibrinolytic activity on the first postoperative day, the "postoperative fibrinolytic shutdown."[93] This relationship between impaired fibrinolysis and postoperative DVT may be particularly important,[64] with preoperative and early postoperative elevations in PAI-1 correlating with the development of thrombosis in orthopedic patients.[93] Complications are also an important trigger: in a large VA study involving more than 76,000 patients, the strongest predictors of postoperative VTE included myocardial infarction, blood transfusion (>4 units), and urinary tract infection.[94]

Trauma

The prevalence of DVT among autopsied trauma casualties has been reported to be as high as 65%, comparable to the 58% incidence among injured patients in modern venographic series.[11] Substantially lower DVT rates, ranging from 4% to 20%,[95] have been noted in series using duplex ultrasonography, although many patients studied were receiving prophylaxis and the limitations of ultrasound in screening asymptomatic patients are well recognized. Recent trauma was associated with nearly a 13-fold increase in risk.[89]

Although the risk of DVT may be less than 20% in some injured patients,[11] certain subgroups are at particularly high risk. Age (OR, 1.05 for each 1-year increment), blood transfusion (OR, 1.74), surgery (OR, 2.30), fracture of the femur or tibia (OR, 4.82), and spinal cord injury (OR, 8.59) have been significantly associated with the development of DVT in this population.[11] Other reported risk factors are a hospital stay longer than 7 days,[96] increased Injury Severity Score (ISS),[96-98] pelvic fractures,[99] major venous injury,[100] presence of femoral venous lines,[101] the duration of immobilization,[102] and prolongation of the partial thromboplastin time.[103]

As with postoperative DVT, several pathophysiologic elements may be responsible for the high incidence of DVT in trauma patients. Immobilization by skeletal fixation, paralysis, and critical illness are associated with venous stasis, whereas mechanical injury is important after direct venous trauma and central venous cannulation. Less well appreciated is the hypercoagulable state after depletion of coagulation inhibitors and components of the fibrinolytic system. Fibrinopeptide A levels rise after injury,[104] consistent with activation of coagulation, whereas fibrinolytic activity has been found to increase initially and then decrease.[105,106]

Pregnancy

The incidence of VTE in the pregnant population is 6 to 10 times greater than matched controls[107] and causes approximately 10% of all maternal deaths.[108] Using clinical evaluation, VTE has been reported at a rate of 1.3% to 7% during pregnancy and 6.1% to 23% in the postpartum period.[109] However, studies that used venography, Doppler ultrasonography, or ventilation-perfusion scans for evaluation of clinically suspected thromboembolism have suggested an incidence of 0.029% to 0.055% in this population.[110] The risk of thrombosis appears to be two to three times greater during the puerperium, with the highest incidence found after cesarean section.[111] Interestingly, when VTE has been objectively documented, the occurrence of thrombosis is equally distributed throughout all three trimesters.[112]

DVT in pregnancy has been attributed to impaired venous outflow due to uterine compression because 97% of reported thromboses have been isolated to the left leg.[112] Furthermore, pregnancy is associated with a transient hypercoagulable state due to increases in the levels of fibrinogen, von Willebrand factor, and factors II, VII, VIII, and X. Compounding this acquired functional resistance to activated protein C is also seen during pregnancy.[113] Similarly, protein S levels are decreased by 50% to 60% early during pregnancy, with free protein S levels comparable with hereditary heterozygous protein S deficiency.[114,115] The fibrinolytic system is also altered in pregnancy: levels of tissue plasminogen activator (tPA) are decreased and PAI-1 and PAI-2 increased.[116]

Both retrospective and prospective studies have demonstrated that between 30% and 50% of women with a pregnancy-associated VTE also have an inherited thrombophilia. This high incidence has led to the recommendation of screening for thrombophilia in those pregnant patients with a personal or family history of VTE.[117,118] The risk of puerperal DVT also increases with maternal age, suppression of lactation, hypertension, and assisted delivery but not with the number of pregnancies.[119]

Oral Contraceptives and Hormonal Therapy

As suggested by case reports in the early 1960s, further studies have now established the use of oral contraceptives as an independent risk factor for the development of DVT. These studies noted ORs of 3.8 to 11.0 for thrombosis,[120] and an unweighted summary relative risk among 18 controlled studies was 2.9.[121] Approximately one-quarter of apparently idiopathic thromboembolic events among women of childbearing age have

been attributed to oral contraceptives. Early studies also suggested that thromboembolism is responsible for approximately 2% of deaths in young women, with contraceptive-associated mortality rates of 1.3 and 3.4 per 100,000 among women aged 20 to 34 and 35 to 44 years, respectively.[122] The increased risk of thromboembolism appears to diminish soon after oral contraceptives are discontinued and is independent of the duration of use.[123]

Risk is correspondingly higher when oral contraceptive use is combined with other factors, such as surgery[124] and inherited inhibitor deficiencies.[125] The factor V Leiden mutation may be particularly important in this regard; resistance to activated protein C has been reported in up to 30% of patients with contraceptive-associated thromboembolism.[126] The use of third-generation oral contraceptives may act synergistically with the factor V Leiden mutation, raising thromboembolic risk 30- to 50-fold.[127-129]

Estrogenic compounds also increase the risk of VTE when used for lactation suppression[119] in treatment of carcinoma of the prostate and as postmenopausal replacement therapy.[130] Although estrogen doses used for postmenopausal replacement therapy are approximately one-sixth those in oral contraceptives, some data support an increased thromboembolic risk at these doses as well. Several studies show a twofold to fourfold higher risk of VTE among women taking hormone replacement therapy.[130-134] This increased risk is greatest during the first year of treatment.[131,134] However, given the relative infrequency of thromboembolism, this risk represents only one or two additional cases of thromboembolism per year in every 10,000 women in this age group.

Estrogen in pharmacologic doses is associated with alterations in the coagulation system that may contribute to this thrombotic tendency. Such alterations include decreases in PAI-1[135] and increases in blood viscosity, fibrinogen, plasma levels of factors VII and X, and platelet adhesion and aggregation.[136,137] An associated prothrombotic state is implied by rises in markers of activated coagulation occurring in conjunction with elevations of circulating factor VIIa and decreases in antithrombin and protein S inhibitor activity.[136,138] The extent to which antithrombin and protein S are depressed is significantly less with lower-estrogen preparations.[139]

Blood Group

There also appears to be a relationship between VTE risk and the ABO blood groups, with a higher prevalence of blood type A and correspondingly lower prevalence of blood type O groups.[140,141] In reviewing the literature, Mourant and colleagues[142] found the relative incidence of type A to be 1.41 times higher among patients with thromboembolism than among controls. The effect of blood type was greater in young women who were taking oral contraceptives or were pregnant; the relative incidence of type A among patients with thromboembolism was 3.12 in those taking oral contraceptives and 1.85 in those who were pregnant. A relationship between soluble endothelial cell markers and ABO blood group is known to exist, with significantly lower levels of von Willebrand factor among those with type O blood.[143]

Geography and Ethnicity

There are also geographic differences in the frequency of VTE, as the incidence of postoperative DVT in Europe has been noted to be nearly twice that of North America.[81,87] Higher rates of thromboembolism have also been noted in the central United States compared with either coast.[144] Autopsy series suggest that although the prevalence of thromboembolism is identical among American black and white patients, it is significantly higher than in a matched Ugandan black population.[145] A similar autopsy series noted the prevalence of thromboembolism to be 40.6% in Boston and 13.9% in Kyushu, Japan.[146]

Unfortunately, regional variations in underlying medical and surgical conditions, as well as in prophylactic measures and diagnostic methods, may confound any apparent differences in the incidence of thromboembolism among different ethnic and geographic groups. Nevertheless, it is certainly conceivable that differences between ethnic groups might arise from either genetic and/or environmental factors. Such differences seem likely based on recognized geographic differences in the spectrum of mutations leading to congenital anticoagulant deficiencies.[147] Such theoretical concerns are also supported by geographic variability in the incidence of the factor V Leiden mutation. The factor V Leiden allele has a prevalence of 4.4% in Europeans, corresponding to a carrier rate of 8.8%, but the allele has not been identified in Southeast Asian or African populations.[148]

Inflammatory Bowel Disease

Clinical series have reported VTE to complicate inflammatory bowel disease (IBD) in 1.2% to 7.1% of cases.[149,150] Crohn disease has incidence rates of 31.4/10,000 person-years and 10.3/10,000 person-years for DVT and PE, respectively. Ulcerative colitis also has a high incident rate of 30.0/10,000 and 19.8/10,000 person-years for DVT and PE, respectively. Such thromboses frequently occur among young patients, are more common with active disease, and may affect unusual sites, such as the cerebral veins.[149,150] Greater extent of colonic disease in ulcerative colitis portends a higher risk of VTE. Most cases are not associated with inherited hypercoagulable states. However, fibrinopeptide A elevations in IBD suggest that active inflammation is associated with activation of coagulation, possibly mediated by endotoxin-induced monocyte activation.[149-151]

Systemic Lupus Erythematosus

A syndrome of arterial and venous thrombosis, recurrent abortion, thrombocytopenia, and neurologic disease may complicate systemic lupus erythematosus (SLE) when accompanied by the presence of antiphospholipid antibodies.[152] Lupus anticoagulant and anticardiolipin antibodies may be seen in association with SLE; with other autoimmune disorders; with nonautoimmune disorders, such as syphilis and acute infection, with drugs, including chlorpromazine, procainamide, and hydralazine; and with older age.[153]

Lupus anticoagulant is present in 34% of patients with SLE and anticardiolipin antibodies in 44%, in comparison with 2% and 0% to 7.5%, respectively, of the general population.[153]

Among patients with SLE, those with lupus anticoagulant are at a sixfold higher risk for VTE, whereas those with anticardiolipin antibodies are at a twofold greater risk.[154] The incidence of arterial or venous thrombosis is 25% in patients with lupus anticoagulant and 28% in patients with anticardiolipin antibodies.[153]

Varicose Veins

Varicose veins are also included as a risk factor for acute DVT, although frequently only as a marker of either previous venous disease.[155] Most studies evaluating thrombotic risk have been performed in inpatients with other major risk factors for DVT. Such studies have inconsistently supported varicose veins as a risk factor in postoperative, post-stroke, or postmyocardial infarction cases.[155-157] The importance of varicose veins in otherwise healthy outpatients with DVT has been questioned by some researchers[158] because varicose veins were not identified as independent risk factor in young women,[159] although some studies of postmenopausal women have reported varicose veins or superficial thrombophlebitis to be associated with ORs of 3.6 to 6.9 for the development of thromboembolism.[131,134]

However, Heit and associates[160] found that varicose veins were independent predictors of DVT. They also reported that age is an important factor in these patients, reporting a higher correlation between DVT and varicosity in young patients. For example, 45-year-old patients with varicose veins had a fourfold higher risk of VTE, 60-year-old patients had a twofold greater risk, and 75-year-old patients had no increase in risk. This group also found that patients with previous superficial vein thrombosis were more than four times more likely to have DVT or PE.[160] See Chapter 150.

Iliac Vein Compression

The association of VTE and anatomic anomalies or syndromes represents a congenital risk factor responsible for DVT in both the upper and lower extremities. Left iliac vein compression by the right iliac artery and fifth lumbar artery was first described by May and Thurner in cadavers who hypothesized that chronic pulsation of the right iliac artery and mechanical obstruction led to intimal hypertrophy of the vein wall and subsequent venous obstruction.[161] In actuality, it was Virchow who had initially observed iliofemoral vein thrombosis was five times more likely to occur in the left leg than in the right leg over a century earlier.[162] Although left lower extremity venous hypertension associated with or without left iliofemoral DVT has come to be known as May-Thurner syndrome, it is important to recognize, if only for historical nomenclature, that a similar syndrome was described by Cockett in 1965 (Cockett syndrome) and took popularity over the term May-Thurner syndrome in Europe. However, it was Cockett who associated the acute phase of iliofemoral DVT secondary to compression of the iliac vein with the long-term consequence of chronic venous insufficiency (CVI). In addition, it was Cockett who noted surgical intervention for the purpose of alleviating the skin ulcers and varicosities associated with iliac vein compression was ineffective unless the underlying disease process was identified.[163]

May-Thurner syndrome is more common in young to middle-aged women, especially after multiple pregnancies. The presenting symptom is often acute onset of left leg pain and swelling secondary to thrombosis. Atypically, patients may present with symptoms of CVI that are unresponsive to compression stockings, leg elevation, and a calf exercise program.[164] Early 20th century postmortem dissections revealed a 22% to 32% incidence of left iliac vein compression.[165] Modern computed tomography imaging has revealed that in an asymptomatic population, the average amount of compression on the left iliac vein was 35%, and 24% of this population demonstrated greater than 50% compression.[165] Although individuals in such series were asymptomatic, the incidence of symptomatic left common iliac vein compression presenting with either edema or DVT is estimated to be between 37% and 61%.[166,167] Interestingly, the presence of an abdominal aortic aneurysm was associated with a significantly less amount of compression on the left common iliac vein by the right common iliac artery secondary to a higher prevalence of tortuosity in that artery.[168]

Popliteal Vein Entrapment

Although arterial entrapment syndrome is well described in the literature, popliteal vein entrapment has been reported to occur either alone or with the artery in 10% of cases.[169] Anatomic anomalies of the medial head of the gastrocnemius have been associated with popliteal vascular entrapment. However, when venous entrapment occurs in a setting without arterial entrapment, both the medial or the lateral head of the gastrocnemius have been shown to contribute.[170] Bony tumors and hypertrophied fibrous fascia have also been associated with isolated venous involvement.[171,172] Traditionally, popliteal artery entrapment has been more associated with the male gender; venous entrapment has been reported to occur 70% of the time in females.[173] The presentation is often that of a young adult with signs of CVI, including leg swelling varicosities, skin changes, and DVT.

Other Risk Factors

Risk factors for VTE covered in other sections in this book include inherited thrombophilias (Chapter 38), thoracic outlet syndrome (Chapter 123), central venous catheters (Chapter 149), and inferior vena cava anomalies (Chapter 163). Traditional risk factors for VTE have included obesity and cardiac disease; however, the evidence supporting these risk factors remains equivocal. Among postmenopausal women, a body mass index of greater than 25 to 30 kg/m^2 has been associated with a significantly increased risk of VTE.[132,134] Some investigators have reported obesity to be associated with a twofold greater risk for postoperative DVT, although multivariate analyses by others has not shown obesity to constitute an independent risk.[155] Obesity (and past tobacco smoking) was not an independent risk factor of DVT in the Olmsted County study[160] and has not been proven to be a risk factor for the development of DVT after stroke.[157] However, obesity is a risk factor for recurrent DVT.[174]

Systemic hypercoagulability, congestive heart failure, and enforced bed rest may predispose patients who are hospitalized with acute myocardial infarction to DVT. The incidence of DVT in this population has been reported to be 20% to 40%.[87,156,175] Some investigators have noted the incidence of DVT to be higher among patients in whom myocardial infarction was confirmed (34%) than in those in whom the diagnosis was excluded (7%). The prevalence of PE among autopsied patients has also not differed substantially from that in other inpatients.[144,145]

Although MI as a risk factor may be in question, those older than 60 years with congestive heart failure have a DVT rate of 54%.[176] However, the evidence supporting congestive heart failure as an independent risk factor for DVT is also conflicting. A variety of thromboembolic complications account for nearly half the deaths among patients who did not undergo anticoagulation after hospitalization for congestive heart failure, but congestive heart failure has not been identified as an independent risk factor for postoperative DVT. The balance of evidence suggests that severely ill medical patients are at significant risk for VTE,[177] although it is difficult to define the additional risk associated with cardiac disease.

NATURAL HISTORY

The relative balance between organization, thrombolysis, propagation, and rethrombosis determines outcomes after human thrombosis. From a clinical perspective, the most important events after thrombosis are recanalization and recurrent thrombosis.

Recanalization

Impedance plethysmography was the first widely available noninvasive test permitting serial evaluations of outflow obstruction due to an acute DVT. Although this test could not distinguish between recanalization and the development of collateral venous outflow, results of such studies were found to normalize in 67% of patients by 3 months and in 92% of patients by 9 months.[178] Venous duplex ultrasonography allows individual venous segments to be observed over time and has further documented that recanalization does occur in most patients after acute DVT. In 21 patients monitored prospectively with duplex scanning, recanalization occurred in 44% of patients at 7 days and in 100% of patients by 90 days after the acute event.[179] Several additional studies[180,181] confirm the histologic findings that recanalization begins early after an acute DVT, with the greatest reduction in thrombus load occurring within 3 months of the event. Complete thrombus resolution has been reported in 56% of patients monitored for 9 months.[179,182] However, recanalization may continue for months to years after the acute event.[181]

Recurrent Venous Thrombosis

Nearly 30% of patients will develop a recurrence within a 10-year time span.[183] Recurrences are more likely with the same event type as the incident event; for example, those who initially developed a PE are more likely to develop another PE instead of a DVT.[184] Independent predictors for recurrent DVT include increasing age, obesity, malignant neoplasm, and extremity paresis. In a series of landmark trials, among patients with proximal DVT, recurrent thromboembolic events were found in 5.2% of patients treated with standard anticoagulation for 3 months, compared with 47% of patients treated with a 3-month course of low-dose subcutaneous heparin.[185,186]

Despite the significance of these observations, reports of serial noninvasive follow-up examinations suggest that these studies may underestimate the incidence of new thrombotic events. In a series of 177 patients, most of whom were treated with standard anticoagulation measures, recurrent thrombotic events were observed in 52% of patients.[187] New thrombi were observed in 6% of uninvolved contralateral extremities, whereas propagation of thrombi to new segments occurred in 30% of involved limbs and rethrombosis of a partially occluded or recanalized segment in 31% of extremities. Propagation in the ipsilateral limb tended to occur as an early event at a median of less than 40 days after presentation, whereas rethrombosis and extension to the contralateral limb tended to occur sporadically as late events.

Mortality

The severity of PE is shown in 30-year autopsy studies, which demonstrated a 26% incidence of PE in hospitalized patients, of which 9% was fatal. This translates to a 1% incidence of PE and a 0.36% incidence of death from PE in all hospitalized patients per year.[188] See Chapter 151.

SUMMARY OF RECOMMENDATIONS FOR VENOUS THROMBOEMBOLISM PROPHYLAXIS IN SURGICAL PATIENTS 1935

The incidence of venous thromboembolism (VTE) is variable depending on the setting. For patients with a recent or current hospitalization, the rate is 330 per 100,000, compared with 8 per 100,000 for those in the community.[1] These hospitalizations are 2.5 times more costly to the healthcare system than for those without VTE. The greatest cost related to treating VTE patients occurs in the first 3 months, almost $17,000 per patient. The risk of death among those who suffer a pulmonary embolism (PE) is 18 times higher compared with patients who have deep venous thrombosis (DVT) only. For approximately 1 in 4 patients with PE, the presentation is sudden death. The crude percentage of postoperative DVT is reported to be as high as 22% in groups with no prophylaxis.[2] Given these figures and the higher probability of VTE in the postoperative scenario, it is of utmost importance to have defined strategies for targeted prevention.

In this chapter we provide an overview of the process of personalizing VTE prevention based on risk estimates and available evidence of efficacy.

RATIONALE FOR RISK STRATIFICATION AND PROPHYLAXIS

Both patient specific and procedural factors confer various degrees of thrombotic risk, thus, individualized risk assessment is recommended.[3] Risk factors associated with the development of VTE have been known for a long time (Fig. 146.1).[3a] Pioneering work by Maxwell Borow in 1983 identified risk factors including length of surgery, age, obesity, infection, length of surgery over 1 hour, and cancer. In addition, there was a linear

Abstract

This chapter begins by emphasizing the importance of individual risk assessment for surgical patients; it describes the use of the Caprini score to stratify patients according to risk and suggest appropriate prophylactic regimes. The current data regarding physical and pharmacologic methods are presented, along with specific recommendations for individual surgical populations. The chapter concludes by presenting the concept of selecting prophylaxis based on combining evidence-based guidelines and clinical practice experience.

venous thromboembolic disease
venous thromboembolism

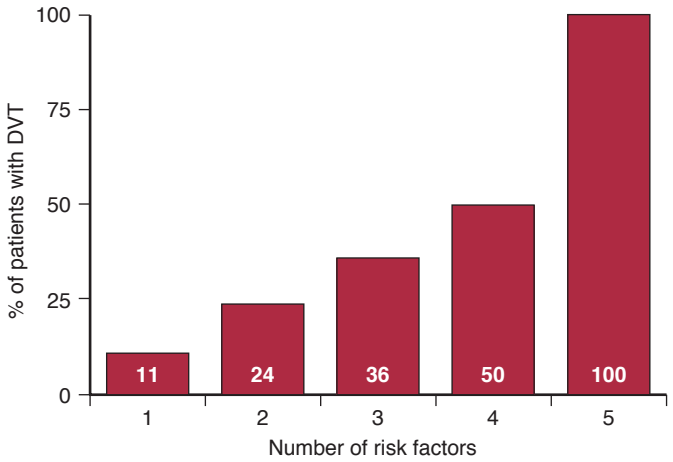

Figure 146.1 Proportion of patients with confirmed deep venous thrombosis (DVT) relative to number of risk factors. Study of 1464 patients who underwent impedance plethysmography for DVT diagnosis. (Data adapted from Wheeler HB, Anderson FA Jr, Cardullo PA, Patwardhan NA, Jian-Ming L, Cutler BS. Suspected deep vein thrombosis. Management by impedance plethysmography. *Arch Surg*. 1982;117(9):1206-1209.)

relationship between the length of surgery and the incidence of thrombosis.[4] Historically, operations to replace a joint of the lower extremity without prophylaxis are associated with a 20% to 50% incidence of VTE.

Patients with a prior history of VTE are at greatly increased risk for recurrent events, particularly when they have surgery, develop a serious illness, or are immobilized for long periods of time. Borow found in a series of 500 surgical patients that 66% of those with a history of VTE developed postoperative VTE.[4] Samama reported in a case-control study that patients with a VTE history of VTE were eight times more likely to develop a new VTE during a high-risk period compared with those without a prior history.[5] Similarly, an important yet often overlooked risk factor for VTE is a family history of thrombosis, usually among first-degree relatives.

The incidence of VTE varies with congestive heart failure, depending on the ejection fraction. This observation illustrates the fact that a risk factor can be associated with a variable incidence of thrombosis.[6] Preoperative pneumonia is associated with postoperative VTE.[7] A number of studies support an association between increasing age and a higher incidence of VTE, the risk approximately doubling with each decade. In a prospective observational cohort study of cancer patients' history of VTE, superficial phlebitis or the presence of varicose veins was associated with an elevated incidence of VTE.[8] Inflammatory bowel disease, including regional ileitis and ulcerative colitis, is a powerful risk factor for the development of VTE, and the risk remains even when the disease is not active.

Early ambulation is important after surgical procedures. Ambulatory status was defined in the MEDENOX study as the ability to attain, unassisted, a walking distance of greater than 10 m (~33 ft). Nonambulatory patients without prophylaxis had a statistically significant increase of VTE (19.7% vs. 10.6%; $P = .03$). The incidence of DVT is also higher among patients with leg plaster casts.[9]

Hypercoagulable states are important risk factors for VTE and may be inherited or acquired. Factor V Leiden is the most common congenital thrombophilic defect, affecting 5% of the Caucasian population. For these patients the lifetime probability of developing VTE is approximately 10%; an adjusted hazard ratio (HR) of 2.2 (95% CI, 2.0 to 2.5) for people with heterozygous mutations and 7.0 (95% CI, 4.8 to 10) for homozygous mutations has been reported. The prothrombin gene (*G20210A*) mutation is the next most common thrombophilic defect, and prevalence in the United States is approximately 1% to 2%. The adjusted risk for VTE in patients with a homozygous prothrombin gene defect is higher (HR 11 [95% CI, 2.8 to 44]) than for those with a heterozygous mutation (HR 1.5 [95% CI, 1.2 to 1.9]).[10]

Defects of the natural anticoagulant proteins include antithrombin and proteins C and S. The latter two defects are vitamin K–dependent anticoagulants synthesized in the liver. These inherited thrombophilic defects are relatively uncommon but represent significant thrombotic risks and must be accounted for.

Hormonal contraceptives represent a risk factor for VTE. The rates of VTE in users of oral contraceptives are estimated to be 9 to 10 per 10,000 women per year compared with 4 to 5 per 10,000 in nonusing women of childbearing age. It has also been estimated that VTE rates in pregnancy average 29 per 10,000 overall and approach 300 to 400 per 10,000 individuals in the immediate postpartum period. Oral contraceptives with less than 35 μg of ethinyl estradiol are associated with a slightly lower incidence of VTE in the community compared with those containing more than 50 μg.[11]

Last, VTE is a common cause of death among surgical patients with cancer. In a large study of patients (2373) undergoing a wide variety of abdominal surgical procedures, the incidence of VTE was 2.1%.[12] Forty percent of the events occurred more than 21 days post surgery. The death rate was 1.72%, and 46.3% of these events were due to VTE.

Patients suffering multiple trauma are subject to a very high risk of developing VTE. In a study by Geerts, thrombosis was seen in 47% of trauma patients, including a 12% incidence of proximal venous thrombosis within the first 2 weeks. This study included 56% of patients with lower extremity orthopedic or pelvic injuries. Spinal cord injury is associated with thrombosis in approximately 35% to 40% of patients during the first 3 months of a paralytic event. Once a flaccid paralysis occurs, the incidence of VTE is dramatically reduced.[13]

Risk-Assessment Models

Prophylaxis suggested for each individual should be based on the relative balance between the incidence of thrombosis and the risk of bleeding as well as available resources within the institution. A number of risk-assessment models have been proposed over the years, but most of them have not been formally validated. For nonorthopedic surgical patients, the Rogers score was derived from 183,069 patients in the Patient Safety and Surgery Study involving general, vascular, or thoracic procedures in the Veterans Administration system between 2002 and 2004. This score used

factors found to be independent predictors of VTE risk. The level of the score correlated with the incidence of symptomatic thrombotic events. Well-known risk factors not captured in the model include obesity, inflammatory bowel disease, obstetric accidents, personal or family history of thrombosis, congestive heart failure, myocardial infarction, stroke, and central lines.

The Caprini score, which was first described in 1991 (Fig. 146.2), discriminates between patients at low, moderate, and high risk for VTE and has been widely validated in a variety of patient populations.[13a] Up to now a total of 32 publications in peer-reviewed journals involving more than 128,000 combined medical and surgical patients have evaluated the Caprini score. Recently Pannucci presented the results of a meta-analysis (unpublished data) indicating that the Caprini score predicts both the baseline VTE risk and effectiveness of chemoprophylaxis. The analysis included 13,412 patients and identified a 22-fold variation in VTE risk among 5216 surgical patients who received no prophylaxis.[14] Patients at each ascending risk level were significantly more likely to have a VTE event than patients at lower risk levels. Patients with a score greater than 8 were significantly less likely to have a VTE event when chemoprophylaxis was provided. The Caprini score did not correlate with bleeding outcomes.

One recent case study consisted of a program of early mobilization, intermittent pneumatic compression (IPC), and mandatory risk stratification linked to specific anticoagulant prophylaxis protocols using the Caprini score.[15] Before implementation of this program the incidence of DVT was 1.9% in 1569 patients. Following implementation the thrombosis rate decreased to 0.3% (1323 patients), an 84% decrease. PE was seen in 1.1% of these 1569 patients and dropped to 0.5% in the 1323 patients after the program was initiated (Table 146.1).

1 point	2 points
○ Age 41-60	○ Age 60-74
○ Minor surgery	○ Arthroscopic surgery
○ Prior major surgery (<1 mo)	○ Malignancy
○ Varicose veins	○ Major surgery >45 min
○ Inflammatory bowel disease	○ Laparoscopic surgery >45 min
○ Swollen legs	○ Confined to bed (>72 h)
○ Obesity	○ Immobilizing cast (<1 mo)
○ Congestive heart failure	○ Central venous access
○ Sepsis (<1 mo)	**3 points**
○ Lung disease, i.e., pneumonia (<1 mo)	○ Age > 75
○ Abnormal pulmonary function (COPD)	○ History of VTE
○ Medical patient in bed	○ Family history of VTE
○ Other _____	○ Factor V Leiden
○ On estrogen supplementation	○ Prothrombin gene mutation
○ Pregnant or puerperium	○ Elevated homocysteine
○ History of unexplained stillborn, recurrent abortions, premature birth with toxemia or growth-restricted infant	○ Lupus anticoagulant
5 points	○ Positive anticardiolipins
○ Elective lower extremity arthroplasty	○ Heparin induced thrombocytopenia
○ Hip, pelvis, or leg fracture (<1 mo)	○ Other thrombophilia
○ Stroke (<1 mo)	**Total score =**
○ Multiple trauma (<1 mo)	
○ Spinal cord injury (<1 mo)	

Figure 146.2 Validated 2005 Caprini Risk Score. *VTE*, Venous thromboembolism. (Adapted from Caprini JA. Thrombosis risk assessment as a guide to quality patient care. *Dis Mon*. 2005;51(2-3):70-78.)

METHODS OF PROPHYLAXIS

Venous stasis plays a major role in the pathogenesis of thrombosis because it prevents the local clearance of activated coagulation factors and reduces their binding and inactivation by physiologic inhibitors. In addition, when associated with venous dilation, stasis may alter the normal linear blood flow, allowing platelets and leukocytes to contact the endothelium. In this regard, dilated veins may result in endothelial cracking and exposure of subendothelial collagen and other molecules, such as vitronectin and fibronectin, resulting in local thrombosis. Endothelial damage may also occur in patients undergoing manipulation of or trauma to deep veins, as is the case during pelvic operations for tumors, hip or knee arthroplasty, and hip fracture surgery. For these reasons, available methods for the prophylaxis of VTE include either mechanical measures, based on compression of the lower limbs and aiming to reduce stasis by improving venous flow, or pharmacologic interventions, using anticoagulants to prevent or counteract hypercoagulability. These methods may be used separately or combined, depending on the potential thrombotic and hemorrhagic risk faced by the patient.

General Measures

Adequate hydration, analgesia, and ambulation are important measures to improve postoperative recovery and reduce the risk of VTE. For those patients who are immobile in bed, active flexion and extension of the ankle joints and leg elevation will reduce stasis by enhancing venous flow. From this perspective, we should encourage early and progressive ambulation rather than early *angulation*, or having patients seated in a chair, which will promote venous stasis in the legs.

Mechanical Methods of Prophylaxis

Depending on their mechanism of action, mechanical methods may be divided into two main categories: passive and active. Among passive methods, elastic compression stockings are the preferred modality, particularly in surgical patients. Regarding active methods, intermittent pneumatic compression (IPC) of the legs is widely used alone, as in patients who cannot receive pharmacologic prophylaxis with anticoagulants or in combination with anticoagulants in patients at very high thrombotic risk.

TABLE 146.1 Boston University Algorithm for Prescribing Thrombosis Prophylaxis

Caprini Score	Risk	Recommendation	Duration
0	Lowest	Early ambulation only, OR Compression boots, OR Low dose Heparin; OR Low molecular weight heparin	Hospitalization
1-2	Low	Compression boots, OR Low dose Heparin, OR Low molecular weight heparin	Hospitalization
3-4	Moderate	Compression boots, AND Low dose Heparin, OR Low molecular weight heparin	Hospitalization
5-8	High	Compression boots, AND Low dose Heparin, OR Low molecular weight heparin	1-10 days
9 or more	Highest	Compression boots, AND Low dose Heparin, OR Low molecular weight heparin	30 days

Compliance was 100% in the low- and moderate-risk groups, 89% in the high-risk group, and 77% in the highest-risk group.

Elastic Compression Stockings

Graduated elastic compression stockings (GCSs) reduce the cross-sectional area of the veins and increase the velocity of venous blood flow. The optimal pressure profile is around 18 to 23 mm Hg at the ankle, decreasing to 8 mm Hg in the popliteal fossa or upper thigh. Noticeably, this profile is different from that of therapeutic compression stockings, used for the management of established chronic venous insufficiency or to attempt to prevent postthrombotic syndrome after a DVT (30 to 40 mm Hg at the ankle).

In surgical patients, a systematic review from the Cochrane Collaboration analyzed seven randomized controlled trials.[16] The incidence of postoperative DVT was significantly reduced from 29% in the control group to 15% in the GCS group (P <.001). Similarly, a meta-analysis of 11 studies evaluated the efficacy of GCSs in moderate-risk patients undergoing mainly abdominal surgery, showing a significant 68% reduction in the incidence of DVT.[17]

Most studies with GCS have important limitations, including small samples, incomplete blinding, uncertain concealment of treatment allocation, and use of asymptomatic DVT as an outcome. However, evidence suggests that GCSs used alone are effective in moderate-risk general surgical patients; there is lack of data in high-risk patients, such as those undergoing cancer or major orthopedic surgery. In addition, there is no evidence indicating that GCSs reduce the incidence of PE in surgical patients. A more recent systematic review and network meta-analysis shows that GCSs with pharmacologic prophylaxis is more effective than knee-length GCSs without anticoagulants for the prevention of VTE in surgical patients.[18] Overall, patients prefer knee-length stockings.

In medical patients, two trials evaluated GCSs in immobilized patients after acute stroke. The first trial compared thigh-length GCSs with no stockings in about 2500 patients and found that GCSs were ineffective at preventing the combined outcome of asymptomatic, ultrasound-detected, and symptomatic proximal DVT (odds ratio [OR] 0.98).[19] This trial did not demonstrate that stockings were effective at preventing VTE in stroke patients (OR 0.98). However, the use of GCSs was associated with a fourfold increase in the risk of skin complications (5.1% vs. 1.3%), including breaks, ulcers, blisters, and necrosis. The second trial compared thigh-length with below-knee stockings in more than 3000 patients with acute stroke and found fewer cases of VTE with thigh-length stockings (OR 0.69).[20] In this study, skin complications were observed in 3.9% of patients in the thigh-length-stocking group.

Advantages of GCSs are that they are less expensive and easier to use than IPC devices. Moreover, GCSs may be combined with pharmacologic agents in patients at very high risk of VTE. On the contrary, limitations of GCSs include lack of standardization of pressure profiles and difficulty in their application in patients with unusual leg shapes or sizes. Stockings should not be used in patients with peripheral artery disease with lack of palpable foot pulses or an ankle-brachial index less than 0.8, in patients with severe leg edema secondary to congestive heart failure, or in patients with dermatitis.

Regarding compliance, one study identified that 65% of patients in acute-care units were actually wearing GCSs as prescribed.[21] However, complaints about discomfort were higher among patients using thigh-length stockings compared with those using knee-length stockings. The most common and concerning issue was that stockings were folded or rolled down, creating a garter-like or rubber-band effect. Williams and coworkers reported similar results in orthopedic patients, with 56% of thigh-length stockings producing constriction bands, compared with 13% of knee-length stockings.[22]

Intermittent Pneumatic Compression of the Legs

IPC of the lower limbs is the most extensively studied of the mechanical methods of thromboprophylaxis and is considered the most effective. Most IPC devices consist of inflatable boots or sleeves, wrapped around the legs and secured by Velcro, that are connected to an electrical compressor that intermittently insufflates air to a preselected pressure. The sleeves can be applied to the calf alone, calf and thigh, foot and calf, or whole limb.

Some types of IPC devices inflate the sleeves sequentially, first distally, then proximally to increase venous flow. Some hemodynamic studies have shown that uniform IPC devices might trap blood in the distal veins of the leg, whereas sequential compression enhances venous return. The frequency of

compression cycles can be fixed, or it can vary in more sophisticated systems, depending on the rate of venous refill and based on a plethysmograph incorporated in the garment.[23] Portable battery-operated IPC devices offer the potential advantage of continued use during ambulation and the early postoperative period. In contrast, conventional nonportable devices must be removed or disconnected when patients ambulate or are transferred to another unit.

Apart from improving venous hemodynamics, IPC stimulates local fibrinolytic activity and could reduce hypercoagulability by different mechanisms, including the release of endothelial tissue-type plasminogen activator (t-PA), prostacyclin, and tissue factor pathway inhibitor (TFPI).[24-26]

Regarding the prevention of VTE in surgical patients, most studies show that IPC is effective in preventing postoperative DVT in general and major orthopedic surgery, neurosurgery, gynecologic, and urologic procedures. In major orthopedic surgery, the ninth American College of Chest Physicians (ACCP) guideline considers that the available evidence is of low quality, based on the lack of blinding.[27] However, a relative risk reduction of 50% is observed for both DVT and PE, and the estimated absolute risk difference is 16 fewer symptomatic VTE events per 1000 patients receiving IPC compared with controls without compression after major orthopedic surgery. In nonorthopedic surgery, the ACCP estimates a reduction in symptomatic VTE from 60 to 30 per 1000 as a result of using IPC in high-risk patients.[3]

A systematic review of the literature that analyzed 19 trials including 2225 patients concluded that IPC as monotherapy reduced DVT from 23% in patients without IPC to 10% in those receiving IPC ($P < .0001$).[28] Similarly, a meta-analysis of 15 studies with 2270 patients who underwent different types of surgery showed that, in comparison with no prophylaxis, IPC reduced the risk of DVT by 60% ($P < .001$).[29] A very recent review has shown that in high-risk surgical patients undergoing hip or knee arthroplasty, there were no significant differences between IPC and pharmacologic prophylaxis in the incidence of postoperative DVT.[30] The same review suggests that the combination of IPC plus anticoagulants might provide better protection than pharmacotherapy alone.

As the risk of bleeding complications is not increased by mechanical methods, IPC is an attractive alternative to anticoagulants in patients at high risk of bleeding (trauma and pelvic surgery) or in whom minor bleeding may be serious, as in neurosurgery. A recent meta-analysis evaluated IPC in major orthopedic and neurosurgical patients, showing a significant reduction in the incidence of DVT from 5.3% in the control group to 2.26% in patients with IPC ($P = .004$) and low major bleeding events. However, there were no significant differences in the incidence of PE.[31]

IPC is particularly useful in patients with contraindications for the use of anticoagulants. In this regard, the ENDORSE study revealed that 9% of surgical patients considered at high VTE risk had some contraindication to receive pharmacologic prophylaxis and therefore would be good candidates for mechanical prophylaxis.[32] For these reasons, the ninth edition of the ACCP guidelines recommends using IPC in surgical patients at high risk for VTE and contraindications to receive anticoagulants and in combination with pharmacologic agents in those at very high thrombotic risk without such contraindications.[3]

In medical patients immobilized with acute stroke, the CLOTS 3 trial evaluated the efficacy of IPC for the prevention of VTE. A compression duplex ultrasound of both legs (femoral and proximal veins) was performed 7 to 10 days and 25 to 30 days after randomization.[33] The mean duration of IPC use was 12.5 days and mean adherence was 59%. The rate of proximal DVT detected by compression ultrasound was 8.7% and 5.8% in the control and IPC groups, respectively ($P = .003$). Likewise, there was a significant reduction in the incidence of symptomatic DVT (proximal or calf), from 6.3% to 4.6% ($P = .045$). Although the rate of skin breaks was higher in the IPC group (3.1%) than in the control group (1.4%) ($P = .002$), only 0.7% of patients had skin breaks attributed to IPC.

Apart from the aforementioned skin problems, IPC has occasionally caused peroneal nerve palsy. IPC should be avoided in patients with skin infections and severe edema of the legs secondary to congestive heart failure. The presence of an acute DVT contraindicates the use of IPC because theoretically the thrombus could be detached from the venous wall and embolize to the lungs, although direct evidence for this is lacking.

A significant limitation of IPC is related to lack compliance, inadequate fitting, and discomfort reported by patients. In a study conducted in several acute nursing units, only 29% of patients with prescribed sequential compression devices (SCD) had the devices applied to their legs. The most common reasons for noncompliance with IPC were that devices were not reapplied after bathing or ambulating or were removed because patients complained of discomfort.[21] Overall, patients preferred and were more compliant with knee-length sleeves. Similar results have been reported in urologic patients[34] and after cesarean delivery.[35] A small trial found better adherence with a portable calf IPC device (77%) than with a conventional SCD calf device (59%).[36]

Foot Compression Devices

Also known as foot pumps, these devices consist of inelastic slippers or boots with an air bladder in the area of the sole of the foot. This chamber is rapidly inflated to a pressure up to 200 mm Hg over 3 seconds every 20 seconds. This plantar compression increases venous outflow and reduces stasis in the legs. Several studies showed a reduction in venographically detected DVT in patients with the foot pump compared to controls without prophylaxis after major orthopedic surgery.[28] Nonetheless, several trials have documented better results with low-molecular-weight heparin (LMWH) than with foot compression devices after total knee replacement.[37,38] A trial assessed foot compression under a plaster cast in patients with Achilles' tendon repair.[39] At 2 and 6 weeks postoperatively, the incidence of DVT was assessed by color duplex scans. The study was prematurely interrupted after 24 patients were included because of the high rate of DVT in both the foot pump group (75%) and control group (50%).

In summary, there are limited and conflicting data demonstrating a beneficial effect of foot compression in surgical patients.

However, foot pumps could represent an alternative in trauma patients in whom anticoagulants are contraindicated and leg IPC cannot be used because of the presence of casts or external fixators.

Pharmacologic Methods of Prophylaxis

Aspirin

There is renewed interest in aspirin as a simplified strategy for postoperative VTE prevention. Even at small doses of less than 100 mg, aspirin irreversibly acetylates cyclooxygenase 1 which inhibits platelet generation of thromboxane A2, mediating the antithrombotic effect. In a multicenter randomized controlled trial powered for noninferiority, 778 patients were randomized after elective unilateral total hip arthroplasty. All patients received 10 days of LMWH prophylaxis and then either aspirin (81 mg) or LMWH (dalteparin 5000 U) for a total of 28 days. Aspirin was noninferior to the LMWH strategy; however, it should be noted that the study was stopped prematurely and the allowed clinically relevant difference was a rather large 2%, indicating that the results should be interpreted with caution. There was no significant benefit on major bleeding or clinically significant nonmajor bleeding rates between both strategies.[40] In a meta-analysis evaluating aspirin versus an anticoagulant in the orthopedic population with pooled information on 1408 participants, the rates of DVT did not differ statistically between aspirin and anticoagulants (relative risk [RR]: 1.15 [95% CI, 0.7 to 2.0]). The risk of bleeding, however, was lower in the aspirin group.[41] There is less agreement regarding validation of aspirin as a single preventive agent for the population at highest risk.

Warfarin

The onset of action of warfarin is slow, requiring at least 3 to 5 days; it is not typically practical for acute perioperative prophylaxis. In a study of 149 consecutive patients who underwent total joint arthroplasty, the VTE incidence using warfarin was 16% compared with a VTE incidence of 24% in the pneumatic compression group.[42] Patients with a subtherapeutic international normalized ratio (INR) have the highest postoperative rate of DVT.[43] In a study of 125 patients all receiving compression as well as heparin and warfarin, the rate of proximal DVT at 1 month after total hip replacement was 8.2%. The INR was less likely to be therapeutic among those who suffered an event (61% vs. 11%, $P < .001$) compared with those with a therapeutic INR.

Heparins

Unfractionated heparin (UFH) is a sulfated polysaccharide with a molecular weight of 15,000 Da; anticoagulant effects include inactivation of thrombin and factor Xa and reducing thrombin-induced platelet activation. In a prospective trial involving 84 patients undergoing total hip arthroplasty, the frequency of DVT in those receiving 5000 U/8 hours of UFH was 32%, compared with 69% in the control group using I-125 fibrinogen scanning confirmed with venography.[44] The small size of these trials has limited the certainty with which we can estimate the benefit of UFH on the prevention of fatal PE. The largest trial evaluating the use of UFH prophylaxis was a multicenter randomized trial involving 4121 postoperative patients. Sixteen patients in the control group and 2 in the heparin group had autopsy-confirmed fatal PE ($P < .01$).[45] A large meta-analysis involving 8874 patients evaluating thrombosis prophylaxis using UFH was associated with an odds reduction of 68% (95% CI, 65 to 71%) regarding the risk of DVT.[2] The odds reduction for PE was 47% ± 20 (20 of 2230 UFH versus 38 of 2250 controls). Fatal PE in this study using UFH included 243 deaths among 7307 patients versus 287 deaths among 6777 controls; $P < .02$). The absolute bleeding risk was 2% higher in the UFH group.

LMWH is derived from UFH using enzymatic or chemical depolymerization to create fragments of ~5000 Da. The mechanism of action includes inhibition of factor Xa and to a lesser extent thrombin. The reduced protein binding capacity results in more predictable pharmacodynamic behavior obviating the need for routine testing. LMWH is excreted by the kidneys and requires adjustment for those with renal insufficiency. It is not recommended for patients with renal failure. Among postoperative patients with high VTE risk, LMWH is at least as effective as UFH and has become a preferred prevention strategy.[46] In a meta-analysis assessing 24 orthopedic and 34 general surgery studies comparing LMWH to UFH prophylaxis, the relative risk of DVT was lower for LMWH (RR 0.7; 95% CI, 0.6 to 0.9). The effect was similar between general (RR 0.8; 95% CI, 0.6 to 0.9) and orthopedic surgery (RR 0.7; 95% CI, 0.5 to 0.9).[47] For PE, LMWH was superior for prevention (RR 0.4; 95% CI, 0.3 to 0.7). There was no statistically significant increase in major bleeding.

Fondaparinux

Fondaparinux is a synthetic pentasaccharide administered via subcutaneous injection and has a half-life between 17 and 21 hours, is renally excreted, and is a valid alternative to LMWH. The mechanism of action is inhibition of factor Xa. Several studies support its efficacy.

In a double-blind study that included 1711 high-risk orthopedic surgery patients, there was a significant risk reduction by day 11 (RR = 56; 95% CI, 39% to 70%) among patients who received fondaparinux at 2.5 mg compared with enoxaparin 40 mg once daily. There were no differences in bleeding outcomes.[48] Among patients with hip fracture in the PENTHIFRA study, 656 patients undergoing hip fracture were randomized to placebo after 8 days of receiving therapy. The patients on fondaparinux had a reduced incidence of venographically proven VTE, with 1.4% versus 35% on placebo (RR 96% 95% CI, 87% to 99.7%). Moreover, the incidence of symptomatic events was also reduced from 2.7% to 0.3%. There was no significant increase in the rate of major bleeding, validating the use of extended prevention strategies in this high-risk population.

In a meta-analysis of four randomized trials among 7344 patients undergoing orthopedic procedures, the efficacy of a subcutaneous 2.5 mg, once-daily regimen of fondaparinux starting 6 hours after surgery and continued for 11 days was superior to LMWH (RR = 55.2; 95% CI, 45.8 to 63.1%;

$P < .001$). The incidence of major bleeding at 11 days was higher in the fondaparinux arm (2.7% vs. 1.7%; $P < .01$).[49]

Direct Oral Anticoagulants

The currently approved direct oral anticoagulants (DOACs) include dabigatran, a direct thrombin inhibitor, and the factor X inhibitors including edoxaban, apixaban, and rivaroxaban. The data do not allow direct comparisons among these agents, but there is robust information individually when these agents are compared with LMWH. Dabigatran used at 220 mg daily for total knee or hip replacement was similar to LMWH (RR 0.95; 95% CI, 0.8 to 1.1) in a pooled analysis of the prevention trials without significant differences in bleeding. Rivaroxaban ($n = 4657$), when used at a dose of 10 mg orally, compared with LMWH ($n = 4692$) in a pooled analysis comparison of 9581 patients was more effective for the composite outcome of symptomatic VTE and all-cause mortality (OR 0.4; 95% CI, 0.2 to 0.8), with a similar bleeding risk of 0.2% per arm.[50] Similar meta-analytic data exist for apixaban. For the outcome of postoperative VTE among orthopedic surgery patients, apixaban ($n = 6145$) compared with enoxaparin ($n = 5976$) was not superior (RR 0.8; 95% CI, 0.4 to 1.6). There was, however, a small benefit in the rate of clinically relevant bleeding (RR 0.8; 95% CI, 0.69 to 0.98).[51] Edoxaban 30 mg once daily ($n = 307$) in a phase 3 randomized trial was superior to enoxaparin 20 mg twice daily ($n = 303$), with a 2.4% versus 6.9% VTE rate and a statistically similar major bleeding rate of 0.7% for edoxaban versus 2% for enoxaparin.[52] For total knee arthroplasty, edoxaban 30 mg once daily started 6 to 24 hours after surgery, compared with enoxaparin 20 mg twice daily was also superior for efficacy (22/299 patients on edoxaban versus 41/295 on enoxaparin) with a relative risk reduction of 46.8%. The cumulative incidence of major bleeding or clinically relevant nonmajor bleeding was numerically higher for edoxaban 6.2% versus 3.7% but not statistically different ($P = .13$).[53]

There are good-quality data for VTE prophylaxis with DOACs in orthopedic patients. Using pooled data accumulating 15,977 participants, extended-duration DOAC compared with heparin was not significantly better (OR 0.7; 95% CI, 0.3 to 1.7). The rate of major bleeding (OR 1.1; 95% CI, 0.8 to 1.5) and clinically relevant nonmajor bleeding (OR 1.1; 95% CI, 0.9 to 0.3) was also similar.[54]

In summary, there are several distinct agents that may be used for VTE prevention postoperatively. A direct comparison among all of them is not feasible with the current literature outside a network meta-analysis. However, such data do exist, at least for artificial joint replacement. In a pooled population of over 30,000 patients, warfarin was more effective than LMWH and DOACs.[55]

Combination of Mechanical and Pharmacologic Methods

The combination of mechanical and pharmacologic methods for VTE prevention will theoretically improve the efficacy of these methods used separately, because this approach will address two of the components of the Virchow triad: stasis and hypercoagulability. After all, they should be considered as complementary rather than being competitive. In a systematic review of the literature from the Cochrane Collaboration, the combination of heparin and GCSs was better than heparin alone in the prevention of VTE in patients who underwent colorectal surgery.[56] In a study of 2551 cardiac surgery patients randomized to receive either heparin alone or in combination with IPC, the incidence of PE was 62% lower in patients who received combination therapy (4% vs. 1.5%).[57]

Further support for the benefit of combined mechanical and pharmacologic prophylaxis for the prevention of postoperative VTE came from the APOLLO study. In this double-blind, placebo-controlled trial, patients who underwent major abdominal surgery received IPC with or without fondaparinux. The incidence of VTE was reduced from 5.3% (IPC alone) to 1.7% (IPC plus fondaparinux).[58]

A recent meta-analysis has compared combined compression and anticoagulants with either modality alone in surgical patients.[59] This study shows that most compression studies were of low quality because of methodologic weakness and publication bias. On the contrary, studies using anticoagulants were considered of moderate quality because of more frequent blinding of physicians and outcome assessors. The addition of compression to anticoagulants decreased the risk of DVT by 49% ($P < .001$) (47% reduction with GCS and 57% with IPC) compared with anticoagulants alone. However, these differences were not significant regarding proximal DVT or symptomatic DVT. The addition of anticoagulants to compression reduced the risk of all DVT by 44% ($P < .001$) and of proximal DVT by 57% ($P < .001$) without resulting in significant reduction of symptomatic DVT or PE. The risk of any bleeding increased by 74% with the addition of anticoagulation to compression ($P < .001$). Similarly, there was a nonsignificant 73% increase in major bleeding with the addition of anticoagulants ($P = .08$).

In conclusion, adding anticoagulation to compression significantly reduces the risk of DVT after major surgery, a benefit counterbalanced by an increased risk of bleeding. Although adding compression to anticoagulation was also shown to reduce DVT risk, this finding is undermined by strong evidence of publication bias.

SPECIFIC SURGICAL GROUPS

Cancer

Among nearly 7000 patients having major oncologic operations, the safety and efficacy of adding preoperative chemoprophylaxis was evaluated among patients with colorectal, gastric, mixed tumor, gynecologic, thoracic, or urologic surgical procedures. The rates of DVT were (1.3% vs. 0.2%; $P < .001$), and PE (1.0% vs. 0.4%; $P < .02$) were significantly lower in the postintervention group, with no significant bleeding increase. The duration of the prophylactic strategy in this high-risk group has also been studied. Among 225 patients with colorectal cancer who underwent laparoscopic surgery, a complete compression ultrasound was done at day 28. Compared with 1 week of prevention, the extended 4 weeks of prevention group had

a lower rate of VTE at 3 months (9.7% vs. 0.9% RR 91% 95% CI 30% to 99%).[60]

Vascular Surgery

Thirty-day postoperative outcomes were recorded in over 4000 patients having percutaneous endovascular aneurysm repair (PEVAR) versus open endovascular aneurysm repair (OEVAR). The incidence of VTE was twice as high (1%) in OEVAR compared to PEVAR (0.5%) procedures. Unfortunately the National Surgical Quality Improvement Program (NSQIP) database does not record details regarding thrombosis prophylaxis.[61] As a general observation, endovascular interventions will have lower rates of VTE compared with open surgery equivalents.

Cardiac Surgery

The results regarding the incidence of VTE in cardiac surgery patients are mixed. In one study, 3% of patients after cardiac surgical procedures developed silent VTE events. In a large cohort of 92,699 patients undergoing coronary artery bypass grafting, the overall incidence of VTE with mechanical versus pharmacologic prophylaxis or combined therapy was not statistically different. It was also noted that there were no differences in major bleeding whether or not mechanical or pharmacologic prophylaxis was used. It is recommended that individual risk assessment be done for these patients and, based on the level of risk, prophylaxis be provided similar to what was done in other groups.[62] This population has a high incidence of seroconversion to heparin antibodies, making HIT a consideration. Another factor that increases the incidence of VTE is congestive heart failure.[63] Surgeons should pursue aggressive thromboprophylaxis in these patients.

Bariatric Surgery

The bariatric surgical population is at very high risk for developing VTE due to the presence of obesity. It has been estimated that these patients are 2 to 3 times more likely to have a VTE and twice as likely to suffer from delayed thrombotic events. The postthrombotic syndrome is another problem frequently seen in these patients. High intra-abdominal and venous pressure occurs secondary to extensive truncal obesity. Pharmacokinetic studies have demonstrated that standard fixed doses of prophylaxis are suboptimal in these patients, so investigators either adopt a fixed high-dose LMWH strategy (enoxaparin 40 mg twice daily), or adjusted dose LMWH (0.5 mg/kg per day). In one recent study using this strategy, the incidence of VTE was cut in half, from 1.48% to 0.77%, without an increased risk of bleeding.[64]

A large database of 97,218 bariatric surgical procedures was queried for concurrent prophylactic placement of an inferior vena cava filter at the time of surgery. The authors concluded that this practice was associated with increased health resource utilization and a higher mortality in patients undergoing bariatric surgical operations.[65] They were unable to establish an outcomes benefit for the placement of these filters. In addition, in considering oral anticoagulants, one must be aware that gastric bypass operations may interfere with the gastrointestinal absorption of the oral drugs.

Neurosurgery

Patients undergoing neurosurgical procedures are at high risk for developing VTE, since they tend to have additional risk factors including benign and malignant tumors, immobility, prolonged hospitalizations, and prolonged courses of corticosteroids. A NSQIP database containing 94,620 patients identified 0.60% of patients with DVT and a 1.12% incidence of PE. The authors concluded that the relative risk of hemorrhage versus thrombosis must be evaluated in each individual. Most studies suggested that prophylaxis with anticoagulation is safe within 48 to 72 hours following most intracranial surgical procedures.[66] In the Computerized Registry of Patients with Venous Thromboembolism (RIETE) database, containing 40,663 patients with VTE, 0.96% had VTE in less than 60 days after neurosurgery.[67] Subtherapeutic doses of anticoagulation were given in one-third of these patients and 2.6% of them died from a fatal PE. No bleeding deaths were seen in these patients and the authors conclude that neurosurgical patients developing VTE were more likely to die from PE than from bleeding in the first week despite anticoagulation.

Trauma

Critically ill trauma patients with severe injuries are at high risk for VTE and bleeding simultaneously. Mechanical prophylaxis when possible and starting anticoagulation as soon as the bleeding risk decreases are important strategies. Studies have shown that mortality due to PE in trauma patients with severe injuries is low relative to other causes of mortality. Despite these data, the placement of a temporary vena cava filter is often advocated. One important study evaluated the cost-effectiveness and outcomes of three VTE prophylaxis strategies from a cohort of trauma patients with severe injuries (ISC >12) admitted to the intensive care unit (ICU) of a regional trauma center.[68] The incidence of DVT at 12 weeks was 14.9% in patients treated with IPC, 15.0% for those followed with serial ultrasound screening, and 25.7% in those receiving vena cava filters. Expected mortality and quality-adjusted life years were nearly identical for all three management strategies. Costs were slightly lower using the ultrasound screening protocol compared with the other strategies. It would appear from these data that a combination of IPC plus serial screening would be the best approach for those patients who cannot receive appropriate anticoagulant prophylaxis.

EVIDENCE-BASED GUIDELINES VERSUS REAL CLINICAL PRACTICE

Many patients are encountered who do not fit the guidelines, since every clinical scenario cannot be tested in clinical trials. Clinically based registry data that identify what was actually

done in real-world practice are valuable for making individual decisions regarding thrombosis prophylaxis not covered by the guidelines. The RIETE registry contains 63,698 patients from 10 countries, including one site in the United States. A RIETE manuscript published in 2008 evaluated the issue of when patients developed VTE relative to their hospitalization. The study included 1602 postoperative patients, and most of the thrombotic events (77%) developed following discharge, including 55% that appeared after prophylaxis was stopped.[69] The average time elapsed from surgery to VTE was 22 ± 16 days. The incidence of fatal PE was 1.3% at 3 months. Although guidelines lack advice for many patients regarding postdischarge prophylaxis, these registry data can be used to guide decisions for patients at very high risk.

The Million Woman Study is another data source that can help to guide decisions regarding prophylaxis in situations where guideline data are unavailable. Participants included 947,454 middle-aged women followed for 6 years. Operative procedures were necessary in 239,614 patients, including 5419 hospital admissions that resulted in 270 VTE deaths.[70] The authors concluded that the risk of VTE after surgery is substantially increased in the first 12 postoperative weeks and varies by type of surgery. Postoperatively, women were 70 times more likely to be admitted with VTE in the subsequent 6 weeks (RR 69.1; 95% CI, 63.1 to 75.6).

SUMMARY OF RECOMMENDATIONS FOR VENOUS THROMBOEMBOLISM PROPHYLAXIS IN SURGICAL PATIENTS

The basis for deciding about thrombosis prophylaxis in surgical patients is best done using an individual risk assessment to determine the likelihood of clinically relevant VTE. Important new data have emerged since 2012 identifying a very high-risk group of individuals. Patients with a Caprini score of greater than 8 were found to have clinically relevant risk of developing VTE ranging from 6% to 18%. These findings provide data suggesting that patients in this risk category should have their anticoagulant prophylaxis continued following discharge. There are insufficient data to indicate how long this prophylaxis should be continued, but the experience of the Boston University group would suggest at least 30 days of prophylaxis to be appropriate (Fig. 146.2).

When possible, we advocate that in patients with a Caprini risk of 1 to 2, early ambulation is an adequate preventive measure. Among those with a score of 3 to 4, pneumatic compression before, during, and after surgery should be added. In addition, a physician declining to use anticoagulant prophylaxis in these low-risk patients should document the rationale for such a decision. Patients with a score of 5 or more are at high risk for developing VTE; for them we recommend anticoagulant prophylaxis and IPC in addition to ambulation. The anticoagulant prophylaxis should be continued for the period of time shown in clinical trials to be efficacious, usually 7 to 10 days. Finally, among patients with a risk score greater than 8, we recommend that prophylaxis be extended for 30 days after discharge.

SELECTED KEY REFERENCES

Amaragiri SV, Lees TA. Elastic compression stockings for prevention of deep vein thrombosis. *Cochrane Database Syst Rev*. 2000;(1):Art. No.: CD001484, doi:10.1002/14651858.CD001484.

This Cochrane review assesses the role of elastic compression stockings for the prevention of deep venous thrombosis in hospitalized patients. The authors conclude that stockings are effective in reducing the risk of DVT and suggest that in combination with other methods they are even more effective.

Caprini JA. Thrombosis risk assessment as a guide to quality patient care. *Dis Mon*. 2005;51(2–3):70–78.

This is the original article that outlined the Caprini score, which has been used in over 200,000 patients worldwide and published in 25 languages.

Cassidy MR, Rosenkranz P, McAneny D. Reducing postoperative venous thromboembolism complications with a standardized risk-stratified prophylaxis protocol and mobilization program. *J Am Coll Surg*. 2014;218(6):1095–1104.

This work represents the best example of using the Caprini score coupled to a mandatory prophylaxis program; it has resulted in one of the lowest VTE incidence rates of actual events at 30 days in a large nonorthopedic population (0.1%).

Longitudinal Treatment of Deep Venous Thrombosis 1948

Acute thrombosis of the lower extremity deep veins remains one of the most significant public health problems. It affects more than 350,000 people in the United States annually and is responsible for between 100,000 and 300,000 deaths.[1,2] Its economic impact is substantial; in the United States alone, the annual cost of deep venous thrombosis (DVT) was estimated to be 7.5 to 39 billion US dollars in 2010.[3]

New therapeutics extend the ability to safely treat acute thrombotic episodes, prevent recurrent thrombosis, and prevent DVT in high-risk patients. The result is a continuous shift toward early treatment of the majority of the patients based on the clinical information, reserving more expensive diagnostic tests for patients who require invasive treatment.[4]

CLINICAL ASSESSMENT

The clinical manifestations of acute DVT vary from an absence of symptoms and signs to the dramatic presentation of phlegmasia cerulea dolens and venous gangrene. Such broad variation is a result of multiple pathologic processes, with different timing and severity occurring during an acute thrombotic episode. Anatomic distribution of thrombosed venous segments, degree of occlusion in each affected vein, time of thrombus development, severity of inflammation, functional status of the lymphatic system, preexisting venous and lymphatic insufficiency, and many other factors determine the presentation at the time of clinical evaluation. Symptoms tend to be more severe in proximal

DVT and when more venous segments are involved, and symptoms tend to be less severe in calf vein thrombosis and in older and postoperative patients. The most common symptoms and signs of DVT are dull ache or pain in the leg, tenderness, swelling, erythema, cyanosis, and fever. Edema, cyanosis, and pain are features of phlegmasia cerulea dolens. Venous gangrene is a rare condition that occurs usually in patients with cancer, can occur with heparin-induced thrombocytopenia with thrombosis, and is generally associated with warfarin-mediated protein C depletion.[5,6]

The diagnostic value of signs and symptoms of DVT and their combinations have been extensively studied.[7-11] The most common symptom, calf pain, has been reported to have sensitivity between 75% and 91% and specificity between 3% and 87%. The reported sensitivity of calf swelling for DVT diagnosis ranges from 35% to 97%, and its reported specificity ranges from 8% to 88%. In part, such variability is due to the high prevalence of the same signs and symptoms in patients without DVT.[11] In patients at high risk for DVT, the diagnostic value of clinical signs and symptoms is substantially higher. For example, in cancer patients, the negative predictive value of absence of swelling is as high as 97% for outpatients and 92% for inpatients.[12] A valid alternative diagnosis, such as cellulitis or a musculoskeletal disorder that explains the presence of signs and symptoms, may also improve the negative predictive value of the clinical examination.[13]

High variability and lack of specificity limit the role of clinical examination in patients with suspected DVT. A meta-analysis of studies evaluating individual clinical features of DVT showed that only a past history of DVT and malignant disease are useful for diagnosis, and no individual clinical feature is useful for ruling out DVT.[14] The delay of clinical manifestations makes the clinical diagnosis of DVT even more challenging. On average, patients are seen by a medical professional 4.4 days after onset of symptoms, and in more than 22% of patients, the onset of symptoms occurred more than 10 days before presentation.[15,16] For these reasons, withholding treatment on the basis of clinical evaluation in primary care settings leads to inadequate management of more than 10% of patients with DVT.[17]

DIAGNOSTIC TESTS

D-Dimer

The concentration of D-dimer (DD) in plasma has become a widely used marker for the diagnosis of DVT. DD is a product of fibrin proteolysis by plasmin; therefore, its elevated levels signify that fibrinolysis of complexed fibrin is occurring. This commonly occurs as part of the response to injury in patients undergoing surgical procedures or trauma, part of the normal physiologic changes during pregnancy, and part of the pathophysiologic process in patients with cancer or thrombotic disorders. The degree of DD elevation in patients with DVT varies with the size and extent of the thrombus, the time from its onset, and the use of anticoagulation. Currently used assays differ in the specificity of antibody to various binding sites on the DD molecule, in units of measurements, and in reference values. In addition, their sensitivity for DVT diagnosis ranges from 60% to 96%.[18,19] Assays also vary with respect to speed of testing, cost, and labor involved. The most sensitive of the assays, conventional enzyme-linked immunosorbent assay, is also the most laborious and slow.[18,20-22] Rapid point-of-care assays are probably the most practical, as the results are obtained within minutes and their sensitivity is comparable to that of the enzyme-linked immunosorbent assay.[23,24]

Low specificity limits the use of DD in patients with suspected DVT. However, concentration of DD below the cutoff value indicates a very low probability of DVT, and it does not exclude it with sufficient accuracy, especially in cases of distal thrombi, use of anticoagulation, or long duration between the onset of thrombosis and testing.[19,22,25] Similar to clinical evaluation, the use of DD as a single diagnostic tool may result in inadequate management of more than 15% of patients with suspected DVT.[19] DD is best integrated with a clinical risk assessment of the patient, as discussed later in this chapter.

Duplex Ultrasonography

Duplex ultrasonography remains the dominant diagnostic test of choice for the detection of DVT. It has almost completely replaced venography because of its accuracy, lack of radiation, portability, noninvasiveness, and relative cost-effectiveness. In addition, ultrasound can distinguish among nonvascular pathologic processes such as inguinal adenopathy, Baker's cyst, abscess, and hematoma.

The technique of venous duplex scanning is discussed in Chapter 23. Duplex ultrasound diagnostic criteria for DVT include increased intraluminal echogenicity, increased venous diameter, inability of the vein to collapse under moderate pressure from the transducer, absence of spontaneous blood flow, and absence of flow augmentation with distal compression (Figs. 147.1–147.5). Among these factors, inability to compress the vein is the most widely used objective criterion for the diagnosis of DVT.[26] Even as a stand-alone criterion, noncompressibility has excellent sensitivity and specificity for the detection of proximal DVT, with sensitivity and specificity of 97% and 94%, respectively, for proximal DVT.[27]

A significant limitation of compression ultrasound is its lack of accuracy in the evaluation of calf veins, fresh thrombi, and small segmental thrombi. Compression ultrasound has limited use in obese patients[28] and when significant edema, especially in the deep tissues, is present.[29] Addition of evaluation of venous flow with color Doppler and spectral Doppler can improve the accuracy of compression ultrasonography.

Because the risk of proximal extension of the thrombus exists in patients with DVT even when they receive appropriate anticoagulation,[30] repeated ultrasonography has been advocated.[31] Additional ultrasound 7 to 14 days after an initial examination can reduce the rate of thromboembolic complications to 1% during a 3-month follow-up period[32] compared to 2.5% with no additional testing.[33,34] The diagnostic gain from repeated ultrasound is estimated to be 1.34% of positive studies, with a positive predictive value of 89%,[14] which makes this option cost-ineffective.[35] Limiting indications for repeated ultrasonography to

patients with positive DD assays and normal initial ultrasound findings increases its clinical utility.[13,32,36]

Pitfalls in venous duplex imaging include misidentification of veins; missing of duplicate venous systems; systemic illness or hypovolemia resulting in decreased venous distention; suboptimal imaging in obese or edematous patients; and areas not amenable to compression such as the iliac veins, the femoral vein at the adductor canal, and the subclavian veins. As with most ultrasound-based imaging studies, the quality of the examination depends on the skill of the technologist performing the study.

Recent systematic reviews and meta-analyses challenge the common perception that duplex ultrasound is sufficiently accurate in all patients. In contrast to 94.2% sensitivity of

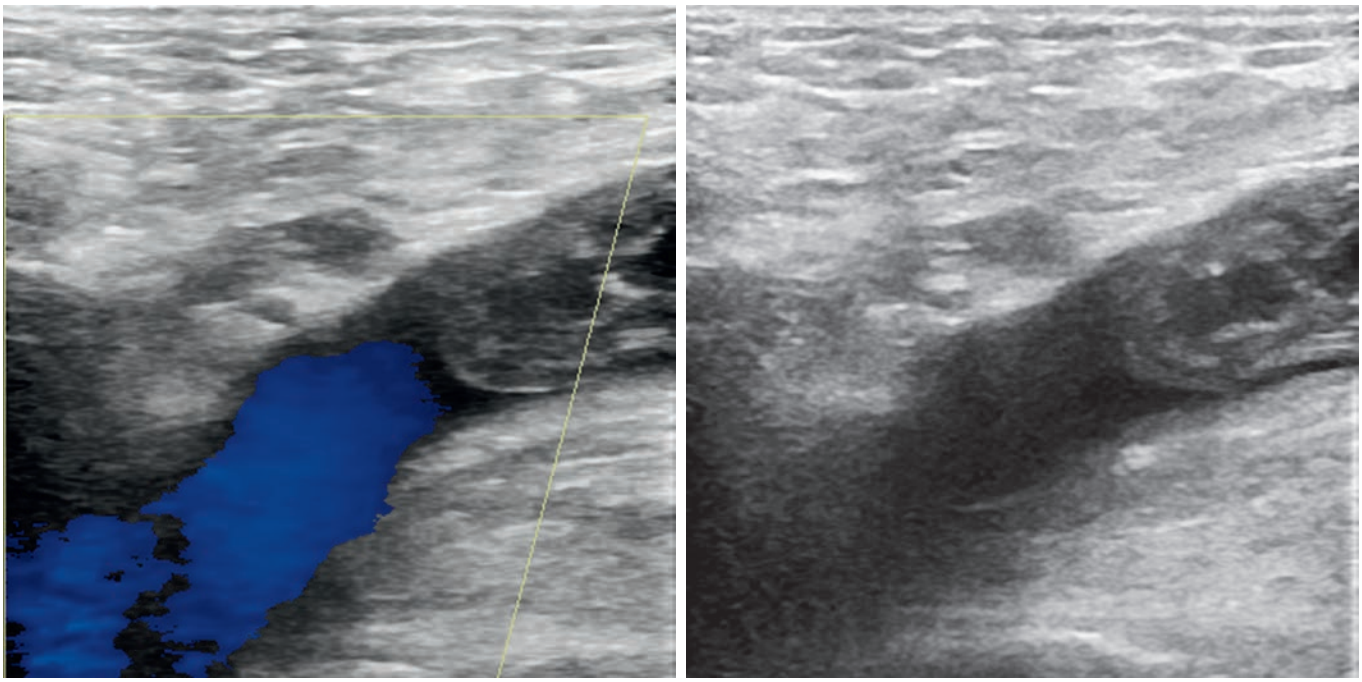

Figure 147.3 Thrombus in the Common Femoral Vein Extending Into the External Iliac Vein. The most proximal part of the thrombus appears free-floating. The flow from tributaries is present proximal to the thrombus.

compression ultrasound for detection of proximal DVT, the sensitivity is only 63.5% for distal DVT. This result of overall sensitivity was 89.7% and specificity 93.8%.[14] The diagnostic properties of duplex ultrasound are substantially different in the subpopulations of symptomatic outpatients. In patients with a high Wells score, sensitivity is 91% and specificity approaches 100%, whereas sensitivity and specificity are 61% and 99%, respectively, in patients with an intermediate Wells score (see later), and 67% and 98% in patients with a low Wells score.[37] In asymptomatic patients, sensitivities of duplex ultrasound for detection of proximal and distal DVT are 66.7% and 39.0%, respectively, with an overall specificity of 96.5%.[14] These data indicate that the use of duplex ultrasound in low-risk patients may result in a significant number of false positives. In symptomatic patients, duplex ultrasound can reliably rule out proximal but not distal DVT; and in asymptomatic patients, ruling out DVT based on sonographic findings is highly questionable.

Although clinical relevance of calf vein DVT is still debated, significant limitations of existing data have become apparent recently. Studies consistently showed that about half of all calf vein DVTs are calf muscle vein thromboses (CMVT). The overall pulmonary embolism (PE) incidence in patients with calf DVT is in the range of 10% to 15%.[38] However, in patients with CMVT, the incidence of PE is as high as 50%.[39]

CMVTs are also more symptomatic and more likely to propagate proximally compared to tibial and peroneal DVTs.[40] However, reliability of ultrasound detection of CMVT is low, which can be largely explained by a lack of training and irregularity of reporting.[29] The lack of studies that separate CMVT from tibial and peroneal DVT is a substantial obstacle in our understanding of clinical importance of distal thrombosis, which led to the absence of appropriate management guidelines. The existing limited literature suggests that the duplex ultrasound reports should be more specific in identification of which calf veins are affected by thrombosis, and patients with CMVT should be treated and followed more aggressively.

Venography

Contrast venography for the sole purpose of diagnosing DVT is largely of historical interest; however, it is invaluable when it is used as part of the treatment plan (see Chapter 26). Reasons for its dramatic decline are obvious in light of the utility, accuracy, and safety of duplex ultrasonography. It is expensive and inconvenient compared with other diagnostic modalities and potentially causes patient discomfort.[41,42] Potential complications of the examination include nephrotoxicity, allergy, phlebitis, and the need for intravenous access. Venography may be helpful in cases when duplex ultrasound suggests the presence of proximal obstruction by demonstrating a loss of the flow phasicity but fails to visualize the thrombus in iliac veins.

There are two basic techniques for the performance of contrast venography. The Rabinov-Paulin technique uses spot film, and the long-leg technique uses cine film. Although both techniques are useful, Lensing et al.[43] demonstrated that 20% of examinations were inadequately interpreted by the Rabinov-Paulin technique versus only 2% by the long-leg technique. In addition, they went on to show a 21% interobserver disagreement with the Rabinov-Paulin technique, whereas the long-leg technique had only a 4% disagreement.

Despite the disadvantages of contrast venography, it continues to be perceived as the "gold standard" for the diagnosis of acute DVT. Comparisons of contrast venography with duplex ultrasound using DD for the confirmation of thrombus with both

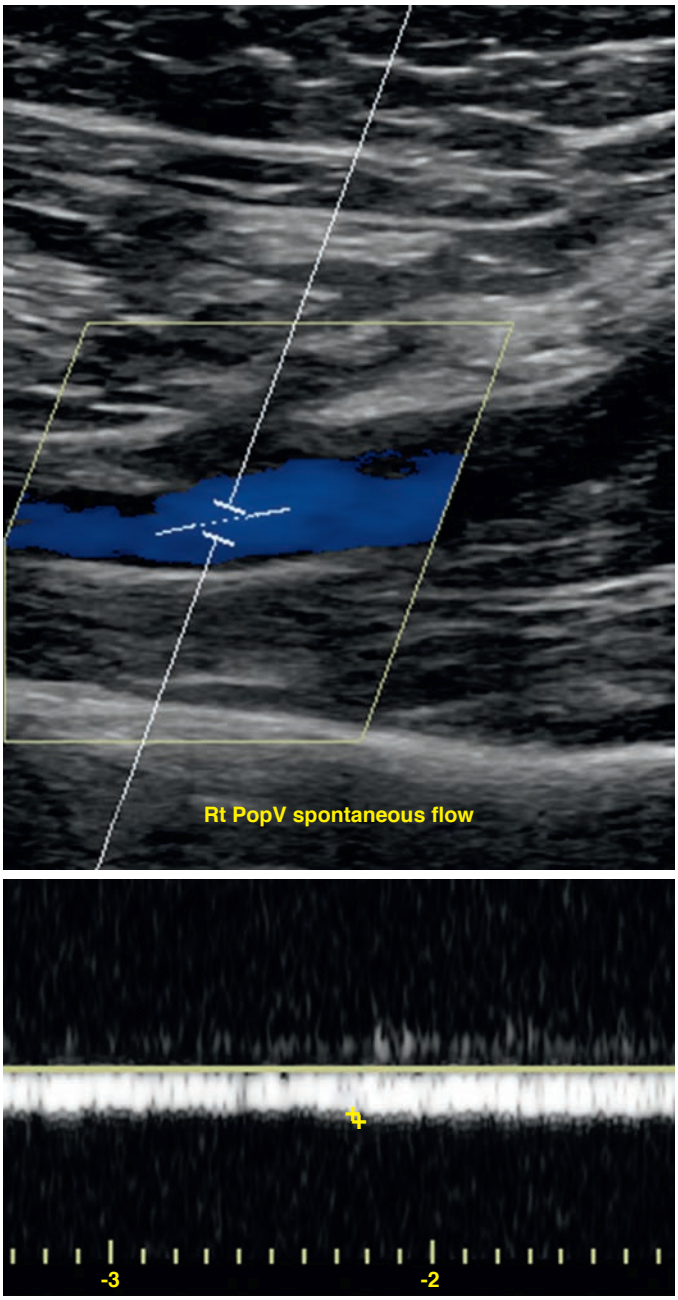

Figure 147.4 Triplex ultrasound image of popliteal vein in extremity with acute femoral-popliteal venous thrombosis during spontaneous flow. Color Doppler indicates the presence of the flow in the popliteal vein. The spectral Doppler demonstrates low-velocity continuous flow with lost phasicity (respiratory and cardiac) indicating more proximal obstruction.

diagnostic modalities confirmed a sensitivity and specificity of 96% and 91%, respectively, for contrast venography and 78% and 97%, respectively, for duplex ultrasonography.[44] Moreover, in the same study, calf vein acute DVT was diagnosed in only 74% of patients already positively diagnosed with contrast venography. Similarly, Ozbudak et al.[45] showed that contrast venography diagnosed 19% of acute DVT that duplex ultrasound failed to identify. de Valois et al.[46] demonstrated that duplex ultrasonography obtained 92% sensitivity and 90% specificity compared with contrast venography, concluding that contrast

venography should be used as the "golden backup" when the diagnosis of acute DVT remains in question after a venous duplex examination.

Computed Tomographic Venography

Computed tomographic arteriography is an excellent technique for the diagnosis of PE. However, its venous counterpart, computed tomographic venography (CTV) has yet to gain traction for the diagnosis of acute DVT in the lower or upper extremities. The diagnostic capabilities of CTV are remarkable in the thigh and pelvis compared with duplex ultrasound; it has a sensitivity of 98% and specificity of 100% in the thigh and sensitivity and specificity of 94% and 100%, respectively, in the pelvis. Overall positive predictive and negative predictive values are 92% and 100%, respectively.[47-50] Thomas et al.[51] conducted a meta-analysis of 13 studies evaluating CTV for the diagnosis of DVT in patients with suspected DVT and PE. The sensitivity ranged from 71% to 100% and the specificity ranged from 93% to 100%. The pooled estimate of sensitivity was 95.5%, whereas the pooled estimate of specificity was 95.2%. They concluded that CTV has a sensitivity and specificity similar to those of ultrasonography for the diagnosis of acute DVT but must be viewed with caution, as duplex ultrasound does not have perfect sensitivity or specificity, which may lead to overestimation of the accuracy of CTV. In addition, when CTV is used in conjunction for evaluation of PE, it adds only 3 to 5 minutes to the examination, making it an attractive option as the sole diagnostic modality for acute lower extremity DVT.[52]

Not all authors have shown as promising results for diagnosis of acute DVT with CTV. Peterson et al.[53] demonstrated that although the sensitivity is high at 93%, producing a 97% negative predictive value, the ability of CTV to accurately diagnose DVT has a specificity of 71%, giving a positive predictive value of only 53%. Others have shown a 50% false-positive rate for CTV for pelvic DVT; at the same time, magnetic resonance venography (MRV) had a 100% rate of false positivity.[54]

Magnetic Resonance Venography

MRV has become an attractive option for vascular imaging. The technology is based on the detection of moving versus stationary tissues. MRV is less expensive than contrast venography but more expensive and less operator dependent than duplex ultrasound. In addition, MRV overcomes many of the anatomic limitations encountered with duplex ultrasound when the inferior vena cava (IVC) and iliac vessels are imaged.

MRV can be used with or without contrast enhancement. Non–contrast-enhanced techniques include time-of-flight imaging and the phase-contrast technique relying on flow-related enhancement.[55] Contrast-enhanced MRV can provide the user with three-dimensional imaging, provided contrast material is injected in a timed sequence. Postprocessing can then remove the arterial anatomy, leaving only the venous segments in the display image.[56] Although it is not used to diagnose DVT, Figure 147.6 is a good example of time-resolved magnetic resonance imaging (MRI) of the central veins.

When MRV is used to diagnose acute DVT, results are impressive for larger venous segments, but sensitivity diminishes when smaller diameter veins are evaluated. Carpenter et al.[56] reported nearly identical findings compared with contrast venography in 97% of patients with acute DVT and 100% agreement in the extent of thrombus burden and whether thrombus was occlusive. Laissy et al.[57] found 100% sensitivity and specificity compared with contrast venography, with 95% sensitivity in detection of the extent of thrombus. The femoropopliteal venous segment had a 97% sensitivity for the same readers, whereas the iliofemoral segment had a 100% sensitivity.[58] Moreover, vessel wall enhancement can be visualized with acute thrombus, allowing the examiner a crude detection of thrombus age.[59]

Comparisons between the two modalities of MRV have also been examined. Time-of-flight MRV and duplex examinations had sensitivities and specificities of 100% and 96%, respectively, compared with contrast venography. Positive and negative predictive values were 90% and 94%, respectively.[56] When more proximal iliocaval DVT is examined, time-of-flight MRV had 100% sensitivity and specificity compared with contrast venography versus 87% and 85%, respectively, for duplex ultrasonography.[57] Perhaps the most impressive and useful aspect of time-of-flight MRV was its 95% sensitivity and 99% specificity in detection of the proximal extent of thrombus in the iliocaval segment compared with 46% and 100%, respectively, for duplex ultrasonography.[56] Contrast-enhanced MRV provides the examiner with 100% sensitivity and specificity for iliac thrombus and 100% sensitivity with a 97% specificity for the detection of femoral thrombus,[60] while being more reliable in distinguishing the proximal extent of these thrombus burdens.[59] With the addition of axial true fast imaging with steady-state precession, MRV has a sensitivity and specificity of 100% for iliocaval thrombus, 100% and 98% for femoral thrombus, and 68% and 94% for below-knee thrombus, producing an overall lower extremity sensitivity and specificity of 87% and 98%, respectively.[60]

Figure 147.6 Time-resolved magnetic resonance imaging after intravenous administration of a long-acting contrast agent in a female patient with symptoms consistent with pelvic congestion syndrome. The image shows early reflux through the left ovarian vein into pelvic varices. The patient also has compression of the left renal vein between the superior mesenteric artery and aorta, consistent with the "nutcracker syndrome."

Although MRV technology demonstrates excellent accuracy for the detection of acute DVT, several disadvantages can make the examination prohibitive. The examination demands a nonmoving patient and long imaging times that, when paired, can be a significant hurdle. The below-knee segments of venous anatomy are often paired, accounting for significant artifact during postprocessing of the images.[55,61] In addition, gadolinium can be toxic in patients with renal dysfunction, and the need for frequent examinations can produce problematic utilization issues in larger institutions. However, MRV certainly has a role in the diagnosis of DVT, especially in the detection of thrombus in centrally located venous structures not always accessible to duplex ultrasonography. Not only is MRV useful for detection

of hypogastric venous thrombosis,[56] a remarkable 27% of patients who sustained a PE with no detectable source of thrombus by duplex ultrasound had thrombus identified with MRV.[62]

A meta-analysis of the accuracy of MRI for the diagnosis of acute DVT[63] showed a range of sensitivity from 0% to 100% with a specificity of 43% to 100%. The pooled estimate of sensitivity was 91.5%, and pooled estimate of specificity was 94.8%.[63] The sensitivity and specificity were higher for proximal DVT than for below-knee thrombus.

^{18}F-Labeled Fluorodeoxyglucose Positron Emission Tomography/Computed Tomography

During the past several years, technology used for detection of primary and metastatic cancer has shown value in the diagnosis of acute DVT. Largely by serendipity, ^{18}F-labeled fluorodeoxyglucose positron emission tomography/computed tomography (^{18}F-FDG PET/CT) has been shown to detect acute DVT, to determine thrombus age, and to differentiate acute thrombus from tumor thrombus.[64] ^{18}F-FDG is a glucose analogue that is actively and avidly absorbed by tissues and cells with rapid metabolism. Among these are tumor cells, endothelial cells, macrophages, and lymphocytes. Several studies have reported the ability to detect acute DVT with ^{18}F-FDG PET/CT,[65-68] but until recently, only one study has examined its utility for the direct diagnosis of acute DVT. Rondina et al.[69] studied 12 patients with duplex ultrasound–proven proximal acute DVT with ^{18}F-FDG PET/CT for a mean of 32.5 days. They demonstrated a sensitivity of 87.5% and specificity of 100% using a maximum standardized uptake value of 1.645 or higher. Decreasing the maximum standardized uptake value to 1.49 or higher increased the sensitivity to 100% but decreased the specificity to 84.2%. Sharma et al.[64] showed that depending on the maximum standard uptake value, one could reliably differentiate tumor thrombus from acute DVT, with the higher value corresponding to tumor thrombus and the lower corresponding to acute DVT.

DIAGNOSTIC STRATEGIES

Risk Assessment

In the absence of a single reliable, accurate, and inexpensive diagnostic test, stratification of patients based on their risk of DVT substantially enhances clinical decision making. In addition to increased accuracy of diagnostic tests in high-risk patients, the very low incidence of DVT in low-risk patients allows the clinician to differentially order expensive options without sacrificing clinical outcomes. Availability of effective, convenient, and safe therapeutics for initial and extended treatment of DVT makes additional diagnostic testing unnecessary in low and moderate-risk patients.[4] In high-risk patients, however, treatment should be initiated immediately, and duplex ultrasound or other diagnostic tests can be safely delayed in most patients to the next business day. Such a contemporary approach to management of patients with suspected DVT requires identification of risk factors for development of DVT and stratification of patients based on predicted probability of a thrombotic event.

The relatively low prevalence of inherited causes of DVT combined with the high cost and questionable clinical value of their detection makes testing for thrombophilias impractical for assessment of DVT risk in an individual patient. However, the known presence of such coagulation abnormalities is valuable clinical information (see Chapter 38). The risk of DVT in patients with heterozygous antithrombin (AT) deficiency is increased by 5 to 50 times.[70-72] In patients with protein C deficiency, it is increased 3-fold;[71] and in patients with protein S deficiency, it is increased up to 10-fold.[72] The lifetime probability of symptomatic DVT in patients with heterozygous factor V Leiden mutation is about 10%, but concurrent thrombophilic conditions increase this risk significantly.[73] Other thrombophilias, such as elevated factors VII and IX, hyperhomocysteinemia, dysfibrinogenemia, and hypofibrinolysis, increase the risk of DVT twofold or less.

Acquired risk factors include age, malignant disease, immobility, exposure to surgery or trauma, use of oral contraceptives or hormone replacement therapy, obesity, pregnancy, and history of venous thromboembolism (VTE). The relative role of each individual risk factor in estimation of DVT probability varies. In the absence of prophylaxis, the risk of DVT is 36% after hip arthroplasty, 33% after urologic surgery, 25% after general surgery, 23% after neurosurgery, 19% after abdominal surgery, and 15% after peripheral vascular surgery. Half of the patients with hip fractures and one-third of burn patients develop DVT.[74] This risk continues after discharge from the hospital.[75]

The risk of DVT increases when several risk factors are present, which is the basis for the development of clinical scores that risk-stratify patients by combining several risk factors with clinical symptoms and signs. The most widely used score for symptomatic patients with suspected DVT is the Wells score. This instrument assigns one point to each of the nine clinical characteristics and subtracts two points if an alternative diagnosis is at least as likely as DVT. The nine clinical characteristics are as follows: (1) active cancer (patient receiving treatment for cancer within the previous 6 months or currently receiving palliative treatment); (2) paralysis, paresis, or recent plaster immobilization of the lower extremities; (3) recently bedridden for 3 or more days or major surgery within the previous 12 weeks requiring general or regional anesthesia; (4) localized tenderness along the distribution of the deep venous system; (5) entire leg swollen; (6) calf swelling at least 3 cm larger than on the asymptomatic side (measured 10 cm below the tibial tuberosity); (7) pitting edema confined to the symptomatic leg; (8) collateral superficial veins (nonvaricose); and (9) previously documented DVT.[76] The Caprini score is used as a risk assessment tool for selection of DVT prophylactic measures in asymptomatic hospitalized surgical patients.[77] The Wells score has been shown to be a consistent, reproducible instrument to stratify patients into high, intermediate, and low risk of DVT. It has been validated in a variety of patient populations, confirming its clinical utility. A meta-analysis of 24 studies that used the Wells score showed that in a population with 15% prevalence of DVT, the Wells score alone will classify 18% of the patients as high risk

with a DVT prevalence of 47%, 40% as intermediate risk with a DVT prevalence of 12%, and 42% as low risk with a DVT prevalence of 4%.[14]

Diagnostic Strategies for Symptomatic Deep Venous Thrombosis

Currently, there is no single modality that has perfect characteristics for diagnosis of DVT. To achieve a combination of reasonable accuracy, reliability, convenience for patients, practicality, and reduced costs, the clinical strategy should be selected based on the risk-benefit ratio of treating patients with and without DVT and the clinical and cost benefits of performing a sequence of diagnostic tests. It is increasingly recognized that the optimal approach to DVT diagnosis includes risk stratification based on simple low-cost methods, such as the Wells score and DD assay, followed by diagnostic testing in high-risk patients and in patients who require advanced treatment modalities.

In low-risk patients, the combination of a Wells score and negative DD result reaches a negative predictive value approaching 100%.[78,79] Because most of the studies of low-risk patients were done in outpatient settings and excluded patients with a history of DVT, a clinical suspicion of PE, and the use of anticoagulants,[37,80] these factors should be considered in addition to the Wells score.

Similar results were shown in intermediate-risk patients when a combination of Wells score and DD assay was used for DVT diagnosis.[20,81,82] Without treatment, the incidence of DVT during 3 months in patients who are classified as intermediate risk by a Wells score and have a negative DD result is 0.6%,[83] indicating that no additional testing is necessary in these groups, as it is unlikely to improve clinical outcome.

Evaluation of patients with a high probability of DVT is more problematic. Negative DD results in these patients are associated with PE rates of up to 15%.[84] This unexpectedly high rate of VTE indicates that treatment should be started before additional testing is completed. When anticoagulation is initiated, delay in definitive diagnostic studies has been shown to be safe.[4,85] The majority of inpatients fall into the high-risk category, which complicates use of the Wells score for this patient population. In hospitalized patients who could be classified as low risk based on a Wells score, the incidence of DVT has been reported as high as 10%.[86] In addition, both sensitivity and specificity of DD testing are substantially lower in inpatients than in outpatients. Unlike outpatients, most hospitalized patients with a clinical suspicion of DVT need confirmatory diagnostic testing.

The diagnosis of DVT during pregnancy adds an additional level of complexity. The risk of bleeding complications limits the use of anticoagulation to cases with confirmed DVT. DD levels have been known to increase during the course of a normal pregnancy and are of unproven utility during pregnancy.[87] For these reasons, ultrasound remains the preferred diagnostic test for detection of DVT in pregnancy. In pregnant patients thought to have DVT, repeated ultrasound is recommended if the initial examination findings are normal.

Several diagnostic algorithms for evaluation of suspected DVT in symptomatic patients have been published. However, as the new generations of anticoagulants become available, the utility of such algorithms may change. In outpatients, a combination of a low Wells score and a negative DD result is sufficient to rule out DVT. A positive DD result in intermediate and high-risk patients is an indication for immediate anticoagulation to be started and venous duplex examination to be scheduled for the next business day.

Diagnosis of Deep Venous Thrombosis in Emergency Departments

The diagnostic approach to patients with suspected DVT in the emergency department setting may be influenced by the available access to additional testing and the volume of cases that need to be triaged. The high number of emergent priorities and the substantial waiting time to obtain duplex ultrasound testing make fast and safe strategies more desirable. Patients with a low Wells score and no additional risk factors may be safely discharged from the emergency department to continue follow-up care by their primary care physician. A negative DD test result in these patients and in patients with intermediate probability effectively excludes the diagnosis of DVT. For patients with high probability of DVT, immediate anticoagulation without any additional testing is a valid choice while duplex ultrasound is obtained. If patients present at times when venous duplex ultrasound is not available, this approach is efficient and effective (Figs. 147.7 and 147.8). This approach is recommended by the American College of Chest Physicians based on a rigorous analysis of available evidence,[4] age of the thrombus, and diagnosis of recurrent thrombosis.

Thrombus Age and Diagnosis

Venous thrombosis initiates a sequence of biologic processes within the thrombus itself and in the venous wall. Organization of the thrombus and vein wall remodeling occur at a variable pace; within 7 to 10 days thrombus becomes adherent to the vein wall, making treatment modalities such as systemic thrombolysis and thrombectomy less effective and impossible in 30% of patients.[88-91] It is desirable, therefore, to be able to diagnose an acute DVT and to determine the age of the thrombus.

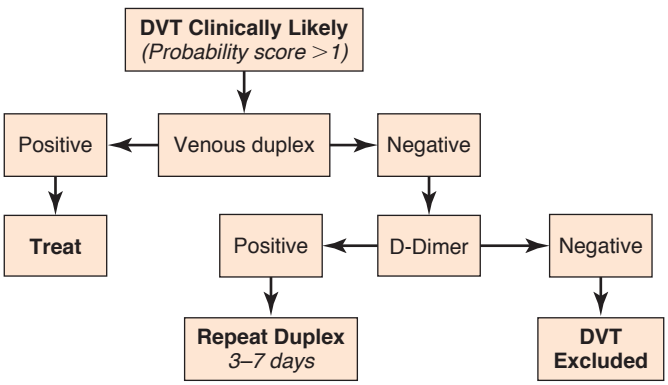

Figure 147.7 An example of a diagnostic algorithm for evaluation of symptomatic patients with high probability of deep venous thrombosis *(DVT)*.

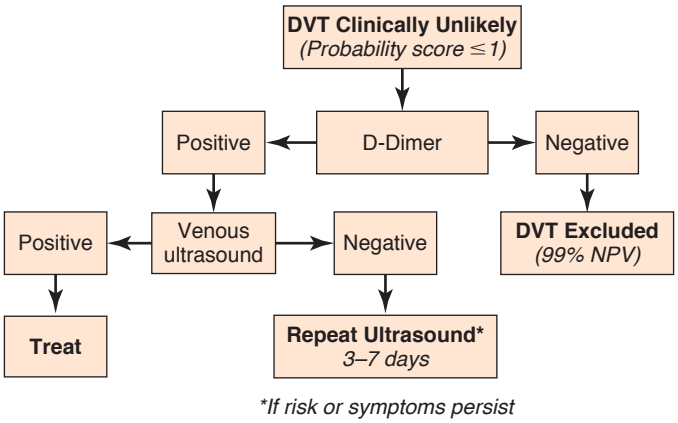

Figure 147.8 An example of a diagnostic algorithm for evaluation of symptomatic patients with low probability of deep venous thrombosis *(DVT)*. *NPV,* Negative predictive value.

The onset of the clinical manifestations of DVT is an unreliable indicator of the start of thrombosis, and conventional imaging techniques are rarely helpful in determining the age of the thrombus.[7] Initial results with ultrasound elastography to gauge thrombus age were promising[92,93] but were later shown to be inconsistent.[94] Most of the studies of ultrasound elastography were done in animal models or ex vivo,[95] and clinical validation of this technique has yet to be performed.

Use of radiolabeled markers, such as recombinant tissue plasmin activator, showed the ability to determine if the thrombus is more than 30 days of age,[96] and MRI may show that the time from onset of thrombosis exceeds 6 months.[97] These tests, however, are more suitable in the diagnosis of rethrombosis than in determining the age of the initial thrombus.

If thrombus neither lyses spontaneously nor is removed by treatment, pathologic processes continue, leading to postthrombotic disease in some patients and predisposing patients to recurrent thrombosis.[98] Recent data from placebo groups of randomized controlled trials showed that recurrent DVT occurs in 11% to 18% of patients during the first year after DVT.[99-101]

Diagnosis of recurrent ipsilateral DVT is a challenging task. Conventional risk assessment tools, such as the Wells score, are not helpful as they classify all patients with a known history of DVT as high risk. Clinical presentation of rethrombosis is frequently identical to manifestations of postthrombotic disease. Imaging diagnostic modalities are unable to reliably detect acute thrombus when postthrombotic changes are present in the venous wall and vessel lumen. Postthrombotic changes lead to partial or complete incompressibility of deep veins. In one study, 70% of patients at 3 months and 40% of patients at 12 months had abnormal compression test results after their first episode of proximal DVT.[102] This would increase the frequency of false-positive results when this criterion is used for recurrent DVT. The false-negative results of compression ultrasound have been reported in 5% of patients with suspected recurrent DVT.[102,103] Availability of ultrasound images obtained before an episode of suspected recurrence may be helpful; however, the interpretation of such images has been shown to have poor to moderate intraobserver agreement.[104]

MRI may be able to differentiate thrombi from fibrotic changes in the vein at 6 months after acute DVT,[97] but neither MRI nor CTV has been tested in patients with suspected recurrence. Despite its high negative predictive value, the DD test does not perform well in patients with recurrent DVT. In 46% of patients who have their warfarin discontinued, DD remains elevated for at least 3 months.[105] Other causes of DD elevation contribute to even more prevalent positive results, which limits the ability of DD to exclude recurrence in only 15% to 18% of patients, even when it is used in combination with risk assessment tools.[106,107]

Because no evidence is currently available to suggest that any test may be useful to determine the age of thrombus, and no evidence exists to show that the diagnostic approach to recurrences should be different from what is used for initial DVT, the practice remains dependent on conventional testing and good clinical judgment.

MEDICAL TREATMENT OF ACUTE LOWER EXTREMITY DEEP VENOUS THROMBOSIS

Treatment of DVT depends on the ability to stabilize a developing thrombus within the deep veins of the lower extremities, to prevent thrombus extension and embolization, and to permit the body's natural fibrinolytic system to dissolve fibrin using anticoagulant therapy. Since the landmark paper in 1961 by Barritt and Jordan,[108] anticoagulation therapy in both enteral and parenteral forms has remained the mainstay of VTE treatment.

The introduction of a new class of oral anticoagulants has led to the increasing safety of outpatient treatment for lower extremity DVT (see Chapter 39). Many patients can begin treatment in the outpatient clinic or emergency department and be sent home, even if imaging diagnostics are delayed. Contraindications for outpatient treatment of lower extremity DVT should be considered, such as the following: active or high risk bleeding, severe symptomatic venous obstruction, thrombocytopenia, poor hepatic function, unstable renal function, noncompliance, and a poor support environment at home.

Beyond anticoagulation, nonpharmacologic measures such as compression therapy and leg elevation have been long accepted within the doctrine of DVT treatment in both the acute and chronic settings. Early ambulation has been added to these recommendations from data over the past two decades, which have replaced the prior dogma of strict bed rest.

The objectives for DVT treatment therefore can be divided into two major categories: (1) immediate reduction of morbidity and mortality in the short term and (2) reduction of late postthrombotic morbidity (see Chapter 156). The latter category concentrates on thrombus burden and recurrence.

Medical Treatment of Calf Deep Vein Thrombosis

Guidelines for the treatment of this group have been conflicting. In electronic polls performed in 2009 at the American Venous

Forum and the American College of Phlebology annual meetings, there was true clinical equipoise regarding anticoagulation for calf deep vein thrombosis (C-DVT). The antithrombotic guidelines of the 2016 American College of Chest Physicians (ACCP) gives a grade 2C recommendation for 3 months of anticoagulation for C-DVT but states that it is "anticipated" that not all patients with distal DVT will be prescribed anticoagulants.[109] A different contemporary guideline published by Streiff et al. places a higher value on anticoagulation for 3 months over duplex surveillance,[110] although the latter approach is preferred over IVC filter placement for individuals who are thought to be too high risk for bleeding. Risk factors for thrombus extension should be considered if surveillance is to be considered rather than anticoagulation; these factors include elevated DD, which veins are involved, thrombotic burden, history of VTE, or significant thrombophilic state such as active cancer.

Medical Treatment of Femoropopliteal Deep Vein Thrombosis

Involvement of the femoral and/or popliteal veins is most frequently encountered in proximal lower extremity DVT, and it is the most straightforward to diagnose with compression ultrasound. With isolated femoral vein thrombosis, even if limited to the upper thigh, patients often do well with anticoagulation alone. This is mostly due to the excellent collateral drainage from the popliteal vein via the profunda femoris vein. Early, and even late, recanalization of thrombus is not particularly important if the common femoral and popliteal veins remain unobstructed.

Distal popliteal vein thrombosis involving the so-called "trifurcation" can result in severe acute symptoms due to obstruction of venous outflow from the calf, which can lead to significant postthrombotic complications.[111] When axial drainage of the calf is compromised, early thrombus removal is likely to prevent postthrombotic morbidity.[111]

Medical Treatment of Iliofemoral Deep Vein Thrombosis

The most severe DVT symptoms and long-term morbidity is associated with iliofemoral DVT. This is due to obstruction of the main outflow tract of the lower extremity. Anticoagulation alone commonly results in incomplete resorption of thrombus leaving a persistently obstructed lumen containing a fibrous "scar" consisting mostly of type 1 and type 3 collagen.[112] In a cohort of patients with iliofemoral DVT treated with anticoagulation alone, Akesson and colleagues observed that 5 years after the initial DVT 95% had valvular dysfunction, with 30% of patients having either venous claudication or ulceration.[113] Recurrence is higher than infrainguinal DVT due to the greater thrombus burden and residual venous obstruction.[114] External compression such as the classic May-Thurner syndrome is implicated, especially in left-sided iliofemoral DVT. Recanalization with correction of the common iliac vein stenosis is now accepted as a standard of care supported by the SVS.[115] Beyond anticoagulation, surgical and interventional therapies should be strongly considered in such patients; a discussion of these methods supported by evidence is reviewed in Chapters 160 and 161.

Anticoagulation (see Chapter 39)

Anticoagulation should be initiated as soon as there is a high level of suspicion for DVT and should not be delayed for confirmation with objective imaging. This can be facilitated with a high Well's score of greater than 2 in the presence of a positive DD utilizing a sensitive enzyme-linked immunosorbent assay. The traditional treatment to achieve timely therapeutic anticoagulation was unfractionated heparin (UFH) followed by vitamin K antagonist (VKA) therapy with warfarin, but (despite refinements in management and delivery over time) there continues to be pharmacologic and logistical limitations with this approach. In addition to intravenous or subcutaneous UFH followed by warfarin, there are fortunately now several other options for the initial anticoagulant treatment of VTE: subcutaneous low-molecular-weight heparin (LMWH), subcutaneous pentasaccharide (fondaparinux), intravenous direct thrombin inhibitors (DTIs), and direct-acting oral anticoagulants (DOACs). A review of the anticoagulants used in treating DVT is presented in Table 147.1.

Unfractionated Heparin

Intravenous UFH is an effective method for treatment of DVT that is still commonly used for the initial 5 to 10 days to bridge oral anticoagulation with warfarin. Its anticoagulant activity is dependent on binding to the serine protease inhibitor AT to potentiate its activity, which for various reasons may be deficient in some individuals.

Monitoring is necessary because of the nonspecific binding of heparin to other sites such as plasma proteins, endothelial cells, platelet factor 4, and macrophages, which leads to its sometimes unpredictable pharmacodynamics and its narrow therapeutic window.[116] The therapeutic range is 1.5 to 2.5 times the control. Alternatively, establishing a therapeutic range using an anti-factor Xa assay to establish a plasma heparin level with a concentration in the range of 0.3 to 0.7 IU/mL can be used as a more accurate method of monitoring. A high incidence of recurrent VTE has been reported in individuals who failed to promptly reach a therapeutic aPTT.[117]

Major drawbacks with the use of UFH include the need for hospitalization, frequent blood draws, variable response, difficulties in promptly achieving the target therapeutic range, and the potential for life-threatening allergenic response causing heparin-induced thrombocytopenia (HIT).

Low-Molecular-Weight Heparin

Since their discovery in 1976, LMWH fractions have been developed, each having slightly different pharmacokinetic profiles. These include the current fractions that are marketed in the United States: enoxaparin, tinzaparin, and dalteparin. The LMWHs have improved bioavailability, more consistent response, and more predictable pharmacokinetics and pharmacodynamics

TABLE 147.1 Comparison of Anticoagulant Drugs for the Treatment of Deep Venous Thrombosis

	Mechanism	Venous Indications	Efficacy vs. LMWH/VKA	Bleeding Risks (vs. LMWH/VKA)	Other Risks	Reference
UFH	Factor II and X inhibition via AT	VTE treatment VTE prophylaxis	Equivalent	**Major:** 2.0%	HIT 0.5%-2%	Mismetti et al.[151]
LMWH Enoxaparin, Dalteparin, Tinzaparin	More selective factor X inhibition via AT	VTE treatment VTE prophylaxis	n/a	**Major:** 2.0%	HIT <1%	Mismetti et al.[151]
Fondaparinux	Selective factor X inhibition via AT	VTE treatment VTE prophylaxis	Equivalent	**Major:** 1.2% vs. 1.2%	Thrombocytopenia 0.5%	Büller et al.[152]
Parenteral DTI Argatroban	Direct factor II inhibition	VTE treatment HIT treatment (initial)	n/a	**Major:** 1.3%[a]	Hypotension tachycardia	Koster et al.[153]
Bivalirudin	Direct factor II inhibition	VTE treatment	n/a	**Major:** 3.5%; (vs. UFH): OR 0.49 (0.36-0.67)[a]	Hypotension bradycardia	Farag et al.[154]
VKA/warfarin	Vitamin K-dependent factor inhibition (II, VII, IX, X)	VTE treatment VTE prophylaxis HIT treatment (longitudinal)	n/a	**Major:** 1.2%-1.9% (see below)	Multiple drug-drug, drug-food interactions	See below
DOACs Apixaban	Oral direct inhibitor of factor Xa	VTE treatment VTE prophylaxis (for hip and knee replacement in apixaban and rivaroxaban only)	Noninferior	**Major**: 0.6% vs. 1.8%; HR 0.31 (0.17-0.55) **Major+CRNM:** 4.3% vs. 9.7%; HR 0.44 (0.36-0.55)	CrCl <30: 44% increased exposure	Amplify[b]
Rivaroxaban			Noninferior	**Major**: 0.8% vs. 1.2%; HR 0.65 (0.33-1.30) **Major+CRNM:** 8.1% vs. 8.1%; HR 0.97 (0.76-1.22)	CrCl <30: 64% increased exposure Child-Pugh B: 2.3-fold increased exposure	Einstein-DVT
Edoxaban			Noninferior	**Major:** 1.4% vs. 1.6%; HR 0.84 (0.59-1.21) **Major+CRNM:** 8.5% vs. 10.3%; HR 0.81 (0.71-0.94)	CrCl <30: 72% increased exposure Abnormal LFT (7.8%)	Hokusai-VTE[b]
Dabigatran	Oral direct factor IIa inhibitor	VTE treatment	Noninferior	**Major:** 1.6% vs. 1.9%; HR 0.82 (0.45-1.48) **Major+CRNM:** 5.6% vs. 8.8%; HR 0.63 (0.47-0.84)	CrCl < 30: 6.3-fold increased exposure	Re-cover[b]

[a]Bleeding data is based on patients with acute coronary syndrome.
[b]Pulmonary embolism patients were analyzed in these trials alongside deep venous thrombosis patients; bleeding data therefore includes a pooled analysis.
CRNM, clinically relevant nonmajor; DOACs, direct-acting oral anticoagulants; *DTI*, direct thrombin inhibitor; *DVT*, deep venous thrombosis; *HIT*, heparin-induced thrombocytopenia; *LMWH*, low-molecular-weight heparin; *n/a*, not available, not applicable; *VKA*, vitamin K antagonist; *VTE*, venous thromboembolism; *UFH*, unfractionated heparin.
Major bleeding generally defined as including fatal bleed, intracranial bleed, bleeding into a critical site.

compared to UFH. They are also more uniformly absorbed from subcutaneous depots with a longer half-life in the range of 3 to 5 hours. LMWHs do not require routine monitoring, but patients with renal insufficiency or significant obesity may require dose adjustments or monitoring of LMWH-anti factor Xa activity (0.5-1.0 IU/mL) to determine proper dosing.

LMWHs have undergone rigorous testing in clinical trials showing less major bleeding and reduced mortality versus UFH with a nonsignificant trend toward reduction in minor bleeding.[119]

Malignancy poses a particularly high risk for VTE. Patients with cancer and VTE have poorer survival than those with cancer alone.[120] The failure rate of VKA therapy in malignancy has been shown to be higher than with LMWH,[121] which generated studies that eventually led to guidelines recommending LMWH over VKA for the treatment of acute VTE.[122,123] The

10th edition of the ACCP guidelines (2016) continues to recommend LMWH over VKA or DOACs for the initial 3 months of treatment of acute VTE associated with cancer (Grade 2C).

Parenteral Direct Thrombin Inhibitors

Direct inhibition of the thrombin molecule blocks its interaction with other substrates and reduces thrombus formation and activation. HIT is increasingly recognized and parenteral DTIs are the treatment of choice for this condition. With a suspicion of HIT, heparin or LMWH (in rare cases fondaparinux) should be discontinued and an appropriate alternative anticoagulant, such as a DTI, should be started while awaiting serologic test results. As of 2016, parenteral DTIs are the only class of anticoagulants that carry a specific Food and Drug Administration (FDA) package label to treat HIT. Although three intravenous DTIs have been licensed in North America, lepirudin, argatroban, and bivalirudin, only the latter two have been commercially available in the United States since 2012.

Vitamin K Antagonists

Oral anticoagulation with VKAs such as warfarin produces their anticoagulant effects by inhibiting the production of vitamin K-dependent coagulation factors. There is also significant inhibition of the natural anticoagulants protein C and protein S, which have a much shorter half-life than the procoagulant factors. This explains why VKAs produce a procoagulant state in the first 3 days of their administration before they reach their anticoagulant effect, irrespective of the INR in this early phase. Warfarin compounds must therefore be administered alongside parenteral anticoagulation for the initial 4 to 5 days or longer to achieve therapeutic anticoagulation. Unopposed VKA therapy in the setting of acute thrombosis can lead to thrombus propagation, early recurrence, and devastating thrombotic complications, not the least of which is the scourge of warfarin skin necrosis because of the rapid depletion of protein C and S. The effective reduction in the concentration of factors II and X (below 30% activity) usually requires at least a 5-day overlap with heparin.

Ongoing monitoring with the protime (typically an INR range of 2.0-3.0 for standard VTE treatment and secondary prophylaxis) is necessary with VKAs for a variety of reasons. This includes the presence of a narrow therapeutic window, variability in dose-response among individuals, interaction with dietary vitamin K and other dietary substances, and many drug-to-drug interactions. One common interaction is the prolongation effect on the INR caused by certain antibiotics when an individual is taking warfarin. This is the result of the destruction of the natural gut flora that otherwise produces vitamin K and acts as a major source of this nutrient.

Direct-Acting Oral Anticoagulants

The DOACs have generated justifiable enthusiasm ever since rivaroxaban was the first in this group to be approved by the FDA for the treatment of VTE in 2012. These drugs selectively target either the factor Xa molecule (rivaroxaban, apixaban, edoxaban) or thrombin (dabigatran) and obviate the need for routine monitoring and frequent dose adjustments. They have predictable pharmacokinetics and high bioavailablity with relatively few drug-to-drug and no significant food interactions compared to VKA therapy. Efficacy of these drugs has been shown to be equivalent to warfarin in the large industry-sponsored trials that is reviewed in greater detail later. Safety in these trials was also shown to be equivalent although intracranial bleeding and fatal bleeding were significantly lower in all three of the Xa inhibitors. No head-to-head comparisons of these drugs have been published as of the writing of this chapter.

The EINSTEIN trials of rivaroxaban[124,125] reported recurrent VTE in 2.1% of patients receiving rivaroxaban versus 3% in the standard group ($P < .001$ for noninferiority, $P = .08$ for superiority). Major and clinically relevant nonmajor bleeding was 8.1% in each group. An extended treatment study showed superiority for rivaroxaban versus placebo with an 82% relative risk reduction for recurrent VTE.[126]

Apixaban was investigated in a double-blinded noninferiority study.[100] Recurrent VTE occurred in 2.3% of the apixaban group and 2.7% receiving conventional therapy ($P = .001$ for noninferiority). Major bleeding occurred significantly less in the apixaban group versus conventional therapy (0.6% vs. 1.8%; $P < .001$ for superiority). Apixaban has less renal clearance (27%) than the other factor Xa inhibitors and, for its VTE indication, does not require dose adjustment for renal dysfunction.

Edoxaban[127] trial demonstrated similar efficacy to warfarin but proved to be superior to standard therapy with respect to bleeding.

Dabigatran is the only oral DTI approved for the treatment of VTE.[128,129] Two trials showed noninferiority of dabigatran to warfarin. The safety analysis showed significantly less major or clinically relevant nonmajor bleeding (HR 0.62; 95% CI: 0.45-0.84) and less any bleeding (HR 0.67; 95% CI: 0.56-0.81). In 2016, the humanized monoclonal antibody fragment, idarucizumab, was approved as a specific reversal agent for dabigatran for emergency surgery or for life-threatening bleeding in dabigatran.[130] Idarucizumab is generally administered as a single 5 g IV dose with immediate reversal of anticoagulation effect, which persists for more than 24 hours.

Adjunctive Measures for Acute Deep Venous Thrombosis Management

Elevation of the legs above the heart reduces the acute edema and reduces pain. However, bed rest is no longer recommended for patients with VTE. The benefit of compression with ambulation was observed in two randomized trials that applied gradient elastic compression and began early ambulation for the acute treatment of lower extremity DVT compared to bed rest with elevation.[131,132] Reductions in the progression of thrombus length and volume along with reduced pain and edema were observed in those with compression and ambulation. There was no increase in the incidence of PE with early ambulation, which has been further supported by large registry data.[133] A more recent study, using surveillance lung scanning, showed that bed rest did not reduce PE.[134] Some studies indicate that immobility increases the risk for development of PE.[135] Furthermore, structured leg exercise may decrease the incidence of postthrombotic syndrome

(PTS).[136] Most guidelines recommend initiating anticoagulation prior to allowing patients to ambulate.[110]

Apart from ambulation, the value of using graduated compression for DVT treatment has been debated. In a widely referenced randomized trial in 1997, Brandjes et al. demonstrated that 30 to 40 mm Hg thigh-length gradient compression stockings (GCS) were shown to be effective at reducing pain and the incidence of PTS by 50% when used consistently for 2 years.[137] Further evidence supporting the use of GCS was provided by Prandoni et al. who also showed a 50% decline in PTS sequelae using knee-high 30 to 40 mm Hg GCS.[138] The assumption was that the calf compression aided in priming the calf muscle pump. More recently, however, these data have been scrutinized by the ACCP due to inadequate blinding in light of the more contemporary SOX trial.[109] This larger, placebo-controlled trial with over 800 participants found that the routine use of GCS neither reduced the incidence for PTS, nor did it show benefit in the reduction in pain during the first three months following DVT diagnosis.[139] This publication led to a reversal in the former recommendation of GCS in the 9th Edition of the ACCP guidelines to a grade 2B suggestion against their routine use for PTS prevention in the 10th Edition of the Guidelines for Antithrombotic Therapy. The ACCP authors are careful to note, however, this recommendation focuses on the chronic complication of PTS and does not constitute a statement on the use of GCS to treat symptoms; they further state that for both acute and chronic symptoms, a trial of GCS is often justified.

Longitudinal Treatment of Deep Venous Thrombosis

The proper duration of anticoagulation treatment is the pivotal question determining freedom from VTE recurrence. Risk factor analysis is often complex and confusing. Duration of anticoagulation needs to be balanced with the risk of bleeding for individuals being considered for extended treatment.

Thrombus burden has been shown to be a predictor of recurrence.[140] This supports approaches using duplex ultrasound to assess residual deep vein obstructions to guide duration of therapy. Prandoni et al. demonstrated that the risk of recurrence was significantly higher in patients with residual venous obstruction (HR 2.9; $P = .001$).[141] In a follow-up study, recurrence rate of 17.2% in those randomized to the fixed-duration arm versus 11.9% in those allocated to flexible-duration therapy was found.[142] Patients in this cohort with a history of unprovoked DVT realized the greatest benefit with an adjusted hazard ratio of 0.61 compared to 0.81 for those with a provoked event.

Increased thrombus activity as measured by the DD tests is associated with an increased risk of recurrence. The presence of elevated levels of DD along with residual postthrombotic luminal obstruction assessed by compression ultrasound has been associated with an increased risk of recurrent VTE. Extending anticoagulation when either or both these markers exist has been shown to significantly reduce recurrence.

Trials have been performed to evaluate the role of DD for the duration of anticoagulation. In the PROLONG trial, those with an abnormal DD were randomized to either resume anticoagulation or remain off anticoagulation. Those with a normal DD remained off therapy.[143] This trial showed a significant increase in recurrence at 1.4 years for patients with elevated DD who went untreated compared to untreated patients with a normal DD ($P = .003$). Several studies independently confirmed these relationship.[144,145]

Platelet inhibition can also play a role in the long-term treatment for patients with VTE.[146-148] The WARFASA and ASPIRE trials showed a 32% reduction in VTE recurrence and a 34% reduction in major vascular events without a significant increase in bleeding. These studies along with an ongoing INSPIRE collaborative have reopened the discussion of aspirin as an adjunct for long-term secondary VTE protection.

Another approach to extended treatment is the role of subtherapeutic doses of anticoagulants. The concept is to offer protection against recurrence while reducing risk of hemorrhagic complications.[149]

Extended anticoagulation was investigated in the AMPLIFY-EXT trial using apixaban at a therapeutic dose (5 mg bid) or a reduced dose (2.5 mg bid) compared to placebo after 6 to 12 months of therapeutic anticoagulation.[150] The primary outcome of symptomatic recurrent VTE or death occurred in 8.8% receiving placebo versus 1.7% who were receiving both 2.5 mg and 5 mg of apixaban ($P < .001$ for both groups compared to placebo). Clinically relevant nonmajor bleeding was 2.3% in the placebo group, 3.0% in the apixaban 2.5 mg group (RR 1.29 vs. placebo; 95% CI 0.72-2.33), and 4.2% in the apixaban 5 mg group (RR 1.82 vs. placebo; 95% CI 1.05-3.18). The NNT of 14 to prevent one VTE recurrence in 1 year appears sufficiently low to justify incorporating this into patient management protocols. The number needed to cause one episode of major or clinically relevant nonmajor bleeding was sufficiently high at 200. There were only 15% of patients over the age of 75 and few patients with CKD ≥3 or low body weight such that these results may not be generalizable to all patients.

Acute deep venous thrombosis (DVT) represents a disease spectrum ranging from asymptomatic calf vein thrombosis to the painful, blue, swollen limb of phlegmasia cerulea dolens resulting from extensive multisegment thrombosis involving the iliofemoral venous segment. Until 2008, national and international guidelines for the treatment of patients with acute DVT recommended only anticoagulation. However, the eighth American College of Chest Physicians (ACCP) Consensus Conference on Antithrombotic and Thrombolytic Therapy[1] and the American Heart Association Scientific Statement on the management of iliofemoral DVT (IFDVT)[2] as well as the Society of Vascular Surgery (SVS) guidelines[3] suggest interventional strategies for thrombus removal that include surgical and catheter-based techniques to reduce the incidence of post-thrombotic syndrome (PTS), especially in patients with extensive venous thrombosis. This chapter reviews the evidence for the severe morbidity associated with PTS following IFDVT, the avoidance of the severe postthrombotic sequelae when the thrombus is eliminated and unobstructed venous drainage to the vena cava is restored, and a review of the contemporary techniques used to successfully eliminate thrombus.

POSTTHROMBOTIC SYNDROME

The most important consideration leading to guideline recommendations for thrombus removal in patients with extensive DVT is the severe morbidity associated with the PTS and the evidence that early elimination of thrombus prevents or reduces postthrombotic morbidity.

Morbidity

PTS is defined as the signs and symptoms resulting from acute DVT. This is usually the consequence of venous hypertension resulting from valve reflux and/or luminal obstruction. Studies have shown that patients with PTS have a significant reduction in quality of life (QoL).[4,5] The severity of the patient's acute DVT is predictive of postthrombotic morbidity, especially when

Abstract

The underlying premise of this chapter, Acute Lower extremity Deep Venous Thrombosis: Surgical and Interventional Treatment, is that patients with a large burden of thrombus occluding the single common outflow channel from their leg are at high risk of developing disabling postthrombotic syndrome (PTS), and that adopting a management strategy of thrombus removal reduces their risk of severe PTS.

Technology has continuously evolved and improved with catheter based techniques which integrate mechanical methods of thrombus removal with the judicious use of plasminogen activators replacing surgical thrombectomy in the majority of patients. The majority of these techniques are reviewed with their associated outcomes presented.

However, just as catheter based techniques have advanced, so have operative procedures, which now integrate contemporary imaging, venous balloon dilation and stenting and adjunctive, low dose plasminogen activators in addition to regionally delivered anticoagulation. These advances improve outcomes and reduce procedure related complications.

Unfortunately, randomized trial results often lag behind technology. None-the-less, randomized trial data provide big picture analysis of treatments, with subset observation suggesting important details which can be used as the hypothesis for developing future care.

Post-Thrombotic Syndrome

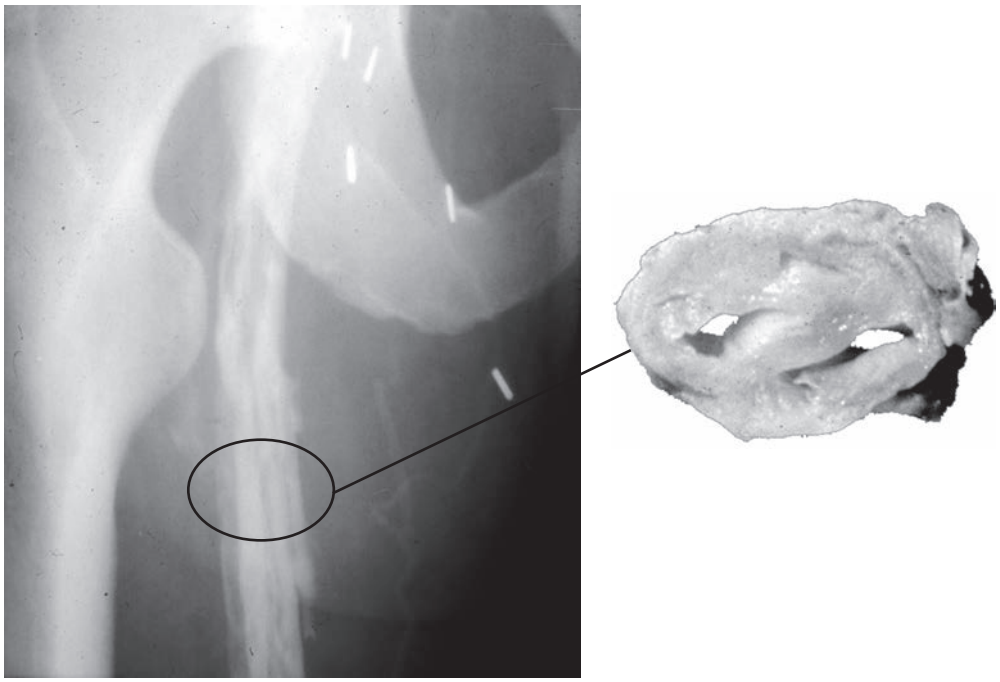

Figure 148.1 Postthrombotic venous disease illustrating the inability to identify obstruction as part of the pathophysiology of chronic venous disease. This patient had had iliofemoral deep venous thrombosis 10 years earlier and was treated with anticoagulation alone. Severe postthrombotic syndrome developed, and the patient underwent multiple hospitalizations for venous ulceration. An ascending phlebogram showed recanalization of the iliofemoral venous system; however, the radiologist's interpretation was that there was "no obstruction" of the deep venous system, and a 3-second maximal venous outflow test was "normal." A classic Linton procedure was performed and showed *(insert)* the cross section of the femoral vein at the corresponding location on the phlebogram, just below the profunda femoris vein.

it involves the iliofemoral segment. Patients with IFDVT appear to be a clinically relevant subset with acute venous thrombosis. They have occlusion of their single venous outflow channel from the leg, resulting in severe postthrombotic morbidity when treated with anticoagulation alone.[6-9] In a prospective observational study of anticoagulation for acute DVT, IFDVT was found to be the most powerful predictor of severe PTS (HR 2.23).[9] Labropoulos et al.[10] monitored venous pressures in patients with PTS after treatment for their acute DVT. They found that patients who were treated for IFDVT had the highest venous pressures. This confirmed prior observations that IFDVT patients treated by anticoagulation alone had ambulatory venous hypertension, with 40% demonstrating venous claudication and up to 15% developing venous ulceration within 5 years.[6-8] Essentially all these patients will have a reduced QoL. The morbidity of PTS escalates substantially with ipsilateral recurrence.[11] A meta-analysis of outcomes after treatment for acute DVT demonstrated that recurrence occurs more commonly in patients with a large burden of thrombus.[12]

Etiology

The pathophysiology of postthrombotic venous disease is ambulatory venous hypertension, which is defined as elevated venous pressure during exercise.[13,14] Ambulatory venous pressure is linearly linked to the pathophysiologic changes observed with chronic venous disease, such as swelling, pigmentation, and lipodermatosclerosis.[15] Microcirculatory changes leading to dermal breakdown follow.

The anatomic components contributing to ambulatory venous hypertension are venous valvular incompetence and luminal obstruction. The most severe postthrombotic morbidity is associated with the highest venous pressures, which occur in patients with both valvular incompetence and luminal venous obstruction.[13,16] Although valvular function can be reliably assessed with ultrasound by quantifying valve closure times, techniques are not yet available to assess the relative contribution of venous obstruction to the pathologic venous hemodynamics leading to clinical postthrombotic morbidity. Fig. 148.1 succinctly illustrates the difficulty of identifying even extensive venous obstruction, either hemodynamically or radiologically. Neither ascending phlebography performed and interpreted by a skilled radiologist nor the maximal venous outflow test performed in an accredited vascular laboratory identified venous obstruction in the patient presented. A cross-section of the proximal femoral vein removed during a classic Linton procedure clearly showed recanalization channels through what was once occlusive thrombus, which resulted in chronic obstruction of a large proportion of the luminal surface area. Unfortunately noninvasive physiologic techniques cannot detect venous hemodynamic impairment of even this advanced degree of obstruction when they are performed on resting patients. This example is not unique but rather is common to postthrombotic morbidity. It is evident that venous hemodynamics are adversely

affected long before imaging techniques can detect obstruction. Our inability to noninvasively quantitate obstruction has led physicians to underappreciate its contribution to postthrombotic pathophysiology. Luminal venous obstruction causes the most severe forms of PTS, especially when it involves the common femoral and iliac veins. Obstruction of the distal popliteal vein is also associated with significant PTS. Therefore treatment strategies for thrombus removal should be developed during the initial encounter with the patient and, if successful, can eliminate obstruction as part of the long-term pathophysiology and should significantly reduce the incidence of PTS. We and others have observed that successful elimination of thrombus can also preserve venous valve function.[17]

Experimental observations in canine models of acute DVT have shown that successful thrombolysis preserves endothelial function and valve competence.[16,18] These experimental observations appear to translate into improved clinical outcomes when put into the perspective of natural history studies of acute DVT treated with anticoagulation alone. Investigators have found that distal valve incompetence can develop in patients with persistent venous obstruction treated with anticoagulation alone, even when the distal veins are not initially involved with thrombus.[19] When spontaneous lysis occurred, defined as clot resolution within 90 days, valve function was frequently preserved.[20] These investigators confirmed that the combination of valvular incompetence and venous obstruction was associated with the most severe postthrombotic morbidity.[21,22] It is intuitive that successful elimination of acute venous thrombus eliminates luminal obstruction and increases the likelihood that normal valve function will be preserved. It follows, then, that in patients whose thrombus is mechanically or pharmacologically eliminated, postthrombotic morbidity should be avoided or at least significantly reduced.

RATIONALE FOR THROMBUS REMOVAL

There is a large body of evidence supporting the rationale for a strategy of thrombus removal, especially in patients with IFDVT. When a strategy of thrombus removal is successful, venous patency is restored, valve function is maintained, QoL is improved, and the risk of recurrence is reduced. Qvarfordt and Eklof[23] measured compartment pressures in patients presenting with acute IFDVT before and after operative venous thrombectomy. Compartment pressures (a surrogate for venous pressures) were pathologically elevated upon presentation, consistent with acute compartment syndrome pressures, and normalized after operative thrombectomy. These important observations documented significant physiologic benefit by restoring the main venous outflow to the lower extremity and formed the basis for a randomized trial of operative venous thrombectomy and anticoagulation alone.

Scandinavian investigators randomized patients with IFDVT to operative venous thrombectomy plus arteriovenous fistula (AVF) and anticoagulation or to anticoagulation alone. This multicenter randomized trial demonstrated that patients undergoing venous thrombectomy enjoyed improved iliac vein patency ($P < .05$), lower venous pressure ($P < .05$), less edema ($P < .05$), and fewer postthrombotic symptoms ($P < .05$) than did patients receiving anticoagulation alone.[24-26] They also observed that patients undergoing venous thrombectomy were more likely to retain venous valve function in the femoropopliteal segment than were those treated by anticoagulation alone. This observation is consistent with that reported by Killewich and coauthors, who demonstrated that persistent proximal obstruction leads to distal valve incompetence in veins not initially involved with thrombus and that elimination of iliofemoral thrombosis maintains distal valve function.[19]

A rapidly growing body of evidence suggests that catheter-directed thrombolysis (CDT) is of benefit, especially in patients with IFDVT.[27-30] A case-controlled study demonstrated significantly improved QoL in patients treated by CDT versus anticoagulation alone for IFDVT.[31] In a subsequent analysis, the QoL benefit associated with CDT directly correlated with the volume of thrombus removed.[27] The more residual thrombus at the end of CDT, the worse the QoL. This also correlated with objective measures of PTS: the greater the degree of lysis, the fewer symptoms of PTS observed.[30]

Baekgaard et al.[32] followed 103 patients for 6 years after they were treated with CDT for IFDVT. They reported that 86% of veins were patent without reflux and only 6% of patients developed recurrence during the follow-up period.

Pharmacomechanical techniques have been shown to improve outcomes compared with CDT using the drip technique alone. Pharmacomechanical techniques have shortened treatment time, reduced dose of lytic agent, and reduced length of ICU and hospital stay.[33-35]

Recurrence

An underappreciated but important benefit of successful thrombus removal is the reduction in the rate of recurrent DVT. As mentioned earlier, patients with IFDVT have an exceptionally high recurrence rate compared with those with less extensive thrombosis.[12,36] Hull et al.[12] performed a systematic review and showed that treated patients with a large thrombus burden had a greater risk of recurrence than those with a smaller thrombus burden. As mentioned previously, Baekgarrd observed an unexpectedly low 3-year recurrence after CDT for IFDVT. Aziz et al.[29] observed that patients with IFDVT treated with catheter-directed techniques appeared to have a low recurrence rate. Upon further analysis, the benefit accrued to those patients who had successful thrombus removal, whereas those with the bulk of the thrombus remaining (unsuccessful lysis) had a significantly higher recurrence rate.

Valve Function

Vogel et al.[17] addressed the issue of whether pharmacomechanical techniques compromised valve function, presumably due to valve injury. In a sequential analysis of CDT versus pharmacomechanical thrombolysis, there did not appear to be any adverse effect on valve function using pharmacomechanical

techniques. The important observations were that valves functioned best in patients who had successful results. An interesting observation was that 35% of the veins in the noninvolved limbs had incompetent valves.

There is no argument that data from large randomized trials are the best evidence. The results of recent randomized trials of CDT versus anticoagulation for acute DVT combined with the substantial body of observational, clinical, and case-control evidence support a strategy of thrombus removal, especially in patients with extensive venous thrombosis.

RANDOMIZED TRIALS OF CATHETER-DIRECTED THROMBOLYSIS

Elsharawy et al.[37] reported a small randomized trial comparing anticoagulation versus CDT. Based upon point estimates used to calculate sample size, they appear to have achieved their goal. They demonstrated that patients treated with CDT had significantly improved venous patency and a reduction in valvular incompetence compared with those treated with anticoagulation alone. These observations are often overlooked in the absence of measures of QoL and objective analysis of postthrombotic morbidity using such measurements as the Villalta scale or the Venous Clinical Severity Score. However, very few if any patients with patent deep veins with normal valve function develop PTS.

The recently published CaVenT trial reported the long-term outcome after additional CDT to anticoagulation versus anticoagulation alone for acute IFDVT.[28] These investigators randomized 209 patients. Their primary endpoint was iliofemoral patency at 6 months and PTS at 2 years. CDT was performed with the UniFuse catheter (AngioDynamics, Latham, New York). Alteplase was infused at a dose of 0.01 mg/kg per hour for a maximum of 96 hours. The alteplase was prepared by mixing 20 mg in 500 mL of 0.9% NaCI. This would result in a 70-kg man being infused with 0.7 mg of recombinant tissue plasminogen activator (rt-PA) in 17.5 mL of infusate. This appears to be an unusually small volume of infusate, which might potentially disadvantage patients.

The mean duration of thrombolysis was 24 hours; 43% had complete thrombolysis, 37% had partial thrombolysis, and 10% were deemed unsuccessful. Patients receiving CDT had a mean clot resolution of 82%. Patients treated with additional CDT had significantly improved iliofemoral venous patency at 6 months ($P = .012$) and less PTS at 2 years ($P = .047$). The authors reported that lower thrombus scores at completion of CDT were associated with increased patency ($P < .04$) and that patency of the iliofemoral venous system correlated with a reduction in PTS ($P < .001$). There was an absolute risk reduction in PTS of 14.4% in patients receiving CDT. Major bleeding complications occurred in 3.3% of patients undergoing CDT. Only one inferior vena cava filter was used in this group and there was no symptomatic pulmonary embolism (PE) observed.

These results demonstrate a significant benefit in those patients receiving additional CDT. The actual benefit would likely have been substantially greater if patients entered into this trial truly had IFDVT. In reality, only 45% of the patients randomized to thrombolysis and 36% of those in the anticoagulation group had IFDVT. Therefore although approximately 60% of patients randomized in this trial had less than IFDVT, significant benefit was observed. The authors reported that the number needed to treat (NNT) to prevent one PTS was seven, but this author believes that the relative reduction of postthrombotic morbidity would have been substantially greater (and the NNT smaller) if indeed all patients in CaVenT had truly had IFDVT.

The largest study to date, the ATTRACT trial, sponsored by the National Institutes of Health, prospectively randomized 692 patients with symptomatic proximal DVT.[38] Patients with iliofemoral and femoropopliteal DVT were stratified at entry into the study to catheter-based techniques of thrombolysis versus anticoagulation alone. The primary endpoint was PTS at 24 months. The ATTRACT trial will also evaluate the relative benefits of pharmacomechanical techniques versus the CDT drip technique and will include a careful cost analysis. Recruitment concluded in December of 2014. The basic design of ATTRACT is illustrated in Fig. 148.2.

The ATTRACT Trial (NCT00790335) is the largest randomized trial to date designed to evaluate whether a strategy of acute thrombus removal using pharmacomechanical catheter-directed thrombolysis (PCDT) plus anticoagulation reduces post-thrombotic syndrome (PTS) compared to patients assigned to anticoagulation alone (ref). This NHLBI funded clinical trial randomized 692 patients with proximal DVT to PCDT plus anticoagulation (N = 336) to anticoagulation alone (N = 355). Upon entry into the study, patients were stratified by extent of their thrombosis (Iliofemoral vs. Femoral-Popliteal DVT) prior to their randomization (see figure ATTRACT Trial). The primary efficacy outcome was any PTS (Villalta Score >4) at two years post-treatment. The primary safety outcome was major bleeding. Clinically important secondary outcomes were resolution of acute pain and swelling, moderate to severe PTS and quality of life at two years (Veines QOL Sym).

Results demonstrated that there was no difference in PTS at two years between those randomized to PCDT and those randomized to anticoagulation alone, 47% and 48% respectively. Major bleeding was low in both groups, but significantly higher with PCDT, 1.7% than in the anticoagulation group, 0.3%, p = 0.049. Fewer patients in the PCDT group developed moderate to severe PTS (Villalta Score >9) at two years compared to the anticoagulation group, p = 0.035. Although there was a trend in improved QOL in the PCDT group at two years, the difference did not reach significance, p = 0.08.

Data have not yet been released whether PCDT benefitted patients with the larger thrombus burden, ie: Iliofemoral DVT, compared to femoral-popliteal DVT patients. Such observations will be important for the future selection of patients for catheter based strategies of thrombus removal.

Future analyses from the robust data set from the ATTRACT Trial are anxiously awaited, as are the results from the Dutch CAVA Trial (NCT00970619).[38a]

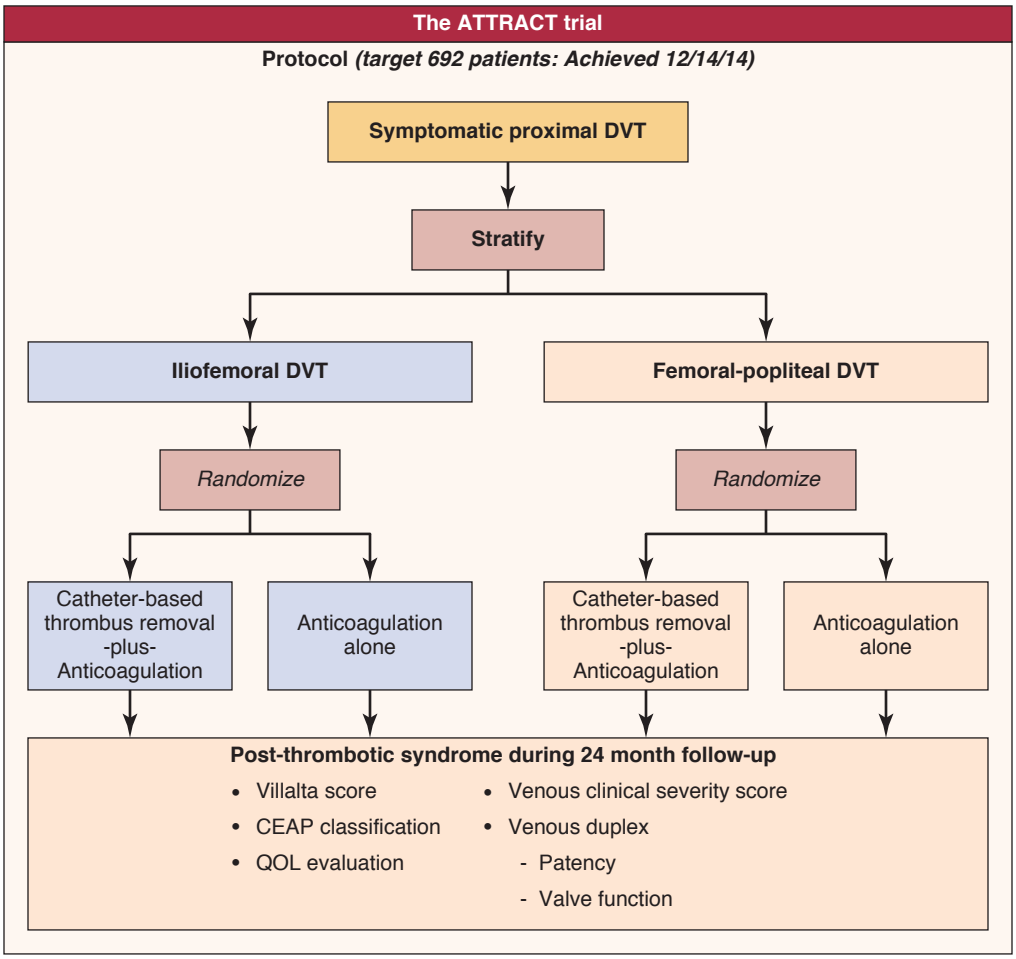

Figure 148.2 Basic design of ATTRACT.

STRATEGIES FOR THROMBUS REMOVAL

Randomized trials demonstrating positive outcomes for patients undergoing a strategy of thrombus removal are now available,[24-26,28] and the largest is in its follow-up phase.[38] CDT is the preferred treatment option for most patients who have no contraindication to thrombolytic therapy. Pharmacomechanical techniques are becoming increasingly popular and tend to shorten treatment time and reduce the lytic dose.

Contemporary venous thrombectomy is generally available to all patients from vascular surgeons who are comfortable operating on the venous system. There are few contraindications to operative thrombectomy short of old remote thrombus that is adherent to the vein wall and cannot be removed. All thrombus or chronic fibrous obstruction within the operative field can be removed. The goal of venous thrombectomy is to remove the iliofemoral and infrainguinal thrombus and restore unobstructed venous return to the vena cava. Knowing the full extent of thrombosis preoperatively and having good imaging intraoperatively are crucial for a well-planned and successful procedure.

Thrombolytic Therapy

Initial attempts at pharmacologic resolution of acute DVT used systemic thrombolysis. Early studies involving systemic delivery of plasminogen activators resulted in high rates of bleeding complications and less than optimal lytic results. Many patients were treated for infrainguinal DVT; therefore, even when lytic therapy was successful, the benefits were not as apparent as in patients with IFVDT. A summary of studies comparing anticoagulation with systemic thrombolysis has been reported.[39] Results were disappointing, considering the increased bleeding risk. However, an important observation demonstrated the improved long-term outcome in patients with phlebographically successful systemic thrombolysis. Catheter-based procedures have rapidly replaced systemic thrombolysis as the preferred method of treating patients with extensive DVT.

Intrathrombus Catheter-Directed Thrombolysis

During the process of thrombosis, Glu-plasminogen binds to fibrin, which is converted to Lys-plasminogen. This modification produces more binding sites for plasminogen activators and therefore more efficient production of plasmin. The basic mechanism of thrombolysis is the activation of fibrin-bound

plasminogen and resultant production of plasmin. It is intuitive that delivery of the plasminogen activator within the thrombus is more effective and potentially safer than systemic infusion of plasminogen activators. Additionally, intrathrombus delivery protects plasminogen activators from circulating plasminogen activator inhibitor and, more importantly, protects the active enzyme plasmin from neutralization by circulating antiplasmin. This neutralization of circulating plasminogen is so effective that the half-life of plasmin in the systemic circulation is only a fraction of a second.

Numerous reports have demonstrated good outcomes of CDT for acute DVT and most have been tabulated.[39] In general, when patients with acute DVT are treated, success rates in the range of 75% to 90% can be anticipated. The rate of bleeding complications generally ranges from 5% to 11%. Fortunately, serious distant bleeding is uncommon and intracranial bleeding a rarity. Most bleeding complications are localized to the venous access site. Symptomatic PE during infusion is uncommon and fatal PE a rarity.

An interesting report by Chang and coworkers documents the benefit of sequential intrathrombus bolus dosing of rt-PA without a continuous infusion in a small group of patients (12 lower extremities with acute DVT).[40] His careful observations lend credence to high-pressure bolus dosing (pulse-spray) of plasminogen activator into the acute thrombus. These observations underscore the importance of saturating the thrombus with a plasminogen activator and the effective activation of Lys-plasminogen.

Outcomes From the National Venous Registry

The report of National Venous Registry is the largest one to date of patients treated with lytic therapy for acute DVT, with 71% having IFDVT.[39] Although significant advances in treatment have been made since the publication of this report, a number of the early observations remain important for clinicians to recognize.

There was a significant correlation ($P < .001$) of thrombosis-free survival with the results of initial therapy. At 1 year, 78% of the patients with initially complete clot resolution had patent veins versus only 37% of patients who had less than 50% lysis. In the group of patients with first-time IFDVT who initially had successful thrombolysis, 96% of the veins remained patent at 1 year. Initial lytic success also correlated with valve function at 6 months. Of patients with less than 50% thrombolysis, 62% had venous valvular incompetence, whereas 72% with complete lysis had normal valve function ($P < .02$).

A cohort-controlled QoL study was performed to determine whether lytic therapy altered QoL in patients with IFDVT in the National Venous Registry.[41] The results demonstrate that CDT is associated with better QoL than anticoagulation alone. QoL was directly related to initial success of thrombolysis. Patients who had a successful lytic outcome reported a better Health Utilities Index, improved physical functioning, less stigma of chronic venous disease, less health distress, and fewer overall postthrombotic symptoms. Not surprisingly, patients in whom CDT failed had outcomes similar to those treated with anticoagulation alone. As mentioned earlier, successful thrombus elimination appears to reduce the risk of recurrence.

Available data to date present a compelling argument for CDT. Institutions participating in randomized trials should make every effort to enroll patients who are eligible. Those not participating in trials should adopt a strategy of thrombus removal that is based on evidence to date.

Pharmacomechanical Thrombolysis

Although good results can be achieved with CDT, treatment times are often unacceptably long; therefore, bleeding risk and cost associated with therapy are unacceptably high. This was succinctly characterized by Sillesen and colleagues when they reported that 93% of their patients were successfully treated and discharged with patent veins and that more than 90% of the patients discharged with patent veins had normal venous valve function at 1 year. The treated patients had a mean duration of symptoms of just 7 days, and patients with symptoms exceeding 14 days were excluded. Therefore lysis would be expected quickly in these patients because they truly represented acute DVT. However, treatment time for CDT averaged 71 hours. This duration of acute care is logistically difficult if not impossible for many practitioners and many medical centers to manage. The associated cost is high because all patients receiving lytic therapy are generally monitored in intensive care units (ICUs).

Endovascular Mechanical Thrombectomy

Mechanical techniques alone or in combination with thrombolysis have been developed to more rapidly clear the venous system. Vedantham and associates evaluated the effectiveness of mechanical thrombectomy alone or in combination with pharmacologic thrombolysis in 28 limbs of patients with acute DVT.[42] They evaluated multiple devices, including the Amplatz (ev3, Inc., Plymouth, Minnesota), AngioJet (Possis Medical, Minneapolis, Minnesota), Trerotola (Arrow International, Reading, Pennsylvania), and Oasis (Boston Scientific/Medi-tech, Natick, Massachusetts) catheters. Venographic scoring was performed at each step of the procedure. Some 26% of the thrombus was removed by mechanical thrombectomy alone, whereas adding a plasminogen activator solution to the mechanical technique (pharmacomechanical) removed 82% of the thrombus. This tabulation includes patients with chronic occlusion who did not respond. Mechanical thrombectomy alone was successful in removing intraprocedural thrombus, which is generally gelatinous and not cross-linked with fibrin. The average infusion time was approximately 17 hours per limb, and 14% of patients had major bleeding complications.

Lin and coauthors reported their 8-year experience with pharmacomechanical thrombolysis (via a rheolytic thrombectomy catheter).[32] Of their 98 patients, 46 received CDT alone and 52 underwent pharmacomechanical thrombolysis. Pharmacomechanical thrombolysis with the AngioJet catheter was associated with significantly fewer phlebograms, shorter ICU stays, shorter hospital stays, and fewer blood transfusions. Bleeding complications were not different between the two groups. A smaller patient group treated by rheolytic thrombectomy was reported by Kasirajan and associates, who demonstrated that mechanical thrombectomy alone was less effective than combined pharmacomechanical thrombolysis.[42]

Ultrasound-Accelerated Thrombolysis

Parikh and coauthors reported their initial clinical experience with ultrasound-accelerated thrombolysis in 53 patients treated for acute DVT with the EKOS EndoWave (Bothell, Washington) system.[34] Unfortunately both upper- and lower-extremity DVT patients were included in this report, and a variety of lytic agents were used. Complete lysis (≥90%) was observed in 70% of patients and overall lysis (complete and partial) in 91%. The median infusion time was 22 hours, and 4% of the patients had major complications, which were essentially puncture site hematomas. The authors' impression was that as compared with historical controls (a weakness of this report), treatment time and the doses of lytic agents were reduced with ultrasound-accelerated thrombolysis.

A randomized trial evaluating the benefit of adding ultrasound accelerated thrombolysis (USAT) to CDT for IFDVT was reported by Engelberger et al.[43] They randomized patients with IFDVT to CDT alone (ultrasound infusion catheter without ultrasound activation) versus USAT. Patients' thrombus was quantified at baseline. Patients received 20 mg of rtPA over 1.5 hours and a repeat phlebogram performed with residual thrombus quantified by a physician blinded to treatment allocation. Patients receiving CDT alone had 54% lysis and those with USAT had 55% lyisis ($P = .91$).

Isolated Segmental Pharmacomechanical Thrombolysis

An interesting technique is isolated segmental pharmacomechanical thrombolysis (ISPMT), which is achieved by using the Trellis catheter (Covidien, Mansfield, Massachusetts). This double-balloon catheter is inserted into the thrombosed venous segment with the proximal balloon positioned at the upper edge (cephalic end) of the thrombus. When the balloons are inflated, plasminogen activator is infused into the thrombosed segment isolated by the balloons. The intervening catheter assumes a spiral configuration and spins at 3500 rpm for 15 to 20 minutes. The liquefied and fragmented thrombus can be aspirated and treatment success evaluated by repeat segmental phlebography. If successful, the catheter is repositioned and additional thrombosed segments are treated; if residual thrombus persists, repeat treatment or other appropriate intervention (rheolytic thrombectomy, balloon angioplasty, and stenting) is performed. Martinez and coworkers reviewed 52 consecutive limbs treated for IFDVT, the first 27 with CDT and the following 25 with ISPMT plus CDT when necessary.[30] Thrombus burden and treatment outcomes were quantified. Ninety-three percent of the patients were treated with rt-PA, venoplasty and stenting were used to correct underlying stenoses in all patients, and all received long-term therapeutic anticoagulation. Sixteen of the 27 legs treated by CDT required other adjunctive mechanical techniques to clear the thrombus, such as the AngioJet, ultrasound-accelerated lysis, or pulse-spray techniques, whereas only 7 of the 25 limbs treated with ISPMT required additional adjunctive techniques. A larger percentage of the thrombus was removed with ISPMT than with CDT. Complete lysis (≥90%) was achieved in 11% of the limbs of CDT patients as opposed to 28% of the limbs treated by ISPMT ($P = .077$). Treatment time was shorter (23.4 vs. 55.4 hours, $P < .001$), and the rtPA dose was lower (33.4 vs. 59.3 mg, $P = .009$) with ISPMT. Hospital and ICU length of stay was no different, which is the result of underlying patient comorbid conditions. If the ISPMT catheter was used alone, only 18% of the limbs underwent complete lysis. This is consistent with the observations of O'Sullivan and associates.[44] Bleeding complications occurred in 5% of patients undergoing CDT alone, as well as 5% of the patients treated by ISPMT.

Endovascular Aspiration Thrombectomy

Although CDT is effective in reducing the thrombus burden, it can be associated with increased risk of bleeding, prolonged time required for effective lysis, need for close monitoring during lysis, and increased cost of treatment. Similarly, mechanical thrombectomy devices can be associated with hemolysis and hemoglobinuria. Aspiration thrombectomy can be an effective alternative to these techniques. This includes use of large-sized catheters or sheaths for aspiration of thrombus. Jia et al.[45] performed a retrospective analysis on 68 patients with IFDVT treated with aspiration thrombectomy. A retrievable IVC filter was placed in all patients. Large-sized catheters (either a 9 Fr guiding catheter [Vista Brite Tip Guiding Catheter, Johnson & Johnson, Miami, Florida] or a 10 Fr OptEase retrieval catheter [Cordis, Miami, Florida) was advanced over a 0.035-in guidewire with the catheter tip placed in either the iliac or femoral vein. The guidewire was then removed and the catheter slowly pulled back while aspirating the catheter with a large syringe. This process was repeated until thrombus was completely removed. The authors reported a 100% technical success rate. Aspiration alone was successful in 47 patients; the remaining 21 required additional thrombolysis, and 32 required venous stenting. At a mean follow-up of 21.9 months, 11% recurrent thrombosis was found.

Operative Venous Thrombectomy

Contemporary venous thrombectomy for iliofemoral venous thrombosis offers effective short- and long-term outcomes with relatively few complications. In a report of 230 patients, no fatal PE and only one operative death occurred.[46] The long-term benefits of venous thrombectomy relate to its ability to achieve proximal patency and maintain distal valve competence. Both are influenced by the initial technical success and avoidance of recurrent thrombosis. Therefore attention to operative detail, removal of all thrombus, and correction of underlying lesions as well as maintenance of therapeutic anticoagulation postoperatively are crucial.

Pooled data from a number of contemporary reports on iliofemoral venous thrombectomy (Table 148.1)[25,47-58] indicate that the early and long-term patency rates of the iliofemoral venous segment is 75% to 80% versus 30% in patients treated by anticoagulation alone.[7] Femoropopliteal venous valve function is preserved in the majority of patients. The Scandinavian investigators reported their randomized trial of operative venous thrombectomy versus anticoagulation alone in patients with

BOX 148.1 Overview of the Technique of Contemporary Venous Thrombectomy

1. Identify the cause of the extensive venous thromboembolic process
   a. Complete thrombophilia evaluation
   b. Rapid CT scan of the chest, abdomen, and pelvis
2. Define the full extent of the thrombus
   a. Venous duplex examination
   b. Contralateral iliocavagram, MRV, or spiral CT
3. Prevent pulmonary embolism (numerous techniques)
   a. Anticoagulation
   b. Vena caval filter (if nonocclusive caval clot)
   c. Balloon occlusion of the vena cava during thrombectomy
   d. Positive end-expiratory pressure during thrombectomy
4. Perform complete thrombectomy
   a. Iliofemoral (vena cava) thrombectomy
   b. Infrainguinal venous thrombectomy (if required)
5. Ensure unobstructed venous inflow to and outflow from the thrombectomized iliofemoral venous system
   a. Infrainguinal venous thrombectomy (if required)
   b. Correct iliac vein stenosis (if present)
6. Prevent recurrent thrombosis
   a. Arteriovenous fistula
   b. Continuous therapeutic anticoagulation
   c. Catheter-directed postoperative anticoagulation (if infrainguinal venous thrombectomy is required)
   d. Extended oral anticoagulation

CT, Computed tomography; *MRV*, magnetic resonance venography.

iliofemoral venous thrombosis.[21-23] Patients underwent systematic follow-up with venous imaging and physiologic measurements. As a result, 6-month, 5-year, and 10-year follow-up showed that patients randomized to venous thrombectomy demonstrated improved patency ($P < .05$), lower venous pressure ($P < .05$), less leg edema ($P < .05$), and fewer postthrombotic symptoms ($P < .05$) than did patients treated with anticoagulation alone.

Rodriguez et al.[59] recently reported their experience treating 71 patients with IFDVT. They compared the results of 40 patients treated with a hybrid operative thrombectomy with 31 treated with catheter-directed thrombolysis. The hybrid operative thrombectomy included balloon catheter, thrombectomy completion venogram, and balloon venoplasty and stenting if needed. An AVF was not performed.

The investigators reported eight major bleeds in patients with CDT compared with those in the operative thrombectomy group ($P = .04$). CDT patients had a longer length of hospital stay (13.3 vs. 10 days; $P = .028$) compared with thrombectomy patients. At 2-year follow-up there was no difference in femoropopliteal reflux. Although operative thrombectomy patients had a lower clinical class of their CEAP score, there was no difference in their Villalta scores (2.1 vs. 1.9, $P = .8$).

Technique of Contemporary Venous Thrombectomy

A brief summary of the important points of contemporary venous thrombectomy is provided in Box 148.1. The principles of venous thrombectomy are those of basic vascular surgical technique: remove the thrombus, provide unobstructed outflow from the iliofemoral venous segment into the vena cava and unobstructed inflow from the infrainguinal venous segment, correct any underlying lesions, and prevent rethrombosis. The sequential salient technical points follow.

Preoperative Care

Preoperative anticoagulation is generally initiated with unfractionated heparin (UFH) because it has a short half-life and can be controlled more easily than low-molecular-weight heparin or direct factor Xa inhibitors. The full extent of thrombus (distal and proximal) is identified (see Box 148.1 and Fig. 148.3).

Vena caval filtration is not routinely used except in patients who have nonocclusive thrombus extending into the vena cava (see Fig. 148.3). Permanent or optional vena caval filters and proximal balloon occlusion of the cava during thrombectomy are reasonable options.

The thrombectomy is performed under fluoroscopic guidance with the balloon of the venous thrombectomy catheter filled with contrast material. The entire abdominal vena cava and pelvic venous system must be in the fluoroscopic field. An autotransfusion device should be available.

Operative Care

General anesthesia is usually recommended for patients undergoing operative venous thrombectomy.

A longitudinal inguinal incision exposes the common femoral vein, femoral vein, saphenofemoral junction, and profunda

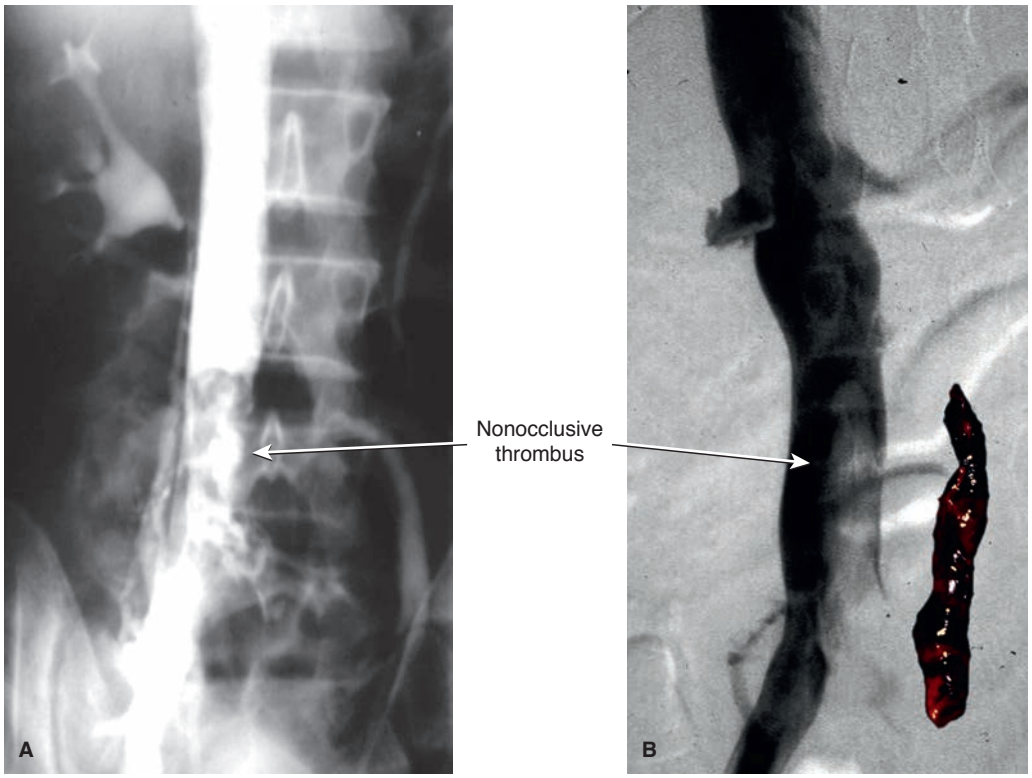

Figure 148.3 A, Contrast iliocavagrams show nonocclusive thrombus in the vena cava and illustrate the importance of imaging to detect the proximal extent of thrombus. In B, the outlined area shows where the adjacent thrombus was extracted from the vena cava by balloon catheter thrombectomy. The proximal vena cava was protected with the balloon catheter (see Fig. 148.6).

femoris vein or veins (Fig. 148.4A). A longitudinal venotomy is made in the common femoral vein to ensure access to the origin of the saphenous and profunda femoris branches.

If infrainguinal thrombus is present, the leg is elevated and compressed with a tightly wrapped rubber bandage. The foot is dorsiflexed and the calf and thigh are squeezed. If all infrainguinal thrombus is removed, balloon thrombectomy of the iliofemoral venous system then proceeds.

If the infrainguinal thrombus persists, a cut-down is performed to expose the distal posterior tibial vein. A No. 3 Fogarty catheter is advanced from the distal posterior tibial vein to and through the common femoral venotomy. The Silastic stem of an intravenous catheter (12- to 14-gauge) is amputated from its hub and slid halfway onto the balloon catheter exiting the common femoral venotomy. Another balloon catheter (No. 4 Fogarty) is placed in the opposite end of the Silastic sheath (see Fig. 148.4A). Pressure is applied to the two balloons by a single operating surgeon to ensure that the catheters remain secure inside the sheath. The No. 4 balloon catheter is guided distally through the thrombosed venous valves and clotted veins (see Fig. 148.4B) to the level of the posterior tibial venotomy (see Fig. 148.4C). The infrainguinal venous thrombectomy is then performed, with passage repeated as necessary (see Fig. 148.4D and E).

After infrainguinal balloon catheter thrombectomy, the infrainguinal venous system is flushed by placing a large red rubber catheter into the proximal posterior tibial vein and vigorously flushing with a heparin-saline solution via a bulb syringe to hydraulically force residual thrombus from the deep venous system (Fig. 148.5). Frequently an impressive amount of thrombus will be expelled with this maneuver. Once the infrainguinal venous system is adequately cleared, a vascular clamp is applied below the femoral venotomy and the infrainguinal venous system is filled with dilute plasminogen activator solution consisting of approximately 4 to 6 mg of rt-PA in 200 mL of saline. The plasminogen activator solution remains in the infrainguinal veins for the remainder of the procedure. This amount of local rt-PA will bind to fibrin-bound plasminogen in residual thrombus and promote further clot dissolution; however, it will not cause a systemic lytic response. If the infrainguinal venous thrombectomy is not successful because of chronic thrombotic disease of the femoral vein, the femoral vein is ligated and divided below the profunda femoris vein. Patency of the profunda is ensured by direct thrombectomy if necessary.

Floppy guidewire passage from the common femoral venotomy distally can be attempted. If successful passage is achieved, a distal thrombectomy with an over-the-wire balloon thrombectomy catheter is performed. All other principles remain the same except for the heparin-saline flush from below. In these cases, a small catheter would be placed into the posterior tibial vein under ultrasound guidance for postoperative anticoagulation. An arbitrary dose of 800 IU UFH is infused into the LE catheter. It is believed that the target vein will receive a high concentration of heparin, but an overall lower dose will be systemically delivered, thereby reducing the risk of bleeding at the operative site.

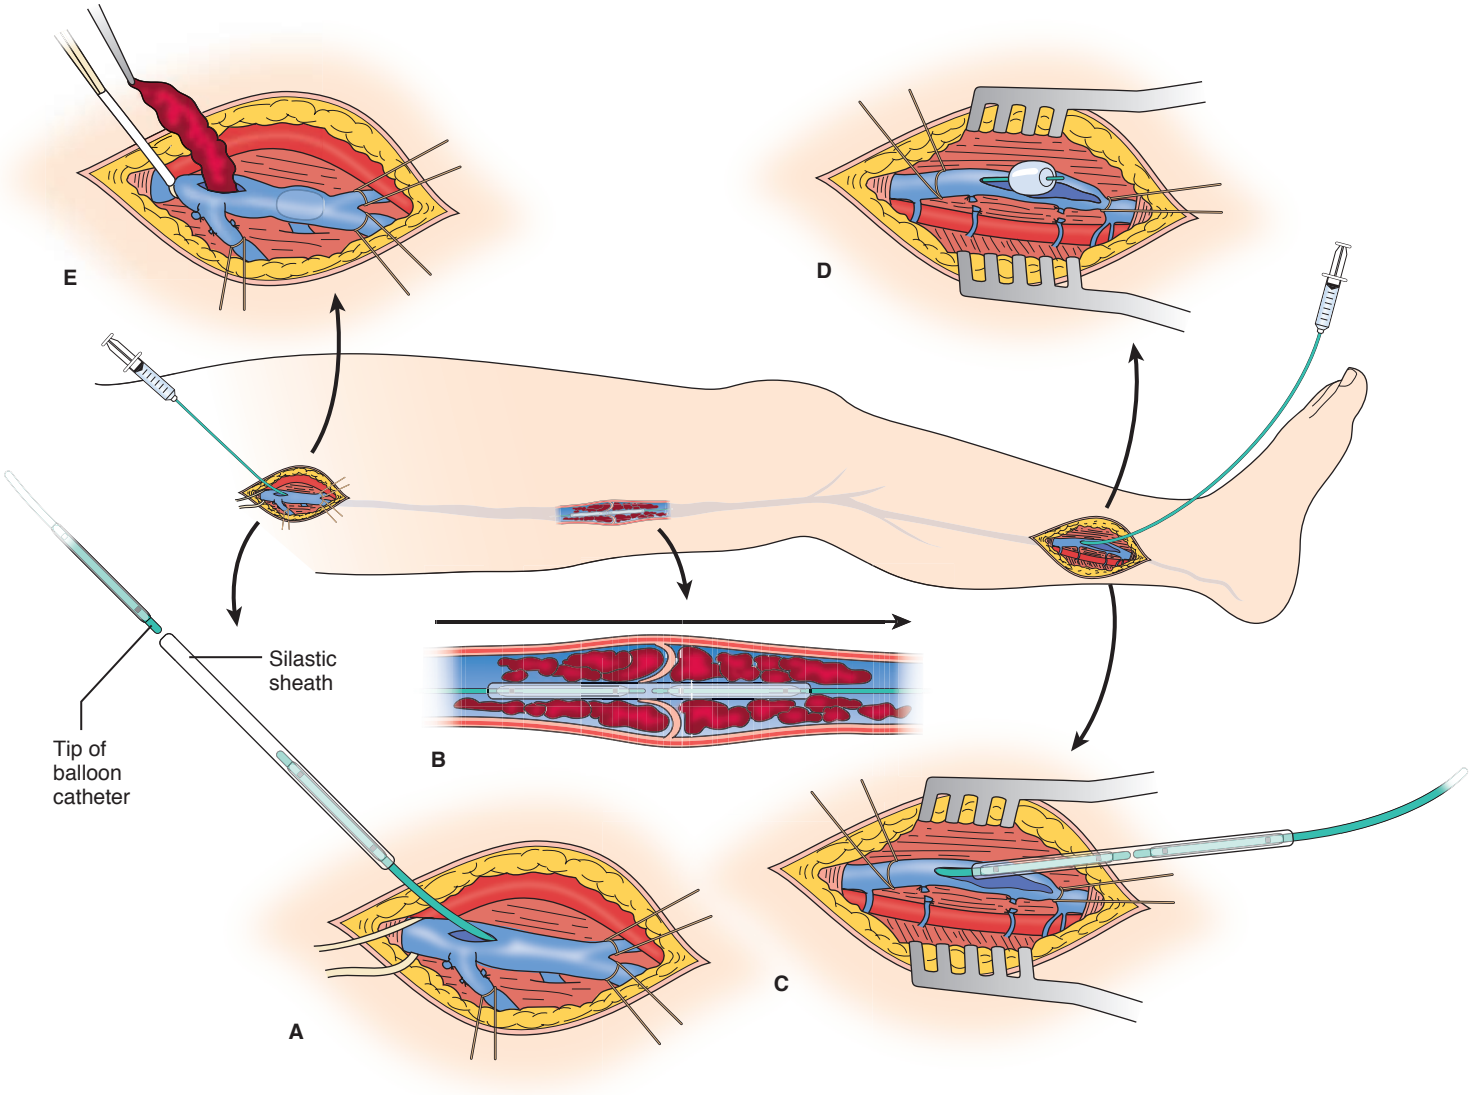

Figure 148.4 Operative thrombectomy for acute venous thrombosis. (A) Longitudinal inguinal incision to expose the common femoral vein, femoral vein, saphenofemoral junction, and profunda femoris vein. (B and C) The balloon catheter is guided distally through the thrombosed venous valves and clotted veins to the level of the posterior tibial venotomy. (D and E) Performance of infrainguinal venous thrombectomy, with passage of the balloon catheter repeated as necessary.

Iliofemoral venous thrombectomy is then performed by passing a No. 8 or 10 venous thrombectomy balloon catheter partially into the iliac vein for several passes to remove the bulk of the thrombus before advancing the catheter into the vena cava. The proximal thrombectomy is always performed under fluoroscopic guidance with contrast material in the balloon, especially if a vena caval filter is present, there is clot in the vena cava, or resistance to catheter passage is encountered. During this part of the procedure, the anesthesiologist applies positive end-expiratory pressure to further reduce the risk of pulmonary embolization. If a clot is present in the vena cava, caval thrombectomy can be performed with a protective balloon catheter inflated above the thrombus as an alternative to vena caval filtration (Fig. 148.6).

After completion of the iliofemoral venous thrombectomy, intraoperative phlebography/fluoroscopy is performed to evaluate for underlying iliac vein stenosis and assess the nature of the venous drainage into the vena cava. Intravascular ultrasound is often better than single-view phlebography for detecting iliac vein stenosis. Any underlying iliac vein stenosis is corrected by balloon angioplasty and stenting if venous recoil occurs. If an iliac vein stent is used, a 12-mm or larger-diameter stent is recommended.

Once the venotomy is closed, an end-to-side AVF is constructed by anastomosing the amputated end of the proximal saphenous vein or a large proximal branch of the saphenous vein to the side of the superficial femoral artery. The anastomosis should be limited to 3.5 to 4.0 mm in diameter. The purpose

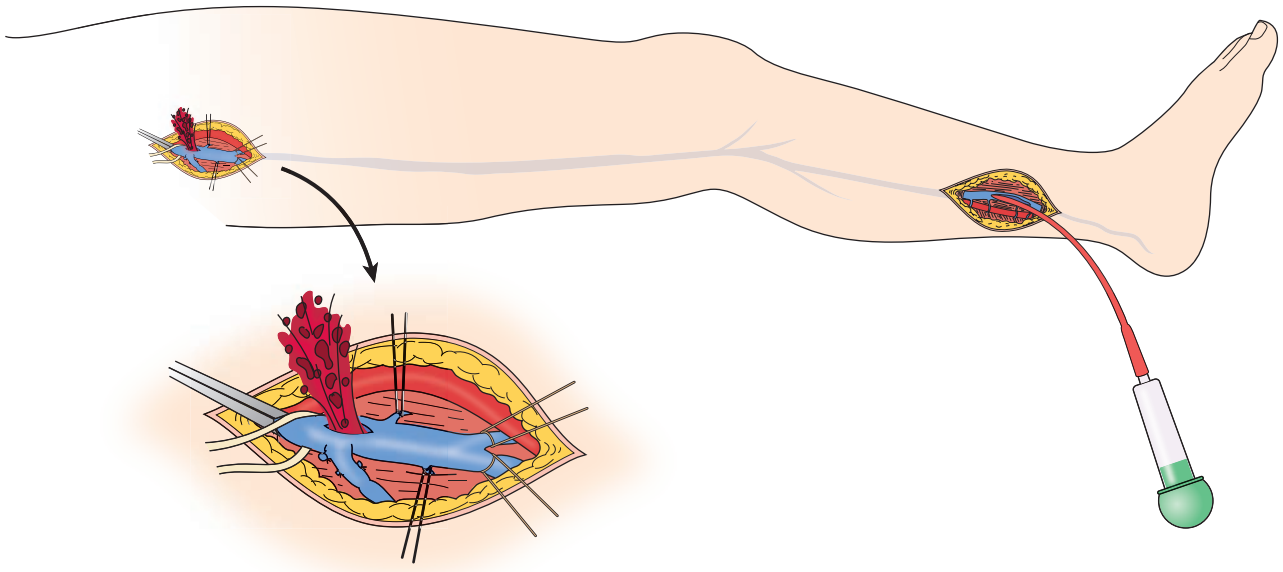

Figure 148.5 After infrainguinal balloon catheter thrombectomy, flushing of the infrainguinal venous system with a heparin-saline solution is performed by placing a large red rubber catheter into the proximal posterior tibial vein and flushing vigorously with a bulb syringe.

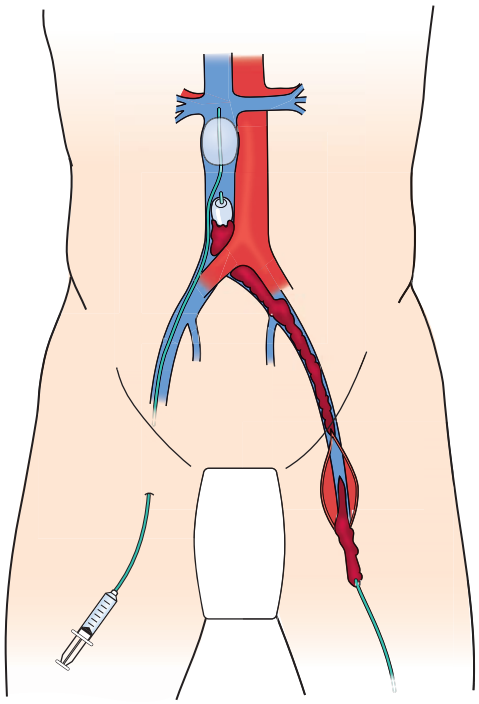

Figure 148.6 If a clot is present in the vena cava, caval thrombectomy can be performed with a protective balloon catheter inflated above the thrombus as an alternative to vena caval filtration.

of the AVF is to increase venous velocity but not venous pressure. Common femoral vein pressure is recorded before and after the AVF is opened. No increase in pressure should be observed when the AVF is opened. If the pressure increases, the proximal iliac vein should be reevaluated for residual stenosis or obstruction and the proximal lesion corrected. If the pressure remains elevated, the AVF is constricted to decrease flow and normalize pressure.

A piece of polytetrafluoroethylene or Silastic is placed around the saphenous AVF and a large permanent monofilament suture (No. 0) looped and clipped, with approximately 2 cm left in the subcutaneous tissue (Fig. 148.7A). This will serve as a guide for future dissection in the event that operative closure of the AVF becomes necessary; however, most do not.

If serous wound accumulation is observed, a diligent search for transected lymphatics is performed with careful ligation and coagulation. A closed suction drain is generally placed in the wound to evacuate any serosanguineous fluid that may accumulate postoperatively. The drain exits through a separate puncture site adjacent to the incision. The wound is closed with multilayered running absorbable sutures to achieve hemostatic and lymphostatic wound closure and ensure elimination of all dead space.

The distal posterior tibial vein is ligated. A small infusion catheter (pediatric feeding tube) is brought into the wound via a separate stab incision in the skin and inserted and fixed in the proximal posterior tibial vein (see Fig. 148.7B). This catheter is used for postoperative anticoagulation with UFH and predischarge phlebography. Anticoagulation via this catheter ensures maximum heparin concentration in the thrombectomized veins, as previously stated. A 2-0 monofilament suture is looped around the proximal posterior tibial vein (and catheter), and both ends exit the skin. The ends of the suture are passed through the holes of a sterile button, which is secured snugly to the skin when the catheter is removed. This obliterates the proximal posterior tibial vein at the time of catheter removal and eliminates the risk of bleeding. As mentioned, before removal of the catheter, an ascending phlebogram is performed through the catheter to assess patency.

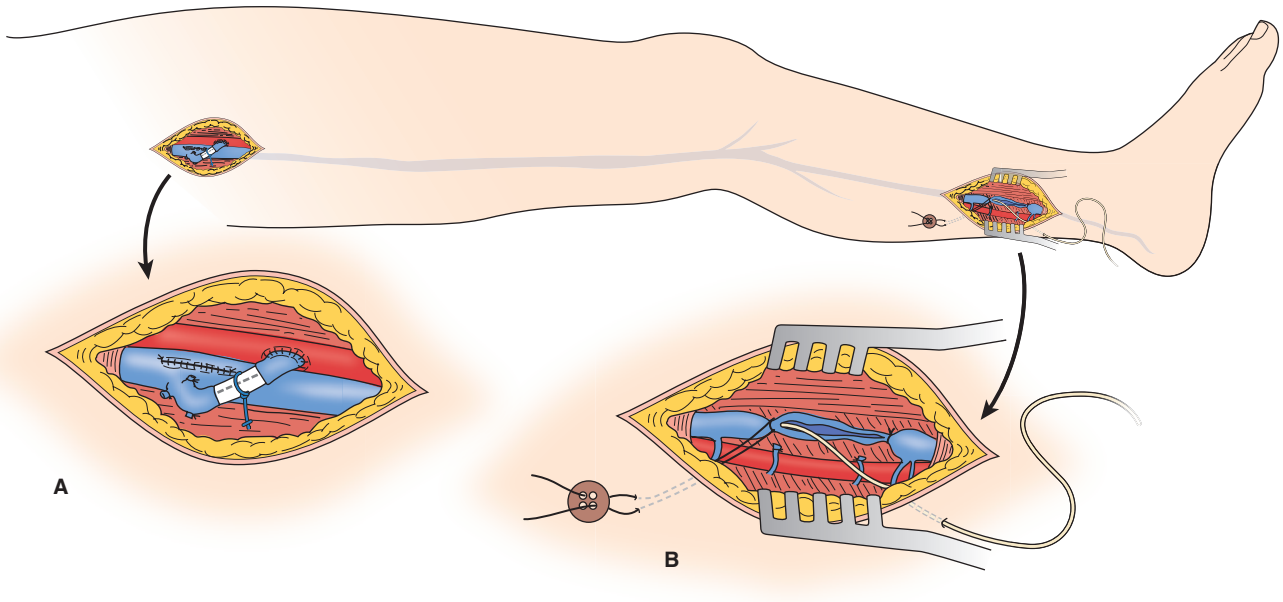

Figure 148.7 (A) Placement of a piece of polytetrafluoroethylene or Silastic around the saphenous arteriovenous fistula. A large permanent monofilament suture is looped and clipped, with approximately 2 cm left in the subcutaneous tissue. (B) Placement of a small infusion catheter (pediatric feeding tube) into the wound via a separate stab incision in the skin. It is inserted and fixed in the proximal posterior tibial vein.

Antibiotic ointment is applied to all wounds beneath sterile dressings. The patient's leg is wrapped snugly with sterile gauze and multilayered elastic bandages from the base of the toes to the groin. The posterior tibial vein catheter exits between the layers of the bandage.

Postoperative Care

Anticoagulation is continued with UFH at 800 IU/hr through the posterior tibial vein catheter attached to a pump on an intravenous pole with wheels so that the patient can ambulate. Before removal of the posterior tibial vein catheter, an ascending phlebogram is performed. Oral anticoagulation is begun when the patient awakens and resumes oral intake. Heparin infusion is continued for an overlap of 4 to 5 days if warfarin is used until the international normalized ratio reaches 2 to 3. Oral anticoagulation is continued for an extended period, generally for 1 year or more.

Intermittent pneumatic compression garments are used on both legs postoperatively when the patient is not ambulating. Before discharge, the patient is fitted for 30- to 40-mm Hg ankle-gradient below-knee compression stockings and instructed to wear the stockings from waking in the morning until bedtime. Randomized trials have demonstrated at least a 50% reduction in postthrombotic morbidity with the use of such stockings.[60,61]

If an IVC filter was used, it is removed early after completion of the procedure. When the patient is fully recovered and back to baseline activity, repeat venous duplex and venous function studies are performed to evaluate patency and vein valve function, which serve as a baseline for future studies.

CHOOSING THE APPROPRIATE TREATMENT OPTION

Risk Assessment

One concern of many physicians is the risk for procedure-related PE. Patients at highest risk for procedure-related PE are those with nonobstructive (free-floating) thrombus in the vena cava (see Fig. 148.3). Therefore it is important to know the proximal and distal extent of thrombosis and particularly the amount and level of vena caval involvement. This helps guide the decision whether vena caval filtration or other forms of embolic protection (i.e., balloon occlusion) are indicated.

Traditional contraindications to the use of thrombolytic agents that focus on bleeding risk are softened by direct intrathrombus infusion and the adoption of pharmacomechanical techniques. Reducing the dose and duration of lytic infusion lessens or eliminates a systemic response to the infused plasminogen activator. Circulating plasminogen activator inhibitors and antiplasmins serve to neutralize the systemic effects of lytic therapy if the dose is limited, thereby reducing bleeding risk, especially bleeding distant from the procedural entry site.

Patient Selection

Patients with IFDVT should be considered for a strategy of thrombus removal. Our current approach to patients with IFDVT is summarized in Fig. 148.8 and by the patient described

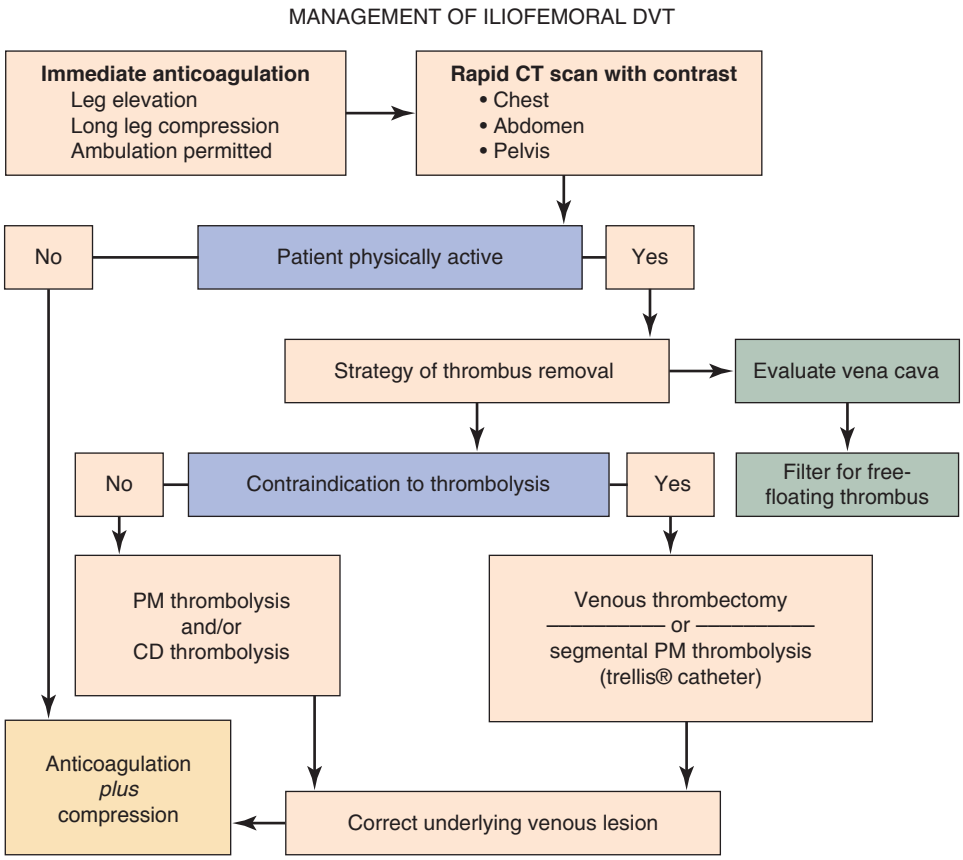

Figure 148.8 Algorithm illustrating our current treatment protocol for patients with iliofemoral deep venous thrombosis (DVT). *CD*, Catheter-directed; *CT*, computed tomography; *PM*, pharmacomechanical.

in Fig. 148.9. Assuming that the patient is ambulatory, contraindications to either surgical or catheter-based techniques should be objectively reviewed. In general, our approach is to offer all patients with IFDVT a strategy of thrombus removal unless a reason exists otherwise (see Fig. 148.8). Individuals with occlusive thrombus of the common femoral vein have effectively obliterated venous drainage from the lower extremity and are subject to severe postthrombotic morbidity. This is the ultrasound diagnostic equivalent of IFDVT. Although most patients in whom acute DVT is diagnosed are treated as outpatients, those with occlusion of the femoral vein should be admitted and considered for a strategy of thrombus removal.

Another subset of patients likely to have severe postthrombotic morbidity are those with thrombotic obliteration of the popliteal vein and the adjoining proximal tibial veins. Adequate collaterals around this area often do not develop, leaving patients with severe distal venous hypertension. This subgroup of patients should also be considered for a strategy of thrombus removal.

Pretreatment Evaluation

Patients with spontaneous, extensive venous thrombosis frequently have a clinically obvious etiology (trauma) or perhaps an occult cancer. Although we routinely performed a full thrombophilia evaluation earlier in our experience, we now know that it is unnecessary, as the patient's extensive DVT imparts such substantial risk for future recurrence that the risk conferred by the acute thrombotic event exceeds the risk of any identified thrombophilia.[62,63] A potentially serious issue is the underestimation of future thrombotic risk resulting from a negative thrombophilia evaluation. However, it is important to test first-degree female relatives of childbearing potential for factor V Leiden, prothrombin 20210 mutation, and antithrombin III, as the results may impact their care during subsequent pregnancy.

Importance of Imaging

The proximal and distal extent of thrombus should be well characterized in all patients. Imaging of the vena cava is important to assess the degree of vena caval involvement. If catheter-based techniques are being offered, a vena caval filter is recommended for patients with free-floating nonocclusive vena caval thrombus. During surgery, either proximal balloon occlusion of the cava or caval filtration is appropriate.

In patients with normal renal function, a computed tomography (CT) scan of the head, chest, abdomen, and pelvis with contrast enhancement is an important part of the pretreatment evaluation. In at least 50% of these patients an asymptomatic pulmonary embolus will be found. Although such emboli require no specific change in the treatment plan, the value of this diagnosis is often not appreciated until 3 to 5 days later, when

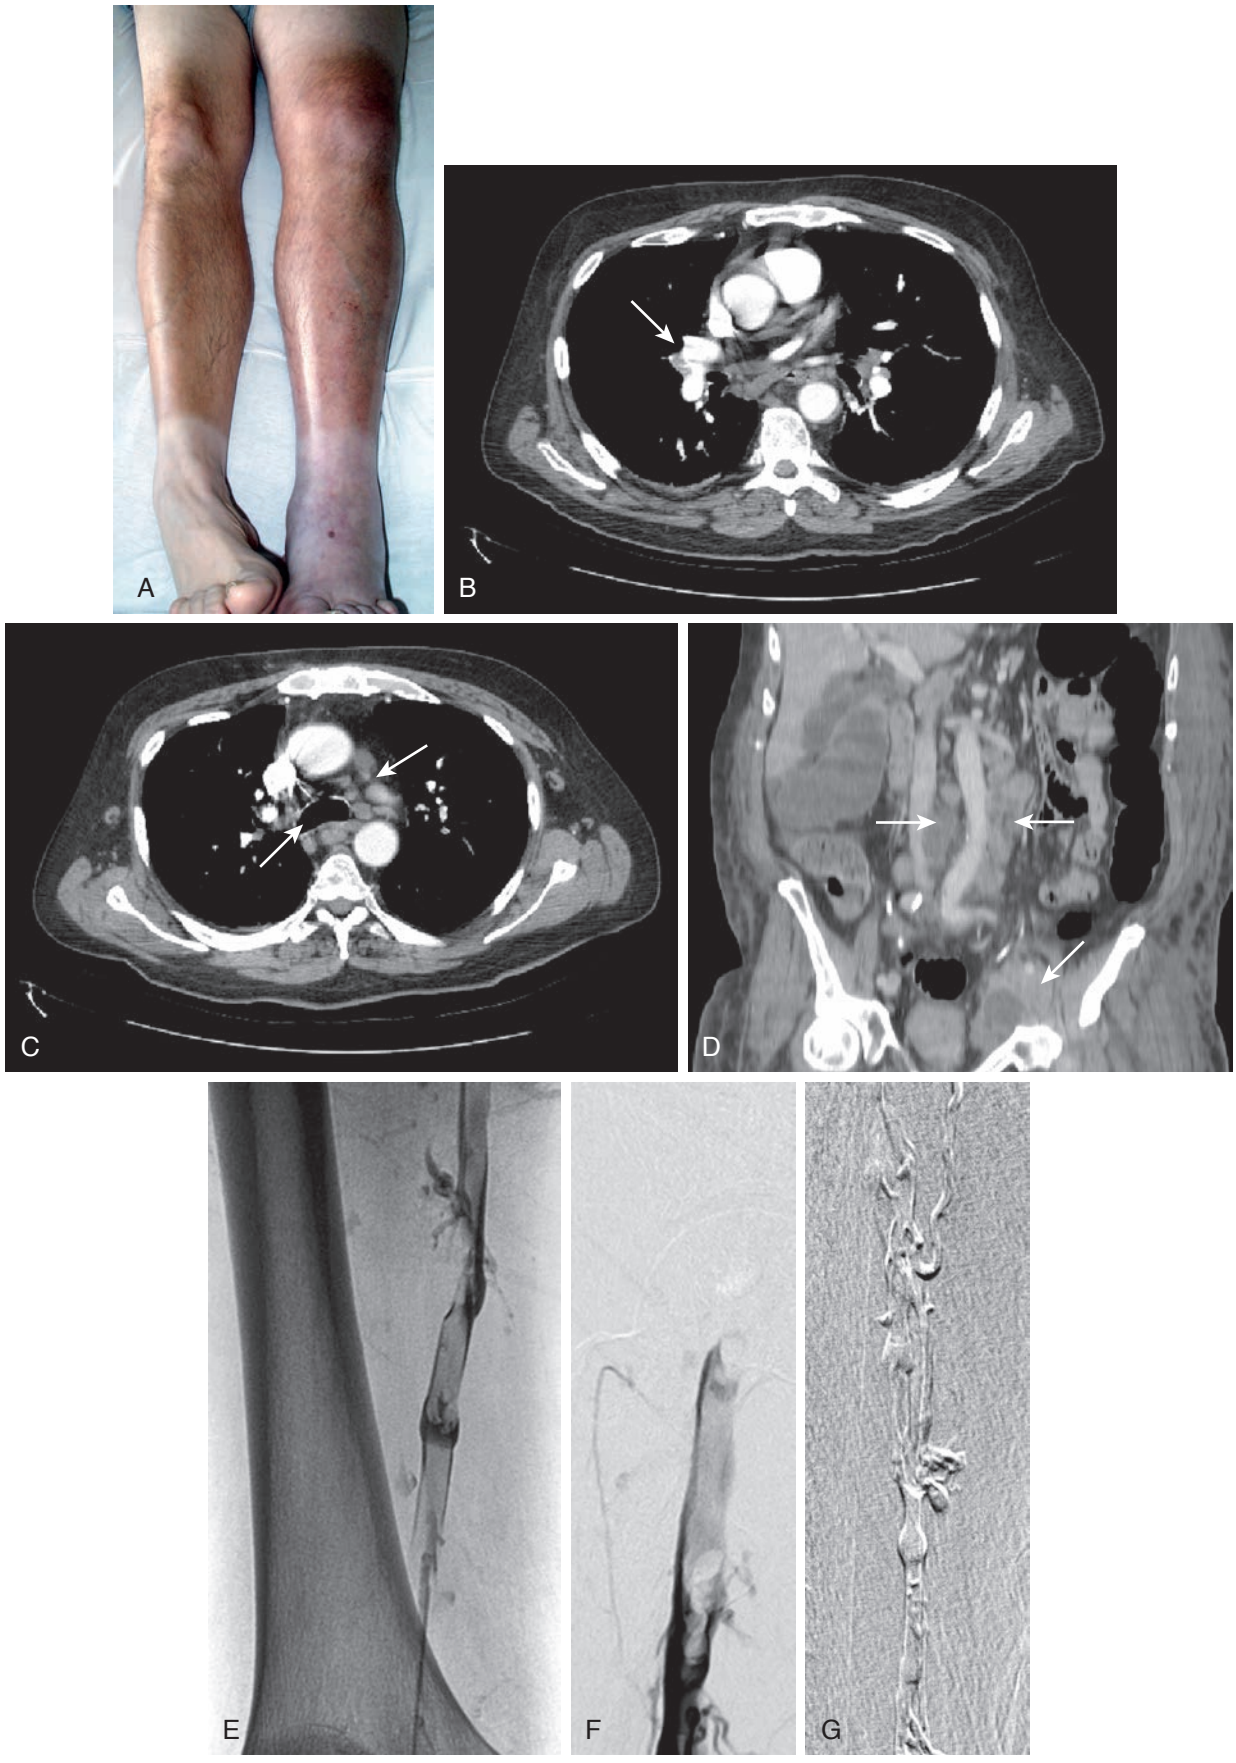

Figure 148.9 A 65-year-old man was referred with phlegmasia cerulea dolens of his left leg (A) 36 hours after major abdominal laparotomy. Venous duplex demonstrated clot in the posterior tibial veins extending to the external iliac vein. A contrast-enhanced computed tomography (CT) scan of the chest, abdomen, and pelvis was performed and demonstrated asymptomatic pulmonary emboli (B) and mediastinal (C), retroperitoneal (C, *arrows*), and pelvic lymphadenopathy (D, *arrows*). The extensive thrombus is demonstrated by a catheter phlebogram of the femoral vein (E and F) and the silhouette of the calf thrombus (G) by the catheter in the posterior tibial vein at the ankle.

Continued

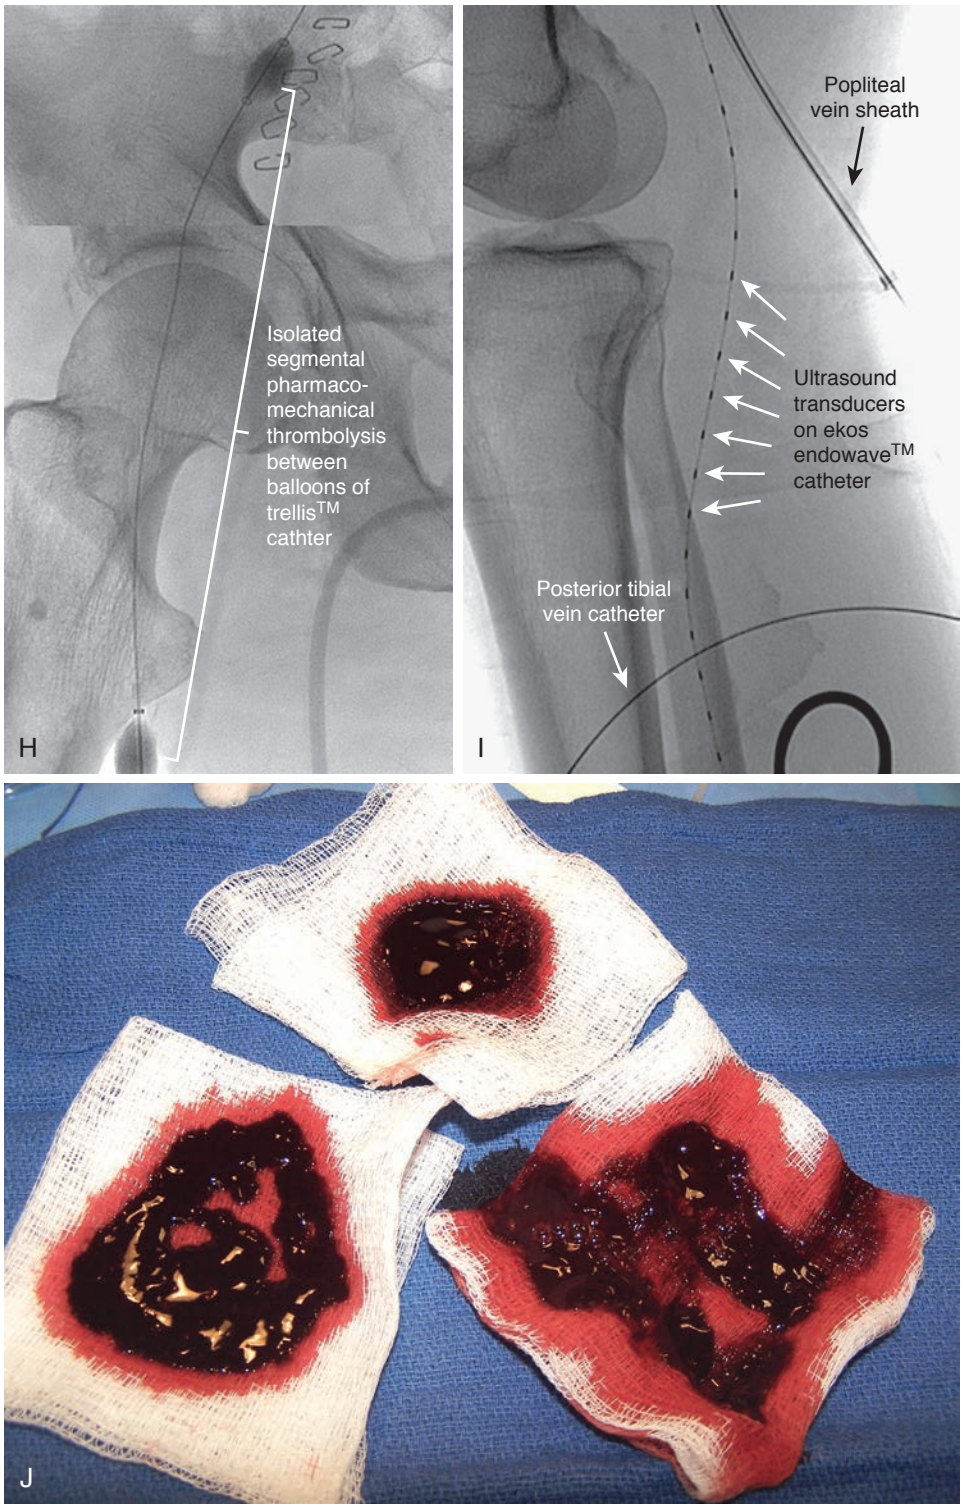

Figure 148.9, cont'd The bulk of the thrombus from the proximal popliteal vein to the common iliac vein was treated with the Trellis catheter via an ultrasound-guided popliteal vein approach (H). The clot in the posterior tibial and popliteal veins was treated with the EKOS EndoWave system (I). Liquefied and fragmented thrombus resulting from ISPMT was aspirated via the Trellis catheter (J).

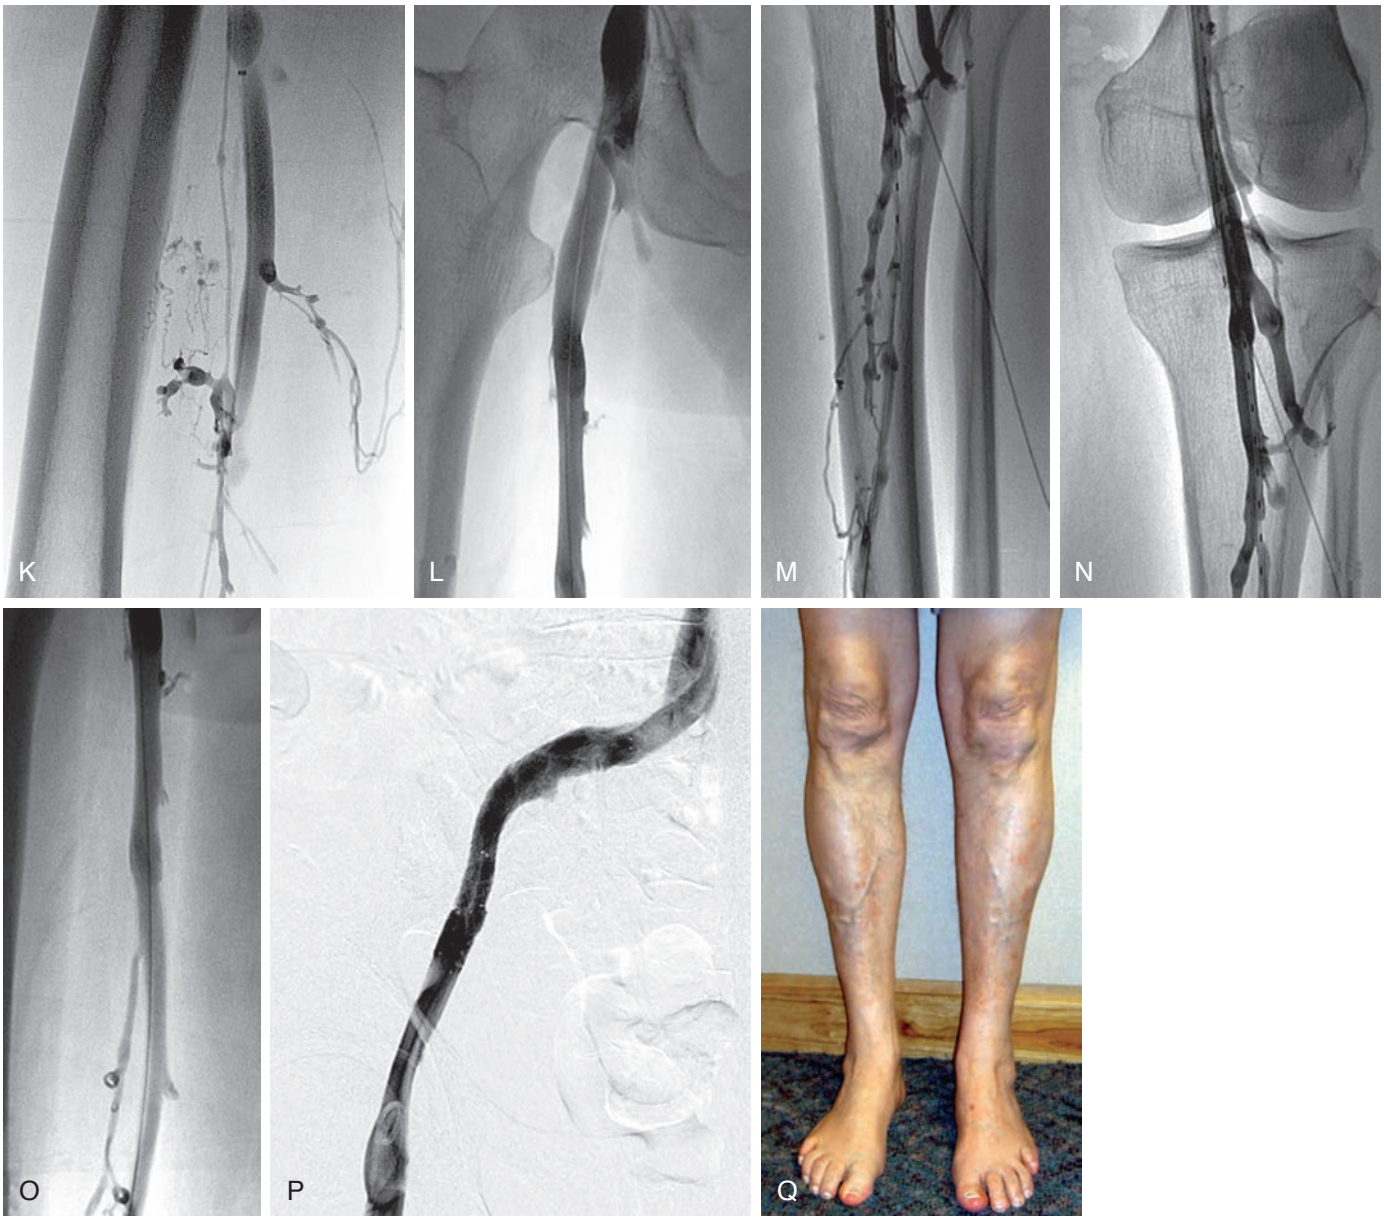

Figure 148.9, cont'd Segmental phlebography is performed to check the results of treatment before moving to an adjacent thrombosed segment (K and L). Residual thrombus is removed by rheolytic thrombectomy with the AngioJet, and the iliac vein compression is treated with a stent. A completion phlebogram shows patency of the calf, popliteal, femoral, and iliac veins as well as supple valve cusps, thus suggesting that valve function persists (M–P). The patient was treated with systemic chemotherapy for his underlying lymphoma. At 16 months (Q) the patient was asymptomatic, had no postthrombotic symptoms, maintained lower extremity venous patency with normal valve function, and fortunately had no evidence of lymphoma recurrence.

pleuritic chest pain develops in up to 25% of patients.[56] Without a previous diagnosis of PE, physicians may assume that this is a "treatment failure" or an embolic complication of either lytic therapy or venous thrombectomy. Realizing that this is merely a delayed manifestation of the previous PE assists in putting these symptoms in proper perspective. The CT scan often identifies additional thoracic, abdominal, or pelvic pathology (see Fig. 148.9B–D). Martinez and colleagues reviewed the results of CT scan evaluation of 47 patients with IFDVT and found PE in 48% and other unexpected thoracic, abdominal, or pelvic pathology in 23%.[64]

PUBLISHED GUIDELINES

It was gratifying that the 8th ACCP Consensus Committee on Antithrombotic Therapy for Venous Thromboembolic Disease made definitive recommendations regarding treatment strategies for thrombus removal in patients with acute IFDVT.[1] These recommendations were continued in the American Heart Association (AHA) guidelines[2] and those published by the SVS.[3] However, suggestions for thrombus removal as primary therapy for selected patients were dropped from the ACCP 2012 and 2016 guidelines, predominantly due to their focus on the

methodologic quality of the available studies. A strategy of thrombus removal for patients with IFDVT was validated by the CaVenT trial results, which were published 6 months after the ACCP 2012 guidelines. However, contemporary venous thrombectomy is an effective treatment option in patients who are not otherwise candidates for CDT or in medical communities where catheter-based techniques are not available.

The AHA Scientific Statement on the management of IFDVT states that CDT or pharmacomechanical CDT is reasonable as the first-line treatment of patients with acute IFDVT to prevent PTS in selected patients at low risk of bleeding complications (class IIA; level of evidence: B). Patients with IFDVT at centers that lack endovascular thrombolysis should be considered for transfer to a center with this expertise if indications for endovascular thrombolysis are present (class I; level of evidence: C). Surgical venous thrombectomy by experienced surgeons may be considered in patients with IFDVT (class IIB; level of evidence: B). Systemic fibrinolysis should not be given routinely to patients with IFDVT (class III; level of evidence: A). Stent placement in the iliac vein to treat obstructive lesions after CDT, pharmacomechanical CDT, or surgical venous thrombectomy is reasonable (class IIA; level of evidence: C). Following either operative venous thrombectomy or percutaneous catheter techniques, patients should receive the same intensity and duration of anticoagulation as patients not receiving a strategy of thrombus removal (class IIA; level of evidence: C).

Salient features of the SVS guidelines include the following: A recommendation against routine use of the term "proximal venous thrombosis" in favor of a more precise characterization of thrombi involving the iliofemoral or femoral popliteal venous segments grade (IA); early thrombus removal strategies in ambulatory patients with good functional capacity and a first episode of IFDVT of <14 days duration (grade 2C). A strategy of thrombus removal recommended in patients with limb-threatening ischemia due to iliofemoral venous outflow obstruction (grade IA); and suggests pharmacomechanical strategies over CDT alone if resources are available. Surgical thrombectomy should be considered if thrombolytic therapy is contraindicated (grade 2C).

The ATTRACT trial has been fully enrolled (N = 692). Patients with acute femoropopliteal DVT and IFDVT were stratified and randomized to catheter-based strategies of thrombus removal versus anticoagulation. The primary endpoint is PTS at 2 years. There were no safety concerns during the treatment phase.

Comerota AJ, Grewal N, Martinez JT, et al. Postthrombotic morbidity correlates with residual thrombus following catheter-directed thrombolysis for iliofemoral deep vein thrombosis. *J Vasc Surg*. 2012;55(3):768–773.

This retrospective analysis of patients treated with CDT for IFDVT demonstrated a direct correlation of the amount of residual thrombus at the end of CDT with postthrombotic morbidity. Patients who had ≥90% lysis had no PTS.

Enden T, Haig Y, Klow NE, et al. Long-term outcome after additional catheter-directed thrombolysis versus standard treatment for acute iliofemoral deep vein thrombosis (the CaVenT study): a randomised controlled trial. *Lancet*. 2012;379(9810):31–38.

This randomized trial of CDT added to anticoagulation versus anticoagulation alone for patients with IFDVT demonstrated significant benefit (reduced PTS) of CDT. The reduced postthrombotic morbidity was directly correlated with patency of the iliofemoral venous segment.

Kahn SR, Kearon C, Julian JA, et al. Predictors of the post-thrombotic syndrome during long-term treatment of proximal deep vein thrombosis. *J Thromb Haemost*. 2005;3(4):718–723.

This prospective evaluation of patients with acute DVT was the strongest predictor of severe postthrombotic syndrome (PTS). The odds ratio for patients with IFDVT to develop PTS was 2.23.

Plate G, Akesson H, Einarsson E, Ohlin P, Eklof B. Long-term results of venous thrombectomy combined with a temporary arterio-venous fistula. *Eur J Vasc Surg*. 1990;4(5):483–489.

The Scandinavian investigators report the long-term follow-up of patients with IFDVT randomized to operative thrombectomy and AVF with anticoagulation versus anticoagulation alone. Patients randomized to operative thrombectomy had better patency, lower venous pressures, and less postthrombotic morbidity.

INTRODUCTION

Acute upper extremity deep venous thrombosis (DVT) characterizes a disease process that ranges from an acutely swollen and painful extremity to one that is asymptomatic. This condition can be classified as either primary or secondary. Primary upper extremity DVT is related to either effort thrombosis (i.e., Paget-Schroetter syndrome) or is idiopathic. Secondary upper extremity DVT develops in patients with either a cancer or an indwelling central venous catheter. As the prevalence of central venous catheter placement increases, secondary thromboses are increasingly outnumbering those related to primary causes.

The Computerized Registry of Patients with Venous Thromboembolism (RIETE) study is the largest known prospectively collected registry of all patients with DVT. Approximately 4.4% of patients in the registry have an upper extremity DVT, almost half of which are catheter-related.[1] Furthermore, in comparison with lower extremity DVT, patients who suffer from upper extremity DVT have a higher mortality rate (up to 48% vs. 13% at 6-months). The high mortality rate in this population is reflective of the associated severe comorbidities, rather than the central catheter or the thrombosis itself.[2]

In the United States, greater than five million catheters are inserted yearly to administer fluids, antibiotics, nutrition, and provide hemodialysis needs.[3] With an increasing number of central venous catheters inserted, the overall incidence of catheter-related venous complications, including thrombosis, sepsis, pulmonary embolism (PE), and death, is simultaneously becoming a considerable issue. There is certainly an elevated incidence of thrombosis in cannulated veins versus noncannulated veins. This was demonstrated in an autopsy study as the risk of venous thrombosis among cannulated versus noncannulated vessels was 36% versus 1.6%, respectively.[4,5] Therefore our discussion will focus on acute upper extremity catheter-related deep venous thrombosis.

CLINICAL FINDINGS

Patients with catheter-related upper extremity DVT can be asymptomatic. For example, in a study documenting catheter-related thrombosis in cancer patients, the authors demonstrated that asymptomatic thrombi were present in 29% of patients (range 5%-62%) versus symptomatic thrombi in 12% of patients (range 5%-54%).[6]

Abstract

Indwelling central venous catheter placement is associated with a significant incidence of upper extremity deep vein thrombosis (UEDVT). Prior data has demonstrated that an upper extremity deep venous thrombosis (DVT) can lead to pulmonary embolism, postthrombotic syndrome, and death. In patients with acute upper extremity deep vein thrombosis, full systemic anticoagulation is recommended with or without catheter removal for a period of 3 to 6 months.

central line

Erythema, pain, or swelling located at neck, chest, or arm are few of the common symptoms, if present.[7-13] In patients with significant disease, there is often tremendous engorgement of the veins along the chest wall or the extremity. In rare instances, phlegmasia cerulean dolens has been reported.[14,15]

Pulmonary embolism is known to occur in 5% to 20% of patients with upper extremity DVT. A prospective study of patients with upper extremity DVT routinely performed ventilation-perfusion scans to determine the prevalence of PE among all patients with upper extremity deep vein thrombosis (UEDVT). The scans demonstrated that 13 out of 86 (15.1%) patients developed a PE. The most common underlying comorbidity for these patients was cancer (31.4%). In addition, Monreal et al. found that the higher incidence of PE (20%) occurred in the patients that had DVT associated with an underlying indwelling catheter.[16,17] In many cases these are not hemodynamically significant.

Postthrombotic syndrome (PTS), consistent with a painful and swollen extremity after the acute episode, is also known to occur after upper extremity DVT. In a retrospective study by Hingorani et al., a 13-month follow-up of 170 patients yielded a 4% prevalence of symptoms consistent with PTS. However, others have reported the incidence of postthrombotic syndrome to be as high as 35%.[18]

DIAGNOSTIC STRATEGIES

Duplex ultrasonography is the mainstay for diagnosis of most upper extremity DVT. It is noninvasive and more cost-effective than other diagnostic modalities. The diagnosis is confirmed with augmentation maneuvers without clinical response in flow, compressibility of the venous segment, or the signal echogenicity in B-mode along a venous segment.[19]

A 2009 review article demonstrated duplex ultrasonography to be 86% to 100% specific and 78% to 100% sensitive in the diagnosis of upper extremity DVT. Diminished sensitivity of duplex ultrasonography may be seen with studies that incompletely assessed the veins, or when the thrombus was located at the proximal subclavian or brachiocephalic veins. Furthermore, a prospective study in 66 patients with leukemia evaluated the role of ultrasonography and venography to evaluate patients with asymptomatic upper extremity DVT. These patients underwent bilateral venography and duplex ultrasound evaluation. The authors found an overall prevalence of 29% upper extremity DVT in this cohort. They then concluded that the sensitivity of their ultrasound (37%) was far inferior to venography (79%). It was also determined by these authors that the most common missed thrombotic sites were internal jugular vein during venography and subclavian vein during duplex ultrasonography.[20] It was also their recommendation that in those patients with suspected thrombosis, but without a confirmed diagnosis based on one test, additional testing with or without the use of adjunctive maneuvers should be performed.

We recommend that if the duplex ultrasound fails to reveal a thrombus and clinical suspicion is elevated for acute upper extremity DVT, then obtain venography by either a computed tomography (CT) or magnetic resonance (MR). Use of D-dimer may be useful in this circumstance; if negative, the likelihood of DVT is almost nil. Although catheter-directed venography is seldom used, it remains the gold standard to determine central thrombosis.

RISK FACTORS AND PREVENTION

Biomarkers

Biomarkers, along with clinical exam and blood tests, are often utilized to identify patients at high risk for thrombosis. In a 2014 study by Kleinjan et al., the authors aimed to generate a management strategy for patients based on a risk assessment score.[21] They used the clinical decision score to predict UEDVT based on a single point assigned to the presence of catheter in a venous system, localized pain, or unilateral edema. If another diagnosis was at least as likely to be present as thrombosis, a negative point was assessed to the patient and resulted in risk of 12%, 20%, or 70% for 1, 2, or 3 points, respectively.

A prospective study by Boersma et al. evaluated 212 patients with a 9% incidence of catheter-related thrombosis. The authors determined that patients with symptomatic thrombosis presented with elevated levels of factors VIII ($P = .023$), elevated white blood cell count ($P = .042$), and plasminogen activator inhibitor-1 ($P = .008$).[22] The authors advocated for the use of thromboprophylaxis in this selected population.

Role of Thromboprophylaxis

While limited prior series had shown promise with the use of chemical thromboprophylaxis using anticoagulation for all patients with central catheters, published guidelines and most recent data have failed to support the idea. One of such studies was by Timset et al. in 1998. The authors of the study demonstrated that for age ≥65 years ($P = .001$), internal jugular vein use ($P = .005$) and absence of therapeutic anticoagulation at time of catheter placement ($P = .04$) were all associated with increased risk of thrombosis.[23] Further support of anticoagulation prophylaxis comes from a small series of cancer patients that were evaluated by D'Ambrosio et.al. Their analysis determined a lower risk of symptomatic catheter related thrombosis than control among patients that received anticoagulation for prophylaxis (RR = 0.61, 95% CI, 0.42-0.88).[24] In addition, Monreal demonstrated in a 1994 series that dalteparin infusion 2 hours prior to central catheter insertion in cancer patients reduced the risk of thrombosis.[25] Yet the results have been largely irreproducible, and the role of chemical thromboprophylaxis use prior to or during catheter insertion is not clearly supported.[26] Therefore we do not recommend routine anticoagulation for patients with central venous catheters.

Measures to address catheter thrombogenicity have also been addressed to diminish thromboses. Murray et al. demonstrated increased catheter thrombogenicity of polyethylene catheters compared with polyurethane catheters and rigid catheters compared with compliant catheters.[27] A number of authors have also lamented that less trauma to the vessel wall during

insertion and during the life of the implant, as well as the persistence of the catheter to remain in an optimal location, was paramount in safeguarding against catheter-related thrombosis.

Moreover, the role of heparin-bonded catheters remains inconclusive at best. Their prophylactic effects against upper extremity DVT in adults have not been consistent. In 2014 a Cochrane review compared heparin-bonded catheters with nonheparin bonded catheters in the pediatric population. The review failed to demonstrate a difference in thrombotic outcomes (RR = 0.34, 95% CI, 0.01-7.68).[28]

Catheter/Patient-Related Causes

It is prudent to understand that thrombosis can be due to multiple causes: patient-related, catheter-insertion related, or a combination of both. One of the earliest series to warn against the dangers of indwelling catheters associated with upper extremity DVT was completed in 1970. Tilney and Griffeths documented their 25-year experience and demonstrated that 31 of 48 (65%) of upper extremity DVT were associated with catheters.[29] In 1998 Horattas et al. documented their cohort of patients with upper extremity DVT and found that 39% were catheter-related and 12% of those patients with upper extremity DVT presented with a PE. Horattas et al. further found that the risk of upper extremity DVT increased with larger catheter diameter, multiple punctures needed during insertion, and overall duration of catheter placement.[30]

A patient's history of a previous thrombotic event, inherited thrombotic disorders, malignancy, and an acute infection have also been associated with an increased risk of thrombosis. A retrospective study evaluated 105 consecutive cancer patients undergoing chemotherapy with clinical suspicion of upper extremity DVT. The authors concluded that patients with acute catheter-related infection were more likely to have DVT than those without acute infection (RR 17.6, 95% CI, 4.1-74.1).[31]

Peripherally inserted central venous catheter (PICC) associated UEDVT has an incidence of 1.6% to 3.5%. Large PICC diameter (≥ 5Fr) (OR = 3.9, 95% CI, 1.1-13.9) and concurrent malignancy (OR = 4.1, 95 %CI, 1.9-8.9), as demonstrated in a study among all patients that underwent PICC placement over a 1-year period, were found to be associated with a higher risk of development of upper extremity DVT.[32] In a study of a fluid analysis model utilizing different PICC diameters, the authors noted a decrease in up to 80% of segmental venous flow rate with the use of a 6 Fr. PICC.[33] This finding was consistent with a prospective study with an established increased risk of symptomatic DVT in patients with 4 Fr. PICC (up to 2.9%) compared with patients with a 6 Fr. PICC (up to 9.8%). Another study to demonstrate the flow limit concept was performed in patients with cardiac lead devices. The study retrospectively evaluated patients with implanted cardiac leads and demonstrated a higher risk of upper extremity DVT in patients with multiple pacemaker leads (27%) versus a single pacemaker lead (7%; RR = 3.8, 95% CI, 1.0-15.0).[34]

In addition, catheter site selection and distal tip position have also been demonstrated to be of great significance. The French National Federation of Cancer Centers workgroup on Standards, Options, and Recommendations established their guidelines on prevention of catheter related thrombosis by reviewing 36 publications over an almost three decade period (1990–2007).[35] Their analysis found that catheter position is one of the most important factors and recommended the distal tip of all central venous catheters be located at the junction of right atrium and the superior vena cava.

A systematic review of an internal jugular vein versus subclavian vein insertion site for central venous catheters found that internal jugular vein route had a lower rate of malposition (5.3% vs. 9.3%; RR = 0.66, 95% CI, 0.44-0.99).[36] Yet the analysis failed to demonstrate a difference in thrombotic outcomes based on site of insertion. Furthermore, a study evaluating left versus right side central catheter insertion in cancer patients found that the incidence of thrombosis was much more common after left-sided catheter insertion (25.6%) than right-sided catheter insertion (6.8%). This result was reproducible in two additional studies that documented a relative risk in cancer patients of 2.6 and 4.4 for upper extremity DVT occurring after left-sided insertion and right-sided catheter insertion, respectively.[37]

The correlation between the routes of catheter insertion to incidence of DVT was addressed in a 2012 Cochrane review. The authors evaluated three randomized controlled trials and compared internal jugular vein versus subclavian vein insertion sites of central venous catheters and assessed risk for associated thrombosis.[38] The review failed to find a difference in thrombotic complications (RR = 1.97, 95% CI, 0.87-4.48) between internal jugular or subclavian vein route. The analysis did find a significantly increased risk of thrombosis for femoral vein insertion compared with subclavian vein catheter insertions (RR = 11.53, 95% CI, 2.80-47.52). The authors concluded that the subclavian route was preferred to femoral vein insertion for central venous catheters, but no clear thrombotic difference was noted between the internal jugular and the subclavian vein routes.

TREATMENT

The standard treatment for upper extremity DVT is anticoagulation. We present a proposed treatment algorithm (Fig. 149.1). These data, in large part, have been extrapolated from lower extremity data. In addition, the recent addition of direct oral anticoagulants as an effective and efficacious treatment modality for lower extremity DVT should yield them to be considered as enhanced alternatives to vitamin K antagonists.

The American College of Chest Physicians' (ACCP) guidelines recommend UEDVT to be treated with 3 to 6 months of anticoagulation and removal of the central catheter if the patient does not require it.[39-41] The role of thrombolytic agents or thrombectomy is not clearly established, but the use of this therapy may be beneficial in patients with phlegmasia.[42] Specifically, according to the 2016 *Chest* guidelines, the following cohort of patients may benefit from catheter-directed thrombolysis: those with severe symptoms, thrombus involving most of the subclavian and axillary veins, symptoms present for less than 14 days, good functional status, life expectancy greater than 1 year, and low risk for bleeding.[43]

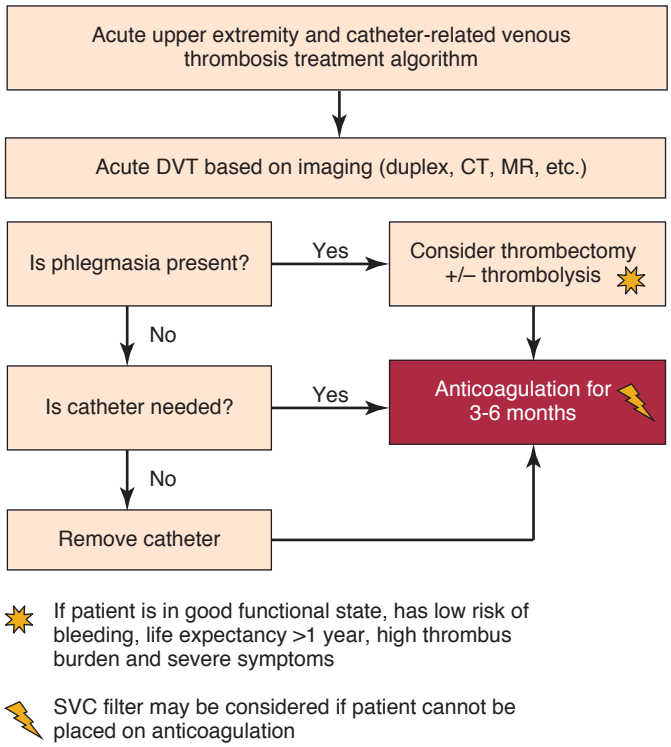

Figure 149.1 Proposed treatment algorithm for upper extremity catheter-related venous thrombosis treatment. *CT*, Computer tomography; *DVT*, deep venous thrombosis; *MR*, magnetic resonance.

Superior vena cava filter placement to prevent PE may be considered in a subset of patients that are unable to receive anticoagulation or catheter removal.[44-46] It is crucial to note the study by Usoh et al. demonstrated that a high degree of caution should be noted in younger male patients who undergo superior vena cava filter placement. They documented that among 154 patients with a mean follow-up of 256 days after filter placement, there were three cases of caval perforations. All three cases occurred in males less than 60 years old. No other cases of perforation occurred in older males or females of any age. Whether an SVC filter decreases mortality is unknown.

CONCLUSION

Acute upper extremity venous thrombosis occurs frequently after the insertion of indwelling catheters. Although patients with this condition may remain asymptomatic, some will develop a classic clinical picture including pain, erythema swelling, and even signs of PE. If possible, the indwelling catheter should be removed when a catheter-related upper extremity DVT is noted. However, if the patient does not have a safe alternative, the catheter can be left in place. The current treatment guidelines recommend full anticoagulation for a period of 3 to 6 months.

Superficial venous thrombophlebitis (SVT) has been the focus of increased attention because of growing recognition of its potential morbidity and mortality associated with it. Although a global disorder, SVT develops in approximately 125,000 people per year in the United States; nonetheless, it is underestimated because many cases go unreported.[1]

It has been historically assumed that SVT is a self-limited process of little consequence and of small risk. However, new evidence on the natural history of SVT has led to improvements in evaluation and treatment. A meta-analysis reported a 6% to 44% incidence of deep venous thrombosis (DVT), a 20% to 33% incidence of asymptomatic pulmonary embolism (PE), and a 2% to 13% incidence of symptomatic PE in patients in whom SVT is diagnosed.[2] Improved diagnostic evaluation of SVT with duplex scanning, lung scanning, and blood tests has helped to identify predisposing risk factors and potential complications.

This chapter examines current data regarding SVT and its management, with the goal of improving recognition and treatment of the underlying disorders to prevent recurrence and its life-threatening complications.

EPIDEMIOLOGY AND PATHOGENESIS

Although SVT is a frequently observed condition, its incidence and prevalence have never been adequately assessed. The classic Tecumseh Community Health Study from 1973 reported that the incidence of SVT increases with age from 0.05 per 1000 per year in males in their third decade to 1.8 per 1000 per year in their eighth decade. In females the incidence similarly rises from 0.31 per 1000 per year to 2.2 per 1000 per year from their third decade to their eighth decade.[3] Moreover, other studies have also demonstrated an increased prevalence of SVT in females.[4,5]

Overall, the incidence of lower extremity SVT has been reported to be 3% to 11% in the general population. A useful classification is the recognition that SVT may occur in two forms, those with, and those without varicose veins, or alternatively, SVT may be primary involving the vein wall only or secondary involving a more systemic inflammatory process. Primary SVT is most common in the saphenous veins and their tributaries, followed by the upper extremity cephalic and basilic veins. The greater saphenous vein (GSV) is affected in 60% to 80% cases, followed by the small saphenous vein (SSV) in 10% to 20%, and bilateral lower extremity SVT in 5% to 10%.[6] Patients with varicose veins are affected far more frequently than in the general population, with a prevalence of SVT ranging from 4% to 62%.[3,5,6]

Risk factors can be classified in accordance with Virchow's triad: endothelial injury from trauma or insertion of venous catheters; venous stasis as seen in varicosities; and hypercoagulable states such as factor V Leiden, prothrombin G mutation, protein C and protein S deficiency, antithrombin III abnormalities, and malignancies including both solid tumors and hematologic

conditions of Hodgkin lymphoma, leukemia, thrombocytosis, polycythemia vera, cryoglobulinemia, and nocturnal paroxysmal hemoglobinura.[6,7] Patients in whom SVT develops without an inciting physical event or varicosities may need to be fully evaluated for the presence of such disorders.

Other secondary causes for the development of SVT include the use of oral contraceptives, hormonal replacement therapy, pregnancy, obesity, prolonged immobilization, recent surgery, trauma, sclerotherapy, history of venous thromboembolism, and some drugs (e.g., diazepam, amiodarone, vancomycin, heroin, some chemotherapy). Intravenous catheter use with or without bacterial infection places patients more at risk for the development of SVT.[3,5-8] In addition, patients with autoimmune disorders, including systemic lupus erythematosus and vasculitis, such as Behçet and Buerger disease, have also been identified as being susceptible to the development of SVT. A 2006 review of 2319 patients with Behçet's disease found that 14.3% of these patients have vascular involvement. Of these 332 patients, 53.3% had SVT and 29.8% had DVT.[9] Patients with Buerger disease appear to have an increased incidence of SVT because the inflammatory process involves small arteries and veins of the extremities. It can be diagnosed from biopsy findings of acute superficial thrombophlebitis showing the characteristic acute phase lesion—inflammation of all three layers of the vessel wall with occlusive cellular thrombosis.[10]

The main concern related to SVT is the likelihood that the thrombus will extend into the deep veins, causing DVT and potential PE. Several older studies have evaluated this risk especially in relation to the proximity of GSV SVT to the deep veins. Chengelis et al. followed 263 patients with isolated SVT and performed follow-up ultrasound at 2 to 10 days (mean 6.3 days).[11] Thirty (11%) patients experienced progression to DVT while not receiving anticoagulation. The most common site was propagation of the SVT in the GSV into the common femoral vein. In a small retrospective review, 185 patients with SVT and 370 age- and sex-matched controls were evaluated.[12] A minority (13%) received nonsteroidal antiinflammatory drugs (NSAIDs) or rarely LMWH therapy. At 6 months, overall 2.7% had developed DVT and 0.5% PE. SVT conferred a 10-time increased risk of developing DVT compared with controls without SVT. This study represents an estimate of the natural history of SVT because few patients received pharmacologic management. Another focused study evaluated the incidence of PE in 21 patients with isolated SVT in the thigh.[13] Nuclear perfusion lung scans were performed within 3 hours of SVT diagnosis and demonstrated seven patients with PE (33%), including one symptomatic patient. Of note, there were no significant differences in the distance of the SVT from the common femoral vein, or the presence of common risk factors for thrombosis compared with those with SVT that did not experience a PE. Although a small study, these findings highlight the potential serious consequences of SVT and suggest the need for anticoagulant therapy to prevent these complications.

Two recent large studies have evaluated the epidemiology and natural history of SVT in patients, most of whom received medical therapy. In the POST trial, Decousas et al. prospectively followed a cohort of 844 consecutive patients with symptomatic SVT of the lower limbs confirmed by ultrasound testing.[14] Patients with recent surgery within 10 days or SVT due to sclerotherapy in the previous 30 days were excluded. Patients were initially assessed for concomitant DVT, and then those with isolated SVT (634 patients) were followed with ultrasound again at 10 days and then at 3 months. A secondary outcome was overall mortality at 3 months. DVT or PE was confirmed in 24.9% of patient with SVT (82 patients with proximal DVT, 33 patients with PE). In 41.9% of patients with DVT, both proximal and distal, the DVT was not contiguous with the SVT. Of 634 patients with SVT, 90.5% received one or more anticoagulant medications, mostly therapeutic LMWH. Sixty patients (10.2%) had venous surgery. Fourteen patients were lost to follow-up. Of the remaining 586 patients, 58 had thromboembolic complications (10.2%), including seven with symptomatic proximal DVT, three with PE, and five with extension of SVT to DVT. Multivariate analysis showed that male sex, history of DVT or PE, previous cancer, and no varicose veins were independent risk factors for symptomatic VTE at 3 months including recurrence or extension of SVT.

A recent pooled analysis of the POST study and the OPTIMEV trials involving 1074 cases revealed that in symptomatic patients with SVT, only male sex significantly and independently increased the risk of VTE recurrence after multivariate analysis. Cancer and saphenofemoral/popliteal junction proximity were associated with VTE recurrence on univariate analysis.

The OPTIMEV study evaluated 788 patients with SVT of 8256 patients that were referred for VTE.[15] The median age of these patients was 65 years, 36% were men and 16% were inpatients. Similar to the POST study, 29% were found to have concomitant DVT. Patients with both SVT and DVT had risk factors of presence of nonvaricose veins involved, age greater than 75 years, inpatient status, and active cancer, compared with isolated SVT, which was independently associated with anticoagulant treatment at inclusion and pregnancy or post-partum state. Compared with SVT of varicose veins, SVT in nonvaricose veins was a strong risk factor for concurrent DVT but did not convey a higher risk of 3-month adverse outcomes of death, VTE recurrence, or bleeding. In this study, 76% of those with isolated SVT were treated with anticoagulants, including 92.5% with full-dose LMWH.

More recently, there has been greater awareness of the presence of hypercoagulable states in patients with SVT. These patients have a higher probability of developing DVT and recurrent SVT and may require long-term anticoagulation to prevent complications. Milio et al. evaluated 107 patients with unprovoked SVT for common thrombophilic conditions.[16] The patients underwent duplex evaluation at baseline and every 48 hours for 8 days, with notation whether the SVT occurred in varicose or nonvaricose veins. In the overall cohort, factor V Leiden was detected in 22.4%, MTHRF in 17.7%, and factor II G20210 mutation in 8.4%. Patients with thrombophilia and SVT in nonvaricose veins had a higher rate of extension of thrombus to deep veins. However, because all patients were treated with either LMWH or NSAIDs and the results were not analyzed by treatment group, it is difficult to draw definitive conclusions regarding the role of thrombophilia and DVT extension. Similar

studies have supported the presence of acquired and inherited thrombophilic disorders as being a risk factor for the development of SVT, such as factor V Leiden and prothrombin (G20210A) gene mutations; deficiencies of antithrombin, heparin cofactor 2, protein C, and protein S; lupus anticoagulant; anticardiolipin antibodies; and abnormal fibrinolytic activity.[3,5,9,10,17-19]

An analysis published in 2014 including 1294 patients with SVT concluded that in patients with SVT not associated with varicose veins, malignancy, or autoimmune disease, thrombophilia screening may be considered due to a higher incidence of thrombus progression.[20]

Although a number of studies have described the pathophysiology and various changes that take place in leukocyte–vessel wall interactions, cytokines/chemokines, and various other factors involved in the development and resolution of DVT, data on changes in patients with SVT have not been identified. Although some authors have alluded to the observation that the underlying pathologies of SVT and DVT may be analogous, this viewpoint remains mostly unsupported to date.

CLINICAL PRESENTATION

Evaluation for SVT by physical examination is based on the presence of erythema and tenderness in the distribution of the superficial veins and with the thrombosis being suspected by a palpable cord. Pain, erythema, and swelling are the most common symptoms.[21] There are a number of conditions discussed later that present unique risk factors or clinical presentations of SVT.

Superficial Thrombophlebitis With Varicose Veins

The most common predisposing risk factor for the development of SVT is varicose veins. Because it has been reported that DVT will develop in only 3% to 20% of SVT patients with varicose veins as compared with 44% to 60% of SVT patients without varicose veins,[22,23] therefore it appears that patients with varicose veins may have a different pathophysiology from those without varicose veins.

SVT involving varicose veins may remain localized to the cluster of tributary varicosities or may extend into the GSV.[5,6,10,24,25] SVT of varicose veins themselves may occur without antecedent trauma. SVT is frequently found in varicose veins in conjunction with venous stasis ulcers. This diagnosis should be confirmed by duplex ultrasound because the degree of SVT may be much greater than that based solely on clinical examination. SVT in varicosities may manifest as tender nodules with localized induration and erythema.

Traumatic Thrombophlebitis

Traumatic SVT is often seen in individuals using illicit drugs or undergoing drug therapy in a hospital or outpatient setting. It is associated with direct endothelial injury from the intravenous catheter used for the infusion of medications and irritating solutions, particularly when the indwelling catheter has been in place for long periods. Its onset is usually heralded by the development of pain, tenderness, and erythema at the site of catheter insertion or infusion. Treatment usually consists of cessation of the infusion, removal of the offending access device, and sometimes anticoagulation depending on the severity of symptoms and underlying hypercoagulable condition. The induration may take weeks to months to resolve.

Septic and Suppurative Thrombophlebitis

Suppurative SVT (SSVT) is also associated with the use of an intravenous cannula; however, SSVT may cause additional morbidity because of its association with septicemia. Signs and symptoms of SSVT include pus at an intravenous site, fever, leukocytosis, and local intense pain.[26] Aerobic, anaerobic, and mixed infections have been reported in SSVT. Organisms associated with SSVT include *Staphylococcus aureus*, *Pseudomonas* species (spp.), *Klebsiella* spp, *Enterococcus* spp, *Fusobacterium* spp, and recently, fungi such as *Candida* spp.[26] Treatment begins with removal of the foreign body and intravenous administration of antibiotics. Excision of the vein is rarely needed to clear the infection, although occasionally speeds the healing process.

Migratory Thrombophlebitis

Migratory thrombophlebitis was first described by Jadioux in 1845 as an entity characterized by repeated thrombosis developing in superficial veins at varying sites but most commonly in the lower extremity.[25] This entity may be associated with carcinoma (Trousseau syndrome) and may precede diagnosis of the carcinoma by several years. Consequently, evaluation for occult malignancy is warranted when the diagnosis of migratory thrombophlebitis is made. Migratory thrombophlebitis also occurs in the presence of some forms of vasculitis such as Behçet disease, Buerger disease, and polyarteritis nodosa.[7]

Mondor Disease

Mondor disease is defined as thrombophlebitis of the thoracoepigastric vein of the breast and chest wall (Fig. 150.1). It is thought to be associated with breast carcinoma or hypercoagulable states, although cases have been reported with no identifiable cause.[18] Tender, cordlike structures can be seen extending from the lower portion of the breast toward the costal margin or in the anterolateral aspect of the breast.[27] The condition is considered benign and self-limited, and treatment is conservative, rarely involving systemic anticoagulation.[28]

The term *Mondor disease* has also been applied to SVT of the dorsal vein of the penis. This phenomenon occurs in patients with DVT, after hernia operations, and in association with excessive sexual intercourse. Treatment consists of NSAIDs and dorsal penile vein resection if the symptoms are refractory.[29]

Small Saphenous Vein Superficial Thrombophlebitis

Although the bulk of attention has been focused on SVT of the GSV, SVT of the SSV is also clinically significant. SSV SVT may

Figure 150.1 Mondor disease: superficial thrombophlebitis of the thoracoepigastric vein of the breast.

progress to popliteal DVT. In a group of 56 patients with SSV SVT, 16% had PE or DVT.[24] In one study, it was found that 65.6% of 32 patients with SSV SVT also had DVT over a 1-year period.[30] Therefore it is crucial that patients with SSV SVT be treated similarly to those in whom GSV SVT is diagnosed—the same careful duplex examination, follow-up, and anticoagulation or ligation if the SVT approaches the popliteal vein.

Upper Extremity Superficial Thrombophlebitis

Although very little appears in the literature, upper extremity SVT often results from intravenous cannulation and infusion of caustic substances that damage the endothelium. Typically, the basilic or cephalic veins are involved particularly if the catheter is inserted at or near the antecubital fossa. Interestingly, progression of upper extremity SVT to upper extremity DVT or PE is less common when compared with lower extremity SVT.[31] Initial treatment of upper extremity SVT is catheter removal followed by conservative measures with anticoagulation occasionally required.

Superficial Thrombophlebitis After Endovascular Venous Obliteration

Minimally invasive endovascular techniques have emerged and gained popularity as alternatives to GSV ligation and stripping for GSV insufficiency and treatment of varicose veins. Endovenous laser ablation and radiofrequency ablation (RFA) have become widespread because of superior pain scores and feasibility as office-based procedures. In a prospective study of 67 patients undergoing EVLT and 66 patients undergoing RFA of the GSV or SSV, the rate of SVT was 1.5% in the EVLT group compared with 0% in the RFA group.[32] In another prospective study of 155 patients who underwent RFA of the GSV or SSV, only one patient (1.4% treated veins) developed SVT that occurred at a puncture site.[33] The incidence of SVT was higher in 150 patients who underwent SSV RFA (4%).[34] Zuniga et al. also reported a higher incidence of SVT of 10% to 15% in 667 RFA procedures of the GSV.[35] A meta-analysis of 104 studies evaluating the use of endovenous foam sclerotherapy for the treatment of venous disorders found an incidence of SVT of 11%.[36] This is somewhat higher compared with what has been reported for other endovenous procedures. Similarly, in a large randomized prospective study of 500 consecutive patients comparing EVLT, RFA, foam sclerotherapy, and stripping for GSV varicose veins, SVT occurred in 4 patients (3.2%) undergoing EVLT, 12 (9.6%) patients undergoing RFA, 17 patients (13.7%) with foam sclerotherapy, and 5 patients (4%) with surgical stripping.[37]

DIAGNOSIS

A positive diagnosis of SVT is primarily established by identifying the clinical and physical signs described earlier. Typically, pain, erythema tenderness, and induration corresponding to one or more superficial veins or dilated varicose veins are evidence with possible edema over the inflamed vein. Painful "cords" are palpable, and fever or leukocytosis may be present if associated with a systemic infection. Typically, the inflammatory reaction may last 2 to 3 weeks, and either vein fibrosis or vein recanalization occurs over the ensuing 6 to 8 weeks. Postinflammatory hyperpigmentation may occur and last several months.[7] However, the potential presence of occult or symptomatic DVT or PE concomitantly with SVT warrants further imaging studies. A study of 141 patients with SVT of the GSV found a significantly greater thrombus extension when examined by ultrasound compared to physical exam, affirming the value of imaging for SVT evaluation.[38] A small study found that recurrent SVT correlated with thrombus in tributary veins, but other risk factors of varicose veins, previous DVT, cancer, or hypercoagulable state were not predictive.[39]

Duplex ultrasound scanning has become the initial test of choice for the diagnosis of DVT and evaluation of SVT since first introduced by Talbot in 1982. The availability of reliable duplex ultrasonography of the deep and superficial venous systems has made routine determination of the location and incidence of DVT in association with SVT precise and practical (Fig. 150.2; see Chapter 23). Furthermore, the extent of involvement of the deep and superficial systems can be more accurately assessed with this protocol. Duplex ultrasound imaging also offers the advantage of being inexpensive and noninvasive and can be repeated for follow-up examination. Because venography may contribute to the onset of phlebitis and duplex imaging affords an accurate diagnosis, venography is not a first choice for investigation. Although initial studies generated enthusiasm for the use of scintigraphy and computed tomographic venography, their poor specificity and lack of anatomic detail have led to duplex ultrasonography remaining the primary diagnostic modality for SVT.

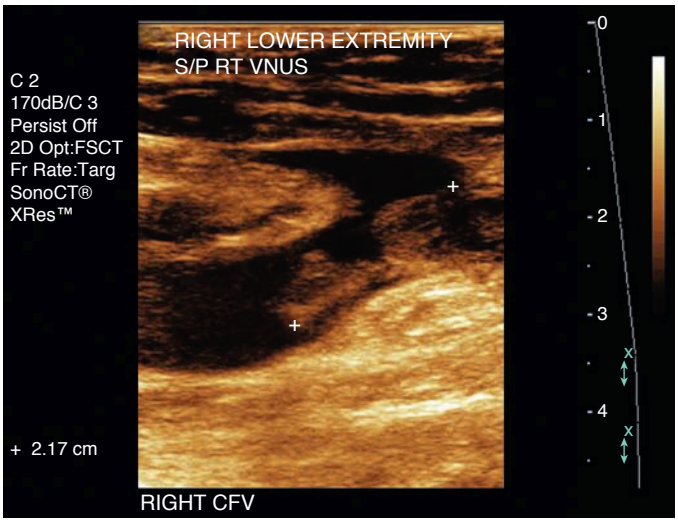

Figure 150.2 Ultrasound image of thrombophlebitis with free-floating thrombus extending from the great saphenous vein into the femoral vein.

Patients with SVT may or may not have elevated levels of D-dimer, thus offering little assistance with respect to the negative or positive predictive value of the disease. Blood tests in patients with SVT should be directed toward testing for acquired and congenital hypercoagulable states or malignancies if clinically indicated, particularly in patients with nonvaricose vein SVT.

TREATMENT

Treatment depends on the cause and location of the SVT. The goals of therapy are decreasing the acute symptoms of SVT including pain and erythema and preventing potential serious complications such as DVT and PE, as well as extension or recurrence of SVT. Historically, treatment was dictated by the proximity of the thrombus to the deep veins. Treatment for SVT has evolved from primarily surgical options to emphasis on medical treatment with the introduction of LMWH. Although warm compresses and compression hose have been recommended, there are little data supporting their use. A trial of 73 patients with SVT comparing use of compression stockings for 1 week compared with no compression revealed no difference in quality of life, pain, or use of analgesics, although thrombus regression measured on ultrasound was faster in the compression group.[40]

LMWH

One of the first trials evaluating modern medical management of SVT was the STENOX trial, a randomized double-blind trial of 427 patients with acute SVT of at least 5 cm length of the legs.[41] Patients were randomized to receive enoxaparin 40 mg daily, enoxaparin 1.5 mg/kg daily, oral tenoxicam 20 mg daily, or placebo for 8 to 12 days. Follow-up ultrasound was performed between day 8 to 12. The study excluded patients who were at high risk, such as those with thrombophilia; a history of DVT, PE, or SVT; two or more episodes of SVT; a history of venous sclerotherapy; or pregnancy. The overall rate of DVT by day 12 was 3.6% placebo group. 0.9% enoxaparin 40 mg group, 1% enoxaparin 1.5 mg/kg group, and 2.1% tenoxicam group. The study found that 30% of patients in the placebo group eventually had the combined outcome of extension of the SVT toward the saphenofemoral junction, recurrent SVT, and progression to DVT or PE by day 12. Fifteen percent of the NSAID group, 8% of those receiving 40 mg enoxaparin, and 7% of those receiving 1.5 mg/kg enoxaparin had the combined outcome for thrombotic events showing that all active treatment groups significantly reduced DVT and SVT progression. At 3-month follow-up after cessation of therapy, there was still a significant decrease in the combined outcome of DVT and SVT in the active treatment groups, but not in DVT alone. There were no episodes of major bleeding or death during the study. Overall, this study showed a significant risk for DVT and SVT extension in the absence of medical treatment and suggested that LMWH, used either as a prophylactic or treatment dose, was the most effective therapy for prevention of thrombotic complications. Furthermore, the results suggest that the duration of therapy required further evaluation because most the recurrent VTE events in the treatment groups occurred after active treatment halted.

Since publication of the STENOX trial in 2003, there have been four additional randomized trials evaluating the use of medical therapy for the treatment of STP. The Vesalio investigators randomized 164 consecutive patients with acute SVT of the GSV not within 3 cm of the SFJ to nadroparin fixed prophylactic dose (2850 units) subcutaneously versus body weight–adjusted therapeutic doses of nadroparin for 1 month in a double-blind double-dummy fashion.[42] The main outcome of VTE complications at 3 months occurred in 7 prophylactic dose patients compared with six treatment dose patients (NS). No patients in either group developed major bleeding.

The CALISTO study group randomized 3002 patients with acute SVT not within 3 cm of the SFJ to fondaparinux 2.5 mg subcutaneously daily or placebo for 45 days. At 47 days follow-up,[43] the primary combined outcome of symptomatic VTE, death, extension to the SFJ, or symptomatic SVT recurrence occurred in 13 or 1502 patients (0.9%) of the fondaparinux group and 88 of 1500 patients (5.9%) receiving placebo. Major bleeding occurred in one patient in each group. Except for the outcome of death, all components of the primary outcomes were significantly reduced in the fondaparinux group.

A post hoc analysis revealed that SVT extension occurred in 3.6% of patients and DVT/PE occurred in 9.3% and 8.9%, respectively, in the placebo group compared with less than 1.0% SVT extension and no DVT/PE in the fondaparinux group. This analysis supported the conclusion that symptomatic SVT extension confers significant morbidity whether near the deep saphenous junction or not. Fondaparinux treatment was associated with less consumption of medical resources related to thromboembolic complications.[44]

Rathbun et al. randomized 72 patients with acute SVT of the upper or lower limb regardless of proximity to the deep veins to dalteparin 200 units/kg body weight (maximum dose, 18,000 units) day 1 then 10,000 units daily for up to 13 additional days versus ibuprofen 800 mg three times daily for up to 14 days with the primary outcome of SVT extension or

VTE at 14 days and 3 months.[45] Four patients receiving ibuprofen compared with no patients receiving dalteparin had thrombus extension at 14 days ($P = .05$); however, there was no difference in thrombus extension at 3 months. Both treatments significantly reduced pain. There were no episodes of major or minor bleeding during the trial. Of note, extension of thrombus during the time after ibuprofen and dalteparin were discontinued suggested that the treatment duration of 14 days may have been too brief or that there is a rebound phenomenon after the medication is halted. Finally, most recently, Cosmi et al. randomized 664 patients with SVT of the GSV or SSV or tributaries of at least 4 cm in length to parnaparin either 8500 IU daily for 10 days followed by placebo for 20 days (group A), or 8500 IU daily for 10 days followed by 6400 IU daily for 20 days (group B) or 4250 IU daily for 30 days (group C) in a double-blind fashion. The primary outcome of the composite of symptomatic and asymptomatic DVT, symptomatic PE, and relapse and/or symptomatic or asymptomatic SVT recurrence in the first 33 days with 60 days follow-up occurred in 15.6% group A, 1.8% group B, and 7.3% group C. No major hemorrhages occurred. The authors concluded that an intermediate dose of parnaparin for 30 days was superior to either 30-day prophylactic dose or 10-day intermediate dose treatment of SVT.[46]

A post hoc analysis for evaluation of risk factors showed that previous VTE, SVT, and/or family history of VTE were associated with the measured composite outcome. After LMWH treatment was stopped, the absence of varicose veins, previous VTE/SVT, or family history of VTE were associated with the outcomes. The authors suggested that these patients may deserve a higher intensity or longer duration of anticoagulant treatment.[47]

Nonsteroidal Antiinflammatory Medications

In addition to the trials discussed previously, the effectiveness of NSAIDs for SVT treatment has been the focus as part of a Cochrane systematic review.[2] Five trials overall (including STENOX) were evaluated. This analysis found that NSAIDs significantly reduced the risk of SVT extension or recurrence by 67% (OR 0.33; 95% CI 0.16-0.068), compared with placebo. However, there was no difference in the rate of VTE or resolution of symptoms. No episodes of major bleeding were recorded in these trials.

A JAMA clinical evidence synopsis of treatment for lower extremity SVT concluded that LMWH and NSAIDs are associated with lower rates of SVT extension or recurrence, but the effect on the reduction of symptomatic VTE was inconclusive. The authors stated that the data regarding topical or surgical therapy were inconclusive.[48]

Surgery

For SVT within 1 cm of the saphenofemoral junction, management by high saphenous ligation with or without saphenous vein stripping has been suggested to be the treatment of choice because of the recognized potential for extension into the deep system and embolization.[11,49-52] There have been only two randomized trials over the past 15 years that have evaluated surgery for the treatment of SVT. The first was a prospective study consisting of 444 evaluable patients randomized to six different treatment plans for the management of superficial thrombophlebitis: compression only; early surgery, with and without stripping; low-dose subcutaneous heparin; LMWH; and oral anticoagulant treatment.[53] Patients with SVT and large varicose veins but without any suspected/documented systemic disorder were included in this study. Criteria for inclusion were venous incompetence (by duplex investigation), a tender indurated cord along a superficial vein, and redness and heat in the affected area. Exclusion criteria were obesity, cardiovascular or neoplastic diseases, nonambulatory status, bone/joint disease, problems requiring immobilization, age older than 70 years, and the presence of superficial thrombophlebitis without varicose veins. Color duplex ultrasound scans were used to detect concomitant DVT and to determine extension or reduction of SVT at 3 and 6 months.

The incidence of SVT extension at 3 and 6 months was higher in the elastic compression alone group and in the saphenous ligation alone group ($P < .05$) compared with the groups with medical therapy or surgical therapy with ligation and stripping. There was no significant difference in the incidence of DVT at 3 months in any of the treatment groups. The results of this study are difficult to evaluate because the details of the treatment protocols were lacking. Furthermore, the exclusion criteria would eliminate many of the patients in whom SVT is routinely diagnosed in clinical practice limiting the generalizability of the findings.

Lozano et al. randomized 60 patients with above knee GSV SVT to saphenofemoral disconnection under local anesthesia with short-term compression bandage or enoxaparin 1 mg/kg twice daily for 1 week and then once daily for 3 weeks.[54] All patients in the trial were instructed to use compression stockings. Although the rate of VTE was less in the enoxaparin group (RR 0.2; 95% CI: 0.01-4), it did not reach statistical significance. The rate of wound infections was 6.7% (2/30 patients) in the surgical group. A systematic review of six studies included 246 patients altogether that received GSV ligation with or without stripping compared to 88 patients that received intravenous heparin followed by vitamin K antagonist for 6 weeks to 6 months showed no difference in SVT progression, DVT, or PE. The overall surgical complication rate including hematoma, seroma, or infection was 7.7%.[55]

Topical Therapy

As part of the previously mentioned Cochrane systematic review, seven trials that included topical treatment for SVT were evaluated.[2] One of these small trials compared the use of a novel liposomal heparin spray versus LMWH (Clexane 40 mg daily subcutaneously) in 46 outpatients. The main outcomes measures of erythema size and duplex assessment of thrombus regression were comparable in the two groups; however, there were three cases of DVT in the heparin spraygel group compared with one in the LMWH group.[56] To date, no further follow-up

studies have been published and the spray is not available for commercial use. Other topical treatments that have been evaluated include methythioadenosine, diclfenac gel, and etofenak gel. Although these treatments did demonstrate reduction in local signs and symptoms, none of these studies evaluated the effect on VTE or SVT extension.

Other therapies that have been evaluated in small trials include oral vasotonin, venoruton, oral heparansulfate, oral sulodexide, oxyphenbutazone, oral vitamin K antagonists, enzyme therapy, and desmin.[2] Most provided local symptomatic relief. The most recent Cochrane systematic review that included analysis of 30 randomized controlled trials for treatment of SVT concluded that both LMWH and NSAIDs reduced the incidence of extension or recurrent SVT without any significant effect on VTE. Topical treatments improved local symptoms.[55] More information will be forthcoming from two RCT: A clinical trial based on Europe is underway evaluating the use of the oral anticoagulant rivaroxaban 10 mg daily compared with fondaparinux for the treatment of SVT (NCT 01499953 clinicaltrials.gov). A second clinical trial for treatment of SVT in Canada compares rivaroxaban 10 mg to placebo (NCT 02123524).

To summarize, LMWH seems to provide the best outcomes for treatment of SVT with the least complications. However, questions remain regarding the duration of therapy, with 1 week likely being too short. The most recent American College of Chest Physicians guidelines have not changed and give the following recommendations for treatment of patients with SVT of the lower limb[57]:

1. *In those with SVT at least 5 cm in length, the use of a prophylactic dose of fondaparinux or LMWH for 45 days is suggested over no anticoagulation (Grade 2B).*

2. *In those with SVT who are treated with anticoagulation, fondaprinux 2.5 mg daily over a prophylactic dose of LMWH is suggested (Grade 2C).*

The most recent ACCP guidelines 2012 state low-level recommendations for the treatment of symptomatic SVT: 8.1.1. In patients with superficial vein thrombosis (SVT) of the lower limb of at least 5 cm in length, we suggest the use of a prophylactic dose of fondaparinux or LMWH for 45 days over no anticoagulation (grade 2B). 8.1.2. In patients with SVT who are treated with anticoagulation, we suggest fondaparinux 2.5 mg daily over a prophylactic dose of LMWH (grade 2C). The updated 2016 ACCP guidelines do not change these recommendations.

The Superficial Thrombophlebitis Treated by Enoxaprin Study Group (Decousus H et al). A pilot randomized double-blind comparison of a low-molecular-weight heparin, a nonsteroidal anti-inflammatory agent, and placebo in the treatment of superficial vein thrombosis. *Arch Intern Med*. 2003;163:1657–1663.

This double-blind study of 427 patients with symptomatic SVT compared the efficacy of enoxaparin prophylactic and therapeutic dose with NSAID and placebo for prevention of SVT progression and VTE and found all active treatments superior to placebo. Interestingly, there was no difference in outcomes for prophylactic and therapeutic enoxaparin.

The Vesalio Investigators Group (Prandoni P et al.). High vs. low doses of low-molecular-weight heparin for the treatment of superficial vein thrombosis of the legs: a double-blind randomized trial. *J Thromb Haemost*. 2005;3:1152–1157.

This multicenter, prospective, controlled, double-blind, double-dummy trial,164 patients with great saphenous vein SVT were randomized to receive fixed versus weight-adjusted nadroparin for 1 month. Therapeutic weight-adjusted nadroparin was found to be no more effective in preventing SVT progression and VTE at 3-month follow-up.

INTRODUCTION

Acute pulmonary embolism (PE) is a partial or complete occlusion of the pulmonary arteries, with hemodynamic consequences determined by the size and location of the embolus, preexisting cardiopulmonary disease, and the severity of ventilation and oxygenation compromise.

Acute PE is the third leading cause of cardiovascular mortality, with well over 100,000 deaths per year in the United States.[1] Recent registries and cohort studies suggest that approximately 10% of all patients with diagnosed acute PE will die within 3 months after diagnosis.[2,3] Despite being the most preventable cause of hospital mortality and despite advances in diagnosis and management, it accounts for 5% to 10% of in-hospital deaths.[4] The annual incidence rate of PE is estimated between 75 and 269 cases per 100,000 individuals as shown by studies in Western Europe, North America, Australia, and southern Latin America, with individuals 70 years of age or older having an incidence of up to 700/100,000.[5] The incidence continues to rise both because the population is aging and because contemporary diagnostic modalities are more sensitive.[6]

The physical obstruction of the pulmonary arteries is accompanied by hypoxemic vasoconstriction and release of potent pulmonary arterial vasoconstrictors, which further increase pulmonary vascular resistance and right ventricular (RV) afterload. The increasing RV afterload can cause RV hypokinesis and dilation, tricuspid regurgitation, and ultimately RV failure with subsequent life-threatening reduction in coronary perfusion and cardiac output. Although in the majority of the survivors pulmonary thromboemboli will gradually resolve, in

Abstract

Acute pulmonary embolism (PE) is a leading cause of cardiovascular mortality. Clinical presentation varies from asymptomatic to fatal; symptoms depend on the embolic burden and the severity of any underlying cardiopulmonary disease. While in the majority pulmonary thrombo-emboli will gradually resolve, in some patients, it may organize into fibrotic deposits permanently occluding the pulmonary arteries leading to chronic thromboembolic pulmonary hypertension (CTPH). Computed tomographic pulmonary arteriography (CTPA) is the method of choice for imaging the pulmonary vasculature in patients with suspected PE and transthoracic echocardiography (TTE) is the most common first-line examination to diagnose the signs of right ventricular dysfunction. The main goal of therapy is to prevent mortality; a secondary goal, recently suggested, is the prevention of late-onset CTPH to improve quality of life. Systemic anticoagulation is the standard of care and treatment can be escalated in the setting of high or intermediate risk PE. Treatment options include systemic thrombolysis, catheter directed interventions and surgical thromboembolectomy. Patient selection criteria, hemodynamic and clinical outcomes continue to be defined to determine the indications and benefits of invasive interventions.

some patients, it may organize into fibrotic deposits permanently occluding the pulmonary arteries, leading to chronic pulmonary hypertension and RV dysfunction. In the majority of patients with PE the cause is lower extremity or pelvic venous thrombosis.

CLINICAL PRESENTATION

Clinical presentation varies from asymptomatic (incidentally diagnosed) to fatal. Development of symptoms depends on the embolic burden and the severity of any underlying cardiopulmonary disease. The diagnosis of PE is never made in approximately 70% of those who survive the initial event. Thus it is critical that a high level of suspicion is maintained.

In most patients, PE is suspected on the basis of dyspnea, chest pain, presyncope or syncope, and/or hemoptysis. The onset of dyspnea may be acute and severe usually representing a PE in the main or lobar vessels; in small peripheral PE, it is often mild and may be transient. Chest pain is a frequent symptom and is usually caused by pleural irritation due to distal emboli causing pulmonary infarction. In central PE, chest pain may have a typical angina character, possibly reflecting RV ischemia and requiring differential diagnosis with acute coronary syndrome or aortic dissection. Hemoptysis can occur in case pulmonary infarction.

Common clinical signs include tachypnea, tachycardia, rales or decreased breath sounds, jugular venous distension, and rarely fever mimicking pneumonia. Half of the patients will also present with symptoms of leg deep venous thrombosis (DVT) or rarely with symptoms of upper extremity DVT. Arterial hypotension and shock are rare (<10%) but critical clinical presentations because they indicate central PE and/or a severely reduced hemodynamic reserve. Syncope is infrequent but may occur regardless of the presence of hemodynamic instability.[7]

DIAGNOSIS

A high index of suspicion is required for the diagnosis of PE because symptomatology is nonspecific and overlaps with other pathologies, such as acute coronary syndromes, aortic dissection, pericardial tamponade, new onset arrhythmia, pneumonia, and pneumothorax.[8,9] Clinical impression alone has a sensitivity and specificity of 85% and 51%, respectively.[10] For this reason, clinical prediction algorithms have been developed (see later). Various laboratory and imaging tests are complimentary of the clinical suspicion.

Laboratory Tests

Routine blood tests in patients with PE are nonspecific and may include leukocytosis, elevated LDH and AST, CRP, and ESR. Plasma D-dimer levels, preferably using a high-sensitivity assay, are useful in patients who are unlikely to have PE or the clinical probability is low or intermediate targeting to reduce unnecessary computed tomography pulmonary arteriography (CTPA) or lung scans. In these cases a normal D-dimer level (<500 ng/mL) practically excludes PE. On the contrary, a positive D-dimer test is associated with a notoriously low specificity and should prompt further testing. Fibrin is otherwise produced in a wide variety of conditions such as cancer, inflammation, bleeding, trauma, surgery, and necrosis. For patients in whom PE is likely, a normal D-dimer is not sufficient to rule in or out PE. Overall, D-dimer is a sensitive but not specific diagnostic tool for patients with suspected PE. The specificity decreases even more with age. However, if D-dimer cutoff values are adjusted to age (age × 10 mg/L older than 50 years) the rate of patients in whom PE can be excluded increases from 6.4% (using 500 mg/L as cutoff level) to 30%, without any additional false-negative findings.[11,12]

Biomarkers of RV dysfunction include troponin and brain natriuretic peptide (BNP). Their diagnostic value is limited because they are neither sensitive nor specific. However, in patients with confirmed PE, cardiac troponin (TnT or TnI) and BNP (or its precursor NT-proBNP) tests are recommended for further stratification of patients at intermediate risk (see later).[13,14] The standard cutoff values for TnT, TnI, and BNP are 0.1 ng/mL, 0.4 ng/mL, and 90 pg/mL, respectively, although they may vary depending on the assay and the lab. Similar to D-dimers, age-adjusted and not standard values are better predictors of adverse outcomes for troponin (e.g., high sensitivity TnT is prognostic at 45 pg/mL instead of 14 pg/mL for patients older than 75 years).[15] NT-proBNP has its optimal prognostic value when it exceeds 600 pg/mL instead of the previously proposed 300, 500, or 1000 pg/mL.[16] An alternative novel marker of myocardial injury is the heart-type fatty acid–binding protein emerging as a significant predictor of mortality in patients with intermediate risk PE.[17-19]

Arterial blood gases are also nonspecific and do not assist in the diagnosis of PE. However, hypoxemia may have a prognostic value for confirmed PE as an indicator of anticipated complications, respiratory failure, or death.[20] However, pulse oximetry is a more reasonable noninvasive alternative, at least for the low- or intermediate-risk patients.

Electrocardiogram

Electrocardiographic changes associated with acute PE are neither sensitive nor specific. They are similar to all other causes of pulmonary hypertension (e.g., acute bronchospasm, pneumothorax). The S1Q3T3 (prominent S wave in lead I, Q wave and inverted T wave in lead III) pattern is a sign of acute RV overload (acute cor pulmonale) and reflects strain; it is seen in less than 20% of diagnosed PEs. The greatest utility of the ECG in a suspected PE is to rule out acute myocardial infarction.

Chest X-ray

Chest radiographs are not sensitive or specific for PE but can rule out alternative diagnoses (e.g., pneumothorax). Frequently patients with PE have a normal chest x-ray. Atelectasis or parenchymal density and pleural effusion are probably the most frequent findings. Radiographic signs such as the Fleischner sign (enlarged pulmonary artery), Hampton hump (peripheral

wedge of airspace opacity—lung infarction), Westermarck sign (regional oligemia), and knuckle sign (abrupt tapering or cutoff of a pulmonary artery) are rare but should raise the suspicion of PE.[21]

Computed Tomographic Pulmonary Arteriography

Computed tomographic pulmonary arteriography (CTPA) is the method of choice for imaging the pulmonary vasculature in patients with suspected PE (Fig. 151.1A). It allows adequate visualization of the pulmonary arteries down to at least the segmental level and has a high predictive value, particularly when combined with clinical probability. Based on the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) II trial, CTPA has a sensitivity of 83% and a specificity of 96% and several studies have demonstrated its efficiency as a stand-alone imaging test for confirming or excluding PE.[22-26]

CTPA, particularly if it is electrocardiogram gated, can further serve as a prognostic tool for the severity and outcomes of PE.[22-30] Heart chamber dimension measurements may detect RV enlargement as an indicator of RV dysfunction, typically defined as a right-to-left ventricular end-diastolic dimensional ratio ≥0.9 (see Fig. 151.1B).

Echocardiogram

Transthoracic echocardiography (TTE) is the most common first-line examination to diagnose the signs of RV dysfunction but cannot definitely diagnose PE because an elevated RV pressure may be the result of other conditions such as pulmonary hypertension and RV infarction. Echocardiography is most useful in patients with diagnosed PE, for prognostic purposes. Confirmation of RV dysfunction is a key determinant of PE prognosis because it seems to increase the risk of death by at least twofold.[31]

A variety of different methods for the assessment of RV dysfunction on TTE have been proposed, and the literature shows variable results for the prognostic power of TTE signs of RV dysfunction to predict adverse outcomes.[32]

RV/LV end-diastolic diameter ratio has been commonly used as an indicator of RV dysfunction, defined as RV/LV end-diastolic ratio greater than 1, but its reproducibility is fair because the ventricular walls cannot always be well defined (see Fig. 151.1C).[33,34] Tricuspid annular plane systolic excursion (TAPSE) is a quantitative echocardiographic parameter that is the least user dependent and most reproducible. Another sign of RV dysfunction is the depressed contractility of the RV free wall compared with the RV apex (McConnell sign), reported to retain a high positive predictive value for PE, even in the presence of preexisting cardiorespiratory disease.[33-35] Finally a relatively rare finding suggestive of PE is thrombus in the RV, also known as thrombus in transit. Thrombus in the pulmonary arteries can be seen with transesophageal echocardiography.

Overall, echocardiography is not recommended as part of the routine diagnostic workup in patients with suspected PE, unless they are hemodynamically unstable. On the other hand, confirmation of RV dysfunction may justify emergency reperfusion treatment for PE if immediate CTPA is not feasible.[8]

Other Imaging Modalities

Ventilation/perfusion (V/Q) scans are rarely used currently unless the patient with a suspected PE is pregnant or has renal insufficiency that prohibits CTPA. V/Q scanning is a highly sensitive but poorly specific study for the diagnosis of PE. When the V/Q scan is inconclusive (and CTPA contraindicated) magnetic resonance pulmonary angiography can be a reasonable alternative, acknowledging the complexity of the protocol, suboptimal resolution, and low sensitivity. Finally, invasive pulmonary angiography is a historical "gold standard," that currently would be justified only for diagnostic purposes provided that some kind of catheter-directed intervention (CDI) is planned (e.g., catheter thrombolysis or aspiration thrombectomy) upon confirmation of PE (see Fig. 151.1D).

Lower extremity venous duplex will show a DVT in 30% to 50% of patients with PE, and finding a proximal DVT in patients suspected of having PE is considered sufficient to warrant anticoagulant treatment without further testing. Out of those who have symptoms or clinical signs of DVT, only half will have it confirmed by ultrasound. Patients with acute symptomatic PE and confirmed DVT have an almost twofold higher risk of short-term death when compared with those without a DVT.[8,36]

Probability Algorithms and Diagnostic Strategies

Despite the limited sensitivity and specificity of symptoms, signs, and common tests, the combination of findings evaluated by clinical judgment or by the use of probability algorithms allows the classification of patients with suspected PE into distinct categories of clinical or pretest probability that correspond to an increasing actual prevalence of confirmed PE. Clinical judgment is crucial and of outmost importance; however, it lacks standardization; therefore, several explicit clinical prediction rules have been developed. These rules apply to ***nonpregnant hemodynamically stable*** patients. Hemodynamically unstable patients with suspected PE are expected to receive an expeditious life-saving reperfusion therapy (e.g., systemic thrombolysis), skipping a potentially time-consuming probability assessment. For these hemodynamically stable patients in whom PE is suspected, following clinical and laboratory assessment, the pretest probability is most frequently assessed using the Wells or modified Geneva scores, both of which were recently simplified and validated (Table 151.1).[37-42]

Among patients who are likely to have PE based on these scores or unlikely but with a D-dimer level ≥500 ng/mL, CTPA is the imaging modality of choice. If negative, no further testing is required; if positive, treatment (anticoagulation) should be initiated. While awaiting the CTPA, initiation of empiric anticoagulation can be individualized based on the clinical scenario. Patients who are unlikely to have PE do not require a CTPA but a sensitive D-dimer test. If the levels are less than 500 ng/mL, no further testing is required (Fig. 151.2).

RISK STRATIFICATION

PE severity should be based on an individual estimate of PE-related early mortality risk rather than the extent of pulmonary vascular obstruction. Although it is attractive to stratify types of acute PE on the basis of the anticipated mortality, this approach is hampered by the presence of comorbidities; for example, a non–high risk PE might be associated with a high mortality risk in a patient with obstructive airway disease or congestive heart failure.[43] Despite this relative weakness, PE risk stratification guides major treatment decisions in all major guideline documents.[8,44,45]

PE is classified as low, intermediate (or submassive), and high (or massive) risk based on the anticipated 30-day mortality rate. The terms "submassive" and "massive" were initially suggested on the basis of angiographic burden of emboli by use of the Miller Index, but these are now of limited use as the embolic burden is a poor indicator of mortality.[46,47]

With small variations in their definitions as given by societal guidelines, low-, intermediate-, and high-risk PE are defined as follows:

- Low risk: normotensive patients without imaging evidence of RV dysfunction or elevated cardiac biomarkers. Approximately 40% of all PE patients fall into this category. They have excellent short-term prognosis with a mortality rate approximately 1% to 2% or less.[44,48]

TABLE 151.1 Probability Scores for Pulmonary Embolism

Wells Score[41]	PROBABILITY SCORE Original	Simplified
Previous PE or DVT	1.5	1
Heart rate ≥ 100 b.p.m	1.5	1

DVT, Deep venous thrombosis; *PE*, pulmonary embolism.

- Intermediate risk: normotensive patients with either imaging evidence of RV dysfunction or elevated cardiac biomarkers or both. This group constitutes approximately 55% of all PEs, and the mortality rate ranges between 3% and 15%.[44,49-51]
- High risk: hemodynamically unstable patients with sustained shock or hypotension (<90 mm Hg) or cardiac arrest. These patients are rare, approximately 5%, but in-hospital mortality ranges between 15% and 30% or may exceed 60% for those requiring cardiopulmonary resuscitation.[3,50-53]

Several scoring systems have been devised for risk stratification, the most widely used being the Pulmonary Embolism Severity Index (PESI) and its simplified version, both validated to identify clinical factors associated to poorer outcomes (Table 151.2).[43,54] Approximately one-third of PE patients are at low mortality risk of an early adverse outcome as indicated by a PESI class I or II (mortality up to 3.5%) or a simplified PESI of 0 (mortality up to 2.1%). Patients in PESI class III to V have a 30-day mortality rate of up to 24.5%, and those with a simplified PESI ≥1 up to 11%. Normotensive patients in PESI class ≥III or a simplified PESI of ≥1 are considered to constitute an intermediate-risk group. The prediction is enhanced when these scores are combined with imaging or laboratory findings, because there is no single test with sufficient positive predictive value that could justify an aggressive treatment. Within the intermediate-risk category, further risk assessment can be elaborated focusing on the status of the RV and/or on cardiac biomarkers (Table 151.3). Multiple observational studies and meta-analyses have suggested that the combination of clinical variables (e.g., tachycardia, mild hypotension), myocardial injury (e.g., high troponin), and RV dysfunction (e.g., RV dilatation, high BNP) particularly in those with concomitant DVT, identifies the more severe intermediate-risk patients with acute PE.[55] Recently, the European Society of Cardiology introduced the terms intermediate low and intermediate high risk, with intermediate high risk encompassing patients having both imaging findings of RV dysfunction and positive biomarkers (troponin or BNP/proBNP).[8]

TREATMENT

The main goal of therapy is to prevent mortality; a secondary goal, recently suggested, is the prevention of late-onset chronic thromboembolic pulmonary hypertension (CTEPH) to improve quality of life.[4,8,44-46,56-59]

Initial Supportive Therapies

Although patients classified as low-risk PE do not require any specific support, it is vital that those with intermediate- or high-risk PE receive supportive treatment. The initial approach to patients suspected with PE should assess hemodynamic stability; if a patient is unstable (or borderline stable), general support should be provided while diagnostic evaluation is ongoing and includes:

- Airway, breath, and oxygenation assessment using pulse oximetry
- Oxygen supplementation targeting O_2 saturation ≥90. Severe hypoxemia or respiratory failure should prompt consideration for intubation. When mechanical ventilation is required, positive end-expiratory pressure should be applied with caution because it may reduce venous return and worsen RV failure in patients with massive PE.
- Pulse rate and blood pressure assessment

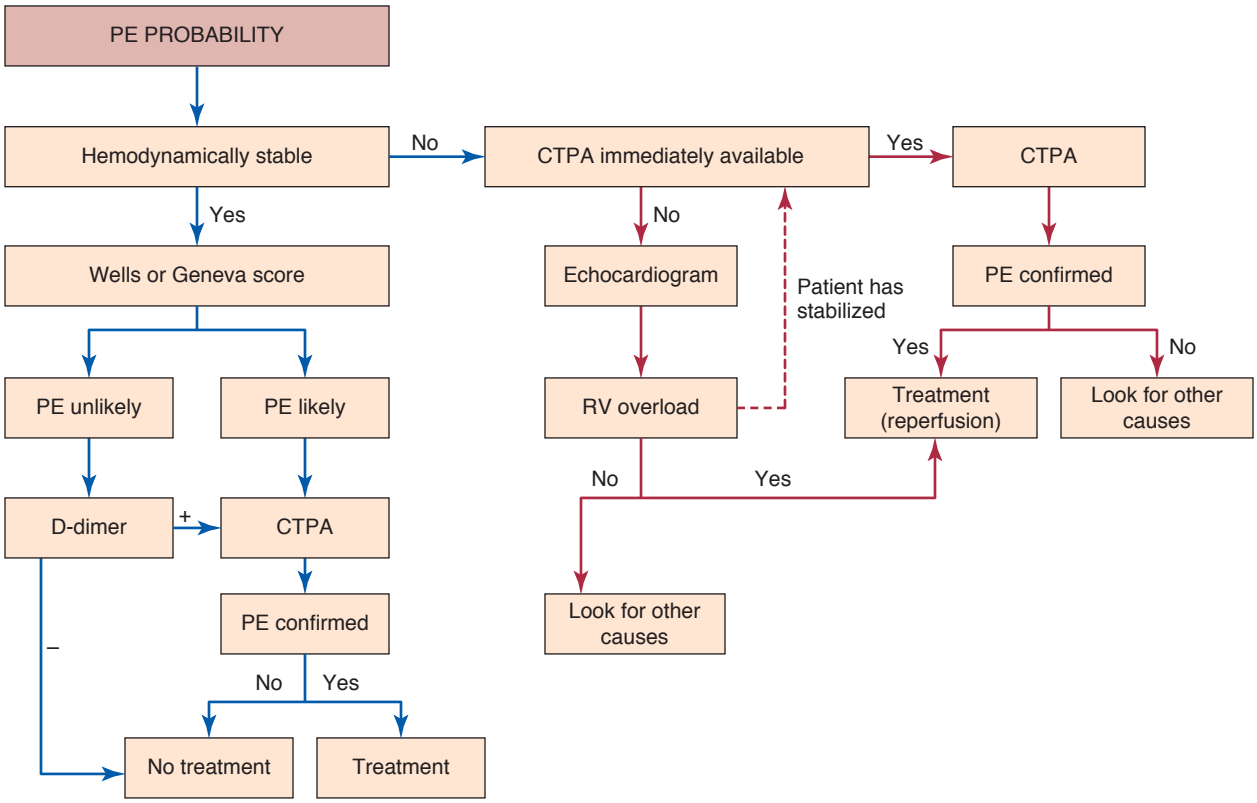

Figure 151.2 Diagnostic algorithm for patients with suspected pulmonary embolism. *CTPA,* Computed tomography pulmonary arteriography; *PE,* pulmonary embolism; *RV,* right ventricular.

TABLE 151.2 Pulmonary Embolism Risk Stratification Based on the Pulmonary Embolism Severity Index (PESI)

Predictor	PESI SCORING	
	Original	Simplified
Age	Age in years	1 (if >80 years)
Men	10	—
Cancer	30	1
Heart failure	10	1
Chronic lung disease	10	
Pulse ≥110 b.p.m	20	1
Systolic pressure <100 mm Hg	30	1

Saturation <90%	20	1
Risk		
Very low risk (class I)	≤65	0
Low risk (class II)	66–85	
Intermediate risk (class III)	86–105	≥1
High risk (class IV)	106–125	
Very high risk (class V)	≥126	

- Peripheral intravenous access with or without fluid administration. In hypotension, intravenous fluid should be administered in small volumes (500-1000 mL of normal saline) to avoid overloading an otherwise stretched RV. Should the fluid challenge fails, vasopressor therapy should follow. Norepinephrine is the most suitable agent because it is less likely to cause tachycardia and exacerbate hypotension. Norepinephrine improves RV function via a direct positive inotropic effect, while also improving RV coronary perfusion by peripheral vascular alpha-receptor stimulation.
- Empiric initiation of anticoagulation balancing the clinical suspicion of PE, the hemodynamic profile, the risk of bleeding, and the expected timing of the diagnostic tests should be considered. For the hemodynamically unstable patients who are anticipated to receive thrombolysis or embolectomy, unfractionated heparin is preferred. Empiric anticoagulation can be also initiated in hemodynamically stable patients with a high or moderate clinical suspicion of acute PE, when the diagnostic evaluation is expected to take longer than 4 hours.[45,60]

Anticoagulation

Unless contraindicated, all patients with acute PE should receive systemic anticoagulation with the objective of preventing both early death and recurrent symptomatic or fatal event. Anticoagulation should be initiated during the diagnostic workup in

TABLE 151.3 Imaging and Laboratory and Clinical Tests for Risk Stratification of Pulmonary Embolism (PE)

	Markers of Non–Low Risk PE	Remarks
Echocardiogram[31-35]	RV/LV EDD >1 TAPSE ≤ 1.6 cm TRJV >2.6 m/s^{-1} Estimated RVSP ≤52 mm Hg McConnell Sign + IVC collapsibility >50% + RV hypokinesia + Leftward shifting of IVS +	RV dysfunction parameters have been identified as independent predictors of death. With the exception of TAPSE, the complex geometry of the RV and the subjective nature of the measurements are limiting factors.
CT Angiogram[22-30]	RV/LV EDD ≥0.9	RV dilatation has been identified as independent predictor of death. No clear association has been shown for clot burden.
Lower Leg Duplex[36]	DVT +	Proximal DVT in patients with symptomatic PE is an independent predictor of death (OR 1.9; 95% CI 1.5-2.4).
Troponin[13,15,16]	TnT >0.1 ng/mL TnI >0. 4 ng/mL	High troponin levels are independent predictors of death. Limited detection time-window (peak at 8 hours). Optimal cutoff values are yet to be defined. High sensitivity assays and age adjusted values may be more accurate.
BNP[13,14,16]	>90 pg/mL	High levels predict death (OR 6.5; 95% CI 2.0–2.1)
Pro-BNP[14,16]	>600 pg/mL	High levels predict death (OR 6.3; 95% CI 2.2-18.3)
HFAB[17–19]	>6 µg/lt	Novel biomarker with significant prognostic value for mortality (OR 40.8; 95% CI 11.8-140.1).
PESI[43,54]	Original: ≥86 (class III-V) Simplified: ≥1	Validated widely used clinical score.

patients with intermediate or high clinical probability of PE. The standard duration of anticoagulation should cover at least 3 months (see Chapter 39).[8,44,45]

In the acute PE phase, parenteral anticoagulation (unfractionated heparin, low-molecular-weight heparin [LMWH], or fondaparinux) should be initiated first, followed by the parallel administration of a vitamin K antagonist (warfarin) for at least 5 days and until INR reaches the desired therapeutic level (2.0-3.0). Novel oral anticoagulants, factor Xa inhibitors (rivaroxaban, apixaban, edoxaban), and direct thrombin inhibitors (dabigatran) do not require monitoring and dose adjustments or prolonged bridging therapy. These agents are noninferior to warfarin.

Inferior Vena Cava Filter

As a general guideline, inferior vena cava (IVC) filters are indicated in patients with acute PE who have absolute contraindications to anticoagulant drugs and in patients with objectively confirmed recurrent PE despite adequate anticoagulation.[8,44,45] This is irrespective of the presence of lower extremity thrombus because it may remain undetected in the pelvis. Current guidelines are against the routine use of IVC filters in patients who can be anticoagulated. However, because it is uncertain if there is benefit to placing an IVC filter in anticoagulated patients with severe PE (e.g., hypotension), this recommendation against insertion may not apply to this select subgroup (see Chapter 152).[61]

Thrombolysis

Thrombolysis is reserved for high-risk and selected cases of intermediate-risk PE.[8,44,45,62] The greatest benefit is observed when treatment is initiated within 48 hours of symptom onset, but thrombolysis can still be useful in patients who have had symptoms for up to 14 days. The standard route for administration of lytics is intravenous through a peripheral line; however, catheter-directed lytic administration directly into the pulmonary arterial tree is increasingly entering clinical practice. Contraindications to thrombolysis in PE patients have not been exclusively studied in this patient population but have been extrapolated from patients with myocardial infarction.[44,63] It is unclear to what extend these apply for catheter-directed thrombolysis, and preliminary data are controversial regarding bleeding events in the setting of a "contraindication."[64-68]

Systemic Thrombolysis

Systemic intravenous thrombolysis is universally recommended for high-risk PE but remains controversial for intermediate-risk PE. The most widely suggested regimen is 100 mg alteplase (recombinant tissue plasminogen activator [rtPA]) over 2 hours.

Other rtPAs such as reteplase and desmoteplase have been tested against alteplase in acute PE, with similar results in terms of hemodynamic parameters; tenecteplase has been tested against placebo (heparin alone) in patients with intermediate-risk PE.[8,58,69,70] Heparin infusion is typically held during thrombolysis.

An analysis of the US nationwide inpatient sample (1999-2008, $n = 72.230$) demonstrated an all-cause (47% vs. 15%) and PE-related (42% vs. 8.4%) mortality benefit for thrombolysis in massive PEs.[71] A large meta-analysis of thrombolysis for PE reported pooled data from 16 trials comprising 2115 patients (1775 intermediate risk).[72] Thrombolysis was associated with lower mortality risk compared with standard anticoagulation (2.17 vs. 3.89%, $P = .01$). The mortality benefit persisted when the analysis was limited to patients with intermediate-risk PE (1.39% vs. 2.92%, $P = .03$). However, thrombolysis was associated with higher rates of major bleeding (9.24 vs. 3.42%, $P < .001$) and intracranial hemorrhage (1.46 vs. 0.19%, $P = .002$). The increased major bleeding was primarily driven by patients older than 65 years.

A meta-analysis (1990-2013, 440 patients) suggested that a low-dose protocol (e.g., 50 mg) has similar efficacy and may be safer than the standard 100 mg dose.[73]

Interestingly, despite the marked reduction of case fatality rate with systemic thrombolysis in unstable patients, only 30% receive it, partly because of various contraindications to lytics and concerns for complications.[53,71] Still, data suggest that withholding thrombolytic therapy in the elderly or those with comorbid conditions might not be the safest approach in terms of mortality. Unstable patients with PE who received thrombolytic therapy have a lower in-hospital case fatality rate irrespective of age and comorbid conditions.[74] For intermediate-risk PE, given that mortality is infrequent, it is difficult to demonstrate a survival benefit. Quality of life measures such as late-onset CTEPH and functional disability may be more relevant outcomes, so the verdict is still out.

Catheter-Directed Interventions

The limitations and complications of systemic thrombolysis are driving contemporary practice toward CDIs as a first-line treatment in the appropriate clinical setting as a way to provide the benefits and minimize adverse events of systemic thrombolytic therapy. Despite the publication of the first comparative studies (CDIs vs. anticoagulation or vs. high- or low-dose systemic lysis), there is lack of sufficient robust evidence to confirm the assumption of combined efficacy and safety, particularly in the high-risk population.[46,65,75,76]

The Ultrasound Accelerated Thrombolysis of Pulmonary Embolism (ULTIMA) trial was the first randomized controlled trial to include CDIs for intermediate-risk PE comparing standardized fixed-dose ultrasound-assisted thrombolysis (USAT) (10 mg of tPA per lung for 15 hours) and anticoagulation with anticoagulation alone.[75] In the USAT group but not in the anticoagulation group, the mean RV/LV ratio was significantly reduced at 24 hours but became comparable between the two groups at 90 days. The RV systolic function was significantly improved in the USAT group versus the heparin group at both 24 hours and 90 days. In both study groups, minor bleeding complications were rare, and there were no major bleeding complications. However, in real-world practice, CDIs are not risk-free procedures.[64,65,72] The pooled major bleeding rate, from 10 studies with 469 patients is 3.5% (Fig. 151.3).[64] This pooled major bleeding rate is similar to that obtained from the U.S.

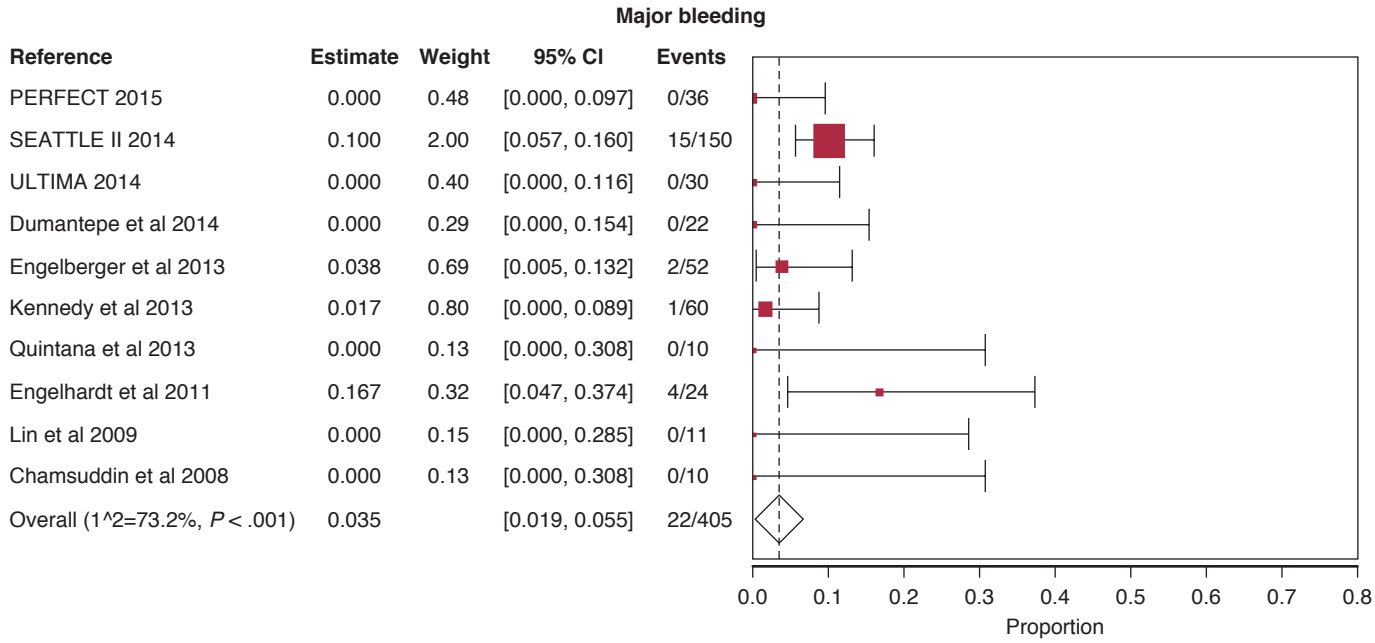

Figure 151.3 Fixed-effect meta-analysis for major bleeding in ultrasound-assisted catheter-directed interventions for pulmonary embolism. The figure presents major bleeding rates from individual studies, 95% confidence interval (CI) for each trial and overall estimate of pooled proportion with 95% CI. (Figure obtained with permission from Abou Ali AN, Liang NL, Chaer RA, Avgerinos ED. Catheter interventions for pulmonary embolism: are they really that safe? *Am J Cardiol.* 2016;118:307–308.)

Figure 151.4 Catheter-directed thrombolysis. (A) Five-French standard multi-sidehole catheter. (B) Ultrasound-assisted thrombolysis catheter, EkoSonic (Endovascular System, EKOS Corporation; Bothell, Washington). The catheter is composed of a 5.2-F multi-sidehole infusion catheter and a microsonic core wire containing the ultrasound elements.

nationwide inpatient sample analysis (4.9%) and our recently published experience (6.2%).[65,74] Catheter interventions can be related to unique adverse events like heart and lung injuries, contrast-induced nephropathy and other device-related complications.[67] A combination of these major adverse events with major bleeding rates exhibits better the safety profile of these interventions, which still seems to be better than that of systemic lysis. The stroke rate in the majority of studies is essentially 0%. CDIs should be provided in selected patients where appropriate expertise is available. These interventions appear to be safer than systemic thrombolytics for the treatment of acute PE, but they are definitely not as safe as initially thought.

As a general rule, whenever thrombolysis is considered as a treatment option, either in the setting of high- or intermediate-risk PE, CDIs may be the only alternative for patients at a high bleeding risk (e.g., recent surgery) and can be considered a reasonable alternative in patients at low risk for bleeding.

Technical Considerations for Catheter-Directed Interventions

Contemporary CDIs are variable and can be performed with or without thrombolysis. The latter include thrombus fragmentation and/or aspiration techniques, with no lytic agents, for patients with absolute contraindications to thrombolysis; however, their efficacy and safety remain controversial.[46,67,77,78]

The standard technique involves administration of local thrombolytics through a multi-sidehole catheter placed unilaterally or bilaterally into the pulmonary artery thrombus (transjugular or transfemoral). The use of ultrasound to enhance thrombolytic permeation of large emboli holds currently the highest level of evidence in both efficacy and safety.[75,77] The EkoSonic Endovascular System (EKOS Corporation; Bothell, Washington) combines a multi-sidehole drug infusion catheter with a multielement ultrasound core wire and was approved by the U.S. Food and Drug Administration (FDA) for use in patients with PE (Fig. 151.4). However, the clinical superiority of USAT over conventional catheter-directed thrombolysis has not been proven.[66,79] With or without ultrasound acceleration the optimal tPA dose has not been set yet, but in published studies it ranges between 15 and 25 mg, reflecting an uncertainty as to when to terminate lysis. A clinically relevant improvement, rather than thrombus reduction, should guide therapy. Apart from clinical parameters (pulse rate, blood pressure, oxygen requirements), invasive pressure tracings (right atrium, right ventricle, main pulmonary artery) or cardiac echocardiographic parameters can be used as adjuncts to monitor the progress of therapy. In high-risk PE, reversal of hemodynamic instability should primarily guide the termination of treatment. In patients with intermediate-risk PE, termination should be guided by improved pulmonary artery pressures and/or reversal of right heart strain

and/or overall clinical improvement (e.g., reduced oxygen requirements, improved pulse rate). It remains unclear at what rate heparin infusion should be maintained during lytic infusion. Some recommend DVT therapeutic heparin protocols; others recommend minimal heparin (500 units/hour) just to prevent sheath thrombosis. Our group has established a therapeutic low-dose heparin protocol (atrial fibrillation protocol: target aPTT 60-80 seconds).

Several adjuncts and technical alternatives have been described in various combinations, targeting rapid clot debulking for the unstable patients, particularly when lytics are contraindicated. The majority of these technical adjuncts and devices lack background evidence and are not approved by the FDA for treatment of PE. As such, no standardized technical algorithm yet exists, and as new technology evolves many of the adjuncts that were used a few years ago are currently obsolete.[46,78]

Rotating pigtail or balloon embolectomy catheters have been broadly reported for thrombus fragmentation.[78,80-82] Because fragmentation may lead to distal clot embolization, adjunctive aspiration thrombectomy and subsequent lysis may be needed. The rational of fragmentation is that it allows exposure of a greater embolic surface area to the lytic drug's effect; otherwise local thrombolytic infusion will be no more efficacious than systemic delivery because it tends to rapidly wash into nonoccluded arteries.[78,81] The Angio-Jet Rheolytic Thrombectomy System (Boston Scientific, Marlborough, Massachusetts) provides pharmacomechanical thrombolysis and has been used in the past for PE, with several adverse events and deaths reported. As a result, the FDA has issued a black box warning on the device label. Despite a recent study advocating its use in the setting of massive PE, it should probably by avoided.[46,78]

Thrombus aspiration can be performed as an adjunct to any CDI or as a stand-alone technique using dedicated large bore suction devices. The simplest aspiration technique is by using any 5- to 9-F end-hole catheter, or dedicated steerable aspiration catheters 10- to 14-F in size (Fig. 151.5). A novel, but with limited evidence in the PE setting, device is the Vortex AngioVac aspiration system (AngioDynamics, Latham, New York) that is composed of an extracorporeal bypass circuit that facilitates drainage, filtration, and reinfusion of blood cleared from clot.[83] A funnel-shaped distal tip facilitates en bloc removal of the embolus. The technique is FDA approved, and successful outcomes in the setting of PE have been reported in small case series. The device requires a 26-F delivery sheath and can be used from the femoral or jugular approach and allows embolectomy without the use of lytic agents (Fig. 151.6). Smaller profile devices are being evaluated, such as the Aspire Mechanical Thrombectomy System (Control Medical Technology, Park City, Utah), the Indigo System CAT 8 Aspiration Catheter (Penumbra Inc., Alameda, California), and the Flowtriever (Inari Medical, Irvine, California).

Surgical Thrombectomy

Traditionally, surgical pulmonary thromboembolectomy is reserved for patients with documented central PE and refractory cardiogenic shock despite maximal supportive therapy and who have absolute contraindications to or have failed thrombolytic therapy. Surgical thrombectomy aims to rapidly reduce RV afterload by physically removing proximal pulmonary artery thrombi.[84-87]

Outcomes have improved in the past 2 decades, with mortality declining from 30% to well below 10% in centers with appropriate expertise.[87-90] Mortality should be anticipated to be significantly higher when surgical thrombectomy follows a failed thrombolysis and even worse after a cardiac arrest; best results are achieved with primary early surgery.[88,91,92]

Surgical embolectomy is performed through a median sternotomy using a normothermic cardiopulmonary bypass. Aortic cross-clamping and cardioplegic cardiac arrest are usually not needed. The main pulmonary artery is opened and the thrombotic material is extracted. The right atrium and ventricle are also explored for possible thrombi and a patent foramen ovale is closed, if present.

Extracorporeal Membrane Oxygenation

Transportable extracorporeal membrane oxygenation (ECMO) assistance systems with percutaneous femoral cannulation can be helpful in critical situations, ensuring circulation and oxygenation until definitive diagnosis. ECMO unloads the acutely failing right heart, providing effective hemodynamic and respiratory support for patients who develop massive PE until recuperation of the initial pulmonary insult. It has been increasingly used in some centers for unstable PE patients who are not responding to other treatment modalities or as a bridge for catheter-based or surgical embolectomy.[93-96]

There are no clear prognostic indicators to appropriately select unstable PE patients who are likely to benefit from ECMO support. Although it seems reasonable to offer ECMO as a last resort to PE patients who are otherwise expected to die, this decision has to be reached on an individual basis to avoid providing futile care and wasting resources. Several factors should be considered in this decision, including patient's comorbidities and the local expertise.

Early Discharge and Home Treatment

Outpatient treatment of PE, giving the first dose of anticoagulation in the hospital, can be safe and effective in select patients who fulfill certain criteria. Clinical probability scores, mainly the PESI score, are predominately used to preselect these patients. The value of NT-proBNP as a laboratory biomarker for selecting candidates for home treatment has been evaluated, and, among those with clinically defined very-low-risk PE and NT-proBNP levels less than 500 pg/mL, none died or suffered recurrence of VTE or major bleeding complications during a 3-month follow-up.[97] Still, the value of cardiac biomarkers or echocardiography to exclude RV dysfunction before early discharge have not been thoroughly investigated, and they are not routinely recommended.[45]

Randomized studies and meta-analyses have set the following features as mandatory for consideration of early discharge[98-101]:

- Low-risk PE as defined by the original or simplified PESI score

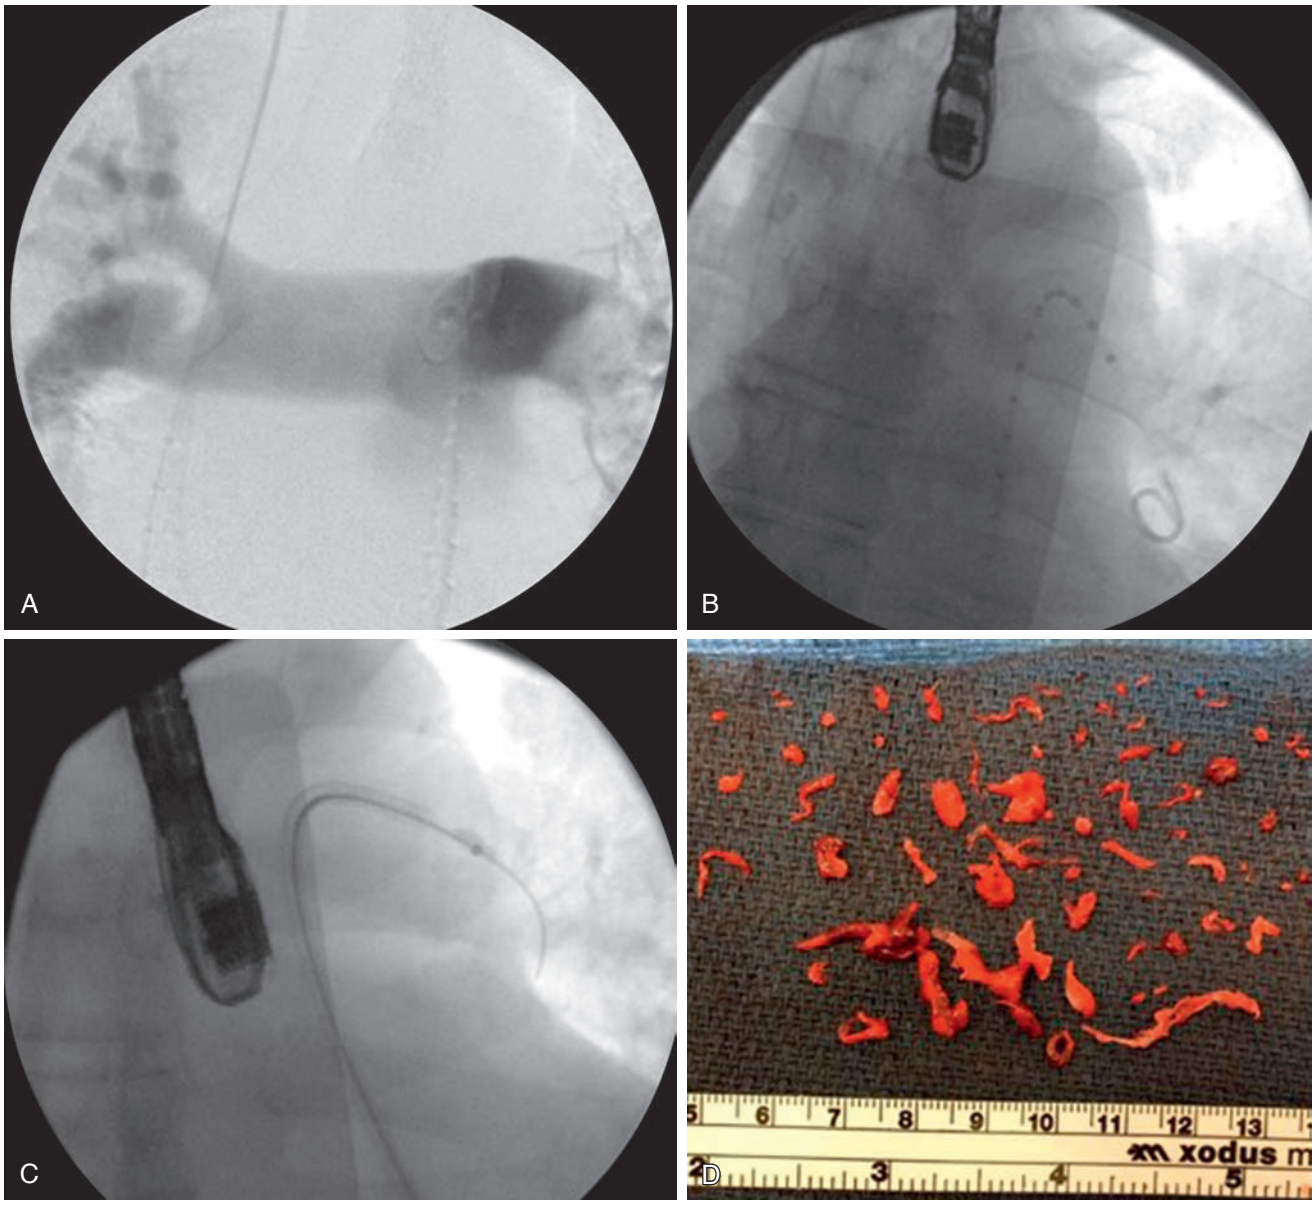

Figure 151.5 Massive pulmonary embolism (right ventricular strain and hemodynamic decompensation) on a patient with recent surgery and with intrapulmonary bleed due to the pulmonary infarct. (Figure obtained with permission from Avgerinos ED, Chaer RA. Catheter-directed interventions for pulmonary embolism. *J Vasc Surg*. 2015;61:559–565.)

- Normal pulse and blood pressure
- No oxygen requirements
- No risk factors for bleeding including thrombocytopenia (<70.000/mm^3)
- No serious comorbid conditions (e.g., coronary artery disease, heart failure, chronic pulmonary disease, renal or liver failure)
- Mental capacity to understand the risk and the benefits
- Patient not living alone and having access to telephone and ability to return to hospital promptly if there is clinical deterioration
- Absence of major symptomatic DVT

Treatment Algorithm

Hemodynamic status remains the most important short-term prognostic factor for patients with acute PE, so patients need to be practically divided to stable and unstable, the unstable ones requiring emergent revascularization and systemic thrombolysis being their first alternative. The stable ones should be further divided to those who are at low and those who are at intermediate risk for a PE complication. Among the intermediate-risk patients, the clinician needs to further identify those who are most likely to decompensate and may benefit from a more

aggressive treatment. Current guidelines are summarized in Table 151.4.[8,44,45]

Due to lack of appropriate high-quality evidence, these guidelines lack strong recommendations for all but the lowest-risk PE patients. Many times, treating physicians will face dilemmas to what approach will best balance the benefits of intervention against potential risks of cardiopulmonary failure or death. The proliferation of novel interventional devices and technology underscores the need to have an integrative multidisciplinary approach flexible enough to evaluate and use multiple options, even in the absence of controlled clinical trial data or guideline recommendations. This need has been recently addressed by the creation of Pulmonary Embolism Response Teams (PERTs). A PERT brings together multiple specialists to rapidly evaluate intermediate- and high-risk patients with PE, formulate a treatment plan, and mobilize the necessary resources to provide the highest level of care. The PERT is staffed by select experts from cardiovascular medicine, vascular and cardiac surgery, interventional cardiology, radiology, echocardiography, emergency medicine, hematology, pulmonary, and critical care medicine, all of whom have a particular interest and competency in treating PE.[102,103]

An algorithm combining the recommended therapeutic strategies and our institutional experience on acute PE is suggested in Fig. 151.7.

Special Populations

Incidental Subsegmental Pulmonary Embolism

The clinical relevance of incidentally diagnosing subsegmental (asymptomatic) PE in a chest CT is uncertain, and the optimal therapy is controversial.[45,104] As a general rule,

patients with risk factors for recurrent or progressive venous thromboembolism, who are hospitalized or have reduced mobility for another reason, have active cancer or a low cardiopulmonary reserve or marked symptoms, favor anticoagulant therapy; a high risk of bleeding favors no anticoagulant therapy.

Thrombus in Transit

Floating right heart thrombus, also known as "thrombus in transit," is a rare but potentially fatal condition of varying etiology, most commonly clots transiting toward the pulmonary vasculature from peripheral venous circulation. It is encountered in approximately 4% of all PEs according to ICOPER[105]; it usually coincides with massive PE, and the mortality rate can be as high as 40%.[106] There are no distinct guidelines established for the management of free-floating thrombus, and the results of anticoagulation only, thrombolysis, or surgical thrombectomy are variable.[107]

Pregnancy

PE is the leading cause of pregnancy-related maternal death in developed countries. The risk of PE is higher in the postpartum period, particularly after a caesarean section. Because pregnant women frequently complain of shortness of breath, this symptom should be interpreted with caution.[8] Data on the validity of clinical prediction rules for PE in pregnancy are lacking, but a retrospective series of pregnant women who were referred for CT angiography showed that no patient with an original Wells score of less than 6 points had a PE.[108] The usefulness of D-dimer is controversial, and although D-dimers physiologically increase throughout pregnancy, the usual cutoff values are used to rule out PE.[8] With a positive D-dimer, lower extremity duplex ultrasound can rule in DVT and anticoagulation initiated to avoid a CT scan. However, if duplex ultrasound is negative, a CT angiogram will be necessary. The radiation delivered is well below the threshold for fetal injury.[109] Nevertheless, lung scintigraphy, when available, may be preferred over CT, mainly to avoid radiation to the female breast and its potential effect on breast cancer.[110]

Adjusted dose of LMWH is the anticoagulant of choice in pregnancy. For high-risk PEs that will require thrombolytics, published data on 28 pregnant women treated with 100 mg of rtPA suggest that the risk of complications for the mother may be similar to that in the nonpregnant population.[111] Catheter interventions have a promising role, but evidence is still scarce.[112,113] Thrombolytic treatment should not be used peripartum, except for critical cases; surgical or catheter mechanical thrombectomy may have better results.

Cancer

Venous thromboembolism is four and six times more prevalent in cancer patients and in those undergoing chemotherapy, respectively.[1,114] Cancer is a risk factor for adverse outcomes in acute PE; patients are at a higher risk for bleeding, shock and death, or recurrent PE.[115,116] For most cancer patients with DVT, first-line therapy should be weight-based LMWH monotherapy for at least 3 to 6 months or as long as the cancer or its treatment is ongoing.[8,44,45]

Long-term anticoagulation with LMWH instead of warfarin appears to be more effective at preventing recurrent venous thrombosis without a statistically significant increase in bleeding risk. It is recommended to wait 6 months after cure or complete remission before stopping therapy, but consideration should be given to stopping therapy earlier in patients with a high bleeding risk, if the PE occurred post surgery or in those with lower risk of recurrence.[116]

Nonthrombotic Pulmonary Embolism

Nonthrombotic PE refers to the pulmonary arterial embolization of cell clusters (e.g., adipocytes, amniotic or tumor cells), bacteria or fungi, gas, or foreign materials.[8] Although clinical symptoms are similar to those of thrombotic PE, diagnosis can be a challenge and relies on a high index of suspicion and typical imaging findings.

Fat embolism is a rare entity, usually occurring after long bone fracture or orthopedic surgery and is classically described as triad of pulmonary (respiratory distress), central nervous system (altered mental status) and skin manifestations (petechial rash).[117] Treatment mainly includes supportive measures, although the use of steroids has been controversial.[8]

Amniotic fluid embolism is a rare but catastrophic condition. It involves a complex sequence of events triggered by entrance into the maternal circulation of material from the fetal compartment, resulting in an abnormal activation of proinflammatory mediators and a subsequent systemic inflammatory response. The typical presentation of amniotic fluid embolism includes a triad of sudden hypoxia and hypotension, followed in many cases by coagulopathy, all occurring in relation to labor and delivery. It should be considered in the differential diagnosis in any pregnant or immediately postpartum woman who suffers sudden cardiovascular collapse or cardiac arrest, seizures, severe respiratory difficulty, or hypoxia, particularly if such events are followed by a coagulopathy that cannot be otherwise explained.[118] Analysis of the national U.S. registry reveals that 70% of cases of amniotic fluid embolism occur during labor, 11% after a vaginal delivery, and 19% during a cesarean delivery.[118] Management is mainly supportive.

Tumor cell embolization is rarely diagnosed before death. Carcinoma of the prostate gland, digestive system, liver, and breast are the most commonly implicated. Tumor cell macroembolism is indistinguishable from the thrombotic PE. Treatment should target the underlying malignant disease.[8]

Septic embolism to the pulmonary circulation is a rare event commonly associated with right-sided endocarditis and manifests as sepsis with respiratory distress. Risk factors include intravenous drug abuse, infected indwelling catheters or pacemaker wires, and septic thrombophlebitis from the tonsils and the jugular, dental, and pelvic regions.[8,119] Eradication of the responsible bacterial or fungal microorganism and its source is the cornerstone of treatment.

Air embolism is an iatrogenic complication, with the lethal volume estimated between 100 and 500 mL. Supportive measures include high oxygen concentrations, volume expansion, aspiration with a central catheter, and patient placement in the left lateral decubitus position to prevent RV outflow obstruction by airlock.[8]

Pulmonary embolization of foreign materials has increased proportionally to the increase of venous endovascular interventions. Filter, stent, wire, or catheter particles have all been reported to have embolized in the pulmonary circulation. Retrieval when possible to prevent thrombosis and sepsis is recommended.[8]

PROGNOSIS

The prognosis of acute PE strongly varies, depending on the severity of pulmonary arterial obstruction and its impact on the RV function. RV failure is the most common cause of death in acute PE. As discussed earlier, RV strain is associated with an adverse in-hospital outcome, not only in hypotensive but in hemodynamically stable patients too. PE without RV dysfunction has a less than 2% death rate. RV dysfunction shifts mortality rates to 3% to 15% for normotensive and greater than 15%.[50,51,120] Anticoagulation, contemporary supportive treatment, and thrombolytic therapies continuously decrease these rates.[121,122] Among survivors, later mortality is unlikely to be related to PE, and it is most frequently attributed to other cardiovascular risk factors or underlying malignancies.[123,124] However, PE recurrence or CTEPH should be anticipated.

PE recurrence is not infrequent; for this reason, certain patient cohorts (e.g., cancer or unprovoked PE) are candidates for indefinite anticoagulant treatment after an initial episode. Recurrence while on anticoagulation is commonly the result of subtherapeutic anticoagulation. As a general rule, anticoagulants are discontinued when the perceived risk of anticoagulation-related bleeding and the inconvenience of remaining on treatment outweigh the risk of recurrent PE. Late recurrence has been reported to be 13% at 1 year, 23% at 5 years, and 30% at 10 years.[125,126] Interestingly, a recent large prospective study showed similar recurrence rates in patients with symptomatic subsegmental versus more proximal PE; however, the topic remains controversial.[127,128]

CTEPH is usually the result of at least one or multiple recurrent PEs, even if many times they may go unnoticed. Residual accumulating thrombus in the pulmonary arterial tree is remodeled into connective and elastic tissue, leading to vessel narrowing and remodeling. This will subsequently progress to small-vessel arteriolar vasculopathy.[44,129] Pulmonary hypertension results when the capacitance of the remaining healthy vascular beds cannot absorb the cardiac output. It is defined as mean pulmonary-artery pressure greater than 25 mm Hg that persists 6 months after the PE event, and, although it may be subclinical

for a long period, it may eventually manifest as dyspnea, fatigue, and exercise intolerance. It is estimated to occur in 2% to 4% of patients after acute PE, usually within 2 years.[130,131] There is some evidence that thrombolysis may potentially decrease the clinical occurrence of CTEPH because it seems to alter exercise tolerance and quality of life.[56,58,59,132] It is recommended that patients 6 weeks after an acute PE should be screened with an echocardiogram for persistent pulmonary hypertension that may predict the development of CTEPH.[44]

SUPERIOR VENA CAVA FILTERS 2007

Venous thromboembolism (VTE) is a significant cause of morbidity and mortality that affects approximately 1 per 1000 of the population, with an annual estimate of 600,000 cases of clinically significant pulmonary embolism (PE) and approximately 200,000 deaths in the United States.[1,2]

Understanding that lower extremity deep venous thrombosis (DVT) can fragment and travel through the inferior vena cava (IVC) to the lung, the concept of vena cava interruption has been around since the 1700s. In 1784 John Hunter performed the first femoral vein ligation for thrombophlebitis, and in 1893 Bottini reported successful ligation of the IVC to prevent PE. Since then, numerous techniques of vena cava interruption have been described for the prevention of PE, including femoral vein and IVC ligation and partial interruption of the IVC by means of plastic clips, plication, or mechanical staplers.[3-6] These later measures were developed to compartmentalize the vena cava to allow blood flow but trap large emboli, and they were the mainstay of treatment through the 1950s and 1960s. Despite these measures, there were high rates of IVC occlusion and significant lower extremity venous-related problems with little improvement in outcome of patients with PE. With the development of techniques to allow transvenous delivery of intravascular vena cava devices, in 1967 the Mobin-Uddin umbrella filter was introduced. Structured as a silicone membrane with a hole to allow blood flow, it was associated with a high rate of vena cava thrombosis and was subsequently discontinued. In 1973 the original stainless steel Greenfield filter was introduced, followed by titanium Greenfield filter in 1989 and lower profile stainless steel Greenfield filter in 1995, and, as the most extensively studied filter, is the filter design with which all modern filters are compared. Over the past few decades, several additional filter designs have been developed that have favorable properties, including ease of deployment, clot-trapping effectiveness, preservation of IVC flow, and in more recent years, optional filter designs that allow retrieval of the filter.

FILTER DESIGN

Design Considerations

The functional goal of filters is to prevent PE by trapping venous thromboemboli in the vena cava, not to prevent or treat venous clots. Based on this design goal, there are several features that are preferred for optimal function and minimal compromise,

Abstract

Use of Vena Cava Filters continues to evolve. This chapter reviews filter design features, current available filter types, clinical indications and evidence based guidelines for use, anatomic considerations, and techniques for placement and retrieval.

including the use of nonthrombogenic, biocompatible, nonferromagnetic, durable implantable material. Filtering efficiency should be high without impedance of flow, and there should be a single trapping level and conical design, which provides the highest filtering-to–flow volume ratio (Fig. 152.1). Ideally, the filter should have a self-centering mechanism with secure fixation to the vena cava wall, a filter hook length and angle sufficient to prevent migration when the filter is in place, and the ability to be retrieved when no longer needed without limitation of the time frame for incorporation. The optimal filter should be highly visible on imaging with ease of percutaneous delivery through a low-profile system and a simple release mechanism. Repositioning and retrievability should also be possible, and the potential for complications should be negligible. The financial cost of filter delivery should be low.

Vena cava filter design categories include the following:

1. *Permanent filter*. Placed with the intention of providing permanent, lifelong filtration, permanent filters have design characteristics that maximize secure fixation.
2. *Temporary filter*. Not currently available in the United States, these filters are not designed for permanent placement and do not have any means of fixation to the vena cava wall. Rather, temporary filters are attached to a wire or catheter that traverses the venous system and either protrudes from the skin or is buried in adjacent subcutaneous tissue. Removal is required before the filter or tether becomes incorporated.
3. *Convertible filter*. Functioning initially as a permanent filter with elements allowing attachment to the vena cava wall, convertible filters can be altered structurally after implantation to a nonfiltration state with removal of the filtration portion through a separate percutaneous procedure.
4. *Optional/retrievable filter*. Similar to a conventional permanent filter, optional or retrievable filters have the added feature of removal capability. Retrievable filters adhere to the wall of the vena cava with hooks, barbs, or radial force (or any combination of the three) but can be retrieved by image-guided catheter techniques within a device-specific time interval.[7]

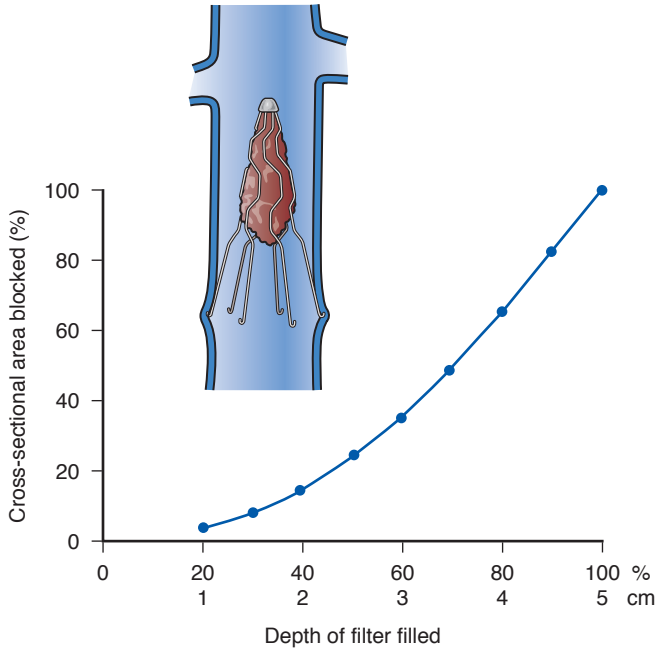

Figure 152.1 Relationship between the percentage and depth of thrombus trapped within the filter and the percentage of cross-section occluded.

Filter Types

Understanding individual filter designs, advantages, and limitations is important before placement to ensure proper filter selection. For the purpose of this chapter, only US Food and Drug Administration (FDA)-approved permanent and optional/retrievable filter designs are discussed (Table 152.1 and Fig. 152.2).

Conical filter design is most optimal and permits progressive central filling while allowing circumferential blood flow peripherally, which helps to maintain vena cava patency. For example, the conical geometry of the Greenfield filter makes it possible for thrombi to fill and occlude 70% of the filter cone, a volume of thrombus of approximately 4 cm^3 (34.3% of the total volume), while reducing the cross-sectional area by less than 50%. If the cone is filled to 80% of total volume, the reduction in cross-sectional area is 64%, at which point venous flow begins to decrease and venous pressure proximal to the filter begins to increase.[8] The ability of this conical filter design to trap clinically significant emboli without impeding flow has been demonstrated.

Although other filter designs have double trapping levels or double basket designs and have higher capacity to capture smaller emboli, flow dynamics are reduced compared with single trapping conical designs and may be associated with higher vena cava occlusion rates. In addition, although rapid and stable incorporation may be desirable for permanent filter design to maintain position and prevent migration, retrievable filter designs need to have sufficient incorporation to prevent migration but not so much that retrieval cannot be accomplished. Altering the filter hook contact point to allow retrievability may have the disadvantage of an increased tendency for filter leg penetration or filter migration. This has also resulted in different filter hook length and angle configurations. Although some filters (such as Greenfield filter) incorporate recurved configuration to create a contact angle of 80 degrees, allow better hook incorporation without full penetration into the vena cava, other filters (such as Celect, Denali, OptionElite, ALN Optional filters) use different hook configuration to prevent excessive incorporation and facilitate retrievability. Filter designs such as Vena Tech LP, OptEase, and Crux filters do not depend on filter legs for fixation, thereby minimizing potential for penetration. Similarly, although some filters do not have self-centering features, others have included independent self-centering mechanisms. To improve self-centering of the filter, some designs have increased contact points with the vena cava wall, which prevents tilt but may lead to increased incorporation and a possible tendency for vena cava occlusion. These additional filter features do not offer any additional filtering capacity, may change flow dynamics, and can potentially lead to filter centering strut penetration of the vena cava wall.

Newer filter technology has led to availability of convertible filter designs (such as Vena Tech Convertible) which functions as a filter upon deployment but allows for removal of the filter portion and conversion to an open configuration when clinically indicated. When choosing the best filter option, these design characteristics should be considered, weighing the risks and benefits of the filter design to the clinical scenario for filter placement.

CLINICAL INDICATIONS

Recommended indications for the use of vena cava filters are shown in Box 152.1. Without anticoagulation, the risk of PE developing in patients with VTE is high, and it may be fatal in as many as 25% of patients (see Chapter 151). Because of this significant risk, vena cava interruption with an implantable filtering device should be considered in patients with documented VTE and contraindications to anticoagulation. Resumption of anticoagulation as soon as possible is recommended because, although vena cava filters are effective in preventing PE, they are not effective for prevention of DVT.

Evidence-based guidelines from the 2012 American College of Chest Physicians (ACCP)[9] recommend vena cava filter placement in patients with documented VTE and a contraindication to anticoagulation, complication of anticoagulation, or recurrent VTE despite therapeutic anticoagulation. Contraindications to or complications of anticoagulation can include need for major surgery, intracranial hemorrhage, pelvic or retroperitoneal hematoma, ocular injury, solid intra-abdominal organ injury, uncorrected major coagulopathy, coagulation disorder, peptic ulcer disease, and other associated medical problems. In the updated 2016 ACCP guidelines on Antithrombotic Therapy for VTE Disease, there is further recommendation against the routine use of vena cava filters in addition to anticoagulation for acute DVT or PE if the patient can be therapeutically anticoagulated, thereby supporting the prior recommendations.[10]

Beyond these strong evidence-based guidelines, expanded relative indications based on inconclusive evidence have included

BOX 152.1 Evidence-Based Guidelines, Relative Expanded Indications, and Contraindications to Vena Cava Filter Placement

Evidence-Based Guidelines

- Documented VTE with contraindication to anticoagulation
- Documented VTE with complications of anticoagulation
- Recurrent PE despite therapeutic anticoagulation
- Documented VTE with inability to achieve therapeutic anticoagulation

Relative Expanded Indications

- Poor compliance with anticoagulation
- Free-floating iliocaval thrombus
- Renal cell carcinoma with renal vein extension
- Venous thrombolysis/thromboembolectomy
- Documented VTE and limited cardiopulmonary reserve
- Documented VTE with high risk for anticoagulation complications
- Recurrent PE complicated by pulmonary hypertension
- Documented VTE—cancer patient
- Documented VTE—burn patient
- Documented VTE—pregnancy
- VTE prophylaxis—high-risk surgical patients
- VTE prophylaxis—trauma patients
- VTE prophylaxis—high-risk medical condition

Contraindications

- Chronically occluded vena cava
- Vena cava anomalies
- Inability to access the vena cava
- Vena cava compression
- No location in the vena cava available for placement

PE, Pulmonary embolism; *VTE*, venous thromboembolism.

BOX 152.2 Relative Recommendations for Vena Cava Filter Use as Venous Thromboembolism Prophylaxis, Including High-Risk Patient Factors and/or High-Risk Situation Combined With an Increased Bleeding Risk

Prophylaxis in High-Risk Patients

- Critically ill
- Previous DVT
- Family history of DVT
- Morbid obesity
- Malignancy
- Known hypercoagulable state
- Prolonged immobility

Prophylaxis in Trauma

- Multiple traumatic injuries
- Spinal cord injury
- Closed head injury
- Complex pelvic fractures
- Multiple long-bone fractures

Increased Bleeding Risk

- Major operation
- Intracranial hemorrhage
- Solid intraabdominal organ injury
- Pelvic or retroperitoneal hematoma
- Ocular injury
- Medical problems (cirrhosis, end-stage renal disease, peptic ulcer disease, medication, coagulation disorder)

DVT, Deep venous thrombosis.

poor compliance with anticoagulation; free-floating iliocaval thrombus; renal cell carcinoma with renal vein extension; placement in conjunction with venous thrombolysis or thromboembolectomy; presence of DVT and limited cardiopulmonary reserve or chronic obstructive pulmonary disease; recurrent PE complicated by pulmonary hypertension; proven DVT in an oncology, burn, or pregnant patient; and venous prophylaxis in high-risk surgical, medical, or trauma patients. A clinical decision algorithm for vena cava filter use for prophylaxis of VTE is shown in Box 152.2. Recommendations should be based on a combination of high-risk patient factors or situations with a high risk of bleeding prohibiting use of anticoagulation for prophylaxis.

Permanent Versus Optional Retrievable Filter

Filter use has expanded significantly in the United States over the past few decades, especially for prophylaxis of VTE.[11] Unfortunately, evidence-based recommendations for vena cava filter use are derived predominantly from nonrandomized data, with substantial differences existing among studies in terms of study populations, immediate and long-term end points, and duration of follow-up. Because of difficulties comparing data on different filters, several guidelines outlining reporting standards for filter devices have been published.[12-14] Overall reported complications for vena cava filters include PE (2%–5%), fatal PE (0.7%), death linked to filter insertion (0.12%), venous access site thrombosis (2%–28%), filter migration (3%–69%), vena cava penetration (9%–24%), vena cava obstruction (6%–30%), venous insufficiency (5%–59%), filter fracture (1%), and guide wire entrapment (1%).[15,16]

Although it is unclear whether filters actually improve survival, they do provide protection against PE. Because the risk for PE in patients with proven VTE and contraindications to anticoagulation is high, potential complications of filters must be balanced against the risk of no filter. Despite the large number of filters placed, randomized evidence on permanent filters is limited. In the PREPIC (Prevention of Recurrent Pulmonary Embolism by Vena Cava Interruption) trial, 400 patients with proximal DVT with or without PE were randomized in a 2 by 2 factorial study design to filter placement versus no filter and unfractionated heparin versus enoxaparin. There was a significantly lower incidence of PE with filter protection during the first 12 days (1.1% vs. 4.8%), but the filter group had a significantly increased incidence of recurrent DVT at 2 years (20.8% vs. 11.6%).[17] Eight-year follow-up data from the PREPIC trial confirmed the previous findings of cumulative recurrent PE (6.2% vs. 15.1%, filter versus no filter, respectively) but increased recurrent DVT (35.7% vs. 27.5%) and no difference in postthrombotic venous insufficiency or survival.[18] The authors concluded that although permanent filter use may be beneficial in patients at high risk for PE, systematic use in the general

population with VTE is not recommended. Unfortunately, no firm conclusions regarding filter efficacy in the prevention of PE can be drawn from the PREPIC trial given that the study design varies significantly from the wider application in current clinical practice (i.e., patients with documented VTE in whom anticoagulation has failed or cannot be administered).

Although the potential for significant adverse outcomes with permanent filters is low, there are long-term complications that could be avoided with optional filters. However, given the paucity of randomized data, determining the best permanent versus optional filter design is difficult. Some studies have used meta-analysis of data to compare the different filter designs and document the efficacy of filters in the prevention of PE and complication rates.[19-21] In the randomized open label, blinded end point PREPIC-2 trial for hospitalized patients with acute PE, the use of retrievable vena cava filters plus anticoagulation compared with anticoagulation alone did not reduce the risk of symptomatic recurrent PE at 3 months. Although PREPIC-2 did not support the use of retrievable filter in patients with acute PE who can be anticoagulated, the role of retrievable filters in patients who cannot be anticoagulated, those with DVT but no PE, or for other selected relative indications remains unclear based on current evidence.[22]

Table 152.2 summarizes data on different filter types. Overall, most of the available filters are approximately equivalent in prevention of PE, but there is some variation in complication rates.[23,24] Penetration of the IVC wall by filters is also being noted with increasing frequency. In a systematic review of the literature from 1970 to 2014, overall frequency was 19%, with 8% exhibiting symptoms usually due to organ/structure involvement. Although asymptomatic filter penetration is often noted incidentally on imaging, endovascular retrieval or surgery is usually required for symptomatic patients.[25]

Data on the efficacy and safety of retrievable filters are derived from small series with insufficient long-term data in comparison to other permanent filter designs to warrant permanent implantation. With the lack of extended outcome data for optional filters, the decision to use a retrievable filter instead of a permanent filter should be based on the intent to discontinue filtration. Factored into this decision should be the anticipated required duration of protection from VTE versus the risk associated with anticoagulation. In patients with proven VTE, anticoagulation should be resumed as soon as possible when the risk has diminished. For patients in whom filters are placed for prophylaxis of VTE, anticoagulation should be restarted in accordance with published VTE prophylaxis guidelines. When the risk of resuming anticoagulation is extended, permanent filtration would be preferable.

Further complicating the decision to use retrievable filters is poorly defined timing of possible retrieval. Based on FDA indications for use (IFU), retrieval of Günther Tulip filters is recommended within 20 days, OptEase filters within 14 days, and the Celect filter within 52 weeks. More recently approved filters like Denali, OptionElite, ALN Optional, and Crux do

[a]Insufficient systematically reviewed published data to report.

PE, Pulmonary embolism.

Data from Hann CL, Streiff MB. The role of vena cava filters in the management of venous thromboembolism. *Blood Rev.* 2005;19:179–202; and Angel LF, Tapson V, Galgon RE, et al. Systematic review of the use of retrievable inferior vena cava filters. *JVIR.* 2011;22(11):1522-1530.

not have clearly specified time windows based on FDA IFU. Further confusing optimal timing are case reports suggesting that potential retrieval at extended periods is possible for all filters but can be more problematic with a higher failure rate.[26-29] Regardless, the longer a filter is in place, the less successful retrieval will be, as shown in a recent systematic review showing technically successful retrieval rates of 99% at 1 month and 94% at 3 months, falling to 37% at 12 months.[30] Until further data are available, the optimal period for retrieval of currently available optional filters probably falls within a few months of placement, after which the technical success of retrieval will diminish.

With the expanding use of retrievable vena cava filters, there has been a growing body of literature and reports to the FDA Manufacturer and User Facility Device Experience (MAUDE) database that led FDA to issue a communication of risk of adverse events with long-term use[31] on August 9, 2010: "Since 2005, the FDA has received 921 device adverse event reports involving IVC filters, of which 328 involved device migration, 146 involved embolizations (detachment of device components), 70 involved perforation of the IVC, and 56 involved filter fracture." The FDA raised concern that some of these events may be related to retrievable filters being left in place for extended time, beyond the time when risk of PE has subsided. As a result, the FDA recommended that "implanting physicians and clinicians responsible for the ongoing care of patients with retrievable IVC filters consider removing the filter as soon as possible when protection from PE is no longer needed." In an external follow-up study of the MAUDE database of 1606 reported adverse events involving 1057 filters, 86.8% involved retrievable filters versus 13.2% for permanent filters, although this data source is limited by self-reporting mechanisms and may underestimate true filter complication rates.[32] To determine optimal timing for filter retrieval based on a mathematical model, the FDA published a quantitative decision analysis weighing risk of PE versus risk of IVC filters over time showing a risk-benefit profile cross point favoring removal of IVC filter between 29 and 54 days.[33] The FDA has since updated the original 2010 safety communication on May 6, 2014, reiterating the importance of filter removal as soon as protection from PE is no longer needed and when the risk/benefit profile favors removal based on the patients overall health status.[34] In addition, the FDA is now requiring collection of clinical data for currently marketed IVC filters in the United States to address further safety questions for both permanent and retrievable filter designs either by manufacturers conducting postmarket studies (522 studies) or through manufacturer's participation in the ongoing PRESERVE (PREdicting the Safety and Effectiveness of InferioR VEna Cava Filters) study, which began enrolling in 2015.[35]

Also limiting retrieval has been patients being lost to follow-up. Once a retrievable filter has been placed, evidence has suggested that active protocols that follow patients after filter placement and determine optimal timing of retrieval are more successful than passive protocols in terms of limiting lost to follow-up and improved filter retrieval rates.[36-39]

In conclusion, retrievable filters should be considered in the following clinical scenarios: (1) indications for permanent filters are not present, (2) the risk of clinically significant PE is acceptably low, (3) return to high risk for VTE is not anticipated, (4) life expectancy is long enough that the benefit of filter removal will be realized, and (5) the filter can be removed safely or converted.[7] Optional/retrievable filters should not be used as a replacement for a permanent filter if permanent PE prevention is needed.

Specific Patient Groups

Trauma Patients

The risk of VTE in trauma patients is high, with a reported incidence of DVT without prophylaxis as high as 50% and incidence of PE as high as 30%.[40,41] The 2012 ACCP recommendation for trauma patients with at least one risk factor is to receive some form of thromboprophylaxis, preferably with an anticoagulant if there is no contraindication based on bleeding, or mechanical prophylaxis.[42] For patients who cannot receive anticoagulation, mechanical thromboprophylaxis is recommended but not the use of vena cava filters. Although VTE prophylaxis with anticoagulation protocols is recommended by the 2012 ACCP and also by the 2002 Eastern Association for the Surgery of Trauma guidelines,[43] there is a lack of level I data supporting any recommendation for or against filters.

Because of the risk of bleeding in severely injured trauma patients, standard pharmacologic thromboprophylaxis may not be possible. Routine prophylactic filter placement has been recommended by some for use in trauma patients who were considered at very high risk for VTE, with most series reporting a decreased incidence of all PE and fatal PE with the use of vena cava filters in appropriately selected high-risk patients.[44-47] Level II and III data would indicate that the risk to benefit ratio of prophylactic filter placement is favorable in high-risk trauma patients. In a retrospective review of 9721 patients, high-risk categories included head injury plus spinal cord injury, head injury plus long-bone fracture, severe pelvic fracture plus long-bone fracture, and multiple long-bone fractures.[48] A meta-analysis demonstrated a 0.2% incidence of PE with filters as opposed to 1.5% in controls without a filter and 5.8% in historic controls.[41] In a comparison of 40 critically injured patients who received a filter and 80 matched historic controls, PE occurred in 3% versus 18%, respectively.[49] At a 5-year follow-up of 132 trauma patients receiving prophylactic filters, Rogers and coauthors reported a 2.3% incidence of PE after filter placement and a mortality of 4.4% with one fatal PE episode.[50]

With the availability of optional filters, there has been an increased trend in many trauma centers for the use of prophylaxis. Most studies evaluating retrievable filters in high-risk trauma patients have reported a high technical success rate and low incidence of PE, but the actual rate of retrieval has been variable.[51] In a large multicenter study, 446 patients received a retrievable vena cava filter, with the majority (76%) being placed for prophylaxis, but only 22% were retrieved.[52] Meier and coworkers analyzed 35 trauma patients in whom prophylactic retrievable vena cava filters were placed; retrieval was possible in 86%, and 36% had trapped clot or thrombus within the

device.[53] In a study of 127 multitrauma patients with retrievable filters, Rosenthal and coauthors reported that 52% underwent uneventful retrieval after pharmacologic prophylaxis was initiated. Of the remaining filters not removed, most were left because of contraindications to anticoagulation and only a few because of thrombus trapped within the filter.[54]

Analysis of the results of filter placement in trauma patients is limited mainly by the lack of adequate control groups, with most series using unmatched cohorts or historical data for comparison. Several reports and a meta-analysis of prospective studies found no difference in rates of PE in patients with and without prophylactic filters.[55] In a review of a trauma quality collaborative registry, use of IVC filter placement had no effect on reduction of trauma patient mortality and were associated with an increase in DVT events.[56] To date, there have been no randomized clinical trials in which the prophylactic use of vena cava filters was shown to be more beneficial than other effective prophylactic measures. Until these issues are resolved by level I evidence-based data, use of IVC filters is indicated in patients with proven DVT and a contraindication to therapeutic anticoagulation. Based on level II and III data in patients without documented DVT, use of vena cava filters as prophylaxis for thromboembolism may be considered only for those who have very high-risk criteria and cannot receive anticoagulation.

Bariatric Patients

Obesity is a strong independent risk factor for the development of VTE. PE is considered the most important cause of perioperative mortality in bariatric surgical patients, with an incidence of 1% to 3%, but the incidence has been reported to be as high as 17%, especially in superobese patients (body mass index = 55 kg/m^2).[57-59] Combined with the added risk associated with surgery, the potential risk for VTE is increased.

Difficulty in proper dosing of anticoagulation thromboprophylaxis in obese patients increases susceptibility to venous thromboembolic–related morbidity and mortality. In a 2000 survey of American Society of Bariatric Surgery members, more than 95% of participants reported using prophylaxis routinely, and 38% used two prophylactic measures simultaneously.[60] Despite the routine use of thromboprophylaxis, the incidence of PE in bariatric surgery patients has remained relatively stable, even with the addition of standardized heparin protocols and the application of minimally invasive approaches to bariatric surgery. Several authors have compared various thromboprophylactic regimens, but no conclusive results on the safest and most effective form of anticoagulation were reached.[61-64] Furthermore, several studies suggest that the risk for PE after bariatric surgery extends to the period after hospital discharge, a finding compounded by the decreased hospital stays after minimally invasive bariatric surgery.[65,66]

Because of these limitations of anticoagulation, placement of vena cava filters for thromboprophylaxis in bariatric surgical patients has become increasingly common. In a study of 5554 bariatric operations by Hamad and Bergqvist, risk factors for postoperative VTE, including body mass index greater than 60, truncal obesity, and hypoventilation syndrome, were identified and recommended as indications for prophylactic filters.[67] In a comparison of the incidence of VTE in 248 high-risk bariatric patients receiving vena cava filters and 2852 low-risk patients who did not receive filters, Obeid and colleagues showed that the incidence of PE was not significantly different.[68] The use of prophylactic IVC filters reduced the risk for PE in high-risk obese patients, a group known to have a much greater incidence of morbidity and mortality, to a rate comparable to the baseline risk of a low-risk group.

With the recent availability of optional/retrievable filters, there is the potential for using vena cava filters as a bridge during the highest risk period with subsequent removal. Piano and colleagues analyzed outcomes from a standardized approach in which retrievable filters were inserted in 59 patients undergoing bariatric surgery who met high-risk criteria.[69] All filters were placed immediately before surgery, and removal was attempted 4 weeks postoperatively. There was one postoperative PE (1.7%) and no fatal PE or deaths.

However, evidence from these studies favoring prophylactic vena cava filters in high-risk bariatric patients is significantly limited by small study sample size, lack of prospective data, no adequate control populations, and variable approaches to VTE prophylaxis. In a recent systematic review of IVC filter use for prevention of VTE in obese patient undergoing bariatric surgery, published data reporting safety and efficacy was noted to be heterogeneous and there was no clear evidence to suggest the potential benefit of IVC filters outweighing risk in this population.[70] Given the relative infrequency of fatal PE after bariatric surgery, much larger trials are required before the indications for and efficacy of vena cava filter placement in the bariatric surgery population can be better defined.

Orthopedic Patients

Patients undergoing major orthopedic surgery, including total hip arthroplasty, total knee arthroplasty, and traumatic lower extremity fracture repair, have a significantly increased risk for VTE.

The role of the IVC filter in elective major orthopedic procedures is not well delineated. Several studies support the efficacy of filter placement for the prevention of VTE in selected orthopedic patients. In a cohort of 95 joint arthroplasty patients either with confirmed PE or at high risk for the development of PE in whom an IVC filter was implanted, Austin and colleagues showed that vena cava filter placement was effective in preventing fatal PE in all patients.[71] Golueke and coauthors reported no filter-related complication or PE in 88 joint arthroplasty patients who received a vena cava filter in the perioperative period.[72] Vaughn and associates observed fatal PE in 1 of 24 total joint arthroplasty patients who underwent filter insertion and concluded that placement of an IVC filter is a safe, easy, and effective method of preventing fatal PE in selected joint arthroplasty patients.[73]

Optional filters may be more appropriate in these high-risk orthopedic patients because they provide temporary protection at the time of increased risk and are intended to be retrieved when the risk for VTE has diminished. Strauss and coworkers reported on 58 high-risk orthopedic patients in whom retrievable IVC filters were placed as an adjunct to standard venous

thromboprophylaxis.[74] There was minimal morbidity associated with filter placement and two deaths unrelated to the filter or PE. Sixty-four percent of the filters were removed at a mean of 37.8 days, whereas others were left in place for up to 238 days, which allowed them to serve as temporary prophylaxis and avoid the development of long-term complications. The authors concluded that for high-risk orthopedic patients, placement of a retrievable IVC filter as an adjunct to standard pharmacologic or mechanical prophylaxis is an effective means of preventing PE.

Although the use of retrievable filters has the advantage of bridging high-risk orthopedic patients during the period of most increased risk, in the absence of randomized studies their use should be limited at this time. Based on current evidence-based guidelines, use of either permanent or optional vena cava filters in high-risk orthopedic patients should be reserved for those with documented VTE and a contraindication to or complication of anticoagulation.

Cancer Patients

Malignancy is an independent risk factor for the development of VTE, with a reported incidence of 7% to 50% and a risk for PE twofold to fourfold higher in patients with malignancy than without.[75] Although some authors have suggested that primary filter placement in patients with malignant disease may be beneficial, others have favored anticoagulation.[76-78] Lin and associates suggested that vena cava filters may be a reasonable alternative to long-term anticoagulation in a subgroup of patients at high risk for recurrence, provided that their quality of life is reasonable and a decrease in the risk for fatal PE is justified.[79] In a review of 308 patients, Wallace and colleagues showed that filters can be placed in patients with VTE and cancer without higher rates of procedure- or filter-related complications than in historical controls, although patients with a history of DVT and bleeding or metastatic/disseminated disease have the lowest survival.[80]

The fiscal impact of filter placement in cancer patients may be less than anticoagulation therapy because of the added costs of treating bleeding complications of anticoagulation therapy.[81] Marcy and associates reviewed 30 patients with malignancy who had filters placed; 76% were alive at 1 month, 56% at 3 months, and 40% at 6 months.[82] In comparing the complication rates and cost, vena cava filter placement was favored if reasonable survival was expected. Chau and coworkers used a Markov model to compare the cost-effectiveness of filters versus anticoagulation.[83] Vena cava filters were not cost-effective in patients with brain tumors, but when the model was applied to the anticipated 5-year survival for a breast cancer population, vena cava filter placement appeared to be more cost-effective than did anticoagulation alone. From the available data, it appears that filter placement is most cost-effective in cancer patients with documented VTE, good functional status, and anticipated survival.

A problem with filters as primary therapy for cancer patients is the finding of increased VTE events—PE, recurrent DVT, or vena cava thrombosis. The rate of recurrent VTE events after filter placement in cancer patients varies from 4% to 62%.[84-86] Inhat and colleagues, in a review of 166 cancer patients with VTE, showed that although technical complications of filter placement are low, serious life-threatening or limb-threatening thromboembolic complications developed in 17% of patients, and survival was poor in all patients regardless of treatment,[87] thus leading to support for a conservative approach of routine anticoagulation therapy with selective filter placement. Thus filters should be reserved for cancer patients with documented VTE, contraindications to or complications of anticoagulation, and longer anticipated survival and should be discouraged in patients with advanced malignant disease and a poor prognosis.

High-Risk General Surgical Patients

The incidence of DVT in general surgical patients not receiving prophylaxis varies between 15% and 30%, with rates of fatal PE between 0.2% and 0.9%.[88-92] The type and duration of surgery clearly influence the risk for VTE, with most outpatient surgeries having a low frequency, and more extensive inpatient operative procedures increasing risk. Although mechanical methods of prophylaxis are attractive options in general surgery patients who are at high risk for bleeding, they have not been studied as extensively as pharmacologic thromboprophylaxis but appear to reduce rates of DVT. The ACCP 2012 consensus statement recommends that mechanical prophylaxis be considered for patients who have a particularly high risk of bleeding.

Overall use of prophylactic vena cava filters for high-risk general surgery patients is not well defined. There are some perceived advantages of IVC filters in high-risk surgical patients in avoiding the bleeding risk associated with thromboprophylaxis and extending VTE prophylaxis past discharge. In a registry of 1375 consecutive patients with DVT who had undergone recent major surgery, VTE prophylaxis was used in only 44%, and IVC filters were more common in these surgical patients than in medical patients.[93] Vena cava filter use in general surgery patients should be limited to the standard indications for documented VTE in patients with contraindications to or complications of anticoagulation.

Pregnant Patients

Indications for IVC filters during pregnancy fall in line with the standard indications for documented VTE and complications of or contraindications to anticoagulation. What differs for vena cava filter placement in pregnancy is the recommendation for suprarenal positioning because of compression of the infrarenal portion of the vena cava by an enlarging pregnant uterus, especially in the third trimester. Use of jugular access may also be preferred to avoid catheterization of the vena cava adjacent to the gravid uterus. Matchett and associates have shown in a series of 22 patients that suprarenal permanent filter insertion is safe without kidney dysfunction,[94] and AbuRahma and Mullins showed that placement of a permanent IVC filter in 18 pregnant patients with DVT significantly decreased maternal morbidity and mortality with low complications.[95] Suprarenal insertion of optional filters can be problematic during pregnancy because of higher potential for possible migration than with permanent filters.[96] Use of optional filters seems to

be an attractive alternative for providing VTE prophylaxis to high-risk patients with proven DVT, particularly those with a short-term contraindication to anticoagulation. In eight pregnant women with DVT, Kocher and colleagues showed that suprarenal placement and removal can occur in the perinatal period without major complications.[97]

INFERIOR VENA CAVA FILTERS

Anatomic Considerations

The normal IVC is located on the right side and is composed of four main segments in the craniocaudal direction: the hepatic, suprarenal, renal, and infrarenal segments (Fig. 152.3). The IVC is formed by the confluence of the left and right iliac veins and drains the venous return from the lower extremities, pelvis, and abdomen back to the heart. At its origin around the L4 to L5 vertebral level, the IVC is posterior to the right common iliac artery, where it ascends to the right of the aorta and receives additional branch drainage from lumbar veins. The renal veins drain into the IVC at the L1 to L2 vertebral level, with the right renal vein shorter and more caudal and the left renal vein longer, more cephalic, and crossing over the aorta. The left gonadal vein typically drains into the left renal vein, whereas the right gonadal vein is more variable and sometimes drains into the right renal vein, directly into the IVC, or at the confluence of the IVC and the right renal vein. At this level the IVC runs posterior to the head of the pancreas and ascends posterior to the liver as the infrahepatic portion. The left, middle, and right hepatic veins and often a separate branch from the caudate lobe join the infrahepatic vena cava before it passes behind the right crus of the diaphragm to enter the right atrium.

There are some anatomic variations of the IVC that reflect incomplete involution or persistence of the cardinal veins during embryologic development (see Chapter 2).[98-100] These variations are important to identify before filter placement because their presence and location may affect filter placement.

1. *Renal vein anomalies*. Multiple bilateral renal veins and retroaortic or circumaortic left renal vein anomalies are the most common and may be present in 5% to 7% of the population. Although a retroaortic renal vein will not affect filter placement, circumaortic renal veins may have a large confluence with the IVC or may have separate drainage. Although the tip of the filter should be positioned inferior to the lowest portion of any circumaortic vein, it is critical to identify any additional renal veins to avoid inadvertent tilting caused by entrapment of one of the filter legs.
2. *IVC transposition*. Transposition of the vena cava occurs in 0.2% to 0.5%. The left-sided IVC usually drains into the left renal vein, which crosses to the right and continues cephalad in the normal position. Filters can still be positioned in a transposed vena cava, but anatomic landmarks, especially the location of the right renal veins, need to be accurately defined, and suprarenal vena cava placement may be preferred.
3. *IVC duplication*. Vena cava duplication is present in 0.2% to 0.3%. The right-sided IVC typically drains the right iliac vein and right renal vein, whereas the left-sided IVC, which is usually smaller in diameter, drains the left iliac veins and joins the left renal vein, where it crosses over into the right-sided vena cava. Demonstration of this anomaly is important because placement of a filter in the right IVC only may not provide adequate prevention of PE in a patient with a left-sided DVT. For duplicated vena cava anomalies, placement of a filter in each vena cava or in the suprarenal vena cava after the left renal vein crosses over is required.[101]
4. *IVC agenesis*. Absence of the infrarenal segment of the IVC is an extremely rare anomaly, but hepatic segmental anomalies occur when the right subcardinal vein fails to anastomose with the hepatic sinusoids and is referred to as an abnormal IVC with azygos drainage or infrahepatic interruption of the IVC with azygos continuation. In this anomaly the infrarenal IVC is normal, whereas the renal segment drains into the azygos system and right atrium through the superior vena cava. Cardiovascular defects, such as dextrocardia, atrial septal defect, and pulmonary artery stenosis, and visceral anomalies, such as polysplenia/asplenia and renal defects, are associated with this anomaly.[102,103] Filter placement in an enlarged azygos vein pathway in patients with this congenital anatomic variation of the IVC has also been described.[104]

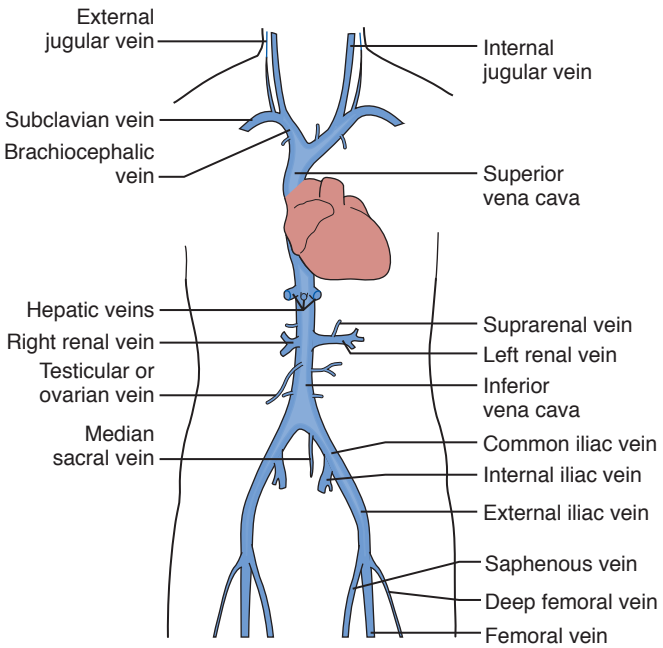

Figure 152.3 Normal inferior vena cava anatomy.

Technical Considerations

The reported technical success rate is usually 98% to 100% with low complication potential. Overall, acute procedure-related complications of venographic-guided filter placement include malpositioning (1.3%), hematoma (0.6%), air embolism (0.2%), arterial puncture (0.04%), arteriovenous fistula (0.02%), and pneumothorax (0.02%).[105] Fatal complications are rare and occur in 0.13% of insertions. Although a higher procedural mortality rate has been noted to be associated with the bird's

nest filter (0.34%) than with the titanium Greenfield filter (0.15%), stainless steel Greenfield filter (0.11%), and Vena Tech filter (0.07%), with scant reports for the other filters, most of these fatal events are more likely due to patient comorbid factors and not necessarily filter-related problems.[106,107]

Suprarenal filter placement may be required if thrombus is present in the IVC; for malpositioning of an infrarenal filter, a duplicate IVC, and ovarian vein thrombosis; or when a filter is needed during pregnancy. In a series of 22 suprarenal filters, Matchett and coauthors reported renal insufficiency in 6%, recurrent PE in 6%, filter migration in 28%, filter fracture in 6%, and filter penetration in 6%.[108] In a series of 148 suprarenal filters, Greenfield and Proctor reported that recurrent PE occurred in 8%, caval occlusion in 8%, filter penetration in 7%, and migration in 15%.[109] Although data are limited, suprarenal filter placement can be performed but should be reserved for selected patients in whom the risk for PE outweighs the potential development of these filter complications.

Bedside placement of IVC filters under either transabdominal duplex ultrasound or intravascular ultrasound guidance has been shown to be safe, effective, and reliable.[101-104,110-113] Transport of critically ill and immobilized patients to the interventional suite for filter placement is not without complications; requires extra support staff, cost, and time; and poses additional risk from exposure to radiation and contrast agents.[114,115] In a collective reported experience, 498 patients were initially imaged by transabdominal duplex ultrasound, and technical feasibility was determined in 435 patients (87.3%).[116-118] The procedural technical success rate for filter placement with transabdominal duplex ultrasound guidance when IVC visualization was adequate was 97.7% (n = 425 patients). If visualization with transabdominal duplex ultrasound was determined to be inadequate, bedside imaging with intravascular ultrasound was then performed. Of 53 patients imaged with intravascular ultrasound, technical feasibility was determined to 96.2% (n = 51 patients), and the procedural technical success rate for placement under intravascular ultrasound guidance was 96.1% (n = 49 patients). The potential for malpositioned IVC filters as a result of suboptimal imaging remains a risk with bedside insertion, but this risk is low, approximately 2% to 3%. In an experience of 396 bedside filter placements using IVUS in critically ill patients over a 5-year period, IVUS guidance continued to be a safe and effective option in a high-risk population, with noted time-dependent improvement in outcome measures.[119] Although malpositioned filters have traditionally been managed by either observation or insertion of a second filter, percutaneous retrieval and repositioning techniques have been described, even for "nonretrievable" filters, thus allowing an effective rescue technique without significant additional morbidity or mortality.[120]

Venographically Guided Filter Placement

Use of fluoroscopy either in an operating room setting with a mobile C-arm fluoroscope or in an endovascular or radiology suite with fixed-arm imaging is the standard approach for most filter placements. Depending on the clinical situation and the filter type used, femoral, jugular, or antecubital percutaneous access is obtained. Although some techniques described included placement of filters based on bony landmarks alone, this approach should be discouraged because there is some variability in renal vein positioning and potential venous anomalies that need to be better defined before filter delivery. Guide wire and catheter access into the vena cava is obtained for initial nonselective venography. Venographic images of the IVC are obtained for confirmation of venous landmarks, correlation with bony vertebral levels, and exclusion of the presence of thrombus at the intended deployment level.[121,122] Correlation of bony landmarks with venography showed that the lowest most renal vein corresponded to the L1 vertebral body in 17.3%, the L1 to L2 disk space in 36.5%, the L2 vertebral body in 34.6%, the L2 to L3 disk space in 7.7%, and the L3 vertebral body in 3.8%. Similarly, the common iliac vein confluence corresponded to the L5 to S1 disk space in 3.8%, the L5 vertebral body in 80.8%, the L4 to L5 disk space in 11.5%, and the L4 vertebral body in 3.8%.[123] Although guidance by nonselective venography is usually adequate for defining the iliac confluence and renal vein levels before filter deployment, additional selective venography may be an important consideration if these important venous landmarks cannot be defined. With selective catheterization of the renal veins and across the iliac confluence, important venous anomalies, especially a duplicate IVC, can be identified. With the addition of selective venography, detection of aberrant anatomy or some abnormal finding that leads to a change in the intended location for filter deployment occurred in 11% to 30% of patients in some series.[124-126] Additional large venous branches in the infrarenal portion of the IVC are also identified to avoid deployment of a filter leg into the branch and prevent tilting of the filter. Based on venographic guidance, the filter is then ideally positioned with the tip at the lowest most renal vein and the base above the iliac confluence.

If suprarenal filter placement is required, venographic imaging of the suprarenal vena cava is required to confirm the level of the renal veins for the distal landmark and the position of the hepatic vein confluence. Usually this will align with the T11 to L1 vertebral body levels. The suprarenal vena cava is generally larger than the IVC, and accurate diameter measurements should be made to confirm a diameter smaller than 28 mm. For suprarenal filter positioning, it is important to align the filter leg attachment point just above the most cephalic renal vein to avoid deployment of the filter hook into a renal vein, which may cause the filter to tilt. Although the level of the tip of the filter is less important, if possible it is best for it to be below the hepatic vein confluence to avoid potential hepatic vein thrombosis (Fig. 152.4).

Transabdominal Duplex Ultrasound–Guided Filter Placement

Transabdominal duplex ultrasound is performed to determine whether visualization of the IVC at the renal vein level is adequate in both the transverse and longitudinal axis views.[127] Identification of the right renal vein is important because it is usually the lowest most renal vein. In the longitudinal axis, the level of the right renal artery serves as an indirect landmark for the right renal vein. Percutaneous venous access is obtained and a guide wire is passed into the IVC under duplex ultrasound

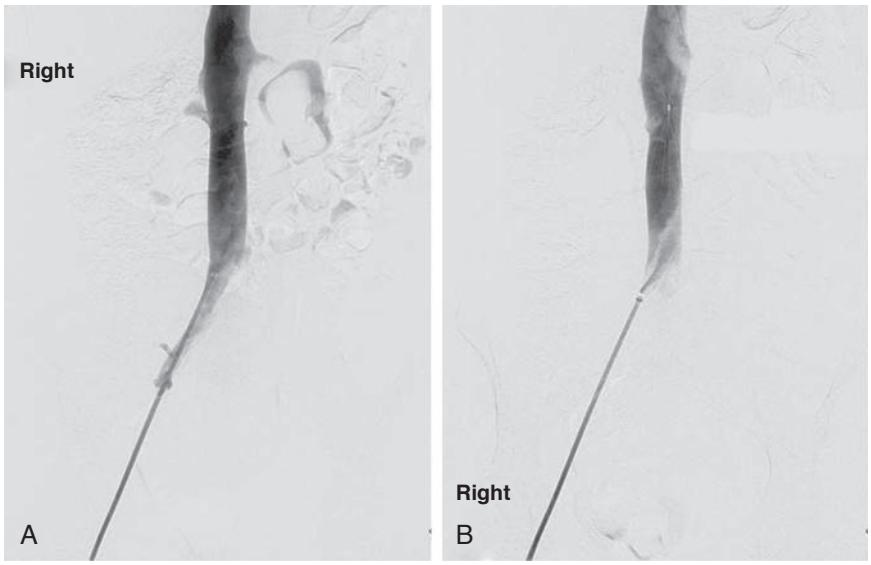

Figure 152.4 Suprarenal vena cava filter placement in a patient with a tortuous and enlarged infrarenal segment **(A)**. Note the base of the filter just above the renal vein origins, the tip below the hepatic vein confluence, and the filter in straight axial alignment in the suprarenal segment of the vena cava **(B)**.

visualization. The introducer sheath is inserted to a level just past the renal vein confluence under duplex ultrasound guidance. For over-the-wire filter systems, the guide wire needs to be removed to be able to differentiate the end of the filter delivery catheter. The right renal vein–IVC junction is visualized transversely, and the filter delivery catheter is advanced inside the sheath to the renal vein level (Fig. 152.5). With the filter delivery catheter in the correct position, the sheath is slowly pulled back to expose the filter delivery catheter tip at the renal vein level. The filter delivery catheter can be moved back and forth to confirm its position, and when the tip of the filter delivery catheter disappears and reappears in this view, the intended deployment position has been reached. In the longitudinal view the tip of the filter delivery catheter should be easily visualized and in proper alignment. Under direct visualization with duplex ultrasound in the longitudinal view, the filter is deployed. Postdeployment duplex ultrasound imaging confirms full expansion and proper position of the filter in the IVC (Fig. 152.6).

Intravascular Ultrasound–Guided Filter Placement

After adequate local anesthesia, percutaneous femoral venous access is obtained. Depending on the intravascular ultrasound system used, usually an 8-Fr sheath is needed. Although smaller profile intravascular ultrasound probes can be used, the image size produced with the increased-megahertz probe is generally too large for adequate visualization of adjacent anatomic landmarks. The intravascular ultrasound probe is inserted into the sheath over the guide wire and directed into the IVC to the level of the right atrium of the heart. Using a pull-back technique, the venous anatomic landmarks are sequentially identified, including the right atrium, hepatic veins, renal veins, and confluence of the iliac veins (Fig. 152.7). If the location of the iliac vein confluence is unclear, additional contralateral femoral venous access is obtained for passage of a second guide wire to allow precise identification of this confluence at the level where this second contralateral wire is visualized in the IVC. The intravascular ultrasound probe is directed just below the level of the lowest most renal vein, and IVC diameter

measurements are made before proceeding with deployment of the IVC filter.

A single–venous access technique can be used if the filter delivery kit sheath exceeds 8 Fr. Sheath exchange is performed over the guide wire, and the sheath is advanced to the predetermined level of the renal veins. The intravascular ultrasound probe is used to precisely direct the end of the sheath to the level of the lowest most renal vein. For filter systems with predetermined marks (such as the Günther Tulip and Celect filters), the filter delivery catheter is advanced to the mark by aligning the tip of the filter with the end of the sheath, and then the sheath is withdrawn in a "pin-pull" fashion to allow deployment of the filter at the infrarenal level.[128] For filter systems without predetermined marks (such as the Greenfield filter), the sheath is first pulled back over the intravascular probe a distance equivalent to the length that the filter delivery catheter extends beyond the sheath (for the Greenfield filter, this distance is approximately 7 cm) so that when the filter delivery catheter

is loaded into the sheath, the tip of the filter will precisely align with the lowest most renal vein on deployment.

If filter placement is not feasible with the single-puncture technique or for lower profile filter systems, a dual–venous access technique is required.[129,130] The intravascular ultrasound probe is left at a position just below the renal veins. Separate percutaneous access is obtained, preferably in the contralateral femoral vein, which allows confirmation of the iliac confluence and avoids double large sheaths in the same femoral vein. If contralateral venous thrombosis is present, the ipsilateral femoral vein adjacent to the intravascular ultrasound probe can be used, but the potential for access site thrombosis is increased. With real-time intravascular ultrasound imaging, the filter delivery catheter is directed to the level of the renal veins through the additional femoral access (Fig. 152.8). Once position of the filter delivery catheter tip is confirmed, the intravascular ultrasound probe is pulled back and the filter is deployed. The intravascular ultrasound probe can be carefully advanced to confirm apposition of the filter legs to the IVC wall, but care should be taken when advancing the filter tip to avoid dislodgement. Postprocedure plain abdominal radiographs are obtained to verify filter position and alignment.

Filter Retrieval

When an optional/retrievable filter is placed, a retrieval timeline should be determined. Retrieval should be timed for a period when the risk for PE is low, when anticoagulation can be restarted if continued VTE treatment or prevention is required, and when retrieval can be performed safely with low complication potential. At the time of retrieval, the integrity of the filter should be radiographically confirmed to make sure that there are no filter-related problems that would make retrieval not possible. Venography should be performed first to determine whether thrombus is present within the filter, in which case the filter should be left in place. Depending on the type of optional filter used, different approaches and techniques are required. For the Cordis OptEase filter, percutaneous femoral access is obtained and a snare is used on the caudal hook to recapture the filter into a 10-Fr sheath. For the Cook Günther Tulip and Celect filters, percutaneous jugular access is obtained and a snare is used on the cephalic hook to recapture it into an 11-Fr sheath. For the Bard Denalifilter, ALN Optional filter, and OptionElite filter which incorporates a hook at the apex of the filter, retrieval options using snare techniques via jugular access are also performed. The Crux filter has bidirectional retrieval options from either jugular or femoral access using snare techniques. The VenaTech Convertible filter has a release mechanism at the filter apex which when retrieved using a snare catheter allows open conversion and deactivation of the filter portion leaving the attachment struts in place.

Independent of filter type, during the retrieval process difficulty releasing the filter from the IVC attachment may occur, and retrieval should be aborted if the filter does not release with modest tension. For malpositioned or difficult-to-retrieve filters, additional advanced techniques using various wire/catheter combination techniques to free up filter hook, balloon angioplasty of attachment points, and bronchoscopic forceps to directly grab filter hook have also been described but should be reserved for special situations.[131-133]

SUPERIOR VENA CAVA FILTERS

Upper extremity DVT is becoming increasingly common, especially with the expanding use of central venous access, pacemakers, and implantable defibrillators. Other contributing factors, including thoracic outlet–related venous occlusion, malignancy, congestive heart failure, sepsis, and thrombophilia, have also been implicated. The risk for PE with upper extremity DVT is approximately 5% to 10% in most series, but risk as high as 28% and several cases of fatal PE have been reported.[134-138]

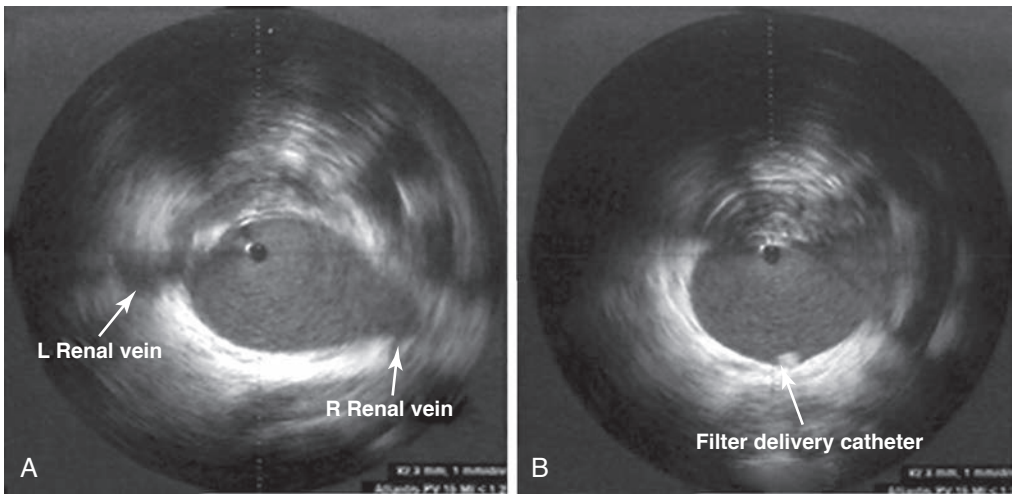

Figure 152.8 Visualization of the tip of the filter delivery catheter just below the right renal vein **(A)** at the level of the infrarenal inferior vena cava **(B)** during bedside placement of the filter under intravascular ultrasound guidance using a dual–venous access technique. (Reprinted with permission from Passman MA, Dattilo JB, Guzman RJ, Naslund TC. Bedside placement of inferior vena cava filters by using transabdominal duplex ultrasonography and intravascular ultrasound imaging. *J Vasc Surg.* 2005;42:1027–1032.)

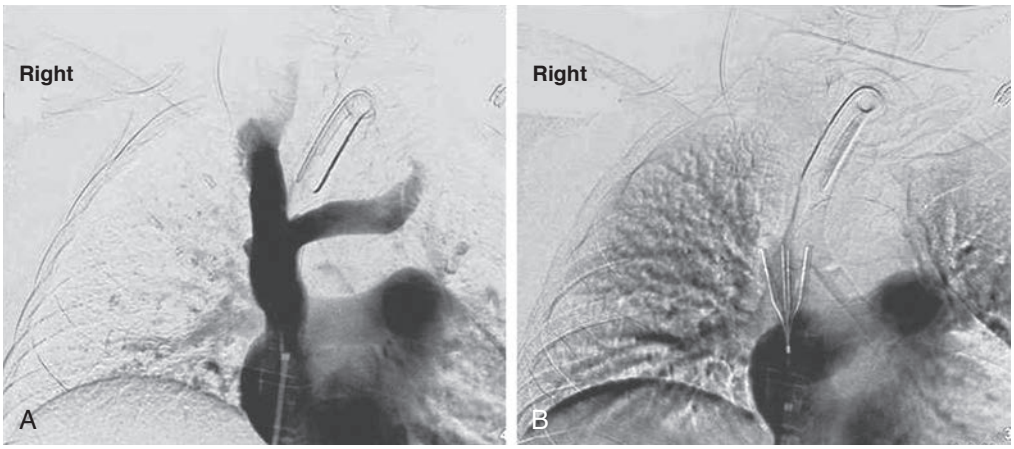

Figure 152.9 Venogram of the superior vena cava **(A)** followed by superior vena cava filter placement with the filter base just distal to the confluence of the brachiocephalic veins and the tip at the junction of the right atrium **(B)**.

Although standard treatment of upper extremity DVT is anticoagulation, when anticoagulation is contraindicated or complications of anticoagulation develop,[9] superior vena cava placement may be an option in selected cases, with experimental data on the use of filters in the superior vena cava based on animal models, case reports, and case series growing.[139-147]

For patients with both upper and lower extremity DVT, simultaneous placement of both inferior and superior vena cava filters has been described. Although use of permanent Greenfield filters for superior vena cava placement has mostly been described, there have been some reports of optional filter use and retrieval.[144,148,149] Because of superior vena cava anatomic constraints, conical filters with filter leg hook attachment points are preferred over more rigid filter designs.[150] Until a specifically designed filter for superior vena cava use is available, current IVC filters will continue to be adapted to this use.

Superior vena cava filter placement can be performed via jugular or femoral percutaneous venous access. For proper filter orientation, a jugular set is used for femoral insertion and a femoral set for jugular insertion. If inferior and superior vena cava filters are being placed simultaneously, the sequence of filter placement is dependent on the site of venous access, with the most distal filter requiring placement first. Any previously placed central venous catheters need to be removed or retracted before placement to avoid entrapment. Detailed venography is performed to define the anatomic landmarks of the superior vena cava. Any superior vena cava anatomic anomalies must be appreciated and a decision made whether safe and effective placement of the filter is possible. A duplicated superior vena cava occurs in approximately 0.1% to 0.3% of the population and can be a potential bypass for emboli if not identified.[151] Thrombus or occlusion of the superior vena cava and azygos or hemiazygos enlarged collaterals needs to be assessed if present. The intended filter position for filter leg attachment is just at the confluence of the innominate veins and is defined by venography (Fig. 152.9). The filter length deployed must be taken into consideration to avoid extended protrusion into the right atrium. Superior vena cava measurements are based on preprocedure computed tomography, venography, or intravascular ultrasound, and filter placement in a superior vena cava with a diameter greater than 28 mm is not recommended. With correct positioning and sizing, the filter delivery catheter is passed through the sheath and the filter deployed.

No randomized controlled study of superior vena cava use has been published to date. In the largest experience of superior vena cava filter placement for upper extremity DVT reported by Ascher and colleagues, 72 patients were included with a mean follow-up of 22 months.[147] Complication occurred in 1.3% and included filter malpositioning without migration, but no PE. Although mortality in this series was 47%, causes of death were unrelated to filter placement and were more reflective of the serious illness in this patient population. Others have documented complications, including superior vena cava perforation, cardiac tamponade, dislodgement by central line placement, guide wire entrapment, superior vena cava thrombosis, pneumothorax, and erosion into the thoracic aorta.[152] Based on the limited available evidence, superior vena cava filter placement is a safe and effective alternative for prevention of PE in selected patients with upper extremity DVT when anticoagulation is not possible.

INTRODUCTION

Phlegmasia cerulea dolens (PCD) and venous gangrene are the most severe manifestations of acute deep venous thrombosis (DVT), yet their pathophysiology is different and often misunderstood. This chapter addresses the proper definition of terms and differentiates the complex pathophysiology underlying these conditions. It also addresses the associated conditions of symmetric peripheral gangrene, purpura fulminans, cancer-associated disseminated intravascular coagulation (DIC), heparin-induced thrombocytopenia (HIT), and the common warfarin-associated coagulopathy, all of which are frequently associated with venous limb gangrene.

Digit or limb necrosis in the face of palpable distal pulses or documented patent arteries is a particularly difficult clinical scenario; venous limb gangrene is such a condition. It occurs in patients with large vein thrombosis who generally have multiple comorbidities. These comorbidities are often associated with fulminant prothrombotic states that produce unchecked and excessive thrombin generation at the microvascular level, which can be paradoxically accelerated by anticoagulants, particularly vitamin K antagonists. The magnitude of the venous thrombosis and tissue necrosis depends on the patient's underlying prothrombotic condition. Our present understanding of venous limb gangrene is clouded by statements equating PCD with venous limb gangrene and describing phlegmasia alba dolens as iliofemoral DVT (IFDVT) causing early compromise of arterial flow,[1] neither of which is correct.

Initial descriptions of venous limb gangrene described acral necrosis in a limb with extensive DVT. These early descriptions focused on the extensive nature of the large vein thrombosis compromising proximal venous return. The underlying pathophysiology of the tissue necrosis was attributed to the obstruction of large veins and their collaterals, leading to venous hypertension, severe tissue edema, and subsequent occlusion of arterioles and capillaries as a consequence of the venous hypertension.[2] This view of the pathophysiology of venous limb gangrene has led to misconceptions that continue today. Unquestionably, venous hypertension due to large central vein occlusion increases venous pressures, increases compartment pressures, produces edema, and reduces arterial perfusion; however, the underlying common denominator leading to tissue necrosis is small vein and microvascular thrombosis, which occur in very few patients with extensive DVT and very few patients with PCD. These patients with microvascular thrombosis are

among the most difficult to manage, due to their multiple and serious comorbidities, with high limb morbidity and high patient mortality.

Fasciotomy has been proposed as part of a management strategy for patients with extensive acute and chronic venous disease. The underlying pathophysiology is venous hypertension, producing increased compartment pressures. Since venous hypertension is the result of large vein obstruction, it is intuitive that the elimination of the venous obstruction and restoring venous return reduces venous pressures, often to normal.[3] Reducing venous (and compartment) pressures is a more preferable approach than enlarging the leg compartments with a fasciotomy, in order to accommodate the persistently high venous pressure. Often overlooked by advocates of fasciotomy are the adverse outcomes and persistently deranged venous hemodynamics in those who have lower extremity fasciotomy for acute IFDVT.[4]

PHLEGMASIA CERULEA DOLENS

The term *phlegmasia* is derived from the Greek root *phlegma*, indicating inflammation. The remaining two terms, *cerulea* and *dolens*, have Latin roots. *Cerulea* derives from the Latin word *caeruleus*, which means "dark blue." The Latin term of *dolens* refers to "hurting or suffering." Put together, phlegmasia cerulea dolens is the swollen, blue, painful limb that is most often observed in patients with iliofemoral DVT.

Phlegmasia alba dolens is the swollen, "white," painful limb. It is observed in patients with IFDVT who have enough venous drainage to remove subdermal and dermal venous blood before cyanosis occurs.

Phlegmasia alba dolens and PCD (Fig. 153.1) are found in patients with limb manifestations of large central venous obstruction. The clinical picture reflects the severity of their thrombosis.

Phlegmasia cerulea dolens is not synonymous with venous limb gangrene. Venous limb gangrene is associated with other comorbidities producing complex prothrombotic conditions. The paradoxical presentation of tissue ischemia and necrosis without arterial compromise, often in patients receiving anticoagulants, underscores the importance of recognizing the confounding clinical scenarios contributing to venous limb gangrene. While this form of tissue necrosis can rarely be observed in patients with PCD, the underlying pathology leading to tissue necrosis is thrombosis involving the microcirculation.[5] In these patients, distal pulses are often palpable or at least detectable with a Doppler.

Most patients with IFDVT present with swelling that involves the entire limb, causing varying degrees of discomfort. Phlegmasia alba dolens (see Fig. 153.1A) generally results from a more limited occlusion of the iliac veins, which causes leg discomfort and edema. However, the venous return is efficient enough to clear the dermal and subdermal venous blood before cyanosis occurs. The difference between phlegmasia alba dolens and PCD (see Fig. 153.1B and C) is the amount of deoxyhemoglobin in the venous plexus of the skin and subcutaneous tissue and the degree of discomfort produced by the associated venous hypertension and elevated compartment pressures.[6]

Cyanosis is caused by an increase in deoxyhemoglobin in the subdermal tissues at levels of 1.5 to 5 mg%.[6] With central deep venous occlusion leading to venous hypertension and sluggish venous return, there is stagnation of venous blood in the dermal and subdermal venous plexus, resulting in bluish discoloration of the leg.

PCD is characterized by extensive thrombosis, usually involving the iliofemoral venous system, most often involving the common femoral vein and perhaps the infrainguinal venous segments as well. The clinical presentation of PCD is often preceded by phlegmasia alba dolens.[7] Progressive lower extremity edema from the thigh distally is a constant feature that can

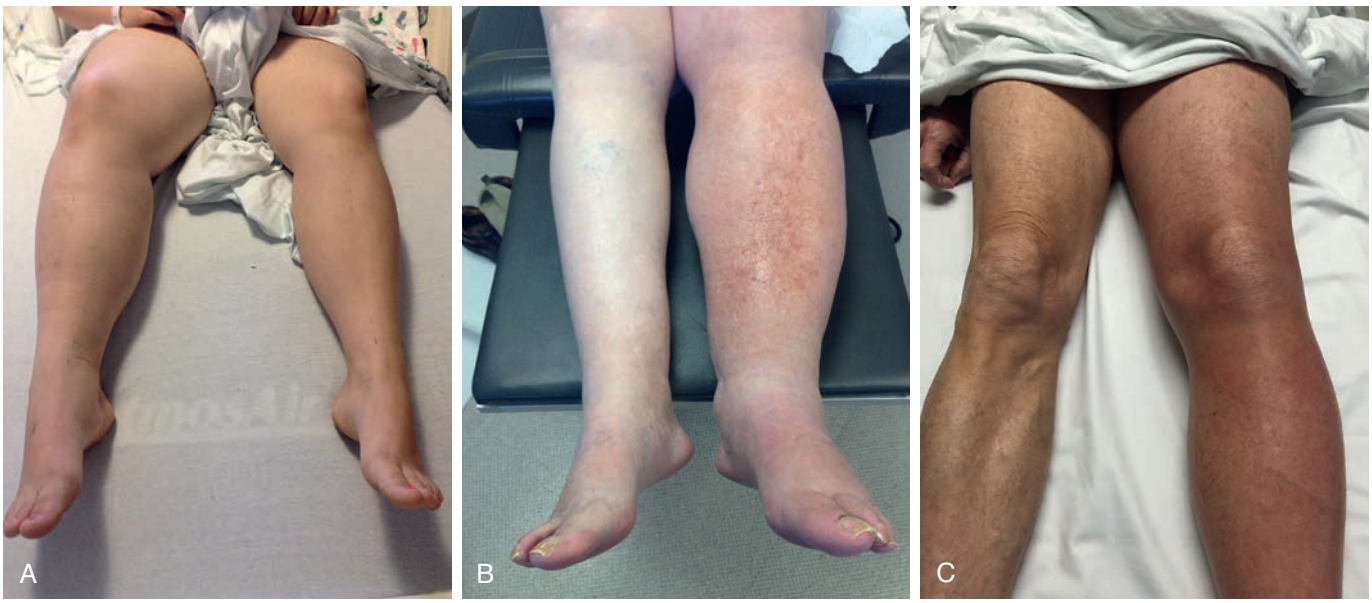

Figure 153.1 Clinical examples of phlegmasia alba dolens (A) and phlegmasia cerulea dolens (B and C).

occur rapidly after occlusion of the venous drainage from the limb. When the edema is massive, the skin is often tight and has a shiny appearance. The edema can range from pitting to firm and tense and be described as indurated on palpation. Cyanosis is a constant feature and may range from a slight bluish hue to a deep violaceous discoloration. Patients can have petechiae or purpuric areas scattered about their extremity, which quickly resolve after venous drainage is restored. Pain is a constant feature of PCD, ranging from an aching discomfort to a severe bursting pain causing extreme disability.

In some patients with advanced PCD, cutaneous blisters or bullae develop, which are usually filled with serous tissue. If hemorrhagic bullae develop, this portends a poorer prognosis indicating underlying tissue necrosis, associated with venous limb gangrene.

Early in the course of PCD, distal pulses are palpable. As the venous hypertension increases and as the edema becomes more tense, palpation of distal pulses becomes difficult; however, arterial Doppler signals usually remain audible. In patients who progress to venous gangrene, the extreme hypoperfusion leading to tissue death is the result of small vessel and microvessel thrombosis rather than primary arterial hypoperfusion of occlusion.

Clinically patients with lower extremity PCD have extreme discomfort, difficulty walking, and a tense swollen cyanotic limb. The degree of pain and disability is related to the extent of venous occlusion and the efficiency of collateral venous drainage, which determines the severity of their venous hypertension and compartment pressures. Although arterial perfusion is reduced when venous pressures are elevated, PCD alone rarely results in tissue necrosis. PCD is fully reversible if thrombus is successfully eliminated from the deep venous system, and unobstructed drainage to the vena cava re-established.

Animal studies have improved our understanding of the acute hemodynamic changes that occur with extensive proximal venous occlusion.[7,8] The hemodynamics of acute massive venous occlusion were studied in anesthetized dogs by Snyder et al.,[9] after they ligated all the iliac and femoral veins and all of their branches. One hour after venous occlusion, the limbs were circumferentially swollen and cool with violaceous mottling. Although arterial pulses were palpable, arterial blood flow was diminished by 25%. Total body blood volume fell by 13% due to serous fluid sequestration into the soft tissue of the swollen limbs, with limb volume increasing by 117% and hematocrit increasing to 115% of normal. Tissue pressure increased from 1 to 7 mm Hg and limb venous pressure increased 12-fold. Six hours after occlusion the animal showed hypovolemia with tachycardia and hypotension. Limb swelling was pronounced, as was limb cyanosis. In most animals, arterial pulses were no longer palpable due to the massive edema, blood volume was reduced by 40%, and hematocrit was increased by 35%. Interestingly, arteriography demonstrated a patent arterial system.

Patients presenting with phlegmasia alba dolens or PCD are best treated with a strategy of thrombus removal, as reviewed in Chapter 148. Upon diagnosis, patients are therapeutically anticoagulated, their limbs elevated and wrapped snuggly from their toes to their inguinal crease. This reduces their pain and edema. Within 24 hours, these patients will either undergo a contemporary operative venous thrombectomy or more commonly a catheter-based technique, to remove their thrombus.

As soon as a lumen is restored, permitting at least some degree of venous drainage, cyanosis rapidly resolves, venous and compartment pressures fall, the leg softens, and pain disappears. The best outcomes occur in patients who have complete or near complete thrombus resolution.[10]

VENOUS GANGRENE

Venous limb gangrene indicates soft tissue necrosis in a limb with DVT. Tagariello reported the clinical presentation of venous limb gangrene more than 50 years ago.[7] He described that venous gangrene was always the result of an extensive venous obstructive process, which passes through successive clinical phases. The first phase is phlegmasia alba dolens, indicating central large-vein obstruction with preservation of compensatory collateral venous drainage. The next phase, PCD, is characterized by progressive edema with pain in the calf and/or thigh and diffuse cyanosis of the limb. He attributed the eventual loss of arterial pulsations to "arterial spasm," which we now know is not part of the pathophysiology. He indicated that the changes characterizing the phase of PCD were still reversible and did not necessarily lead to gangrene.

He reported that venous gangrene is always preceded by PCD, which must be considered an obligatory phase. In the final analysis, the anatomic specimens at autopsy showed that all small veins were obstructed by thrombus. He stated, "*It seems logical to attribute all the pathogenic importance of venous gangrene to the thrombotic obstruction involving the extreme venous ramifications [small veins and microvasculature]*." In other words, venous gangrene was ultimately the result of small vein and microvascular thrombosis, not central large-vein thrombosis.

In early reports, malignancy was observed in many of the patients who developed venous gangrene. In the authors' clinical experience, all patients treated for venous limb gangrene have had malignancy and other serious conditions complicating their proximal DVT. These additional conditions include heparin-induced thrombocytopenia with warfarin exposure, disseminated intravascular coagulation, the procoagulant state of warfarin, sepsis, purpura fulminans, hypotension requiring pressors, and/or acute hepatic dysfunction. In most patients with venous limb gangrene managed by the authors, multiple prothrombotic conditions co-existed with malignancy, resulting in their limb loss and excessively high mortality.

Venous limb gangrene indicates soft tissue necrosis in a limb with large burden proximal DVT. The previously accepted pathophysiology of high venous and interstitial pressures causing compression of small nutrient vessels[11,12] was only recently supplanted by our understanding of the underlying coagulopathy leading to their microvascular thrombosis. Their acquired prothrombotic state(s) invariably include cancer-associated consumptive coagulopathy,[13] heparin-induced thrombocytopenia,[14] antiphospholipid antibody syndrome,[15] and warfarin administration.[16]

HEPARIN-INDUCED THROMBOCYTOPENIA

Heparin-induced thrombocytopenia (HIT) is a serious, potentially fatal, immunologically mediated drug reaction, usually to unfractionated heparin (UFH) or, less commonly, low molecular weight heparin (LMWH; see Chapter 38). HIT develops twice as often in women than men.[17,18] Thrombotic complications lead to the high morbidity and can be associated with a 20% to 30% mortality rate.[19]

Two distinct types of HIT have been identified.[20] Type I is the innocuous benign thrombocytopenia occurring within 2 days of heparin initiation, which has been reported in 10% to 30% of patients receiving UFH. Platelet counts generally normalize with continued heparin administration, and these patients are not at increased risk for thrombotic events. Type II HIT refers to the antibody mediated disorder that requires cessation of heparin, avoidance of vitamin K antagonists, and immediate treatment with an alternative anticoagulant (direct thrombin inhibitor) to avoid further thrombosis. When physicians discuss HIT, they typically refer to the immunologically mediated thrombocytopenia.

HIT is a prothrombotic immune-mediated reaction most commonly produced by an immunizing exposure to UFH. IgG antibodies bind heparin to platelet factor-4, producing a prothrombotic state. Patients with malignancy and those undergoing orthopedic surgery have been recognized as being particularly at risk for HIT. Women and patients with malignancy have a twofold increased risk for HIT. Furthermore, the combination of HIT with cancer is strongly associated with thrombosis compared with HIT alone.[21] Patients undergoing orthopedic surgery and those with malignancy are known to have high levels of inflammatory cytokines and other procoagulant proteins.[22]

HIT typically develops 5 to 10 days after the start of UFH infusion. Those with a recent exposure to heparin (1 to 12 weeks) can develop a "rapid onset" HIT, such as an intraoperative thrombosis after a single bolus dose of UFH, due to existing platelet-heparin antibodies (Fig. 153.2). Depending upon the magnitude of the HIT response, HIT sera can activate platelets in the absence of heparin. This has been termed heparin independent activation of platelets, which is the scenario when HIT begins or worsens after heparin is discontinued, often after the patient is discharged from the hospital. This phenomenon is termed "delayed onset" HIT.

Dr. Ted Warkentin characterized HIT as "the greatest paradox in medicine."[23] That is, patients develop clotting in the presence of therapeutic anticoagulation, tissue necrosis occurs in the presence of patent arteries, and patients have additional clotting with the administration of more anticoagulants with a particularly aggressive prothrombotic state developing when warfarin is administered. Clotting causing tissue necrosis occurs at the venular and microcirculatory level. Two examples of warfarin-induced tissue necrosis are shown in Fig. 153.3. Warfarin-induced skin necrosis can occur in central skin and subcutaneous tissue typically overlying areas of adipose tissue, illustrated by the breast and thigh necrosis in these examples. Venous limb gangrene is a result of DVT progression, usually in the setting of a supra-therapeutic international normalized ratio (INR).[5]

HIT is a prothrombotic condition that can precipitate large artery and large vein thrombosis. Left untreated, 50% to 89% of patients will develop a thrombotic complication.[19] If warfarin is administered or if the patient has cancer or concurrent DIC, a powerful prothrombotic state is produced, resulting in excessive production of thrombin in the absence of naturally occurring anticoagulants (proteins C and S), leading to microvascular thrombosis and tissue necrosis.

Since the platelet fibrin thrombus causing the large vessel occlusion appeared white when removed from thrombosed arteries (Fig. 153.4), vascular surgeons initially characterized this as "white clot syndrome."[24]

Venous thromboembolic complications are the most common thrombotic consequence of HIT. However, arterial thrombotic events are frequently observed in patients who have been treated for complications of atherosclerotic arterial disease. Patients with HIT are at risk for macro- and microvascular thrombosis, especially when warfarin is administered, or when HIT is complicated by disseminated intravascular coagulation.

The use of vitamin K antagonists in patients with HIT increases the risk of venous limb gangrene or other thrombosis. A characteristic feature of HIT patients who receive warfarin

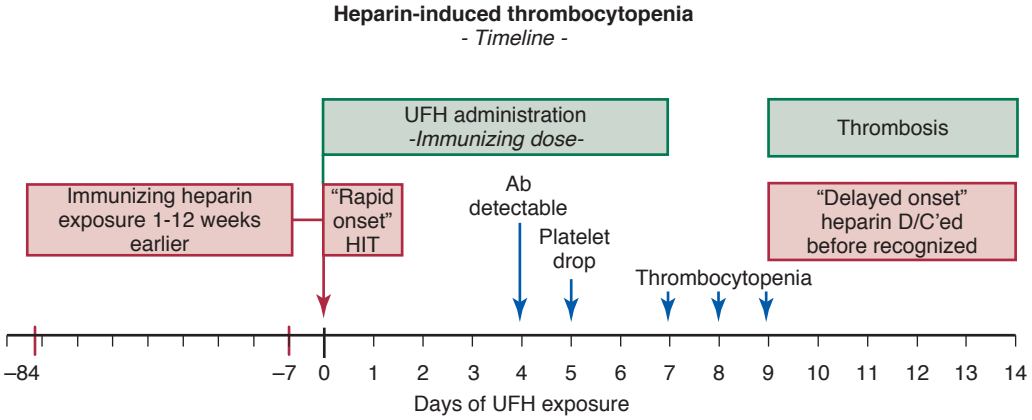

Figure 153.2 Schematic of timeline for heparin-induced thrombocytopenia (HIT). *UFH,* Unfractionated heparin.

Figure 153.3 Two examples of warfarin-induced skin necrosis in patients with heparin-induced thrombocytopenia (HIT). A 74-year-old male who was being treated for postoperative deep venous thrombosis (DVT), following total hip replacement. Three days after the initiation of warfarin, he developed skin necrosis of the calf and thigh of the involved limb (A). A 69-year-old woman developed HIT after being treated with heparin for acute postoperative lower extremity DVT after a hysterectomy for endometrial cancer. The patient also developed catheter induced axillo-subclavian DVT. Two days after warfarin was initiated, the patient began to develop skin necrosis of the right breast (B).

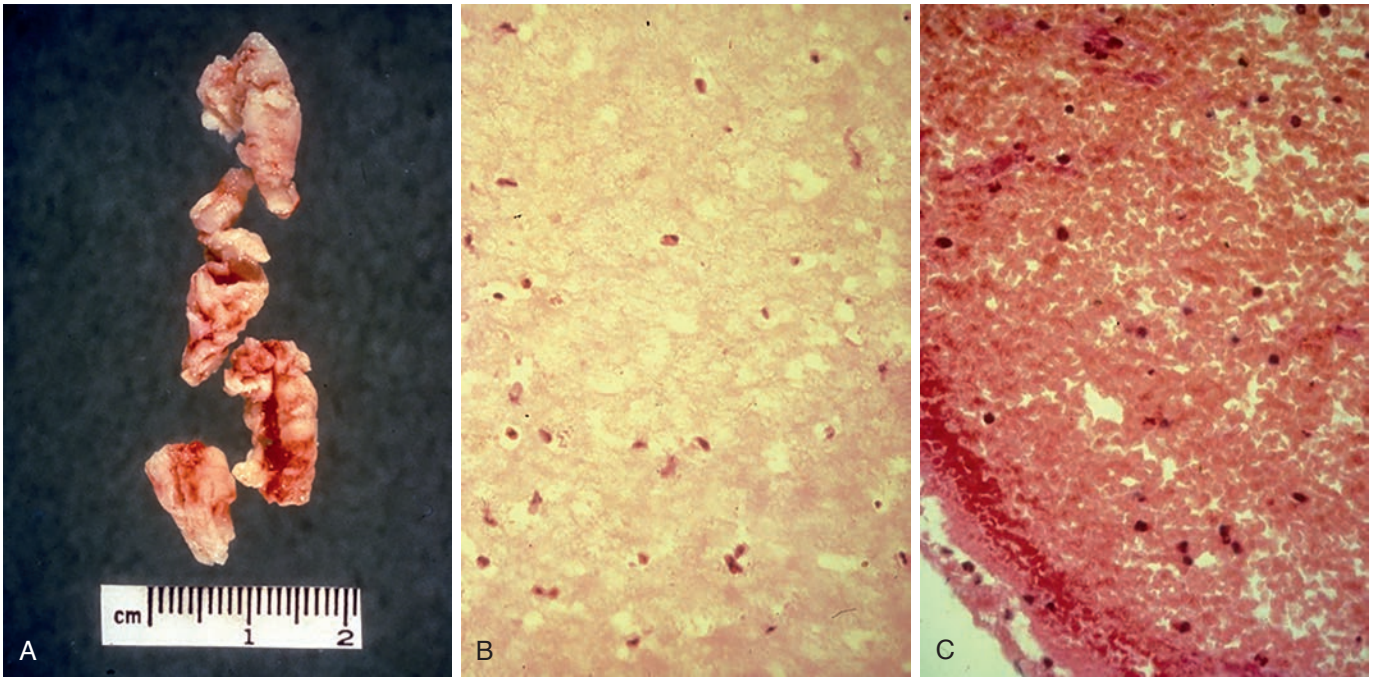

Figure 153.4 Thrombectomy specimen removed from the femoral arteries in a patient who developed heparin-induced thrombocytopenia, causing acute lower extremity ischemia. Specimen (A) is a platelet-fibrin thrombus, demonstrating why the term "white clot" was coined. The microscopic exam of the "white clot" shows a platelet-fibrin histologic appearance (B), compared with a standard acute thrombus with large amounts of RBCs (C).

is a markedly elevated INR in the face of clinically progressive thrombosis.[5] The elevated INR is due to the rapid depletion of factor VII, which has a short half-life, and the progressive thrombosis occurring because of the near complete depletion of protein C, which is also vitamin K dependent and has an equally short half-life.

When warfarin is given to patients with HIT, an accelerated prothrombotic state develops with unchecked thrombin generation. Protein C, a naturally occurring anticoagulant, is vitamin K dependent and has a half-life of 9 hours. Factor VII, also vitamin K dependent, has a half-life of 5 hours. After a patient is given warfarin, protein C production is significantly diminished (<10%), as is factor VII. Low factor VII levels result in a markedly elevated INR, which is also an indirect indicator of reduced protein C (plasma concentrations of 65 nm). This value is substantially lower than the major procoagulant factor prothrombin, which has a half-life of 60 hours and a plasma concentration of 1500 nm.[5] These facts explain why despite

the high INR, thrombin generation is accelerated and microthrombosis occurs. In these patients, the administration of vitamin K (at least 10 mg by slow intravenous infusion, with 5 to 10 mg repeated 12 hours later if the INR remains prolonged) will blunt the warfarin effect and allow the liver to produce protein C. Therapeutic anticoagulation is required with either a direct thrombin inhibitor or a direct Xa inhibitor.[14]

CANCER-ASSOCIATED DISSEMINATED INTRAVASCULAR COAGULATION WITH VENOUS LIMB GANGRENE

When venous limb gangrene occurs in patients with cancer, an underlying procoagulant state is often related to the pathogenesis of their limb ischemia. In many such patients, their extensive DVT and venous limb gangrene often precedes the diagnosis of cancer.

Cancer is a strong risk factor for DVT. High levels of tissue factor, tumor necrosis factor, inflammatory cytokines, and disordered coagulation often leads to extensive DVT.[22] Cancer alone, without its associated DIC, has rarely been implicated as causing venous limb gangrene.

Anticoagulation is effective treatment for these patients. Until recently, heparin followed by warfarin was the most commonly prescribed method of anticoagulation. Warkentin et al.[13] described the problem of warfarin-induced venous limb gangrene complicating cancer as a distinct syndrome, separate from heparin-induced thrombocytopenia associated with thrombosis. They outlined a clinical picture of which a consumptive coagulopathy is the characteristic basis for this prothrombotic condition. In patients with cancer-associated DVT who were initially treated with heparin, there was an initial rise in the platelet count. After warfarin was given, there was frequently a supratherapeutic INR. When heparin was discontinued, the platelet count dropped and thrombosis progressed. Limb ischemia, consistent with venous limb gangrene, developed due to the underlying consumptive coagulopathy. These patients have a severely disturbed procoagulant-anticoagulant balance. When warfarin is given, thrombin generation is accelerated, confirmed by a marked increase of thrombin-antithrombin complexes and reduced protein C levels. Warfarin does not inhibit cancer-associated hypercoagulability, but paradoxically predisposes the patient to microvascular thrombosis.

Warkentin et al. performed a detailed analysis of the clotting factors and platelet specific antibodies in patients with cancer-associated venous limb gangrene.[13] It is interesting that all had cancer-associated DIC, were receiving warfarin, had a supratherapeutic INR, and were subsequently diagnosed with metastatic disease. In this detailed analysis, vitamin K dependent clotting factors, proteins C and S, and thrombin-antithrombin complexes (TAT; a marker of in vivo thrombin generation) were analyzed in addition to other indicators of DIC (fibrinogen and fibrin-D-dimer).

In all patients, venous limb gangrene occurred only in the limb with proximal venous thrombosis. In the three patients with bilateral DVT, venous limb gangrene occurred in the limb with the largest burden of thrombus, which had the most recent DVT. The most meaningful blood test results indicating the degree of prothrombotic activity were the TAT/PC (thrombin antithrombin/protein C activity) ratio. This ratio was high, indicating a marked imbalance of thrombin production uninhibited by protein C.

The supra-therapeutic INR explains the parallel reduction of factor VII and protein C, both of which are vitamin K dependent and have short half-lives; therefore, both rapidly fall after warfarin is given. An elevated INR can be considered a surrogate for the depletion of protein C (a strong inverse relationship). Since the other clotting factors with longer half-lives remain functional and in high concentration, the administration of warfarin induces a significant paradoxical prothrombotic state. When heparin was resumed, platelet counts increased, consistent with heparin, reducing the existing consumptive coagulopathy. Others have shown that cancer-associated DIC can be controlled with therapeutic dose heparin.[25]

When a patient presents with unexplained extensive DVT and a rise in platelet count is observed after the initiation of heparin, a cancer-associated DIC should be suspected. In this clinical scenario, vitamin K antagonists should be avoided, as they will generate an aggressive prothrombotic state.

DISSEMINATED INTRAVASCULAR COAGULATION

DIC occurs when there is disordered activation of hemostatic mechanisms. Platelet aggregation and pathologic thrombin generation occur, resulting in intravascular deposition of fibrin uncontrolled by endogenous fibrinolysis and the naturally occurring anticoagulant proteins C and S.[26] If allowed to progress, the microvascular thrombosis leads to organ dysfunction, digital and limb gangrene, and is associated with significant limb loss and mortality.

The clinical diagnosis of DIC is made by (1) an underlying disease state known to be associated with DIC; (2) prolongation of the thrombin time and partial thromboplastin time; (3) a platelet count of less than 100,000 or a rapid fall in platelet count; (4) presence of fibrin (fibrinogen) degradation products; and (5) low levels of antithrombin III.[26]

Often DIC occurs and contributes to patient deterioration before it is recognized. The predisposing factors that ignite the disordered coagulation are mediators which include proinflammatory cytokines such as tissue factor and tumor necrosis factor (cancer patients), alpha-1 interleukin-1 beta, interleukin-6 (or -7), monocytes, leukocyte stimulated endothelial damage, and sepsis induced downregulation of endothelial thrombomodulin. Disordered endogenous fibrinolysis also occurs, allowing microvascular thrombosis to continue unchecked. The fibrinolytic system is suppressed by an increase in plasminogen inhibitor-1. Clinical studies have demonstrated that the residual fibrinolytic capacity is too low to control the systemic deposition of fibrin.[27]

Bacterial endotoxins (producing inflammatory cytokines), tissue injury, shock, metabolic acidosis, and tumor-derived procoagulant microparticles trigger the initiation of DIC. Venous limb gangrene, whether associated with a malignancy or a severe nonmalignant comorbidity, is usually a soft tissue manifestation of DIC, often accelerated by the procoagulant effect of warfarin and the hypoperfusion of shock magnified by pressors. In patients with symmetric peripheral gangrene, DIC is often a common denominator.

SYMMETRIC PERIPHERAL GANGRENE (PURPURA FULMINANS)

Symmetric peripheral gangrene is often associated with or can be called purpura fulminans and can be mistaken for venous gangrene. Large vein thrombosis is not part of this clinical picture. This is a complication of infection and often septic shock (requiring pressors) and disseminated intravascular coagulation, resulting in skin and soft tissue necrosis. Septicemia, heart failure, metabolic acidosis, and hypotension requiring vasopressor support are the common predisposing factors leading to the coagulopathy resulting in microvascular thrombosis.

Warner et al. reported 70 cases of purpura fulminans. More than half were infants or children, most commonly infected with Neisseria meningitides (69%) or streptococcus (13%). Older adult patients were predominately infected with streptococcus.[28]

With sepsis, endothelial dysfunction occurs. Endothelial cells become edematous, capillaries dilate, and RBC extravasation occurs, producing petechial hemorrhages, which can coalesce producing areas of ischemic necrosis. Excessive thrombin generation is triggered by the proinflammatory cytokines produced by the underlying infection, tissue factors from tissue damage, and procoagulant microparticles, among others. This sets the stage for the intravascular coagulopathy that is the foundation for microvascular thrombosis, leading to tissue necrosis. This process is often magnified by the administration of warfarin, the presence of HIT, or both.

Patients develop acral necrosis involving their toes, forefoot, and fingers of their hands (Fig. 153.5A and B). Other nonlimb areas can be affected, such as genitalia, ears, nose, and scalp. In patients with purpura fulminans, nonacral tissue necrosis is common. However, in those who are hypotensive requiring pressors, finger and toe and foot ischemia are usually present.

Patients initially develop pale, cool feet and toes, which progress to nonblanching cyanosis. Blisters containing serous fluid may occur. When hemorrhagic bullae develop, underlying tissue necrosis is usually present. As the necrosis progresses, it often becomes sharply demarcated. Tissue biopsies generally show dermal microthrombi involving capillaries and venules (see Fig. 153.5C and D).[29]

Patients deteriorate as other organs become involved with the systemic nature of microthrombosis.[30,31] Mortality often exceeds 50% in these critically ill patients. Table 153.1 highlights the important differences.

FASCIOTOMY FOR VENOUS DISEASE

The most effective use of extremity fasciotomy is to relieve acutely elevated compartment pressures endangering neurologic function and tissue perfusion in patients suffering crush injury or reperfusion injury. The increase in venous pressure associated with extensive obstructive venous disease is not associated with the same pathophysiology as reperfusion injury following severe acute arterial ischemia or crush injury. An example is a recent report of two patients with extensive proximal venous thrombosis successfully treated with catheter-directed thrombolysis.[32] Despite successful lysis of large central vein occlusions in two patients, their limbs deteriorated, they became progressively acidotic, developed multiple organ system failure, and died. The focus of the authors' discussion was the "reperfusion injury" occurring as a result of successful thrombolysis. In both of these cases, however, metastatic cancer was present. The patients developed the picture of progressive disseminated intravascular coagulation associated with multiorgan system failure as a result of their consumptive coagulopathy. Microvascular venous occlusion occurred as part of the cancer-associated venous limb gangrene and DIC, leading to the patients' ultimate demise. Reperfusion could not have been achieved because of the microvascular thrombosis. A fasciotomy was performed in one of these patients without benefit.

Another misconception leading to unsuccessful fasciotomies in patients with acute large vein thrombosis is that mechanical forces are solely responsible for the ongoing deterioration of the limb and the patient. The simple theory that tissue pressure is elevated to a level that exceeds transmural pressure on the arteriole, leading to collapse of the vessel, is not entirely accurate. It is often stated that there is a decrease in hydrostatic pressure in patients with PCD due to shock and the marked increase in tissue pressure due to edema. This simple understanding fails to recognize that patients with PCD leading to venous limb gangrene uniformly have cancer, DIC, or both, which result in microvascular thrombosis, tissue necrosis, and often a fatal outcome. Once the large vein thrombosis is eliminated and venous drainage is restored, venous hypertension is rapidly relieved. In patients without microvascular thrombosis, once venous hypertension is relieved and the ongoing capillary leak eliminated, normal lymphatics resorb the excess tissue fluid.

FASCIOTOMY FOR ACUTE VENOUS THROMBOSIS (PHLEGMASIA CERULEA DOLENS)

Fasciotomy is rarely performed in patients with extensive DVT in light of the underlying pathophysiology of acute extensive venous occlusion, the lack of benefit observed in those undergoing fasciotomy, and the enormous benefit achieved with successful thrombus removal. Qvarfordt et al.[33] measured intramuscular pressures in the anterior compartment and superficial posterior compartment of the lower leg in 17 men and 17 women (normal volunteers) while at rest, during standardized exercise, and with venous and arterial occlusion. They found that men had higher

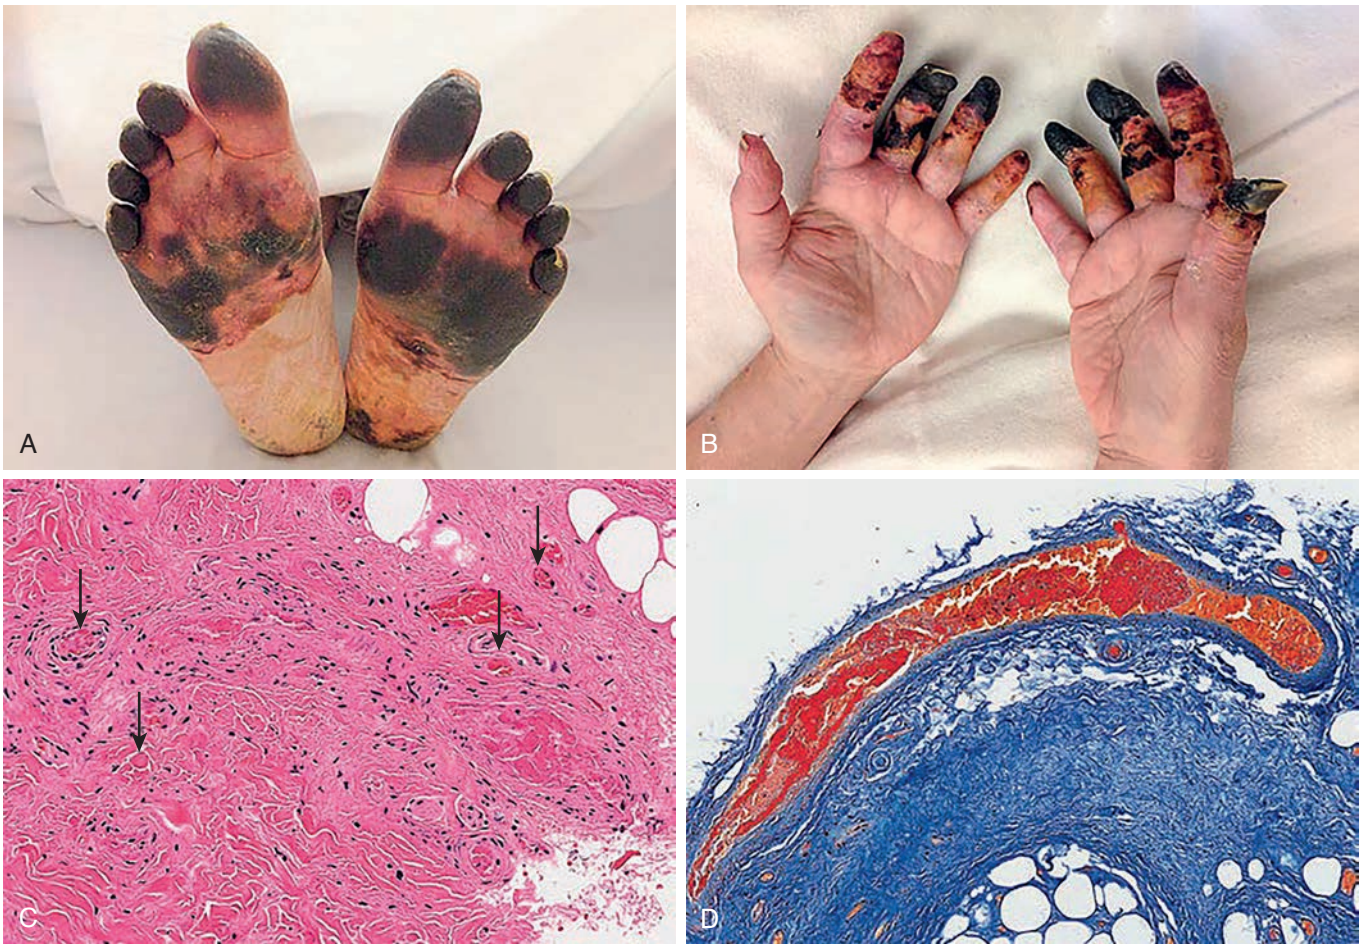

Figure 153.5 In a 62-year-old man with uncontrolled ulcerative colitis that was resistant to immunotherapy, an acute onset of swollen, discolored, and painful feet and fingers with progression to ischemic necrosis of both forefeet (A) and hands (B). No evidence of bacterial endocarditis or microvascular arterial disease was found. Laboratory evidence of inflammation included elevated C-reactive protein levels, along with hyperfibrinogenemia, hyperferritinemia, thrombocytosis, and anemia of inflammation. Autoimmune markers and antiphospholipid antibodies were negative. Studies did not support a diagnosis of decompensated disseminated intravascular coagulation: platelet count, 472,000 per cubic millimeter; international normalized ratio 1 : 1; activated partial thromboplastin time, 39 seconds; fibrinogen, 650 mg per deciliter (reference range, 160 to 420); and fibrin D-dimer, 1390 µg per milliliter of fibrinogen equivalent units (reference value <500). Skin biopsy of the left hallux showed multiple fibrin thrombi within small vessels *(arrows)*, as seen on hematoxylin and eosin staining (C) and Martius scarlet blue staining, in which fibrin is colored red (D). The patients' proinflammatory process improved after treatment with high-dose glucocorticoids and unfractionated heparin. (Reproduced with permission from The Massachusetts Medical Society. STG, Split thickness skin graft; *VLU,* venous leg ulcer.

anterior compartment intramuscular pressures than women and younger subjects had higher intramuscular pressures than older subjects, most likely due to muscle tone and muscle volume. Resting and exercise pressures were always higher in the anterior compartment. Resting pressures in the anterior compartment were 8.4 mm Hg (mean), which increased to 26.5 mm Hg with exercise. Venous occlusion increased the intramuscular pressures in the deep compartment. Arterial occlusion had minimal effect on intramuscular pressures.

The same investigators then measured the intramuscular pressures in the anterior and deep posterior compartment in patients with three different levels of acute venous thrombosis: calf DVT, IFDVT, and PCD.[3] Resting pressures were higher in those with the most extensive thrombosis. Pressures were measured after the Homan maneuver (passive dorsi flexion/plantar flexion of calf muscles).

A small but significant increase in intramuscular pressures was observed in patients with calf DVT. A larger increase in pressure was observed with iliofemoral thrombosis. Markedly elevated pressures were recorded in patients with PCD. During the Homans maneuver pressures significantly increased, especially in patients with IFDVT and PCD. The Homan maneuver was observed to cause pain when there was a significant but short-lasting increase in intramuscular pressure, indicating that the pain was related to the higher intramuscular pressure activating pain receptors. The one patient with venous gangrene (microvascular thrombosis) had persistently elevated pressures. Perhaps the most instructive of the authors' observations was the rapid fall in pressure in patients with PCD who underwent venous thrombectomy. They stated that venous thrombectomy appears to be the most specific form of treatment since venous outflow was reestablished. The literature supports strategies of thrombus removal as being the most effective form of therapy in patients with IFDVT.

In an earlier clinical experience, Fogarty and Cranley et al.[8] reported eleven patients treated for PCD. They also reviewed the United States literature of which there were 49 cases with sufficient information. They reported the marked benefit of eliminating the thrombus burden with venous thrombectomy, reported the initial results of using a balloon catheter for venous thrombectomy, and also commented on the potential benefit of ligating the femoral vein, common iliac vein, or vena cava to prevent subsequent pulmonary embolism. They also remarked that fasciotomy was not necessary in the majority of the patients if venous thrombus was removed.

Brockman and Vasco[34] performed a collective review of 279 cases of PCD. All but 9% of these cases had some other associated disease, such as malignancy, sepsis, trauma, congestive heart failure, or other serious comorbidity. Thrombectomy was recommended as the most effective form of management. The authors stated that thrombectomy was the only procedure followed by rapid cure of PCD. When fasciotomy was performed, it was associated with higher complication and failure rates. The theoretical benefits of fasciotomy were addressed; however, because of the mediocre results in a few patients, prolonged wound healing, infection, and poor results in most patients, the authors stated that fasciotomy was unwarranted.

The benefit of successful thrombectomy with restoration of unobstructed venous drainage is illustrated in Fig. 153.6. A young man sustained a high velocity gunshot wound to the right side of his abdomen, transecting his iliac artery and vein, in addition to small bowel and colon injury. His small bowel and colon injury were managed with appropriate resection and ileostomy. His iliac artery was reconstructed; however, his common, external, and internal iliac veins were ligated. Total leg fasciotomies were performed. Anticoagulation was withheld due to the risk of bleeding. The patient developed extensive

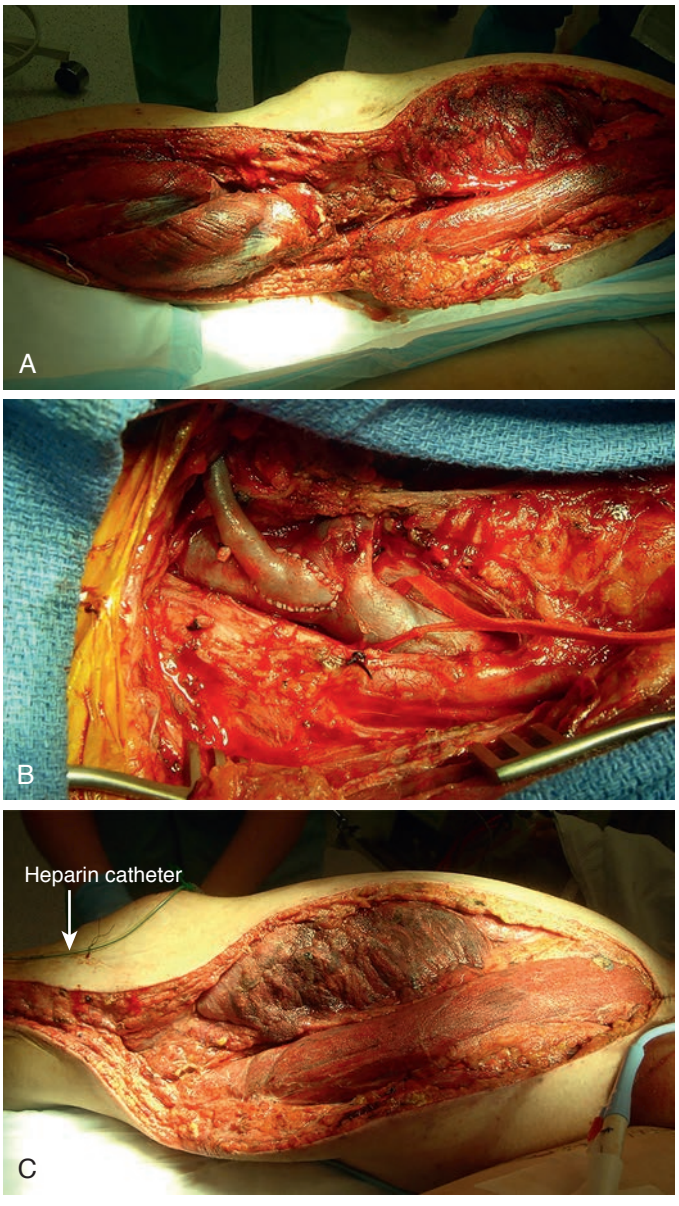

Figure 153.6 Example of massive edema resulting from iliac artery reconstruction and iliac vein ligation following a high velocity gunshot wound (A). A full-leg fasciotomy was performed. The patient developed extensive venous thrombosis. A full-leg venous thrombectomy was performed and a cross-pubic venous bypass was performed using the contralateral saphenous vein (B). The edema rapidly resolved permitting fascial closure of the calf within 48 hours (C). Note the heparin infusion catheter, which was secured into the posterior tibial vein at completion of the thrombectomy. This permits high heparin concentrations in the target leg while a low overall dose of heparin is infused, reducing the risk of bleeding.

DVT from his calf veins to the ligated external iliac vein. He presented with profound edema of his entire leg (see Fig. 153.6A). A venous thrombectomy was performed from the posterior tibial vein to the common femoral vein, and a pediatric feeding catheter was secured in the posterior tibial vein for postoperative regional heparin infusion at a dose lower than that used systemically. A cross-pubic venous bypass was constructed using his contralateral saphenous vein (see Fig. 153.6B). Within 48 hours the patient's edema resolved to the point that the fascial layer of his calf could be closed (see Fig. 153.6C). While this patient had reperfusion injury due to his iliac artery injury and repair, the remarkable resolution of his edema underscores the benefit of elimination of central venous thrombus and the restoration of unobstructed venous drainage.

Fasciotomy has been shown to alter venous physiology over the long term. Garfin et al.[35] reported the importance of an intact fascia on muscle force and calf muscle pump function. Rosfors et al.[36] performed a complete venous physiologic evaluation of 21 patients who had prior fasciotomy and concluded that an intact muscle fascia was important for normal venous return and calf muscle pump function.

Bermudez et al.[4] tested the hypothesis that fasciotomy impaired calf muscle pump function and led to chronic venous insufficiency. Seventeen patients who underwent fasciotomy were studied. Eight had fasciotomy for arterial reperfusion, six due to bone injury, and three for soft tissue infection. Follow-up physiologic evaluation demonstrated significant reduction in calf muscle pump function and elevation of ambulatory venous pressures compared with the subject's opposite unaffected limb. This suggested that fasciotomy could lead to chronic venous insufficiency.

Fasciotomy for Chronic Venous Disease

In patients with chronic anterior compartment syndrome, subcutaneous fasciotomy relieves pain, normalizes intramuscular pressure, and increases muscle blood flow and skeletal muscle metabolism.[37] It was with these observations in mind that paratibial fasciotomy was proposed as adjunctive therapy for patients with venous ulceration associated with the postthrombotic syndrome (PTS) and superficial venous insufficiency (SVI).

The most careful and objective analysis of fasciotomy for chronic venous disease was reported by Christensen.[38] He reported 25 limbs with venous ulcers, 11 due to PTS, and 14 due to SVI, treated with adjunctive subcutaneous paratibial fasciotomy, compared with 24 limbs with venous ulcers, 11 due to PTS, and 13 due to SVI, which were treated similarly but without subcutaneous fasciotomy.[38] All SVI patients were treated to eliminate their superficial reflux, and all patients were treated with 30 mm Hg compression stockings. All patients had intramuscular and subcutaneous pressures recorded, as well as $TcPO_2$ prior to, immediately after, and 3 months after surgical intervention. Ulcer healing was recorded.

The IM pressure was higher in patients with PTS compared with SVI. However, subcutaneous pressures and $TcPO_2$ did not differ between groups. When fasciotomy was performed, muscular and subcutaneous tissue pressure decreased and $TcPO_2$ increased significantly. In the SVI group IM, tissue pressure was significantly decreased at 3 months in the group without fasciotomy. Fasciotomy improved ulcer healing in both the PTS and SVI patients. In this interesting cohort of patients with difficult-to-heal venous ulcers, paratibial subcutaneous fasciotomy was associated with significant benefit to ulcer healing at 3 months. It remains unknown for how long fasciotomy remains effective in these patients with chronic venous disease, especially those with PTS. The patients in this series with PTS all had patent deep veins, which is probably not the case in those with the most severe PTS. It is not known how patients with greater degrees of postthrombotic obstruction will respond. It has been shown that subcutaneous fasciotomy is beneficial for up to 2 years for chronic anterior compartment syndrome.[39]

In the past, venous disease received relatively little attention in the public arena and in vascular training programs despite the fact that it is more prevalent in the United States than coronary artery disease, peripheral arterial disease, congestive heart failure, and stroke combined.[1] The latter half of the 20th century saw dramatic advances in diagnostic testing; however, surgical treatment of varicose veins benefited from only modest refinements after this flurry of innovation. The 21st century has begun with a resurgence of interest and innovation in venous disease. Increased awareness of thrombotic and venous reflux disease has been coupled with advances in the diagnosis and treatment of acute deep venous thrombosis (DVT) (see Chapters 147, 148, 151, and 152), and endovenous ablation (EVA) techniques for the treatment of chronic venous disease have proved appealing to patients and physicians alike (see Chapter 155). Although sclerotherapy and EVA occupy preeminent roles in the contemporary management of superficial venous disease, surgical approaches remain relevant when applied appropriately

Abstract

Surgical treatments for varicose veins have been a core component of general and vascular surgery for 100 years. The modern vascular specialist now has a broad array of options to employ in the treatment of lower extremity varicose veins. Recent years have seen an explosion in catheter-based venous ablations procedures as well as advancements in sclerotherapy techniques and compounds. The dramatic increase in endovascular ablation over the last decade has been accompanied by a gradual decline in the frequency of varicose vein surgery these techniques remain a valuable tool for the management of a wide array of venous diseases. This chapter will review current guidelines regarding varicose vein surgery and will discuss the implications of anatomical variations relating to the great saphenous, small saphenous, and popliteal area veins. This chapter will review specific techniques and anatomical considerations which impact the safe and effective performance of superficial venous surgical techniques. We will also review data comparing the outcomes of open surgical and catheter-based venous procedures. Lastly, patient management and reimbursement considerations reflecting the current economic realities will be discussed.

and executed expertly. In addition to treatment of the great saphenous vein (GSV) and tributary varicosities, this chapter emphasizes management of the small saphenous vein (SSV) and other veins of the popliteal fossa; these veins are increasingly being recognized as important contributors to chronic venous insufficiency (CVI), and they are particularly well suited for treatment with open surgical techniques. In a guidelines publication, Gloviczki et al.[8] recommended specific diagnostic and treatment steps for varicose veins, with the strength of recommendation and quality of supporting evidence. Recommendations specific to the open treatment of axial reflux and tributaries are reported in the table in this chapter, titled Varicose Vein Guidelines (VVGL).

DECISION MAKING

Pathophysiology and Natural History

Varicose veins are defined as "subcutaneous veins in the lower extremities which are dilated to ≥3 mm in diameter in the upright position".[9] They can occur in the axial superficial veins (GSV and SSV) and/or in any of their tributaries. Current thinking is that they represent primary venous disease and occur as a result of structural weakening of the vein wall, which can be focal in nature or diffuse. This weakening is most likely the result of underlying morphologic or biochemical abnormalities, although the exact nature of these abnormalities is not understood. Valvular incompetence in the superficial veins is usually present, but it is not clear if this represents an inciting factor or a secondary result of vein wall dilation. Varicose veins can also occur as a result of secondary venous disease—for example, as a sequela of DVT.[8,10]

Varicose veins constitute a progressive disease; remission does not occur except after pregnancy and delivery. During its course the disease produces symptoms and complications that usually prompt the patient to seek medical care. Symptoms and signs include lower extremity pain and swelling, particularly after prolonged standing, and a feeling of heaviness in the lower extremities. The most frequent complications are superficial thrombophlebitis, acute bleeding originating in one of the thin-walled varices, eczema, and skin ulceration. Depending on his or her age, general health condition, and symptomatology, a patient with varicose veins may be offered one or more of the following: no treatment, conservative management with compression, sclerotherapy, or surgical treatment (open or endovascular). CVI is extremely common in western societies and affects approximately one-third of the adult population. Fortunately only a small proportion of these patients develop the most severe form of venous insufficiency—namely venous ulcers. Though affecting only a small fraction of the population with venous insufficiency, venous ulcers are reported to occur in up to 4% of people older than 65 years.[11,12] Even though nonoperative management of venous disease—including compression, elevation, and skin care—is clearly beneficial,[13] such therapy does not correct the underlying pathology, allows recurrence of symptoms if patients are unable to comply with the elevation and compression regimen, and is associated with a high incidence of recurrent ulceration and progression of disease.

Treatment Options

Invasive treatment of superficial venous incompetence can be accomplished by techniques that result in removal, ablation, or ligation of the refluxing venous segment. Current options for eliminating this target reflux include high ligation, ligation and stripping (L&S), EVA, sclerotherapy, and ambulatory phlebectomy. Each of these techniques has a role in the treatment of patients with symptomatic varicose veins. The modern vascular surgeon should be comfortable in applying these procedures in a thoughtful manner based on the patient's individual needs. As requested by insurers, a trial of compression treatment is generally employed with compression hose (20-30 mm Hg) for patients in CEAP classification C2 to C4 to determine whether the patient's symptoms are relieved. For patients with an ulcer (CEAP C6), compression therapy with garments that exert a pressure of 30 to 40 mm Hg is recommended, because the Effect of Surgery and Compression on Healing and Recurrence (ESCHAR) study showed that compression was comparable to compression plus L&S of the GSV in promoting healing (Table 154.1, VVGL 9.1, 9.2, and 9.3).[14]

Patient Risk Assessment

When considering any intervention, the patient's general medical status and venous anatomy should be considered. Because venous insufficiency results in chronic discomfort and stasis changes that may be ameliorated by the judicious use of compression garments, skin care, and lifestyle changes, venous surgery must always be considered somewhat elective; accordingly, prudent consideration of general medical factors is indicated. Patients who are the most fit, with longer life expectancies, have not only a reduced risk for complications from the procedure but also a longer period during which the benefits of the procedure may accrue. The advent of less invasive treatment by EVA has expanded the range of ages being treated; indeed, patients over 70 years of age are now routinely undergoing therapy, usually for more severe and recalcitrant symptoms. Patients in generally poor health with limited life expectancy or other severe comorbid conditions are typically best managed with conservative measures alone. In recognition of the shorter recovery time and reduced pain and morbidity, the VVGL recommends endovenous thermal ablation over open treatment of saphenous incompetence (see Table 154.1, VVGL 11.2).

Anatomic Considerations

The lower extremity venous system is unique in its constant need to overcome the force of gravity while returning blood toward the heart. An elegant calf muscle pump and the vein valve system normally accomplish this task efficiently. The thin bicuspid semilunar vein valves float open in the venous stream during prograde flow. During calf muscle relaxation, retrograde flow and higher supravalvular pressure cause the margins of the

Number	Guideline	Strength of Recommendation	Quality of Evidence
9.1	We suggest compression therapy using moderate pressure (20-30 mm Hg) for patients with symptomatic varicose veins.	2	C
9.2	We recommend against compression therapy as the primary treatment of symptomatic varicose veins in patients who are candidates for saphenous vein ablation.	1	B
9.3	We recommend compression as the primary therapeutic modality for healing venous ulcers.	1	B
11.2	Because of reduced convalescence and less pain and morbidity, we recommend endovenous thermal ablation of the incompetent saphenous vein over open surgery.	1	B
10.1	For treatment of the incompetent great saphenous vein, we suggest high ligation and inversion stripping of the saphenous vein to the level of the knee.	2	B
10.3	For treatment of small saphenous incompetence, we recommend high ligation of the vein at the knee crease, about 3 to 5 cm distal to the saphenopopliteal junction, with selective invagination of the incompetent portion of the vein.	1	B
10.7	We recommend ambulatory phlebectomy for treatment of varicose veins performed with saphenous vein ablation, either during the same procedure or at a later stage. If general anesthesia is required for phlebectomy, we suggest concomitant saphenous ablation.	1	B
10.5	We suggest that preservation of the saphenous vein using the ambulatory conservative hemodynamic treatment of varicose veins (CHIVA) technique be used only selectively in patients with varicose veins and only when performed by trained venous interventionists.	2	B
10.6	We suggest that preservation of the saphenous vein using the ASVAL under local anesthesia procedure be used only selectively in patients with varicose veins.	2	C

ASVAL, Ambulatory selective varices ablation; *CHIVA*, Cure Conservatrice et Hémodynamique de l'Insuffisance veineuse en Ambulatoire.
Modified from Gloviczki, Comerota AJ, Dalsing MC, et al. The care of patients with varicose veins and associated chronic venous diseases: clinical practice guidelines of the Society for Vascular Surgery and the American Venous Forum. *J Vasc Surg*. 2011;53(Suppl):2S–48S.

valve cusps to move to the midline and oppose, so that caudad reflux is prevented. These valves can be disrupted by a thrombotic event (secondary), can be congenitally absent or atretic, or can become dysfunctional over time as the vein wall or valve loses integrity (primary). CVI has traditionally been classified on the basis of anatomy, function, and clinical severity. The anatomic classification of CVI is important because it links the location of CVI with its subsequent clinical management.

Great Saphenous Vein

The GSV arises anterior to the medial malleolus and courses obliquely and posteriorly as it crosses the anteromedial surface of the calf. At or below the knee joint, the posterior arch vein joins it. A solitary vein is found in the calf in about two-thirds of cases, whereas a duplicated system is present in the remainder. In the vast majority of cases, the GSV at the calf level is anterior-dominant. As the main saphenous trunk continues in a slightly more superficial plane around the knee joint, an anterior accessory vein often merges. The GSV then courses cephalad on top of the deep fascia and deep to the superficial fascia (Fig. 154.1). The GSV may run within this envelope for the entire length of the thigh or may enter at some distance above the knee. If the GSV is "duplicated," both veins will run in this fascial envelope; there may be anterior and posterior accessory veins that enter the fascial envelope to join the GSV, but they exist primarily in the extrafascial plane. Three anatomic variants have been characterized and are demonstrated in Fig. 154.2.

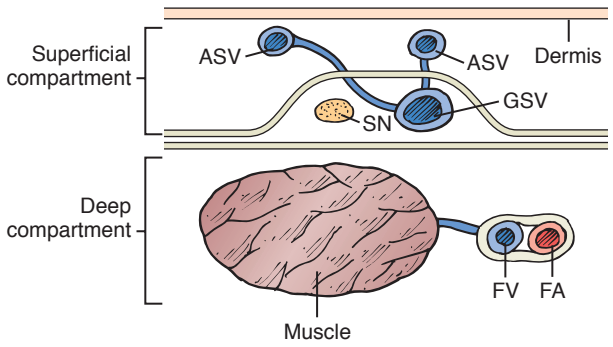

Figure 154.1 The saphenous compartment is bounded by deep and superficial layers of fascia. Tributaries to the saphenous vein pierce the superficial fascia, and it is they that become varicose. *ASV*, Accessory saphenous vein; *FA*, femoral artery; *FV*, femoral vein; *GSV*, great saphenous vein; *SN*, saphenous nerve.

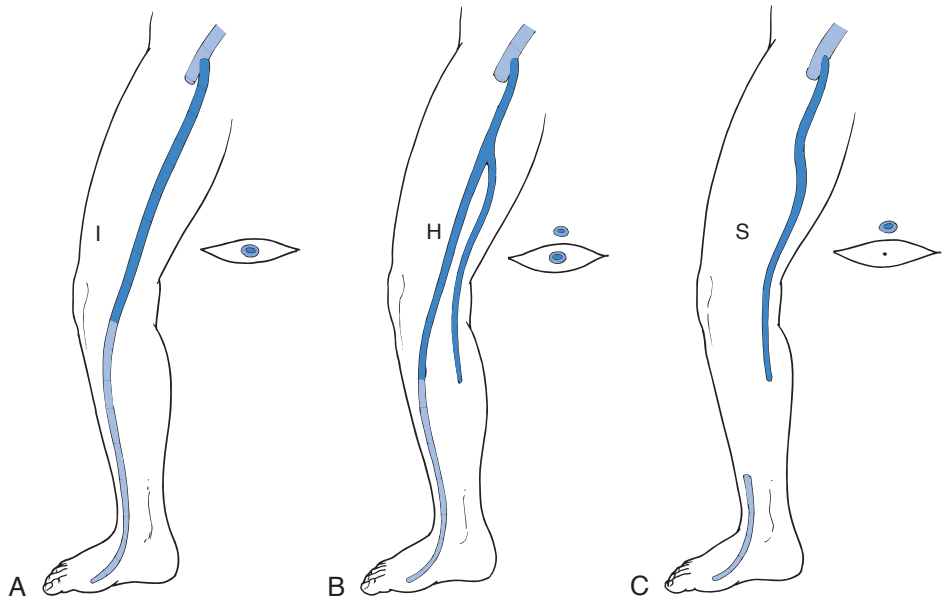

Figure 154.2 Anatomic types of the great saphenous vein (GSV) with respect to the fascial envelope. (A) I type. The GSV is present within the fascial envelope along its entire length. (B) H type. There is a subcutaneous collateral running parallel and superficial to the main saphenous trunk (left). (C) S type. The caudal portion of the GSV in the thigh is atretic, and the extrafascial tributary is dominant.

Kupinski and coauthors reported their experience with duplex ultrasound (DUS) evaluation of the GSV in nearly 1500 limbs.[15] At the thigh level in 60% of the limbs the GSV had a single medial-dominant system, whereas a branching double system was observed in nearly 20%, a complete double system in 10%, and a closed-loop system in another 10%. Of interest was a lateral-dominant system, present in 8%.

Small Saphenous Vein

The confluence of the SSV with the popliteal vein has long been recognized as variable (Fig. 154.3). Approximately 33% of SSVs terminate at a (high) above-knee popliteal vein site; a low termination site is unusual (<10%).[16-18] We have observed that DUS examination of the SSV allows exact perioperative and intraoperative localization of the saphenopopliteal junction for appropriate placement of the skin incision.

Gastrocnemius Veins

The gastrocnemius veins arise from both the medial and lateral heads of the gastrocnemius muscle and may join the popliteal vein directly or merge with the SSV to form a common trunk and then enter the popliteal vein.[19] Conversely, the SSV may join with the gastrocnemius vein to enter the popliteal vein. Hobbs and Vandendriessche reported a 20% incidence of incompetence of the gastrocnemius veins,[19] a proportion similar to that described by Gillet and colleagues in 180 operations for SSV reflux.[20] If the SSV is ligated distal to its junction with a common trunk and an incompetent gastrocnemius vein, persistent reflux will occur.

Intersaphenous Vein

The second important non-SSV vein of the popliteal fossa, the intersaphenous (formerly named Giacomini) vein, has been classically described as coursing up the posterior medial aspect of the thigh.[21] The intersaphenous vein usually arises off the SSV either as a branch or as a truncal continuation of the SSV, and it courses along a subfascial plane to join the GSV more frequently (64%) than the deep venous system (45%).[21] Reflux is less frequent in the intersaphenous vein than in either saphenous vein. The proportion of limbs with intersaphenous vein incompetence, however, is greatly increased when incompetence of the SSV is found alone (odds ratio of 11.94) or combined with GSV incompetence (odds ratio of 11.7),[21] and this vein may facilitate reflux between the GSV and SSV.[22] In our series a dominant and incompetent intersaphenous vein that formed a common trunk with the SSV was observed in 8.5% of limbs undergoing surgery for SSV reflux. Delis and colleagues' DUS study of 818 limbs also showed a low 3% incidence of popliteal area veins,[23] the third non-SSV vein of the popliteal fossa. By contrast, Dodd's classic study of 444 operations in the popliteal fossa showed popliteal area veins in 177 cases (40%), and in 60% they were branches of the SSV (50%) or gastrocnemius veins.[24] They directly entered the popliteal vein in 37% of cases.

Neurovascular Relationships in the Popliteal Fossa

Surgical exploration of the popliteal fossa can be associated with postoperative neurologic disability and, rarely, disastrous vascular complications. Two motor nerves, the tibial (medial popliteal nerve) and occasionally a low-lying sciatic nerve, can be juxtaposed near the SSV and its termination with the popliteal vein. The tendon-like appearance of both motor nerves may falsely encourage the surgeon to perform a less delicate dissection or to retract more vigorously in a deeper plane than would be carried out when a nerve is clearly identified. The sensory

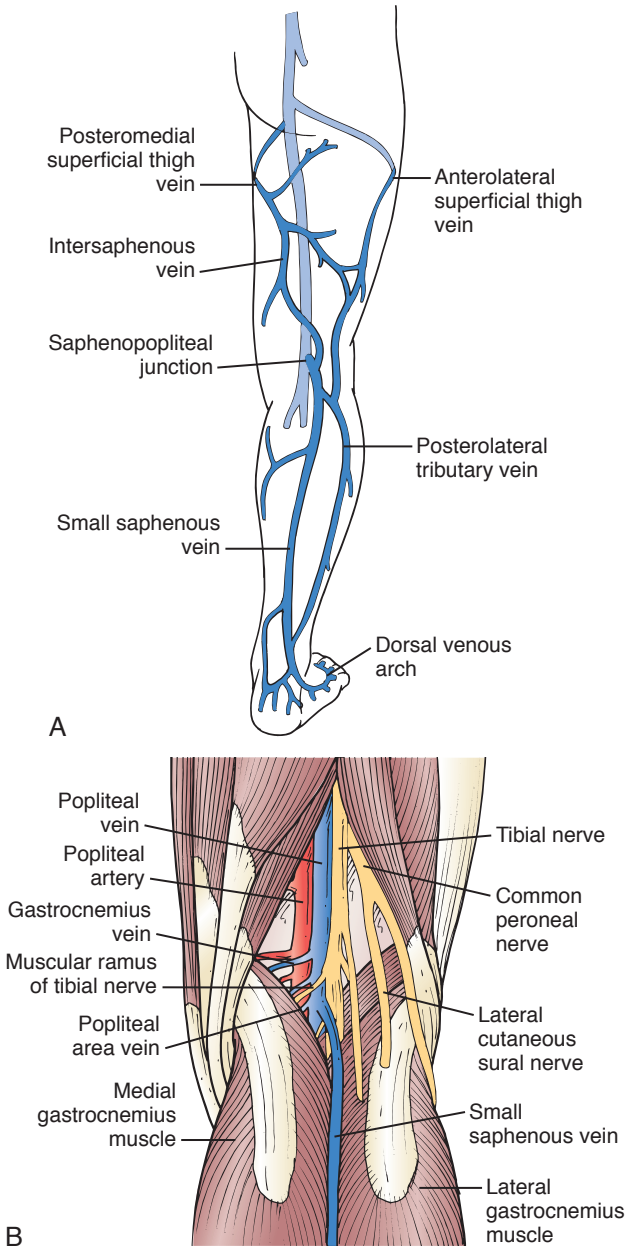

Figure 154.3 (A) The small saphenous vein dominates the posterolateral superficial venous drainage and originates in the dorsal venous arch. At the posterolateral aspect of the ankle, it is intimately associated with the sural nerve. Note the important posterolateral tributary vein and the posterior thigh vein, which ascend and connect the small saphenous venous system with the GSV. The anterolateral superficial thigh vein and the posterolateral tributary vein can be very important in congenital venous anomalies, such as Klippel-Trenaunay syndrome. (B) The most common neurovascular configuration of the popliteal fossa, although the site of anastomosis is highly variable.

sural nerve courses superficial to the SSV or may intertwine with it, and this nerve can also be damaged by retraction or dissection.

Perforating Veins

Perforating veins connect the superficial venous system to the deep venous system and are discussed in detail in Chapter 158.

SURGICAL TECHNIQUES

Surgery for superficial varicose veins should be individualized according to the patient's preoperative evaluation. A combination of ligation, axial stripping, and stab phlebectomy may be applied as needed to the GSV, SSV, tributary veins, and perforating veins. Technical considerations for each of these techniques are summarized in the following sections.

After preoperative evaluation and elucidation of the necessary scope of surgery, a decision will be made regarding the appropriate method of anesthesia and site of service. Any of the surgical procedures can be performed under general or regional anesthesia in an operating theater, and this level of care may be appropriate for patients undergoing multiple incisions requiring extended procedure times or those with medical issues requiring close monitoring by an anesthesiologist. However, extensive experience in the use of tumescent local anesthetic techniques, with or without sedation, allows essentially any of these vein operations to be performed in an office procedure room if it is appropriately equipped and staffed. Ultimately the decision is influenced primarily by local resources, physician experience, and patient expectations. Preoperative marking of the patient in the standing position with an indelible marker is important in any case where stab phlebectomy or direct perforator ligation is contemplated. Such marking is essential because visualization of varicose tributaries may be impossible once the patient is prepared and the leg elevated.

High Ligation of the Great Saphenous Vein

The GSV is most easily approached through an oblique incision 1 cm above and parallel to the groin crease. This location provides the best cosmetic results and the most reliable access to the saphenofemoral junction. The incision should start over the palpable femoral artery and extend medially to balance the better cosmesis of limited incisions with the necessity to ensure appropriate visualization of the saphenofemoral junction and its tributaries. Preoperative DUS-guided marking of the saphenofemoral junction further improves the precision of incision placement and allows minimal incision size and subcutaneous dissection. As the subcutaneous tissue is split, the main trunk of the GSV is identified. A self-retaining retractor is helpful, and the plane over the saphenous vein is extended toward the saphenofemoral junction. This anterior plane is generally free of encumbrances and allows exposure to the junction. Care should be taken to ligate a small branch of the femoral artery, which frequently crosses anterior to the saphenofemoral junction and can cause troublesome bleeding. Each of the tributaries is divided and ligated because the saphenofemoral junction must be clearly identified. Failure to clearly define the saphenofemoral junction has resulted in disastrous injuries to the femoral vein or artery.[25,26]

There are six main tributaries joining the GSV near its termination (Fig. 154.4). However, the number and position of these tributaries vary greatly; therefore, it is necessary to dissect the femoral vein 2 cm above and below the confluence to be sure that no additional tributaries join the femoral vein

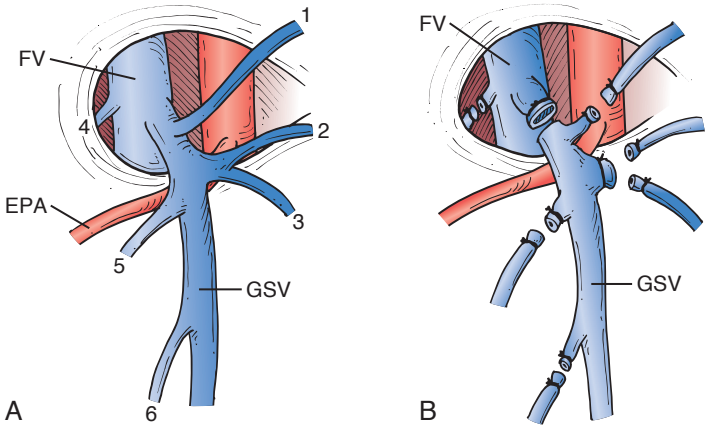

Figure 154.4 (A) The most common arrangement of tributary veins at the saphenofemoral junction. The external pudendal artery (EPA) usually runs between the great saphenous vein (GSV) and the femoral vein (FV), but it may pass above the GSV and is then more susceptible to injury during dissection. 1, Inferior epigastric vein; 2, superficial circumflex iliac vein; 3, lateral accessory saphenous vein; 4, deep external pudendal vein; 5, superficial external pudendal vein; 6, medial accessory saphenous vein. (B) All vessels must be individually divided and ligated to prevent recurrence. If no stripping of the GSV is to be performed, the proximal 5 to 10 cm of the GSV should be resected.

directly. Lateral and medial accessory saphenous veins may enter the main trunk between 2 and 20 cm below the confluence. When stripping is planned, these distal tributaries are avulsed, but if ligation alone is planned, the dissection should be extended caudal for approximately 10 cm to ensure division of these hidden tributaries. High ligation of the GSV is performed close to the femoral vein. Double ligation is generally performed on a proximal stump with the second ligation being a suture ligature. Care should be taken to avoid narrowing the femoral vein in the process. Equally important is to avoid leaving a long stump with a risk for thrombus formation and potential embolism. Alternatively, the GSV may be divided close to its termination and the femoral side closed with a two-layered monofilament suture. If high ligation alone is to be performed, one should resect the segment of GSV exposed in the surgical field, generally 5 to 10 cm in length. The incision is closed in layers by approximating the subcutaneous tissue with absorbable suture and the skin with absorbable subcuticular sutures. The requirement for sufficient exposure of the saphenous vein and its tributaries should be tempered by data suggesting that extensive dissection results in local humeral changes and upregulation of vascular growth factors that lead to neovascularization, which in turn is believed to be an important cause of recurrent varicose veins.[27]

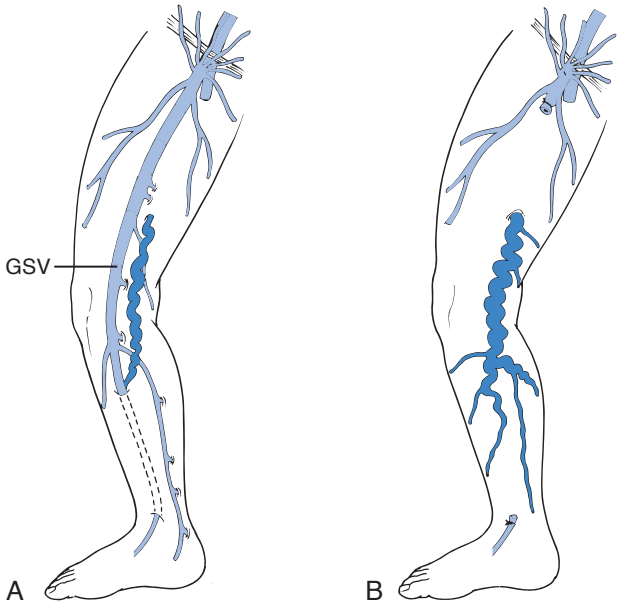

Figure 154.5 Stripping of a competent great saphenous vein (GSV) serving as runoff for a varicose collateral vein (A) results in postoperative worsening of the collateral varicosity because of resistance to outflow (B).

Great Saphenous Vein Stripping

GSV stripping is the central component of the classic operation for varicose veins. Recurrence rates are markedly reduced when the GSV is stripped as opposed to when high ligation is performed alone[28,29]; therefore, stripping is usually performed in conjunction with ligation. During preoperative marking for L&S of the GSV, the surgeon should review the extent and distribution of reflux disease in the saphenous system. The GSV in the thigh is incompetent in only about two thirds of patients undergoing surgery for symptomatic varicose veins or CVI.[30,31] In addition, unless the caudal below-knee saphenous vein is obviously incompetent and varicose, there is no need to remove it. Similarly, when H- or S-type anatomy is defined (see Fig. 154.2), it is not necessary to treat normal or atretic segments of the GSV; in fact, such treatment may worsen the clinical situation by removing competent drainage paths (Fig. 154.5). This targeted approach to stripping leaves normal distal veins, avoids injury to the saphenous nerve, and results in less postoperative pain and bruising without compromising the goals

of surgery.[32-34] Incompetent accessory saphenous veins should be addressed during the initial surgery. It is likely that the high recurrence rates noted for vein stripping in the past have resulted in part from unrecognized accessory veins. The availability of DUS and awareness of the issue may result in improved efficacy in the future; thus preoperative duplex definition of anatomy and marking is essential in any modern-day operation on the great or small saphenous vein.

After flush ligation is performed, a transverse venotomy is created and a stripper is passed distally. Wire strippers or disposable plastic strippers are commonly used. In most cases the presence of reflux allows easy passage of the stripper to the level of the knee. A second small incision is made over the palpable stripper near the knee, which can be defined by preoperative or intraoperative duplex. The caudal incision is made transversely, and the subcutaneous tissues are dissected to allow recovery of the saphenous vein. This top-down passage of the stripper not only facilitates identification of the saphenous vein at the knee and allows a small lower incision to be made but also avoids the potential for the stripper passed from below to enter the femoral vein through a thigh perforator and cause the femoral vein to be mistaken for the saphenous vein. The GSV should be stripped in a downward direction, which results in improved avulsion of tributaries and diminished injuries to the saphenous nerve.[32] To avulse the vein with the endoluminal stripper, one must affix the catheter to the most cephalad portion of the vein. This may be accomplished by attaching the classic stripper head (Fig. 154.6) to the top of the disposable stripper after first placing a silk ligature around the vein and the stripper just below the head. Using the smallest head size minimizes tissue injury and bruising, whereas a larger head size will improve the chance of recovering the entire vein and the tributary segments. A long trailing silk suture is initially attached at the stripper head and drawn through the tunnel with the vein. After all the tributaries have been avulsed and the caudal GSV has been divided and ligated, the vein and stripper are drawn back up to the groin incision, thereby minimizing the size of the distal incision.

Although many variations of this technique have been described, the most common alternative approach involves invagination of the GSV into itself. This technique may be performed with a disposable plastic Codman vein stripper without attaching a stripper head but instead intussuscepting the vein, as shown in Fig. 154.7.[35] Alternatively, a reusable metal cannula may be used in a similar fashion.[36,37] This technique minimizes the diameter of the tunnel created by vein removal in an effort to diminish local trauma to soft tissues and nerves. However, the saphenous vein is susceptible to tearing at the sites of tributary confluence; thus the technique could result in incomplete stripping of the target vein. Consequently, when the vein is removed, it should be unfurled and compared with the planned treatment length. When the vein is torn during stripping, the caudal end typically remains in place at the lower incision. In this case, if a trailing heavy silk suture has been affixed to the stripper (see Fig. 154.7), a second inversion technique can be performed in the opposite direction (Fig. 154.8) (see Table 154.1, VVGL 10.1).

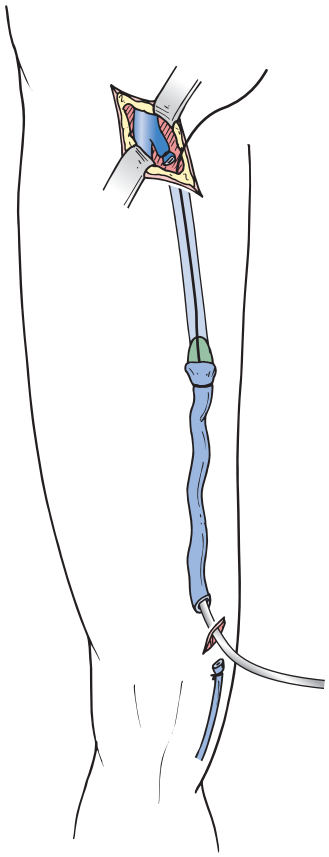

Figure 154.6 The intraluminal stripper is passed distally, the vein fixed by ligature proximally, and the stripping head secured. Stripping distally minimizes lymphatic and tributary damage and avoids avulsion of the saphenous nerve branch. When the stripper head reaches the distal incision, the distal vein fixed to the stripping device by ligature can be recovered through the proximal incision, thereby minimizing surgical trauma at the lower incision.

Adjunctive Considerations for Stripping Procedures

Saphenous vein stripping is commonly perceived as a painful and morbid procedure by patients and referring physicians alike. The memory of large incisions, extensive bruising, significant pain, and prolonged disability from antiquated techniques is a major concern of patients and referring physicians. However, these undesirable effects can be significantly ameliorated by using relatively simple adjunctive techniques.

Ultrasound Guidance

DUS should be used preoperatively to mark the saphenofemoral or saphenopopliteal junction, as well as the course and distal location of the saphenous vein at the knee. This allows precise placement of the skin incision and permits very small incisions with limited subcutaneous dissection. Incompetent accessory veins should also be marked.

Tumescent Anesthesia

The GSV in the thigh lies within a fascial envelope for most of its length, which allows modest infusion of tumescent anesthesia (200-500 mL) to fully surround the saphenous vein.

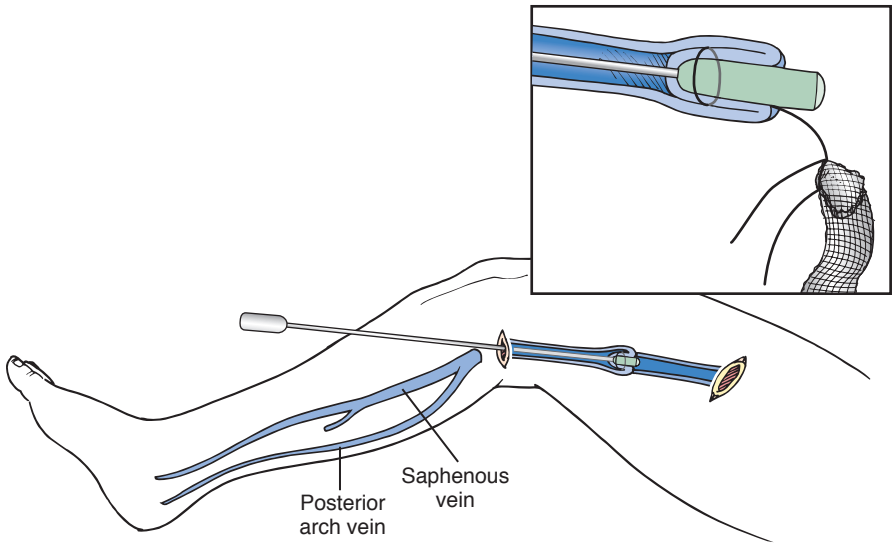

Figure 154.7 The endoluminal device, commonly a disposable plastic stripper, can be introduced from above downward and the vein ligated around the stripper proximally. As distal traction is applied, the vein is then inverted into itself and removed distally in the region of the knee. Roll gauze moistened with epinephrine may be attached to the stripper and drawn temporarily into the tunnel to enhance hemostasis.

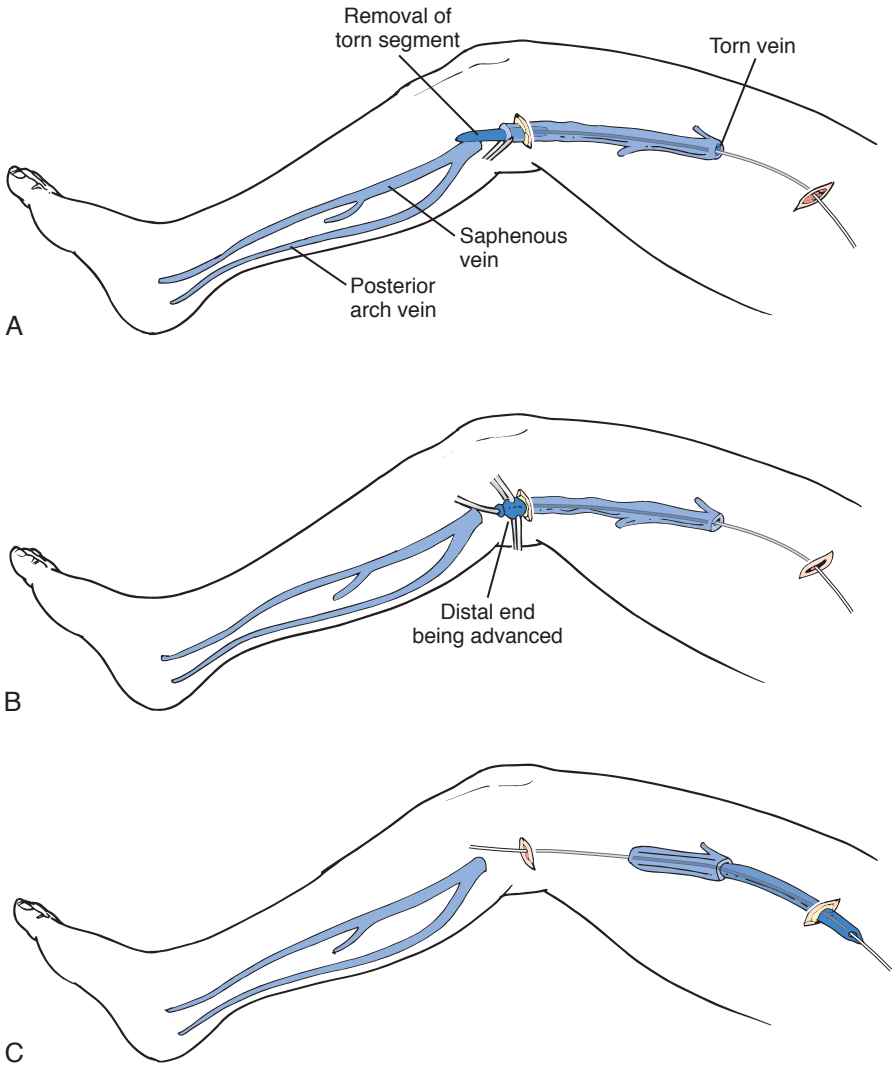

Figure 154.8 Steps in removal of a residual venous segment after proximal vein tearing. (A) Removal of the torn segment. (B) Attachment of the distal segment of vein to the intraluminal stripper and initiation of reverse invagination as the vein is removed from below upward. (C) Removal of the remaining venous segment.

We use a combination of 40 mL of 1% lidocaine with epinephrine, 10 mL of sodium bicarbonate, and 450 mL of normal saline in the tumescent mixture, which is administered under duplex scanning using an infusion pump. This technique provides excellent anesthesia and allows vein stripping to be performed under straight local anesthesia in the office. In addition, the vasoconstriction from the epinephrine and the direct compressive effects of the instilled volume result in rapid hemostasis from the avulsed tributaries and a marked decrease in postoperative ecchymosis and pain.

Minimization of Accumulation of Blood in the Stripping Tunnel

If blood is left in place in the stripping tunnel, a firm palpable cord, sometimes called pseudothrombophlebitis, results. This will eventually reabsorb but contributes to the significant early discomfort traditionally associated with vein-stripping procedures. In addition to the use of tumescent anesthesia, we recommend that stripping be performed as the last step of the procedure if concurrent tributary varices and/or perforator disease are to be addressed at the same setting. In this way the leg can be immediately wrapped in a compressive dressing and elevated after the vein stripping is performed. If the vein is to be removed from the knee incision, the groin incision can be closed with the stripper head in place and only the distal incision at the knee left to close after stripping. Alternatively, one may tie a length of roller gauze soaked in lidocaine with epinephrine to the end of the stripper (see Fig. 154.7). This provides direct compression, absorption of blood in the tunnel, and application of epinephrine to the avulsed tributary sites.[35,38] The gauze is then removed before closure.

Leg Elevation Before and During Stripping

Elevation of the leg reduces the venous bleeding and ecchymosis associated with stripping. The leg should be elevated before the actual stripping procedure is performed. Postoperatively, the patient should ambulate as soon as possible. Most varicose vein surgery is currently performed either on an outpatient basis or as an office-based procedure.

Proximal Tourniquet

This technique is usually reserved for patients with massive varices in the calf or thigh, as is common in Klippel-Trenaunay syndrome, to prevent major hematomas. Esmarch bandage drainage of the limb is followed by placement of a proximal sterile pneumatic tourniquet, which is inflated to 200 mm Hg. The tourniquet is deflated once the GSV is stripped and its branches removed.

Surgery on the Small Saphenous Vein and Veins of the Popliteal Fossa

SSV disease is often neglected or incompletely treated by surgeons. This problem may be explained in part by the following factors: (1) the paucity of studies emphasizing a significant contributory role of SSV incompetence to CVI; (2) the lower proportion of limbs with SSV reflux compared with GSV incompetence; (3) technical considerations, such as the need to reposition the patient if both GSV surgery and SSV surgery are being performed in the same treatment session; and (4) the intimate and variable neurovascular relationships of the SSV, which can present significant potential for morbidity. However, the few papers that have addressed the role of the SSV in CVI have described a strong association of SSV reflux with (1) posterior calf varicosities,[39] particularly in individuals with recurrent varicosities after superficial venous surgery; (2) isolated lateral malleolar ulcers[40]; and (3) ulcer recurrence after subfascial endoscopic perforating surgery.[41]

A survey conducted among members of the Vascular Surgical Society of Great Britain and Ireland, which was motivated by the poor outcomes and high litigation rates associated with SSV surgery, characterized surgeons' attitudes toward SSV surgery.[42] Although nearly 90% of surgeons carried out preoperative duplex imaging, only 50% added preoperative skin marking of the saphenopopliteal junction. In an effort to avoid damage to neurovascular structures and DVT, few surgeons (10%) exposed the popliteal vein during this procedure, which would make identification and treatment of gastrocnemius or popliteal area veins less difficult.

An understanding of the relationship of the SSV to other veins of the popliteal fossa—the gastrocnemius veins, the intersaphenous vein, and popliteal area veins—is important to achieve optimal results with SSV surgery. If these veins are ignored, they can be a factor in the persistence of reflux.[19,22] These veins are particularly well suited to open surgery as opposed to EVA or sclerotherapy, particularly when they enter the popliteal vein directly.

Operative Technique for Small Saphenous Vein Procedures

After the induction of general, regional, or local anesthesia, patients are positioned prone with care taken to pad bony areas and breasts. To provide laxity of the neurovascular structures in the popliteal fossa, the limb is slightly flexed at the knee. Preoperative marking guided by DUS allows a small transverse skin incision to be made just distal to the saphenopopliteal junction. The length of the incision is dictated by the thickness of the subcutaneous tissue (shorter incision for thinner legs). The fascia is opened along the line of the skin incision and the SSV is identified. The SSV is traced distally to its position between the fascia and calf muscles. Because of the effects of sustained venous hypertension, the SSV can resemble an artery (popliteal), so continuous-wave Doppler may be used to provide the surgeon with assurance that the structure is indeed venous in nature. The SSV is then divided between two right-angle clamps. Care is taken to dissect in the perivenous plane, and any nerve structure—usually sural—is carefully dissected from the SSV. Gentle retraction is used to avoid injury to the tibial nerve and to visualize the saphenopopliteal junction. However, if DUS identifies reflux in the gastrocnemius or popliteal area veins, the exposure is extended and the target veins are ligated. The stump of the SSV is ligated with a 3-0 monofilament transfixion suture. If present, the common trunk of the SSV

with either the gastrocnemius or intersaphenous veins is ligated proximally just above the popliteal vein.

If preoperative DUS identifies incompetence of individual gastrocnemius, intersaphenous, or popliteal area veins, they are ligated as well. The distal SSV is dissected to a point beneath the fascia, and a segment is excised. We do not usually strip the SSV because of the risk of injury to the sural nerve, which is generally adherent to the SSV in its distal third. The SSV is ligated distally with 3-0 monofilament suture. The popliteal wound is then irrigated and closed in layers with particular attention to approximating the fascia to avoid unsightly hernias. The short skin incision is approximated with running 5-0 subcuticular suture. The preoperatively marked posterior calf varicosities are removed by stab phlebectomy. Particular attention is paid to ligating any incompetent gastrocnemius perforating veins that connect with the SSV branches (see Table 154.1, VVGL 10.3).

Excision of Local Varicosities (Ambulatory Phlebectomy)

Ligation and/or stripping of the GSV or SSV directly reduces axial reflux and therefore results in the preponderance of hemodynamic benefit in most vein operations. However, if left uninterrupted, the remaining superficial varicosities will drain via alternative pathways and may remain both symptomatic and cosmetically displeasing. In the past, these tributary varices were dealt with by making several large incisions, and dramatic transverse scars were left in many cases. Refinements in technique have resulted in improved cosmetic results with effective elimination of tributary varices through small (1-3 mm) stab incisions.[43,44] Effective use of these minimally invasive techniques requires planning, experience, and patience. It is common for procedures to require in excess of 20 phlebectomies, which can be time consuming. Preoperative marking is very important in ambulatory phlebectomy. These target veins are often difficult to see when the patient is reclining.

Although local, regional, and general anesthesia are all options, ambulatory phlebectomy, especially performed in isolation, is well suited to local infiltration anesthesia. This can be accomplished by superficial subdermal infiltration around the vessel of interest or by large-volume tumescent techniques. At the end of the infiltration the skin appears pale because of the epinephrine-induced vasoconstriction. However, direct visualization of varicosities during phlebectomy is generally not a problem. Inclusion of epinephrine in the anesthetic may be contraindicated in patients with diabetes, glaucoma, coronary heart disease, cardiac dysrhythmias, hypertension, hyperthyroidism, and peripheral arterial disease. In such cases, epinephrine may be omitted from the anesthetic mix, which results in somewhat more bleeding, which can generally be controlled by a few minutes of digital compression. The patient is positioned to optimize surgical exposure. Phlebectomy is best performed on a horizontal plane, and because many patients are treated under a local anesthetic, it is often possible to have them rotate the extremity during the procedure to maximize exposure.

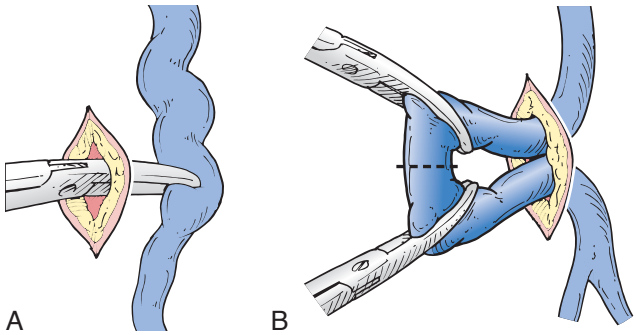

Figure 154.9 Ambulatory phlebectomy. (A) A 2- to 3-mm stab incision oriented transversely at the groin, knee, or ankle or longitudinally along Langer's lines elsewhere in the leg provides access for phlebectomy. (B) The target varicosity is drawn through the incision, divided, dissected, and avulsed.

Mueller is credited with popularizing and refining the technique of stab avulsion.[44] He considered a 2-mm incision to be large. Although the process of removing the vein often stretches the small skin incision, the combination of postoperative compression and the intrinsic elasticity of the skin allows retraction to the original small incision size. The skin incision is most commonly made with a no. 11 blade but, alternatively, 18-gauge needles and blood lancets have been used effectively. The incisions are typically oriented longitudinally except in the groin, knee, and ankle, where a transverse orientation aligns with the lines of Langer.

Three types of instruments are recommended for vein retrieval: hooks, iris forceps, and fine-pointed clamps. The small dermal varicosities are hooked and avulsed. Larger veins are grasped and brought up through the incision (Fig. 154.9). The vein loop is cleared of fat, doubly clamped, and divided. By applying in-line traction, varicosities can be teased out and several centimeters removed from each end, much like the proverbial robin pulling a worm through a small hole in the ground. Rolling of the vein onto the clamp prevents the vein from avulsing prematurely. The varicose segments should be removed in their entirety, and if the vein breaks during the process, it may be reobtained through a new incision. These varicosities are typically tributaries of the axial veins and do not require ligation unless an incompetent axial vein is to be left in place (which is generally to be avoided). On the other hand, perforating veins associated with clusters of varices should be ligated. The skin incisions are small enough that Steri-Strip closure is usually sufficient. Should an individual incision be larger than usual, a single interrupted absorbable subcuticular or nylon skin closure will suffice (see Table 154.1, VVGL 10.7).

Transilluminated Powered Phlebectomy

Transilluminated powered phelbectomy, or TriVex, uses tumescent dissection, transillumination, and powered phlebectomy to accomplish extensive ambulatory phlebectomy. Because of the tumescent anesthesia component, this technique can be carried out without general or regional anesthesia. The device used to transilluminate the veins and perform the phlebectomy is similar to devices used to remove subcutaneous fat. It is inserted into

the subcutaneous tissue through a small incision and moved forward and backward over as much area as possible to disrupt and remove the varicosities.

The technique has the proposed advantages of decreasing the number of incisions and reducing operative time. Aremu and colleagues' randomized controlled trial (RCT) of 141 patients and 188 limbs compared TriVex with conventional stab phlebectomy.[45] The TriVex group had fivefold fewer incisions (5 vs. 29), whereas postoperative pain and other patient-reported measures were comparable. There was a nonsignificant trend toward a shorter operative time with the TriVex group. A subsequent RCT of similar design carried out in Australia showed that fewer incisions were required but reduced operative time was not seen.[46] In contrast to the Aremu study, early postoperative bruising, pain, and quality of life were worse in the TriVex group. Finally, a meta-analysis conducted by Luebke and associates of five RCTs noted that the reduced operating time for TriVex applied only for large and extensive varicosities—and at the expense of more hematoma formation and a higher mean pain score than with standard hook phlebectomy.[47] This technique in rarely employed in current practice.

Saphenous-Sparing Operations

Routine use of duplex ultrasound to map flow dynamics within the great and small saphenous veins, as well as in associated varicosities, has led to the development of hemodynamic-based "saphenous-sparing operations." These procedures challenge the hypothesis, initially promulgated by Trendelenburg, that an incompetent saphenous vein is the cause of varicosities. This thesis holds that reflux from the deep to the superficial system at the saphenofemoral or saphenopopliteal "connections" produces incompetence in the saphenous trunk, which descends proximally to distally, then outward to form superficial varicosities. The detailed duplex studies of Labropoulos and others challenged this theory and supported an "ascending" cause of varicose veins, which is initiated in the "distal superficial venous network." Proponents of this theory remove only refluxing segments, concentrating on the varicosities of the peripheral venous network rather than the saphenous vein, thus sparing it. Two groups of procedures accomplish this approach: the Cure Conservatrice et Hémodynamique de l'Insuffisance veineuse en Ambulatoire (CHIVA)[48-50] and ambulatory selective varices ablation (ASVAL)[51] techniques.

Conservatrice et Hémodynamique de l'Insuffisance veineuse en Ambulatoire

A detailed preoperative duplex ultrasound study determines where the reflux starts, the entry point, and where it reenters, with the goal of promoting normal superficial-to-deep flow through reentry perforating veins during muscular diastole. Determination of the competence of the terminal and preterminal valves of the saphenous guides the decision of whether it should be ligated. The tributaries are assessed for competence (flow into saphenous) or incompetence (flow into tributaries and associated varicosities). Incompetent tributaries are ligated and the varicosities removed. Franchesci classified several types of communications between the superficial and deep system, which dictate the required surgical steps: type I, with reentry by a venovenous shunt at the saphenous trunk; type II, with no reflux from the deep system but with reflux from the superficial venous network, not surrounded by the superficial fascia or through a communicating superficial vein; type III, with reentry on an extrasaphenous superficial perforator; and type IV, with reflux from the pelvic circulation. Carandina and associates[52] compared CHIVA with standard high-ligation and stripping (HLS) in an RCT of 150 patients. Outcome measures at 10 years were as follows: recurrence of varicose veins (VVs) by objective clinical and duplex criteria; clinical outcome (Hobbs score), as judged by an independent observer; and patient-reported subjective symptoms. Although there was no difference in the Hobbs score between the two groups, recurrence of VVs at 10 years was lower in the CHIVA group (18%) than in the HLS group (35%) (P <.04).

The definitive large RCT on CHIVA conducted by Parés and colleagues[53] compared CHIVA with two control groups: HLS as marked clinically and HLS as marked by duplex. The primary outcome was recurrence of VVs as observed by independent physicians. In this RCT, "cure" of VVs was twice as frequent in the CHIVA group as in the two HLS groups, whereas the OR favoring the CHIVA group was 2.64 (95% CI, 1.76-3.97; P <.001) over the HLS clinical and 2.01 over the HLS duplex group. Several criticisms, however, have been leveled at the study: (1) the study had a high incidence of patients with mild disease, C2; (2) a significant number of patients underwent treatment for cosmetic purposes in the absence of symptoms; and (3) no patient-reported outcome measure was used—an important consideration in mild disease and particularly when cosmesis is the indication. Finally, in a small RCT, Zamboni and associates showed superiority of CHIVA over compression treatment in CEAP C6 patients.[52] This RCT, however, had narrow inclusion/exclusion criteria, no postthrombotic limbs, and no deep venous reflux/obstruction. Time to ulcer healing was shortened, and the 38% recurrence rate in the compression group was reduced to 9% in the CHIVA group. CHIVA has shown excellent results in lowering the recurrence of varicose veins; however, despite increasing facility with intraoperative DUS and minimally invasive techniques, this approach has not found widespread adoption its pure form (see Table 154.1, VVGL 10.5).

Ambulatory Selective Varices Ablation

This procedure is performed under local and tumescent anesthesia with removal of the venous varicose reservoir (multiple varicosities) through multiple stab incisions (average, 30), generally using Muller phlebectomy hooks.[51] In Pittaluga and associates' large contemporaneous and comparative trial, which was conducted in 831 limbs, ASVAL was performed in 303 limbs of 221 patients and HSL in the remainder.[51] The extent of varices to be treated was divided into 32 zones on the limb. Follow-up was at 1 and 6 months and then yearly for 4 years, reporting the following: duplex presence of reflux as well as CEAP clinical class, recurrent VVs, venous disability score, and patient reported outcomes for symptoms and esthetics. At 4 years following ASVAL, saphenous

reflux was reduced in 66.3% of limbs, symptoms disappeared or "improved" in 78%, and freedom from recurrent varicosities was 88.5%. It should be noted than one-third of the limbs were asymptomatic before treatment, whereas 16% had competent saphenofemoral junctions and only 8.6% had total SV reflux. A curious aspect of this study is that a comparison between ASVAL and HLS was limited to preoperative baseline characteristics and not postoperative outcomes. ASVAL would appear appropriate for mild disease (C2) and minimal symptoms with low-volume saphenous reflux in a mildly dilated saphenous vein. (see Table 154.1, VVGL 10.6).

Endovenous Ablation

The evolution of minimally invasive techniques for the treatment of GSV reflux has culminated in the development of EVA. These techniques are discussed in Chapter 155.

RESULTS

For a century L&S was the "gold standard" for the treatment of GSV incompetence and tributary avulsion for residual varicose veins. The preponderance of data advocating a surgical approach to CVI is derived from clinical reports of L&S. The role of L&S has diminished greatly in the United States with the advent of EVA by either thermal or nonthermal methods, and sclerotherapy has replaced tributary avulsion in many cases. L&S has decreased from 155,000 procedures in 1999 to less than 30,000 in 2016. By contrast, EVA has grown from none in 1999, to 355,000 procedures in 2016. What accounts for this change? Is there valid evidence to show that EVA is superior to L&S? This section reviews the evidence from RCTs when available.

As Ruckley and colleagues stated, "Evidence-based medicine has not so far been a strong feature of phlebologic practice."[54] Although most reports contain some meaningful information, some data are more compelling than others. Levels of evidence are often described as a pyramid, with 1A level at the top—RCTs composed of studies such as Cochrane systematic reviews, Agency for Healthcare Research and Quality evidence reports, and other systematic reviews. Well-designed single or multicenter RCTs are at the 1B level. Case-control and cohort studies are lower, at 3B, and case series fall at either level 4 or 5. Unfortunately the majority of studies that examine L&S and EVA are case series.

Results of Surgery on the Great Saphenous Vein Versus Conservative/Nonoperative Treatment

The ESCHAR trial was the first large prospective randomized trial to address this fundamental question. Patients with severe sequelae of CVI (C5-C6) and superficial or mixed deep and superficial venous insufficiency were randomized to medical therapy (elevation, compression, and exercise) either with or without surgical treatment of superficial venous reflux. Although no difference was found in rates of healing, a dramatic reduction was seen in ulcer recurrence (12% vs. 28% at 12 months; $P = .001$) in the group that received surgery as well as medical therapy. It is notable that 20% of the patients in the surgical arm refused surgery but remained in the surgical arm according to an intention-to-treat analysis plan. This probably resulted in understating the treatment effect of surgery.[14] Michaels and colleagues carried out an RCT that examined the impact of superficial venous surgery on quality of life in 246 patients with uncomplicated varicose veins who were randomized to compression and lifestyle changes versus surgery with L&S of refluxing segments and multiple phlebectomies.[55] The study was well designed and incorporated clinically relevant changes in health status as determined by the Short Form 36 (SF-36) and the EuroQol 5D (EQ5D). The surgical group showed significant improvement in quality-adjusted life years over the compression group. Quality-adjusted life years as assessed by SF-36 were improved by 0.083 over the medically treated group and by 0.13 as assessed by the EQ-5D. In addition, the surgical group demonstrated significant anatomic and symptomatic relief. These large RCTs provide a grade A recommendation for surgery in addition to conservative treatment in patients with varicose veins caused by GSV reflux.

Comparison of Results of Endovenous Ablation Versus Ligation and Stripping of the Great Saphenous Vein

Ten groups reported RCTs in which EVA was compared with L&S. Several groups provided follow-up on reports that supplemented the initial data in meaningful ways. Eight of these reports compared laser treatment with L&S,[56-61] whereas five reported on radiofrequency ablation with L&S.[60,62,63] The studies were of modest size, with 28 to 580 limbs being treated. Many of the RCTs were lacking some elements of proper study design: a priori calculation of sample size, comparability of baseline characteristics between groups, and intention-to-treat analysis. Desirable outcome measures such as quality of life were used in all but one series, whereas eight of the ten groups provided a disease-specific evaluative score so that preoperative values could be compared with postoperative values. Table 154.2 shows the objective endpoints for the comparisons between L&S and EVA. Overall, EVA showed an early postoperative advantage in quality of life; but by 1 month, the disease-specific scores were comparable. "Soft" outcome measures, such as return to normal activities or work and less postoperative pain, also favored EVA. Rasmussen,[56] Perälä,[66] and Darwood[57] and their colleagues found no differences between L&S and EVA in disease-specific scores by 1 month postoperatively. Six RCTs (Rasmussen and colleagues,[56,60] Kalteis and colleagues,[58] Carradice and colleagues,[66] Christenson and colleagues,[65] Gauw and colleagues,[59] Rass and colleagues[61]) showed no difference in quality-of-life measures, whereas two demonstrated an advantage for EVA (Rautio and colleagues[62] and Lurie and colleagues[63]). Morbidity is putatively less with EVA because the vein is ablated in place. L&S, however, involves stripping the vein with avulsion of branches and some tract bleeding, which can be mitigated but will never be completely eliminated. Certainly if thrombophlebitis develops in the ablated GSV,

Φ, No difference; ⊕, better with EVA.

the pain can be as severe as that with stripping. The use of postoperative analgesics is usual with L&S, in contrast to EVA. We have observed that local tumescent anesthesia results in reduced pain and bruising with vein stripping and phlebectomy as well as with EVA. Rasmussen and colleagues compared L&S and EVA in a randomized trial in which tumescent anesthesia was used in all patients.[56] In this report, 121 patients (137 limbs) were randomized to high L&S with local anesthesia or endovenous laser treatment. Both groups had varicosities removed through miniphlebectomies and received perivenous tumescent solution and intravenous fentanyl. L&S was performed by the perforate-invaginate (PIN) stripping technique. The two treatments were found to be equally effective in eliminating GSV reflux, with no differences in times to resume normal activities or return to work. There was more pain and bruising in the L&S group but no change in pain medication use between the groups. No difference was observed in the venous clinical severity score or in the Aberdeen score between the two groups at any time point. The bodily pain score component of the SF-36 was higher after L&S than after EVA 12 days postoperatively.

Taken as a group, these data demonstrate an early postoperative advantage in pain for the EVA procedures. We analyzed this group of RCTs in a systematic review and meta-analysis to investigate the timing and mode of failure (recurrence of varicose veins after surgery: REVAS).[68] We found no difference in the overall incidence of the recurrence of varicose veins after surgery (REVAS) between EVA and L&S, nor was there a difference in the rates of reoperation. In addition, REVAS was progressive over time, with more than a doubling of clinical recurrence in Rasmussen's trial between years 1 and 5.[60] There is a different pattern of causes, however, with the two techniques. Neurovascularization was more common after L&S, whereas recanalization occurred more frequently after EVA. Although there was individual variation as to the site of REVAS within each study, meta-analysis showed that the thigh and calf are comparable as sites of recurrence for EVA.

Results of Surgical Treatment of Veins of the Popliteal Fossa

Reported rates of recurrent varicosities and reflux after SSV surgery are often high. In a DUS survey, Tong and colleagues reported a 61% incidence of recurrent SSV reflux,[69] and Mitchell and colleagues in their series observed a 50% incidence of recurrent SSV-popliteal reflux despite using preoperative DUS.[70] The latter series would appear to underline the critical role of surgical technique in addition to preoperative DUS in achieving optimal results. In Creton's review of 125 reoperations for recurrence of SSV reflux, the majority (>60%) were due to inadequate ligation of the proximal SSV: 13.6%, intact SSV trunk; 42.4%, residual long stump of the SSV off the popliteal vein; and 3%, small residual and incompetent small saphenous trunk.[71] A less frequent cause of recurrent reflux in the popliteal fossa was an incompetent popliteal area perforating vein. A smaller series by De Maeseneer and colleagues showed results similar to those of Creton: 1 of 12 patients had a long untreated SSV stump, which they ascribed to a high SSV-popliteal junction.[72]

Although Tong and colleagues[69] found that SSV reflux was the cause of recurrent varicosities in 43 of 70 limbs (61%), an appreciable incidence of non-SSV incompetence was noted. In fact, Rettori identified incompetence of a gastrocnemius vein as the cause of recurrent popliteal fossa varices in 34% of his cases.[73] The retrospective series of Tong and colleagues,[69] Creton,[71] and De Maeseneer and associates[72] were based on patients with presumed recurrence of SSV reflux. Mitchell and colleagues, however, carried out a prospective study of SSV surgery and found SSV reflux in 33% of patients and gastrocnemius reflux in 17%. These findings underline the importance of defining by perioperative DUS exactly which veins are incompetent in the popliteal fossa as well as their relationship to the SSV. Armed with preoperative DUS findings, the surgeon can plan the operative approach accordingly but must be committed to correcting it.

A single RCT investigating surgery versus EVA of the SSV[74] reported on 106 patients. Abolition of SSV reflux was significantly higher after EVA (96.2%) than after surgery (71.7%) ($P < .001$). Postoperative pain was significantly lower after EVA ($P < .05$), allowing an earlier return to work and normal function ($P < .001$). Minor sensory disturbance was significantly lower in the EVA group (7.5%) compared with the surgical group (26.4%) ($P = .009$). Both groups demonstrated similar improvements in venous clinical severity score and quality of life. These data suggest that the application of EVLA to the SSV may have an increasing role in clinical care; however, concern about potential thermal injury to the many nerves in the popliteal fossa has limited its application at this point. By combining a thorough preoperative evaluation with an aggressive surgical approach aimed at eliminating all refluxing segments in the popliteal fossa, we found no sensory or motor nerve injuries, no hematomas or wound infections, no DVT, and no reflux of the SSV, popliteal junction, or other veins of the popliteal fossa in a recent study of 47 consecutive limbs.[75] Additionally, at 6-month follow-up, the mean venous clinical severity score had decreased significantly to 2.5 from a preoperative value of 7.0, with no cases of recurrent reflux in the popliteal fossa. These data support a continued central role for well-planned and well-executed venous surgery in the treatment of popliteal fossa venous disease.

MULTIMODALITY AND INDIVIDUALIZED CARE

The many approaches advocated by passionate and compassionate experts from around the globe serve to emphasize that no single treatment for venous disease is appropriate for all patients or, for that matter, for all venous issues in a single patient. Modern venous specialists have many tools at their disposal, and it is common to employ a combination of EVA, HLS, phlebectomy, sclerotherapy, and stenting—potentially in a single patient. For example, Kalodiki et al. randomized patients with GSV reflux and tributary varicose veins to high ligation plus either

phlebectomy or foam sclerotherapy to treat the tributaries. At 3 and 5 years of follow-up, the tributary treatments were equally effective, as demonstrated by VCSS, VSDS, and the SF-36 physical component score.[76] These authors also found that follow-up sclerotherapy was commonly used in both groups, and they suggested a "dental plan" approach, in which patients receive routine interval treatments.

PATIENT MANAGEMENT AND REIMBURSEMENT CONSIDERATIONS

Most insurers have well-defined criteria for the approval of the treatment of varicose veins, termed medical review criteria, which are used to preauthorize interventional treatments. The underlying attitude of some insurers is captured by the following statement in the overview on one insurance policy: "Most varicose veins do not require surgical or other procedures; wearing specially fitted elastic stockings is all that is needed in many cases." Policies vary between carriers and regions, but typically insurers require that three conditions be satisfied to authorize treatment for axial reflux: (1) symptomatic varicose veins; (2) duplex evidence of reflux greater than 1 second (some also require a minimum GSV diameter [e.g., >4 mm]); and (3) a trial of compression stockings for 6 weeks to 3 months without relief of symptoms. Other indications for intervention may include the following: a venous ulcer; lipodermatosclerosis; more than one episode of minor hemorrhage from a superficial varicosity; a single significant hemorrhage from a ruptured superficial varicosity, especially if transfusion was required; two or more episodes of superficial thrombophlebitis; and persistent superficial thrombophlebitis unresponsive to 4 weeks of conservative therapy.

Insurers usually do not distinguish between authorization for EVA or L&S, nor do they dictate the setting. Reimbursement to the physician, however, can vary greatly depending on the site of service. If the procedure is performed in a hospital facility or surgical center, the insurer pays a professional fee to the physician as well as a facility fee to the hospital. By contrast, in office-based procedures, the surgeon receives a global reimbursement. This system typically results in higher costs to the payer and lower margins for the physician for hospital-based venous procedures. These financial realities, the decreased invasiveness of modern venous interventions, the proliferation of vein centers, and the ease of use of the office setting have resulted in a dramatic shift of venous surgery to offices and away from hospitals. Comparing the costs of conventional surgery versus EVA, Lees reported a prospective randomized trial in which 91 patients were randomized to RFA versus L&S in the United Kingdom.[77] Ablation was more expensive (mean hospital cost per patient £1275.90 vs. £559.13 for L&S) in their setting; however, they concluded that in employed patients the quicker return to work (mean 12.2 vs. 19.8 days, $P = .006$) justified the additional procedural cost. However, in certain settings or populations, the reduced procedural costs of conventional surgical techniques may well influence surgical decision making.

Indications for Ligation and Stripping of the Great Saphenous Vein in the Current Climate Favoring Endovenous Ablation

Listed here are the indications the authors use to identify patients who will receive the most benefit from L&S of the GSV as opposed to EVA.

1. Superficial saphenous tributary. The most common indication for L&S of GSV is to treat a superficial saphenous vein or tributary that is closely adherent to the skin. This vein can be an "extrafascial" continuation of the main GSV as a superficial branch or, alternatively, a separate anterior accessory saphenous vein or a truly duplicated GSV. The inability to create at least a 1-cm buffer zone between the skin and the vein with tumescent anesthesia during thermal ablation increases the risk for skin burns and is a clear contraindication to thermal EVA. Nonthermal techniques have eliminated the burn issue, but inflammation and pigmentation remain issues when the treated vein is very superficial. These patients more frequently undergo a stab phlebectomy of this venous segment rather than the classic L&S.
2. GSV dilation or aneurysmal venous segments. Dilation of the proximal GSV to greater than 2.5 to 3 cm or large aneurysmal venous segments along the course of the GSV are also indications for L&S. Despite external compression, copious tumescent solution, and the use of newer endovenous techniques, the proximal GSV may be difficult to ablate effectively and may be more prone to thrombotic complications in these circumstances.
3. Chronic thrombophlebitis. The formation of synechiae within the GSV as a sequela of superficial thrombophlebitis may prevent advancement of the radiofrequency ablation catheter or laser sheath. This may occur even if a guidewire crosses the diseased segment. In this situation it is often possible to perform high L&S with the flexible Codman stripper or the relatively stiff wire PIN strippers. If this also fails, simple ligation plus segmental excision is performed. In addition, if the vein wall is noted to be markedly thickened on DUS, it will not constrict appropriately in response to thermal ablation and would be more effectively treated with L&S.
4. Excessive tortuosity (same considerations as in No. 3).
5. Acute superficial thrombosis. Acute superficial vein thrombosis with extension to the saphenofemoral junction remains an indication for anticoagulation, GSV ligation, or both to prevent extension to the common femoral vein. EVA is clearly contraindicated in any vein with acute thrombus.
6. Economic consideration. Capital costs for establishing an endovascular vein ablation program may easily exceed $50,000. In addition, there are high per-case consumable costs. Even though venous interventions are considered to provide a solid return on financial investment, the up-front capital costs may prove a significant barrier to entry. In addition, if patients are responsible for the costs of their treatment, they may favor the typically less costly open procedures.

In summary, L&S has decreased in popularity as a technique for treating GSV reflux because of the less invasive nature of EVA. However, for the previously stated reasons, L&S of the GSV remains a relevant procedure with a definite though diminished place in a modern venous practice.

BACKGROUND

Endovenous treatments for varicose veins emerged in response to the disadvantages of open surgery and are now the standard of care due to improved efficacy and safety.[1,2] The most widespread technologies used for the treatment of truncal vein reflux are radiofrequency ablation (RFA) and endovenous laser ablation (EVLA). Sclerotherapy remains the treatment of choice for telangiectasias and reticular veins, but it has a smaller role for larger varicosities and truncal reflux.

RELEVANT ANATOMY

Superficial veins in the lower extremities are predominantly suprafascial and function as the principal collecting system for the lower extremity. They are highly expansible and dilate significantly to accommodate large volumes of blood, acting

Abstract

The elimination of refluxing superficial veins represents a fundamental management principle in the treatment of chronic venous insufficiency. Surgical ligation and stripping of refluxing truncal veins was once the standard treatment; however, endovenous ablation technologies have supplanted surgery as the preferred intervention. Furthermore, the application of tumescent anesthesia to the treatment of chronic venous insufficiency has enabled a transition of care from the inpatient to the outpatient setting.

Endovenous laser ablation (EVLA) and radiofrequency ablation (RFA) are the endothermal modalities, and they use thermal energy to effect fibrosis and sclerosis of the vein wall. This chapter reviews the data demonstrating improved efficacy and reduced complication rates with EVLA and RFA as compared to surgical stripping. Non-thermal, non-tumescent technologies have recently come to the market and are gaining traction. These include mechanicochemical ablation (MOCA) and adhesive closure. Safety and efficacy have been demonstrated for the non-thermal technologies, but long-term durability has remained a question.

Sclerotherapy represents a well-established treatment for the management of venous reflux. The sclerosing agent must make contact with the vein wall in order to cause endothelial damage, and this occurs with some variability. Although efficacious for the treatment of telangiectasias and reticular veins, treatment of truncal veins with sclerotherapy is met with variable efficacy as compared to the endothermal technologies. The treatment landscape remains ever-evolving. Fortunately, there has been a trend towards improved clinical outcomes, and more significantly towards improved patient-reported outcomes.

as temporary storage.[3] This enables the collection of blood from the superficial tissues and skin, which is then routed to the deep system for return.

Great Saphenous, Small Saphenous, and Perforating Veins

Of particular interest for endovenous procedures are the two major veins of the superficial system: the great saphenous vein (GSV) and the small saphenous vein (SSV). The GSV originates medially from the dorsal vein of the foot and continues proximally along the medial aspect of the calf and thigh before joining the common femoral vein at the saphenofemoral junction (SFJ).[4] It contains 7 to 10 valves, the most important of which are located at the level of the SFJ and 1 to 2 cm peripherally.[5] True "duplication" of the GSV is rare, and apparent duplications are typically accessory saphenous veins that run parallel to the GSV.[4,6,7]

An anterior accessory GSV is the most common, found in up to 14% of patients.[8,9] The GSV is located in its own subfascial compartment; in transverse ultrasound view it has the appearance of an eye (known as the "saphenous eye"). It has a number of fairly consistent tributaries, including the posterior accessory GSV, the anterior accessory GSV, the posterior thigh circumflex, and the anterior thigh circumflex.[10,11] Tributaries near the SFJ, such as the superficial inguinal veins, are sometimes used as markers to guide positioning of catheters in RFA and EVLA procedures.

The SSV originates inferior and posterior to the lateral malleolus and ascends the posterior aspect of the calf between the gastrocnemius heads to the popliteal fossa.[11] In two-thirds of patients, the SSV connects to the popliteal vein at the saphenopopliteal junction (SPJ), which is most often located within 5 cm of the popliteal skin crease. However, in some patients this junction may be situated as high as 7 cm above the crease. In the remaining one-third of patients, the SSV joins with another vein, such as the GSV, or may have several termination points through its thigh extension.[4,12] Similar to the GSV, the SSV lies within its own fascial compartment and contains between 7 and 10 valves.[4,13] It has one major tributary, the intersaphenous vein, which ascends across the medial aspect of the leg and connects the SSV to the GSV.[4,10]

A discussion of perforating veins can be found in Chapter 158.

Reticular Veins

Reticular veins are thin-walled blue venules lying within the superficial compartment; they have diameters ranging from 1 to 3 mm.[14,15] They may connect to the saphenous veins and form a network of vessels termed the *lateral subdermic venous system* (LSVS).[16] The LSVS is located along the lateral aspect of the leg and extends above and below the popliteal area.[17] Ultrasound studies have revealed that the reticular veins of the LSVS may connect to telangiectasias in up to 88% of patients.[18]

Telangiectasias

Telangiectasias differ from reticular veins in both size and appearance. Telangiectasias are defined as dilated venules, capillaries, or arterioles 0.1 to 1.0 mm in diameter.[12,19] The color of a telangiectasia depends on the origin of the vessel. Telangiectasias that arise from the arterial side of the capillary loop are flat and red, whereas those from the venous side are raised and blue.[12] These veins often appear in the thigh near the LSVS. Reticular veins are frequently "feeder" veins to telangiectasias.

DIAGNOSTIC EVALUATION

Clinical Scoring Systems

Most clinicians have adopted the Clinical, Anatomic, Etiologic, Pathophysiologic (CEAP) system to classify the physical findings associated with chronic venous insufficiency (Fig. 155.1; see also Chapter 156).[10] Any patient in whom an endovenous procedure is contemplated should be evaluated in terms of this classification. Photographs of the target veins should also be taken to document the clinical score and compare the pre- and postoperative results.

Patient-oriented outcomes are becoming central to evaluating venous pathology and its meaningful effects on the patient. The Venous Clinical Severity Score (VCSS) and the Villalta scale are scoring systems that assess severity of disease and quality-of-life issues.[6] As with the CEAP classification, all patients undergoing endovenous procedures should be evaluated using one or both of these systems.

Imaging

Duplex ultrasonography (DUS) of the lower extremities is the standard study for evaluating and diagnosing superficial venous insufficiency. Complete evaluation includes assessment of both reflux and obstruction in the deep, superficial, perforating, and tributary veins.[4] A more complete description of the technique can be found in Chapters 19 and 23. The goals of ultrasound are to identify and map the superficial veins to be treated and determine their locations and degrees of reflux. The deep system should also be interrogated, because obstruction in this system is a relative contraindication to the closure of superficial veins.[5]

TREATMENT SELECTION

The primary goal in treating superficial venous insufficiency is closure of refluxing superficial veins, which alleviates symptoms and prevents complications. The most proximal point of reflux should be treated first. An additional goal of the treatment of telangiectasias and reticular veins is the attainment of satisfactory cosmetic results.[7]

The most proximal point of reflux in the majority of patients is the SFJ or SPJ. Wong et al. evaluated 239 limbs with primary reflux and 225 limbs with recurrent reflux; they found SFJ incompetence in 53% and 69%, respectively, of these limbs.[8]

Figure 155.1 Clinical, Anatomic, Etiologic, Pathophysiologic (CEAP) Classification of Venous Insufficiency. (A) C0: normal asymptomatic leg. (B) C1: telangiectasias or reticular veins. (C) C2: varicose veins greater than 3 mm in diameter. (D) C3: edema. (E) C4a: pigmentation or eczema. (F) C4b: lipodermatosclerosis. (G) C5: healed venous ulcer. (H) C6: active venous ulcer.

In the same patient cohort, 21% of the primary reflux limbs and 25% of the recurrent reflux limbs demonstrated incompetence at the SPJ.[8] Similarly, Guex et al. found that 85% of limbs showed reflux in the GSV (68% at the junction) and 20% in the SSV.[13] Patients with reflux in either of these truncal veins are candidates for an endothermal or nonthermal ablation.

Patients with saphenous reflux may also exhibit varicosities, enlarged reticular veins, or telangiectasias. Currently there is debate as to whether adjunctive procedures to treat these varicosities and telangiectasias should be performed at the same time that truncal reflux is eliminated or in a staged fashion. One study in which patients were simultaneously treated with EVLA and ambulatory phlebectomy found that 94% did not have to return for additional ambulatory phlebectomy procedures.[9] Conversely, in a study of 181 patients who underwent RFA of the GSV, only 25% were able to avoid additional treatment with ambulatory phlebectomy.[20] This issue remains controversial, but it seems apparent that certain subsets of patients may benefit from concomitant ablation and microphlebectomy as compared with a staged procedure.

The Society for Vascular Surgery (SVS) and the American Venous Forum (AVF) have compiled evidence-based recommendations for the care of patients with chronic venous disease.[21] Both EVLA and RFA are considered safe and efficacious and are recommended equally for the treatment of saphenous reflux. Both are recommended in preference to open surgery because of reduced convalescence time and a decreased incidence of postprocedural pain and morbidity. They are also recommended in preference to foam sclerotherapy because of their greater efficacy. Liquid or foam sclerotherapy is recommended for the treatment of telangiectasias, reticular veins, and varicose veins. A guideline for choosing the appropriate endovenous intervention is listed in Table 155.1 and discussed in detail in the following sections.

TABLE 155.1 Endovenous Options for Treatment of Reflux

Type of Treatment	Vessels Treated
Radiofrequency ablation	Saphenous vein trunks Saphenous vein tributaries Perforators
Endovenous laser ablation	Saphenous vein trunks Saphenous vein tributaries Perforators
Ultrasound-guided sclerotherapy	Saphenous vein trunks Saphenous vein tributaries Perforators Varicose veins not connected to saphenous vein trunks
Visual or surface sclerotherapy	Varicose veins Reticular veins Telangiectasias

Thermal Ablation Techniques

Radiofrequency Ablation

RFA is a minimally invasive technology that provides efficacious treatment of superficial venous reflux with minimal postprocedural sequelae and can be performed in an outpatient setting. The current RFA technology uses the "segmental ablation" method employed by the Venefit procedure using the ClosureFAST catheter.[22] It is designed for treating both the GSV and SSV (Fig. 155.2A). The ClosureFAST catheter is constructed such that it must make direct contact with the vein wall to deliver radiofrequency energy. This results in destruction of the endothelium, contraction of vein wall collagen, and thrombus formation. Eventually, fibrosis occurs within the vein, which further constricts its lumen, resulting in a durable ablation.[17]

Contraindications to the use of RFA include superficial venous thrombosis (SVT), deep venous thrombosis (DVT), venous aneurysm, and an ankle-brachial index of less than 0.9. Although the presence of a pacemaker is not a strict contraindication, preprocedural evaluation by the patient's cardiologist should be considered.

Preoperative Planning

On the day of the RFA procedure, the patient should be well hydrated to achieve maximal distention of the leg veins. Venodilation can be further enhanced by warming of the ultrasound gel and keeping the patient warm in the procedure room. Duplex ultrasonography is performed prior to the procedure to mark the skin overlying the target treatment vein.[23]

Radiofrequency Ablation Procedure

For ablation of the GSV, access is initiated no more than a hand's breadth (~10 cm) below the popliteal area. Treatment should be performed only where the vein is deep to the saphenous fascia and at least 1 cm below the skin to avoid skin burns. With the patient in the reverse Trendelenburg position, lidocaine is administered at the selected site, and a 21-gauge needle is used to gain access under ultrasound guidance. A 0.018-in guidewire is inserted into the GSV, and the needle is removed. A 7-Fr by 7- to 11-cm sheath is advanced over the wire, the 0.018-in wire is removed, and the ClosureFAST catheter is inserted. The catheter is advanced to the point where treatment will begin. If it does not advance easily, a 0.025-inch guidewire may be backloaded into the device to assist passage. Optimal positioning of the catheter tip is 2 to 2.5 cm distal to the SFJ, which is thought to reduce the risk of an endothermal heat-induced thrombosis ("EHIT," or extension of thrombus into the common femoral vein).[24,25]

Once tip placement is confirmed by ultrasound, perivenous tumescent anesthesia is administered under ultrasound guidance along the entire treatment length to create a fluid layer around the GSV. Tumescent anesthesia serves not only as an anesthetic but also compresses the vein around the catheter and protects the surrounding tissue and skin from heat damage.[24,26] Enough should be instilled to create a 10-mm diameter around the vein (Fig. 155.3). A typical mixture includes 50 mL of 1% lidocaine

Figure 155.2 (A) Venefit. Covidien ClosureFAST Endovenous Radiofrequency Ablation Catheters brochure (Coviden, Hampshire, UK). (B) Dornier Medilas D laser (Dornier MedTech, Munich, Germany). with epinephrine in 450 mL of normal saline neutralized with 5 to 10 mL of 8.4% sodium bicarbonate.[23] The safe limits for tumescent lidocaine administration have been described as 35 mg per kg body weight.[27]

Most physicians use a pump system with a 22-gauge spinal needle to deliver the tumescent anesthesia because it decreases the time needed for administration as well as the number of needle punctures. Ideal needle positioning is within the saphenous compartment. After administration, the patient should be placed in the Trendelenburg position to assist in vein collapse, apposition, and exsanguination.[26] Following treatment of the whole vein, the sheath and catheter are withdrawn.[26]

During the procedure, compression over the treated vein and catheter with the ultrasound transducer in a longitudinal position improves vein wall apposition and technical success.[28] With the segmental ablation technique of the ClosureFAST system, each 7-cm segment of vein is treated independently for a 20-second interval. The initial treatment segment 2 to 2.5 cm distal to the SFJ requires two 20-second cycles to ensure successful ablation. Aneurysmal or large-diameter segments may also be treated twice at the user's discretion.[24] For each 20-second cycle, the temperature must reach 120°C within 5 seconds after the initiation of delivery of the energy; if this temperature is not achieved within the stated time frame, the segment must undergo another 20-second treatment cycle.[26] The RFG Plus generator monitors all parameters during the treatment cycle and alerts the user if the parameters are not successfully met. A segment should not undergo more than three treatment cycles.[26]

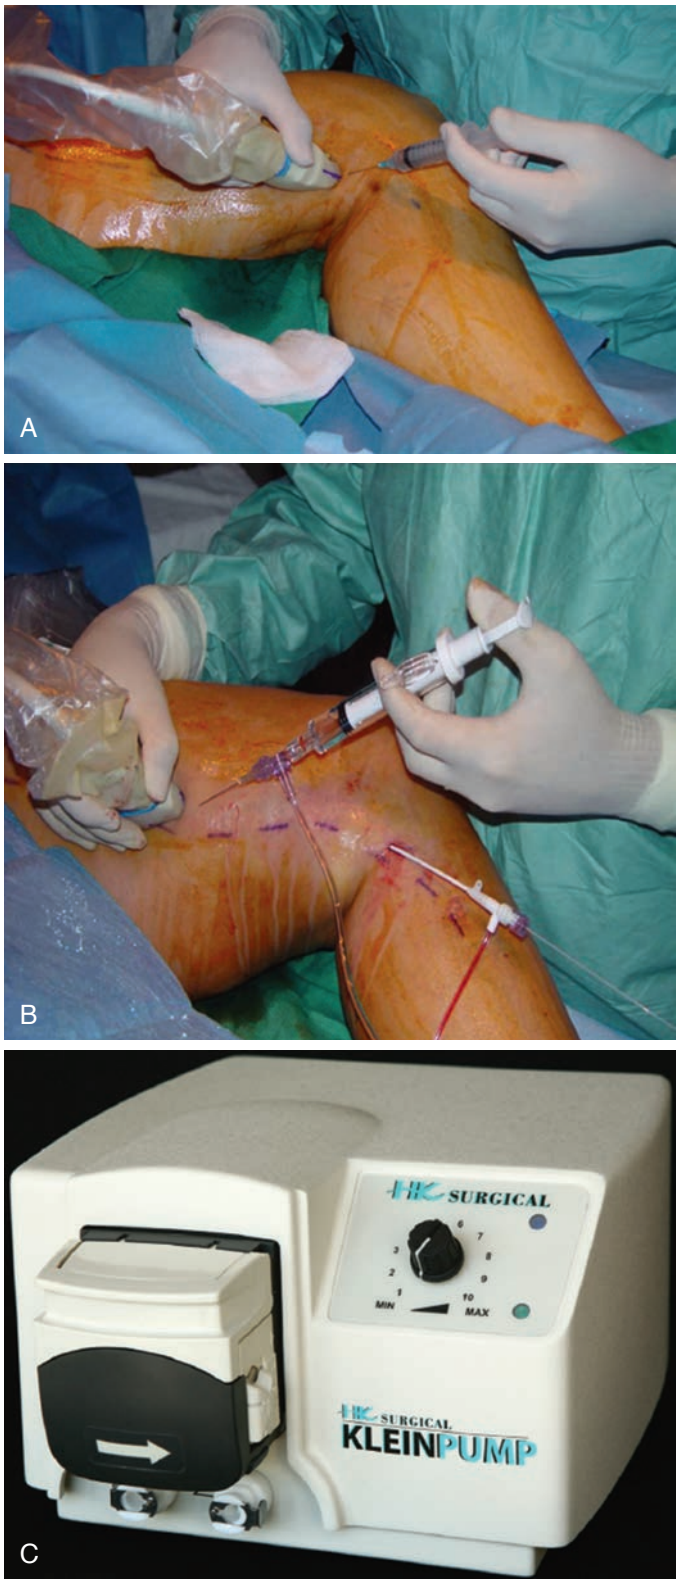

Figure 155.3 (A) Delivery of tumescent anesthesia with the hand injection method. (B) Delivery of tumescent anesthesia with a refillable syringe. (C) HK Klein tumescent pump (HK Surgical Inc., San Clemente, California).

After treatment, duplex ultrasonography is used to assess the treated vein for closure, absence of reflux, and EHIT.

Discharge and Follow-Up

Postoperative compression with a 30- to 40-mm Hg graduated stocking or a multilayer compression dressing is recommended for at least 1 week.[26,29,30] Although well accepted as postprocedural care, the mandatory use of compression is coming into question. In one randomized study of 70 patients undergoing ablation, there was no difference in patient-reported outcome between patients who wore compression and those who did not.[31,32] Patients are instructed to ambulate after the procedure to assist in occlusion of the vessel.[30] A duplex ultrasound follow-up examination is advised at 72 hours to assess for EHIT and closure of the treated veins.[30] Further follow-up evaluations are performed according to physician preference.

Clinical Results: Complications

Complications of RFA include vessel perforation, thrombosis, pulmonary embolism (PE), phlebitis, EHIT, infection, nerve injury, and skin burns or discoloration.[26] Proebstle et al. initially reported comprehensive findings from 6-month data showing a low rate of side effects: ecchymosis, 6.4%; paresthesia, 3.2%; hyperpigmentation, 2.0%; hematoma, 1.6%; erythema, 1.6%; and phlebitis, 0.8%.[24] Thermal skin injury and DVT were not observed; however, during the first year of use of the ClosureFAST in 2007, numerous adverse events related to DVT were reported.[33] The rate of these events has decreased significantly as the current procedures/catheters were developed and clinicians gained experience with the procedure.

The European Closure Fast Clinical Study Group reported on the 3-year European follow-up on the ClosureFAST device, now referred to as the Venefit procedure.[34] The incidence of complications was low; the majority manifested and subsided within the first week after treatment. They included ecchymosis, 5.8%; erythema, 2.0%; hematoma, 1.4%; and phlebitis, 1.0%. Complications persisting beyond the first week included paresthesias (initial rate of 3.4%, which declined to 0.4% at 36 months) and pigmentation (initial rate of 2.4%, which also declined to 0.4% at 36 months). There were no reported cases of DVT or PE.

Clinical Results: Outcomes

The European Closure Fast Clinical Study Group also reported the 3-year efficacy of the ClosureFAST device, demonstrating a rate of 92.6% continued occlusion of treated truncal veins.[34] The Venous Clinical Severity Score (VCSS) improved from an average of 3.9 before treatment to 0.9 at 3 months after treatment ($P < .0001$), which persisted for the duration of the study. Seventy-four percent of patients demonstrated an improvement in CEAP at 36 months.[34]

Endovenous Laser Ablation

EVLA exhibits many procedural similarities to RFA, with the primary differences related to the type of catheter and its

mechanism of action. EVLA uses a bare-tipped or jacket-tipped fiber to deliver laser energy to a target area, resulting ultimately in fibrosis and occlusion of the target vein.[35-37]

Laser Wavelength and Fiber Type

Different laser wavelengths have been used to generate endothelial destruction of varicose veins, including lengths of 810, 940, 980, 1064, 1319, 1320, and 1470 nm (see Fig. 155.2B to G).[38] Research on the optical properties of blood has shown that different wavelengths have varying absorption characteristics; these may loosely be categorized into the hemoglobin-specific laser wavelengths (HSLWs) and the water-specific laser wavelengths (WSLWs).[39]

A limited number of studies have evaluated these wavelengths for both efficacy and adverse events. The first, by Proebstle et al. in 2005, compared the 940- and 1320-nm wavelengths.[40] The study concluded that the wavelengths were equally efficacious but that ecchymosis and pain occurred significantly less often in limbs treated with the 1320-nm laser.[40] In a similar study, an analysis of the 810-nm wavelength versus the 980-nm wavelength also favored the higher wavelength.[41] Additional studies have confirmed these findings.[42] Current research suggests that the various laser wavelengths are equally efficacious but that there is a trend toward less pain and bruising with the higher-wavelength lasers. More significantly, fiber type appears to contribute to postprocedural symptoms to a greater extent than laser wavelength. Specifically, jacket-tipped fibers appear to cause less pain and bruising than bare-tipped fibers.[43]

Preoperative Planning

Preoperative planning for EVLA is the same as that for RFA.

Endovenous Laser Ablation Procedure

GSV access is obtained just distal to the popliteal area with a microaccess set (21-gauge needle, 0.018-in wire, and microsheath), and the distance from the access site to the SFJ is measured. The inner dilator is removed, and a 0.035-in guidewire is advanced through the microsheath to the SFJ under ultrasound guidance. A long sheath is then selected, exchanged for the microsheath, and advanced to a point 2 to 2.5 cm distal to the SFJ.[41] Once in place, the inner dilator and guidewire are removed and a 600-µm bare-tipped or jacket-tipped fiber is advanced into the sheath. The fiber is connected to the generator, and the aiming beam is turned on to help visualize the fiber tip under the skin. Although the fiber is held in place, the sheath is withdrawn to the locking mechanism of the fiber, with the tip of the fiber exposed approximately 2 cm past the end of the sheath. Positioning 2 to 2.5 cm peripheral to the SFJ is reconfirmed with ultrasound, and tumescent anesthesia is injected perivenously, as in RFA.[41,44,45]

Procedural Variations

Variations have developed with regard to procedural technique. Most are related to pullback time and the amount of energy delivered. In 2004, Timperman et al. introduced a modification whereby the amount of energy (joules) delivered per centimeter of vein treated (known as the linear endovenous energy density [LEED]) was assessed.[40,46] These authors found a direct correlation between the LEED and treatment efficacy. The mean energy delivered for successfully treated veins was 63.4 ± 26.6 J/cm, whereas in failed treatments an average of 46.6 ± 13.8 J/cm was emitted.[46] No failures occurred in limbs receiving energy doses of 80 J/cm or greater.[46] In a subsequent study, veins treated with an average of 95 J ± 16 J/cm had a treatment success rate of 91% 9 months after the procedure.[47] In an attempt to assess the efficacy of treatment using higher LEEDs tempered by the increased risk of complications associated with higher energy use, an evaluation of the 1470-nm laser was performed comparing an average LEED higher than 100 J/cm to a LEED lower than 100 J/cm. Although the treatment was technically successful 100% of the time in patients treated using a LEED greater than 100 J/cm, there was an increased incidence of paresthesias in the group receiving the higher LEED. In addition, postprocedural analgesia intake was significantly less in the lower LEED group.[48] Currently, 50 to 80 J/cm is the average treatment energy most often used for EVLA procedures.[41,49,50] Continuous pullback is used while the operator watches the real-time energy readout on the generator and gauges speed with the 1-cm marks on the sheath. This method has proved to be more consistent than using time to gauge pullback because the same amount of energy is delivered in each case, regardless of wattage.

Once tip positioning is confirmed, the laser is switched from standby to ready mode and the foot pedal is depressed to deliver energy. The laser fiber and sheath are drawn through the vessel simultaneously in a continuous fashion. To prevent skin burns or trauma to the entry site, the user stops treatment when the tip of the laser fiber is approximately 1 to 3 cm proximal to the entry site.[44,47] Closure of the vein is visualized by duplex ultrasound.

Discharge and Follow-Up

Discharge and follow-up for EVLA are the same as those for RFA.

Clinical Results: Complications

The incidence of procedure-related complications with EVLA has been relatively low and includes vessel perforation, thrombosis, PE, phlebitis, hematoma, infection, skin pigmentation, neovascularization, paresthesias, complications from tumescent anesthesia, irradiation of nontarget tissue, hemorrhage, necrosis, skin burns, and pain.[50] Rates vary widely in the literature: DVTs, 0% to 5.7%; skin burns, less than 1%; nerve injury, 0% to 22%; and superficial thrombophlebitis, 0% to 25%.[51,52] A rare complication reported in both RFA- and EVLA-treated patients is the development of an arteriovenous fistula, commonly occurring where the external pudendal artery crosses posterior to the GSV.[53] The natural history of these fistulas is still being elucidated, but the majority of patients remain asymptomatic.

As discussed earlier, some evidence suggests that higher-wavelength lasers produce less pain and bruising; however, a prospective large-scale study evaluating all the wavelengths is needed to further substantiate these findings. The mechanism of the EVLA procedure that causes pain and bruising remains unclear, although some experts speculate that it is due to

perforation of the vein wall by laser energy.[40,54] Aside from laser wavelengths, a novel adaptation to laser fibers that has shown a beneficial effect on perforation of the vein wall is the jacket-tipped fiber. This technology features either a stainless steel or ceramic jacket that completely covers the tip of the fiber, with the end of the tip being recessed within the jacket.[55,56] This design prevents the flat emitting face of the fiber tip from coming in contact with the vein wall.[55,56] Kabnick et al. carried out a pilot study to evaluate the efficacy and complications of jacket-tipped fibers versus bare-tipped fibers.[54] At 72 hours after the procedure, both treatment groups demonstrated 100% success; however, in the group treated with the jacket-tipped fiber, pain and bruising scores were lower.[54] Because vessel perforation has been directly linked to bruising, the study concluded that the lower bruising scores achieved in the jacket-tipped fiber group could be attributed to fewer perforations.[54] In order to assess the use of a jacket-tipped fiber in a higher-wavelength laser, Maurins et al. evaluated a 1470-nm laser and compared treatments using a bare-tipped fiber, a jacket-tipped fiber, and a fiber with a radial-emitting tip.[57] All demonstrated similar efficacy in ablation. The fiber with the radial-emitting tip had the lowest LEED requirement, resulting in less post-procedural pain than in the other two groups. In a multicomparison study involving varying laser wavelengths and fiber types, it was reported that fiber type may contribute to a greater extent to postprocedural symptomatology.[43]

Clinical Results: Outcomes

In addition to the low rate of complications demonstrated by EVLA, treatment outcomes of EVLA are at least equivalent to those of all other modalities. The seminal trial for establishing EVLA as an efficacious treatment was published by Min et al. in 2003.[44] Initial treatment results with an 810-nm laser showed a 98.2% initial success rate and an ensuing closure rate of 93.4% at 2 years.[44] Numerous trials have since been conducted for all of the wavelengths currently used. Proebstle et al. performed a study evaluating 1320- and 940-nm (15- and 30-W) lasers and reported favorable efficacy rates at 3 months of 90.3% (940 nm, 15 W), 100% (940 nm, 30 W), and 97% (1320 nm).[40] A large-scale prospective trial involving the use of a 980-nm laser on 500 limbs was published in 2007.[49] A 98% closure rate was reported at the 1-week follow-up and remained constant; the closure rate was 97.1% at the 4-year follow-up.[49]

More recently, the International Endovenous Laser Working Group evaluated long-term outcomes using EVLA for the treatment of patients with truncal reflux. The international registry evaluated 1020 limbs treated using a 980-nm bare-tipped laser. Treatment success rates were 92.3% at 1 year and 86.9% at 2 years, with no additional treatment failures at 3 years.[58]

Sclerotherapy

Sclerotherapy can be used to treat a myriad of vein types and sizes, although it is most commonly used to treat smaller vessels such as the reticular veins and telangiectasias. It is best defined as the introduction of a chemical into the lumen of a vein to induce endothelial damage that results in thrombosis and eventually fibrosis.[59]

Relative contraindications to sclerotherapy include asthma, late complications of diabetes, hypercoagulable state, leg edema, advanced peripheral arterial occlusive disease, and chronic renal insufficiency. Absolute contraindications are a known allergy to the sclerosant, acute cellulitis, acute respiratory or skin disease, severe systemic disease, phlebitis migrans, acute superficial thrombophlebitis, pregnancy, hyperthyroidism, and a bedridden status.

The method used to deliver the sclerosing agent depends on the diameter of the target vein. For smaller veins such as telangiectasias, venulectases, and small reticular veins, liquid sclerotherapy is used.[60] Larger reticular veins and varicosities may also be treated by liquid sclerotherapy with a higher concentration of sclerosing agent or by foam sclerotherapy. Foam sclerotherapy involves the addition of air to a detergent sclerosing agent by means of agitation to produce a foam-like consistency, which allows for enhanced contact with the vein wall.

Because the sclerosing agent must make contact with the vein wall to cause endothelial damage, the primary limitation of sclerotherapy is vein diameter. Until recently, sclerotherapy was not approved in the United States for the treatment of refluxing truncal veins. Polidocanol, a commonly used sclerotherapy detergent agent in both the United States and Europe, has recently gained approval from the US Food and Drug Administration (FDA) for this indication.[61]

Sclerosing Agents

Sclerosing agents are most commonly grouped into categories based on their mechanism of action.[12] Categories of currently available solutions include osmotics, alcohols, and detergents (Table 155.2).[17] Ideal sclerosing agents should effectively damage the endothelium, exhibit a low incidence of adverse events, and be painless to inject.[12]

Osmotic Agents

Osmotic agents are thought to cause dehydration of endothelial cells through osmosis, which leads to endothelial destruction.[17] The primary osmotic agent used in the United States is hypertonic saline (23.4% sodium chloride). Although not FDA-approved for use in sclerotherapy, it has been used by physicians for many years. The second agent consists of 10% sodium chloride mixed with 25% dextrose.[62] The most widely known commercial version of this agent is Sclerodex, manufactured by Omega Laboratories, LTD (Montreal, Canada).[62]

Alcohol Agents

Alcohol agents are relatively weak sclerosants that cause irreversible destruction of endothelial cells on contact.[63] The main alcohol agent used for sclerotherapy is 72% chromated glycerin (Chromex, Omega Laboratories, Ltd. Montreal, Quebec, Canada), which is popular in Europe but is not FDA-approved in the United States. Because of its weak nature, glycerin is used only for telangiectasias.[64] Nonchromated glycerin is also used but is available only through compounding pharmacies.

TABLE 155.2 Sclerosing Agents

Agent	Manufacturer	Category	FDA Approved?	Strength	Advantages	Disadvantages
Hypertonic saline	Multiple	Osmotic	Off-label use	++	Low risk of allergic reaction, wide availability, rapid response	Off-label use, painful to inject, hyperpigmentation, necrosis, rapid dilution; not recommended for facial veins
Sclerodex (hypertonic saline and dextrose)	Omega Laboratories, LTD, Montreal, Canada	Osmotic	No	++	Low risk of allergic reaction, low risk of necrosis, high viscosity	Not FDA-approved, stings when injected, hyperpigmentation
Chromex (72% chromated glycerin)	Omega Laboratories, LTD	Alcohol	No	+	Low incidence of hyperpigmentation, necrosis, and allergic reaction	Not FDA-approved, weak sclerosing agent, highly viscous and painful to inject, may cause hematuria at high doses
Nonchromated glycerin	Compounded at pharmacy	Alcohol	Off-label use	+	Low incidence of hyperpigmentation, necrosis, and allergic reaction	Weak sclerosing agent, typically used only for telangiectasias
Scleromate (sodium morrhuate)	Glenwood, LLC, Englewood, New Jersey	Detergent	Yes	+++	FDA-approved	High incidence of skin necrosis and anaphylaxis
Sotradecol (sodium tetradecyl sulfate)	BionichPharma, Inc,. Morgantown, WV (distributed by AngioDynamics, Latham, New York)	Detergent	Yes	+++++	FDA-approved, low risk of allergic reaction, potent sclerosant	Potential necrosis with extravasation, matting of telangiectasias
Varithena (polidocanol 1%)	BTG International Inc., West Conshohocken, Pennsylvania	Detergent	Yes	+++	FDA-approved, very low risk of allergic reaction, painless to inject	Matting of telangiectasias

FDA, U.S. Food and Drug Administration.

A typical mixture for this solution consists of two parts 72% nonchromated glycerin to one part 1% lidocaine with epinephrine.

Detergent Agents

Detergent agents are potent sclerosants that destroy the target vein by aggregating on the endothelial wall, disrupting the cell surface membrane, and causing thrombosis.[63] Three agents are currently FDA-approved in the United States: sodium morrhuate (Scleromate, Glenwood, LLC, Englewood, New Jersey), ethanolamine oleate, and sodium tetradecyl sulfate (STS) (Sotradecol, BionichePharma USA, Inc., Belleville, Ontario, Canada; distributed exclusively in the United States by AngioDynamics, Latham, New York).

Although sodium morrhuate is FDA-approved, it is not a preferred agent because of the associated high incidence of skin necrosis and anaphylaxis.[65] Similarly, ethanolamine oleate is a viscous solution that is difficult to inject and not commonly used.[63] STS (also FDA-approved) has a long history of safety and efficacy in treating telangiectasias, reticular veins, and varicose veins and is the most frequently used detergent sclerosant.

A fourth detergent agent popular in both Europe and the United States is polidocanol (Aethoxysklerol, Kreussler Pharma, Wiesbaden, Germany).[66] It currently has FDA approval in the United States and is distributed under the trade name Asclera (Merz Aesthetics Inc., San Mateo, California) and AngioDynamics (Latham, New York). In previous studies comparing polidocanol with STS, fewer complications were reported with polidocanol.[67,68]

The proprietary polidocanol microfoam (Varisolve Polidocanol Endovenous Microfoam; Biocompatibles, Inc., West Conshohoden, Pennsylvania) distributed as Varithena, has been approved by the FDA and is commercially available in the United States.[69,61]

Preoperative Planning

Digital photographs of the target veins should be obtained to document their appearance before sclerotherapy is performed. Larger target veins such as varicose veins should be traced with a surgical marker with the patient standing because they may be difficult or impossible to identify with the patient recumbent. Preoperative marking is typically not required for smaller veins

such as telangiectasias and reticular veins. When sclerotherapy is combined with endothermal ablation of the saphenous veins, sclerotherapy below the knee should be performed second. If a staged approach is used, the GSV or SSV should be treated first, with sclerotherapy following several weeks later. Closure of truncal veins may decompress the varicosities and smaller veins, reducing the need for sclerotherapy.[70]

Depending on the amount and severity of veins, multiple sclerotherapy treatments may be necessary. It is important to establish the expectation that several sessions may be required to achieve the desired result.

In planning sclerotherapy, another decision point is whether to use the liquid method, the foam method, or a combination of the two.[71] In the selection of an agent, the strength of the agent should match the size of the vessel to be treated so that the smallest volume and concentration can be used.[72] Sclerosants are diluted by blood immediately on injection, making treatment of larger-diameter veins with liquid sclerotherapy challenging. Liquid sclerotherapy is best reserved for small reticular veins, venulectasias, and telangiectasias.[60] Foamed agents have increased surface area related to the bubbles and stay in contact with the endothelium longer. They are therefore more effective in the treatment of larger reticular veins and varicose veins.[73]

Sclerotherapy Procedure

After preoperative preparation, the sclerosing agent is diluted with 0.9% saline according to the size of the vein (Table 155.3). In general dilutions for STS range from 0.1% to 3%, and for polidocanol from 0.25% to 1%.

Liquid Sclerotherapy

After dilution of the agent, multiple syringes are filled and assembled with 30-gauge needles. Veins should be treated from the largest diameter to the smallest diameter and in a central-to-peripheral direction.[74] For instance, the reticular veins of the LSVS feed telangiectasias. When an agent is injected into a reticular vein, the agent may flow into the telangiectasias, thereby reducing the number of treatments necessary. Transillumination can be beneficial for identifying reticular and feeding veins associated with telangiectasias. Although rare, anaphylaxis can occur, and it is essential to have resuscitation equipment available.[75]

The amount of sclerosant injected per site depends on the size of the vein; for larger varicose veins, 1 mL or less per site is advisable.[59] Reticular veins typically require 0.25 to 0.5 mL per site, with smaller telangiectasias necessitating 0.1 to 0.2 mL per injection.[71,74] While avoiding forceful pressure, injections should be made slowly and not more than a few centimeters from the puncture site (Fig. 155.4). Strong pain during injection may be an indicator of a paravascular injection; in such cases the injection should be stopped immediately.[6] Injections are delivered in 2- to 3-cm intervals until the entire length of the target vessel has been treated.[76] To help minimize bleeding, a 2- by 2-in gauze sponge is placed over each injection site and secured with tape. Graduated compression hose are applied to the treated leg or legs, and patients are instructed to wear them for 1 to 3 days to reduce thrombus formation and improve outcome. A typical initial sclerotherapy session consists of 10 to 20 injections.

Ultrasound-Guided Foam Sclerotherapy

The method widely used today involves the use of a three-way stopcock connected to two syringes; it was developed by Tessari in 1999.[77] One of the main criteria for foam to be viable is that bubble size must be 100 μm or less.[78,79] The pure form of the sclerosing agent is contained on the bubble surface; therefore, concentration is related to bubble size and the air-to-liquid ratio. For the Tessari method, a ratio of one part liquid to four or five parts air is highly effective.[80] The amount of foam to be injected can be calculated using the formula $V = \pi \times (D/2)^2 \times L$ (where V is volume, D is diameter, and L is length).[82] Other factors which contribute to success with foam sclerotherapy are stability and longevity.[79] Using the Tessari method, significant coalescence does not begin until after the first 1 to 2 minutes.[78,79,81-84]

TABLE 155.3 Recommended Concentrations for Sodium Tetradecyl Sulfate

Indications	Recommended STS Concentration (%)
Varicose veins 4-8 mm in diameter	0.5-3.0
Reticular veins 2-4 mm in diameter	0.25-0.5
Telangiectasias 0.1-2.0 mm in diameter	0.125-0.25
Recurrent varicosities	0.5-3.0
Failed segments of endothermal ablation	0.5-3.0
Unsightly veins of the hands and feet	0.25-0.5
Congenital malformations	0.125-0.25
Vascular malformations	0.125-0.25
Facial telangiectasias	0.125-0.25

STS, Sodium tetradecyl sulfate.

Figure 155.4 Liquid Sclerotherapy Injection.

Although many clinicians make their own foam, a polidocanol foam sclerosant (Varithena) is now approved and available in the United States.[61]

Depending on the size and depth of the target veins, duplex ultrasound can be helpful in guiding the injection of foamed sclerosants.[71] Foam is highly visible with ultrasound, allowing for a more accurate injection. It also enables immediate postinjection observation of vein compressibility as a predictor of treatment efficacy.[85]

Ultrasound-guided sclerotherapy using a Tessari-like method is performed in a similar fashion to foam sclerotherapy without ultrasound.[85] Target vein segments should be marked before the procedure. After the treatment area is mapped, access to the first vein to be treated is achieved with a needle or butterfly under ultrasound guidance. Access is confirmed by return of blood, and the needle/butterfly is taped to the patient's leg. The foam solution is created by a rapid mixing of the air and chemical back and forth between two syringes connected via a three-way stopcock for a total of 20 cycles.[78] After most of the solution has been moved to one syringe, the filled syringe is connected to the needle, and intravascular positioning is reconfirmed with ultrasound. A small amount of foam should be injected initially, under ultrasound, to confirm needle placement within the vein. The amount of foam delivered is determined during injection with the use of ultrasound to visualize when the targeted vein is filled with foam (Fig. 155.5). Upon completion, full-length graduated compression stockings (30 to 40 mm Hg) are applied.

Catheter-Directed Sclerotherapy

Sclerosants can also be injected using catheters. An end-hole catheter can be placed distal to the SFJ using ultrasound guidance.[81] The catheter is then withdrawn while the user delivers a foamed sclerosing agent under ultrasound guidance.[84] The technique is similar to that used in ablation procedures. Kolbel et al. achieved clinical success by injecting foamed polidocanol through a long introducer sheath as it was retracted through the GSV.[86] In 2000, Min and Navarro reported using a 5-Fr infusion catheter to deliver STS into the GSV with the patient in the Trendelenburg position.[87] Initial closure rates with this method were excellent; however, long-term efficacy diminished significantly.

Figure 155.5 Ultrasound-Guided Foam Sclerotherapy Injection.

Discharge and Follow-Up

From experience, the senior author recommends that the patient wear a 30- to 40-mm Hg compression stocking for 24 hours after treatment of reticular veins and telangiectasias and for 7-10 days after treatment of varicose veins and perforators.[88] Compression may improve the efficacy of treatment by reducing the diameter of treated veins and by lessening reflux during walking.[71] After ambulating, patients can be discharged from the facility. They may return to activities of daily living but should avoid heavy aerobic exercise involving the lower extremities for 2 weeks. Tylenol may be taken if needed; however, patients should avoid aspirin, ibuprofen, and other antiinflammatory medications for at least 48 hours. In addition, whirlpools, saunas, and hot baths should be avoided for at least 48 hours after the procedure.

Complications

The majority of complications from sclerotherapy are minor and transient.[89] They include hyperpigmentation, telangiectatic matting, pain, and urticaria.[75,89] Hyperpigmentation occurs in 10% to 30% of patients and is believed to depend on the concentration of sclerosant and to a lesser degree the vessel size and agent used (Fig. 155.6).[85,89,90] Spontaneous resolution is observed in 70% and 99% of cases at 6 months and 1 year, respectively.[90] Telangiectatic matting occurs in 15% to 20% of patients, but usually resolves in 3 to 12 months.[90,91] Pain on injection is largely related to the sclerosing agent used. Detergent agents cause little or no pain, whereas hypertonic saline is the most painful to inject. Urticaria is very common but fades within the first 24 hours.[89]

Rarely observed more serious complications include cutaneous necrosis, superficial thrombophlebitis, nerve damage (saphenous, sural), allergic reaction (anaphylaxis), DVT, PE, and inadvertent arterial injection.[75,89] Necrosis is rare and most often caused by extravasation with hypertonic saline. Superficial phlebitis is usually a result of direct injury to the vein and typically occurs 1 to 2 weeks after the procedure.[89] It is characterized by pain, tenderness to touch, heat, and erythema and can be treated by removal of the coagula via puncture extraction.[89] The incidence of DVT is low after sclerotherapy, with less than 2% of patients affected.[92] Bradbury et al.[93] evaluated one of the largest contemporary series for foam sclerotherapy used in the treatment of truncal reflux. A total of 1252 limbs were treated, 3 patients experienced DVT, and there was 1 PE. Five patients experienced neurologic sequelae in the form of transient visual disturbances, presumably from embolization of foam.[94] Treatment for neurologic sequelae consists of administration of 100% oxygen with the selective use of hyperbaric oxygen.

Clinical Results

Sclerotherapy is safe and efficacious. Kern et al., in a study using the liquid sclerotherapy method with chromated glycerin to treat telangiectasias and reticular veins, found that 76% of

Figure 155.6 (A) Reticular veins and telangiectasias before treatment. (B) Hyperpigmentation after the procedure.

patients who wore compression stockings after the procedure had a successful outcome.[95] Goldman reported the results of a prospective trial in 2002 comparing Sotradecol and polidocanol and found both agents to have a 70% rate of efficacy.[67] Belcaro et al. collected data from numerous trials evaluating STS liquid sclerotherapy versus STS foam sclerotherapy and reported efficacy rates of 90.2% and 92.2%, respectively.[86] A related study by Yamaki et al. compared polidocanol duplex ultrasound–guided liquid sclerotherapy and polidocanol duplex ultrasound–guided foam sclerotherapy of the GSV and reported complete closure rates of 17.5% and 67.6%, respectively.[87]

Studies evaluating foam sclerotherapy alone have also shown positive treatment results. Frullini and Cavezzi performed foam sclerotherapy with STS via the Tessari method and reported a success rate of 93.3%.[72] Using ultrasound-guided foam sclerotherapy with polidocanol, Bergan et al. treated 328 lower extremity veins and recorded complete absence of reflux in 79.8% of treated veins.[96] Other studies have reported similar results.[88,97-99]

Preliminary data from two phase III trials evaluating polidocanol endovenous microfoam (Varithena) have recently been published.[100] In the Polidocanol Endovenous Microfoam versus Vehicle for the Treatment of Saphenofemoral Junction Incompetence (VANISH-2) trial, elimination of reflux as demonstrated by DUS occurred in 85% of patients treated with foam compared with 2% in the placebo group. Patient-reported outcomes were improved in 80% of the treatment group compared with 20% of the placebo group. There were no cerebrovascular events or PE, but 13 patients developed DVT, of which 6 were proximal. Half were treated with anticoagulation at the discretion of the investigator, and all resolved within a median time frame of 29 days. The results were durable at 1 year, with no recurrent DVTs.[101]

A recent study published by the Varithena Study Group demonstrated that there were greater improvements in patient- and physician-reported outcomes using polidocanol endovenous microfoam compared with placebo. The HASTI score (heaviness, achiness, swelling, throbbing, itching) improved by 30.7 versus 16.7 ($P < .001$) in the Varithena group. The m-VEINES-QOL/Sym (modified Venous Insufficiency Epidemiological and Economic Study-Quality-of-Life/Symptoms) and VCSS scores also improved in the Varithena group. Adverse events were mild and transient, including contusion, hematoma, limb discomfort.[102]

Comparison of Outcomes of Radiofrequency Ablation, Endovenous Laser Ablation, Sclerotherapy, and Surgery

In a meta-analysis including 12,320 patients from 64 studies who had undergone treatment of truncal veins with RFA, EVLA, foam sclerotherapy, or surgery, the results over 32 months demonstrated better outcomes for RFA and EVLA compared with surgery and foam sclerotherapy. "Success" rates were 84% for RFA, 94% for EVLA, 78% for surgery, and 77% for foam sclerotherapy.[103] Because of long-term treatment failures, Gohel

et al. performed a cost-effectiveness analysis and concluded that foam sclerotherapy may be less cost-effective than RFA or EVLA.[102] The proposed explanation was that despite the lower initial cost for foam sclerotherapy, there was a higher incidence of reintervention than for RFA or EVLA. In a second study, Rasmussen et al. performed a randomized controlled trial comparing RFA, EVLA, ultrasound-guided foam sclerotherapy, and surgical stripping for the treatment of GSV reflux in 500 patients.[104] Concomitant microphlebectomy was performed during every procedure. Foam sclerotherapy demonstrated the highest technical failure rate at 1 year (RFA, 4.8%; EVLA, 5.8%; foam sclerotherapy, 16.3%; surgery, 4.3%; $P < .001$). One patient in the sclerotherapy group had a PE, and one person in the surgical group experienced a DVT. The highest postintervention pain scores occurred in the surgical and laser groups (RFA, 1.21; EVLA, 2.58; foam, 1.60; surgery, 2.25; $P < .001$). All subcategories of patients had similarly improved Venous Clinical Severity Scores and quality-of-life scores at 1-year follow-up.

Mechanicochemical Ablation

One of the benefits of foam sclerotherapy for the treatment of truncal reflux is that tumescent anesthesia is unnecessary. New treatments that do not require the use of tumescent anesthesia are currently being evaluated. One such methodology utilizes a combination of both mechanical and chemical treatments, foregoing the use of heat energy entirely. This mechanicochemical ablation (MOCA) is performed using the ClariVein device (Vascular Insights LLC, Madison, Connecticut). The device consists of a single-use catheter with a rotating wire that protrudes from its tip, which causes mechanical damage to the endothelium and vein wall spasm by rotating at 3500 rpm at 2- to 3-second intervals.[105] The treatment is initiated 2 cm peripheral to the SFJ and, as the catheter is withdrawn, a sclerosant, typically Sotradecol, is dispersed onto the vessel wall. In a recent study, technical success for truncal veins was 99%, and 88% of veins remained closed at 1 year. No major complications occurred. VCSS decreased from 4.0 prior to the procedures to 1.0 at 1 year ($P < .001$).[106]

These data have been corroborated for the SSV by Boersma et al. Their prospective series of 50 consecutive patients undergoing MOCA for treatment of SSV reflux demonstrated 100% technical success, with a 1-year closure rate of 100%. Clinical improvements in the VCSS were also observed.[107]

Adhesive Closure

The VenaSeal Closure System (Medtronic, Minneapolis, Minnesota), which delivers n-butyl cyanoacrylate (nBCA) glue through a catheter, also avoids the use of tumescent anesthesia. The glue polymerizes when it contacts ionic compounds such as the components of blood. The VenaSeal system is composed of an introducer sheath, an infusion catheter, a dispenser gun, and a proprietary cyanoacrylate adhesive. Access is gained into the refluxing truncal vein, and the catheter with the attached loaded dispenser gun is advanced to within 5 cm of the SFJ. Under ultrasound guidance, the glue is injected twice most centrally; then single injections are performed at 3-cm intervals while the catheter is withdrawn. Almeida evaluated the treatment of eight limbs with GSV reflux and reported a technical success rate of 100%.[108] The safety, efficacy, and durability of this procedure were evaluated in a postmarket trial, the European Sapheon Closure System Observational Prospective (eSCOPE) trial.[109] Thirty-eight patients were treated, 36 of whom were available for follow-up at 24 months. The vein occlusion rate was 92% at 24 months, and the VCSS score also improved in all patients in this period (6.1 ± 2.7 vs. 2.7 ± 2.5, $P < .0001$).[110]

POSTPHLEBITIC (THROMBOTIC) SYNDROME: CLINICAL SUMMARY POINTS OF NATURAL HISTORY, EPIDEMIOLOGY, AND PATHOPHYSIOLOGY 2054

INTRODUCTION

Chronic venous disorders (CVD) are a spectrum of venous diseases that affect the lower limb. The manifestations include varicose veins, pain, edema, skin changes, and venous ulcerations. The pathophysiology involves reflux within the deep, superficial, and perforating vein valves and/or venous obstruction, usually postthrombotic in etiology. Both reflux and residual obstruction can produce venous hypertension and the manifestations of CVD. Compared with nonthrombotic etiologies, lower extremity deep venous thrombosis (DVT) often leads to higher rates of the advanced forms of CVD, with skin changes and ulcerations.[1] DVT often begin in the legs (calf) near valve cusps and may propagate proximally.[2] About 50% of leg thrombi resolve spontaneously; however, nearly 20% will extend more proximally into the popliteal, femoral, and iliac veins.[3] The consequences can range from minor leg swelling at the end of the day to severe complications such as chronic debilitating lower-limb pain, intractable edema, and venous leg ulceration.[4] Other symptoms associated with postthrombotic syndrome (PTS) include leg cramping, pruritus, fatigue, heaviness, venous claudication, paresthesias, and bursting thigh pain with exercise, termed *venous claudication*. It is estimated that PTS occurs in 20% to 50% of patients from a few months to 1 to 2 years, following a lower extremity DVT.[5] The importance of PTS is the significant morbidity and reduction of quality of life, and the economic costs associated with treatment of this disease. Early recognition and intervention may reduce the sequela of PTS.

POSTPHLEBITIC (THROMBOTIC) SYNDROME: ETIOLOGY AND EPIDEMIOLOGY

DVT affects up to three individuals per 1000 annually in the general population. DVT is the major cause of secondary CVD, and is strongly associated with PTS.[1] Although primary CVD (CVD in which no etiologic factor can be identified; see Chapters 154, 155, and 157) is much more common than secondary

Abstract

Chronic venous disorders (CVD) are a spectrum of venous diseases that affect the lower limb. The pathophysiology involves reflux within the deep, superficial, and perforator valves and postthrombotic etiology, leading to venous obstruction and resulting venous hypertension. The postphlebitic syndrome (PPS), also termed the postthrombotic syndrome (PTS), arises because of deep venous valvular injury and persistent obstruction resulting from lower extremity venous thrombosis. Signs and symptoms of this disorder include lower extremity edema, pain, lipodermatosclerosis, and venous ulceration. The PTS will develop in 20% to 50% of patients within 1 to 2 years following a lower extremity deep venous thrombosis (DVT). The importance of the PTS is the significant morbidity, reduction in quality of life, and economic costs associated with treatment of this disease. Early recognition and intervention may reduce the sequela of PTS.

CVD, DVT is responsible for CVD in 18% to 28% of limbs. In a study of 64 patients with 73 limbs affected by DVT, 4% of limbs had skin changes at 1 year, increasing to 25% at 5 years.[1]

Recurrent ipsilateral DVT is the most important risk factor for developing PTS, with a sixfold increased risk in one study.[5] Numerous other studies have found significant associations between ipsilateral recurrent DVT and the risk of developing PTS, with increases of up to 630% (Table 156.1).[1] Recurrent ipsilateral DVT is also the most important clinical factor for *progression* of CVD (relative risk [RR] 4.4; 95% CI, 1.4 to 13.3, $P = .0049$).[1] 630%.[4,6]

The incidence of recurrent DVT is 17% at 2 years, 24% at 5 years, and 30% at 8 years.[1,7] It is estimated that 5% to 10% of patients with recurrent DVT develop severe PTS (lipodermatosclerosis, ulceration) after a proximal DVT. Ulceration as a consequence of PTS has a cumulative incidence of approximately 5% over 10 years.[4] However, some studies have reported that the cumulative incidence of PTS continues to increase, even up to 20 years after DVT diagnosis.[8]

In one study, 355 patients (55% male) with a first time symptomatic DVT were followed at 6-month intervals for 8 years. A total of 245 patients (69%) completed 5 years of follow-up, and 148 patients (42%) completed 8 years of follow-up. The mean age was 63 years old (range 29 to 83). The cumulative incidence of recurrent venous thromboembolism was 4.9% after 3 months, 8.6% after 6 months, 17.5% after 2 years, 24.6% after 5 years, and 30.3% after 8 years.[7] Eighty-four patients developed PTS, with a cumulative incidence of 22.8% after 2 years and 28.0% after 5 years. The incidence did not change substantially thereafter. Of the 84 patients with PTS, 30.2% had severe PTS. Of note, the development of ipsilateral recurrent DVT was associated with an increased risk for PTS (hazard ratio 6.4; 95% CI, 3.1 to 13.3) and more predictive of skin damage (odds ratio 5.3; 95% CI, 1.2 to 24.2) compared with nonrecurrence ($P = .001$).[7]

Other features of venous thrombosis, including location and extent of DVT and insufficient anticoagulation, also increase the risk of developing clinically significant CVD.

In one study, patients with DVT were followed for a mean of 3.4 years with duplex ultrasound, to determine the effects of location and extent of DVT on the development of CVD. Patients were divided into a group which presented with multisegment DVT and a group which presented with single-segment DVT. More patients with multisegment disease were found to be symptomatic, and the prevalence of skin damage and ulceration was higher in this group compared with that in the group with single segment DVT (61 of 79 vs. 26 of 41, $P < .001$; 29 of 79 vs. 6 of 41, $P = .019$, respectively).[9]

The most severe forms of PTS, such as venous leg ulcers, produce adverse social and economic outcomes, and significant decreases in quality of life.[10] The economic burden of PTS is significant; costs increase by roughly 50% compared with those associated with DVT without PTS. In the United States it is estimated that the average annual cost per patient with PTS is $7000, which increases with the more severe forms (skin changes and ulceration). The high cost of treating venous leg ulcers is due largely to the need for surgery, lost workdays, and loss of employment. It is estimated that 2 million workdays are lost annually in the United States as a result of venous leg ulcers.[4]

Further examination of all causes (primary CVD and secondary PTS) of venous leg ulcers shows that the annual US expenditure for treating venous leg ulcers is approximately $14.9 billion (quantification of the incremental resource use and costs of treating these patients [$6391 per Medicare patient, and $7086 per privately insured patient]).[11] In addition, PTS has a significant impact on quality of life, which worsens with advanced forms of PTS compared with patients with DVT but no PTS. One study demonstrated that patients with venous ulceration missed more work days than those without ulceration, which resulted in increased work-related costs of 29% in the ulceration group ($P < .0001$). It has been shown that patients with PTS have a generic physical quality of life that is worse than for patients with osteoarthritis, angina, and chronic lung disease.[4]

POSTPHLEBITIC (THROMBOTIC) SYNDROME: CELLULAR AND MOLECULAR MECHANISMS

The critical factor in PTS is DVT formation, with vein wall injury, poor recanalization of thrombus, persistent obstruction of venous outflow, and valvular insufficiency.[12] This leads to ambulatory venous hypertension. Thrombosis of the valve and vein wall involves an acute proinflammatory and prothrombotic state, with damaged endothelium and expression of tissue factor and plasminogen activator inhibitor-1, release of von Willebrand factor, P-selectin and E-selectin, and amplification of the coagulation cascade. A complex process of recruiting leukocytes,

activation of adhesion molecules leading to interactions of endothelium and neutrophils via increased P- and E-selectins, activation of monocytes and macrophages, activation of toll like receptors, microparticles released from platelets, endothelial cells, and procoagulant monocytes and macrophages are then concentrated into the area of thrombosis leading to thrombus amplification, galectin-3-binding protein expression and galectin-3, chemokines, cytokines, matrix metalloproteinases, and growth factors. All are important factors involved in determining the progression or mitigation of coagulation, recanalization with resolution of thrombosis, and/or persistent inflammation and thrombosis with vein wall damage and eventual fibrosis.[13-15] Additional data addressing molecular and cellular mechanisms of PTS formation can be found in Chapters 9 and 145.

POSTPHLEBITIC (THROMBOTIC) SYNDROME: NATURAL HISTORY AND PATHOPHYSIOLOGY

Initial studies suggested that venous valvular insufficiency constituted the primary pathophysiology in patients with PTS. In an older study, strain gauge plethysmography was used measure venous outflow (a measure of chronic obstruction after DVT) and venous refilling times (a measure of valvular incompetence) in normal patients and those with PTS. The authors demonstrated that significantly reduced venous refilling times were associated with severe PTS, including skin changes and ulceration. There were no significant differences in venous outflow between patients with PTS and those without.[16]

More recently, however, studies have found that both the persistence of obstruction and valvular incompetence following DVT impart a greater risk of developing PTS as well as progression of disease.[1,17,18] In a study of 217 limbs in 183 patients, all with previous DVT, the combination of reflux in both the superficial and deep venous systems, especially when reflux involved the entire limb or below the knee, led to the most significant symptoms and signs of skin changes and ulcerations.[19] In another study of 34 patients with PTS, 65% were found to have both reflux and obstruction in the deep veins of limbs with PTS. Obstruction alone was present in 15%, reflux alone in 18%, and only normal findings in 3% (Fig. 156.1). Hyperpigmentation was present in 11 limbs; both reflux and obstruction were found in 9 of the 11 cases.[18]

Understanding the natural history of DVT and PTS is important in determining the factors that are associated with thrombus resolution and avoidance of debilitating, costly PTS. Prior investigations sought to clarify the relationships between lysis of venous thrombi and the development of incompetent valves, and to determine the relationships between development of symptoms of PTS and residual venous occlusion and valvular incompetence. An early study described outcomes in 21 patients (21 limbs) with acute DVT (mean age of 46 years) followed at intervals of 7, 30, 90, 180, and 270 days. The study endpoints were the percentage of patients with lysis of thrombosed segments, development of reflux, and development of early and late onset of venous edema (as a measure of PTS). Eight segments in the deep venous system (common iliac vein to the posterior tibial veins) were investigated using duplex ultrasound. Three patient groups were identified, including those with early recanalization, early thrombus extension, and late thrombus extension. In the early recanalization group, 53% of limbs experienced complete recanalization by 90 days, with 28% of early complete recanalized limbs occurring within 30 days.[20] Within the group with early DVT extension, 14% of patients had extension of DVT within 7 days. Within the group with late DVT extension, 19% of patients had extension of the DVT within 30 to 180 days. All patients were treated with anticoagulation. Valvular insufficiency occurred in 62% of patients; it developed much later than recanalization and in segments not previously occluded, indicating that the mechanism by which valvular insufficiency occurs must involve more than a physical effect of the thrombus on the valve. In 38% of patients valvular insufficiency was not present, and four of the five patients had complete recanalization by 30 days, suggesting that early DVT recanalization may be a protective factor for venous valve function. Assessing edema at the early times (7 to 30 days) may serve as a marker of subsequent PTS. Patients with edema were more likely to have residual occlusion than valvular insufficiency. The late development of edema at 90, 180, and 270 days was more closely correlated with valvular insufficiency.[20]

A key factor leading to valvular insufficiency following DVT appears to be the rate of lysis; preservation of valve function is greatest with early lysis. In an interesting study evaluating the natural history of DVT, 127 patients with acute DVT (55%

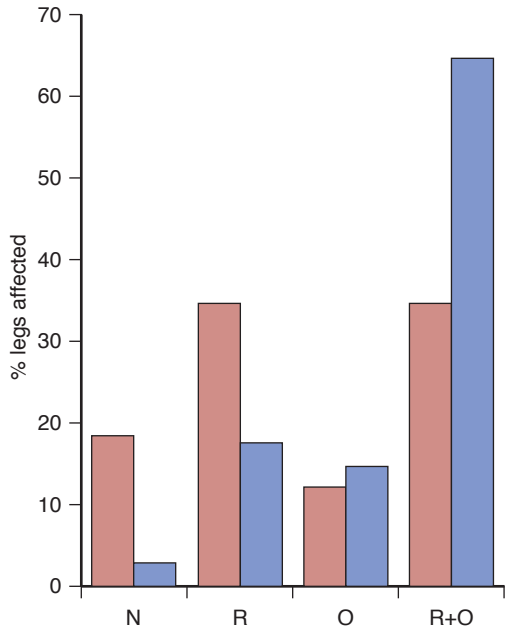

Figure 156.1 Proportion of limbs demonstrating no abnormality *(N),* reflux alone *(R),* obstruction alone *(O),* and reflux with obstruction *(R + O)* after DVT with respect to symptoms. *Blue bars* indicate asymptomatic legs; *red bars* indicate legs with clinical features of PTS. male, average age of 52 years) were assessed at days 1 and 7, at 1-month and at 3-month intervals for the first year, and yearly thereafter. Duplex ultrasound was used to evaluate eight venous segments from the common femoral vein to the posterior tibial veins. Lysis of a vein segment was defined as complete recanalization. Median follow-up was 23 to 25 months for all veins except the posterior tibial vein, which was 12 months. Nearly 90% of patients had anticoagulation treatment. The important findings of the study were that the median lysis times for venous segments developing reflux (214 to 474 days) were 2.3 to 7.3 times longer than for corresponding venous segments not developing reflux (65 to 130 days), for all except the posterior tibial vein (Fig. 156.2). The differences between the two groups (increased lysis time and development of reflux versus shorter lysis time and no reflux) reached statistical significance in the mid femoral vein, popliteal vein, and profunda femoris vein segments (P = .002, .006, and .04, respectively), and a clear trend toward significance was present in all other segments except the posterior tibial vein.[21] When the cumulative percent lysis during the first 9 months was analyzed, a significantly greater proportion of proximal femoral vein segments not developing reflux had lysed by 3 months (56% vs. 13%; P = .012). A similar pattern was present in the distal femoral veins at 6 months (54% vs. 0%; P = .04) and in the great saphenous vein at 9 months (100% vs. 33%; P = .02). The median time at which reflux appeared was less than the median lysis time for all segments (development of reflux coincided with or preceded complete lysis in the venous segments); however, it was only significant for the mid femoral (P = .008) and distal femoral vein (P = .04) segments. This indicated that the onset of reflux appeared prior to complete lysis, and that valves are subject to early reflux even if small amount of recanalizing thrombus is present. If resolved, however, valve function was sometimes restored. Finally, there was a small group of patients in whom vein segments with early lysis developed reflux, and patients in whom vein segments with late lysis (>9 months) did not develop reflux. The authors concluded that early recanalization is important in preserving valve integrity, but other factors (rethrombosis and recanalization, thrombus burden, biochemical factors, incompetence of axial venous channels, residual proximal stenosis, the presence of incompetent perforators and collaterals, differences in fibrinolytic activity in the endothelium) also contribute to valvular insufficiency.[21] Additional information addressing outcomes following lysis of DVT can be found in Chapters 145 and 148.

Other studies have investigated changes in the deep venous system following DVT and development of PTS. In a study of 447 limbs in 429 patients with venous outflow obstruction, the presence of both reflux and obstruction produced more severe signs and symptoms of CVD compared with obstruction alone (CEAP class 4 to 6, 53% vs. 24%, respectively; P < .001). Importantly, venous leg ulcers in limbs with both obstruction and reflux were seen in 24%, compared with 3% in those with obstruction alone (P < .001).[22] These studies indicate that reflux in the presence of obstruction leads to significantly higher rates of severe PTS with skin changes and venous ulcer risk.

In a study of first-time DVT in 120 limbs of 105 patients (59 men, 46 women; mean age of 54 years), patients were stratified into two groups, those with DVT isolated to one venous segment and those with DVT in multiple levels. The majority of patients were treated with anticoagulation. Duplex ultrasound and clinical examination was performed at the initial visit, within the first 6 months, at 1 year, and yearly thereafter. Groups with single level and multilevel involvement were comparable in age and sex. Venous claudication was exclusively found in the multilevel group (8.8%) and was present only when iliac veins were involved. More advanced PTS (skin damage and ulceration) was found in the multilevel group compared with the single level group (26 of 41; P < .001). Skin damage developed in 35 limbs (29%) at a mean follow-up of 3.4 years. The prevalence of skin damage (usually occurring >3 years after DVT) was more common in the multilevel group. Venous pathology (reflux, obstruction, or a combination of the two) was more common in the multilevel group compared with the single level group (P < .0001). Limbs with both reflux and obstruction were more likely to develop skin damage in both

groups. The authors concluded that multisegment venous disease with iliac involvement can lead to venous claudication, and that patients with reflux and obstruction developed increased risk of skin damage than those with reflux or obstruction alone.[9]

In addition to the importance of multilevel and iliac vein involvement, other specific locations had poorer outcomes. It has been shown that poor popliteal vein function correlated with worse clinical manifestations. Patients with popliteal vein abnormalities were found to be greater than 3.5 times more likely to develop PTS when compared with those without popliteal vein involvement. A high peak reflux velocity in the popliteal vein was a strong predictor for CVD, and multisegmental occlusion involving the popliteal vein increased the risk for developing PTS. Thrombosis in multiple calf veins produced more frequent and significant PTS than thrombosis in a single calf vein, and calf vein involvement in the presence of proximal DVT increased the likelihood of PTS.[9]

The rate of progression of CVD is greater with secondary venous disease (DVT) than with primary venous disease (varicose veins and venous insufficiency). An elegant study evaluated 46 limbs in 41 patients with a first episode of DVT. Patients were assessed clinically and by duplex ultrasound at the initial visit, at 3, 6, and 12 months and yearly thereafter for up to 5 years. Outcomes in this group were compared with those in 41 patients with primary disease (50 limbs), age- and sex-matched with disease duration of 5 to 10 years. There was also a control group (15 subjects, 30 limbs), with no evidence of CVD, also matched for sex and age. In the DVT group, at 5 years follow-up, complete obstruction occurred in 9.3%; partial recanalization occurred in 50.9%, and complete recanalization occurred in 39.8%. At the 5-year follow-up, the prevalence of skin damage was 4 times higher in the DVT group compared with patients with primary CVD (23.9% vs. 6%, $P = .019$) and versus control (0%, $P < .01$). In patients with DVT the incidence of skin damage at 1 year was 4%, and significantly increased at 5 years to 24% ($P = .014$). Importantly, in patients with DVT, the combination of proximal and distal obstruction and the combination of reflux with obstruction were more common in limbs with skin damage (CEAP clinical classes 4 to 6; $P = .012$ and $P = .013$, respectively), indicating that proximal obstruction and the combination of reflux and obstruction are significant risk factor for the development of PTS.[23]

Other investigators have demonstrated that skin damage is significantly increased in patients following a first episode of DVT. In a study of 355 consecutive patients, skin damage occurred with a cumulative incidence of 22.8% after 2 years and 28% after 5 years.[7] In another longitudinal study (68 patients with a first diagnosis of lower extremity DVT, 50% male, 73 limbs), a 20.5% prevalence of skin damage was observed at a mean follow-up of 55 months. No active ulcers were present, but 2.7% of the study group had a healed ulcer.[24]

In this study, male patients were significantly more likely to have advanced signs of hyperpigmentation or ulceration compared to female patients (32.4% vs. 8.3%, respectively; $P = .01$). However, enrollment was not large enough for a multiple variable analysis, and further studies are necessary to determine if gender is a risk factor for advanced disease. There is some evidence that women may have differences in the fibrinolytic system, with higher plasminogen levels, lower plasminogen activator inhibitor levels, and increased fibrinolytic activity compared with men both at baseline and after venous occlusion.[24]

Recanalization following acute DVT was also significantly inversely related to baseline levels of activated coagulation prothrombin fragments (conversion of prothrombin to thrombin) and to fibrinolytic inhibition as measured by tPA antigen (primarily reflects PAI-1 levels). At presentation there is marked elevation of prothrombin fragments and D-dimer, which is determined by total thrombus load, and these decrease rapidly with initiation of anticoagulation therapy. However, D-dimer remains elevated long after the initial DVT.[25,26]

The pathophysiology of PTS is complex, but evidence suggests that venous hypertension is central to developing this debilitating disease. In PTS, ambulatory venous hypertension can result from outflow obstruction and/or valvular insufficiency. In this situation, ambulation does not reduce the venous pressure, and a state of ambulatory venous hypertension persists. Sustained venous hypertension can cause structural and biochemical abnormalities of the vein wall, with persistent chronic inflammation, resulting in pathologic effects in the skin and subcutaneous tissues.[4,5]

The relationship between the extent of thrombus on initial presentation and the ultimate clinical outcomes has been addressed, although some controversy remains.[4,24] In one study, PTS developed more frequently in patients who had persistent venous obstruction within the first 6 months after an episode of acute proximal DVT (relative risk 1.6; 95% CI 0 to 2.4).[27] This would suggest that proximal DVT may be more important in terms of developing PTS. In a multicenter study of 387 patients with an acute DVT, patients were evaluated for the frequency, time course, and predictors of PTS (197 men and 190 women, mean age 56 years). Patient follow-up was at 1, 4, 8, 12, and 24 months. Assessment of PTS using the Villalta scale, evaluation of anticoagulation regimens, and use of elastic compression stockings were all performed. At all study intervals, approximately 30% of patients had mild, 10% had moderate, and 3% had severe PTS. More severe postthrombotic category at the 1-month visit strongly predicted higher mean postthrombotic scores throughout 24 months of follow-up. These findings suggest that the pathophysiologic progenitor of PTS occurs in the first few weeks after DVT. Important predictors of PTS included venous thrombosis of the common femoral or iliac vein (2.23 increase in Villalta score vs. calf; $P < .001$), a higher body mass index (0.14 increase in score per 1-kg/m^2; $P < .001$), previous ipsilateral DVT (1.78 increase in score; $P = .001$), older age (0.30 increase in score per 10-year age increase; $P = .011$), and female sex (0.79 increase in score; $P = .020$). The authors concluded that patients with extensive DVT, specifically if the iliac and common femoral veins were involved, and those with more severe postthrombotic manifestations at 1 month after DVT, had much poorer long-term outcomes.[28] Patients with more extensive thrombosis involving the iliac and common femoral veins, may experience worse outcomes due to a greater likelihood of residual thrombosis. Thus early thrombus lysis may help prevent PTS (see Chapter 148). Interestingly, older age and higher BMI are associated with

higher postthrombotic scores, which may relate to age- or weight-related impaired fibrinolysis or vein wall changes.[10] In a large review, at least eight studies demonstrated the relationship between the extent of proximal DVT and the risk of developing PTS, confirming that iliofemoral DVT carries significant weight in the determination of progression to PTS.[4] Importantly, the iliofemoral location of DVT also appears to be a strong predictor of venous claudication, and other studies have found that the risk of PTS associated with proximal venous thrombosis ranges from 40% to 600%.[6]

POSTPHLEBITIC (THROMBOTIC) SYNDROME: CLINICAL SUMMARY POINTS OF NATURAL HISTORY, EPIDEMIOLOGY, AND PATHOPHYSIOLOGY

1. DVT affects up 3 individuals per 1000 annually in the general population.
2. Nearly 20% of calf vein DVT extend into the femoral-popliteal and iliac veins.
3. The greatest changes following a DVT occur during the first 3 months, with an approximate 50% reduction in thrombus burden during this time.
4. Approximately 50% of patients will show complete recanalization within 6 to 9 months of the initial DVT.
5. Median lysis times for venous segments developing reflux are 2.3 to 7.3 times longer than for corresponding venous segments not developing reflux.
6. The incidence of recurrent venous thromboembolism is approximately 17%, 24%, and 30% at 2 years, 5 years, and 8 years, respectively.
7. PTS will develop in 20% to 50% of patients within 1 to 2 years of a symptomatic DVT.
8. About 25% of limbs following DVT will have advanced skin changes at 5 years, with more aggressive progression of skin changes occurring in postthrombotic limbs compared with those with primary venous disease.
9. Ipsilateral recurrent DVT is a strong predictor of progression of CVD (RR, 4.4; 95% CI, 1.4 to 13.3, $P = .0049$).
10. The most important risk factor for developing PTS is a recurrent ipsilateral DVT, which increases the risk of PTS by as much as sixfold.
11. Limbs with the PTS have more than three times the odds of having combined reflux and obstruction compared with limbs without PTS (odds ratio [OR] 3.5, 0.95 CI, 1.4 to 8.6), and limbs with both obstruction and reflux have a higher rates and severity of PTS.
12. Ulceration may develop as a consequence of PTS, with a cumulative incidence of approximately 4% at 20 years.
13. Limbs with multisegment venous disease with iliac involvement are more likely to develop PTS, venous claudication, skin changes, venous ulceration, and venous pathology (combined obstruction and reflux) compared with limbs with only single venous segment involvement.
14. Patients with popliteal vein obstruction and/or reflux were found to be greater than 3.5 times more likely to develop PTS, and patients with multisegmental occlusion involving the popliteal vein are also at increased risk for developing PTS.
15. The pathophysiology of PTS is a complex set of events involving inflammation, thrombosis, resolution of thrombus, and vein wall damage, which result in outflow obstruction, valvular insufficiency, and calf muscle pump dysfunction, which leads to venous hypertension and subsequent signs and symptoms of PTS.
16. Greater postthrombotic symptom severity 1-month following an acute DVT strongly predicts higher mean postthrombotic scores throughout 24 months of follow-up. In other words, higher Villalta scores at 1 month predict worse PTS at later time points.

Chronic venous disease of the lower extremity is one of the most common diseases in western Europe and the United States. The manifestations of chronic venous disease can be different and may encompass telangiectasias, enlarged reticular veins, varicose veins, lipodermatosclerosis, lower extremity pain and swelling, and venous ulcers. Its prevalence reported in studies from different countries ranges from 2% to 56% in men and 1% to 60% in women. In the Edinburgh Vein Study, varicose veins were present in 40% of men and 16% of women, ankle edema was found in 7% of men and 16% of women, and ulcers were seen in 1% of men and women.[1] In the same study, the incidence of superficial vein reflux was noted to be 9.4% in men and 6.6% in women, and to increase with age.[1] In the United States, it has been estimated that 20% of patients with chronic venous disease develop venous ulcers, and 50% of these require treatment periods of more than 1 year.[2-4] The incidence of all clinical manifestations of venous disease also increases with age.[1]

The high prevalence and significant morbidity of chronic venous disease have an important socioeconomic impact, making the appropriate choice of therapy critical to cost-effective care. The disease is progressive and has a high incidence of recurrence, especially in its most advanced stages. In France, the expenditure for patients with chronic venous disease was reported to be €2.24 billion per year in 1991, 34% of which was incurred by inpatient treatment.[4] In this study, chronic venous disease was the eighth most common cause of hospital admission, accounting for 2.6% of the healthcare budget.[4] The impact of more advanced stages of chronic venous disease is even greater. A cost analysis from the Cleveland Clinic Foundation in 1999 examined the inpatient and outpatient costs of a cohort of 78 patients with active venous ulcers from the initiation of treatment until complete healing. A total of 71 patents (91%) healed during the study. Fourteen patients underwent 18 hospitalizations for venous ulcer care.[5] The average total medical cost per patient was $9685 (median, $3036), inflated to $16,524 in 2011 U.S. dollars using the Consumer Price Index for Medical Care, with an average monthly cost of $4095.[6] In another review using the Consumer Price Index for Medical Care, it was observed that the cost to achieve complete healing at 12 weeks was

Abstract

Chronic venous disease of the lower extremities is one of the most common diseases in western Europe and the United States. The nonoperative approach to patients with chronic venous disease includes lifestyle modification, compression, and pharmacologic therapies.

Compression therapy has been shown to be an essential component of the care of patients with chronic venous disease (C2-C6). A number of compression garments are available: gradient elastic stockings, the CircAid garment, paste gauze boots, layered elastic and non elastic compression bandages, and intermittent pneumatic compression devices. High grade compression therapy is the mainstay of treatment of patients with advanced chronic venous disease (C4-C6). Gradient compression stockings (30-40 mmHg) have been shown to be effective not only in ulcer healing but mostly in reducing the risk of ulcer recurrence. The ESCHAR trial (Comparison of surgery and compression with compression alone in chronic venous ulceration) showed that surgical ablation of refluxing veins may be beneficial in addition to compression therapy to prevent ulcer recurrence.

Pharmacologic therapy in venous disease is directed toward symptom control in patients with mild to moderate chronic venous disease and the treatment of venous ulcers. Micronized purified flavonoid fraction (MPFF) is a useful adjunct in the treatment of large and long standing ulcers.

approximately $1357 and significantly increased to $30,765 for more than 12 weeks of treatment.[6,7] Overall it was estimated that in the United States, the annual cost for venous ulcer treatments ranges from $1.5 to $3.0 billion, with the greatest burden on the Medicare system. These costs do not include decreases in mobility and work capacity, patients' out-of-pocket expenses, and adverse psychologic effects related to venous ulcers.[7]

TREATMENT OF CHRONIC VENOUS DISORDERS

Whereas the invasive treatment of chronic venous disease includes surgical (high ligation of the saphenofemoral junction, saphenous vein stripping, stab phlebectomies) or endovascular procedures (saphenous vein thermal and chemical ablation, ultrasound guided sclerofoam/sclerotherapy), the initial treatment of chronic venous disease has traditionally been nonoperative, with the main goals of symptom control and quality-of-life improvement. In addition, conservative measures are currently mandated by most third-party payers in the United States before approval of therapeutic surgical interventions. In this setting, the success of conservative management has long been considered to be a contraindication to more definitive surgical treatments. However, a quality-of-life analysis from Lurie and Kistner[8] questions the validity of this approach. In this study, the authors compare the outcomes of surgical therapy in patients with favorable and unfavorable responses to initial conservative management using the Specific Quality of Life and Outcomes Response–Venous questionnaire. Patients who improved with conservative therapy and who elected to proceed with surgical correction were 15 times more likely to improve with surgery at 1 month and 21 times at 12 months of follow-up, compared with those who did not improve with conservative therapy.[8,9] The authors concluded that conservative therapy should be used as a benchmark to predict success after surgical therapy, rather than as a contraindication to definitive intervention.[9]

Nonoperative Treatment of Chronic Venous Disease

The nonoperative approach to patients with chronic venous disease includes lifestyle modification, compression, and pharmacologic therapies.

Lifestyle Modification

The most common initial recommendations for lifestyle modification in patients with chronic venous disease are moderate exercise and leg elevation.[10]

Exercise

In a review of the most current literature, Brown[10] concluded that although vigorous exercise may increase the likelihood of venous ulcerations, increased mobility and moderate physical activity may be beneficial for ulcer healing and may be an adjunct to compression therapies. Overall, patients with chronic venous disease should be encouraged to engage in regular moderate physical activity.[10] In a study by Roaldsen et al.,[11] it was observed that walking speed, endurance, and self-perceived exertion were significantly lower in 34 women aged 60 to 85 years with current or previous ulcers compared with age-matched controls. It was also noted that ankle plantar flexion and dorsiflexion were significantly reduced in patients with active ulcers, mostly because of pain. In another study from the same authors, patients with low levels of physical activity displayed stronger fear avoidance beliefs and more pain than those with higher levels of physical activity.[10,11] These findings and observations from other studies emphasize the need for physical therapists to be highly involved in the care of patients with advanced C4-C6 disease, highlighting the importance of adequate pain control and a supervised exercise program tailored to improve ankle mobility and overall functional ability.[10]

Leg Elevation

Leg elevation has been shown to aid venous drainage, to increase the venous return to the heart, and to reduce ankle edema.[10] Patients with significant chronic venous disease are advised to elevate their legs 30 cm above the heart several times during the day.[10] In addition, Coleridge-Smith has shown enhancement of cutaneous microcirculation after leg elevation using Doppler fluxmetry in patients with lipodermatosclerosis, with a median 45% Doppler flux increase.[12]

Transcutaneous tissue oxygen saturation levels have been used as an indicator of skin perfusion. These have been found to be reduced in patients with venous ulcers. Several authors have reported higher transcutaneous tissue oxygen saturation levels with compression strategies, standing position, and ambulation compared with leg elevation with or without compression.[13] However, it is unclear how the transcutaneous tissue oxygen saturation levels correlate with ulcer healing. A retrospective Australian study of 122 patients with previous venous ulcers observed for 12 to 40 months found that significantly lower rates of recurrence were associated with compression therapy and longer leg elevation times (33 min/day).[14] Recurrence was observed with a 14-min/day period of leg elevation. The authors of the study recognized limitations due to the retrospective design of their analysis and possible response bias, as all the measures of physical activity, psychosocial scales, and self-care activities were obtained from self-report questionnaires.[14]

Leg elevation seems to be beneficial in symptom control in all patients with chronic venous disease. There is a trend supporting some advantage in ulcer healing, despite the evidence of levels of evidence 1 and 2 studies.[10] In addition, the utility of leg elevation is limited by the practical difficulty of prolonged leg elevation for many patients.

Compression Therapy

Compression therapy is an essential component of the care of patients with chronic venous disease (C2-C6). The rationale for graded external compression is to oppose the main pathogenetic factor underlying chronic venous disease, venous hypertension, but compression therapy has been found to have a number of additional benefits.[15] Given a normal standing

resting venous pressure of 60 to 80 mm Hg, major hemodynamic effects can be expected, with an interface compression of 35 to 40 mm Hg. External compression of more than 60 mm Hg has been found to occlude lower extremity veins in standing individuals. Therefore 60 mm Hg has been considered the safe upper limit for externally applied sustained compression, as shown by dermal blood flow investigations, even in patients with an ankle-brachial index above 0.5 and absolute ankle pressure higher than 60 mm Hg.[15-17]

Compression therapy has also been shown to improve venous pump function. Enhanced venous flow velocities have been noted with low-grade interface pressure of 15 to 25 mm Hg with prevention of thromboembolic events in supine patients.[15] The biomolecular mechanisms by which compression therapy functions are unclear. Animal and clinical studies have documented that compression therapy improves cutaneous microcirculation.[18] Video capillary microscopy showed an increase in capillary density with decreased capillary diameter and pericapillary halo in 20 patients with varicose veins and lipodermatosclerosis treated with compression therapy.[18] Several authors have also noted enhancement of lymphatic drainage and cutaneous oxygenation, as demonstrated by increased transcutaneous tissue oxygen saturation levels.[13,18,19] Decreased serum levels of tumor necrosis factor-α and vascular endothelial growth factor have been observed in patients with healing ulcers treated with four-layer graduated compression.[20] The improved cutaneous microcirculatory environment has been thought to promote venous ulcer healing as has been suggested by several studies.[21-23]

A number of compression garments are available. These include gradient elastic stockings and the CircAid garment, paste gauze boots (Unna boot), layered elastic and nonelastic compression bandages, and intermittent pneumatic compression (IPC).

Gradient Elastic Stockings

Gradient elastic stockings were first developed in the 1950s; they are currently manufactured by numerous companies and are available in various strengths and lengths. The compression applied by the stocking is calculated on the basis of the mechanical properties of the fabric used by each manufacturer. The pressure applied to the ankle by the stocking is expressed as a range and is a function of in vitro measurements based on leg circumferences.

Gradient compression stockings are currently available in four strengths: 10 to 15 mm Hg (class 1; over-the-counter); 20 to 30 mm Hg (class 2; prescription); 30 to 40 mm Hg (class 3; prescription); and 40 to 50 mm Hg (class 3—high compression; prescription). They are also available in different lengths, including knee-high, thigh-high, and panty hose. They are fitted on the basis of measurements of circumference, usually at thigh, midcalf, and ankle levels, and may be individually customized in patients with atypical leg morphology, such as may be seen in the obese or patients with advanced chronic venous disease. Compression garments should be replaced every 6 to 9 months, as the elasticity is lost after this time.[21]

Gradient Compression Stockings in C1-C2 Disease. A number of studies have reported the efficacy of gradient elastic stockings in early and advanced stages of chronic venous disease. In a prospective randomized multicenter trial conducted in France of 125 women with CEAP classification of C1-3SEpAs1-5, it was noted that regular wearing of compression stockings (10-15 mm Hg) during a 15-day period was associated with significant symptom control when a high level of compliance in wearing the hose was achieved.[24] In a review of 11 prospective randomized trials, 12 nonrandomized studies, and two guidelines, no agreement was found regarding the appropriate class of compression for the management of early chronic venous disease stages. Compression improved symptoms in patients with uncomplicated symptomatic varicose veins when high compliance was reached.[25] However, the use of compression stockings was not shown to prevent disease progression or recurrence of varicose veins after treatment. The same review highlighted that the majority of the published literature was often contradictory and had methodologic flaws, and that the results of several studies were confounded by a high number of noncompliant patients.[25]

It can be concluded that wearing of light compression stockings with a pressure below 20 mm Hg may be beneficial in the following indications[16]: symptom control in C1s (grade 1B level of evidence); varicose veins in pregnancy (grade 1B level of evidence); prevention of leg edema related to prolonged sitting and standing (grade 1B level of evidence); and prevention of venous thromboembolism in nonambulatory patients or after surgery (grade 1A level of evidence). The recommendation for use of class 2 compression stockings in uncomplicated symptomatic varicose veins is also weak (grade 2B level of evidence) and only for symptom relief.[17] Class 2 stockings have also been found to be poorly associated with the prevention of varicose veins after surgery and the treatment of venous ulcers (grade 2B level of evidence).[16]

Surgery Versus Compression in C2-C3 Disease. In the "Randomised clinical trial, observational study, and assessment of cost-effectiveness of treatment of varicose veins" (REACTIV trial),[26] 357 patients were randomized to three groups: group 1 (n = 34), minor varicose veins, conservative management versus sclerotherapy; group 2 (n = 77), moderate varicose veins with reflux, conservative management versus surgery; and group 3 (n = 246), severe varicose veins with reflux, conservative treatment versus surgery. Conservative treatment included lifestyle modification, leg elevation, and compression stockings; the surgery arm included high ligation of the saphenofemoral junction, saphenous vein stripping, and phlebectomies. The study demonstrated a significant benefit in quality of life, symptom relief, and patient satisfaction in the surgical treatment at 2-year follow-up in groups 2 and 3. In group 1, sclerotherapy produced an incremental benefit over conservative therapy. Surgery was found to be more cost-effective than conservative management in patients with C2 disease. Injection sclerotherapy also appeared to be cost-effective for patients with superficial venous reflux but was found to produce less benefit compared with surgery.[26]

The most recent guidelines from the Society for Vascular Surgery and the American Venous Forum recommend against conservative therapy alone for patients with C2 and C3 disease

when there is a compelling indication for saphenous stripping or ablation.[16] These guidelines also highlight the lack of scientific evidence to support the initial period of conservative therapy mandated by many health insurers in patients who are suitable candidates for surgical therapy.[16]

Gradient Compression Stockings in C4-C6 Disease. Class 3 gradient elastic stockings are the standard of care in advanced disease (C4-C6). The authors of a cohort study from Oregon Health Sciences University reported a 15-year experience in 113 patients with C4-C6 disease who were treated with initial bed rest, ulcer débridement, dressing changes, and class 3 compression stockings.[27] Ulcer healing required an average of 5.3 months, occurring in 97% of compliant patients, with a 16% recurrence rate. The 2012 update of a Cochrane review from Nelson et al.[28] specifically assessed the effects of compression therapy in preventing ulcer recurrence. Four trials (979 patients) were identified. In one trial (n = 153), recurrence rates were significantly reduced in the compression group at a 6-month follow-up. No difference was noted between high compression (Class 3 and Class 4) and moderate compression (Class 2) in ulcer recurrence in the other three trials. Moderate compression stockings were associated with higher compliance to therapy[28].

Patient compliance with compression therapy is both critical to the successful treatment of chronic venous insufficiency (C3-C6), particularly in patients with C4-C6 disease, and at the same time one of the biggest challenges for patients, particularly those with advanced age, obesity, and arthritis. Patients must be educated about the importance of compression therapy with ongoing reinforcement of this concept. Aids have been developed to allow application of stockings in patients who are challenged; sleeves and metal frames (Fig. 157.1) have been designed and are currently available on the market, although many insurers do not cover these adjuncts.

Gradient Compression Stockings and Prevention of Post-thrombotic Syndrome in Acute Deep Vein Thrombosis. Recent data from the Centers for Disease Control and Prevention estimates that as many as 900,000 people (1-2 per 1,000) are affected by deep vein thrombosis (DVT) and pulmonary embolism (PE), with estimates of 60,000 to 100,000 patients dying from these diseases in the United States.[29] Approximately 33% of the population with DVT/PE will develop a recurrence within 10 years, and 20% to 50% of those patients will experience long term complications such as post-thrombotic syndrome (PTS).[29]

The pathogenesis of PTS is complex and includes a post-thrombotic inflammatory reaction involving the venous wall and valves with subsequent remodeling, development of venous hypertension, varicose veins, skin changes, and ultimately venous ulcers.[30] Gradient compression stockings can potentially reduce the risk of PTS by counteracting this basic pathogenetic mechanism.

In two prospective randomized trials,[31,32] a statistically significant 50% PTS absolute risk reduction was found in patients with a first episode of proximal deep vein thrombosis (iliac, femoral, and popliteal vein) who wore a class 3 compression stocking for 2 years. In a recent multicenter randomized placebo-controlled trial (SOX: Compression Stockings to Prevent the Post-Thrombotic Syndrome after Symptomatic Proximal Deep

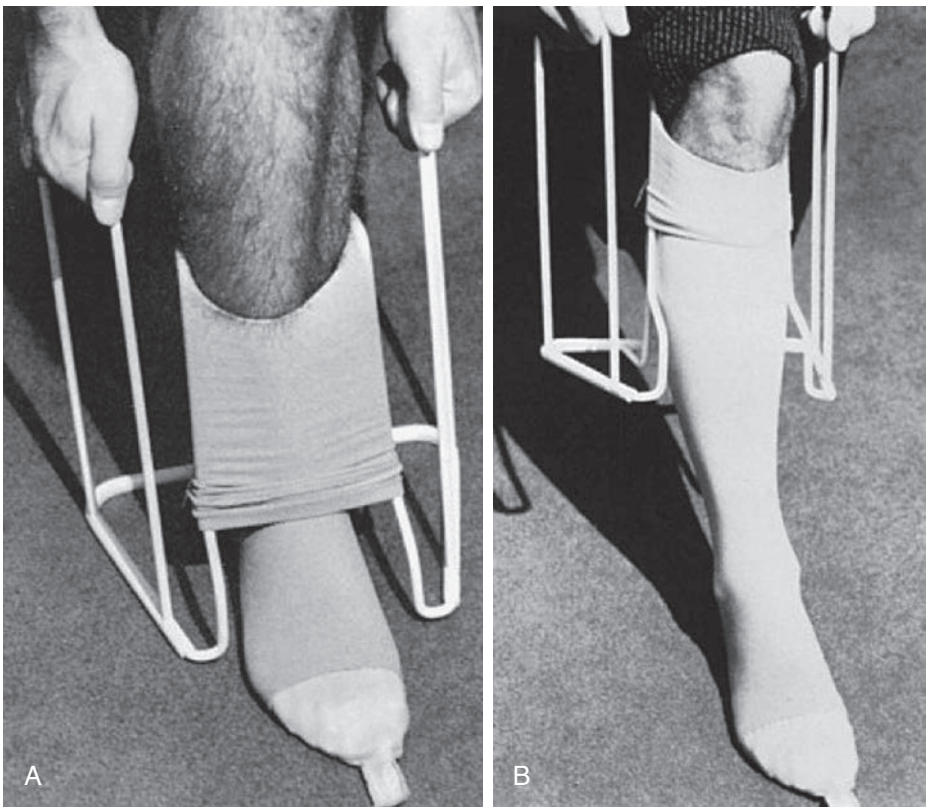

Figure 157.1 Metallic frames and plastic sleeves have been designed to facilitate the application of graduated compression stockings. (From Moneta GL, Partsch H. Chronic venous disorders: nonoperative treatment. In: Cronenwett JL, Johnston KW, eds. *Rutherford's Vascular Surgery.* 7th ed. Philadelphia: Saunders Elsevier; 2010.)

Vein Thrombosis),[33] 410 patients with proximal DVT were randomized to gradient compression stockings (class 3) versus placebo (noncompression hosieries). No statistically significant difference in the incidence of PTS (Ginsberg and Villalta PTS scores) between the two groups was found at a 2 year follow-up.[33] Lack of compliance to compression therapy (55.6% of patients compared to 90% in the previous trials) and patient characteristics, such as the initiation and duration of anticoagulation and the advent of the newer oral thrombin and factor Xa inhibitors, may have affected the results of the SOX trial compared to previous studies.[34] In another prospective randomized study, compression therapy and ambulation in the first 10 days from the acute thrombotic event were associated with benefit in mean Villalta scores, even after a secondary treatment with compression therapy for 2 years.[34]

In conclusion, the evidence that gradient compression therapy prevents PTS after a first DVT episode is currently mixed. Compression stockings may be beneficial in symptom control in patients with severe deep vein thrombosis.

CircAid Garment

The CircAid (Fig. 157.2) is a nonelastic compression appliance with multiple, stiff, pliable, adjustable Velcro bands. The system is as effective as compression stockings in reducing edema and promoting venous pump function, and may be recommended in patients who are unable or unwilling to wear class 3 stockings.[35] In a small prospective randomized trial, including 22 extremities with advanced chronic venous disease (C6) from Villavicencio et al., the CircAid system was found to have a significantly faster ulcer healing rate compared with a four-layer elastic bandage.[36] The CircAid system allows adjustment for limb size changes, ease and speed of application with improvement of comfort, and tolerance compared with compression stockings and bandaging.

Unna Boot

The Unna boot was first developed by the German dermatologist Paul Gerson Unna at the end on the 19th century. It consists of a multilayered compression dressing made of an inner layer of gauze bandage impregnated with calamine, zinc oxide, glycerin, sorbitol, gelatin, and magnesium aluminum oxide, and an outer layer of an elastic wrap exerting graded compression.

The bandage stiffens with drying, with improvement of venous return during ambulation and reduction of edema. The pressure exerted varies from 50 to 60 mm Hg. The dressing is changed weekly or sooner, depending on the amount of drainage.[37]

In a 15-year retrospective survey of 998 patients with venous ulcers, the Unna boot achieved a 91% healing rate for first-time ulcers and overall 73.3% healing rate in compliant patients. All patients were treated 12 times in 32 weeks. The overall wound healing rate was superior with the Unna boot compared with polyurethane dressings in a multiinstitutional randomized study.[38]

Layered Elastic and Nonelastic Compression Bandages

Compression bandages are single-layer or multilayer dressings commonly used in patients with advanced chronic venous disease (Fig. 157.3). Pressure, layers, components, elastic properties, and stiffness are all factors to be considered when such a dressing

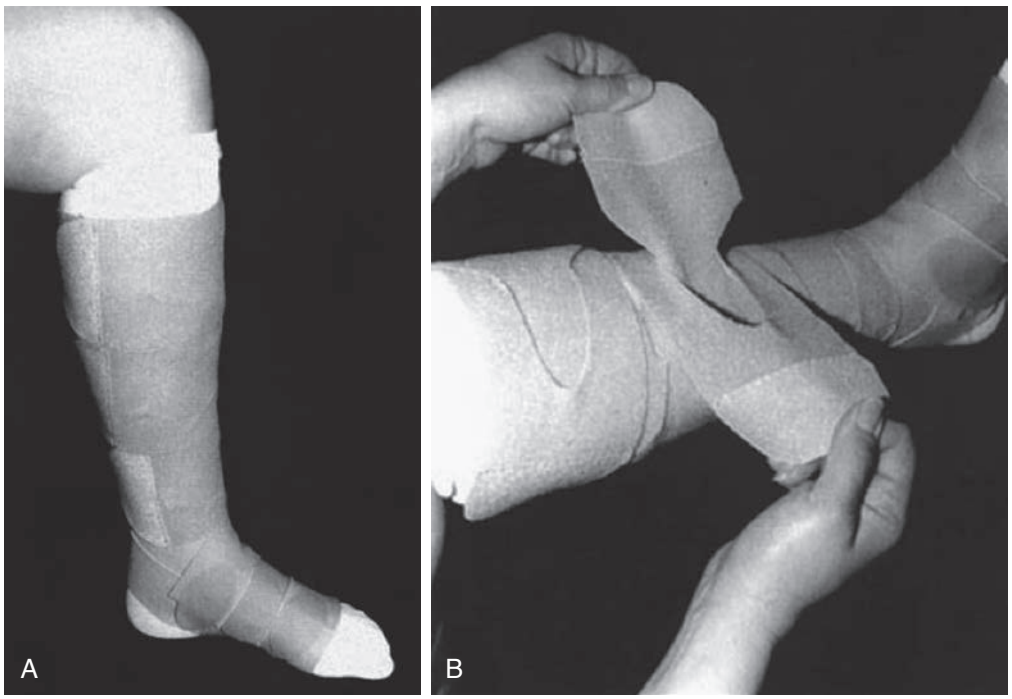

Figure 157.2 The CircAid is a nonelastic adjustable compression appliance with multiple, stiff, pliable, adjustable Velcro bands. (From Moneta GL, Partsch H. Chronic venous disorders: nonoperative treatment. In: Cronenwett JL, Johnston KW, eds. *Rutherford's Vascular Surgery,* 7th ed. Philadelphia: Saunders Elsevier; 2010.)

Figure 157.3 Compression bandages can be single layer **(A)**, nonelastic **(B)**, or multilayer (**C** and **D**). (From Enoch S, Grey JE, Harding KG. ABC of wound healing. Non-surgical and drug treatments. *BMJ*. 2006;332:900–903.)

is applied. The pressure is a function of the outer bandage, and a sustained pressure of 60 to 70 mm Hg is the upper limit, especially over bony prominences.[16,22,23] The choice of dressings varies from wet to dry, hydrocolloids or impermeable (occlusive; Table 157.1) dressings.[39] Indications for each dressing type vary by the characteristics of the ulcer, the degree of skin inflammation, and the presence of infection (see Table 157.1).[39]

Bandages can be elastic, such as the Ace, SurePress, and Perfecta, or nonelastic, such as the Putter, Comprilan, and Coban bandages. The main disadvantage of nonelastic bandages is the loss of pressure over time after application as the limb loses volume in response to compression. Training in application of the bandage is also important, because incorrect overlapping may cause additional ulcers. Elastic bandages are easier to apply. They may exert a higher resting pressure that is maintained over time. Disadvantages are possible discomfort due to higher resting pressure and the possibility of skin ulcer, especially over bony prominences if adequate skin padding is not applied.

In a systematic review from O'Meara et al., 59 prospective randomized trials with 4321 venous ulcer patients were identified. Several bandages systems were compared, with ulcer healing rate as the primary outcome. The results were consistent with an overall increased effectiveness of multicomponent systems containing an elastic bandage versus those with inelastic constituents.[40]

O'Meara et al. compared the effectiveness of four-layer and short stretch single-layer bandages in a meta-analysis published in 2009.[41] Four eligible trials with a total of 887 patients were identified. It was noted that four-layer bandages were associated with shorter healing time and larger ulcers; chronic ulceration and previous ulcerations were found to be independent predictors for delayed ulcer healing.[41]

A systematic review of compression treatment for venous ulcers identified 24 randomized controlled trials. The results confirmed that compression therapy is the treatment of choice in patients with advanced chronic venous disease, and that high compression is associated with an overall significant increase in the odds of healing at 3 months. No difference was found between high compression single-layer versus multilayer systems and the Unna boot. In the same meta-analysis, two small trials showed superiority of compression stockings (84% healed at 3 months) versus short stretch bandages (52% healed at 3 months).[42]

Two systematic reviews from Partsch et al.[43] and Coleridge Smith[44] found that the use of class 3 compression stockings promotes ulcer healing and reduces ulcer recurrence (grade 1A evidence).

In an open, prospective, randomized, single-center trial from Milic et al.,[45] 131 patients with C6 disease (ulcer surface >3 cm^2; duration >3 months) were randomized into three groups of different types of compression systems: a tubular stocking with a colored line signifying where compression is estimated within 30 to 40 mm Hg (Tubulcus; group A); a multicomponent bandaging system composed of the Tubulcus and one elastic bandage (group B); and a multicomponent system made of the Tubulcus and two elastic bandages (group C). Pressure measurements were taken in the supine, sitting, and standing positions. The median sub-bandage pressure values in the supine position and in the standing position were 36.2 mm Hg and 43.9 mm Hg, respectively, in group A; 53.9 mm Hg and 43.9 mm Hg in group B; and 74.0 mm Hg and 87.4 mm Hg in group C. The healing rate was calculated with an intent-to-treat analysis, and it was 25% in group A, 67% in group B, and 74% in group C. Median healing time was 12 weeks in group A, 11 weeks in group B, and 14 weeks in group C. The rate of noncompliance was highest in group C (21%) and lowest in groups A and B (2%). A Cox regression analysis demonstrated that different sub-bandage pressure values, calf circumference,

TABLE 157.1 Different Types of Dressings and Their Uses

Type of Dressing	Trade Names	Features	Indications
Hydrocolloids	Comfeel Plus, DuoDERM E, Algoplaque HP, Askina Biofilm, Suprasorb H, Hydrocoll standard	Thick adhesive 1 application/2-7 days without secondary dressing	Mildly exuding ulcer
	Comfeel Plus transparent, Comfeel Plus Brûlures, Comfeel Ovale, DuoDERM extra thin, DuoDERM extra thin oval, Algoplaque film, Hydrocoll thin	Thin adhesive 1 application/2-7 days without secondary dressing
